The nature of the solvent used for the measurement will also affect the population of the isomers. In a polar solvent, solvation will take place so as to keep the positive and negative centers in the molecule very far apart from each other. Thus, *s-trans* would be a more favorable conformation than *s-cis* in a polar solvent. If the delocalization of the positive charge extended to the ferrocene ring because of the electron-releasing character of the ferrocene nucleus, the predominance of the *s-trans* conformation would be more promoted. However, contrary to expectation, no appreciable solvent effect was observed, probably because the steric effect overcomes the solvent effect.

Supposing a cyclopentadienyl ring in the ferrocene nucleus lies on a plane of the side-chain olefinic double bond, the other part of a ferrocene molecule stands out of this plane and the iron atom is situated so close to the π-orbital of the side chain that a certain anchimeric effect between them may be expected. Therefore, the conjugation of the π-electron system in the side chain with the ferrocene ring in β-ferrocenyl-α,β-unsaturated ketones may be somewhat different in nature from that with the benzene ring in β-phenyl analogs. Thus, such an anchimeric effect might contribute to some extent to the enhanced population of the *s-cis* isomer in β-ferrocenyl-α,β-unsaturated ketones, in addition to the prevailing steric effect.

Experimental

Spectral Measurements. The infrared spectra were measured in carbon tetrachloride with a Hitachi EPI-G2 grating spectrometer, using a rock salt cell 0.052 cm thick. The extinction coefficient, ε', employed in this study is defined as follows:

$$\varepsilon^{a}_{s\text{-}cis}=\frac{\log T_0/T_{s\text{-}cis}}{x_{s\text{-}cis}\cdot c\cdot l}=\frac{\varepsilon'_{s\text{-}cis}}{x_{s\text{-}cis}}$$

$$\varepsilon^{a}_{s\text{-}trans}=\frac{\log T_0/T_{s\text{-}trans}}{(1-x_{s\text{-}cis})\cdot c\cdot l}=\frac{\varepsilon'_{s\text{-}trans}}{1-x_{s\text{-}cis}}$$

where ε^a is a molar extinction coefficient, $x_{s\text{-}cis}$ is the molar ratio of the *s-cis* isomer, c is the molar concentration of the solution measured, l is the path length in cm, and T_0/T is the peak optical density.

The absorbances ($\log_{10} T_0/T$) of both the C=O and C=C absorption peaks were found to have a good linear relationship with the molar concentration of the unsaturated ketone.

The NMR spectra of **2** were measured in $CDCl_3$ with a Hitachi model H-60 spectrometer.

Materials: 4-Ferrocenyl-2-buten-2-one (**1a**), 1-ferrocenyl-1-penten-3-one (**1b**), 1-ferrocenyl-5-methyl-1-hexen-3-one (**1c**), 1-ferrocenyl-4,4-dimethyl-1-penten-3-one (**1d**), and 2-(ferrocenylmethylene)cyclohexanone (**1e**) were each prepared by the base-catalyzed condensation of formylferrocene with the corresponding ketones by means of a procedure reported previously.[7]

1-Ferrocenyl-4,4-dimethyl-1-penten-3-one (1d). Attempts at the chromatographic purification of **1d** were unsuccessful because it easily decomposed on alumina to give formylferrocene and pinacolone. When the crude material was left standing for several months, a small amount of long, dark red needles grew out of the crude solid. When collected, this was proved to be a pure substance by its sharp mp 91—92°C. It was identified as **1d** by means of its IR and UV spectra. λ_{max} (95% ethanol) 225, 260, 305, *ca.* 364(sh), and 480 mμ.

3-Ferrocenyl-1-(*p*-substituted phenyl)-2-propen-1-ones (2). These substances were prepared by the condensation of formylferrocene with *p*-substituted acetophenone in the manner used to prepare 3-ferrocenyl-1-phenyl-2-propen-1-one by Hauser and Lindsay.[9]

3-Ferrocenyl-1-phenyl-2-propen-1-one (2a). The crude product obtained by the condensation of formylferrocene and acetophenone was recrystallized from ethanol to afford violet needles; mp 142—145°C (lit.,[9] 138—140°C). Yield, 55%.

3-Ferrocenyl-1-(*p*-tolyl)-2-propen-1-one (2b). The crude product (92.4% yield) was recrystallized from ethanol to give violet needles; mp 138.5—139.5°C. λ_{max} (95% ethanol) 277.5, 326, 398(sh) and 514 mμ.

Found: C, 72.55; H, 5.59%. Calcd for $C_{20}H_{18}OFe$: C, 72.82; H, 5.46%.

3-Ferrocenyl-1-(*p*-anisyl)-2-propen-1-one (2c). The crude product (80.7% yield) was recrystallized from ethanol to afford purple needles; mp 154.5—155.5°C. λ_{max} (95% ethanol) 279, 327, 390 and 512 mμ.

Found: C, 69.40; H, 5.21%. Calcd for $C_{20}H_{18}O_2Fe$: C, 69.39; H, 5.20%.

3-Ferrocenyl-1-(*p*-chlorophenyl)-2-propen-1-one(2 d). The recrystallization of crude **2d** (88.2% yield) from ethanol gave reddish-orange needles; mp 167—168°C. λ_{max} (95% ethanol) 273, 330, 396 and 520 mμ.

Found: C, 65.08; H, 4.40%. Calcd for $C_{19}H_{15}OClFe$: C, 65.08; H, 4.28%.

3-Ferrocenyl-1-(*p*-nitrophenyl)-2-propen-1-one (2e). On the recrystallization of crude **2e** (8.47% yield) from chloroform – ether (2 : 1), violet needles were obtained; mp 228—230°C. λ_{max} (95% ethanol) 270, 337, 410(sh) and 546 mμ.

Found: C, 62.80; H, 4.28; N, 3.93%. Calcd for $C_{19}H_{15}O_3NFe$: C, 63.18; H, 4.16; N, 3.88%.

Liquid Phase Chlorination of Olefins with Cupric Chloride

Takashi KOYANO

Central Research Laboratory, Toa Nenryo Kogyo Co., Oi-machi, Iruma-gun, Saitama

(Received September 11, 1969)

Reactions of olefins with cupric chloride were studied in methanol at 100—140°C. The reactivity of olefins was in the order, ethylene>propylene>1-butene>2-butenes. A considerable amount of 1-chloro-2-methoxy compounds were found in the reaction products of 1-olefins. Competitive formation of dichloride and methoxychloride was suggested. Chlorination of 2-butenes leads to *meso*- and *dl*-2,3-dichlorobutanes, their ratio being invariable regardless of the starting material *cis*- or *trans*-2-butene. The mechanism is discussed in terms of ionic intermediates.

Although there are a number of investigations on the chlorination of unsaturated organic compounds by cupric chloride, the mechanism of the reaction is somewhat ambiguous. For the liquid phase chlorination of aromatic compounds a polar mechanism[1] or a mechanism involving homolytic decomposition of the π-complex between cupric chloride and the aromatic compound[2] has been proposed. Chlorination of alkenes in the vapor phase has been accepted to proceed through chloronium ion intermediates.[3] However, participation of both radical and ionic mechanisms has recently been demonstrated.[4]

Only a few reports have appeared on the chlorination of simple olefins in liquid phase. Although the photo-induced chlorination of olefinic compounds was noted earlier,[5] the thermal chlorination in aqueous phase was not reported until 1967.[6] Recently, the reaction in alcoholic media has been described in some detail.[7] However, efforts have been concentrated mostly on reaction with styrene and interpretation for the reaction with alkene is not conclusive.

We found that a considerable amount of methoxychloride is formed in addition to the anticipated dichlorides in the chlorination of alkenes in methanol. The object of this paper is to elucidate the mechanism of this type of reaction. A detailed description from the synthetic point of view will be presented later.

Results and Discussion

Several simple olefins were allowed to react with cupric chloride in methanol at 120°C (Table 1). The reactivity based on the conversion of cupric chloride was in the order, ethylene>propylene>

1-butene>2-butenes. This is in line with the facility of complex formation of the olefins with silver ion.[8] This suggests initial formation of olefin-copper complex such as acetylene-copper(II) complex speculated by Castro,[9] rather than olefin-chlorine complex deduced by Arganbright in the vapor phase reaction.[3]

Considerable amounts of methoxy compounds were found in the products. In the reaction of ethylene the ratio of 1,2-dichloroethane (I) to 2-chloroethyl methyl ether (II) increases with increase in the amount of cupric chloride present. This may be interpreted by assuming competitive reactions of the intermediate with chloride ion[10] and with methanol, in sharp contrast to the styrene chlorination reported by Ichikawa[7] where a consecutive reaction has been claimed. Although methanolysis of I is accelerated by the presence of cupric chloride (Table 2), the rate is too small to explain the present data. Since the rate of methanolysis of I is not greater than that of II (Table 3), a simple calculation for the consecutive first order reactions clearly shows that the formation of II by methanolysis should be much less than that actually obtained.[11] In accordance with this, a fairly large quantity of II was produced in the reaction at 100°C, whereas no 1,2-dimethoxyethane (III), which is presumed to be produced exclusively by methanolysis, was detected in the products (Table 4). This means that the methanolysis of I is negligible at this temperature and II is formed through a different route. As is expected, addition of chloride ion favors the formation of I significantly.

A tendency for the ratio of I/II to be larger in the lower temperature reaction may be ascribed to the lower conversion of cupric chloride, *viz.*, the products consist of only those formed at the higher cupric chloride concentration. The fact

10) Although the real attacking species on the intermediate to form I is not fully clear at this stage, its concentration should be higher with the higher cupric chloride concentration due to equilibria in the system.

$$Cu^{++} + Cl^- \rightleftharpoons CuCl^+$$
$$CuCl^+ + Cl^- \rightleftharpoons CuCl_2$$
$$CuCl_2 + Cl^- \rightleftharpoons CuCl_3^-$$

11) In the consecutive first order reactions,

$$A \xrightarrow{k_1} B \xrightarrow{k_1'} C$$

the equation $\ln([A]_0/[A]) = [B]/[A]$ can be derived when $k_1 = k_1'$. However, 0.37 $[A]_0$ is the largest possible solution of [B] for this equation, and [C] should be 0.27 $[A]_0$ in this case. When $k_1 < k_1'$, $[B] = 0.5\ [A]_0$ can not satisfy the equations given in literature.[12]

1.0	40.5	18.3	21.3	6.2	9.1	1.47

Ta autoclave reaction, C_2H_4 0.55 mol (charged at the reaction temperature), MeOH 120 m*l*, $CuCl_2$ 0.20 mol, 100°C

* Yield of products during the initial and the following 30 min.

that the ratio is larger in the earlier stage of reaction at a temperature is also attributable to the same reason (Table 5).

These observations can be rationalized by the following mechanism.

$$C_2H_4 + CuCl_2 \rightleftharpoons [C_2H_4 \cdots CuCl_2 \rightarrow C_2H_4\overset{\delta+}{Cl} \cdots \overset{\delta-}{CuCl}]$$

$$\xrightarrow{CuCl_2} ClCH_2CH_2Cl + 2CuCl \quad (1)$$

$$\xrightarrow[MeOH]{} ClCH_2CH_2OMe + HCuCl \quad (2)$$

$$HCuCl + CuCl_2 \rightarrow 2CuCl + HCl \quad (3)$$

The olefin-copper complex initially formed is transformed into a cationic chlorine complex[13] which is the common intermediate for the formations of dichloride[14] and methoxychloride. Evidence for an ionic intermediate comes from the fact that the products from 1-butene consist of only both 1,2-dichlorobutane and 1-chloro-2-methoxybutane. No other compounds were detected. When methanol attacks the intermediate complex, the resulting HCuCl[15] is rapidly oxidized by another mole of cupric chloride to yield two moles of cuprous chloride and one mole of hydrogen chloride. Cupric chloride undergoes disproportionation only at high temperatures.[9,16] None of the present data suggests the participation of chlorine molecule.[17]

13) The structure of this complex is under investigation and will be discussed in succeeding papers.

14) Equation (1) does not necessarily mean that the attacking species is cupric chloride but it simply shows the stoichiometry on the dichloride side.

15) Existence of the cation CuH^+ and its reaction with cupric ion yielding cuprous ion have been demonstrated; J. Halpern, E. R. Mcgregor and E. Peters, *J. Phys. Chem.*, **60**, 1455 (1956).

16) M. C. Ball and R. F. M. Coultard, *J. Chem. Soc., A*, **1968**, 1417.

17) a) When methanol solution (10 m*l*) of cupric chloride (25 mmol) was heated at 140°C for 3 hr in a test tube, more than 90% of $CuCl_2$ was recovered unchanged. b) No substituted products were detected, *e. g.*, by gas chromatography (Condition *VI*). The products from 1-butene exhibited only two peaks (methoxychloride 9.0 min and dichloride 9.5 min) during 46 min running.

It should be noted that the presence of air reduces the apparent conversion of cupric chloride, regenerated from cuprous chloride and hydrogen chloride (produced according to equation (3)) by oxidation, to increase the total yield of products based on consumed cupric chloride as high as 140% (Table 4).

$$CuCl + HCl + \tfrac{1}{4}O_2 \rightarrow CuCl_2 + \tfrac{1}{2}H_2O \quad (4)$$

This furnishes a hint for a possible catalytic reaction analgous to usual oxychlorination.

* *meso* 62.5%, *dl* 37.5%

** *meso* 59.0%, *dl* 41.0%

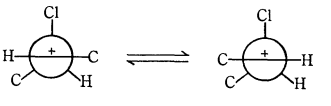
*** A small amount of *threo* compound was also detected.

When *cis*- and *trans*-2-butenes were subjected to reaction, isomeric dichlorides were formed. However, the ratio of *meso*- to *dl*-dichlorides is almost independent of the starting material 2-butene (Tables 1 and 6). Although interconversion of 2-butenes has occurred slightly, the extent is by no means sufficient to account for the result. The stability of the dichlorides was examined to show that both the isomerization and the methanolysis do not take place significantly under the reaction condition. Therefore, the invariable *meso*/*dl* ratio must be determined during the course of reaction. A mechanism which accounts for the results is that the intermediate complex has considerable open-chain character[18] and is in equilibrium between two isomeric forms[20] by rotation around the central C–C bond faster than the attack of nucleophiles. Since the intermediate originally from *trans*-2-butene is less crowded than the one from the *cis* isomer by separating two methyl groups apart, it must be more stable. Thus, by

18) In this respect the intermediate is dissimilar to the strongly bridged chloronium ion intermediates in the chlorination of 2-butenes by chlorine molecule.[19]

19) R. C. Fahey and C. Schubert, *J. Amer. Chem. Soc.*, **87**, 5172 (1965).

20) Scheme of equilibrium:



succesive *trans* addition of chloride ion, *meso*-dichloride predominates over *dl*-isomer. A σ-bonded complex, $Cl(CH_3)CHCH(CH_3)CuCl$, is unlikely to exist under the reaction conditions, although it can not be strictly ruled out.

Experimental

Materials. Olefins were commercially available. Ethylene, 99% pure grade (Nihon Sekiyu Kagaku Co.); propylene, pure grade (Takachiho Chemical Industrial Co.); 1-butene, 99.7% pure grade (Matheson Co.); *cis*- and *trans*-2-butenes, pure grade (Takachiho). Cupric chloride was anhydrous GR grade (Koso Chemical Co.). Methanol was GR grade (Koso), refluxed and distilled from magnesium methoxide[21] under N_2. 1,2-Dichloroethane, GR grade (Koso), and 2-chloroethyl methyl ether, chemical grade (Koso), were distilled after drying over $CaCl_2$. Other materials were the purest reagents commercially available.

Analytical Methods. *a*) Unchanged Cu(II) was determined by iodometry.[22] *b*) Reaction products were analyzed by gas chromatography. The conditions (apparatus, column, temperature, carrier gas) were as follows: *I.* Shimadzu GC-2C, dioctyl sebacate (plus sebacic acid) on Chromosorb W (DOS column), 100°C or 120°C, He; *II.* Shimadzu GC-2C, Triton X-305 on Diasolid L, 80°C, He; *III.* Shimadzu GC-1C, DOS column, 120°C; He; *IV.* Shimadzu GC-1C, Triton X-305 on Diasold L, 130°C, He; *V.* Shimadzu GC-1C, propylene carbonate plus glutaronitrile on Chromosorb W, room temp., He; *VI.* Shimadzu GC-4APT, DOS column, 100°C (program 4°C/min) max. 140°C, He; *VII.* Perkin-Elmer 226 (H_2 flame detector), Silicone DC-550 (300 ft capillary), 30°C (12 min, program 10°C/min) max. 120°C, N_2. *c*) IR spectra were measured by JASCO IR-G spectrophotometer. d) NMR spectra were measured by JEOL JNM-C-60H spectrometer.

Autoclave Reaction. Into a N_2 purged 300 m*l* Ta lined autoclave (with an agitator and a thermo-well made of Ta metal) were placed $CuCl_2$ and methanol, and the measured amount of olefin was added from a pressure bottle. The autoclave was heated with an electric oven with stirring. The reaction time was shown as the heating time after the autoclave reached the prescribed temperature (±1.0°C). After the reaction, the autoclave was immediately cooled with water to room temperature. Cuprous chloride was filtered off from the reaction solution, followed by extraction with methanol. The combined methanol solution was subjected to titration and gas chromatographic analysis (Conditions *I* and *II*, with toluene as the internal standard). The results are summarized in Table 1.

Test Tube Reaction. Since cupric chloride is very corrosive to steel, the methanol solution (10 m*l*)[23] was taken in a 45 m*l* glass test tube and placed in a 100 m*l* stainless steel autoclave. In the autoclave was placed 30 m*l* methanol in order to adjust partial pressure and minimize vaporization of the reactant methanol. After being flushed with N_2, ethylene was introduced, and the autoclave was heated (±1.0°C) for 3 hr with an oven without stirring. The reaction solution and the outside solution were taken out and analyzed separately. The combined results are shown in Table 4.

The same procedure was applied to methanolysis of I, in which N_2 (50 kg/cm^2) was used in place of ethylene (Table 2).

Methanolysis of I and II. The reaction was carried out in a 50 m*l* glass sealed tube, which was heated (±1.0°C) in a 500 m*l* autoclave with shaking (75/min). The products were analyzed by gas chromatography (Condition *I*). The results are listed in Table 3.

Reaction of 1-Butene. In a 500 m*l* glass lined autoclave (with a stirrer made of Ta metal) was placed cupric chloride (0.10 mol) in 150 m*l* of anhydrous methanol, followed by addition of 13.8 g (0.25 mol) of 1-butene. The autoclave was heated at 140°C in an oil bath for 3 hr with stirring. After cooling, the reaction solution was analyzed by gas chromatography (Condition *I*, 120°C). The products were 1,2-dimethoxybutane (trace, retention time 10.5 min), methoxychlorobutane (IV) (1.94 g (14.8 mmol), 13.5 min), and 1,2-dichlorobutane (1.42 g (11.2 mmol), 15.2 min), which were identified by comparing their retention times with those of the synthesized samples. No higher boiling products were detected by programmed gas chromatography.[17b] When the reaction mixture was heated with KOH in a sealed tube at 150°C for 1 hr, the peak at 10.5 min increased while the other two peaks disappeared. This shows that the peak at 10.5 min corresponds to 1,2-dimethoxybutane.

Product IV showed a single peak also in a capillary column gas chrotmaography (Condition *VII*), showing it consisted of a single product. The NMR and IR spectra of IV, which was separated by fractionation and preparative gas chromatography (Condition *III*), were identical with those of synthesized 1-chloro-2-methoxybutane. (NMR (CCl_4 solution): τ 9.05 (triplet, 3H), τ 8.37 (multiplet, 2H), τ 6.54 (singlet, 3H, τ 6.4—6.9 (multiplet, 3H)).

Synthesis of 1,2-Dichlorobutane. Chlorine gas was introduced slowly into 1-butene (10 m*l*) at −20°C with stirring. About 2 m*l* of pure (>99%) 1,2-dichlorobutane (confirmed by NMR and IR) was isolated from the higher substituted substances by fractionation using a spinning band column.

Synthesis of 1-Chloro-2-methoxybutane. This was carried out by modification of olefin chlorination with *t*-butyl hypochlorite[24] and the product was purified by preparative gas chromatography (Condition *III*).

Reaction of 2-Butenes. A methanol solution of cupric chloride was charged in a 500 m*l* glass lined autoclave, and 2-butene was then pressured in from a pressure bottle. The autoclave was heated at 140°C (±1.0°C) in an oil bath with stirring for 3 hr. After cooling to room temperature, gas chromatographic analysis was conducted on both gaseous (Condition *V*) and liquid (Condition *I*) products. The results are presented in

Table 6.

Synthesis of 2,3-Dichlorobutane.[25] 2-Butene was allowed to react with chlorine gas under a dry ice condenser. The products were purified by preparative gas chromatography (Condition *IV*). (NMR(CCl_4 solutions): *meso* (from *trans*), τ 8.39 (doublet, 3H), τ 6.01 (multiplet, 1H); *dl* (from *cis*), τ 8.45 (doublet, 3H), τ 5.82 (multiplet, 1H)). IR spectrum of *dl*-dichloride agreed with the standard chart (Sadtler No. 12165).

A mixture of 0.5 g (4 mmol) of *meso*- and *dl*-2,3-dichlorobutanes, 0.22 g (1.7 mmol) of $CuCl_2$, and 0.17 g (1.7 mmol) of CuCl in 5 m*l* of MeOH was heated in a 10 m*l* sealed glass tube at 140°C for 3.3 hr. Gas chromatographic analysis (Condition *I*) revealed that no isomerization and no detectable extent of methanolysis occurred under the reaction condition: a feed composed of *meso* 99.8% and *dl* 0.2% yielded a mixture of *meso* 99.7% and *dl* 0.3%, while a feed of *meso* 1.7% and *dl* 98.3% gave a mixture of *meso* 1.6% and *dl* 98.4%.

Synthesis of 2-Chloro-3-methoxybutane. The method of olefin chlorination with *t*-butyl hypochlorite[24] was applied to the synthesis. From *trans*-2-butene, the main product (assigned to *erythro*-2-chloro-3-methoxybutane) appeared at 16.3 min in the gas chromatogram (Condition *I*, 100°C) with a small amount of *meso*-dichloride at 18.2 min. On the other hand, *threo*-compound from *cis*-2-butene showed a peak at 17.3 min with *dl*-dichloride at 20.5 min.

The author is indebted to Professor Naoki Inamoto for valuable discussions. He also wishes to thank Mr. Katsumi Kaneko for his assistance in part of this work.

Umwandlung von Aldehyden in 2-monosubstituierte Aziridine. Reduktion von α-Chlor, Brom- und Sulfonyloxynitilen mit Lithiumaluminiumhydrid

Kunihiro ICHIMURA*1 und Masaki OHTA

Laboratorium für Organische Chemie, Tokio Institut für Technologie, Tokio, Meguro-ku, Ookayama

(Eingegangen am 20. September, 1969)

The reductive cyclization of α-chloro, bromo- and sulfonyloxycarbonitriles are described. α-Chlorocarbonitriles were reduced by lithium aluminum hydride to afford aziridines in sufficient yields. The Walden inversion was found to take place in the cource of the reductive cyclization of *S*-α-chloroisocapronitrile. We have found the two-step conversion of aldehydes to 2-monosubstituted aziridines which consists of treating aldehydes with benzenesulfonyl chloride and alkali cyanide to form α-benzenesulfonyloxycarbonitriles which are reduced by lithium aluminum hydride to the corresponding aziridines. The reduction of α-bromocarbonitriles with the hydride yielded *prim.* amines together with the aziridines.

Die allgemeinen und bis jetzt benutzbarsten Darstellungmethoden der Aziridine wurde von Gabriel und Wenker entdeckt.[1] Im Nachteil sind jedoch in manchen Fällen diese beiden Verfahren, weil es sich dabei um die geringere Zugänglichkeit der Ausgangstoffe und um die unangenehm heftigen Reaktionsbedingungen handelt. In diesem Standpunkte ist es erforderlich, diese reaktionsfreudigen Heterocyclen, die zur Herstellung der stickstoffhaltigen Verbindungen als benutzbare Ausgangstoffe dienen können, unter milderen Bedingungen durch Umwandlungen der zugänglicheren funktionellen Gruppe darzustellen.

Vor kurzem sind einige modifizierten Verfahren zur Umwandlungen von Olefinen in Aziridine beschrieben, die auf den Anlagerung von Jodisocyanat,[2] Nitrosylchlorid[3] oder Dichlorurethan[4] an Olefine beruhen.

In dieser Arbeit sollen Umwandlungen der Aldehyde in 2-monosubstituierte Aziridine durch die Reduktion von α-Chlor, Brom- und Sulfonyloxynitrilen mit Lithiumaluminiumhydrid beschrieben werden, und die Stereospezifität des reduktiven Ringschlusses wird aus den folgenden ersichtlich.

Ergebnisse und Diskussion

Reduktion von α-Chlornitrilen mit Lithiumaluminiumhydrid.[5] Die nur wenig bekannte Bildungsweise der Aziridine hatten Booseré[6] und Theunis[7] mitgeteilt, die auf der Einwirkung des Äthylmagnesiumbromids auf einige α-Chlornitrile beruht.

Bei der Umsetzung von sonstigen α-Chlornitrilen mit Grignard-Reagenzien beobachtet man doch nicht immer die Entstehung der Aziridine. Beispielsweise bildet sich nur beträchtliche Menge der harzigen Substanz bei der Reaktion des Chloracetonitrils[8] wie des α-Chlorphenylacetonitriles[9] mit Phenylmagnesiumbromid neben der anderen wenigen Umsetzungsprodukte.

Auf Grund der verwandtschaftlichen Reaktionsweise von Grignard-Reagenzien mit Lithiumaluminiumhydrid (LAH) war mit dem letzteren ein analoger Reaktionsverlauf unter Bildung von Aziridinen zu erwarten.[10]

Bei der Reaktion von α-Chlorvaleronitril mit LAH in Äther bei −5—0°C erhält man, wie erwartet, 2-(*n*-Propyl)aziridin in 82%-iger Ausbeute. Andere 2-monosubstituierte Aziridine konnten in analoger Weise in den befriedigenden Ausbeuten erhalten werden, was in der Tabelle 1 angeführt ist.

Die analogen Ergebnisse hatte schon Krieger mitgeteilt,[14] worüber wir nach unseren Versuchen kennengelernt haben.*2

Er reduzierte mit Erfolg α-Chlornitrile des bicyclischen Heptens und Heptans mit LAH unter Bildung der *spiro*-Aziridine.

Im Gegensatz dazu hatte Wagner-Jauregg bei der LAH-Reduktion des 2-Chlor-3-cyclohexylaminopropionitril nur das entsprechende 1,3-Diamin isoliert.[15],*3

Was die Reaktionsmechanismen betrifft, kann man zwei Reaktionsfolgen zweckmäßig in Betracht

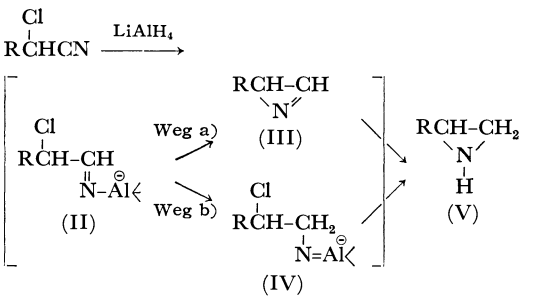

Fig. 1. Die mögliche Reaktionsfolge der reduktiven Cyclisierungsreaktion.

ziehen.

Der Weg a) beruht auf dem Ringschluß des α-Chloraldimin-Derivates (II) in Azirin (III) und der anschließenden Reduktion mit dem Metallhydrid in Aziridin. Der alternative Weg b) besteht in der Reduktion vom α-Chlornitril unter Bildung des α-Chloramin-Derivates (IV), das dann in Aziridin zum Ringschluß gebracht würde.

Im Weg a) kommt es daher auf die Entstehung des ungesättigten Azirins als das Zwischenprodukt an, einige von welcher Klasse isolierbar[16] und in der Tat mit LAH in Aziridin übergeführt sind.[17] Um die Entstehung dieses Zwischenprodukts, Azirins, zu bestätigen, haben wir die Reduktion von α-Chlorisovaleronitril mit Unterschuß von LAH ausgeführt, aber die charakteristische infrarote Bande von Azirin bei etwa 1730—1780 cm^{-1} [16] keinesfalls beobachtet.

Brown und sein Mitarbeiter hatten eine wertvolle Umwandlung der Nitril-Gruppe in die entsprechenden Aldehyde mittels Lithiumtriäthoxyaluminohydrids mitgeteilt.[18] In der Umwandlung bildet sich offenbar das Aldimin-Derivat vor der Hydrolyse. Bei der Anwendung dieses Reagens an α-Chlornitril erwartet man also die Entstehung des α-Chloraldimin-Derivats, das nach der Reaktionsfolge a) Azirin liefern könnte.

Wenn man α-Chlorphenylacetonitril mit diesem Reduktionsmittel unterhalb 0°C behandelt, konnte man auch in diesem Fall keine Bildung des Azirins mittels des IR-Spektrums aufdecken, und *dl*-2,3-Diphenylbernsteinsäuredinitril selber wurde in geringer Ausbeute isoliert.

Diesen Ergebnissen nach mag die Cyclisierungsreaktion im Weg b) stattfinden und wird also als eine modifizierte Gabrielsche Reaktion bezeichnet.

Hinsichtlich des sonstigen Beispiels derartigen Cyclisierungsreaktion des Nitrils in Aziridin hatten Stork und seine Mitarbeiter beobachtet, daß bei der Einwirkung von LAH auf ein Glycidnitril neben einem Aminoalkohol ein Aziridinylcarbinol entsteht.[19] Bei der Umwandlung in Aziridinylcarbinol spielt die Epoxid-Gruppe als eine abspaltende Gruppe die Hauptrolle, gerade sowie Chloratom in der Reduktion der α-Chlornitrile. Sie hatten die Reaktionsfolge als intramolekulare *trans*-Eliminierung gezeichnet, ohne experimentellen Nachweis.

Beim Weg b) handelt es sich dann um die Frage, ob sich die Cyclisierungsreaktion der α-Chlornitrile wie in der Gabrielschen oder Wenkerschen Methode über die stereospezifische *trans*-1,3-Eliminierungsreaktion stattfinden würde.[20] Um diese Aufgabe zu lösen, haben wir optisch aktives α-Chlornitril synthetisiert und mit LAH reduziert.

Das optisch aktive α-Chlornitril, *S*-α-Chlorisocapronitril, wird wie in Fig. 2 dargestellt. Bekanntlich werden α-Aminosäure im allgemeinen mit Nitrosylhalogenid in die entsprechenden α-Halogencarbonsäure unter der Beibehaltung der sterischen Orientierung der Substituente übergeführt, mit Ausnahme von Valin und *iso*-Leucin.[21]

Die so erhaltene *S*-α-Chlorisocapronsäure wurde über das Säurechlorid ins Säureamid umgewandelt, das mittels Phosphorpentoxyds unter Bildung des *S*-α-Chlorisocapronsäurenitrils entwässert wurde.

Das so erhaltene α-Chlorisocapronitril, das sich mit Sicherheit in dem *R*-System befindet, wurde unterhalb 0°C mit LAH versetzt, und in 78%-iger Ausbeute entsteht 2-*iso*-Butylaziridin von $[\alpha]_D$

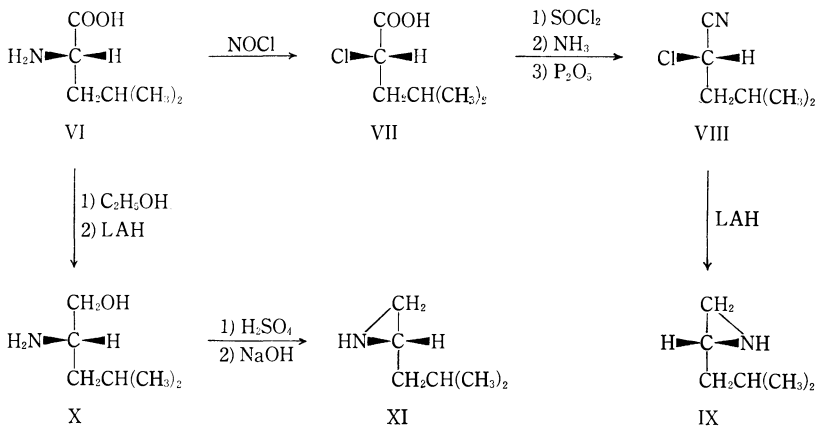

Fig. 2. LAH-Reduktion des optisch aktiven α-Chlornitrils.

+20.6°.

Um die absolute Konfiguration des Aziridins ins klare zu bringen, haben wir *S*-2-*iso*-Butylaziridin über L-Leucinol nach dem Verfahren von Tsuboyama synthetisiert,[22] und das so gebildete optisch aktive Aziridin zeigt $[\alpha]_D$ −26.4°.

Man kann auf dem Grunde dieser Ergebnisse schließen, daß das bei der Reduktion vom α-Chlornitril entstehende Aziridin die R-Chiralität hat, und daß also die Waldensche Umlagerung bei der Reduktionsstufe stattfindet.

Reduktion von α-Sulfonyloxynitrilen mit Lithiumaluminiumhydrid. Die synthetischen Anwendungen der oben beschriebenen reduktiven Cyclisierungsreaktion sind jedoch zur Synthese der Aziridin wegen der geringeren Ausbeuten an den α-Chlornitrilen und besonders wegen der heftigen Reaktionsbedingungen zur Herstellung der Nitrile so beschränkt, daß man die Verfahren zweckmäßig modifizieren sollte.

Wohlbekannt ist die Tatsache, daß sich Sulfonsäurealkylester sogleich wie Alkylhalogenid verhalten. Das veranläßt uns dazu, α-Sulfonyloxynitril mit LAH zu reduzieren, unter Erwartung der Bildung der Aziridine, indem die Hydrogenolyse des Sulfonsäureesters mittels LAH eine Prozedur ist, die Hydroxy-Gruppe mit Wasserstoff auszutauschen.[23]

Die Herstellung von α-Sulfonyloxynitril unter Benutzung des Sulfonylchlorids, Alkalicyanids und Aldehyds ist schon von einigen Arbeitern mitgeteilt.[24] Wir setzten die wäßrige Lösung des Alkalicyanids in Acetonitril-Lösung des Aldehyds und Chlorids unterhalb 0°C zu, und das α-Benzolsulfonyloxynitril wurde in befriedigenden Ausbeuten erhalten, was man in Tabelle 2 ersichtlich ist.

Im allgemeinen sind die von aromatischen Aldehyden ausgehenden α-Sulfonyloxynitrile bei Raumtemperatur zersetzlich. Beim Fall von Anisaldehyd beobachtete man jedoch bei erniedrigter Temperatur nach der flüchtigen Bildung der kristallinen Masse das beträchtliche Zerfließen und konnte das α-Sulfonyloxynitril keinesfalls isolieren.

Im Gegensazt dazu sind die von aliphatischen Aldehyden stammenden α-Sulfonyloxynitrile bei Raumtemperatur haltbar und unzersetzt destillierbar.

Interessant ist die Abwesenheit der Nitrilbande in den IR-Spektren der α-Sulfonyloxynitrile, gerade wie im Fall von α-Acyloxynitrilen.[25] Diese α-Sulfonyloxynitrile zeigen die charakteristischen Banden bei 1380, 1190, 1180, 1095, 930—1100, und 710—730 cm^{-1}.

Bei der Einwirkung von Alkalicyanid auf Benzolsulfonylchlorid und α,β-ungesättigte Aldehyde, Crotonaldehyd und Zimtaldehyd, konnte man keine gereinigten Verbindungen erhalten. Das Reaktionsgemisch zeigte keine Bande des Sulfonsäureesters.

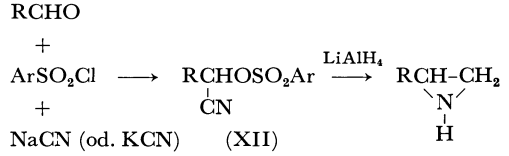
Methansulfonylchlorid kann zur Herstellung der entsprechenden α-Sulfonyloxynitrile nicht dienen.

Die Einwirkung des Alkalicyanids und Benzolsulfonylchlorids auf Cyclohexanon und Aceton wurde versagt.

Nach der Reduktion des α-Benzolsulfonyloxyvaleronitrils (XIIb) mit äquimolarem LAH polymerisiert das Reaktionsprodukt beim Erhitzen unter Bildung vom Polyäthylenimin, im Gegensatz zur Reduktion der α-Chlornitrile. Um diese Phänomena handelt es sich auch bei den Fallen von α-Sulfonyloxyisovaleronitril (XIIc) und 2-Phenylpropionitril (XIIe) bei Benutzung von äquimolarem LAH.

Die Polymerisierung der Aziridine verursachen bekanntlich mancherlei electrophile Reagenzien. Im vorliegenden Fall kann also α-Sulfonyloxynitril selbst als das Initiator dienen. Wenn man 2-*iso*-Butylaziridin in Gegenwart eines Tropfens des α-Benzolsulfonyloxyisovaleronitrils zu destillieren versucht, entsteht Polyäthylenimin, wie erwartet, und das Aziridin kann nicht mehr übergehen.



Diese unangenehmen Phänomena können bei Benutzung des anderthalbmolaren Metallhydrids vermieden werden, und 2-monosubstituierte Aziridine werden in befriedigenden Ausbeuten erhalten, was in Tabelle 3 angeführt ist.

Die Frage, ob sich die Hydroxy-Gruppe oder Acyloxy-Gruppe auch als die abspaltende Gruppe zur Bildung der Aziridine verhalten könnte, its für synthetische Anwendung interessant. Bekanntlich sind α-Cyanhydrin und Acyloxynitril nur in β-Aminoalkohol mittels LAH reduziert.[26] Wir haben auch diese Tatsache bei der Reduktion von α-Acetoxyisovaleronitril beobachtet, das nur den entsprechenden β-Aminoalkohol liefert.

Reduktion von α-Bromnitrilen mit Lithiumaluminiumhydrid. Unter Erwartung der Bildung der α-Chlornitril kocht man α-Benzolsulfonyloxyphenylacetonitril mit Lithiumchlorid in Aceton und erhält in guter Ausbeute α-Chlorphenylacetonitril. Diese Umwandlung kann man auf α-Benzolsulfonyloxyacetonitril anwenden.

Beim Erhitzen des α-Benzolsulfonyloxyisovaleronitril mit Lithiumchlorid in Aceton wurde das Ausgangsmaterial züruckgewonnen. Beim längeren Erhitzen des Nitrils in DMF mit Lithiumchlorid entsteht β-Methylcrotonitril in 53%-iger Ausbeute.

Durch Anwendung dieses Typs der Substitutionsreaction mittels Lithiumbromids gelang uns, die α-Sulfonyloxynitrile in α-Bromnitrile umzuwandeln. Die Ergebnisse werden in Tabelle 4 angeführt.

26) Ref. 10b, S. 742.

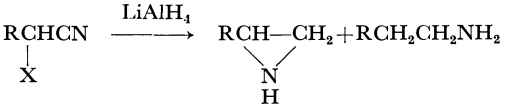
Wenn man α-Bromnitril mit äquimolarem LAH versetzt, beobachtet man bemerkenswerterweise die Entwicklung des Wasserstoffs und die Entstehung des Polyäthylenimins beim Erhitzen zur Destillieren. Wie im Fall der vorher erwähnten Reduktion der α-Benzolsulfonyloxynitrile werden α-Bromnitrile bei Benutzung von anderthalbmolarem LAH mit Erfolg in destillierbares Produkt umgewandelt. Nach der gaschromatographischen Analyse fanden wir, daß das Reaktionsprodukt aus dem 2-monosubstituierten Aziridin und dem entsprechenden *prim.* Amin besteht. Die Ergebnisse der gaschromatographischen Analyse bei der Reduktion der α-Chlor- und Sulfo-

Tabelle 5. Reduktionsprodukte



R	X	Produktsverhältnis Aziridin	*prim.* Amin
n-Pr	Cl	100	0
n-Pr	$OSO_2C_6H_5$	100	0
n-Pr	Br	43	57
i-Pr	Cl	97	3
i-Pr	$OSO_2C_6H_5$	100	0
i-Pr	Br	30	70
i-Bu	Br	34	64
t-Bu	$OSO_2C_6H_5$	100	0

nyloxynitrilen sind auch in Tabelle 5 angeführt.

Wie man in Tabelle 5 sehen kann, sind die Produktsverhältnisse von dem Substituente (R) und der abspaltenden Gruppe (X) abhängig, und im Fall des α-Bromnitrils entsteht das *prim.* Amin in größeren Mengen.

Das ist offenbar, daß bei der Bildung des *prim.* Amins es sich nicht um die hydrogenolytische Ringöffnung des Aziridins handelt. Denn bei der Reduktion des α-Sulfonyloxynitrils beobachtet man keine Bildung des *prim.* Amins.

Um die weiteren Kenntnisse der Reaktionsfolge zu gewinnen, haben wir die LAH-Reduktion des optisch aktiven α-Bromnitrils ausgeführt.

Wie im Fall des α-Chlornitrils wird *S*-α-Bromisocapronsäurenitril über die *S*-α-Bromsäure durch die Entwässerung des entsprecheden α-Bromamids hergestellt. Beim Zugeben des α-Bromnitrils auf die LAH-Aufschlämmung beobachtet man die Entwicklung des Wasserstoffs und isoliert die Reduktionsprodukte, die gaschromatographisch mit 2-*iso*-Butyaziridin und 4-Methylpentylamin identifiziert werden. Durch die präparativen Gaschromatographie fraktioniert man 2-*iso*-Butylaziridin, das $[\alpha]_D$ +25.5° zeigt.

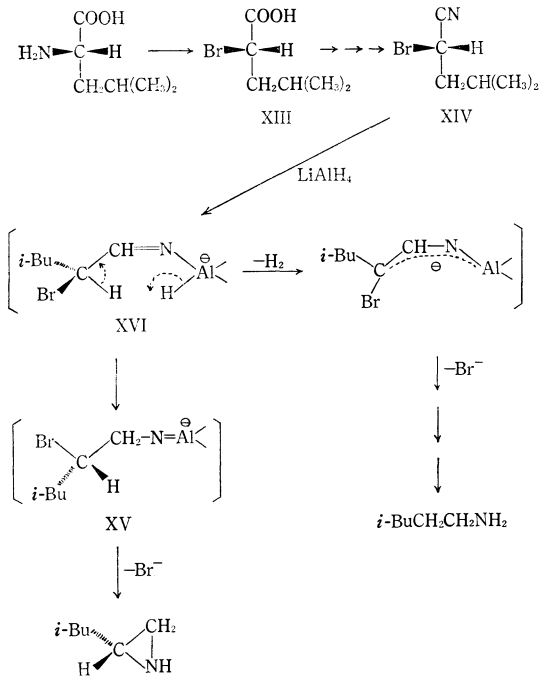


Fig. 3. LAH-Reduktion des optisch aktiven α-Bromnitrils.

Das *prim.* Amin bildet sich daher wahrscheinlich über die in Fig. 3 angegebene Zwischenstufe (XVI) unter Entwicklung des Wasserstoffs, während das Aziridin nach der Sättigung der Nitril-Gruppe so durch die *trans*-Eliminerung entsteht, wie im Fall des α-Chlornitrils.

Beschreibung der Versuche*4

Ausgangsmateriale. Die folgenden α-Chlornitrile wurden durch Chlorierung der entsprechenden Cyanhydrine hergestellet. α-Chlorvaleronitril vom Kp 158—161°C in 33%-iger Ausbeute (bezogen auf Butyraldehyd). α-Chlorisovaleronitril vom Kp 152—155.5°C in 57%-iger Ausbeute. α-Chlorcaprylnitril vom Kp 104.5—105°C/16 mmHg in 20%-iger Ausbeute. 1-Chlor-2-phenylpropionitril vom Kp 77.5—79.5°C/13 mmHg. 1-Chlorcyclohexancarbonitril wurde nach der Stevenschen Methode erhalten.[27]

Reduktion vom α-Chlornitril mit Lithiumaluminiumhydrid. *2-(n-Propyl)aziridin (eine typische Prozedur zur Herstellung der Aziridine).* Man setzt in die Suspension von 2.50 g (66 mmol) Lithiumaluminiumhydrid in 25 m*l* Äther 5.90 g α-Chlorvaleronitril in 10 m*l* Äther tropfenweise unter gutem Rühren und Eis-Kochsalzkühlung zu. Dabei riecht es schon nach dem charakteristischen Aziridin. Nach dem einigstündigen Rühren bei Raumtemperatur setzt man 0.5 g Natriumhydroxyd zu und zersetzt dann das Gemisch vorsichtig mit Wasser unter Eis-Kochsalzkühlung. Nach dem Filtrieren der anorganischen Absätze trocknet man die ätherische Lösung mit Kaliumcarbonat ab und entäthert mittels 20 cm Kolonne. Man destilliert den Rückstand und erhält 3.50 g 2-(*n*-Propyl)aziridin vom Kp 114—118°C. Alle Aziridine, die in analoger Weise hergestellt werden, zeigen die charakteristische Bande in IR-Spektren bei 3050 und 3200 cm^{-1}.

Reduktion des α-Chlorvaleronitrils mit Unterschuß von Lithiumaluminiumhydrid. Man setzt die Suspension von 0.45 g in 30 m*l* Äther teilweise in die ätherische Lösung von 5.00 g α-Chlorvaleronitril unter Eis-Kochsalzkühlung zu und rührt das Gemisch 2 Std bei Raumtemperatur. Nach vorsichtigem Zersetzen des Metallkomplexes und nach dem Freisetzen der anorganischen Absätze trocknet man die ätherische Lösung mit Natriumhydroxid ab und entäthert. Im IR-Spektrum dieses Rückstandes tritt weder die Absorptionsbande des Azirins (etwa 1740 cm^{-1}) noch die des Aziridins (3050 und 3200 cm^{-1}).

Reduktion von α-Chlorphenylacetonitril mit Lithiumtriäthoxyaluminohydrid. Man setzt 2.00 g Essigsäureäthylester in 8 m*l* Äther in die Suspension von 0.58 g Lithiumaluminiumhydrid in 12 m*l* Äther unterhalb 0°C zu. Danach tropft man 2.30 g α-Chlorphenylacetonitril in 8 m*l* Äther in das Reaktionsgemisch unterhalb 0°C ein, rührt 3 Std bei Raumtemperatur und läßt das Gemisch zwei Tage stehen. Man zersetzt das Reaktionsgemisch mit Wasser, trennt die ätherische Schicht ab und trocknet sie mit Kaliumhydroxyd ab. Nach dem Eindampfen des Lösungsmittels erhält man den braunen Rückstand, aus dem man 0.33 g farblose Kristalle des *dl*-α,β-Diphenylbernsteinsäuredinitrils vom Schmp. 163—164.5°C isoliert. Nach einmaligem Umkristallisieren aus Äthanol schemelzen sie bei 164.5—166°C. (Ber Schmp 164°C). Gef: C, 82.94; H, 4.57; N, 12.33%.

Der von Diphenylbernsteinsäuredinitril freigesetzte

*4 Die berichneten Kochpunkte und Schmelzpunkte sind aus Beilsteinschem Handbuch zitiert.

27) C. L. Stevens und T. H. Coffield, *J. Amer. Chem. Soc.*, **73**, 103 (1951).

Rückstand zeigt keine infrarote Absorption von Phenylazirin.

***S*-α-Chlorisocapronsäure.** Man löst 52.5 g L-Leucinol in 800 m*l* 6N HCl ein und setzt Natriumnitrit in kleinen Portionen in die Lösung unterhalb 0°C unter Eis-Kochsalzkühlung und gutem Rühren zu. Nach einhalbstündigem Rühren bei −8°C und dreistündigem Rühren bei Raumtemperatur sättigt man die gelbe Lösung mit Kochsalz ab und äthert die organische Schicht fünfmal aus. Nach Trocknen der ätherischen Lösung mit Natriumsulfat entäthert man sie unter verm. Druck. Man erhält 35.5 g *S*-α-Chlorisocapronsäure vom Kp 110—113°C/13 mmHg. Bei nochmaligem Destillieren siedet die Säure bei 112—114°C/10 mmHg. n_D^{20} 1.4412. $[\alpha]_D^{16}$ −24.6° (*c* 5, EtOH).

***S*-α-Chlorisocapronylchlorid.** Nach gelindem Rückfluß von 18.5 g α-Chlorisocapronsäure und 31.0 g Thionylchlorid erhält man 14.4 g α-Chlorisocapronylchlorid vom Kp 71°C/28 mmHg.

***S*-α-Chlorisocapronamid.** In 200 m*l* konz. Ammoniak tropft man Dioxan (20 m*l*)-Lösung von 14.4 g *S*-α-Chlorisocapronsäurechlorid bei 0——5°C unter Rühren und Eis-Kochsalzkühlung, rührt 30 Min das Gemisch bei 0°C und untscht die abgeschiedenen Kristalle ab. Man erhält 10.00 g *S*-α-Chlorisocapronamid vom Schmp 88—90°C. Nach Umkristallisieren der Kristalle aus wäßrig. Methanol schmelzen sie bei 91—91.5°C. $[\alpha]_D^{17}$ −46.9° (*c* 2, EtOH). Gef: C, 48.62; H, 7.99; N, 9.66%. Ber für $C_6H_{12}NOCl$: C, 48.16; H, 8.09; N, 9.36%.

***S*-α-Chlorisocapronitril.** Nach Mischen des verpulverten 5.0 g *S*-α-Chlorisocapronamid mit 7.2 g Phosphorpentoxyd erhitzt man das Gemisch unter vermindertem Druck über bloßer Falmme, und 3.6 g *S*-α-Chlorisocapronitril geht über und siedet bei 60.0°C/13 mmHg. n_D^{20} 1.4291. $[\alpha]_D^{17}$ −20.0° (*c* 2, EtOH). Gef: C, 54.96; H, 7.54; N, 10.41%. Ber für $C_6H_{10}NCl$: C, 54.76; H, 7.62; N, 10.65%.

***S*-2-Isobutylaziridin.** Man setzt 1.75 g *S*-α-Chlorisocapronitril in die Aufschlämmung von 0.52 g Lithiumaluminiumhydrid in 30 m*l* Äther unterhalb −5°C. Nach einstündigem Rühren bei Raumtemperatur fügt man 4 g Natriumhydroxyd zu, zersetzt das Metallkomplex mit 10 m*l* Wasser bei etwa 5°C unter gutem Rühren und Eis-Kochsalzkühlung. Man filtriert den Niederschlag ab und wäscht ihn dreimal mit Äther. Die vereinigte ätherische Lösung wird über Kaliumhydroxyd abgetrocknet, und nach Abdestillieren des Äthers bei gewöhnlichem Druck mittels 20 cm Kolonne erhält man 1.03 g rohes *S*-2-Isobutylaziridin, das bei nochmaligem Destillieren bei 130—131°C siedet. n_D^{20} 1.4267. $[\alpha]_D^{15}$ +20.6° (*c* 1.828, Bzl).

***R*-2-Isobutylaziridin.** Man versetzt 6.1 g L-Leucinol in 10 m*l* Wasser mit 5.7 g konz. Schwefelsäure und 10 m*l* Wasser und destilliert Wasser unter verm. Druck bei etwa 135°C ab. Das so gebildete Sulfonsäureester wird mit 10.5 g Natriumhydroxyd in 30 m*l* Wasser versetzt und erhitzt. Das Aziridin geht zusammen mit Wasser über. Die wäßrige Schicht wird mit Kaliumhydroxyd abgesättigt und dreimal mit Äther ausgezogen. Die Auszüge wird mit Kaliumhydroxyd abgetrocknet und entäthert. *R*-2-Isobutylaziridin siedet bei 130—134°C und beträgt 3.80 g. n_D^{20} 1.4270. $[\alpha]_D^{17}$ −26.4° (*c* 1.828, Bzl). (Ber, n_D^{28} 1.4242, $[\alpha]_D^{32}$ −24.6° (*c* 1.828, Bzl)).[22]

Allgemeine Vorschrift zur Herstellung der α-Sulfonyloxynitrile. Man versetzt äquimolares Benzolsulfonylchlorid und frisch destilliertes Aldehyd in Acetonitril und kühlt die Lösung bis auf −10°C ab. Unter gutem Rühren setzt man konz. wäßr. Lösung (30—40%) von 1.05 mol. Natrium- oder Kaliumcyanid unterhalb 0°C zu und rührt eine Stunde bei Raumtemperatur. Das Reaktionsgemisch wird anschließend mit Wasser versetzt. und das abgeschiedene Öl mit Methylenchlorid ausgezogen und mit Wasser gewaschen. Nach Abtrocken über Natriumsulfat und Eindampfen der Auszüge erhält man das α-Benzolsulfonyloxynitril als den Rückstand, der durch Vakuumdestillieren oder Umkristallisieren gereinigt wird.

Reduktion des α-Benzolsulfonyloxynitrils mit Lithiumaluminiumhydrid. Man reduziert α-Benzolsulfonyloxynitrile und arbeitet so gleich wie α-Chlornitrile auf. Für die in Äther nur schwer lösliche Sulfonyloxynitrile dient Tetrahydrofuran als besseres Lösungsmittel.

α-Acetoxyisovaleronitril. Man führt 12.5 g frisch destilliertes Isobutyraldehyd in das Cyanhydrin in gewöhnlicher Weise über, das mit 50 m*l* Acetanhydrid in der Gegenwart der katalytischer Mengen der *p*-Toluolsulfonsäure über Nacht umgesetzt. Ausbeute, 9.3 g, Kp 82°C/13 mmHg. n_D^{20} 1.4115. Gef: C, 60.80; H, 7.86; N, 10.45%. Ber für $C_7H_{11}NO_2$: C, 59.55; H, 7.86; N, 9.92%.

Reduktion des α-Acetoxyisovaleronitril mit Lithiumaluminiumhydrid. Man behandelt 7.0 g α-Acetoxyisovaleronitril mit 3.8 g Lithiumaluminiumhydrid in Äther in üblicher Weise und erhält 2.07 g 1-Amino-3-methylbutanol-2. Kp 101°C/44 mmHg. n_D^{20} 1.4447. Gef: C, 64.75; H, 8.07; N, 12.58%. Ber für $C_{12}H_{18}N_2O_2$: C, 64.84; H, 8.16; N, 12.61%.

α-Chlorphenylacetonitril. Man kocht 30 g α-Benzolsulfonyloxyphenylacetonitril und 7.6 g Lithiumchlorid 2 Std in 120 m*l* Wasser, extrahiert zweimal mit Äther und trocknet über Magnesiumsulfat ab. Ausbeute, 15.6 g. Kp 113.5—116.0°C/12 mmHg (Ber Kp 108—110°C/5 mmHg).

β-Methylcrotonitril. Man erhitzt 6.8 g α-Benzolsulfonyloxyisovaleronitril und 1.8 g Lithiumchlorid in Dimethylformamid 8 Std. bei 130—140°C. Die Lösung wird mit Wasser versetzt, und man zieht mit Äther aus und erhält 1.24 g β-Methylcrotonitril. Kp 142°C (Ber, Kp 140—142°C). (Gef: C, 73.88; H, 9.11; N, 16.50%).

α-Bromisovaleronitril. Man kocht 15.0 g α-Benzolsylfonuloxyisovaleronitril und 8.2 g Lithiumbromid 1.5 Std, in 50 m*l* wasserfreies Methyläthylketon unter Rückfluß und erhält nach üblichem Arbeiten 6.7 g α-Bromisovaleronitril vom Kp 59—59.5°C/13 mmHg. n_D^{20} 1.4595. Gef: C, 38.89; H, 5.34; N, 8.57%. Ber für C_5H_8NBr: C, 37.06; H, 4.97; N, 8.65%.

α-Bromvaleronitril. Man erhält das Bromnitril in oben beschriebener Weise in 71%-iger Ausbeute. Kp_{13} 72—73.5°C. n_D^{20} 1.4594. Gef: C, 37.83; H, 5.28; N, 8.27%. Ber für C_5H_8NBr: C, 37.06; H, 4.97; N, 8.65%.

Reduktion von α-Bromvaleronitril mit Lithiumaluminiumhydrid. Man setzt die ätherische Lösung von 7.94 g (0.045 mol) α-Brombutyronitril auf die Aufschlämmung des 2.80 g (0.067 mol) Lithiumaluminiumhydrids in 40 m*l* Äther zu, wobei sich 0.018 mol Wasserstoff entwickelt. Nach der üblichen Aufarbeitung destilliert man die ätherische Lösung mit 30 cm Kolonne und erhält das Reduktionsprodukt vom Kp 100—118°C die 2.67 g beträgt und gaschromatographisch analysiert.

Reduktion von α-Bromisovaleronitril mit Li-

thiumaluminiumhydrid. Gerade wie im Fall des α-Bromvaleronitrils erhält man 1.90 g Reduktionsprodukt von Kp 90—113°C aus 7.13 g α-Bromisovaleronitril und 2.52 g Lithiumaluminiumhydrid.

Gaschromatographische Analyse der Reduktionsprodukte. Die rohen Reduktionsprodukte werden gaschromatographisch analysiert und die Auftrennung der Aziridine und der entsprechenden Amine läßt sich mittels Carbowax-20M-Säule erzielen. Säulenlänge 1.5 m, Trägergas Helium, Strömungsgeschwindigkeit etwa 70 ml/min. Jedes Aziridin hat die längere Retentionszeit als das entsprechende Amin. Die gebildeten *prim.* Amine werden durch den Vergleich der Retentionszeit der authentischen Probe identifiziert.

***S*-α-Bromisocapronsäure.** Man löst 31.2 g L-Leucin und 85.8 g Kaliumnitrit unter gutem Rühren bei −5—0°C langsam zugesetzt wird. Nach einstündigem Rühren bei Raumtemperatur extrahiert man das abgeschiedene Öl viermals mit Äther. Nach Abtrocknen über Magnesiumsulfat der Auszüge destilliert man *S*-α-Bromisocapronsäure vom Kp 132—135°C/12 mmHg (Ber Kp 125—131°C/13 mmHg (der *dl*-Säure)). n_D^{19} 1.4665.

***S*-α-Bromisocapronsäurechlorid.** Man kocht 25 g *S*-α-Bromisocapronsäure und 40 ml Thionylchlorid 3 Std. Ausbeute, 20 g. Kp 75—78°C/15 mmHg.

***S*-α-Bromisocapronsäureamid.** Unter Eiskühlung und Rühren setzt man mit Dioxan verdünntes *S*-α-Bromisocapronsäurechlorid in konz. Ammoniak und rührt eine Std unter Eiskühlung. Man erhält das α-Bromamid vom Schmp 117—118°C, das aus Wasser Äthanol umkristallisiert wird. Gef: C, 37.30; H, 6.17: N, 7.17%. Ber für $C_6H_{12}NOBr$: C, 37.13; H, 6.23; N, 7.22%.

***S*-α-Bromisocapronitril.** Man erhitzt 9 g verpulvertes *S*-α-Bromisocapronsäureamid und 15 g Phosphorpentoxyd in vermindertem Druck und erhält man 7.3 g α-Bromnitril, das 80—81°C/13 mmHg siedet. n_D^{18} 1.4605. $[\alpha]_D^{20}$ −27.4° (*c* 1.950, Bzl). Gef: C, 41.37; H, 5.74: N, 7.75%. Ber für $C_6H_{10}NBr$: C, 40.95; H, 5.73: N, 7.96%.

Reduktion von *S*-α-Bromisocapronitril mit Lithiumaluminiumhydrid. Man setzt 5.98 g *S*-α-Bromisocapronitril und 2.20 g Lithiumaluminiumhydrid in Äther in üblicher Weise um und erhält 1.31 g Produkt von Kp 120—126°C, der durch die oben genannten Carbowax-20M-Säule gaschromatographisch in 4-Methylpentylamin und 2-Isobutylaziridin im Verhältnisse 66 : 34 fraktioniert wird. *N*-Phenylcarbamoyl-Derivat des 4-Methylpentylamins, Schmp 84°C (Ber Schmp 84°C). *R*-2-Isobutylaziridin, $[\alpha]_D^{20}$ +25.5° (*c* 1.035, Bzl).

Laser-induced Chemical Reactions. III. The Decomposition of Metal Salts of Carboxylic Acid and Selective Decomposition

Ko Taki, Pil Hyon Kim and Susumu Namba

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received September 24, 1969)

Various copper metal salts of organic acid were decomposed by laser heating and conventional heating methods. The product distributions were reasonably explained in terms of the expected reaction of the decarboxylated intermediates. Generally the yield percentage of products is higher in laser decomposition than in thermal decomposition. However, in maleate and fumarate the product distribution is quite different in thermal and laser decompositions. The main product is ethylene in the thermal decomposition, but acetylene in the laser decomposition. This difference may be the result of the heating rate. Since rapid heating and quenching are characteristic of laser heating, the formation of acetylene may be brought about by the simultaneous decarboxylation of two carboxyl groups, while the formation of ethylene may be brought about by successive decarboxylation. Selective decomposition by laser heating will also be discussed in binary systems, such as maleate and ethylene.

The chemical reaction induced by a laser beam (ruby laser) has been investigated previously. The reaction mechanism[1] has been considered to be: (1) photodissociation,[2,3] (2) direct heating of the solid, causing vaporization,[3,4] and (3) breakdown of gases.[5] The reaction of carbon vapor produced by the ruby laser and that caused by the breakdown of gases have been previously

reported by the present authors.[6,7] As the ruby laser (photon energy: 1.8 eV) does not have enough energy to dissociate organic molecules, any photochemistry by the ruby laser is restricted and some of the reaction must be performed by multiphoton absorption processes. Therefore, the ruby laser may be most useful for the pyrolysis.

Organic carboxylic acids are well known to be decomposed by heating, resulting in decarboxylation in the presence of a copper catalyst.[8,9] Metal salts of carboxylic acid are also decomposed to produce organic radicals and ketones[10] under decarboxylation.[11] Acetic acid is decomposed at 530—762°C to give methane and ketene.[12]

By the absorption of the pulse ruby laser beam, the target surface is heated rapidly to about 600—800°C,*1 resulting in heat decomposition. As the copper salts of organic acids are blue and green, these salts may absorb the ruby laser beam efficiently and themselves be decomposed.

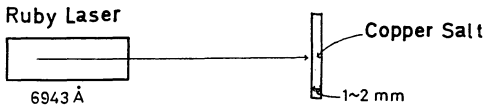
Among the copper salts of organic acids decomposed by laser heating (laser decomposition) and conventional heating (thermal decomposition), both maleate and fumarate give quite different results between the laser and thermal decompositions.

In this experiment the mechanism of laser decomposition has been studied; this paper will also discuss another possibility of the use of a laser beam.

Experimental

Copper maleate and fumarate were prepared by the reaction of maleic acid and copper carbonate, and of fumaric acid sodium salt and a copper sulfate solution, respectively. Each of them has crystal water,*2 and the decomposition temperature was checked by differential thermal analysis and thermal gravimetrical analysis.

The laser used was a pulse ruby laser, the output energy and pulse duration of which were about 3 J and 0.5 msec respectively. The sample target in the cell



output energy 3 J
pulse duration 0.5 msec

Fig. 1. Experimental block diagram.

was irradiated by the laser beam as is shown in Fig. 1; after 2—7 pulse irradiations the gaseous products were analysed by gaschromatography using silica-gel, activated-charcoal, and squalane columns. Quantitative analysis was performed by the internal standard system.

The thermal decomposition (0.1 g salt) was carried out in a metal bath for 30—60 sec at various temperatures.

Results and Discussion

1) Decomposition of Metal Salt. Various copper salts (acetate, propionate, *n*-butyrate, isobutyrate, acrylate, malonate, benzoate, phthalate, succinate, adipate, maleate, and fumarate) were decomposed by both the thermal and laser decomposition methods. The results for several salts are shown in Table 1. Generally, the product distributions are almost the same in the two decomposition methods, but maleate and fumarate are exceptions. The gaseous products can be reasonably explained in terms of the expected reaction of the decarboxylated fragments. The amount of carbon dioxide may be considered to represent the fraction of the decomposed copper salt. For convenience, the product yield may be represented as per cent of carbon dioxide.

In the laser decomposition on both copper maleate and fumarate, the gaseous products consisted of

Table 1. Product yield from copper salts in thermal* and laser decomposition based on CO_2 produced

Substrate	Product	Yield (%) Thermal decomp. (at 400°C)	Laser decomp. (6 pulses)
Copper acrylate	CH_4	0.011	0.39
	C_2H_6	0.0011	0
	C_2H_4	6.7	15
	Butadiene	0.023	3.2
Copper Succinate	CH_4	0.05	0.37
	C_2H_6	0.014	0.07
	C_2H_4	2.3	14
	Propane	0	0.26
	C_2H_2	0	1.7
Copper maleate	C_2H_4	2.2	1.2
	C_2H_2	trace	8—12
Copper fumarate	C_2H_4	2.4—4.7	5.0
	C_2H_2	trace	10—12

* The yield percents of CO_2 for salts used were 80—90% in maleate and 45—50% in fumarate.

*1 The surface temperature was estimated by the ignition point of amorphous carbon and the melamine polymer.

*2 Copper maleate dried at 80°C has 1 mol crystal water (Found: C, 24.5; H, 2.16%, ($C_4H_2O_4Cu+H_2O$)).

Table 2. Product yield from copper maleate and fumarate in laser decomposition based on CO_2 produced

Product	Substrate	
	Maleate	Fumarate
Methane	0.5 %	2.2 %
Ethane	0.05	0.2
Ethylene	1.2	5.0
Acetylene	8—12	10—12

10—15% noncondensable gases at the temperature of liquid nitrogen; the products were methane and carbon monoxide, hydrogen not being detected. 65% of the condensable gases consisted of carbon dioxide, and the rest were hydrocarbon and water. The hydrocarbon consisted of acetylene, ethylene, and a small amount of C_3 and C_4 compounds, as is listed in Table 2. Acetylene is the main product, but the yield is only about 10% of the carbon dioxide (10^{-5}—10^{-6} mol). The decomposition processes are considered to be as follows:

$$\text{Maleate or fumarate} \xrightarrow[\text{irradiation}]{\text{laser}} \text{Decarboxylated intermediate } (-CH{=}CH-) \longrightarrow \text{Acetylene, } C_4 \text{ compounds, and nonvolatile products}$$

On the other hand, the thermal decomposition gives not acetylene but ethylene at 350°C. The high-temperature decomposition gives acetylene, but ethylene is still obtained in a high yield, as is listed in Table 3. In the laser decomposition, the ethylene yield increases as the laser power is lowered by using a copper-sulfate-solution filter, but acetylene is still the main product, as is shown in Table 4. From the above results, the difference between the laser and the thermal decomposition does not seem to depend only on the decomposition temperature. In the laser heating, the temperature rises very rapidly to decompose the salt in a moment, and then two decarboxylations are brought about at the same time to produce an intermediate (-CH=CH-). This intermediate forms acetylene intramolecularly. Therefore, the formation of acetylene seems to depend on the heating rate.

Table 3. The ratio of acetylene to ethylene from copper maleate and fumarate in thermal decomposition at various temperatures

Substrate	C_2H_2/C_2H_4			
	350°C	500°C	570°C	670°C
Copper maleate	0.0015	0.22	—	1.3
Copper fumarate	0.009	0.12	0.15	—

— Detection was not carried out.

Table 4. The ratio of acetylene to ethylene from copper maleate and fumarate in laser decomposition at various transmissions of laser beam by using $CuSO_4$ solution filter

Substrate	C_2H_2/C_2H_4		
	100 % trans.	50% trans.	25% trans.
Copper maleate	6—10	5.8	4.9
Copper fumarate	2—2.4	.2.0	1.3

In the thermal decomposition, the formation mechanism of ethylene and acetylene is not clear because the secondary decomposition may occur at a high temperature. However, on the basis of differential thermal analysis and thermal gravimetrical analysis data, the decomposition occurs over a wide temperature range in copper maleate (170—340°C) and fumarate (170—380°C). Therefore, it may be roughly presumed that the decarboxylation is brought about step by step, that the -CH=CH-COO-Cu- thus obtained may abstract hydrogen to produce an acrylic compound,[13] and that the secondary decarboxylation may give ethylene:

$$\text{Copper maleate or fumarate} \xrightarrow{\text{Decarboxylation}} -CH{=}CH-COOCu- \xrightarrow{\text{Hydrogen abstraction}} CH_2{=}CH-COOCu \xrightarrow{\text{Decarboxylation and hydrogen abstraction}} CH_2{=}CH_2$$

In fact, copper acrylate is decomposed to give ethylene in both the laser and thermal decompositions (Table 1).

The difference between the two types of decomposition may depend on whether or not the two decarboxylations occur at the same time. Moreover, it may be also decided by the property of the one-decarboxylated intermediate. In fact, no difference was found in copper succinate (decomposition temperature range: 280—380°C). In this case, the decarboxylated intermediate, $-CH_2-$

Table 5. Product yield from mixture of benzoate and other salts in laser decomposition based on CO_2 produced

Substrate (Copper salt)	Yield(%)			
	Benzene	Toluene	Ethyl-benzene	Isopropyl-benzene

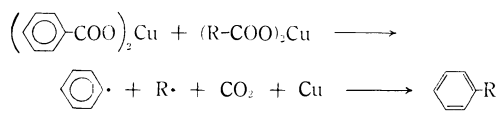
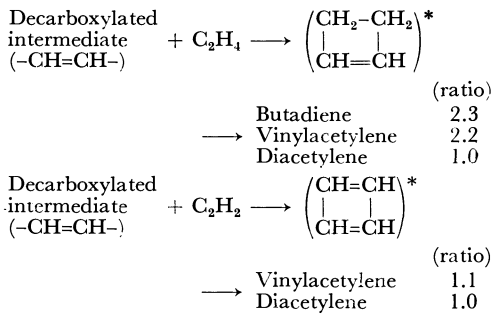
CH_2–COOCu–, may form ethylene intramolecularly in the thermal decomposition. The mechanism of decarboxylation in the laser decomposition may be supported by the following experimental fact. In the mixture of copper benzoate and acetate, benzoate and propionate, and benzoate and isobutyrate, the laser heating of the mixture gives toluene, ethylbenzene, and isopropylbenzene respectively, as is shown in Table 5. However, in the thermal decomposition at 400°C, toluene, ethylbenzene, and isopropylbenzene were not detected or were present in trace quantities only. The alkyl-substituted benzene may be formed by a recombination of the phenyl and alkyl radicals. Therefore, it is necessary for the decarboxylation of the two components to occur at the same time in a mixture of copper salts. The reaction mechanism may be considered to be as follows:



Each component is decomposed to produce R–R and biphenyl by both the laser and thermal decompositions. However, each component is decomposed in a different temperature range (acetate: 125—300°C; benzoate: 220—450°C; isobutyrate: 280—310°C, and propionate; 210—300°C). It is hard to obtain the product,  in thermal heating.

The above experimental results may be explained by the rapid heating and quenching by the laser heating. This type of pyrolysis is only possible in the laser heating.

2) Selective Decomposition. In a binary system, such as copper maleate and ethylene, the laser beam may decompose copper maleate only, and not ethylene, because the laser beam is absorbed on the copper maleate. If some intermediate in the decomposition of copper maleate is produced, the reaction with ethylene will be possible. Because copper maleate is decomposed by the laser heating to produce acetylene, the acetylene precursor, as has been mentioned before, may be the –CH=CH– intermediate. It is also dimerized to produce C_4 compounds. The determination of C_4 compounds was performed in the presence and in the absence of ethylene and acetylene. The data and the relative product yields in the binary system of copper salt and hydrocarbon gas are listed in Table 6. The (–CH=CH–) intermediate intramolecularly forms acetylene mainly, but a fraction reacts with ethylene and acetylene to produce C_4 compounds.



The decarboxylated intermediate (–CH=CH–) reacts with propylene and 1-butene to give C_5 and C_6 compounds respectively. Although C_5 compounds are produced in the laser decomposition of maleate itself, the yields of C_5 compounds in the mixture of maleate and propylene are higher than those in the decomposition of maleate itself.

It is worth noticing that the selective decom-

position and the above-mentioned reaction are only possible in the laser heating.

The authors wish to acknowledge the enthusiastic assistance of Miss K. Motegi in carrying out this work.

The Reaction of Cadalene and Eudalene with Sulfur

Shinji KUROKAWA

Department of Chemistry, Faculty of Education, Saga University, Honjyo-machi, Saga

(Received September 24, 1969)

The action of sulfur on two naphthalenes was investigated. Cadalene was heated with sulfur to give a new sulfur-containing naphthalene, 1,5,8-trimethylnaphtho[2,1-*b*]thiophene. It was formylated at the C_2-position of the thiophene moiety according to the Vilsmeier procedure, while an attempted acetylation according to this procedure was unsuccessful. Similarly, the reaction of eudalene with sulfur gave 3,9-dimethylnaphtho[1,2-*b*]thiophene, whose structure was determined by chromium trioxide oxidation, yielding *o*-quinone, and by a subsequent reaction with *o*-phenylenediamine, forming a quinoxaline derivative.

In a previous investigation of the reaction of azulene with sulfur, it was shown that 3,5,8-trimethylazuleno[6,5-*b*]thiophene and 3,5,9-trimethylazuleno[1,2-*b*]thiophene were, respectively, obtained from *S*-guaiazulene[1,2] and vetivazulene,[3] and that 6- and 7-acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophenes were yielded from 3-acetylguaiazulene, which was also isomerized to 2-acetylguaiazulene through the acetyl migration.[4] The sulfur-containing product in these reactions commonly contains a β-methylthiophene ring formed between an azulene-ring carbon atom and the isopropyl side chain of the azulenes.

The present investigation is concerned with how the action of sulfur on cadalene and eudalene, both naphthalene derivatives containing isopropyl groups, gives two new sulfur-containing naphthalenes. The compound thus obtained from cadalene (I) was determined to be 1,5,8-trimethylnaphtho[2,1-*b*]-thiophene (II), whose structure corresponds to that of furanocadinene[5] except that its oxygen atom of a hetero-ring is replaced with a sulfur atom. Formylation and acetylation by electrophilic substitution on the compound were attempted according to the Vilsmeier procedure.[6] On the other hand, the compound from eudalene (VI) was determined to be 3,9-dimethylnaphtho[1,2-*b*]thiophene (VIIa). Another compound (VIIb), which was also to be expected from the structure of eudalene (VI), could not be found in this reaction, however.

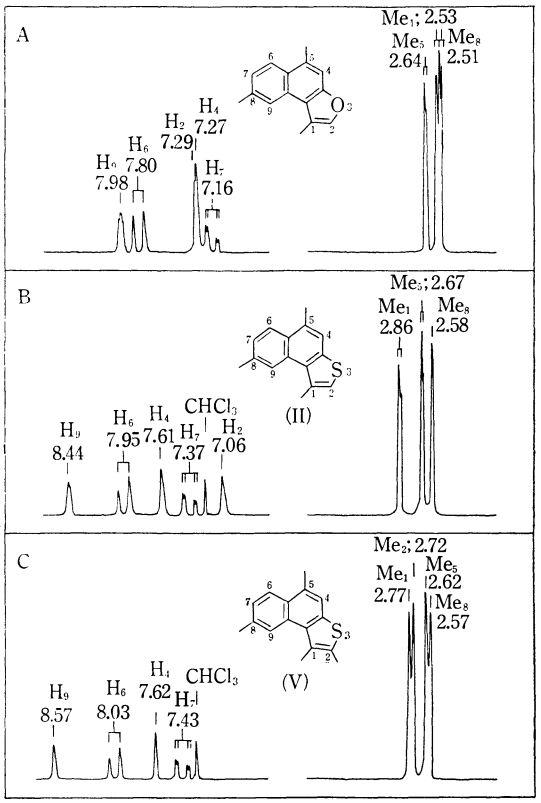
Results and Discussion

The Structure of the Sulfur-containing Cadalene: 1,5,8-Trimethylnaphtho[2,1-*b*]thiophene. The heating of cadalene with sulfur at 260°C for 10 hr produced colorless needles, mp 148—150°C, as the main product.

This compound had the molecular formula of $C_{15}H_{14}S$, and was desulfurized by heating it with Raney nickel catalyst (W-2 type), thus regenerating cadalene in a good yield. Hence, it is certain that the compound retains a cadalene skeleton in its molecule. The UV spectrum of this compound has an absorption maximum at 245.5 mμ; this maximum is 14 mμ more on the bathochromic side than that of the original cadalene. This fact shows the compound to have an elongated conjugate system, and it can be deduced that the compound has the structure of II, which consists of a fused ring system of naphthalene and β-methylthiophene.

This structure was confirmed mainly by the NMR spectrometry as follows. In IR and NMR spectra of this compound, isopropyl signals, which are clearly observed in those of cadalene, are absent; three aromatic methyl signals (2.86, 2.67, and 2.58 ppm, each 3H), corresponding to an increase of one methyl group from those of cadalene, are present in the NMR spectrum (Fig. 1B).



← ppm from TMS

Fig. 1. NMR spectra of furanocadinene (A), 1,5,8-trimethylnaphtho[2,1-*b*]thiophene (B) and 1,2,5,8-tetramethylnaphtho[2,1-*b*]thiophene (C).

In the aromatic-proton region of the NMR spectrum we observed three singlet-like signals at 8.44, 7.61, and 7.06 ppm (precisely, multiplets), one doublet at 7.95 ppm (J=8.8 Hz), and one double doublet at 7.37 ppm (J=8.8 and 1.5 Hz). These aromatic proton signals can be reasonably assigned to H_9, H_4, H_2, and H_6 and H_7 in the structure (II)*1 on the basis of comparisons with the spectra of 3-methylcadalene[7] and benz[*b*]thiophene,[8] and from the results of a double-resonance experiment: irradiation of the double doublet at 7.37 ppm decoupled the doublet at 7.95 ppm.

The methyl signals mentioned above could also be ascribed to methyl groups of the formula (II), as is shown in Fig. 1B, on the basis of a comparison with the spectra of 3-methylbenz[*b*]thiophene,[8] azulenothiophenes,[1-4] and naphthalenes,[7] and on the basis of the results of the irradiation experiment on H_2, which decoupled the doublet at 2.86 ppm.

In structure (II) the oxygen atom of furanocadinene is replaced with a sulfur atom. In fact, the NMR spectrum of the present compound (Fig. 1B) is very close to that of furanocadinene (Fig. 1A), except for the well-known fact regarding a thiophene ring, that an α-H is more shielded, while a β-methyl group is more deshielded than that of a furan ring.[9]

Oxidation of 1,5,8-Trimethylnaphtho[2,1-*b*]-thiophene with Hydrogen Peroxide. In order to clarify the presence of a thiophene nucleus, the sulfur-containing compound was oxidized with hydrogen peroxide. A sulfone was obtained as pale yellow needles, mp 178—179°C, which had sharp absorption bands characteristic to ν_{SO_2} at 1292, 1276, and 1124 cm^{-1} in the IR spectrum. On the other hand, the NMR spectrum (Fig. 2) exhibits the presence of two aliphatic methyl (1.77 ppm, 6H) and four aromatic methyl groups [2.30 (d), 2.67 (s), 2.84 (s) and 3.23 ppm (s), each 3H], and a tri-

*1 If the NMR data concerning the aromatic proton region are neglected, an alternative structure,  must be also taken into account. However, this structure can now be excluded, for one singlet and four doublets would be expected as the aromatic proton signals.

← ppm from TMS

Fig. 2. NMR spectrum of the sulfone dimer (III).

substituted olefinic proton [6.48 ppm (m), 1H], in addition to eight aromatic protons showing complicated signals. Thus, this spectrum cannot be explained in terms of the simple sulfone to be expected from naphthothiophene (II).

In the hydrogen-peroxide oxidation of thiophene, Davies and James have observed that the sulfone, supposed to be the primary oxidation product, was condensed through Diels-Alder addition accompanied by the loss of sulfur dioxide.[10] In the oxidation of 1,5,8-trimethylnaphtho[2,1-*b*]thiophene, also, if its sulfone is thought to be dimerized similarly, structure (III) is possible; it explains well the above spectrometric evidence. The absorption maximum (236 mμ) of the UV spectrum is rather closer to that of cadalene (I) (232 mμ) than to that of naphthothiophene (II) (245.5 mμ). This fact also supports structure (III), which contains a shorter conjugate system than the original trimethylnaphthothiophene.

Electrophilic Substitution of 1,5,8-Trimethylnaphtho[2,1-b]thiophene (II). We attempted to acetylate naphthothiophene (II) with *N,N*-dimethylacetamide in the presence of phosphorus oxychloride, according to the Vilsmeier procedure, but the trial resulted only in the recovery of the starting material. This result is different from the cases of 3,5,8-trimethylazuleno[6,5-*b*]thiophene[4] and 3,5,9-trimethylazuleno[1,2-*b*]thiophene.[3]

On the other hand, a Vilsmeier formylation of the trimethylnaphthothiophene proceeded almost quantitatively to give a pale yellow crystalline substance, mp *ca.* 108°C, which showed an absorption band due to an aldehyde group at 1650 cm^{-1} in the IR spectrum and which furnished semicarbazone, mp 210°C (decomposition).

The crystalline aldehyde, upon Wolff-Kishner reduction,[11] gave a pale yellow crystalline substance, mp 130—131°C, which had a molecular formula of $C_{16}H_{16}S$, representing the increase of one methyl group as compared with the original trimethylnaphthothiophene.

When the NMR spectrum (Fig. 1C) is compared with that of the original compound (Fig. 1B), an aromatic proton signal corresponding to the H_2 (7.06 ppm) of the original compound is absent, and four aromatic methyl signals [2.77, 2.72, 2.62 and 2.57 ppm, each (s) and 3H] are seen, equivalent to an increase of one methyl group from the original trimethylnaphthothiophene. Besides, the methyl signal (2.77 ppm) attributable to Me_1 becomes a singlet in this compound, while it is a doublet in the trimethylnaphthothiophene.

These facts indicate that the introduction of the fourth methyl group, namely, the Vilsmeier formylation, took place at the C_2 position of the trimethylnaphthothiophene.

The Structure of the Sulfur-containing Eudalene: 3,9-Dimethylnaphtho[1,2-*b*]thiophene. The reaction of eudalene with sulfur gave colorless needles, mp 41.5—42.5°C, having a molecular formula of $C_{14}H_{12}S$. This compound regenerated eudalene when it was submitted to reductive desulfurization with a Raney nickel catalyst and successively dehydrogenated with palladium on charcoal. Hence, the compound certainly retains the eudalene skeleton in the molecule.

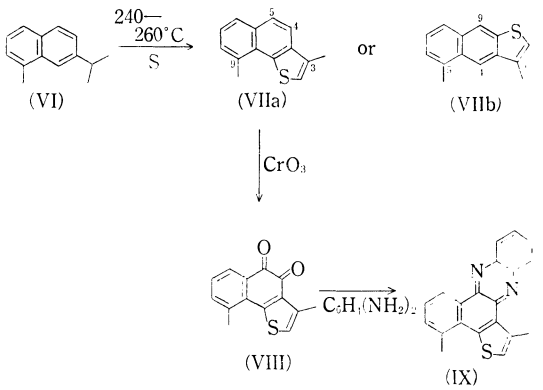

Chart 2

On the other hand, the participation of the isopropyl group of eudalene in the reaction with sulfur was indicated by the absence of splitting bands at 1382 and 1389 cm^{-1} in the IR spectrum and by the lack of NMR signals at 1.35 (doublet, 6H, J=6.7 Hz) and 3.05 ppm (multiplet, 1H) in Fig. 3A, as was seen in each spectrum of the starting material.

In the aromatic-methyl-proton region of the NMR spectrum (Fig. 3A), there is one more methyl doublet (2.52 ppm) than in the spectrum of the starting material, and the spin-coupling constant, J=1.0 Hz, of this newly-appeared doublet is in good agreement with the J value concerning the β-methyl group and the α-proton in 1,5,8-trimethylnaphtho[2,1-*b*]thiophene and in the other β-methyl-

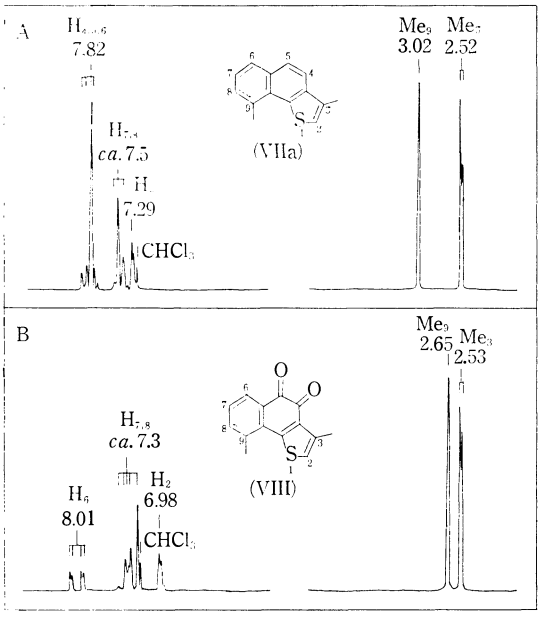

Fig. 3. NMR spectra of 3,9-dimethylnaphtho[1,2-*b*]thiophene (A) and its 4,5-quinone (B).

thiophenic compounds reported earlier.[1-4] Thus, this compound can also be concluded to be a naphthothiophene in which the isopropyl group and one of the aromatic-ring carbon atoms in eudalene forms a thiophene ring with sulfur, as in the reaction of cadalene or azulenes with sulfur. This deduction was powerfully supported by the prominent appearance of the $(M-1)^+$ ion (50.2%) in the mass spectrum of this compound, because the abundant formation of this ion is peculiar to methylthiophenes;[12] this ion can be described as a thiapyryrium ion formed through the expansion of a thiophene ring.

In this manner, two formulae, VIIa and VIIb become possible for the present compound. In order to determine the more reasonable structure of the two, the present compound was oxidized with chromium trioxide in glacial acetic acid to yield red needles, mp 206.5—207.5°C, as the main product. The red crystalline product exhibited $\nu_{C=O}$ bands at 1655 and 1667 cm^{-1} in the IR spectrum, showed two fewer proton signals in the aromatic-ring-proton region of the NMR spectrum (Fig. 3B) as compared with that of the dimethylnaphthothiophene (Fig. 3A), and had a molecular formula of $C_{14}H_{10}SO_2$ based on the parent ion ($M^+=242$) of the mass spectrum. This product is, therefore, a quinone yielded from the dimethylnaphthothiophene by the oxidation of one of two activated carbon positions, $C_{4,5}$ in VIIa or $C_{4,9}$ in VIIb. Besides, this red quinone had an intense absorption maximum at 466 mμ (log ε, 3.34) in the visible region, and in the NMR spectrum (Fig. 3B) the chemical shift between the two methyl groups ($\Delta Me_3 - Me_{9\text{ or }5}=0.12$ ppm) is much smaller than that of the dimethylnaphthothiophene (0.50 ppm) (Fig. 3A). From the latter fact, the quinone can be deduced to have a structure in which Me_3 is closer to the carbonyl group than the other methyl group, Me_9 or Me_5. Thus, these data suggest that the product is not the *p*-quinone expected from VIIb, but *o*-quinone (VIII) of a phenanthraquinone type derived from VIIa.

Supporting this suggestion is the fact that this quinone reacted with *o*-phenylenediamine to form a greenish yellow powder, mp 202—203°C, which was determined to be a quinoxaline derivative (IX) derived from *o*-quinone (VIII) by elementary analysis and by a study of its mass spectrum. From the above evidence, it can be concluded that the colorless needles obtained by the reaction of eudalene with sulfur are 3,9-dimethylnaphtho[1,2-*b*]thiophene of a phenanthrene type; all the data other than those mentioned here support this structure.

Experimental

All the melting points in this paper are uncorrected. The IR spectra were obtained using KBr disks, and the mass spectra, at 70 eV. The NMR spectra were taken at 60 MHz in deuteriochloroform. The thin-layer chromatography (TLC) was carried out by the use of silica gel-G (Merck); unless otherwise stated, all the spots were detected by spraying with a mixture of sulfuric acid and nitric acid (19 : 1).

Reaction of Cadalene (I) with Sulfur. A mixture of cadalene (3.0 g) and sulfur (1.5 g) was heated at 260°C for 10 hr under a nitrogen atmosphere. The reaction mixture, which solidified at room temperature, was crushed into small fragments and ground thoroughly in a mortar with *n*-hexane to give a viscous red oil (0.6 g). This oil was then repeatedly chromatographed on a silica-gel column with *n*-hexane; a colorless crystalline substance (40 mg) (1,5,8-trimethylnaphtho[2,1-*b*]thiophene) was thus isolated. After two recrystallizations from *n*-hexane, it afforded colorless needles, mp 148.0—150.0°C, which showed a single green spot (R_f, 1.81) in TLC with petroleum ether. Mass spectrum: *m/e* 226 (M^+, $C_{15}H_{14}S$), base peak; *m/e* 225 $(M-H)^+$, 22.9%. Relative intensities of isotope ions: Found; M^+ (100), $(M+1)^+$ (17.38), $(M+2)^+$ (5.29%). Calcd for $C_{15}H_{14}S$; M^+ (100), $(M+1)^+$ (17.23), $(M+2)^+$ (5.70%). UV (isooctane): mμ (log ε), 220 sh (4.22), 235 sh (4.49), 245.5 (4.62), 259.5 (4.44), 298.5 (4.02), 306 (4.01), 319.5 (3.58), 334.5 (3.47).

Found: S, 14.46%. Calcd for $C_{15}H_{14}S$: S, 14.17%.

Desulfurization of 1,5,8-Trimethylnaphtho[2,1-*b*]thiophene (II). Trimethylnaphthothiophene (40.8 mg) was dissolved into absolute methanol (20 m*l*); the solution, after the addition of a W-2 Raney nickel catalyst (0.2 g) prepared freshly, was refluxed on a water bath. After 40 min, trimethylnaphthothiophene;

12) H. Bujikiewicz, C. Djerassi and D. H. Williams, "Interpretation of Mass Spectra of Organic Compounds," Holden-Day, San Francisco (1964), p. 231.

the starting material, came to be hardly detected at all in TLC with *n*-hexane. Then the reaction mixture was filtered, washed with water, dried over anhydrous calcium chloride, and concentrated under reduced pressure to leave a colorless oil (50 mg). The oil exhibited a yellowish-green spot (R_f, 2.70) in TLC using *n*-hexane, together with a green spot (R_f, 1.62) attributable to unchanged trimethylnaphthothiophene. By means of preparative TLC, a colorless oil of R_f 2.70 was isolated; it was found to be identical with an authentic specimen of cadalene by UV and IR absorption spectrometry.

Hydrogen Peroxide Oxidation of 1,5,8-Trimethylnaphtho[2,1-b]thiophene (II). Formation of a Sulfone Dimer (III). A solution of trimethylnaphthothiophene (170 mg) in glacial acetic acid (1 m*l*) was mixed with 30% hydrogen peroxide (0.8 m*l*), and the mixture was refluxed on an oil bath for 20 min. The reaction mixture was then diluted with water (30 m*l*) and extracted with chloroform to give an orange, resinous material (200 mg). This material was chromatographed on a silica-gel column with chloroform; unchanged trimethylnaphthothiophene was recovered from a quickly-eluted fraction, and a yellow crystalline compound (71.1 mg) was obtained from the fraction next eluted. Further purification of the crystals by repeated elution chromatogaphy with mixed solvents of methylene chloride and chloroform (1 : 1 and 2 : 1) afforded a sulfone dimer (III) (26.2 mg) as pale yellow needles, mp 178—179°C. These crystals showed a single brown spot (R_f, 4.30) in TLC using a mixed solvent of methylene chloride and chloroform (7 : 3). UV (EtOH): mμ (log ε), 216 (4.82), 237.7 (4.95), 293 sh (4.09), 303 (4.13), 325 sh (3.81).

Vilsmeier Formylation of 1,5,8-Trimethylnaphtho[2,1-*b*]thiophene (II). To a solution of trimethylnaphthothiophene (125 mg) in *N*,*N*-dimethylformamide (4.2 m*l*), another solution of phosphorus oxychloride (0.42 g) in the same solvent (2.1 m*l*) was added under ice cooling. The mixture, after being allowed to stand at room temperature for 2 days, was heated at 60°C for 1 hr to complete the reaction, and then poured into water (160 m*l*). When the aqueous solution was made slightly alkaline by adding powdered sodium carbonate, followed by extraction with chloroform, a viscous yellow oil (255 mg) was obtained. Through the benzene-silica gel elution chromatography of the oil, 2-formyl-1,5,8-trimethylnaphtho[2,1-*b*]thiophene (114 mg) was separated as pale yellow needles, mp *ca.* 108°C, which showed a single reddish-orange spot (R_f, 5.40) in TLC with benzene when sprayed 2,4-dinitrophenylhydrazine.

Semicarbazone. From 2-formyl-1,5,8-trimethylnaphtho[2,1-*b*]thiophene, semicarbazone was obtained as a crystalline mass; this mass gave colorless needles. mp 210°C (decomposition), after being recrystallized from ethanol. IR: $\nu_{C=O}$ splitting band at 1726 and 1717 cm^{-1}, ν_{N-H} 3470 cm^{-1}.

Reduction of 2-Formyl-1,5,8-trimethylnaphtho[2,1-*b*]thiophene (IV). A mixture of formyltrimethylnaphthothiophene (211 mg), 100% hydrazine hydrate (160 mg), and powdered sodium hydroxide (377 mg) was heated at 200°C for 1.5 hr by which time the evolution of nitrogen gas had ceased. The reaction mixture, after being acidified with dilute hydrochloric acid, was extracted with chloroform; crude 1,2,5,8-tetramethylnaphtho[2,1-*b*]thiophene (V) (150 mg) was thus obtained as a reddish-orange crystalline mass, which was purified by means of benzene-silica gel elution chromatography. The purified pale yellow needles, mp 130—131°C (78 mg), showed a single green spot (R_f, 6.77) in TLC with benzene. Mass spectrum: *m/e* 240 (M^+, $C_{16}H_{16}S$), base peak; *m/e* 239 $(M-H)^+$, 22.8%; *m/e* 225 $(M-CH_3)^+$, 81.9%. Relative intensities of isotope ions: Found; M^+ (100), $(M+1)^+$ (17.96), $(M+2)^+$ (5.65%). Calcd for $C_{16}H_{16}S$; M^+ (100), $(M+1)^+$ (18.35), $(M+2)^+$ (5.70%).

Reaction of Eudalene (VI) with Sulfur. Eudalene (2.0 g) was heated with half as much powdered sulfur at 240—260°C for 6 hr. The reaction mixture was dissolved in hot benzene (100 m*l*) and poured into *n*-hexane (200 m*l*) to yield a brown precipitate. The solution, from which the precipitate had been filtered off, was then concentrated under reduced pressure to give a red oil (1.50 g). This oil was treated as has been described above for cadalene (I); a colorless crystalline substance (227.8 mg) was thus isolated. After recrystallization from methanol, dimethylnaphthothiophene (VIIa) was obtained as colorless needles, mp 41.5—42.5°C, which showed a single yellow spot (R_f, 5.8) in TLC with *n*-hexane. UV (EtOH): mμ (log ε), 238 sh (4.42), 245 (4.52), 259 sh (4.55), 266.2 (4.69), 283 (4.08), 294 (3.97), 305 (3.72).

Found: C, 79.19; H, 5.68; S, 15.04%. Calcd for $C_{14}H_{12}S$: C, 79.20; H, 5.70; S, 15.10%.

Desulfurization of 3,9-Dimethylnaphtho[1,2-*b*]thiophene (VIIa). The reaction of dimethylnaphthothiophene (15.07 mg) with a Raney nickel catalyst was carried out in a manner similar to that used in the experiment described for 1,5,8-trimethylnaphtho[2,1-*b*]thiophene (II). When the oil thus obtained (10 mg) was chromatographed on a silica-gel column with *n*-hexane, a colorless oil (7.6 mg) was separated in a pure state. It showed a single brown spot (R_f, 8.5) in TLC with *n*-hexane, and was clearly different from eudalene (R_f, 6.9). This substance may be concluded to be a partially hydrogenated eudalene on the basis of UV and the results of the following dehydrogenation experiment. UV (EtOH): mμ (log ε*[2]) 215.5 (4.02), 220 sh (3.99), 227 sh (3.66), 265 (2.62), 269.5 (2.71), 277.8 (2.70), 291 sh (1.96).

Dehydrogenation of the Desulfurized Product. The colorless oil (7.6 mg) obtained by the above desulfurization of dimethylnaphthothiophene (VIIa) was sealed in a glass tube with 5% palladium on charcoal (20 mg), and the tube was heated at 300°C for 10 min. After being cooled, the reaction mixture was dissolved in chloroform, the solution, from which the catalyst had been filtered off, was then concentrated under reduced pressure to give a colorless oil (50 mg). This oil was confirmed, by TLC with *n*-hexane, to be mainly composed of eudalene. A colorless oil purified by the use of preparative TLC was identical with eudalene (VI) in TLC and UV spectrometry.

Chromium Trioxide Oxidation of 3,9-Dimethylnaphtho[1,2-*b*]thiophene (VIIa). To a solution of the dimethylnaphthothiophene (209 mg) in glacial acetic acid (4.7 m*l*) we added, drop by drop another solution of chromium trioxide (350 mg) in 60% acetic acid (2.0 m*l*), after which the mixture was heated at 50—60°C for 1.5 hr. The reaction mixture was then poured into

*[2] These values were calculated on the assumption that MW=186.

water (53 m*l*) and extracted with chloroform. A viscous red material (250 mg) thus obtained was chromatographed on a silica-gel column with a mixed solvent of benzene-chloroform (2 : 1), a slightly yellow-colored, unchanged naphthothiophene (9.9 mg) fraction was eluted first, and then a red fraction. The red fraction gave, after the removal of the solvent, *o*-quinone (VIII) as red needles, mp 206.5—207.5°C (15.1 mg) which showed a single red spot (R_f, 2.5) in TLC (without any color reagent) when a benzene-chloroform (4 : 1) mixture was used. UV and visible absorption spectra (EtOH): mμ (log ε), 225 (4.39), 241 sh (4.13), 261 sh (4.19), 274 sh (4.33), 280 (4.37), 345.5 (3.71), 466 (3.34), 510 sh (3.17). Mass spectrum: *m/e* 242 (M^+, $C_{14}H_{10}SO_2$), 40.2%; *m/e* 214 $(M-CO)^+$ ($m^*=189.2$), base peak; *m/e* 186 $(M-2CO)^+$ ($m^*=161.7$), 10.4%; *m/e* 185 $(M-2CO-H)^+$, 33.1%.

Reaction of *o*-Quinone (VIII) with *o*-Phenylenediamine. *o*-Quinone (VIII) (8.1 mg) was heated with *o*-phenylenediamine (3.4 mg) on a steam bath for 10 min. At the end of this period, the reaction mixture was heated with ethanol (30 m*l*) and an insoluble part was filtered off. The hot ethanol solution was diluted with water (20 m*l*) and chilled overnight at −20°C; the precipitate of the quinoxaline derivative (IX) was obtained by filtration as a greenish-yellow powder, mp 202.0—203.0°C (2.9 mg). This powder showed a single yellow spot (R_f, 6.2) in TLC with a mixed solvent of chloroform-benzene (1 : 4). UV[*3]: mμ (log ε), 240 sh (4.57), 257 (4.83), 284.2 (4.49), 294.6 (4.52), 309 (4.46), 388 (4.22).

Found: N, 8.51%. Calcd for $C_{20}H_{14}SN_2$: N, 8.91%.

The author wishes to thank Professor Tamon Matsuura and Professor Shûichi Hayashi of Hiroshima University for their kind guidance and advice on this work. Thanks are also due to Professor Shô Itô of Tohoku University for his kind measurement of the NMR and mass spectra.

[*3] Ethanol containing 0.5% of chloroform was used as the solvent.

(Received September 25, 1969)

The Hammett type treatment of the chemical shift of substituted aromatic side chain protons has not always been successful. The failure might be ascribed to the neglect of magnetic long-range effects. When the corrections were made both for the ring current diminution due to the contribution of polar resonance structure of the introduced substituent and for the substituent magnetic anisotropy effect, an excellent equation was obtained to relate the chemical shifts of *meta*-substituted aromatic side chain protons to the Hammett's constants.

Recent studies on the proton chemical shifts of substituted aromatic system have shown that Hammett type treatment[1a-i] of the substituent effects is not practically successful.[2a-i]

It is well established that the substituent effects on the proton chemical shifts can be divided into

two main contributions;[3]

(1) Change of the electron density around the resonating proton.

(2) Change of the long range effect arising from the anisotropic magnetic susceptibility of the rest of the molecule.

Since the electron density can be altered by the substituent polar effect, proton chemical shift in aromatic system might be related to the Hammett σ constants[1a,b,f] or its modifications.[1e-i] This expectation will be realized as far as the chemical shifts are mainly determined by the electron density, as may be seen in the cases of the fluorine NMR chemical shifts of substituted fluorobenzenes[4] and ethynyl proton chemical shifts of substituted phenyl acetylenes[5a,b] where the contribution of factor (2) is relatively small.

General failure of the Hammett type treatment might thus be ascribed to the fact that both effects, (1) and (2), are often of equal magnitude and operate in a conflicting way.

The present paper deals mainly with the contribution of factor (2) and an attempt was made to obtain an excellent correlation between the chemical shifts of aromatic side chain protons as well as those of ring protons, and the Hammett's constant of the substituent.

In *para*-substituted aromatic side chain systems, an excess resonance interaction[6,1g,h] between substituent and a side chain can always result in the complication, leading to some difficulty in evaluating the substituent polar effects. For this reason, only the *meta*-substituent effect is considered in this paper and further studies on *para* system, which are now being undertaken, will appear in future.

Experimental

All the materials were purified by fractionation or by recrystallization and identified with their physical constants and elementary analyses.

1,1-Diphenylethylene[7] and most of substituted 1,1-diphenylethylenes were prepared by the dehydration of 1,1-diphenylethanols in 20% H_2SO_4 (Method a)[7] or by the dehydrochlorination of 1,1-diphenylethyl chlorides in pyridine (Method b).[8] The latter method was generally successful for *meta* halogeno derivatives. The 1,1-diphenylethanols were obtained by adding ethereal solution of ethyl acetate (Method A)[7] or of acetophenone (Method B)[9] to the Grignard solution of substituted bromobenzenes, or by adding ethereal solution of substituted benzophenones to the methylmagnesium bromide solution (Method C).[10]

1,1-Bis(cyanophenyl)ethylenes and 1-(cyanophenyl)-1-phenylethylenes were prepared by refluxing the corresponding bromophenylethylenes and cuprous cyanide in dry pyridine for 5—6 hr. (Method D).[10] The cyanides obtained were hydrolysed in alcoholic potassium hydroxide and the resulting carboxylic acids were esterified by dimethyl sulfates in methanolic potassium hydroxide media (Method E).

1,1-Bis(*m*-nitrophenyl)ethylene and 1-(nitrophenyl)-1-phenylethylenes were synthesized from the corresponding nitrobenzophenones through Wittig's reaction (Method F).[11]

1,1-Bis(*p*-nitrophenyl)ethylene was prepared by the dehydrobromination of 1-bromo-1,1-bis(*p*-nitrophenyl)-ethane in pyridine (Method G).[12] The bromide was prepared from 1,1-bis(*p*-nitrophenyl)ethane by bromination in carbon tetrachloride as usual with *N*-bromosuccinimide. In preparing 1,1-bis(*p*-nitrophenyl)ethane, 1,1-diphenylethane was nitrated by fuming nitric acid

(d=1.5) at −15°C.[13]

The proton chemical shifts, δ_X, for the substituted aromatic side chains were measured at 60 MHz in dilute (0.05—0.10 mol/*l*) carbon tetrachloride solution using a JNM-3H-60 spectrometer. Prior to the measurements of the chemical shifts, an NMR sample tube fitted with a thermometer reaching into the liquid paraffin in the tube, was spinned in the probe and the temperatures were directly read on the thermometer scale. Thus, the temperature of the sample under the condition of NMR measurement was estimated to be 20—25°C. The line positions were determined by linear interpolation between known audio frequency side bands of internal TMS or by direct superposition of the side band on the proton signal. The audio frequencies were measured with a frequency counter. The estimated reproducibility of δ_X was ±0.1 Hz. The observed relative chemical shifts, $\Delta\delta=\delta_X-\delta_H$, and the physical constants of the materials are listed in Tables 1-1—1-4.

Results and Discussion

The plots of relative chemical shifts, $\Delta\delta_m$, against Hammett's σ_m[1f] are shown in Figs. 1-1—1-7.

In the case of phenylacetylenes,[5a,b] a satisfactorily linear relationship is observed between the chemical shifts and Hammett constants (Fig. 1.7) as given

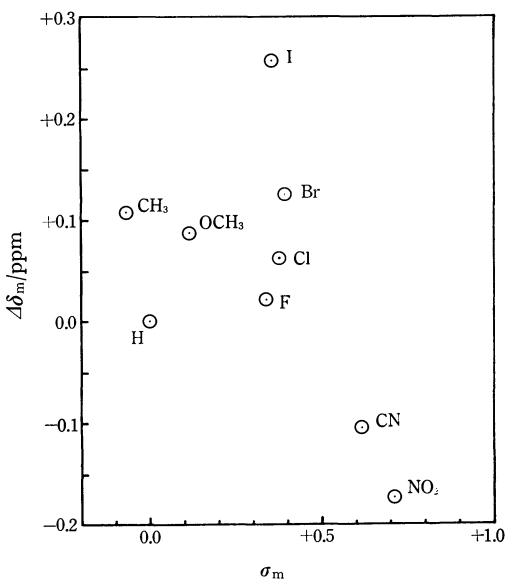

Fig. 1-1. Hammett plot for ring protons[14] *meta* from substituents.

by the equation.

$$\Delta\delta_m = a_m\sigma_m \quad (1)$$

The relationship still roughly holds in the case of diphenylethylenes (Figs. 1-2 and 1-6). The ring protons[14] *meta* to the substituents, however, give no such correlation (Fig. 1-1), the points being scattered seriously. It is noted that the protons located far from the substituent generally give

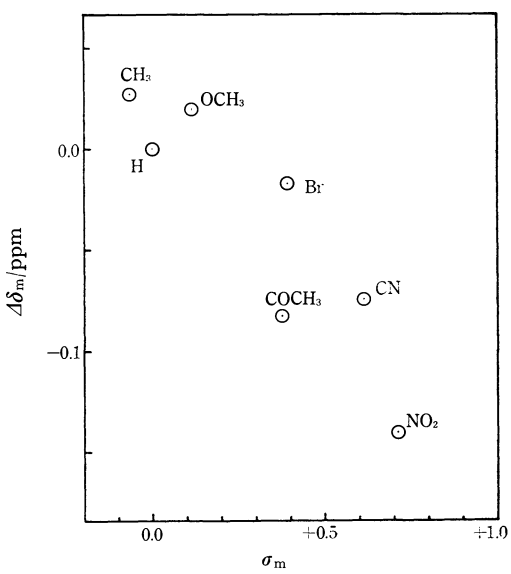

Fig. 1-4. Hammett plot for *meta*-substituted anisoles.

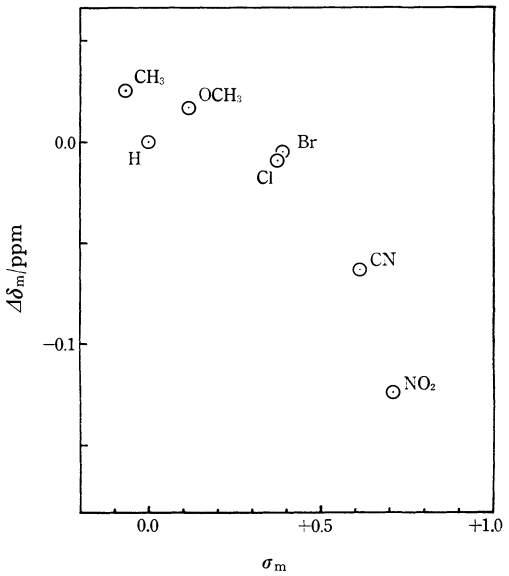

Fig. 1-5. Hammett plot for *meta*-substituted acetophenones.

better correlations.[15] Thus, the failure of correlation (1) could be mainly attributed to the long range effects of substituent magnetic anisotropy.[3,15]

Halogens and cyano group are known to have a large negative (shielding) magnetic anisotropy, $\Delta\chi$, along C-substituent axis.[3,16a-d] In fact, the

remarkable deviations to the high field side are observed for these substituents (Figs. 1-1, 1-3, and 1-4). Methoxy, methyl, and nitro groups, on the other hand, show an interesting feature. Examination of Figs. 1-1—1-7 with these substituents indicates that each of the correlation line along the points of the three substituents does not pass through the origin of the coordinate but deviates remarkably to the high field side, in other words, the effect of electron attracting nitro group seems to be abnormally decreased, whereas the effect of electron releasing methyl and methoxy group, to be abnormally increased. It is important, however, to note that no significant anomaly has generally been observed in the Hammett type plotting of the aliphatic compounds[17a,b] with these three substituents as well as the hydrogen (unsubstituted compound). If we consider this observation as evidence suggesting the zero or negligibly small anisotropy of these four groups (hereafter referred to as the selected substituent), the high field deviations observed in the present experiments should not be ascribed to the substituent magnetic anisotropy effect. This suggestion is supported strongly by both theoretical and experimental evaluation of the anisotropy of the selected substituents as discussed below.

For methyl group anisotropy,[18a-d] even though there may still be many arguments about its magnitude (the positive $\Delta\chi$ along the C–CH_3 axis which should give a deshielding effect on the proton under discussion), an isotropic magnetic susceptibility ($\Delta\chi=0$) was proposed by Pople.[16b] Thus the high field deviation of methyl group can never be reduced but rather enlarged by the correction for the anisotropy effect. For hydrogen, such anisotropy can not be predicted theoretically.[16b] In methoxy group, magnitude and direction were calculated theoretically by Pople.[16b] By the use of Pople's $\Delta\chi$, it can be shown that the methoxy group exerts a shielding effect on the proton under investigation,*1 but the effects are negligibly small at the side chains. There has been no quantitative evaluation of nitro group anisotropy, but a negative $\Delta\chi$ could be supposed to exist along the axis perpendicular to O–N–O plane. This anisotropy, however, should give a low field shift of the protons. The situation for nitro group is therefore the same as for methyl group; the correction would result in the increased high field deviation.

In view of these facts, it can be concluded that the high field deviations observed for the three substituents (CH_3O, CH_3, NO_2) should be ascribed to the contribution of an unknown factor other than the substituent magnetic anisotropy effect.

One possible explanation for the high field deviation may be given by the different way of being

*1 The correction for the anisotropy effect would move the point of methoxy group somewhat downwards (−0.018 ppm in benzene series, −0.009 ppm on toluene series), but the improvement is clearly insufficient.

affected by the polar substituent between the chemical shift and chemical reactivity. According to Buckingham's theory,[19] the polar effect on the proton chemical shift can be given (neglecting the second order term) in terms of the electric field components along the C–H bond as shown in the equation

$$E_z = k_E \sum_i (q_i \cos\theta_i / \varepsilon r_i^2) \qquad (2)$$

where r_i denotes the distance between the resonating proton and the atom i carrying a point charge q_i, and θ_i is the angle between r_i and the C–H bond.

On the other hand, Hammett's σ_m constant, determined from a reactivity measurement, should approximately be related to a potential energy[20] arising from an interaction between the point charge induced at the reaction center and point charges, q_i, which are distributed over the rest of the molecule. Hammett's σ_m constant could thus be related to the term

$$\sum_i (q_i/\varepsilon R_i)$$

where R_i is the distance between the reaction center and the location of charges on the reacting molecule in transition or product state.

It is convenient to divide the electric field effect into two classes:

(a) An effect attributable to the charge distribution brought about in the side chain by a polar effect of substituted phenyl group.

(b) An effect attributable to the charge distribution arising from the C(phenyl)-substituent polarization and to the π-electron distribution affected by the polar resonance of the substituent.

Effect (a) on the chemical shift will be the same in character as that on the potential energy change. Then the effects may be expressed, in both cases, in terms of Hammett's σ_m. For effect (b), however, a somewhat larger contribution of the π-electronic charge in the case of chemical shift could be expected since the distance between the resonating proton and the π-electronic charge, r_π or R_π, will be generally shorter than that between the resonating proton and the charges distributed in the C(phenyl)-substituent dipole, r_μ or R_μ:

We have $r_\pi \ll r_\mu$ and $R_\pi \ll R_\mu$ as cited above and if $\cos\theta_\pi \fallingdotseq \cos\theta_\mu$ as might be expected in the molecule having a long side chain, then

$$\frac{\cos\theta_\pi / r_\pi^2}{\cos\theta_\mu / r_\mu^2} > \frac{1/R_\pi}{1/R_\mu}$$

If this is true, the polar effect on the chemical shift could be expressed in the following form by allowing the additional contribution of π-electronic effect, $k\sigma_\pi$,

$$\Delta\delta_m = a_m\sigma_m + k\sigma_\pi \qquad (3)$$

in which the σ_π is Yukawa-Tsuno's parameter[1i] measuring the resonance ability[4] of the substituent.*2

Another possible cause for high field deviation is a variation in the magnetic anisotropy of benzene ring due to π-electronic perturbation in the ring system brought about by the polar resonance of the substituent. There are two different aspects to interpret the effect of π-electronic perturbation. First of which predicts a decrease on the ring current by +R substituent[4] leading to a high field shift of the protons or an increase in the ring current by −R substituent[4] leading to a low field shift of the protons. If it is assumed that the variation of the π-electronic density on the benzene ring is proportional to the resonance ability, σ_π, of an introduced substituent, the correction for the ring current effect may be given in the same expression as (3).*3

By the use of Eq. (3), the deviations are somewhat reduced than before. However, the improvement is still not quite satisfactory, as may be seen in the case of ring protons and toluenes (Fig. 2). Failure of the additional π-electron contribution model is further verified by the fact that the evaluations of the geometric factors for the side chain systems under investigation show that the relative contributions of π-electronic effect in the chemical shift are generally equal to those in the reactivity and also that the contributions are independent of the nature of side chains at *meta* position.*4

$$\frac{\sum_i (\cos\theta_i/r_i^2)_\pi}{\sum_i (\cos\theta_i/r_i^2)_\mu} \fallingdotseq \frac{\sum_i (1/R_i)_\pi}{\sum_i (1/R_i)_\mu} \fallingdotseq \text{const.} \qquad (4)$$

It is well known that the olefinic protons of

20) T. Ri and H. Eyring, *J. Chem. Phys.*, **8**, 433 (1940).

*2 Yukawa and Tsuno separated the substituent effect into the sigma-inductive effect, σ_i, and pi-electronic effect, σ_π, and demonstrated the generality and utility of this separation.[1i] The success of this separation in explaining the polar effects justifies the use of σ_π here.

*3 Equation (3) is similar in form to the equation proposed by Taft

$$\Delta\delta_m = \alpha\sigma_I + \beta\sigma_R^0 = \alpha\sigma_m + (\beta-\alpha)\sigma_R^0$$

or to the equation[15]

$$\Delta\delta_m = \alpha\sigma_p^0 \fallingdotseq \alpha\sigma_m + \beta'\sigma_R^0$$

Although both these equations gave better correlations than in the simple Hammett relation, no detailed discussion was made about the correction term, $(\beta-\alpha)\sigma_R^0$ or $\beta'\sigma_R^0$.

*4 An exception for the generality (4) is noted in the case of ring protons at *para* position for which a large excess contribution of π-electronic effect to the chemical shift can be calculated from the examination of the geometric functions and this is consistent with the observation that the *para* ring protons[2c] are satisfactorily correlated to the σ_π constants[1i] rather than to the σ_p^0 constants.[4]

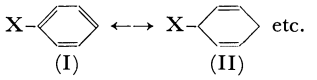
cycloolefin having localized double bonds show somewhat higher chemical shifts as compared with the normal aromatic ring protons. The feature has generally been explained in terms of the lack of ring current in those cyclic molecules.[21a,b] This suggests another possibility to interpret the effect of π-electronic perturbation due to introduced substituent. The introduction of substituent will result in an additional contribution of quinoidal structure (II) in the resonance hybrid and hence



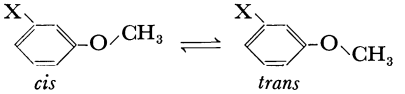
(I) (II)

lead to some decrease of the ring current. The extent of the contribution of structure (II), depending only on the resonating ability of the substituent but not on the direction of electronic displacement, could be estimated by the term, $|\sigma_\pi|$. Correcting for this term, we can express $\Delta\delta_m$ for the selected substituents at *meta* position as

$$\Delta\delta_m = a_m\sigma_m + K|\sigma_\pi| \qquad (5)$$

where K is a proportionality constant describing susceptibility to the contribution of quinoidal structure (II). Figures 3-1 and 3-2 show two examples of the plots of the relative chemical shifts corrected for the quinoidal effect, $\Delta\delta_m - K|\sigma_\pi|$, against Hammett's σ_m constants. The parameters, a_m and K, were determined using least squares method and are summarized in the first four columns of Table 2 where correlation coefficients, r_c and standard deviations, s, also are included. It is clear that the employment of treatment (5) for the given series yields significant improvements in the correlations. Additional evidence for the contribution of decreased ring current term, $K|\sigma_\pi|$, is provided by an examination of the variation of parameter K. Since K is a susceptibility coefficient to the diminution of ring current effect, it should depend only on the geometric relation between the resonating protons and the benzene ring. In order to testify this suggestion, the Johnson and Bovey's ring current shifts[21a] in ppm, $f(\rho,z)$, were utilized as a measure of the geometric factors for the resonating protons located at the usual cylindrical coordinates ρ and z.

In the last column of Table 2, the calculations of $f(\rho,z)$ were performed by averaging over all the reasonable orientations of the side chains; for the methyl protons, $f(\rho,z)$'s were calculated by assuming free rotation of the methyl group. In anisoles and acetophenones, the calculations were based on the planar *cis*- and *trans*-model of equal



cis *trans*

populations. In diphenylethylenes, two benzene rings were twisted 30° out of $C{=}CH_2$ plane[22] and the equal populations of *cis*- and *trans*-form were assumed.

The result of closer examination of the relationship between K and $f(\rho,z)$ is shown in Fig. 4. A linear dependence of K on $f(\rho,z)$,

$$K = -0.4f(\rho, z) \qquad (6)$$

is consistent with the expectation that the effect of the ring current depression on the chemical shift will be nearly proportional to the strength of the ring current field to which the resonating proton is exposed. Using relation (6), we obtain, from (5),

$$\Delta\delta_m + 0.4f(\rho, z)|\sigma_\pi| = a_m\sigma_m \qquad (7)$$

which involves only one parameter, a_m. In applying Eq. (7) to the given side-chain systems, the agreement was quite satisfactory and no essential differ-

current effect were 0.15 ppm for NH_2, 0.08 ppm for OCH_3 and 0.06 ppm for $C\equiv N$. The values are in qualitative agreement with our estimations based on the term, $-0.4f(\rho,z)|\sigma_\pi|$ in Eq. (7). This fact, in addition to the success of correlation (6), suggests strongly that the observed high field deviations result from the decreased ring current due to introduced substituent.

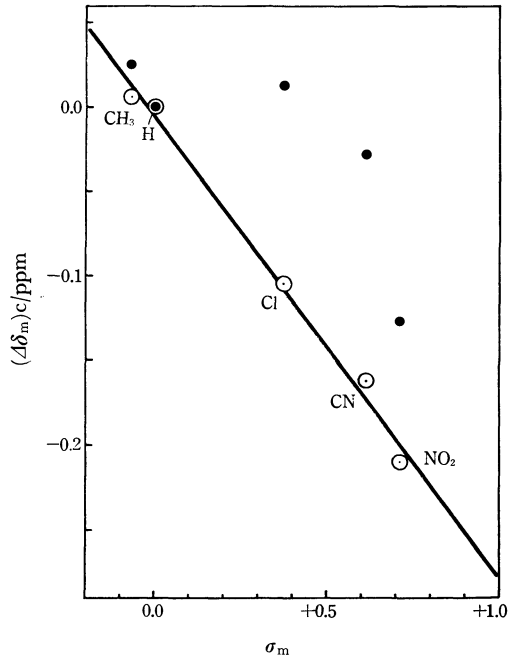

Fig. 5-9. Application of the Eq. (10) to α-protons of *meta*-substituted *trans*-cinnamic acids.[24]

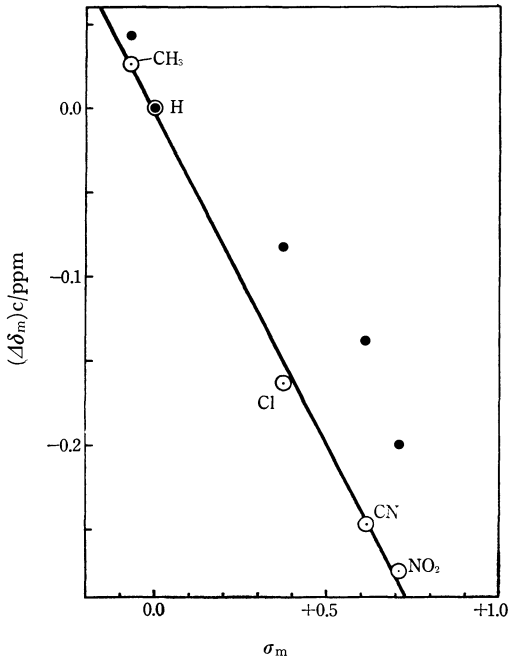

Fig. 5-10. Application of the Eq. (10) to β-protons of *meta*-substituted *trans*-cinnamic acids.[24]

The plot of the anisotropic substituents, however, still shows considerable deviations from the line required by Eq. (7). We may now consider the effect of the anisotropic substituents. If it is assumed that the observed deviation, Δ, is mainly ascribed

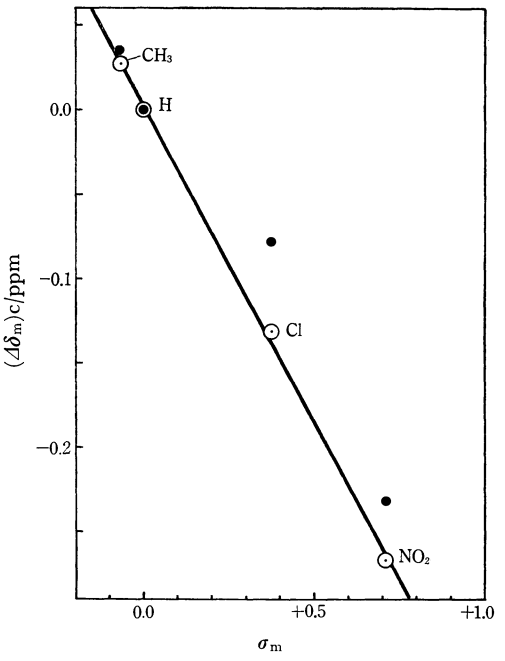

Fig. 5-13. Application of the Eq. (10) to *trans* protons of *meta*-substituted styrenes.[24]

to the anisotropy effect of the substituent, and also that the point dipole approximation[3] is applicable, the relative magnitude of the anisotropy effect between series A and B is given by

$$\frac{\Delta_B}{\Delta_A} = \frac{\Delta\chi(3\cos^2\theta_B - 1)3NR_A^3}{\Delta\chi(3\cos^2\theta_A - 1)3NR_B^3} = \frac{(3\cos^2\theta_B - 1)R_A^3}{(3\cos^2\theta_A - 1)R_B^3} \quad (8)$$

Equation (8) indicates that a magnetic anisotropy effect, Δ, in any side chain system can be calculated experimentally from Δ_A for a specified system A and geometric factors of the respective systems, even if the anisotropy of the substituent $\Delta\chi$ is not known:

$$\Delta = \Delta_A\frac{(3\cos^2\theta - 1)R_A^3}{(3\cos^2\theta_A - 1)R^3} \equiv \mathbf{A}\cdot\frac{3\cos^2\theta - 1}{R^3} \quad (9)$$

where **A** is a substituent anisotropy effect per unit geometric factor

$$\mathbf{A} = \Delta_A\frac{R_A^3}{3\cos^2\theta - 1},$$

and this can be calculated from a particular side chain system taken as the standard. In this study the values of **A** were evaluated by averaging two calculations based on toluenes and bis-(substituted phenyl)ethylenes (Table 3). For each of the halogen substituents, a magnetic point dipole μ_M, was assumed to be along the C(phenyl)-halogen bond, and located at the position of the halogen nucleus. For cyano group, the μ_M directed to the C≡N bond was located at the center of the bond. All the calculations were made on the basis of the same molecular model as that used in the estimation of ring current effect, $f(\rho,z)$.

a) $\Delta\delta_m$ for iodobenzene was omitted from the least squares calculation.
* Correlation coefficient.
** Standard deviation.

Introduction of the substituent anisotropy term (9) into Eq. (7) gives

$$\Delta\delta_m + 0.4f(\rho,z)|\sigma_\pi| + \mathbf{A}\cdot\frac{3\cos^2\theta - 1}{R_3} = a_m\sigma_m \quad (10)$$

which should be applicable to all the substituents including magnetically anisotropic ones. The left hand side of Eq. (10) represents the observed relative shifts corrected for the ring current variation and for the substituent magnetic anisotropy. This corrected value is regarded as an observable relative shift which depends only on the polar effects of the substituent. In Figs. 5-1—5-7, the corrected relative shifts, $(\Delta\delta_m)_c$, are plotted against Hammett's σ_m constants and the results are summarized in Table 4. The agreement is quite satisfactory. The applicability of Eq. (10) was further tested using data reported in literature.[2f,24] The successful results (Figs. 5-8—5-13) are collected in Table 5.

In view of the above results it may be concluded that Eq. (10) is fairly general in spite of the approximate nature of the derivation and useful, because of its simplicity, for estimating substituent chemical shifts and for examining the rotational conformation of the side chains.

It is pointed out that the variation of the susceptibility parameter to the polar effects, a_m, exhibits the same trend as that of ρ for the dissociation constants of corresponding carboxylic acid in a given solvent.[25] The lack of strict linear correlation between a_m and ρ might be attributed to the difference in the geometric functions for the chemical

shift and for the reactivity. The quantitative explanation for this situation will require a precise knowledge of electronic distribution on the side chain.

Exceptions to the applicability of Eq. (10) are the iodo- and bromo-substituted benzene system. This might be partly due to the incorrect estimation of anisotropy effects for these substituents. The point dipole approximation may be no more valid in bromo- and iodobenzenes where the dimension of the anisotropic substituent seems to be too large as compared with the distance R. Nakagawa *et al.* suggested the importance of the spin polarization effects[26] particularly in the molecule possessing heavy atoms such as iodine and bromine. Such effects may also contribute to the relative chemical shifts of ring protons *meta* to the substituent since the transmittance of the spin coupling will be considerably larger than in other side chain systems in which the resonating protons are separated from the spin polarizable substituent by more than three atoms. An investigation of this possibility, in addition to the study on *para* systems, must be the subject of future research.

The authors wish to express their gratitude to Professor Toshio Kinugasa of Kobe University for his constant advice and encouragement and for making facilities available for carrying out the NMR measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1473—1477 (1970)

The Photoreaction of *p*-Substituted *β*-Benzoylacrylic Acids

Noboru SUGIYAMA, Choji KASHIMA, Hiroshi KATAOKA and Keiko TANAKA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received October 3, 1969)

This paper will describe the photoreaction of *trans*-*β*-(*p*-ethylbenzoyl)acrylic acid (II) in methanol to give 5-(*p*-ethylphenyl)-5-methoxy-2-oxo-2,5-dihydrofuran (III), *β*-(*p*-ethylbenzoyl)-*α*-methoxypropionic acid (IV), and its methyl ester (V). The kinetic study of this reaction has revealed that II gives III and IV parallel by the first-order reaction and that IV then changes into V. Furthermore, the irradiation of *p*-substituted *β*-benzoylacrylic acids has been studied. From the product ratio and the substituent effects at the *para* position, the mechanism of the photoreactions of *γ*-oxoacrylic acids in methanol is proposed. This mechanism is also supported by the HMO calculations.

In our previous report[1] on the photoreaction of *β*-benzoylacrylic acid (I), a *γ*-oxoacrylic acid, in methanol, the formation of the methanol-addition product, *β*-benzoyl-*α*-methoxypropionic acid, and the reaction mechanism were described. However this mechanism is not sufficient to explain the photoreaction of *β*-acylacrylic acid, another *γ*-oxoacrylic acid, because *β*-acrylacylic acid is isomerized to 5-alkyl-5-hydroxy-2-oxo-2,5-dihydrofuran by irradiation.[2] Thus, we have examined the photoreaction of *p*-substituted *β*-benzoylacrylic acids in order to find a mechanism appropriate for all *γ*-oxo-acrylic acids.

Results and Discussion

Photoreaction of *β*-(*p*-Ethylbenzoyl)-acrylic Acid in Methanol. As a typical *p*-substituted *β*-benzoylacrylic acid, *β*-(*p*-ethylbenzoyl)acrylic acid (II) was chosen for the kinetic study. The structure of II was confirmed to be of the *trans* form by the coupling constant[1,2] of the olefinic protons (16.4 Hz) in the NMR spectrum. A methanol solution of II was irradiated with a 500-W high pressure mercury lamp for 105 hr at room temperature. From the reaction mixture after 80 hr irradiation, 5-methoxy-2-oxo-2,5-dihydrofuran (III), *β*-(*p*-ethylbenzoyl)-*α*-methoxy-propionic acid (IV) and the methyl ester (V) were obtained (Fig. 1). The yields of III, IV, and V were 27, 4, and 63% respectively.

The structures of these new photoproducts were determined as follows. The IR spectrum of III shows angelica lactone bands at 1820, 1780, and 1680 cm^{-1}, and the UV spectrum shows the absorption maximum at 243 nm. In the NMR spectrum the triplet signal at τ 8.77 was coupled with the quartet signal at τ 7.34 and the singlet signal

corresponding to 3 protons appeared at τ 6.58. The signal at τ 3.91 was split to a doublet with a coupling constant of 6.0 Hz, and the multiplet of 5 protons appeared in the τ 2.36—3.16 region. From these spectral data and elemental analyses, the structure of III was deduced. The structure of V was determined by the IR, UV, and NMR spectra and by elemental analyses. These spectral data were then checked with the corresponding data of methyl β-benzoyl-α-methoxypropionate.[1] IV was methylated with diazomethane, and the product was identified with V.

For the sake of comparison, the reaction without any irradiation and the thermal reaction of II in methanol were carried out. When a methanol solution of II was placed in a dark place for 24 hr, it was found to be 12% methyl *trans*-β-(*p*-ethylbenzoyl)-acrylate (VI) and 88% II. When refluxed for 24 hr in methanol, II was converted into 36% V and 64% VI. Thus, it was recognized that the formation of III, IV, and V from II was induced by the irradiation. The formation of an angelica-lactone-type compound, III, by the irradiation of II suggested that this photoreaction is different from that of I or β-acylacrylic acid.[1,2]

In order to get some information on the reaction mechanism, the behavior of methyl *trans*-β-(*p*-ethylbenzoyl)acrylate (VI) was studied. By irradiation, VI was transformed into a *cis* isomer in a 87% yield, but when refluxed in methanol VI did not show any change. When the photoreaction of II in methanol was examined by means of the NMR spectra, it was observed that II was gradually converted into III and IV. The results are summarized in Fig. 2. The yield of IV reached its maximum after 20 hr, and then decreased. However the total yield of the alcohol adducts, IV and V, increased when the first-order reaction with $k_1 = 8.9 \times 10^{-6}$ sec^{-1}. The decrease curve of II showed a first-order reaction of II with $k = k_1 + k_3 = 13.3 \times 10^{-6}$ sec^{-1}, and the curve of III showed $k_3 = 4.4 \times 10^{-6}$ sec^{-1}. Moreover, III in methanol did not change upon irradiation or refluxing. From these results, it can be assumed that the irradiation of II produces two parallel photoproducts, III and IV, and that IV changes into V.

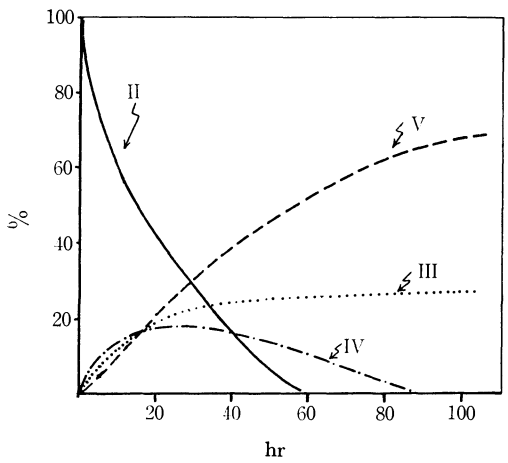

Fig. 2

On the other hand, it has been shown that the photoreaction of I does not occur in acidic or basic methanol, and that *cis*-β-benzoylacrylic acid (I′) is the intermediate of this reaction.[1] Also, it is well known that maleic acid has a partial grouping similar to that of I′ and that it has an intramolecular hydrogen bonding with a seven-membered cyclic ring between the γ-carbonyl and carboxyl groups.[3] From these facts, it can be assumed that the first step of the alcohol addition of *cis*-β-benzoylacrylic acids is the protonation on γ-carbonyl oxygen, and that γ-carbon becomes a carbonium ion, which makes it possible to represent by a resonance hybrid with a carbonium ion at the γ- or α-position. When a methanol molecule attacks the α-carbonium ion, the alcohol adducts will be formed, and when a methanol molecule attacks the γ-carbonium ion, the hemiketal of β-benzoylacrylic acids will be formed. These hemiketals can be cyclized to an angelica-lactone-type compound with ease. Consequently, the preponderance of the carbonium ion at the γ-position will result in the formation of an angelica-lactone-type compound, while that of the carbonium ion at the α-position will result in the formation of alcohol adducts.

Photoreaction of Other *p*-Substituted β-Benzoylacrylic Acids in Methanol. Since it is probable that the substituents at the *para* position of *p*-substituted β-benzoylacrylic acids will affect the preponderance of the carbonium ion at the γ- or α-position, the photoreactions of *p*-substituted derivatives of *trans*-β-benzoylacrylic acid were carried out in methanol. The derivatives used were *trans*-β-benzoylacrylic acid (I), *trans*-β-(*p*-toluoyl)acrylic acid (VII), *trans*-β-(*p*-isopropylbenzoyl)acrylic acid (VIII), *trans*-β-(*p*-*t*-butylbenzoyl)acrylic acid (IX),

trans-*β*-(*p*-anisoyl)acrylic acid (X), *trans*-*β*-(*p*-ethoxybenzoyl)acrylic acid (XI), *trans*-*β*-(*p*-bromobenzoyl)-acrylic acid (XII), and *trans*-*β*-(*p*-chlorobenzoyl)-acrylic acid (XIII), all of them prepared by the method of Papa.[4] Their NMR spectra are shown in Table 1. The coupling constants[1,2] of the olefinic protons in the NMR spectra confirm that the structures of these *β*-benzoylacrylic acids have *trans* configurations.

The methanol solutions of these acids were irradiated with a 500-W high-pressure mercury lamp at room temperature. The reaction mixtures were separated by column chromatography, and the structures of these photoproducts were determined by a study of the IR, UV, and NMR spectra and by elemental analyses. The structure of each *p*-substituted *β*-benzoyl-*α*-methoxypropionic acid was determined to be that of the methyl ester obtained by treatment with diazomethane. Moreover, the yields of these photoproducts were determined by measuring the NMR spectra of the reaction mixtures (Fig. 1 and Table 2).

The methanol-addition reaction was observed in all cases. In the cases of the *p*-alkyl (except *t*-Bu) and *p*-halogeno *β*-benzoylacrylic acids, however 4-methoxy angelica-lactone-type compounds were produced.

From the results of the photo-reaction of *p*-alkyl *β*-benzoylacrylic acids, the hyperconjugation of alkyl groups at the *para* position appeared to have an effect on the yield of the angelica-lactone-type compounds. As is shown in Table 2, the stronger the hyperconjugation effect (Me>Et>*iso*-Pr>*t*-Bu), the higher was the yield of the angelica-lactone-type compound (VII>II>VIII>IX) observed.

4) D. Papa, E. Schwenk, F. Villani and E. Klingsberg, *ibid.*, **70**, 3356 (1948).

Table 3. The Sr^N values of *p*-substituted *β*-benzoylacrylic acids

Compd.	R′	$Sr^N(\alpha)$	$Sr^N(\gamma)$	$Sr^N(\gamma)/Sr^N(\alpha)$
VII	Me	6.3326	5.9856	0.9452
XII	Br	6.2731	5.9264	0.9449
XIII	Cl	6.2514	5.9044	0.9445
X	MeO	5.2183	4.8764	0.9345

The carbonium ion at the *γ*-position can be expected to be preponderant because of the hyperconjugation of the *para* substituents. Thus, the above assumption of the favored formation of angelica-lactone compounds by the preponderance of the carbonium ion at the *γ*-position seems to be reasonable.

Furthermore, in order to support this assumption, the Sr values for the nucleophilic reagent (Sr^N) of zwitter-ion-type intermediates from VII, X, XII, and XIII were calculated by means of the HMO method. These Sr^N values indicate the stability of the carbonium ion and its reactivity toward nucleophilic reagents. Thus, the ratios of the Sr^N for the *α*-position to that for the *γ*-position, $Sr^N(\alpha)/Sr^N(\gamma)$, which are listed in Table 3, are expected to be comparable with the production ratio between the angelica-lactone-type compound and the alcohol adduct. The $Sr^N(\alpha)/Sr^N(\gamma)$ ratio of VII is large, and that of X is small, while the yield of the angelica-lactone-type compound from VII was high and no angelica-lactone-type compound from X was detected. These results also supported the above assumption.

After all, the photoreaction mechanism of the *γ*-oxoacrylic acid system is concluded to be as is shown in Fig. 3. That is, *trans* acid is isomerized

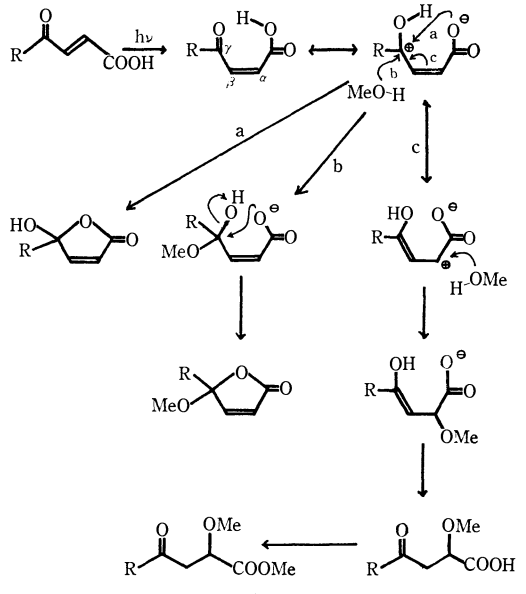

Fig. 3

to *cis* acid, which then undergoes protonation on γ-carbonyl oxygen through the seven-membered cyclic ring by means of intramolecular hydrogen bonding. By the protonation, the carboxyl group becomes the carboxylate anion and γ-carbon becomes the carbonium cation. In the case of β-aroylacrylic acids, this carbonium ion at the γ-position is dominated by the phenyl group and is attacked by the methanol molecule to give a hemiketal, which is then lactonized to 5-aryl-5-methoxy-2-oxo-2,5-dihydrofuran. At the same time, the carbon atom at the α-position can behave as a carbonium ion by means of resonance. The carbonium ion at the α-position is, then, attacked by a methanol molecule to give alcohol adducts. In the last step, the acid of the alcohol adduct is esterified.

In the case of β-acylacrylic acid, the carbonium ion at the γ-position is not stabilized and is attacked by the carboxylate anion. Thus, the production of 5-alkyl-5-hydroxy-2-oxo-2,5-dihydrofuran is also reasonable.

Experimental

Materials. *p*-Substituted *trans*-β-benzoylacrylic acids were prepared by the method of Papa.[4]

trans-β-Benzoylacrylic Acid (I). Mp 94—95.5°C (lit, 98—99°C). λ_{max}^{EtOH} (ε): 237 (10370), 268 (8080) and 357 nm (86). τ^{CDCl_3}: 1.31 (s, 1H), 2.05 (d, 1H), 1.8—2.7 (m, 5H) and 3.16 (d, 1H).

trans-β-(p-Ethylbenzoyl)acrylic Acid (II). Mp 104—106°C (lit, 105—106°C). λ_{max}^{EtOH} (ε): 233 (12460), 287 (10800) and 364 nm (125). τ^{CDCl_3}: 2.07 (d, 1H), 2.13 (d, 2H), 3.20 (d, 1H), 7.28 (q, 3H) and 8.67 (t, 2H).

trans-β-(p-Toluoyl)acrylic Acid (VII). Mp 137—139°C (lit, 137.5—138.5°C). λ_{max}^{EtOH} (ε): 237 (12300), 286.5 (11700) and 370 nm (104). τ^{CDCl_3}: 0.31 (s, 1H), 2.04 (d, 1H), 2.08 (d, 2H), 2.70 (d, 2H), 3.17 (d, 1H) and 7.53 (s, 3H).

trans-β-(p-Isopropylbenzoyl)acrylic Acid (VIII). Mp 100.5—102°C. λ_{max}^{EtOH} (ε): 234 (12700), 285.5 (11700) and 360 nm (127). τ^{CDCl_3}: 2.06 (d, 1H), 2.12 (d, 2H), 2.72 (d, 2H), 3.19 (d, 1H), 9.04 (sept, 1H) and 8.73 (d, 6H).

trans-β-(p-t-Butylbenzoyl)acrylic Acid (IX). Mp 122—124°C (lit, 123—125°C). λ_{max}^{EtOH} (ε): 234 (13200), 287 (12500) and 364 nm (124). τ^{CDCl_3}: 2.04 (d, 1H), 2.09 (d, 2H), 2.54 (d, 2H), 3.18 (d, 1H) and 8.64 (s, 9H).

trans-β-(p-Anisoyl)acrylic Acid (X). Mp 134°C (lit, 138—139°C). λ_{max}^{EtOH} (ε): 233 (17400) and 314 (13900). τ^{CDCl_3}: 1.60 (s, 1H), 2.01 (d, 1H), 2.01 (d, phenyl 2H), 3.07 (d, 1H), 3.18 (d, 1H) and 6.13 (s, 3H).

trans-β-(p-Ethoxybenzoyl)acrylic Acid (XI). Mp 142.5—145°C (lit, 145.5—146.5°C). λ_{max}^{EtOH} (ε): 235.5 (16800) and 315 nm (13200). τ^{CDCl_3}: 2.03 (d, 1H), 2.04 (d, 2H), 3.07 (d, 2H), 3.18 (d, 1H), 5.87 (q, 2H) and 8.55 (t, 3H).

trans-β-(p-Bromobenzoyl)acrylic Acid (XII). Mp 154—156°C (lit, 154—155°C). λ_{max}^{EtOH} (ε): 249 (10070), 278 (8390) and 362 nm (73). τ^{CDCl_3}: 2.06 (d, 2H), 2.17 (d, 1H), 2.54 (d, 2H) and 3.18 (d, 1H).

trans-β-(p-Chlorobenzoyl)acrylic Acid (XIII). Mp 157—159°C (lit, 159—160°C). λ_{max}^{EtOH} (ε): 230 (14500) and 282 nm (13000). τ^{CDCl_3}: 2.13 (d, 2H), 2.14 (d, 1H), 2.37 (d, 2H) and 3.26 (d, 1H).

Instrumentation. The infrared and ultraviolet spectra were recorded on a Hitachi EPI-2-type infrared spectrometer and a Hitachi EPS-3T-type spectrometer respectively. The NMR spectra were recorded on a Hitachi H-60 high-resolution NMR spectrometer, using TMS as the internal standard. A Taika 500-W hgih pressure mercury lamp was used as the irradiation source, and a Pyrex tube was used as the filter and reaction vessel in the reactions.

The Calculation of the Sr values by Means of the HMO Method. The Sr values in this work were calculated by means of the HMO method on a Hypac 103-type computer, using the following parameter:[5]

$$\alpha_x = \alpha + a\beta$$
$$\alpha_{adj} = \alpha + b\beta$$
$$\beta_{ex} = l\beta$$

X	*a*	*b*	*l*
OH	0.6	0	0.7
Me	3	−0.1	1
OMe	0.5	0	0.6
Br	1.4	0	0.7
Cl	1.8	0	0.8
C=O	1.3	0	1.1

Irradiation of *p*-Substituted *trans*-β-Benzoylacrylic Acid in Methanol. A solution of 1 g of *p*-substituted *trans*-β-benzoylacrylic acid in 20 m*l* of methanol in a Pyrex tube was irradiated at room temperature. After the reaction mixture had been worked up by the usual method, the yields of the products were estimated by the intensity of the NMR signals at τ 3.2 (d, olefinic proton of acrylic acid), 3.9 (d, α-olefinic proton of angelica lactone), 5.6 (t, methine proton of alcohol adducts), and 6.3 (s, ester methyl protons of the ester of the alcohol adducts). At the same time, the residue was methylated with diazomethane in ether. Then the reaction products were chromatographed on a silica-gel column with a benzene-ethyl acetate mixture.

Methyl β-(p-Ethylbenzoyl)-α-methoxypropionate (V). ν^{film}: 1745, 1675 and 1605 cm^{-1}. λ_{max}^{EtOH} (ε): 254.5 (17500) and 315.5 nm (117). τ^{CDCl_3}: 2.14 (d, 2H), 2.76 (d, 2H), 5.57 (t, 1H), 6.26 (s, 3H), 6.56 (s, 3H), 6.63 (d, 2H), 7.23 (q, 2H) and 8.78 (t, 3H).

Found: C, 67.18; H, 7.25%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

Methyl β-(p-Toluoyl)-α-methoxypropionate (XIV). ν^{film}: 1740, 1675, 1600 and 805 cm^{-1}. λ_{max}^{EtOH} (ε): 254 (19400), 290 (830) and 319 nm (107). τ^{CDCl_3}: 2.08 (d, 2H), 2.72 (d, 2H), 5.52 (t, 1H), 6.18 (s, 3H), 6.48 (s, 3H), 6.59 (d, 2H) and 7.56 (s, 3H).

Found: C, 65.86; H, 6.86%. Calcd for $C_{13}H_{16}O_4$:

C, 66.08; H, 6.83%.

Methyl β-(p-Isopropylbenzoyl)-α-methoxypropionate (XV). ν^{film}: 1755, 1685 and 1610 cm^{-1}. λ_{max}^{EtOH} (ε): 255 (20900) and 316 nm (123). τ^{CDCl_3}: 2.14 (d, 2H), 2.74 (d, 2H), 5.57 (t, 1H), 6.23 (s, 3H), 6.54 (s, 3H), 6.66 (d, 2H), 7.06 (sept, 1H) and 8.74 (d, 6H).

Found: C, 68.08; H, 7.67%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

Methyl β-(p-t-Butylbenzoyl)-α-methoxypropionate (XVI). ν^{film}: 1755, 1685 and 1610 cm^{-1}. λ_{max}^{EtOH} (ε): 254.5 (20000) and 315.5 nm (118). τ^{CDCl_3}: 2.13 (d, 2H), 2.57 (d, 2H), 5.57 (t, 1H), 6.24 (s, 3H), 6.56 (s, 3H). 6.66 (d, 2H) and 8.67 (s, 9H).

Found: C. 69.19; H. 8.07%. Calcd for $C_{16}H_{22}O_4$: C, 69.04; H, 7.97%.

Methyl β-(p-Anisoyl)-α-methoxypropionate (XVII). ν^{film}: 1760, 1685 and 1610 cm^{-1}. λ_{max}^{EtOH} (ε): 219 (6095) and 274 nm (9225). τ^{CDCl_3}: 2.03 (d, 2H), 3.09 (d, 2H), 5.57 (t, 1H), 6.16 (s, 3H), 6.22 (s, 3H), 6.68 (d, 2H) and 6.54 (s, 3H).

Found: C, 61.67; H, 6.58%. Calcd for $C_{13}H_{16}O_5$: C, 61.89; H, 6.39%.

Methyl β-(p-Ethoxybenzoyl)-α-methoxypropionate (XVIII). ν^{film}: 1750, 1675 and 1600 cm^{-1}. λ_{max}^{EtOH} (ε): 219 (11900) and 276 nm (18700). τ^{CDCl_3}: 2.14 (d, 2H), 3.14 (d, 2H), 5.58 (t, 1H), 5.94 (q, 2H), 6.25 (s, 3H), 6.59 (s, 3H), 6.67 (d, 2H) and 8.59 (t, 3H).

Found: C, 63.07; H, 6.96%. Calcd for $C_{14}H_{18}O_5$: C, 63.14; H, 6.81%.

Methyl β-(p-Bromobenzoyl)-α-methoxypropionate (XIX). ν^{film}: 1750, 1685, 1585 and 815 cm^{-1}. λ_{max}^{EtOH} (ε): 257 (20100) and 289.5 nm (944). τ^{CDCl_3}: 2.13 (d, 2H), 2.41 (d, 2H), 5.55 (t, 1H), 6.22 (s, 3H), 6.52 (s, 3H) and 6.63 (d, 2H).

Found: C, 48.01; H, 4.36%. Calcd for $C_{12}H_{13}O_4Br$: C, 47.85; H, 4.36%.

Methyl β-(p-Chlorobenzoyl)-α-methoxypropionate (XX). ν^{film}: 1745, 1685 and 1590 cm^{-1}. λ_{max}^{EtOH} (ε): 253.5 (19000) and 313 nm (89). τ^{CDCl_3}: 2.16 (d, 2H), 2.63 (d, 2H), 5.59 (t, 1H), 6.24 (s, 3H), 6.56 (s, 3H) and 6.66 (d, 2H).

Found: C, 56.09; H, 5.24%. Cacld for $C_{12}H_{13}O_4Cl$: C, 56.14; H, 5.11%.

5-(p-Ethylphenyl)-5-methoxy-2-oxo-2,5-dihydrofuran (III). ν^{film}: 1820, 1780, 1680 and 1605 cm^{-1}. λ_{max}^{EtOH} (ε): 243 nm (5000). τ^{CDCl_3}: 2.36—3.16 (m, 5H), 3.91 (d, 1H), 6.58 (s, 3H), 7.34 (q, 2H) and 8.77 (t, 3H).

Found: C, 71.57; H, 6.57%. Calcd for $C_{13}H_{14}O_3$: C, 69.88; H, 6.84%.

5-(p-Tolyl)-5-methoxy-2-oxo-2,5-dihdyrofuran (XXI). ν^{film}: 1810, 1775, 1670, 1610, 1200 and 815 cm^{-1}. λ_{max}^{EtOH} (ε): 203 (12000), 245 (5200), 263 (4100), 270 (3000) and 276 nm (3400). τ^{CDCl_3}: 2.61 (d, 2H), 2.68 (d, 1H), 2.79 (d, 2H), 3.86 (d, 1H), 6.64 (s, 3H) and 7.62 (s, 3H).

Found: C, 70.40; H, 5.89%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%.

A Kinetic Study of the Photoreaction of II. A solution of 250 mg of II in 5 m*l* of methanol was divided among 5 Pyrex tubes. These Pyrex tubes were then irradiated for 8, 24, 48, 72, and 96 hr respectively. The concentrations of III, II, IV, and V in each solution were estimated from the intensity of the NMR signals at τ 3.20 (d, olefinic proton of II), 3.91 (d, α-olefinic proton of III), 5.57 (t, methine proton of IV and V), and 6.26 (s, ester methyl protons of V). The results are plotted in Fig. 2.

The Dark Reaction of II in Methanol. A solution of 50 mg of II in 1 m*l* of methanol was left to stand in a dark place for 24 hr, this gave 12% of VI, which was identified by means of comparison with an authentic sample.

The Thermal Reaction of II in Methanol. A solution of 500 mg of II in 10 m*l* of methanol was refluxed for 24 hr, V and VI were thus obtained in 36 and 64% yields respectively.

The Irradiation of VI in Methanol. By irradiation for 120 hr through a Pyrex filter, a solution of 30 mg of VI in 1 m*l* of methanol gave 87% methyl *cis-β-*(*p*-ethylbenzoyl)acrylate.

However VI was recovered when the solution was refluxed for 24 hr in methanol.

The Reaction of III in Methanol. When irradiated for 96 hr through a Pyrex filter, or when refluxed for 24 hr, a solution of 30 mg of III in methanol was not changed.

We wish to thank Dr. O. Kikuchi, Department of Chemistry, Tokyo Kyoiku University, for kindly discussion of the calculations with us.

The Insertion Reaction of Isoprene into Metal-Ethyl Bonds in Various Transition-Metal Salt-Ethylaluminum Compound System

Yoshinobu TAKEGAMI, Toshimitsu SUZUKI and Takashi SHIRAI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 3, 1969)

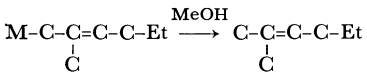
The insertion reaction of isoprene into metal-ethyl bonds in various transition-metal salt (VCl_4, $Fe(AA)_3$, $Co(AA)_2$, $CoCl_2$, $Ni(AA)_2$, or $NiCl_2$-ethylaluminum compound ($AlEt_2Cl$ or $AlEt_3$)) catalyst systems was studied. With the vanadium and the nickel catalysts, 2-methyl-2-hexene and 2-methyl-1-hexene were mainly formed by the methanolysis of the reaction mixture, showing that metal alkenyls, M–C(C)–C=C–C–Et and C=C(M)–C–C–Et respectively, are formed in the reaction system. However, in the iron catalyst, only 2-methyl-2,5-hexadiene and 3-methyl-2,5-hexadiene were formed from M–C(C)–C–C–C=C and M–C–C–C–C(C)=C–C respectively by the elimination reaction. These results suggest that the stability of metal alkenyls decreases in the order: V≫Ni>Co>Fe.

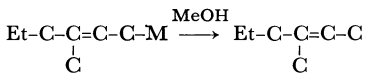
In a previous paper,[1] the insertion reactions of isoprene into metal-ethyl bonds in the $TiCl_4$-$AlEt_3$ catalyst system were studied, and the relation between the insertion products and the mechanism of the polymerization was discussed.

In the case of a Ziegler-type catalyst, it has been reported[2] that the micro structure of the polymer obtained was affected by the species of the transition metal compound and the organometallic compound. However, up to now the insertion processes of isoprene into a metal-carbon bond in a Ziegler-type catalyst system does not seem to have been discussed sufficiently.

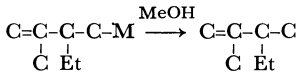
The insertion processes of isoprene into metal-ethyl bonds may be formulated as follows:

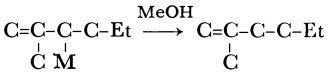
1,4-addition:



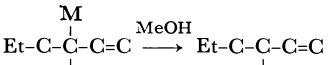


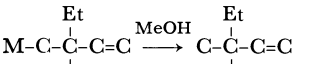
3,4-addition:





1,2-addition:





As has been reported in a previous paper,[1] isoprene inserts into metal-ethyl bonds in the $TiCl_4$-$AlEt_3$ catalyst system to give three metal alkenyls, I_m, III_m, and IV_m. In this paper, the insertion reaction of isoprene into metal-ethyl bonds in various transition-metal salt-ethylaluminum systems will be examined in order to establish the influence exerted by the species of the transition-metal compounds.

Experimental

Materials. The ethyl aluminum compounds were obtained from the Ethyl Corporation and were used without further purification.

The isoprene was distilled, deoxygenated by the freeze-thaw method with pumping, and later stored over calcium hydride. The solvent, toluene, was dried over sodium and distilled just before use.

The other reagents used were commercially-available materials.

1) Y. Takegami, T. Suzuki and T. Okazaki, *Kogyo Kagaku Zasshi*, **62**, 195 (1967).

2) C. E. H. Bawn and A. Ledwith, *Quart. Rev.*, **16**, 361 (1962).

Reaction Procedure. A three-necked flask (30 m*l*) was equipped with a magnetic stirrer, a gas inlet, a self-sealing rubber cap, and a gas outlet connected to a mercury manometer and a vacuum system. The gas inlet was connected with a line for argon. Certain amounts of a transition-metal salt, a solvent (toluene), an internal standard (methylcyclohexane), and an ethylaluminum compound were added, in this order, to the reaction flask in an atmosphere of dry argon. The catalyst mixture was aged for five minutes at a certain temperature, and then isoprene (10 mmol) was introduced to start the reaction. After a certain time, the reaction was stopped by adding an excess of methanol containing 10% hydrochloric acid to the reaction mixture. By this treatment the metal alkenyls formed in the system were converted to the corresponding olefinic hydrocarbons. The polymers, if formed. were filtered off, and the organic filtrate was subjected to gas-chromatographic analysis.

A Hitachi model-F6D gas-liquid chromatograph equipped with a hydrogen-flame ionization detector was employed for the quantitative and qualitative analyses of the products. The operating conditions are presented below:

Column	Golay Z45 (SE30)	Golay R45 (PEG)
Size	0.5 mmϕ × 45 m	0.25 mm × 45 m
Temperature	40°C	50°C
Carrier N_2	0.4 kg/cm^2	0.4 kg/cm^2
Sample size	2 μl	10 μl

Identification of the Products. As standard samples, three C_7 monoolefins, I, III, and IV, were obtained.[1] The isomerization products of 2-methyl-1,5-hexadiene and 3-methyl-1,5-hexadiene were also used for the identification of the C_7 diolefins. This isomerization reaction was carried out with the $Co(AA)_2$-$AlEt_3$ catalyst system.

In the VCl_4-$AlEt_3$ $AlEt_2Cl$ catalyst system, two products were found; they were identified as I and IV by gas-chromatographic analysis.

In the $Fe(AA)_3$ catalyst, two new products, VII and VIII, were found. The structural estimation of VII and VIII was carried out by gas chromatography as follows: a) The relative retention times of VII and VIII in the gas chromatogram were determined (Table 1) and found not to agree with those of the possible monoolefins (I—VI). With the Golay Z-45 column, the relative retention times of VII and VIII were between those of IV and I, but with the Golay R-45 column, those of VII and VIII were larger than those of IV and I.*1 b) After the hydrogenation of the reaction mix-

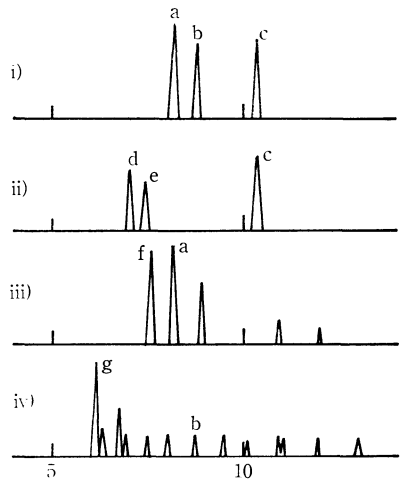


Fig. 1. Retention times of the products in the gas chromatogram.

a) 2-methyl-2,5-hexadiene, b) 3-methyl-2,5-hexadiene, c) methylcyclohexane, d) 2-methylhexane, e) 3-methylhexane, f) 2-methyl-1,5-hexadiene, g) 3-methyl-1,5-hexadiene

Table 1 Relative retention times of the products

Product	Bp (°C)	Relative retention times	
		Golay Z 45(40°C)	Golay R 45(50°C)
III=2,3-Dimethyl-1-pentene	84.3	0.66	0.84
2-Methylhexane	90.1	0.68	—
3-Methylhexane	91.9	0.73	—
XI=3-Methylhexadiene	—	0.75	0.90
IV=2-Methyl-1-hexene	92.0	0.78	0.91
VII=2-Methyl-2,5-hexadiene	91—92.5	0.80	0.95
VIII=3-Methyl-2,5-hexadiene	92.1—92.3[a]	0.83	0.98
I=2-Methyl-2-hexene	95.4	0.87	0.94
XII=3-Methylhexadiene	—	0.91	0.97
Methylcyclohexane	100.9	1.00	1.00
IX=3-Methylhexadiene	—	1.06	1.13
X=2-Methylhexadiene	—	1.13	1.18

a) at 752 mmHg

*1 Usually in the Golay R45 column a more polar substance elutes later than a less polar substance.

ture, the peaks of VII and VIII in the gas chromatogram disappeared and those of 2-methylhexane and 3-methylhexane appeared. The relative concentrations of VII and VIII were compared to those of the hydrogenation products, 2-methylhexane and 3-methylhexane (Fig. 1). c) The gas chromatogram of VII and VIII was compared with that of the isomerization products of 2-methyl-1,5-hexadiene or 3-methyl-1,5-hexadiene (Fig. 1). d) According to the literature[3] 2-methyl-2,5-hexadiene and 3-methyl 2,5-hexadiene were synthesized; the gas chromatograms of VII and VIII coincided with those of synthesized samples. From these analyses, and from the relation between the boiling point and the relative retention time, the structures of VII and VIII are considered to be 2-methyl-2,5-hexadiene and 3-methyl-2,5-hexadiene respectively.*2

In the cobalt catalyst, seven products were found; they were identified as I, IV, VII, 3-methylhexadienes (IX, XI, and XII), and 2-methylhexadiene (X) by the same method described above.*3 From their boiling points, IX and X seemed to be conjugated diolenfins.

The nickel catalyst gave four products, I, IV, XI, and XII.

The zirconium, the niobium, and the chronium catalysts gave two products, I and IV.

Results and Discussion

VCl_4-$AlEt_3$ or $AlEt_2Cl$ System. The results are summarized in Table 2 and Fig. 2. The catalyst system immediately became brown-black and homogeneous when $AlEt_3$ or $AlEt_2Cl$ was added to the VCl_4 solution. In this system, 2-methyl-2-hexene (I) and 2-methyl-1-hexene (IV) were formed, showing that two metal alkenyls, I_m and IV_m, are

formed. The amounts of these products reached maxima at an early stage and thereafter gradually decreased with an increase in the reaction time.

With $AlEt_2Cl$, IV was predominant; this tendency was the more remarkable the lower the temperature. On the other hand, with $AlEt_3$, I was predominant; this tendency was the more remarkable the higher the temperature. Figure 2 shows that IV_m readily isomerizes to I_m at 0°C. This may show that an easy transformation of the $\sigma \rightarrow \pi \rightarrow \sigma$ allyl type has occurred. These results suggest that a lower valence state of vanadium is more favorable for the formation of I_m, and that at lower temperatures IV_m is stable, while at higher temperatures IV_m readily isomerizes to I_m. A small amount of a sticky polymer was always formed. In the vanadium catalyst,

b) $AlEt_2Cl$

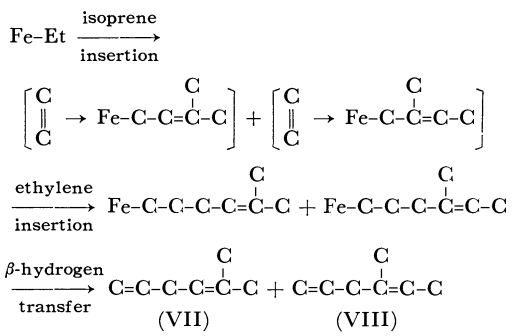
the mode of the insertion reaction was almost the same as that in the titanium catalyst reported on previously.[1]

$Fe(AA)_3$-$AlEt_3$ or $AlEt_2Cl$ System. The results are summarized in Table 3. The catalyst system immediately became brown-black and homogeneous when $AlEt_3$ was added. However, when $AlEt_2Cl$ was added it immediately became dark brown ($AlEt_2Cl/Fe(AA)_3=2$) or milk white ($AlEt_2Cl/Fe(AA)_3=5$) and heterogeneous.

In the case of $AlEt_3$, 2-methyl-2,5-hexadiene (VII) and 3-methyl-2,5-hexadiene (VIII) were formed. On the other hand, no monoolefins was detected in this system. These results suggest that, in the reaction system, the metal alkyls and/or alkenyls are not stable and that diolefins are formed.

One possible process for the formation of the diolefins from the metal alkenyls (I_m—VI_m) is a β-hydrogen transfer of them, with or without a hydride shift. However, this process is considered to give only conjugated and/or allene-type diolefins. Therefore, the selective formation of the isolated diolefins, VII and VIII, cannot be explained in terms of this process.

Hata[4] and Iwamoto[3] have reported that isoprene is co-dimerized with ethylene by the $Fe(AA)_3$-$AlEt_3$ catalyst system under a high pressure of ethylene to give 2-methyl-2,5-hexadiene and 3-methyl-2,5-hexadiene, and that this co-dimerization reaction is probably carried out by the metal hydride. The results obtained in this study are analogous to those obtained by them. However, in this study, even when the gaseous products in the aged mixture were pumped off (−70°C, 15 mmHg, 1 hr), VII and VIII were formed (0.030 and 0.017 mol/mol Fe), shownig that the ethylene is supplied by the iron and/or aluminum complexes having an ethyl bond. From these results, the process of the selective formation of VII and VIII may be formulated as follows:



This insertion reaction is quite different from that in the VCl_4 catalyst.

With $AlEt_2Cl$, no products were detected. This may be because iron-ethyl bonds are not formed in this system, judging from the extraordinary color change.

As for the polymer, it was not formed in every case.

$Co(AA)_2$ or $CoCl_2$-$AlEt_3$ or $AlEt_2Cl$ System. The results are summarized in Table 4. The catalyst system became, either immediately ($Co(AA)_2$) or gradually ($CoCl_2$), brown-black and almost homogeneous when either $AlEt_3$ or $AlEt_2Cl$ was added.

With $AlEt_3$, the I and IV monoolefins and the VII, IX, X, XI, and XII diolefins were formed. The monoolefins are considered to be formed much as in the VCl_4 catalyst. For the formation of these diolefins, two processes are reasonable since, in this case, two conjugated diolefins, IX and X, were also formed. The process which forms the non-conjugated diolefins is the same as in the case of the $Fe(AA)_3$ catalyst. The other process, that which forms the conjugated diolefins, is a β-hydrogen transfer of the metal alkenyls (I_m-VI_m) with or without a hydride shift of them. Therefore, IX and X may be formed by the elimina-

tion reaction from II_m or V_m, and from I_m or IV_m, respectively.

Especially in the case of the $CoCl_2$ catalyst, the conjugated diolefins, IX and X, were selectively formed at the reaction temperature of 30°C. This result was quite different from that in the $Co(AA)_2$ catalyst, in which the I and IV monoolefins and the VII, XI, and XII diolefins were also formed. This may suggest that, in the $Co(AA)_2$ catalyst, the high reactivity of the metal alkenyls for the isomerization reaction give various products.

A very small amount of an oily yellow polymer was formed in several cases.

On the other hand, with $AlEt_2Cl$, no product was detected.

$Ni(AA)_2$ or $NiCl_2$-$AlEt_3$ or $AlEt_2Cl$ System. The results are summarized in Table 5. The catalyst system immediately became brown-black and homogeneous when either $AlEt_3$ or $AlEt_2Cl$ was added except in the case of $AlEt_2Cl$ ($AlEt_2Cl/Ni(AA)_2=2$), in which it immediately became dark green and homogeneous.

In this system, the I and IV monoolefins and the XI and XII diolefins were formed, with the monoolefins the main products in every case. Therefore, in this system, the metal alkenyls, I_m and IV_m, may be rather stable, as in the case of a titanium or vanadium catalyst.

A very small amount of an oily yellow polymer was formed in several cases.

Even with $AlEt_2Cl$, the I and IV monoolefins were formed at the $AlEt_2Cl/Ni(AA)_2$ molar ratio of 2. This result is different from that in the $Fe(AA)_3$ or the $Co(AA)_2$ catalyst.

The results obtained from the variation in the $AlEt_3/M(AA)_n$ ($M(AA)_n$: $Fe(AA)_3$, $Co(AA)_2$, or $Ni(AA)_2$) molar ratio showed that the amount of metal-ethyl bonds (or metal-hydrogen bonds) reaches a maximum at the molar ratio of a unit. This suggests that, with an increase in the $AlEt_3/M(AA)_n$ molar ratio, the valence state of transition metal is reduced to metal(0) and that the

TABLE 6. SEVERAL TRANSITION-METAL SALT-$AlEt_3$ SYSTEMS[a]

c) Aging time: 15 min
d) $AlEt_3$/transition-metal salt molar ratio

amount of the metal-ethyl bonds effective for isoprene insertion decreases. The amount of the products in these systems gradually increased over the reaction time of 120 min, as is shown in Tables 3, 4, and 5.

Others. In the $ZrCl_4$-$AlEt_3$ catalyst system, the catalyst mixture remained heterogeneous; the liquid phase was dark brown, and the solid phase, dark orange.

In this system small amounts of monoolefins, I and IV, were formed. Increases in their amounts were observed when the reaction temperature was made higher.

The catalyst mixture became almost homogeneous after it had been aged for *ca.* 2 hr at 50°C, but when isoprene was introduced into the heterogeneous catalyst mixture at 30°C it became homogeneous and brown-red after 20 min. This shows that the state of the catalyst mixture was changed by adding isoprene. No such behavior was observed in the other systems, perhaps indicating the formation of a new complex participated with isoprene, but no further study was made.

In the $NbCl_5$-$AlEt_3$ catalyst system, the catalyst system became brown-black and homogeneous when $AlEt_3$ was added. In this system, small amounts of I and IV were formed.

In the $Cr(AA)_3$-$AlEt_3$ system, the aged mixture became brown-black and homogeneous, but in the $CrCl_3$ or $CrCl_2$-$AlEt_3$ system, the violet solid phase of $CrCl_3$ or $CrCl_2$ itself remained. In the $Cr(AA)_3$-$AlEt_3$ system, the I and IV monoolefins were formed, but they were present in very small amounts. Kapur *et al.*[5] have reported that the maximum activity of the $Cr(AA)_3$-$AlEt_3$ catalyst system in isoprene polymerization is obtained beyond the molar ratio of 4. In view of this, the insertion reaction was also carried out at the molar ratio of 5; the amounts of the monoolefins thereupon increased slightly. In the $CrCl_3$-$AlEt_3$ system, a small amount of I was formed, but in the $CrCl_2$-$AlEt_3$ system, no products were detected.

In the $Mn(AA)_2$-$AlEt_3$ system, the aged mixture became light brown but remained heterogeneous. In this system, no products were detected, either.

In the zirconium and niobium catalysts, a small amount of a sticky polymer was formed, but in the other systems no polymer was formed.

On the other hand, with $AlEt_2Cl$, no products at all were detected in these systems.

The Effects of Additives. The effects of the addition of a Lewis base to the several catalyst systems studied above were also examined. The catalyst mixture was prepared by adding materials in the following order: a transition-metal salt, a base, a solvent (toluene), an internal standard (methylcyclohexane), and an ethylaluminum compound. The state of the aged mixture was almost the same as that without an additive in every case.

Zambelli *et al.*[6] have reported that, in the polymerization of propylene to a syndiotactic polymer, the addition of a Lewis base such as anisole to the VCl_4-$AlEt_2Cl$ catalyst system (anisole/VCl_4 molar ratio = 1—2) makes the catalyst mixture active. The effect of the addition of anisole on the insertion reaction in this catalyst system was examined. The amounts of I and IV increased at the temperature of −70°C, but quite substantially decreased at 0°C. These findings agree with that obtained by Zambelli *et al.*[6]; the catalyst mixture is stable at temperatures lower than −40°C.

Misono *et al.*[7-9] have reported that a stable

complex with a metal-ethyl bond can be isolated by adding α,α′-dipyridyl to the metal acetylacetonate (metal: Fe, Co, or Ni)-diethylaluminum monoethoxide system. The effects of the addition of α,α′-dipyridyl on the insertion reaction in the Fe(AA)$_3$, Co(AA)$_2$, or Ni(AA)$_2$-AlEt$_3$ catalyst system were also examined. In the iron catalyst, the amounts of VII and VIII increased markedly and XI were newly formed. This may be explained as follows: a) The amount of iron-ethyl bonds (or iron-hydrogen bonds) is increased by the α,α′-dipyridyl. b) The iron-ethyl bonds are slightly stabilized by the α,α′-dipyridyl and the monoolefin (I) is formed by the methanolysis of the corresponding metal alkenyl (I$_m$), which is also stabilized. On the other hand, the effects of the addition of α,α′-dipyridyl were not so pronounced for the cobalt or the nickel system. The difference between Fe and Co or Ni is considered to be due partly to the difference in their valence states.

The effects of the addition of PPh_3 or $P(n\text{-}C_4H_9)_3$ to the Fe(AA)$_3$-AlEt$_3$ catalyst system were also examined. In both cases, the amounts of VII and VIII decreased and IV was newly formed. This result indicates that PPh_3 and $P(n\text{-}C_4H_9)_3$ are more strongly coordinated to metal than α,α′-dipyridyl; therefore, it becomes difficult for the insertion reaction itself to occur, but the iron-ethyl bonds are rather stabilized and the monoolefin (IV) is formed.

From the above results, it can be concluded that the stabilities of the metal alkenyls formed by the insertion reaction decrease in the following order: Ti≅V$\gg$Ni$>$Co$>$Fe.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1484—1489 (1970)

The Insertion Reactions of Olefins into Metal-Ethyl Bonds in the Vanadium Compounds-Ethyl Aluminum Ziegler Catalyst System. A Proposed Mechanism for the Syndiotactic Polymerization of α-Olefin

Toshimitsu SUZUKI and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received October 21, 1969)

In order to clarify the mechanism of the syndiotactic polymerization of olefin, the insertion reaction of several olefins into metal-ethyl bonds in VCl_4-$AlEt_nCl_{3-n}$, $VOCl_3$-$AlEt_nCl_{3-n}$, and $V(AA)_3$-$AlEt_nCl_{3-n}$ systems were studied. Cyclohexene was easily inserted into metal-ethyl bonds in these catalysts to give a metal-ethylcyclohexyl bond at -70°C. Pentene-1 and 4-methylpentene-1 gave M–C–C–Et (I) and M–C–C–Et (II). At -70°C with VCl_4-$AlEt_2Cl$, where the syndiotactic polymerization of propylene proceeds, four times as much (II) as (I) was obtained. However, at 0°C or in the VCl_4-$AlEt_3$ catalyst system, the amount of (I) exceeded the amount of (II). With the $VOCl_3$-$AlEt_nCl_{3-n}$ or the $V(AA)_3$-$AlEt_3Cl_{3-n}$ system, the selectivity for the formation of metal-alkyl (II) was decreased. The above results lead to the conclusion that, in the course of syndiotactic polymerization, the secondary metal-alkyl bond (II) was an intermediate of the polymerization. By means of this mechanism every experimental result reported can be explained without difficulty.

A hypothesis for the mechanism of the syndiotactic polymerization of α-olefin was presented in a previous communication,[1] this hypothesis was based on the results of the insertion reactions of pentene-1 into metal-ethyl bonds in the VCl_4-$AlEt_2Cl$ catalyst system. In this paper, in order to generalize the hypothesis, the present authors will study the mode of the insertion reactions of several olefins into metal-ethyl bonds in various Ziegler-type catalysts containing certain vanadium compounds. Vanadium catalysts are known to be syndiospecific catalysts for propylene at low temperatures[2] and as good copolymerization catalysts for ethylene and propylene, producing random copolymers.[3] However,

the reason for or the mechanism of the special properties of these catalyst systems has not yet been clarified.

Boor and Youngman[4] have suggested a mechanism for the syndiotactic polymerization of propylene, a mechanism in which the polymerization proceeds *via* a coordinate anionic mechanism and in which the steric interaction between substituents of the last-added monomer and the new monomer units plays a very important role in the stereo regulation. However, in this mechanism, in contrast to the isotactic polymerization, the necessity for the syndiotactic configuration is not satisfied.

Recently Zambelli *et al.*[5] have investigated the mode of the double-bond opening of deutero propylene in the course of the syndiotactic polymerization, and have demonstrated that the opening of the double-bond is *cis*, as in the case of the isotactic polymerization with the Natta catalyst.[6] They have also[7] suggested the use of bimetallic catalytic species for the polymerization.

In the course of the isotactic polymerization with a titanium catalyst ($TiCl_3$-$AlEt_3$), a primary metal-alkyl bond was predominantly formed as an insertion product of an α-olefin into metal-ethyl bonds in the catalyst.[8] It can be concluded that the primary metal-alkyl is the intermediate of the isotactic polymerization.

Experimental

Materials. Commercial vanadium tetrachloride and vanadium oxytrichloride were used without further purification and were diluted with olefin-free *n*-octane. Vanadium(III) acetylacetonate ($V(AA)_3$) was synthesized from VCl_3 and acetylacetone under a stream of dry NH_3 and was sublimed under reduced pressure; it was produced as a greenish-brown powder. Toluene, ethylbenzene, and *n*-octane were purified by distillation over dispersion sodium under an argon atmosphere. Commercial pentene-1 and 4-methylpentene-1 were dried by means of calcium hydride, and their purity was determined by gas chromatography.

Procedure. A three-necked flask equipped with a magnetic stirrer, a gas inlet, a gas outlet connected to an argon line and a vacuum line, and a self-sealing rubber cap was flushed with argon, and then a solvent, vanadium salt, an olefin, and an alkyl aluminum were introduced (in this order) at the reaction temperature. After a certain reaction time the reaction mixture was taken off with the use of a hypodermic syringe, quenched with cold methanolic hydrochloric acid, and washed with cold water to remove any methanol and hydrochrolic acid. The metal alkyls thus formed in the catalytic system were converted to the corresponding hydrocarbons and gas chromatographed.

A Hitachi model F6D gas liquid chromatograph with a Golay Z45 and an R45 column was employed for the qualitative and quantitative analyses.

Results and Discussion

Cyclohexene. It is well known that this olefin is not homopolymerized with a Ziegler-Natta-type catalyst, but, as has been shown in previous papers,[9] the insertion reaction into metal-ethyl bonds in the catalyst occurred and the amount of the insertion product is correlated with the amount of the metal-ethyl bond in the catalyst system.

To estimate the amount of the metal-ethyl bond in the vanadium catalyst, cyclohexene was reacted with the VCl_4-$AlEt_nCl_{3-n}$ catalyst system at various temperatures. The results are summarized in Table 1. The results show that, at −70°C, a relatively large amount of ethylcyclohexane was obtained; in the titanium catalyst systems, on the other hand, below 0°C a very small amount of ethylcyclohexane was obtained.*1

Table 1. Insertion reaction of cyclohexene in VCl_4-$AlEt_nCl_{3-n}$

AlR_3	Reaction Temp. (°C)	Reaction Time (min)	Et⟨H⟩ (mmol)	Remarks

	0	60	0.095	
	30	60	0.146	

VCl_4 1.0 mmol solvent (*n*-heptane 15 ml)
AlR_3 3.0 mmol cyclohexene 10 mmol

In contrast to the titanium system, the amount of ethylcyclohexane was slightly affected by the reaction time, and it rather decreased with an increase in the reaction time. This may show that, in this catalyst, the formation of the metal-ethyl bond is very rapid at −70°C and that this metal-ethyl bond is very reactive toward the insertion reactions of an olefin. As the elimination of ethylcyclohexene or other decomposition products from metal-ethyl-cyclohexyl bond was not observed, the decrease in

the amount of ethylcyclohexane with an increase in the reaction time may be explained by the fact that cyclohexene is inserted into the metal-ethylcyclohexyl bond, on account of the high activity of the vanadium alkyl bond in the catalyst system. However, the formation of cyclohexylethylcyclohexane was not confirmed.

With $AlEt_2Cl$, the amount of ethylcyclohexane was not affected by an increase in the reaction temperature. On the other hand, in the case of the catalytic system containing $AlEt_3$ the amount of ethylcyclohexane increased with an increase in the reaction temperature. These results suggest that there are different types of metal-ethyl bonds in the $AlEt_2Cl$ and $AlEt_3$ systems, as will be descibed below. With $AlEt_2Cl$ a metal-ethyl bond which is relatively thermally unstable may be formed.

Pentene-1 and 4-Methylpentene-1. According to Zambelli *et al.*,[7] the mechanism of the anionic coordinated polymerization of propylene to the syndiotactic polymer can be explained by the fact that the bimetallic catalyst complex plays an important role. However, the bimetallic catalyst structure proposed by them has not well been elucidated, for the differences in the syndiotactic and the isotactic polymerizations remain unexplained.

As has been shown in a previous communication,[1] in the VCl_4-$AlEt_2Cl$ catalyst system at $-70°C$ pentene-1 was inserted into the metal-ethyl bond to give, predominantly, secondary metal alkyl (II). The insertion processes of an α-olefin into the metal-ethyl bond can be formulated as follows:

$$C{=}C{-}R \xrightarrow[M\text{-}Et]{}$$

$$\left.\begin{array}{l} -M{-}C(R){-}C{-}Et\ (I) \rightarrow M{-}C(R){-}C(R){-}C{-}Et\ (III) \\ -M{-}C(R){-}C{-}Et\ (II) \rightarrow M{-}C(R){-}C(R){-}C{-}Et\ (IV) \end{array}\right.$$

On the other hand, in the case of the isotactic polymerization catalyst systems, containing $TiCl_3$ or $TiCl_4$, only the insertion reactions occurred to give the primary metal alkyl (I) and (III); From the behavior of the primary metal alkyls (I) and (III), these substances were considered to be intermediates of the isotactic polymerization of the

α-olefin.

When propylene was reacted with the VCl_4-$AlEt_2Cl$ catalyst at −70°C, the metal alkyls (I) and (II) were not detected after the methanolysis of the reaction mixture. However, at an elevated temperature a small amount of metal alkyl (I) was obtained and the polymer showed an IR absorption at 997 cm^{-1} which can be assigned to the isotactic band. These facts strongly support the idea that the formation of the primary metal-alkyl bond is connected with the isotactic polymerization. There are two possible reasons why, at −70°C metal, neither alkyl (I) or (II) was detected. One is that a steady-state concentration of the metal alkyls is very low; that is, the second step of the insertion process is very rapid. The other possibility is that the syndiotactic polymerization proceeds without any insertion process. However, the latter reason can be ruled out on the basis of Natta's experimental finding.*2 Therefore, in the case of propylene the concentration of any metal-alkyl bond formed by propylene insertion should be low.

As has been known, higher olefins, such as pentene-1 and 4-methylpentene-1, were not polymerized with the syndiospecific catalyst.[4] However, cyclohexene was inserted easily into the metal-ethyl bond in the catalyst. From the mode of the insertion reactions of these higher olefins, the insertion process of propylene can be guessed at. As has been shown in Tables 2 and 3, at −70°C these olefins gave the metal alkyls (I) and (II). However, no polymer was obtained at this temperature. The amount of the secondary metal alkyl (II) was larger than that of the primary metal alkyl (I) (runs 1, 2, 15, and 16); these facts are quite different from the results obtained in the case of titanium-containing catalyst systems.[8] On the other hand, at an elevated temperature (runs 3 and 17) or with $AlEt_3$ (runs 4, 5, 18 and 19), the amount of metal alkyl (I) increased and a small amount of a solid polymer containing an isotactic fraction was obtained. This means that, as has been described above in the case of propylene, at 0°C the polymerization proceeds *via* the primary metal alkyl (I), just as in the case of titanium-containing systems.[8] These results show that two types of vanadium-ethyl bonds can be produced; one has a tendency to form a secondary metal-alkyl bond, and the other has a tendency to form a primary metal-alkyl bond. At a low temperature the former vanadium-ethyl bond will be formed mainly. In the case of pentene-1 or 4-

*2 When radioactive $Al(^{14}C_2H_5)_2Cl$ is used, the polymer obtained also has radioactivity.

methylpentene-1, the secondary metal alkyl (II) has the bulky substituent closely attached to vanadium; this substituent causes steric hindrance between the next-coming monomer and the active center.

The vanadium-ethyl bond to form a primary metal-alkyl bond will be formed as a minor product and will be less reactive toward the insertion reaction of olefins. Thus, the polymerization of higher olefins does not occur at low temperatures.

On the contrary, in propylene, if the secondary metal alkyl (II) is formed, the steric hindrance between the growing chain and the next-coming monomer is not so large that propylene can attack the secondary metal alkyl (II) from the less hindered side of the active center. By this alternating-monomer attack on the secondary metal alkyl bond from the less hindered side, the syndiotactic configuration may be obtained. This mechanism is also supported by the results of the copolymerization experiment reported by Zambelli *et al.*[10] In their report, the alternate copolymers of ethylene and propylene, and of ethylene and butene-1, were obtained at the higher molar ratios of propylene or butene-1 to ethylene. These results can be explained by our mechanism thus: first, a higher olefin, which has a high concentration compared to that of ethylene, is inserted into a metal-ethyl bond, and the secondary metal-alkyl bond is formed. Into this secondary metal-alkyl bond ethylene can then be easily inserted, because higher olefin has much steric hindrance. Thus, the primary metal-alkyl bond is regenerated, and into this primary metal-alkyl bond a higher olefin can be inserted. The repetition of the above insertion reaction leads to the formation of the ethylene and α-olefin alternating copolymer.

This theory is also supported by run 6 of our experiment. In this experiment, after reacting pentene-1 with VCl_4-$AlEt_2Cl$ at $-70°C$, a small amount of propylene was introduced into the reaction mixture. The amounts of the metal alkyls (I) and (II) decreased compared with run 1, in which propylene was not introduced. This fact shows that propylene was inserted into the metal alkyls (I) and (II).

To elucidate the nature of the vanadium catalyst in the insertion reaction of olefin, the $VOCl_3$ and $V(AA)_3$-$AlEt_nCl_{3-n}$ systems were also investigated. With $VOCl_3$, even at $-70°C$ with $AlEt_2Cl$ (runs 11 and 22), the selectivity for the formation of the secondary metal alkyl (II) was not as high as in the case of VCl_4 in either olefin. With $V(AA)_3$-$AlEt_2Cl$ at $-70°C$ (run 7) very small amounts of the metal alkyls (I) and (II) were obtained and the tendency for the formation of the secondary metal-alkyl bond was not very large. With $V(AA)_3$-$AlEt_3$ (runs 9, 10 and 21) the formation of the primary metal-alkyl bond (I) is predominant, as in the titanium system. In the $V(AA)_3$ system at 0°C, even with the use of $AlEt_2Cl$, the formation of C_7 olefin is observed in the case of pentene-1 (run 8); the formation of olefin is also observed in the cases of VCl_4 and $VOCl_3$-$AlEt_3$ systems, even at $-70°C$. The structures of the olefins were not determined exactly, but judging from the retention time of the gas chromatogram they seemed to be heptene-3 (main) and 3-methylhexene-1. These olefins are eliminated from metal alkyls (I) and (II) by the β-hydrogen migration of the metal alkyl bond.

The elimination of olefin from a metal alkyl bond was observed in the case of the insertion reaction of cyclohexene into metal ethyl bonds in the $TiCl_4$-$AlEt_3$ and $AlEt_2Cl$ systems at a low Al/Ti molar ratio.[9] It was considered that the Ti(IV)-alkyl bond was unstable and that the elimination of the olefins was followed by a hydride shift. From the results obtained in vanadium systems, it may be shown that in rather lower valence states of vanadium, vanadium alkyl bonds will be more unstable than in titanium systems.

VCl_4, $V(AA)_3$, and $VOCl_3$-$AlEtCl_2$ systems were also investigated, but in these systems, on account of the strong cationic character of the catalyst, olefins were easily polymerized to a low-molecular-weight polymer and no insertion reactions were observed.

The addition of anisole is known to increase the syndiotacticity, but in the cases of the insertion reactions studied in this report, no remarkable changes were found. In the case of cyclohexene, the amount of the metal-ethylcyclohexyl bond decreased, in 4-methyl-pentene-1 no remarkable change was observed, and in pentene-1 the formation of the secondary metal-alkyl bond increased. However, in every case the stability of the metal-alkyl bond seemed to be increased.

From these results, it can be said that α-olefins are generally inserted into a vanadium-ethyl bond to form a secondary metal alkyl bond. Of the systems studied, the tendency to produce the secondary metal alkyl bond reaches its maximum with the catalytic system VCl_4-$AlEt_2Cl$ at $-70°C$. The hypothesis for the mechanism of the syndiotactic polymerization of α-olefin proposed in the previous communication,[1] that is, the secondary metal alkyl bond propagation mechanism, is strongly supported.

As has been reported by Natta,[11] V(III) species are present in the VCl_4-$AlEt_2Cl$ system at $-70°C$. Vanadium (III) has a $3d^2$ electronic structure and in the case of the titanium system the Ti(III) species has a $3d^1$ electronic structure. The difference between the electronic structure of the central

metal is considered to cause the marked difference in the insertion reactions of an α-olefin into the metal ethyl bonds. At an elevated temperature or with $AlEt_3$, the valency state of vanadium was reduced to V(II) and a $3d^1$ electronic structure. In this case, the formation of the primary metal alkyl bond is most likely. Naturally, the differences in the ligands of the vanadium and the valency states of the starting vanadium play an important role, as do the differences among the vanadium salts.

The contribution of the configuration of the active center of the syndiospecific catalyst can not be ruled out, either.

Studies on Hydrogenolysis. LVI.[1] The Effect of Solvent and Additive on the Stereochemistry of Catalytic Hydrogenolysis of 2-Methyl-2-phenylaziridine Derivatives*[1]

Yoshihiro SUGI and Sekio MITSUI

Department of Applied Science, Faculty of Engineering, Tohoku University, Sendai

(Received October 9, 1969)

In order to assess the effects of solvent and additive on the stereochemical course of the catalytic hydrogenolysis of styrene imine derivatives, the hydrogenolysis of optically active 2-methyl-2-phenylaziridine (Ia), 1,2-dimethyl-2-phenylaziridine (Ib), and 1-acetyl-2-methyl-2-phenylaziridine (Ic) was carried out under various conditions. The hydrogenolysis of Ia and Ib over palladium hydroxide occurred preferentially with an inversion of the configuration in ethanol, but with a retention in benzene. Moreover, Ia was hydrogenolysed with a predominant inversion of the configuration in *n*-hexane, and the inverted product increased with a decrease in the adsorption strength of the hydrocarbon solvent. The hydrogenolysis of Ic, however, occurred with a significant inversion of the configuration in both ethanol and benzene. The addition of sodium hydroxide to the reaction mixture strongly promoted a retention of the configuration in the hydrogenolysis of Ia over palladium hydroxide, and finally Ia was hydrogenolysed with a stereospecific retention. In contrast, no such variations could be observed in the cases of Ib and Ic. The stereoselectivity was not affected significantly by the addition of sodium hydroxide in the Raney nickel-catalyzed hydrogenolysis of Ia. However, the addition of sodium hydroxide prompted a retention of the configuration in the case of Ib. These results can be explained consistently by the previously-proposed mechanism.

The mechanism of the hydrogenolysis of benzyl-type compounds at heterogenuous catalytic surfaces has been a subject of discussion for more than a decade.[1-9] Mitsui and his co-workers have reported the stereochemical course of this reaction.[1-6]

It seems established that the configurations of the products are responsible for the free-energy difference at the transition states leading to the π-benzyl intermediates. In a previous paper,[2] the present authors reported the hydrogenolysis of optically active 2-methyl-2-phenylaziridine with palladium, platinum, nickel, and cobalt catalysts. However, ethanol was used as the reaction solvent

in all cases. In this work, we will attempt to assess the possible effects of solvent and additive on the stereochemical course of the catalytic hydrogenolysis of optically active 2-methyl-2-phenylaziridine (Ia), 1,2-dimethyl-2-phenylaziridine (Ib), and 1-acetyl-2-methyl-2-phenylaziridine (Ic) under ordinary pressure and at room temperature.

Results

Effect of the Solvent on the Stereochemistry. The hydrogenolysis of Ia with palladium hydroxide was investigated in several kinds of solvents. The results are summarized in Table 1 (Runs 1—8). The hydrogenolysis in ethanol occurred preferentially with an inversion of the configuration, while the hydrogenolysis in benzene was accompanied by a retention. The inversion of the configuration occurred in several aromatic hydrocarbons other than benzene. In these cases, the inverted products increased in the order: benzene $<$ toluene $\fallingdotseq$ *o*-xylene $<$ *m*-xylene $<$ *p*-xylene $<$ *t*-butylbenzene; this order is associated with the adsorption strengths of these hydrocarbons under hydrogenation conditions.[10-12] The hydrogenolysis also proceeded with a significant inversion of the configuration in *n*-hexane. The stereochemical results of similar experiments on Ib and Ic are also summarized in Table 1 (Runs 9—12).*2 The hydrogenolysis of Ib occurred predominantly with an inversion of the configuration in ethanol, but with a retention in benzene; these results are in agreement with those in the case of Ia. The hydrogenolysis of Ic, however, proceeded with a significant inversion of the configuration in both ethanol and benzene.

On the other hand, no significant effect of the solvent on the stereochemical course was observed in the Raney nickel-catalyzed hydrogenolysis of Ia, in contrast with the case of palladium hydroxide (Runs 13—15).

Effects of Sodium Hydroxide and Potassium Iodide on the Stereochemistry. Table 2 shows the influence of sodium hydroxide on the stereochemical results in the hydrogenolysis of Ia, Ib, and Ic. The hydrogenolysis of Ia over palladium hydroxide occurred with a predominant inversion of the configuration in ethanol, as has been described previously.[2] However, the addition of sodium hydroxide to the reaction mixture strongly promoted a retention of the configuration, and finally Ia was hydrogenolysed with a stereospecific retention (Runs 8, 16—19). No such variations in the stereochemical results could be observed in the hydrogenolysis of Ib (Runs 10 and 23), and the stereoselectivity increases in the case of Ic (Runs 11 and 24).

The hydrogenolysis of Ia with Raney nickel was not seriously affected when sodium hydroxide was

added to the reaction mixture (Runs 15, 25, and 26). A retention of the configuration occurred in the Raney nickel-catalyzed hydrogenolysis of Ib, although the maintained optical activity was only 10% (Run 28). However, the addition of sodium hydroxide to the reaction mixture prompted a retention of the configuration of IIb (Runs 28 and 29). Moreover, the following interesting results were also observed in the Raney nickel-catalyzed hydrogenolysis of Ib. *N*-Methyl-2-phenyl-2-propylamine (IIIb) was not obtained. 2-Phenylpropane (IV) was produced in the absence of sodium hydroxide, whereas IV was not formed in the presence of sodium hydroxide. These results are dissimilar to those in the case of Ia.[2]

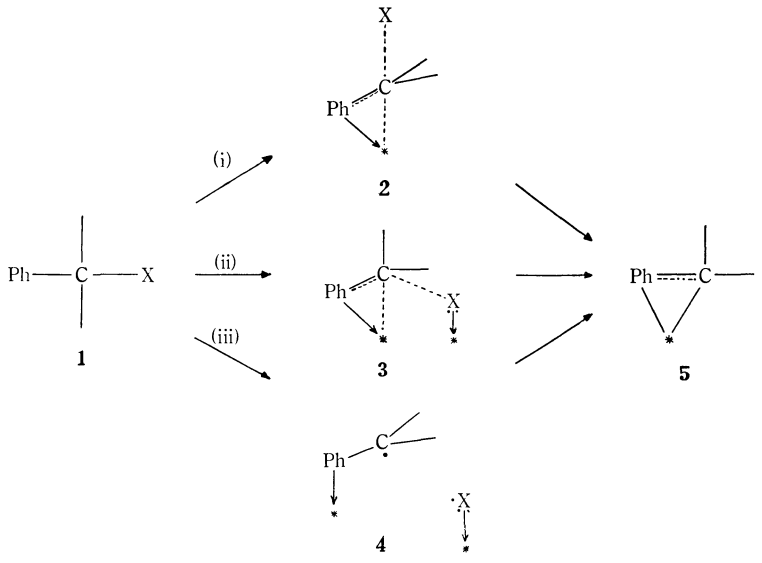
The influence of potassium iodide on the stereochemistry in the hydrogenolysis of Ia is also shown in Table 2. The stereoselectivity decreased over palladium hydroxide (Runs 8, 20, and 21), but no significant variation was observed over Raney nickel (Runs 16 and 27).

Variation in the Stereoselectivity with Platinum Catalysts. Table 3 summarizes the influences of the alkaline substances present in platinum catalysts. The stereoselectivity with platinum black (Run 31) was lower than that with platinum oxide (Run 30) in the hydrogenolysis of Ia.[2] It is well known that platinum oxide contains a trace of alkaline substances. To remove them, platinum black, which had been prepared by the reduction of platinum oxide, was treated with concentrated nitric acid, as will be described in the Experimental Section. The maintained optical activity with this catalyst (Run 32) was lower than those with platinum oxide and platinum black (Runs 30 and 31). The hydrogenolysis of Ib occurred with a significant retention of the configuration with both platinum oxide and platinum black; no serious difference in the stereoselectivity was observed (Runs 33 and 34).

Discussion

It is generally considered[1-6] that the catalytic hydrogenolysis of benzyl-type compounds proceeds to form the π-benzyl intermediate, **5**, *via* different transition states, **2** and **3**, and that the π-benzyl intermediate, **5**, suffers an electrophilic substitution with *s*-type adsorbed hydrogen.[14] In this case, the configurations of the products are responsible for the free-energy difference at the transition states, **2** and **3**; this difference depends on the structure of the compound, the catalyst, the solvent, the additive, and other factors. If the substituent X has a very strong affinity for the catalyst, the radical cleavage reaction (iii) as well as the S*Ni*-type reaction (ii) participates in this hydrogenolysis.[2]

We have previously reported that the hydrogenolysis of Ia in ethanol occurred with a predominant inversion of the configuration over palladium catalysts, but with a predominant retention over platinum, Raney nickel, and Raney cobalt catalysts, although low stereoselectivities were observed over the latter two catalysts.[2] These results may depend on the affinity for the nitrogen lone-pair and the catalyst hindrance.[2] Since palladium does not have so strong affinity for the nitrogen lone-pair, Ia is more probably hydrogenolysed *via* **6** over the palladium catalyst. However, the hydrogenolysis over the platinum catalyst favors the path *via* **7**,



14) T. Toya, *J. Research Inst. Catalysis, Hokkaido Univ.*, **6**, 308 (1958), **8**, 209 (1960), **10**, 236 (1962); *Kinzoku Butsuri*, **10**, 147 (1964).

because platinum is less sensitive to the catalyst hindrance than are nickel and palladium. Nickel and cobalt have stronger affinities for the nitrogen lone-pair than have palladium and platinum. Therefore, the S_Ni-type reaction and the radical cleavage reaction occur competitively *via* **7** over Raney nickel and Raney cobalt catalysts.

Effect of the Solvent on the Stereochemistry. The hydrogenolysis of Ia over palladium hydroxide in benzene occurred preferentially with a retention of the configuration, but with an inversion in several aromatic hydrocarbons other than benzene. In these cases, the inverted product increased with a decrease in the adsorption strengths of these hydrocarbons under hydrogenation conditions.[10-12] Furthermore, the hydrogenolysis proceeded with a significant inversion of the configuration in *n*-hexane and ethanol, which are considered not to be adsorbed so strongly on the catalyst. Similar variations were observed in the hydrogenolysis of Ib. However, the hydrogenolysis of Ic occurred with a significant inversion of the configuration in both ethanol and benzene.

This characteristic behavior of Ia and Ib in benzene suggests the following considerations. The adsorptions of the reactant and hydrogen decrease in benzene since benzene acts as a weak catalytic poison. It is known that the mobility of an electron in platinum foil diminishes upon the adsorption of benzene.[15] From these two reasons, we are led to consider that the nucleophilicity of the catalyst decreases when benzene is used as the reaction solvent. Therefore, the hydrogenolysis of Ia and Ib in benzene is retarded because the adsorption of the reactant and the nucleophilicity of the catalyst decrease as has been mentioned above. In this case, the hydrogenolysis *via* **7** is less inhibited than that *via* **6**, for the nitrogen is adsorbed on the catalyst in the former state, but directed away in the latter. Consequently, when benzene is used as the reaction solvent, the free-energy level of the transition state leading to the π-benzyl intermediate *via* **7** is lower than that *via* **6**, and the configuration of the product will be retained predominantly. However, in solvents other than benzene the free-energy level of the transition state *via* **6** becomes lower than that *via* **7** with a decrease in the adsorption strength of the solvent. Since potassium iodide acts as a catalytic poison, the decrease in the stereoselectivity in the hydrogenolysis of Ia upon the addition of potassium iodide may be explained consistently by the above arguments.

The nitrogen of Ic will be adsorbed less strongly on the catalyst than those of Ia and Ib, for the electron density of Ic becomes lower upon the withdrawal of the acetyl group. It seems, therefore, that the activation free-energy leading to the π-benzyl intermediate *via* **7** increases upon the adsorption of benzene. However, since the acetyl group withdraws the electrons of the benzylic-carbon-nitrogen bond of Ic, the stereoelectronic requirement of the transition state is fulfilled *via* **6**; the hydrogenolysis *via* this state is less inhibited by the adsorption of benzene. Consequently, the free-energy level of the transition state *via* **6** becomes lower than that *via* **7** in both ethanol and benzene; this is in contrast with the cases of Ia and Ib.

On the other hand, no such effect of the solvent and potsssium idodide was observed in the Raney nickel-catalyzed hydrogenolysis of Ia; this is in contrast with the case over palladium hydroxide. Since nickel has a very strong affinity for the nitrogen lone-pair, Ia will be hydrogenolysed without large inhibitions by the adsorption of benzene or potassium iodide.

Iijima and Mitsui[16] have reported similar solvent effects on the hydrogenolysis of 2-phenyl-2-butanol over a palladium catalyst. The retention of the configuration occurred preferentially in benzene, whereas the hydrogenolysis in ethanol, *n*-hexane, and toluene proceeded with a predominant inversion. Thus, these results are in accord with our present findings. Recently, Grimm and Bonner[17] have presented similar variations in the stereochemistry of the Raney nickel-catalyzed desulfuration of 2-phenyl-2-benzenesulfonylpropionamide. These authors have shown that this sulfone was hydrogenolysed with a predominant inversion of the configuration in ethanol, while the acetone treatment of the catalyst and the acetone solvent strongly prompted a retention of the configuration. However, they have not discussed the mechanistic details. These interesting observations can be interpreted consistently by the above arguments, for

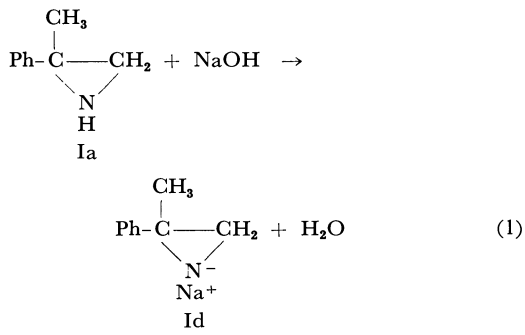
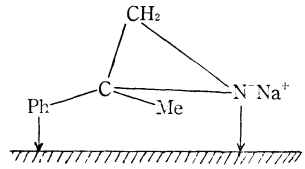
the nucleophilicity of the catalyst decreases upon treatment with acetone.

Effect of Sodium Hydroxide on the Stereochemistry. The hydrogenolysis of Ia in ethanol over palladium hydroxide occurred with a predominant inversion of the configuration in the absence of sodium hydroxide. However, the addition of sodium hydroxide promoted a retention of the configuration, and finally the hydrogenolysis proceeded with a stereospecific retention. On the other hand, no such variations in the stereochemistry were observed in the hydrogenolysis of Ib and Ic. These observations can be explained as follows. Ia and Id will establish an equilibirum as in Equation (1) in the presence of sodium hydroxide. It is difficult for Id to undergo hydrogenolysis *via* **6**, because



(1)

the nitrogen of Id acts as an electron-donor. However, the hydrogenolysis *via* **7** or **8** is less inhibited than that *via* **6**, since the nitrogen of **7** or **8** is absorbed on the catalyst. Therefore, Id participates in the hydrogenolysis of Ia in the presence of sodium hydroxide; consequently, the retained product will increase when sodium hydroxide is added to the reaction mixture. No such influences are observed in the hydrogenolysis of Ib and Ic, thus eliminating an equilibrium like that of Equation (1) and supporting the participation of Id in the hydrogenolysis of Ia in the presence of sodium hydroxide. The stereoselectivity in the hydrogenolysis of Ic over palladium hydroxide increased when sodium hydroxide was added to the reaction mixture; this variation is in accord with the hydrogenolysis of α-methylstyrene oxide with Raney nickel and palladium catalysts.[18] Adsorbed sodium hydroxide will retard the adsorption of the nitrogen lone-pair of Ic. Moreover,



8

the stereoelectronic requirement of the transition state leading to the π-benzyl intermediate is fulfilled *via* the state **6**, since the acetyl group withdraws the electrons of the carbon-nitrogen bond. Therefore, the difference in the free-energies of the transition states *via* **6** and **7** becomes larger upon the adsorption of sodium hydroxide. The variation in the stereoselectivity with platinum catalysts can be explained similarly to that in the case with palladium hydroxide.

The hydrogenolysis of Ib over Raney nickel occurred with a predominant retention of the configuration, and the stereoselectivity increased when sodium hydroxide was added to the reaction mixture. This variation suggests that the radical-cleavage reaction decreases in the presence of sodium hydroxide because adsorbed sodium hdyroxide retards the adsorption of the nitrogen lone-pair of Ib. On the other hand, the hydrogenolysis of Ia with Raney nickel was not significantly affected by the addition of sodium hydroxide; this may be the result of alkaline substances present in the catalyst. We have previously reported the formation of 2-phenyl-2-propylamine (IIIa), in addition to IIa, in the Raney nickel-catalyzed hydrogenolysis of Ia, and have postulated that IIIa forms *via* the state **7**.[2] However, *N*-methyl-2-phenyl-2-propylamine (IIIb) was not formed in the case of Ib. This may be attributed to the inductomeric effect of the *N*-methyl group. Further, a considerable amount of 2-phenylpropane (IV) was produced in the Raney nickel-catalyzed hydrogenolysis of Ib, in contrast with the case of Ia.[2] It seems that the stability of $\cdot\ddot{N}CH_3$ and/or $\cdot\ddot{N}HCH_3$, which are formed according to the radical-cleavage reaction of Ib, is larger than that of $\cdot\ddot{N}H$ and/or $\cdot\ddot{N}H_2$, which are formed from Ia. However, IV was not obtained in the presence of sodium hydroxide. This is consistent with the decrease in the radical-cleavage reaction.

Experimental

Materials. S(+)- and R(−)-2-Methyl-2-phenylaziridines (Ia), S(+)- and R(−)-1,2-dimethyl-2-phenylaziridines (Ib), and R(−)-1-acetyl-2-methyl-2-phenylaziridine (Ic) were prepared by methods described previously.[2,14]

Catalysts. Palladium hydroxide ($Pd(OH)_2$) was prepared according to the literature.[19] Raney nickel (Ra-Ni) was prepared by the method used for W-4,[20] stored in ethanol, and used within a week. Except when ethanol was used as the reaction solvent, Raney nickel was dried in a hydrogen stream at 15—20 mmHg below 60°C just before use. Platinum oxide (PtO_2) was purchased from the Wako Pure Chem Co., Ltd., Osaka. Platinum black used in Runs 31 and 34 was obtained

18) S. Mitsui and S. Imaizumi, *Nippon Kagaku Zasshi*, **86**, 219 (1965).

20) H. Adkins and A. A. Pavlic, *J. Amer. Chem. Soc.*, **69**, 3039 (1947).

by the reduction of platinum oxide with hydrogen and was washed with water. However, platinum black used in Run 32 was prepared as follows. Platinum black which had been prepared from platinum oxide was boiled with concentrated nitric acid for 2 hr and then washed well with water. The resulting catalyst was reduced with hydrogen and washed with water. To remove any nitric acid present in the catalyst, this reduction-washing procedure was repeated three times.

Solvents. The aromatic solvent was purified by treatment with concentrated sulfuric acid and by subsequent distillation over sodium. *n*-Hexane was purified by treatment with Raney nickel under a hydrogen atmosphere and by subsequent distillation over sodium. Ethanol was obtained commercially.

Additives. Sodium hydroxide and potassium iodide were obtained commercially.

Catalytic Hydrogenolysis of Ia. The following general procedure was used.[2] After a definite amount of a catalyst and an additive in an solvent (10 *ml*) had been agitated under a hydrogen atmosphere for 1 hr, 0.01 mol (1. 33 g) of Ia in the solvent (10 *ml*) was added; the resulting suspension was agitated with hydrogen under ordinary pressure and at room temperature. After the theoretical amount of hydrogen had been absorbed, the catalyst was filtered off, and the reaction mixture was analyzed by gas chromatography (PEG 4000 dispersed on fire-brick at 150—180°C using helium as the carrier gas). It was then worked-up as has previously been described, ethanol, benzene, toluene, or *n*-hexane being used as the reaction solvent. However, when *o*-xylene, *m*-xlyene, *p*-xylene, or *t*-butylbenzene was used as the reaction solvent, the filtrate was treated with dilute hydrochloric acid, and the product IIa was obtained from the aqueous layer by treatment with aqueous ammonia. IIa was separated in the usual manner.

Catalytic Hydrogenolysis of Ib. The hydrogenolysis of Ib was carried out by a procedure similar to that used for Ia. However, Ib and IIb were unseparable under our gas-chromatographic conditions. After the evaporation of the solvent, the oily product was treatep with dilute hydrochloric acid and IIb was obtained from the apueous layer by treatment with aqueous ammonia. For the rotation of optically-pure IIb, we adopted $[\alpha]_D$ 25.3° (ethanol), a value calculated from the purity of IIa, as has been described elsewhere.[13]

Catalytic Hydrogenolysis of Ic. The hydrogenolysis of Ic was carried out by a procedure similar to that used for Ia. The reaction mixture was analyzed by gas chromatography (PEG 4000, Golay column (0.5 mm × 15 m), 180°C, using nitrogen as the carrier gas). In this case, Ic was decomposed during the gas-chromatographic analysis. Therefore, we considered the reaction to be complete when the decomposed product became undetectable. IIc was separated in the usual manner. For the rotation of optically-pure IIc, we adopted $[\alpha]_D$ 47.2° (ethanol), a value calculated from the purity of IIa.[13]

The authors are grateful to the Takeda Science Foundation for its financial support.

Oxidative Ring-contraction of Several 1,5-Benzodiazepines with Light

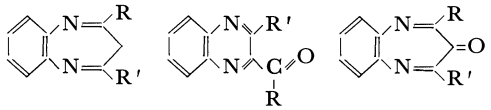
Masakatsu MATSUMOTO, Yoichi MATSUMURA, Akira IIO and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received October 14, 1969)

2,4-dimethyl- (I-a), 2-methyl-4-phenyl- (I-b), and 2,4-diphenyl-1,5-benzodiazepine (I-c) were irradiated with a high-pressure mercury arc under an oxygen atmosphere in benzene and in acetic acid. In all cases oxidative ring-contraction products, 2-acylquinoxalines (II), were obtained. It was found that there was a solvent effect in these reactions ; *e.g.*, in benzene the diazepine (II-d) leads to 2-benzoyl-3-methylquinoxaline (II-d), while in acetic acid it leads to 2-acetyl-3-phenylquinoxaline (II-b).

The oxidation reaction of 2,4-dimethyl-1,5-benzodiazepine (I-a : R, R′=CH_3) and 2-methyl-4-phenyl-1,5-benzodiazepine (I-b : R=CH_3, R′=Ph) with monopersulfuric acid or with peracetic acid has been reported by Barltrop *et al.* ;[1] the corresponding 3,6-diaza-4, 5-benzotropones, (III-a : R, R′=CH_3) and (III-b : R=CH_3, R=Ph), are not obtained, but the ring-contraction products, 2-acetyl-3-methylquinoxaline (II-a) and 2-acetyl-3-phenylquinoxaline (II-b) respectively, are obtained.



(I) (II) (III)

We have also studied the photooxidation of the dimethyl- (I-a) and the diphenylbenzodiazepine

1) J. A. Barltrop, C. G. Richards, D. M. Russel and G. Ryback, *J. Chem. Soc.*, **1959**, 1132.

(I-c) with a low-pressure mercury arc and have previously reported that the benzodiazepine (I-a) is oxidized to the quinoxaline (II-a) and that the photooxidation of the benzodiazepine (I-c) leads to a slight amount of the diazabenzotropone (III-c).[2] We suggested that, in the case of the benzodiazepine (I-a), the 6-oxo intermediate (III-a) may be subjected to a second photochemical reaction, thus forming a ring-contraction product (II-a). In this paper, we will report on the photooxidation reaction of the dimethyl-(I-a), the methylphenyl- (I-b), and the diphenyl-benzodiazepine (I-c) in benzene and in acetic acid employing a 200-W high-pressure mercury arc; the mechanism of the photooxidation reaction will also be discussed.

Results and Discussion

A benzene solution of the dimethylbenzodiazepine (I-a) was irradiated with a 200-w high-pressure mercury arc under an oxygen atmosphere; 2-acetyl-3-methylquinoxaline (II-a) and 3-methyl-2-quinoxalone (IV) were thus formed in yields of 29% and 8% respectively. When glacial acetic acid was used as the solvent, the reaction seemed to be promoted compared with that in benzene. When an 0.1 N sulfuric acid aqueous solution of diazepine (I-a) was irradiated under an oxygen atmosphere at 0-5 and 45–50°C, a slight amount of the quinoxaline (II-a) was formed; it and 2-methylbenziminazole (V-a) was obtained in yields of 5% and 75% respectively. The ring-contraction to 2-methylbenziminazole (V-a) may proceed thermally in an acidic aqueous solution, for it is known to be formed under acidic conditions in the dark.[1]

The auto-oxidation of the quinoxaline (II-a) under the action of light gave the quinoxalone (IV), so the product (IV) was probably formed *via* the second photooxidation of the quinoxaline (II-a) in the photooxidation of the diazepine (I-a).

When the methylphenylbenzodiazepine (I-b) in benzene was irradiated under an oxygen atmosphere, the photooxidation reaction proceeded smoothly and, surprisingly, 2-benzoyl-3-methyl-quinoxaline (II-d) was obtained in a yield of 25%, plus a small amount of 3-methylquinoxalone (IV); the oxidation of the benzodiazepine (I-b) with peracids leads to 2-acetyl-3-phenylquinoxaline (II-b). The abnormal ring-contraction product (II-d) was identified by means of its spectroscopic data, as is shown in Table 1 and Table 2.

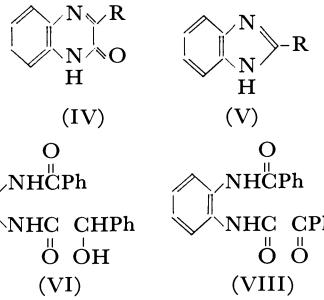
b) See Ref. 1.

On the other hand, in acetic acid the photooxidation of the diazepine (I-b) leads to 2-acetyl-3-phenylquinoxaline (II-b), as in the case of oxidation with peracids. When the diphenylbenzodiazepine (II-c) was treated with peracetic acid, the ring-contraction product, 2-benzoyl-3-phenylquinoxaline (II-c), could not be obtained at all, but an amide (VI) was obtained.[4] On the other hand, in a benzene solution, the benzodiazepine (I-c) was photochemically oxidized very slowly with high-pressure mercury arc to give the corresponding oxidative ring-contraction product, 2-benzoyl-3-phenylquinoxaline (II-c). In the photooxidation of the diazepine (I-c), acetic acid highly promoted the oxidation reaction, and in acetic acid, 2-phenylbenziminazole (V-b), *N*,*N*′-dibenzoyl-*o*-phenylenediamine (VII), and an amide (VIII) were obtained as by-products. These results are shown in Table 3.



(IV) (V)

(VI) (VIII)

In the photooxidation of the benzodiazepine (I), the oxidative ring-contraction to the acylquinoxaline (II) seems to proceed in a different fashion from that in the oxidation with peracids, as has been mentioned above. Though the acylquinoxaline (II) may be produced through the 6-oxo intermediate (III) in the photooxidation of the diazepine (I), as in the oxidation of diazepine (I-a) and (I-b)

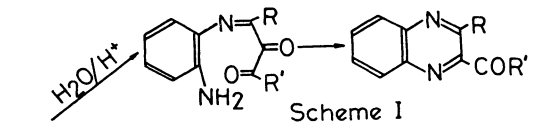
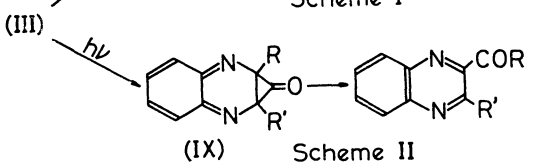
* Oxidation was not completed within 40 hr.
a) See Ref. 1. b) See Ref. 4.

with peracids, diazabenzotropone (III) can not be expected to rearrange to the acylquinoxaline (II) in the case of the photooxidation, particularly in benzene, as in the case of the oxidation with peracids, for neither 2-benzoyl-3-phenylquinoxaline (II-c) nor 2-benzoyl-3-methylquinoxaline (II-d), but rather, the amide (VI) and 2-acetyl-3-phenylquinoxaline (II-b) were obtained upon treatment with peracetic acid. Thus, in the photooxidation of the diazepine (I) in benzene, the 6-oxo intermediate (III) is thought to undergo ring-contraction to the acylquinoxaline (II) photochemically. As is shown in Scheme II, we postulate that the diazabenzotropone (III) formed under the action of light may be subjected to the second photochemical reaction. In this point in Scheme I, as has been described in the work of Barltrop *et al.*,[1] the methylphenyldiazabenzotropone (III-b) rearranges to the acetylquinoxaline (II-b) through hydrolysis and successive dehydration ; in Scheme II, though diazatropone (III-b) rearranges to benzoylquinoxaline (II-d) photochemically.





In Scheme II, Hückel calculation could give a reasonable result providing that this reaction occurred as a consequence of an n-π^* transition due the carbonyl group, as in the photochemical reactions of tropone[5] and tropolone,[6] and providing that the lowest vacant molecular orbital (LV) participates in that n-π^* transition.

Table 4 gives the characteristics of the lowest n-π^* excited state : the 1—3, 1—2, and 2—3 bonds show a tendency to be strengthened, while the 1—7 and 3—8 bonds become weak. The calculated results may support the idea that the photochemical reaction proceeds through a norcaradienone intermediate (IX), as shown in Scheme II. Therefore,

TABLE 4. CHANGES IN BOND ORDERS IN EXCITED DIAZABENSOTROPONE (III-b)

the interaction between the phenyl group and the carbonyl group in (IX) may cause the bond fission of the 1—2 and 3—4 bonds. Thus, we can say that the tropone (III-b) in the excited state may rearrange to favor the formation of benzoylquinoxaline (II-d), but not acetylquinoxaline (II-b).

Experimental

2,4-Dimethyl-1,5-benzodiazepine (I-a). Acetylacetone (20 g) and *o*-phenylenediamine (20 g) were refluxed in dried benzene (100 m*l*) with *p*-toluene sulfonic acid (0.1 g) for 1 hr. Then the violet-coloured reaction mixture was filtered and condensed. The oily residue was chromatographed in benzene on silica gel (200 g). The diazepine (I-a) was then crystallized from 1: 1 benzene-cyclohexane; mp 131°C; yield, 70%.

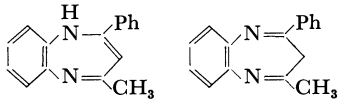
Found: C, 76.39; H, 7.11; N, 16.14%. Calcd for $C_{11}H_{12}N_2$: C, 76.71; H, 7.02; N, 16.27%.

2-Methyl-4-phenyl-1,5-benzodiazepine (I-b). Benzoylacetone (40 g) and *o*-phenylenediamine (20 g) were reacted in xylene (200 m*l*) for an hour, as in the case of the diazepine (I-a). Then the crude product was chromatographed in petroleum ether on silica gel (200 g). Crystallization from aqueous ethanol gave yellow crystals of the diazepine (I-b) monohydrate which melted at 118°C. The IR spectrum showed ν_{N-H} and ν_{OH} at 3450–3300 cm^{-1}. The NMR spectrum in $CDCl_3$ showed three singlets, at $\tau=8.05$ (3H, 2-CH_3 protons), $\tau=6.25$ (2H, water of crystallization), and $\tau=4.10$ (1H, 3-methyne proton), and multiplets at $\tau=3.40$—2.00 (10H). The mass spectrum showed a parent peak at *m/e* 234.

Found: C, 75.84; H, 6.38; N, 11.06%. Calcd for $C_{16}H_{14}N_2\cdot H_2O$: C, 76.16; H, 6.39; N, 11.10%.

From these results, the diazepine (I-b) which melted at 118° was determined to have the 1-H form (I-b)′.

Veibel and Hromadko[7] give a mp of 87—88°C for the diazepine (I-b); we also obtained crystals which melted at 87°C. The NMR spectrum of the diazepine (I-b) which melted at 87°C in $CDCl_3$ showed two singlets, at $\tau=7.77$ (3H, CH_3 protons) and $\tau=6.83$ (2H, 3-methylene protons), and multiplets at $\tau=2.90$—1.85 (9H). Thus, the diazepine (I-b) which melted at 87°C was 3-H form (I-b)″.



(I-b)′

(I-b)″

2,4-Diphenyl-1,5-benzodiazepine (I-c). The diazepine (I-c) was prepared from dibenzoylmethane and *o*-phenylenediamine as has been described by Barltrop *et al.*[1] The diazepine (I-c) was crystallized from methanol as colourless needles; mp 140°C.

Found: C, 85.20; H, 5.41; N, 9.51%. Calcd for $C_2H_{16}N_2$: C, 85.11; H, 5.44; N, 9.45%.

Photooxidation of the Diazepine (I-a) in Benzene. The diazepine (I-a) (3.0 g) in benzene (330 m*l*) was irradiated with a 200-W high-pressure mercury arc under an oxygen atmosphere for 8 hr. The irradiation was continued until the reaction mixture did not colour upon the addition of acetic acid. After irradiation, the reaction mixture was condensed *in vacuo*, and the oily residue was chromatographed in benzene on silica gel (200 g). 2-Acetyl-3-methylquinoxaline (II-a) was obtained as colourless needles which melted at 87°C by crystallization from aqueous ethanol yield 29%. Then 3-methyl-2-quinoxalone (IV) was obtained, mp 243°C from hot water as brown crystals; yield, 8%.

The quinoxaline (II-a): $\nu_{C=O}$ (in KBr) at 1689 cm^{-1}. Its phenylhydrazone, mp 174°C.

Found: C, 80.02; H, 5.46; N, 15.93%. Calcd for $C_{11}H_{10}ON_2$: C, 79.95; H 5.41; N, 15.95%.

The quinoxalone (IV); $\nu_{C=O}$ (in KBr) at 1668 cm^{-1}.

Found C: 67.49, H: 5.10, N: 17.40%, Calcd for $C_9H_8ON_2$ C: 67. 48, H: 5.03, N: 17.49%.

Photooxidation of the Diazepine (I-a) in Acetic Acid. After irradiation for 5 hr while an oxygen gas was being bubbled in, a violet-coloured acetic acid solution (330 m*l*) of the diazepine (I-a) (3.0 g) faded to a reddish brown. From the reaction mixture, acetic acid was removed *in vacuo*; the residue was treated as in previous experiments. The quinoxaline (II-a) and the quinoxalone (IV) were thus obtained in yields of 31 and 9% respectively.

Photooxidation of the Diazepine (I-a) in a 0.1 N H_2SO_4 Aqueous Solution. When a violet solution of the diazepine (I-a) (3.0 g) in a 0.1 N H_2SO_4 aqueous solution (330 m*l*) was irradiated for 5 hr at 0—5°C, the solution turned a reddish brown. After the solution had been neutralized by alkali and dried *in vacuo*, the dark brown oil was washed with chloroform. The washings, chromatographed on silica gel and eluted with benzene, gave, successively, the quinoxaline (II-a) and 2-methylbenziminazole (V-a) in yields of 2 and 5% respectively.

When the diazepine in a 0.1 N H_2SO_4 aqueous solution was photooxidized at 45—50°C, the quinoxaline (II-a) and the benziminazole (V-a) were obtained in yields of 2 and 75% respectively. 2-Methylbenziminazole (V-a): mp 175°C obtained as needles from ethanol.

Found: C, 72.81; H, 6.13; N, 21.13%. Calcd for $C_8H_8N_2$: C, 72.70; H, 6.10; N, 21.20%.

Photolysis of 2-Acetyl-3-methylquinoxaline (II-a). The quinoxaline (II-a) (0.5g) in benzene (100 m*l*) was irradiated with a 100-W high-pressure mercury arc, while oxygen gas was being bubbled in, for 5 hr. The product was chromatographed on silica gel in chloroform, giving, successively, the starting material (210 mg) and 3-methylquinoxalone (IV) (30 mg); mp 245°C (from hot water).

Photooxidation of the diazepine (I-b) in Benzene. The diazepine (3.5 g) in benzene (330 m*l*) was irradiated under an oxygen atmosphere for 6 hr. The mixture was concentrated to a small bulk and then chromatographed on silica gel in benzene; we thus obtained 2-benzoyl-3-methylquinoxaline (II-d) and the quinoxalone (IV) in yields of 25 and 3% respectively. The quinoxaline (II-d) was in the form of colourless needles which melted at 88—89°C. Upon crystallization from aqueous ethanol and which were identified as has been described above. The quinoxaline (II-d) oxime was obtained as needles, which melted at 208°C.

The quinoxaline (II-d): $\nu_{C=O}$ (in KBr) at 1665 cm^{-1}.

Found: C, 77.46; H, 4.92; N, 11.32%. Calcd for $C_{16}H_{12}ON_2$: C, 77.40; H, 4.87; N, 11.28%.

Photooxidation of the Diazepine (I-b) in Acetic Acid. The diazepine (3.5 g) was oxidized photo-

7) S. Veibel and S. F. Hromadko, *Chem. Ber.*, **93**, 2752 (1960).

chemically in acetic acid (330 ml) for 8 hr, after which the reaction mixture was condensed and chromatographed on silica gel in benzene. Then 2-acetyl-3-phenylquinoxaline (II–b) was isolated as needles, mp 110°C by crystallization from ethanol. Lutz and Stuart[8] give a mp 110—111°C. The quinoxaline (II–b): $\nu_{C=O}$ at 1698 cm^{-1}.

Found: C, 77.45; H, 4.92; N, 11.33%. Calcd for $C_{16}H_{12}ON_2$: C, 77.40; H, 4.87; N, 11.28%.

Photooxidation of the Diazepine (I-c) in Benzene. The diazepine (3.0 g) in benzene (330 ml) was irradiated for 40 hr under an oxygen atmosphere. Almost the only thing recovered was the starting material; the oxidation product, 2-benzoyl-3-phenylquinoxaline (II–c), was detected only by T. L. C.

Photooxidation of the Diazepine (I-c) in Acetic Acid. The diazepine (3.0 g) in acetic acid (330 ml) was irradiated under an oxygen atmosphere. After 36 hr, the violet solution was faded to a reddish brown. The reaction mixture was then concentrated *in vacuo*, chromatographed on silica gel, and eluted with chloroform; it thus gave, succesively, 2-benzoyl-3-phenylquinoxaline (II–c) (14%), the amide (VIII) (0.7%), *N,N'*-dibenzoyl-*o*-phenylenediamine (VII), and 2-phenylbenziminazole (V–b) (16%). The quinoxaline (II–c) was identified by comparing it with a specimen prepared from diphenyltriketone and *o*-phenylenediamine. Colourless needles; mp 153.5—154.5°C; crystallization from diethyl ether. $\nu_{C=O}$ (in KBr) at 1660 cm^{-1}.

Found: C, 81.33; H, 4.60; N, 9.00%. Calcd for $C_{21}H_{14}ON_2$: C, 81.27; H, 4.55; N, 9.03%.

The amide (VIII) was in the form of colourless needles which melted at 198°C and which were crystallized from benzene-petroleum ether. The mass spectrum showed a parent peak at *m/e* 344. The IR spectrum showed $\nu_{C=O}$ at 1670 and 1650 cm^{-1} in KBr.

Found: C, 73.27; H, 4.73; N, 8.19%. Calcd for $C_{21}H_{16}O_2N_2$: C, 73.24; H, 4.68; N, 8.14%.

The amide (VII) and *N,N'*-dibenzoyl-*o*-phenylenediamine prepared by the condensation of *o*-phenylenediamine and benzoyl chloride had identical infrared spectra. Mp 324°C, $\nu_{C=O}$ at 1664 cm^{-1}.

Found: C, 76.01; H, 5.13; N, 8.79%. Calcd for $C_{20}H_{16}O_2N_2$: C, 75.93; H, 5.10; N, 8.86%.

The iminazole (V–b) melted at 313—314°C.

Found: C, 80.45: H, 5.26; N, 14.50%. Calcd for $C_{13}H_{10}N_2$: C, 80.38; H, 5.19; N, 14.42%.

Reactions of Diazoketones in the Presence of Metal Chelates. III. Reactions with Carbonyl Compounds*[1]

Matsuji TAKEBAYASHI, Toshikazu IBATA and Kozaburo UEDA

Department of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received October 18, 1969)

The reaction of α-diazoacetophenone with carbonyl compounds such as benzaldehyde, acetophenone and *p*-phenylacetophenone, has been studied in the presence of bis(acetylacetonato) copper (II). The reaction gave the corresponding tetrahydrofurans and dioxolanes accompanied by some by-products derived from benzoylcarbene. The mechanism of the reaction has been discussed in terms of an intermediate with a structure of betaine type, produced by the reaction of a ketocarbene-metal chelate complex with carbonyl compounds.

In previous papers,[1),2)] we reported that the reactivity of α-diazoacetophenone (I) toward alcohols could be modified by bis(acetylacetonato)copper (II) to give alkoxyacetophenones, instead of alkyl phenylacetate, and that the reaction with *cis*- and *trans*-stilbenes afforded the stereospecific addition products of benzoylcarbene to the double bond of these olefinic compounds. We also pointed out that the catalyzed reaction of α-diazoacetophenone with acetone gave mainly an enol-ether[3)] when copper powder was employed as a catalyst.[4)] The mechanism of these reactions could be explained by assuming the intermediacy of a ketocarbene-copper chelate complex (II).

This paper deals with the copper chelate-catalyzed reaction of α-diazoacetophenone with aromatic carbonyl compounds such as benzaldehyde, acetophenone and *p*-phenylacetophenone.

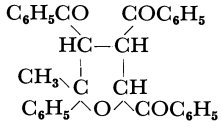
Results and Discussion

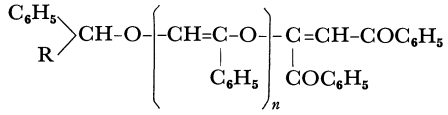
The following two kinds of methods, A and B, were adopted for the copper chelate-catalyzed reaction of α-diazoacetophenone with carbonyl compounds. A. Dropwise addition method: A benzene solution of α-diazoacetophenone was added dropwise to a solution of a carbonyl compound and bis(acetylacetonato) copper (II) ($Cu(acac)_2$) in benzene at 80°C during the course of 2 hr under stirring. B. Mixed method: A mixture of α-diazoacetophenone, Cu $(acac)_2$ and a carbonyl compound was warmed gradually under an atmosphere of nitrogen.

Reaction of α-Diazoacetophenone with Acetophenones. In method A, 2-methyl-2-phenyl-3,4,5-tribenzoyltetrahydrofuran (III, 29%) and an oligomer (IVa, 44%) of benzoylcarbene were obtained as a by-product besides α-hydroxyacetophenone (V, 1%). In method B, however, 2,4-dimethyl-2,4-diphenyl-5-benzoyl-1,3-dioxolane (VIa, 7%) was produced accompanying small amounts of by-products such as V (1.7%), dibenzoylethane (VII, 1%) and a dilactone (VIII, 1%) in addition to III (8.3%) and IVa (10%).

The data of IR and NMR spectra indicate that the three benzoyl groups of III are oriented *trans* to each other, and that IVa is a linear oligomer consisting of 3—4 molecules of benzoylcarbene and one molecule of acetophenone.

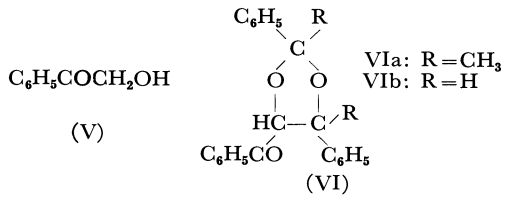


(III)



(IV)

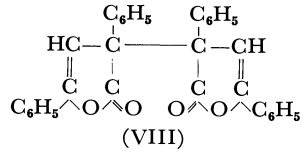
n: 1—3 IVa: R=CH_3, IVb: R=H
IVc: R=OCH_3



(V) (VI)

VIa: R=CH_3
VIb: R=H

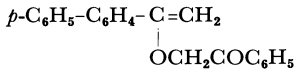
(VII)



(VIII)

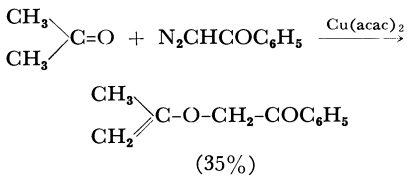
When *p*-phenylacetophenone was employed instead of acetophenone, the reaction (method B) gave *cis*- and *trans*-dibenzoylethylenes (IX, 1.2% and X, 6.2%), formal dimers of benzoylcarbene, and an oligomer (IVa, 12%) with a small amount (—1%) of an enol-ether (XI). However, neither dibenzoylethane, tetrahydrofuran nor dioxolane derivatives were obtained, in contrast to the case of acetophenone.

(IX, X)



(XI)

The formation of enol-ether (XI) is noteworthy though the yield is very low, because such enol-ethers have been scarcely obtained in the reactions with aromatic ketones. Enol-ethers corresponding to XI have been obtained in the reactions with aliphatic and alicyclic ketones such as acetone and cyclohexanone.[3]



(35%)

The reaction with substituted acetophenones will be discussed elsewhere in connection with the results obtained above.

Reaction of α-Diazoacetophenone with Benzaldehyde. In method A, the reaction gave *trans*-dibenzoylethylene (X, 4.8%), an oligomer (IVb, 6.7%) and a copolymer (XIII) of benzaldehyde and benzoylcarbene.

In method B, the reaction, contrary to method A, yielded 2,5-diphenyl-4-benzoyl-1,3-dioxolane (VIb, 2.3%), an oligomer (IVb, 9%) and two kinds of copolymers (XII and XIII) of benzaldehyde and benzoylcarbene. IR and NMR spectra showed that XII, major product, and XIII were rich in benzaldehyde- and benzoylcarbene-moieties, respectively. Both copolymers have one benzyl group at one end of polymer chain and one benzoyl group at the other end.

Ried and Omran[5] observed that the thermal reaction of *p*-methyl- and *p*-methoxy-α-diazoacetophenones with substituted benzaldehydes gave dioxoles (XIV) in 25—33% yield. However, no dioxole was detected in our catalytic reaction products. The results suggest that the mechanism of copper chelate-catalyzed reaction between α-diazoacetophenone and benzaldehyde is quite different from that of purely thermal reaction.

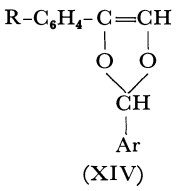
Table 1. Effects of the amount of methyl benzoate

Method	$C_6H_5COCHN_2$ (I) (mol)	$C_6H_5COOCH_3$ (ester) (mol)	[Ester]/[I]	Product (%) IX+X	IVc	VIII
A	0.034	0.17	5	1	89	0
	0.034	0.034	1	51	39	0
	0.034	0.007	1/5	83	12	0.16
	0.034	0	—	82	13	0.43
B	0.068	1.25	18	61	8.8	0



(XIV)

Reaction of α-Diazoacetophenone with Methyl Benzoate. In order to compare the behavior of esters to that of aldehydes and ketones, the reaction was carried out using methyl benzoate.

A large amount (89%) of oligomer (IVc) was produced accompanying a trace (1.1%) of *trans*-dibenzoylethylene (X) in method A, whereas dibenzoylethylenes (IX and X) (*cis*, 2.9%; *trans*, 58%) were obtained as main products with a small amount (8.8%) of oligomer (IVc) in method B. Neither tetrahydrofurans nor dioxolanes were obtained in both cases.

The effect of the amount of methyl benzoate on the yields of dimers (IX and X) and oligomer (IVc) was studied. The results are summarized in Table 1.

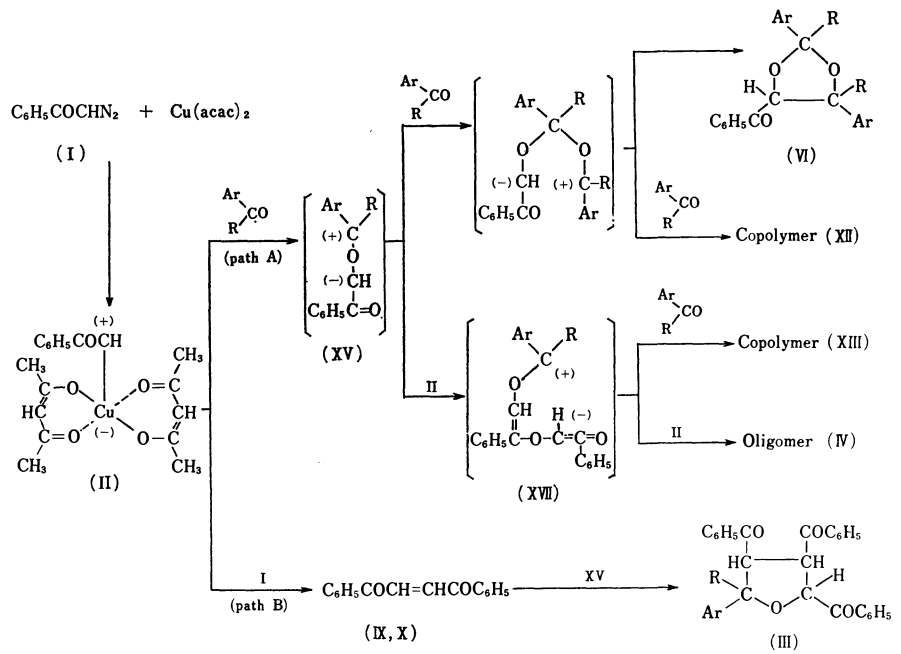
The data listed in Table 1 indicate that the yield of dimers (IX and X) of benzoylcarbene increases with decrease of the amount of methyl benzoate while that of oligomer decreases proportionally, and that dilactone (VIII) is produced when the ratio of the concentration of ester to I is low.

Mechanism

Diazoketone (I) reacts with the copper chelate to afford a ketocarbene-copper chelate complex (II).[1] The complex should react in two ways (path A and path B) according to the reactivity of carbonyl compounds employed.

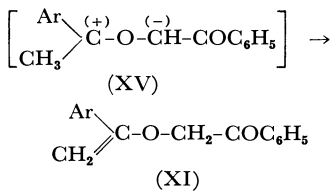
In the case of acetophenone and benzaldehyde, the reaction of path A takes place in preference to that of path B to produce another intermediate (XV) with a structure of betaine type, from which tetrahydrofuran (III), oligomers (IV), dioxolanes (VI) and copolymers (XII and XIII) are derived. In the case of *p*-phenylacetophenone and methyl benzoate, however, the reaction of path B proceeds preferentially to give dimers (IX and X). The mechanism of the formation of these products is summaried in Scheme 1.

The fact that the yield of III increases by the addition of dibenzoylethylene (X) to the reaction mixture supports the reaction path to give III.



Scheme 1

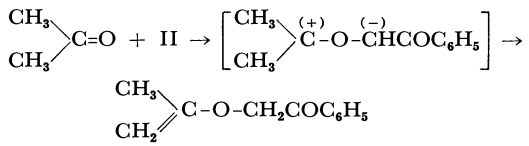
The migration of proton in the intermediate (XV) will give XI.



(XV)

(XI)

Generally, the proton migration hardly takes place in the intermediate from aromatic carbonyl compounds, since the intermediate (XV) is stabilized due to the resonance effect of aryl group.[6] However, the proton migration is expected to occur easily in the intermediate derived from aliphatic or alicyclic carbonyl compounds.



Apparently, the enol-ethers are produced by the insertion of benzoylcarbene to the O–H bond of enolated ketones. But this insertion mechanism can hardly explain the fact that the enol-ethers are obtained by the reactions with ketones having less enolic character such as acetone and cyclohexanone, and that no enol-ether is obtained by the reaction with more enolizable acetylacetone under the same conditions. Thus, the mechanism of the formation of enol-ethers can be explained by assuming an intermediate with the structure of betain type.

By-products such as α-hydroxyacetophenone (V), dibenzoylethane (VII) and dilactone (VIII), are derived from complex (II) as shown in Scheme 2. The formation of α-hydroxyacetophenone (V) arises from the reaction of complex (II) with a trace of water, because the yields of (V) vary from 1.7 to 10% according to the amount of water contained in the reaction mixture. If complex (II) abstracts a hydrogen atom from the solvent to give phenacyl radicals, recombination of the radicals takes place and affords dibenzoylethane (VII) as has been recognized in the cases of thermal[7] and copper chelate-catalyzed decomposition[3] of I in various solvents. When free benzoylcarbene is expelled from complex (II), the free carbene rearranges to the phenylketene and gives monolactone by reaction with I; the monolactone is easily oxidized to afford dilactone (VIII).[8,9]

Experimental

All melting and boiling points are uncorrected. The IR spectra were measured in potassium bromide disks for crystals and in liquid film for liquid samples, respectively, on a Hitachi Infrared Spectrometer, model EPI-S2. The NMR spectra were recorded at 60 Mc with a Varian Associates model A-60 Spectrometer, using tetramethylsilane as an internal standard. The UV spectra were taken on a Shimadzu Multipurpose Recording Spectrophotometer, model MPS-50L.

of the reaction mixture turned dark brown with evolution of nitrogen. After the reaction was over, the reaction mixture was fractionated under a reduced pressure. The distillate (A) boiling at 60—90°C/1 mmHg crystallized at room temperature. The fractional recrystallization of A using light petroleum gave a trace of benzoic acid and 0.05 g (1%) of α-hydroxyacetophenone (V), mp 86.0—87.0°C (mp 86.0—87.0°C[13]).

Found: C, 69.99; H, 5.68%. Calcd for $C_8H_8O_2$: C,70.57; H, 5.92%. IR (KBr disk): 3380, 1685, 1405 and 1110 cm^{-1}.

The distillation residue (B) was dissolved in a mixture of benzene and *n*-heptane and allowed to stand for 2 days. A dark red solid (B-1) was isolated from the solution, and red oily substance (B-2) was separated from the filtrate by concentration. Recrystallization of B-1 from benzene-*n*-hexane gave 1.55 g (29%) of 2-methyl-2-phenyl-3,4,5-tribenzoyltetrahydrofuran (III), mp 167.0—168.0°C.

Found: C, 81.18; H, 5.44%. Calcd for $C_{32}H_{26}O_4$: C, 80.99; H, 5.52%. The NMR spectrum is shown in Fig. 1; UV: λ_{max}^{EtOH} 2683 Å (ε 1770) and 2734 Å (ε 5200). IR: 1685, 1450, 1280, 1245, 1215 and 985 cm^{-1}.

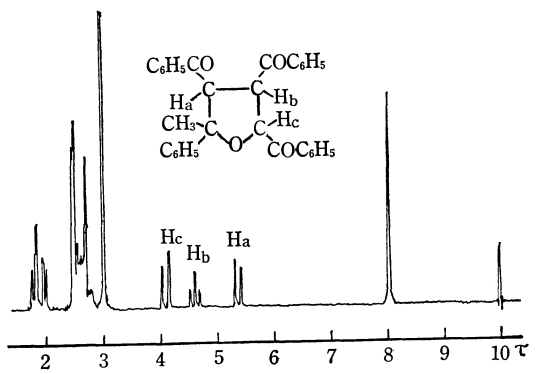

Fig. 1. NMR spectrum of III.

When a benzene solution of oily substance (B-2) was poured into *n*-hexane, a brown solid was obtained. This product did not crystallize from any solvents, but the data of IR and NMR spectra indicated that the product was an oligomer of benzoylcarbene with one molecule of acetophenone (IVa), and that the oligomer has a skeleton of vinyl ether. The yield of oligomer was 1.7 g (44%).

Found: C, 80.75; H, 5.38%. Calcd for $C_{32}H_{26}O_4$ ($C_6H_5COCH_3$+3 C_6H_5COCH:): C, 80.79; H, 5.52%. UV (in dichloromethane): λ_{max} 2480 Å (ε 14200) IR: 1640, 1445 and 1220 cm^{-1}. NMR: 2.65 τ (s, broad). Mol wt (Rast): Found, 490. Calcd for $C_{32}H_{26}O_4$, 474.5.

Reaction of I with Acetophenone (Method B). A solution of 5.0 g (0.034 mol) of I and 0.05 g (3.8×10^{-4} mol) of $Cu(acac)_2$ in 150 g of acetophenone was warmed gradually under an atmosphere of nitrogen. By distillation of the reaction mixture under a reduced pressure after removal of unreacted acetophenone, a distillate (C) boiling at 60—85°C/0.1 mmHg and a tarry residue (D) were obtained. Fractional recrystallization of C from light petroleum gave a trace of benzoic acid and 0.076 g (1.7%) of α-hydroxyacetophenone (V).*2

Besides, 0.04 g (1%) of dibenzoylethane (VII), mp 147.0—148.0°C (lit,[14] mp 140°C), was separated from the concentrated mother liquor after one week.

Found: C, 79.11; H, 5.85%. Calcd for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%. IR: 1687, 1225, 990, 743 and 698 cm^{-1}. The distillation residue D was treated with benzene. A small amount of precipitate was collected by filtration. This precipitate did not dissolve in usual organic solvents. The IR spectrum was completely superimposable with that of dilactone (VIII, 1%) prepared by the photolysis of I in benzene solution.[8,9]

From the benzene layer, 0.39 g (10%) of oligomer (IVa) was separated out by adding *n*-heptane. Moreover, 0.45 g (8.3%) of tetrahydrofuran (III) was obtained from the mother solution after being left to stand for several days at room temperature. Evaporation of the solvent gave a yellow oil. The oil could not be distilled, but the substance was deduced to be 2,4-dimethyl-2,4-diphenyl-5-benzoyl-1,3-dioxolane (VIa, 0.88 g, 7%) by means of IR spectra.

Found: C, 81.85; H, 6.44%. Calcd for $C_{24}H_{22}O_3$: C, 81.42; H, 6.19%.
IR: 1690, 1450, 1370, 1270, 1100, 1060 and 1020 cm^{-1}.

Reaction of I with *p*-Phenylacetophenone (Method B). The reaction of I (5.0 g, 0.034 mol) with *p*-phenylacetophenone (8.24 g, 0.024 mol) was carried out by the mixed method in benzene solution (150 g) in the presence of $Cu(acac)_2$ (0.05 g, 3.8×10^{-4}mol). Unreacted *p*-phenylacetophenone was separated by adding ligroin to the reaction products, and the solvent was removed by distillation. The residue was treated with light petroleum to separate insoluble part (E) from soluble part (F). The insoluble part E was dissolved in cyclohexane at the reflux temperature, and was kept standing overnight at room temperature. 0.48 g (12%) of oligomer (IVa) was separated out from the solution, and 0.1 g (1%) of yellow needles of enol-ether (XI), mp 91.0—92.0°C, precipitated from the filtrate after one week at 10°C.

Found: C, 83.65; H, 5.64%. Calcd for $C_{22}H_{18}O_2$: C, 84.05; H, 5.64%. IR: 1680, 1655, 1295, 1263, 1018 and 960 cm^{-1}.

The bromination of enol-ether (XI) in CCl_4 gave its dibromide, mp 117.0—119.0°C.

Found: C, 57.60; H, 3.53%. Calcd for $C_{22}H_{18}O_2Br_2$: C, 55.84; H, 3.62%. IR: 1685, 1290 and 990 cm^{-1}.

The soluble part F was allowed to stand for several days at room temperature. A yellow solid (F-1) precipitated in preference to solid (F-2). The solid F-1 was recrystallized from light petroleum, and was identified as *trans*-dibenzoylethylene (X) in a good agreement with elemental analyses and IR spectra with the authentic sample; mp 111.0—112.0°C, yield 0.25 g (6.2%).

Found: C, 81.84; H, 5.12%. Calcd for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12%. UV: λ_{max}^{EtOH} 2608 Å (ε 19700).

13) L. Wolff, *Ann. Chem.*, **325**, 143 (1902).

*2 The yield of α-hydroxyacetophenone varied from 1.7 to 10% according to the amount of water contained in the acetophenone employed. When acetophenone was treated with anhydrous magnesium sulfate for one week at room temperature and then distilled, the yield was found to be 1.7%. If the treatment with anhydrous magnesium sulfate was omitted, the yield increased up to 10%.

14) C. Grundman and H. Trischmann, *Ann. Chem.*, **536**, 29 (1938).

IR: 1655, 1600, 1450, 1325, 1295, 1194 and 1023 cm^{-1}.

The solid F-2 was purified by recrystallization from benzene-*n*-hexane, and was identified as *cis*-dibenzoylethylene (IX) by elemental analyses and UV, IR and NMR spectra; mp 136.0—137.0°C, yield 0.05 g (1.2%).

Found: C, 81.43; H, 4.99%. Calcd for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12%. IR: 1665, 1600, 1450, 1400, 1233 and 1015 cm^{-1}. UV: λ_{max}^{EtOH} 2608 Å (ε 26000). NMR (12 $CDCl_3$): 2.89 (s, 2H), 2.7—2.5 (m, 6H) and 2.2—2.0 τ (m, 4H).

Reaction of I with Benzaldehyde (method B). The reaction of I (5.0 g, 0.034 mol) with benzaldehyde (150 g, 1.42 mol) was carried out in the presence of $Cu(acac)_2$ (0.05 g, 3.8×10^{-4} mol) by the mixed method. After removal of unreacted benzaldehyde by distillation, the residue was dissolved in hot benzene under heating, and a small amount of ligroin was added to the solution. A white precipitate (G-1) was separated out from the solution. The precipitate G-1 was dissolved again in benzene and poured into *n*-hexane under stirring. When the mixture was let to stand overnight, a white substance precipitated from the solution. The precipitate was collected by filtration, and was confirmed to be copolymer (XII) of benzaldehyde-benzoylcarbene, 4.8 g, mp 127°C. IR: 1690, 1450, 1100 and 710 cm^{-1}. UV (in dichloromethane): λ_{max} 2500 Å. NMR (in $CDCl_3$): 3.3—3.1 (m, 2H), 5.5—4.0 (m, 15H) and 4.0—2.1 τ (m, 85H).

The copolymer (XII) is so stable that no change was observed during the treatment with hot concentrated hydrochloric acid or 10%-sodium hydroxide solution.

To the filtrate was added *n*-heptane under heating and allowed to stand overnight. A black oily substance (G-2) separated out, and then a brown oil (G-3) precipitated by concentrating the filtrate. After evaporation of the solvent, the residue was dissolved in benzene. The benzene solution was let to stand for 3 days to give yellow substance (G-4). The oil G-2 was confirmed to be oligomer of benzoylcarbene with one molecule of benzaldehyde (IVb) by means of IR spectrum; yield 0.29 g (6.7%). IR: 1675, 1600, 1445, 1215 and 1020 cm^{-1}.

The oil G-3 was dissolved in methyl alcohol, and the solution was allowed to stand at room temperature to give a brown precipitate. The IR spectrum indicates that the precipitate is another copolymer of benzaldehyde-benzoylcarbene (XIII) 0.38 g, mp 68—73°C. UV (in dichloromethane): λ_{max} 2500 Å. IR: 1675, 1600, 1450, 1240 and 1100 cm^{-1}.

Recrystallization of the product G-4 from methyl alcohol gave white needles. The crystalline product was identified to be dioxolane (VIb), yield 0.26 g (2.3%); mp 167.0—168.0°C.

Found: C, 80.41; H, 5.49%. Calcd for $C_{22}H_{18}O_3$: C, 79.98; H, 5.49%. The NMR spectrum is shown in Fig. 2. UV: λ_{max}^{EtOH} 2600 A (ε 10400). IR: 1690, 1450, 1410, 1215, 1090, 1052 and 1010 cm^{-1}.

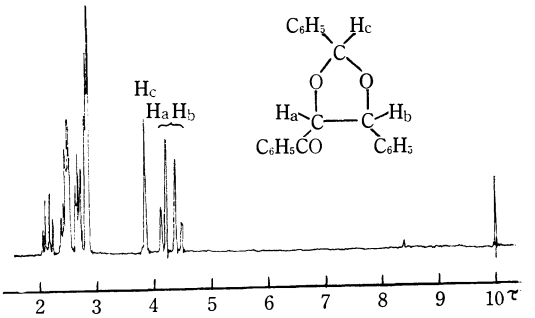

Fig. 2. NMR spectrum of VIb.

Reaction of I with Methyl Benzoate (Method B). The reaction of I (10.0 g, 0.068 mol) with methyl benzoate (150 g, 1.25 mol) in the presence of $Cu(acac)_2$ (0.05 g, 3.8×10^{-4} mol) was carried out by the mixed method. Unreacted methyl benzoate was removed by distillation. No distillate was obtained at 130°C under 0.1 mmHg. The fractional recrystallization of residue gave *cis*-dibenzoylethylene (IX) (0.5 g, 2.9%), *trans*-dibenzoylethylene (X) (4.8 g, 58%) and oligomer of benzoylcarbene with one molecule of methyl benzoate (IVc) (0.65 g, 8.8%).

Found: C, 78.30; H, 5.00%. Calcd for $C_{32}H_{26}O_6$: C, 78.35; H, 5.34%. IR: 1760, 1675, 1220 and 698 cm^{-1}.

The authors express their cordial thanks to Mr. Hiroyuki Kaburagi for his assistance in experiments, and also to the Ministry of Education for a grant-in-aid for Scientific Research.

Studies of Diazosulfides. II.*1 The Dissociation of *trans*- and *cis*-Diazosulfides and the Isolation of *cis*-Diaryldiazosulfides

Takashi YAMADA*2

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received October 20, 1969)

The reaction of *trans*- and *cis*-*N*-aryl-*S*-triphenylmethyldiazosulfides (I) with β-naphthol in alkaline ethanol was investigated. It was found that the dissociation of I occurs not only with the *cis* isomers, but also with the *trans* isomers, even in the dark. The kinetic study suggested that the *trans*-diazosulfides can dissociate not only through the *cis* form, but also directly, contrary to Zwet and Kooyman's suggestion. The dissociation of the *trans* isomer of diaryldiazosulfides (II) was also discussed analogously. Further, by a preparation at −78°C several *cis*-diaryldiazosulfides were isolated which had never before been isolated. The rate constant of the isomerization of *cis*-*N*-(*p*-cyanophenyl)-*S*-(*p*-tolyl)diazosulfide (IIf) was 2.55×10^{-3} sec^{-1} (at 0°C, in ethanol); this value is much larger than that for *cis*-I.

Recently, both *cis* and *trans* isomers of diazosulfides were isolated by Zwet and Kooyman.[1] In their paper, it was concluded that the ionization of diazosulfides can occur with only the *cis* isomers, whereas the *trans* isomer cannot dissociate unless it is first converted photochemically to the *cis* isomer. Similar behavior has been reported for diazocyanides and diazosulfonates.[2] However, the present author and his co-workers found previously that diaryldiazosulfides, which could be identified as having the *trans* form according to the UV spectral discussion,[1] dissociated at an appreciable rate and coupled with β-naphthol to afford azo-dyes in alkaline ethanol.[3] On the basis of the previous results,[3] it was suggested that the *trans* form of diazosulfides may generally dissociate, and that the *trans*-*N*-aryl-*S*-triphenylmethyldiazosulfides (I) treated by Zwet and Kooyman also dissociate, even though at a very low rate. In other to confirm this suggestion, the present author prepared both *trans* and *cis* forms of I and examined their reaction with β-naphthol. Further, in connection with the study of the dissociation of *trans*-diaryldiazosulfides (II), the author could successfully isolate the *cis* isomers of II, which had never before been isolated.

In the present paper, the author wishes to report the findings of his kinetic study of the reaction of *cis* and *trans* forms of diazosulfides (I) with β-naphthol in alkaline ethanol, and of his study of the isolation of *cis*-II isomers and their thermal isomerization.

(II)

Results and Discussion

Reaction of *cis*- and *trans*-Diazosulfides (I) with β-Naphthol. The reaction of *trans*-*N*-aryl-*S*-triphenylmethyldiazosulfides (I) with β-naphthol was carried out in alkaline ethanol at 30.0°C. It was found that the *trans*-diazosulfides (Ia-c, X= OCH_3, CH_3 and H) reacted very slowly, but positively, to produce azo-dyes even in the dark, contrary to Zwet and Kooyman's observation.[1]

The first-order rate constants of the reaction of *cis*-and *trans*-I are summarized in Table 1. The table shows that the *cis* isomer reacts much faster than the *trans* isomer, as is expected, and that the electron-donating substituents on the *N*-aryl part of both *cis*-I and *trans*-I promote the reaction. Hammett plots of the rate constants give good straight lines, the ρ-values being -2.05 for the *cis* isomers (ρ_{cis}) and -4.8 for the *trans* isomers (ρ_{trans}) (Fig. 1).

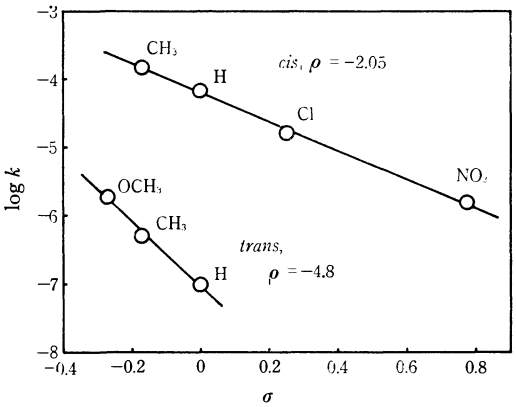

Fig. 1. Hammett plots for the reaction of *cis*- and *trans*-diazosulfides (I), *p*-X-C_6H_4-N=N-S-$C(C_6H_5)_3$, with β-naphthol in alkaline ethanol at 35.0°C.

Table 2. Activation parameters for the reaction of *trans*-diazosulfides (I) with β-naphthol in alkaline ethanol

Diazosulfide	Substituent X	E_a kcal/mol	$\Delta S^{\neq}$ (35°C) e. u.
Ia	OCH_3	24.0	−10.2
Ib	CH_3	25.4	−8.4
Ic	H	26.8	−7.2

Table 2 summarizes the activation parameters calculated from the values for the *trans* isomers listed Table 1. It is interesting that the values of the entropy of activation ($\Delta S^{\neq}$) are comparable with the values for diaryldiazosulfides, whereas the energies of activation (E_a) were considerably larger than that for diaryldiazosulfides; *e.g.*, the E_a value for *N*-(*p*-tolyl)-*S*-(*p*-chlorophenyl)diazosulfide is 10.2 kcal/mol.[3]

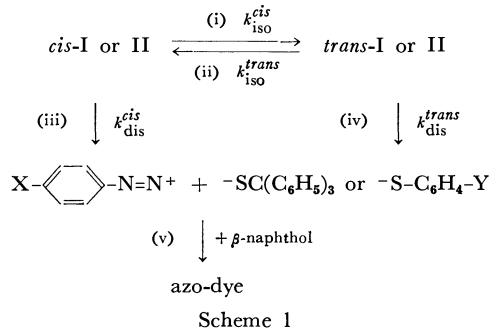
The negative ρ-values (Fig. 1) and the negative values of the entropy of activation (Table 2) suggest that the rate-determining step in this reaction is the dissociation of diazosulfides (I), just as in the case of diaryldiazosulfides (II).[3] Therefore, it seems reasonable that the following discussion of the dissociation of diazosulfides is based on the rate constants shown in Table 1.

The rate constants of the reaction of *cis*-I with β-naphthol at 30.0°C in alkaline ethanol are 10^{-4}—10^{-6} sec^{-1} (Table 1), whereas the isomerization rate constants of *cis*-I at 36.9°C in chloroform are 5×10^{-4} —7×10^{-4} sec^{-1}.[1] Therefore, even if the small solvent effect on the isomerization rate[1] is taken into account, it seems that the thermal *cis*→*trans* isomerization does not proceed through ionization and recombination, as Zwet and Kooyman suggested.

The present author observed the dissociation of the *trans*-diazosulfides. It is also a question whether this dissociation proceeds through the *cis* isomer analogously to Zwet and Kooyman's conclusion (Mechanism A), or whether it occurs directly from the *trans* isomer (Mechanism B). However, Mechanism A will be excluded by the following discussion.

The reaction was always carried out in the dark, and the solution of diazosulfides was quickly prepared in a room lighted as usual. No rate change was observed even for the solution prepared in the dark. Therefore, the photochemical *trans*→*cis* isomerization can be disregarded. We must, then, assume that the *trans*→*cis* isomerization occurs thermally in the course of the reaction of the *trans*-I with β-naphthol if the reaction proceeds by means of Mechanism A.

As has been described above, the rate-determining step of this reaction should be the dissociation of diazosulfides. Table 1 shows that the reaction of the *cis* isomer is much faster than that of the *trans* isomer. Therefore, even if the reaction of the *trans* isomer proceeds *via* the *cis* form, Step (iii) in Scheme 1 cannot be rate-determining.



Scheme 1

On the other hand, Zwet and Kooyman showed that the substituent effect for the *cis*→*trans* isomerization (Step (i)) is negligible. Therefore, on the basis of the principle of the microscopic reversibility, it seems valid to say that the substituent effect on Step (ii) is negligible. This is not, however, in accord with the observed result ($\rho_{trans}=-4.8$). Therefore, it seems unreasonable to say that Step (ii) is the rate-determining step in the reaction of *trans*-I with β-naphthol.

Consequently, it seems reasonable to conclude that the *trans*-diazosulfides (I) dissociate directly, not through the *cis* forms. This may explain well the finding that ρ_{trans} is not the same as ρ_{cis}.

Although the rate data for the dissociation of the *cis* isomers are lacking, the same mechanism may

hold for the dissociation of the *trans*-diaryldiazosulfides (II) described in a previous paper ;[3] if *trans*-II cannot dissociate directly, *i.e.*, if $k_{dis}^{trans} \doteqdot 0$, then $k_{dis}^{cis} \ll k_{iso}^{trans}$ would be valid because the rate-determining step is the heterolytic rupture of the N-S bond of diazosulfide.[3] We shall suppose that the thermal equilibirum between the *cis* form and the *trans* is attained and that its equilibrium constant, $K(=k_{iso}^{cis}/k_{iso}^{trans})$ is larger than 10^{2}.[4] On the other hand, the isomerization rate constant for *cis*-IIf at 35°C (k_{iso}^{cis}), is estimated, by extrapolation from the data shown in Table 4, to be *ca.* 10^{-1} sec^{-1}. This figure gives $k_{iso}^{trans} \leqq 10^{-3}$ sec^{-1} (35°C) ; thus, $k_{dis}^{cis} \ll 10^{-3}$ sec^{-1}. If the substituent effect on the isomerization is neglected as in the case of diazosulfides (I), the rate constant for the net reaction, $k(=k_{dis}^{cis}/K)$, can be expected to be much smaller than 10^{-5} sec^{-1}. The actually-observed rate constants, however, are 4×10^{-3}—10^{-6} sec^{-1} (35°C). Therefore, the *trans* isomers of diaryldiazosulfides also seem to dissociate not through the *cis* form, but directly. In Scheme 1, Steps (iii) and (iv) are shown to be irreversible, because Step (v) may be much faster than those steps.

Isolation of *cis*-Diaryldiazosulfides (IV). Hantzsch and Freese[5] speculated that, in the preparation of diaryldiazosulfides, the *cis* form is first produced, but that it is immediately isomerized to the *trans* form. Similar examples have been reported for diazocyanides and diazosulfonates.[2]

As the bulky mercaptans (*e.g.*, triphenylmethylmercaptan and *t*-butylmercaptan) seemed, on the basis of Zwet and Kooyman's results, to prevent the *cis*→*trans* isomerization, the author first used 2,6-dimethylthiophenol to prepare diaryldiazosulfides (II) at −10—−5°C. However, they were all assigned to the *trans* isomer on the basis of the UV

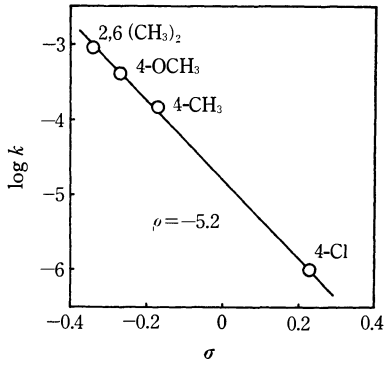


Fig. 2. Hammett plot for the reaction of diazosulfides (IIa-d), X-C_6H_4-N=N-S-$C_6H_3(CH_3)_2$-(2,6), with β-naphthol in alkaline ethanol at 35.0°C.

4) This assumption seems to be valid because the *cis* isomer could not be detected in the recrystallized *trans* isomer.

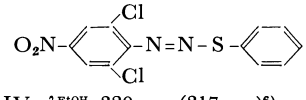
Table 3. Rate constants for the reaction of *N*-Aryl-*S*-(2,6-dimethylphenyl)diazosulfides (II) with β-naphthol in alkaline ethanol at 35.0°C*

	Substituent X	$k\times10^{4}$ sec^{-1}
IIa	2,6-$(CH_3)_2$	8.5
IIb	4-OCH_3	4.0
IIc	4-CH_3	1.5
IId	4-Cl	0.010

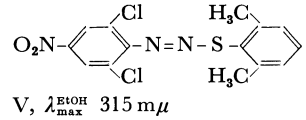
* [Diazosulfide] = 1.0×10^{-4} M, [β-Naphthol] = 1.0×10^{-3} M, [KOH] = 1.1×10^{-3} M.

spectra, *i.e.*, λ_{max} (Table 5) and the lack of spectral change. The Hammett plot of the rate constants for the reaction of II with β-naphthol in alkaline ethanol, summarized in Table 3, shows a straight line with a value of $\rho = -5.2$ (Fig. 2) ; this value is comparable with the value for the same reaction of the *trans*-I. It is interesting that the point for IIa falls on the line when the σ-value for the 2,6-dimethyl group is assumed to be equal to twice $\sigma_{p\text{-}CH_3}$ In other words, the steric effect by two *ortho*-methyl groups of mercaptan does not operate in this instance.

Further, the diazosulfides (IV and V), which have substituents in two *ortho*-positions of the *N*-aryl part, were also prepared. Although they do not have a λ_{max} beyond 320 mμ, they also seem to be *trans* isomers because no spectral change was observed at room temperature. The substituents in the *ortho*-positions of the *N*-aryl part, even in the *trans*



IV, λ_{max}^{EtOH} 320 mμ (317 mμ)[6]



V, λ_{max}^{EtOH} 315 mμ

form, seem to make it difficult for the aromatic ring to be coplanar to the plane containing the N=N group.

Next, diazosulfides were prepared at −78°C. In this case, the diazonium salts with an electron-withdrawing substituent and the mercaptans with an electron-donating substituent were employed so that the *S*-coupling would proceed quickly, even at a low temperature. As a result, the *cis* isomers of five diaryldiazosulfides were isolated, as is shown in Figs. 3 and 4. Figure 5 shows the spectra of the *cis* isomers. These spectral changes cannot be ascribed to the transformations of the ionic dia-

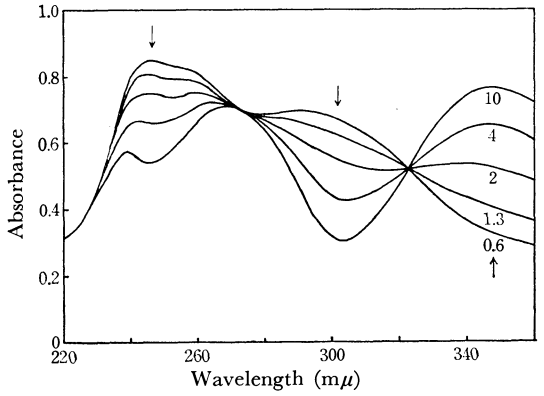

Fig. 3. The progressive spectral change in the *cis*→*trans* isomerization of *cis*-diazosulfide, *p*-O_2N-C_6H_4-N=N-S-C_6H_4-CH_3-(*p*), in ethanol. Numbers refer to time after sample was dissolved (in minutes).

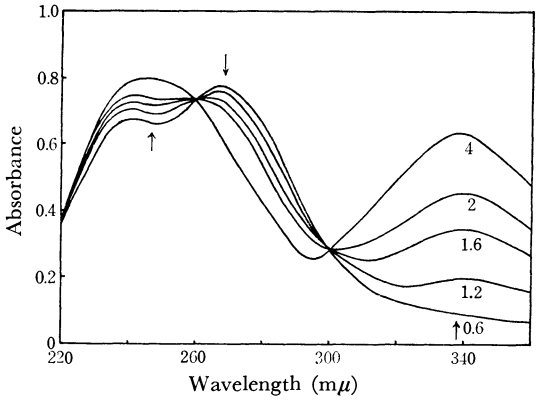

Fig. 4. The progressive spectral change in the *cis*→*trans* isomerization of *cis*-diazosulfide, *p*-NC-C_6H_4-N=N-S-C_6H_4-CH_3-(*p*), in ethanol. Numbers refer to time after sample was dissolved (in minutes).

zonium thiophenoxides into the covalent diazosulfides because of the following evidence: (i) The spectra shown in Fig. 5 have λ_{max} values different from those for the diazonium ions. (ii) *p*-cyanobenzenediazonium ion instantaneusly reacted with β-naphthol in alkaline ethanol to afford red azo-dye at −78°C, whereas diazosulfide (IIf), which was prepared at the same temperature and which was identified as a *cis* isomer, did not react under the same conditions.

The diazosulfides (IV and V) were also prepared at −78°C, but the products were still *trans* isomers. Accordingly, *ortho*-substituents seem to hinder the formation of the *cis* isomer or make the *cis*→*trans* isomerization occur more rapidly.

The rate constants of the thermal isomerization of *cis*-IIf were determined in ethanol (Table 4). It is noteworthy that the entropy of activation is fairly small compared with that for the *cis*-Ic ($\Delta S^{\ddagger}=18.6$ e.u.). The energy of activation for *cis*-IIf is comparable to other examples of the *cis*→*trans* isomerization (*e.g.*, Ic: 29.2 kcal/mol,[1] azonaphthalene: 22.0kcal/mol,[7] azobenzene: 23.0 kcal/mol,[8] diazocyanide: 21.5 kcal/mol,[9] and diazosulfonate: 14.7 kcal/mol[10]).

by the method of Zwet and Kooyman.[1] The physical constants and the UV spectral data of the I thus prepared are summarized in Table 6. The *trans*-*N*-aryl-*S*-(2,6-dimethylphenyl)diazosulfides (IIa–e, g) were prepared by the method described in a previous paper.[3] The analytical data, physical constants, and UV spectral data of II are summarized in Table 5. The α-(2,6-dimethylphenylazo)-β-naphthol was prepared by a method described previously.[3] Mp 147°C, λ_{max} 484 mμ ε 14300 (in alkaline ethanol).

Found: C, 78.44; H, 5.67; N, 10.16%. Calcd for $C_{18}H_{16}N_2O$: C, 78.24; H, 5.84; N, 10.14%.

The UV spectral data of the other azo-dyes were reported in the previous paper.[3]

Kinetic Measurements. The rate constants for the reaction of diazosulfides (I and II) with β-naphthol in alkaline ethanol were determined spectrophotometrically, as has been described previously.[3] The order of reaction with respect to β-naphthol could not be determined.[3] Accordingly, the rate was measured in the presence of excess β-naphthol. In most of the reactions, a rate depression with the time was observed; this may be ascribed to the competitive isomerization or decomposition of diazosulfides. Thus, the initial rates were measured; they are summarized in Tables 1 and 3.

Isolation of *cis*-Diaryldiazosulfides. The *cis*-diaryldiazosulfides were prepared as follows: a solution of 2 mmol of *p*-nitroaniline in 4 ml of 10% hydrochloric acid was diazotized with 2mmol of sodium nitrite in 1 ml of water at −5——10°C. The diazonium solution was then added to a stirred solution of 2 mmol of *p*-methylthiophenol in 50 ml of alkaline ethanol, while the mixture was being cooled by an acetone-dry ice bath. Yellow crystals of *cis*-diazosulfide were immediately formed. The yellow crystals were collected on a well-cooled filter, washed with cold ethanol (*ca.* −70°C), and preserved at

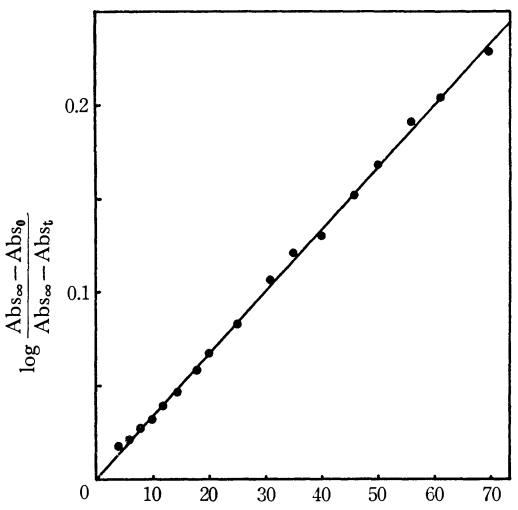

Fig. 6. First-order rate plot for the isomerization of *cis* isomer of diazosulfide (IIf), *p*-NC-C_6H_4-N=N-S-C_6H_4-CH_3-(*p*), in ethanol at −20.0°C.

about −70°C. At this temperature, no change was observed in the UV spectra for at least a day.

Isomerization of *cis*-Diaryldiazosulfides. The isomerization was followed spectrophotometrically using a Hitachi rapid scan spectrophotometer. Some of the *cis*-diazosulfide was dissolved in cold ethanol in a flask immersed in an acetone-dry ice bath. The solution was then quickly transferred into a well-cooled quartz cuvette set in the cell holder, and immediately the UV spectrum was recorded by an oscilloscope unit at appropriate intervals. Because an ambient temperature cell compartment was used, the solution in a cuvette rapidly warmed up, and then the isomerization proceeded acceleratively. Some examples of the spectral change with the time are shown in Figs. 3 and 4.

Kinetic Measurements of the Isomerization of *cis*-*N*-(*p*-Cyanophenyl)-*S*-(*p*-tolyl)diazosulfide (IIf). The rate constants of the isomerization of *cis*-IIf were determined spectrophotometrically. An appropriate amount of *cis*-IIf was dissolved in ethanol so that the concentration of the solution became suitable for the spectral measurements. The temperature was kept constant in a salt-ice bath using a thermos.

Aliquots were removed at intervals and put into a quartz cuvette set in a cell compartment, and the optical densities were immediately measured at 340 mμ (see Fig. 4), the absorption maximum of *trans*-IIf. The first-order rate constants were evaluated by the graphical method shown in Fig. 6 and are summarized in Table 4.

A solution of *cis*-IIf in ethanol can be stored without change for at least two hours at −78°C.

The author wishes to thank Professor Ryōzō Gotō for his encouragement of this work. He is also indebted to Professors Aritsune Kaji and Jun-ichi Hayami for their valuable discussions, and to Mr. Masao Nishikuri for his earnest assistance.

Effect of Carbonyl Compounds on Polymerization by Metal Acetylacetonates

Kyoji KAERIYAMA

Research Institute for Polymers and Textiles, Sawatari, Kanagawa-ku, Yokohama

(Received October 25, 1969)

Some ketones and aldehydes have an accelerative effect on the polymerization of various monomers by various metal chelates of acetylacetone. The conversion increases with an increase in the concentration of these additives in a correspondingly increasing polymerization time. A radical is formed by the equimolar reaction of cyclohexanone and manganese(III) acetylacetonate and by the reaction of two aldehyde molecules and a molecule of the chelate. The order with a monomer is lowered from 1.64 to 1.13 and to 1.07 by the addition of cyclohexanone and caproic aldehyde respectively. The relation between the polymerization rate and the square root of the chelate concentration is linear without any additive ; concave and convex curves are obtained for the systems containing cyclohexanone and caproic aldehyde respectively. The apparent activation energy is lowered from 19.9 kcal/mol to 13.9 and to 14.3 in the presence of cyclohexanone and caproic aldehyde respectively. The effectiveness of ketones is dependent on the nucleophilicity. A mechanism of the initiation reaction which interprets the molar ratio of reactants, the kinetical parameters, and the spectral data is proposed.

Metal acetylacetonates ($Macac_n$) have already been used as initiators for the polymerization of unsaturated compounds.[1-4] The polymerization proceeds *via* radical intermediates. The substituents on the acetylacetone ligand are shown to have an appreciable effect on the initiator activity of the chelate.[5-7] A solvent effect[7] and a high order with a monomer[6,7] are characteristic of a polymerization by $Macac_n$. This indicates the participation of monomers and solvents in the initiation reaction and suggests the presence of additives, a small amount of which accelerates the polymerization by the reaction of the additives with the chelate

prior to that of monomers and solvents. In fact, the addition of pyridine has been found to accelerate the polymerization of styrene by the metal chelate of β-diketone.[8] The effect of carbon tetrachloride has also been discussed.[2,7,9]

The present author has previously shown that the addition of carbonyl compounds accelerates the polymerization of styrene by ceric salt in an organic solvent.[10] In the present study, the effect of ketone and aldehyde on polymerization by $Macac_n$ is investigated.

Experimental

Materials. The monomers, aldehydes, and ketones were distilled under reduced pressure just prior to use. The metal acetylacetonates were commercially obtained (Dotite Reagent) and were used without further purification.

Procedure. In a glass tube we placed a chelate solution in benzene, additives, monomers, and a solvent, in that order, under atmospheric conditions. After the tube had been degassed by repeated freezing, evacuating and thawing, it was sealed off. Polymerization was then carried out in the dark under a mild shaking. The polymer thus produced was precipitated in methyl alcohol containing hydroquinone and hydrogen chloride, filtered, and dried *in vacuo* to a constant weight.

The absorption spectra were measured by a Hitachi recording spectrophotometer, Model EPS-3T.

Results and Discussion

Effect of the Additive. The effects of various additives on the polymerization of styrene by $Mnacac_3$ are shown in Table 1. All the additives used have an accelerative effect. Since caproic aldehyde and cyclohexanone are the most effective of the additives examined, these two reagents will be mainly used as additives in the following parts of this paper.

Table 2 shows the effects of additives on the polymerization by various $Macac_n$. Accelerative effects can be seen in all the chelates used, but there is a large difference in the degree of the effects and in the conversions between the chelates.

The effects of additives on the polymerization of various monomers are shown in Table 3. Methyl

methacrylate and acrylonitrile are polymerized better than styrene. Accelerative effects are, thereby, observed in all the monomers used. It is apparent that some ketones and aldehydes have an accelerative effect on the polymerization of many unsaturated monomers by a variety of metal chelates.

The dependence of the conversion on the concentration of additives is shown in Fig. 1. The conversion increases monotonically with an increase in the concentration of the additive, and it is higher in the presence of caproic aldehyde than in the presence of cyclohexanone in all the concentrations examined. In the run with the highest concentration of caproic aldehyde, the polymerizing mixture lost its color at the end of the polymerization. This indicates the complete decomposition of the chelate. In the run with the second highest concentration of the aldehyde, the color faded. No color change could be observed in the other runs.

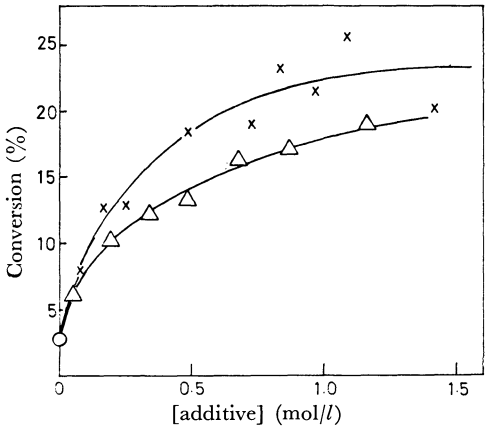

Fig. 1. Dependence of conversion on the concentration of additives.
[styrene]=3.49 mol/l; [$Mnacac_3$]=1.42×10^{-2} mol/l; solvent; benzene; at 60°C for 6.0 hr.
-△- cyclohexanone, -×- caproic aldehyde

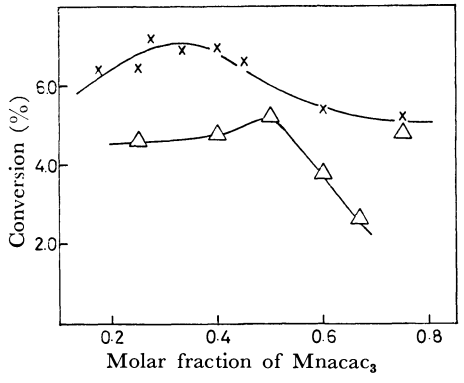

Fig. 2. Dependence of conversion on molar fraction of $Mnacac_3$.
[$Mnacac_3$]+[additive]=3.0×10^{-2} mol/l
[styrene]=3.49 mol/l; solvent: benzene; at 60°C for 7.0 hr.
-△- cyclohexanone, -×- caproic aldehyde

Figure 2 represents the conversion of styrene as a function of the mole fraction of $Mnacac_3$. The maxima do not appear sharp compared with those of other systems, for example, the amide-carbon tetrachloride system.[11] The maxima appear at the optimum fraction, which corresponds to the ratio of the reactants participating in the initiation reaction. In the case of cyclohexanone, the maximum is observed at the equimolar ratio. This implies that a chelate molecule and a cyclohexanone molecule participate in the initiation reaction. In the presence of caproic aldehyde, the maximum seems to be at the molar fraction of 0.33. This suggests that a radical is generated from one manganese tris-acetylacetonate molecule and two caproic aldehyde molecules.

Kinetics. Because a small deviation from a straight line is observed in time-conversion plots, the initial rates of polymerization can be evaluated by graphically determining a tangent at time 0. No change in or fading of the color of polymerizing mixture could be observed in the runs described here.

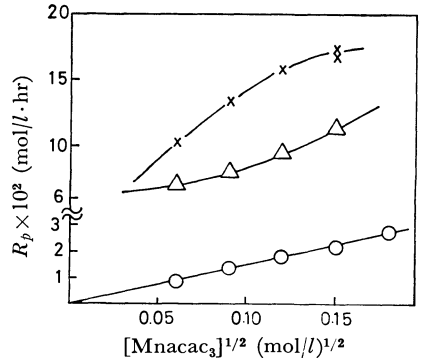

Fig. 3. Dependence of polymerization rate on [$Mnacac_3$]$^{1/2}$.
[styrene]=3.49 mol/l; solvent: benzene; at 60°C
-○- no additive, -△- [cyclohexanone]=0.483 mol/l, -×- [caproic aldehyde]=0.483 mol/l

The dependence of the initial rate of polymerization on the square root of the concentration of $Mnacac_3$ is shown in Fig. 3. In the absence of any additive, the rate is linearly dependent on the square root of the chelate concentration. The polymerization chain is terminated by the bimolecular reaction of polymer radicals. Bamford and Lind[7] have also reported that the polymerization rate of styrene and methyl methacrylate is proportional to the square root of the concentration of $Mnacac_3$. In the presence of cyclohexanone, the curve is concave. As is shown in Fig. 1, the polymerization rate increases with the concentration of cyclohexanone at a constant concentration of

11) K. Kaeriyama, This Bulletin, **42**, 3602 (1969).

$Mnacac_3$, because the ratio of cyclohexanone to the chelate increases. In the case of a constant concentration of cyclohexanone, the ratio of cyclohexanone to $Mnacac_3$ increases with a decrease in the concentration of the chelate. This is the reason why the rate is higher at low concentrations of the chelate than would be expected from the linear dependence on the square root of the chelate concentration. The possibility of the bimolecular termination can not be rejected. In the presence of caproic aldehyde, the curve is convex. If the termination is by the reaction of the polymer radical with the initiator, the polymerization rate is independent of the initiator concentration. In this case, both terminations, by the chelate and by bimolecular reaction of polymer radicals, take place. This is the reason why the curve is convex. Uehara *et al.* have described how the polymerization of acrylonitrile is terminated by copper chelates of β-diketones.[4]

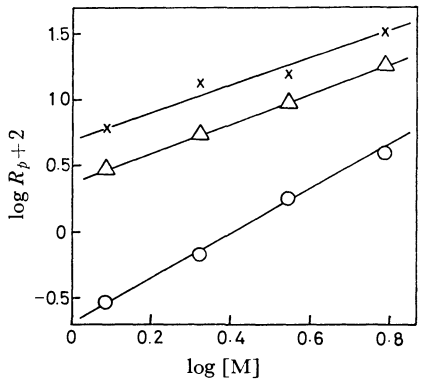

Fig. 4. Dependence of polymerization rate on styrene concentration.
$[Mnacac_3]=1.42\times10^{-2}$ mol/l
solvent: benzene; at 60°C
-○- no additive
-△- [cyclohexanonoe] = 0.483 mol/l
-×- [caproic aldehyde] = 0.483 mol/l

Figure 4 presents logarithmic plots of the initial rate of polymerization as a function of the monomer concentration at constant concentrations of $Mnacac_3$ and additives. The order with the monomer is 1.64 in the absence of any additive. This high order is attributable to the participation of the monomer in the initiation reaction. The order is lowered to 1.13 and 1.07 by the addition of cyclohexanone and caproic aldehyde respectively. This shows that the additive limits the participation of the monomer in the initiation reaction to a lesser extent. Bamford and Lind[7] have reported that the order with the monomer is dependent on the diluent, being 1.5 and 1.2 for toluene and ethyl acetate respectively. These findings are similar to those of present paper in the sense that the use of the carbonyl compound as the solvent lowers the order with the monomer. However, cyclanone is more effective than the ester. Uehara *et al.*[8] have also described that the addition of pyridine lowers the order with styrene from 1.9 to 1.2.

Arrhenius plots are shown in Fig. 5. The apparent activation energies and frequency factors are summarized in Table 4. The additives lower the apparent activation energy by *ca.* 6 kcal/mol. The frequency factors are very low, especially in the presence of cyclohexanone. This is characteristic of the polymerization by these initiator systems.

Spectra. The absorption spectra of $Mnacac_3$ in visible regions are shown in Fig. 6. Because the spectra in benzene and a benzene-styrene mixture (50 vol%) are completely identical, it can be said that styrene does not coordinate to $Mnacac_3$. The behavior of $Mnacac_3$ is different from that of the copper chelate.[6] The spectra in a cyclohexanone solution are essentially identical with those in a benzene solution, although a small deviation can be observed. The spectra in a caproic aldehyde solution are shifted to shorter wavelengths and show higher absorption coefficients. It is apparent that they are different from those in the benzene and cyclohexanone solutions. This can be attributed to the coordination of caproic aldehyde to $Mnacac_3$.

Initiation Mechanism. Although the coordination of cyclohexanone with $Mnacac_3$ can not be deduced from the spectral data, it is clear that

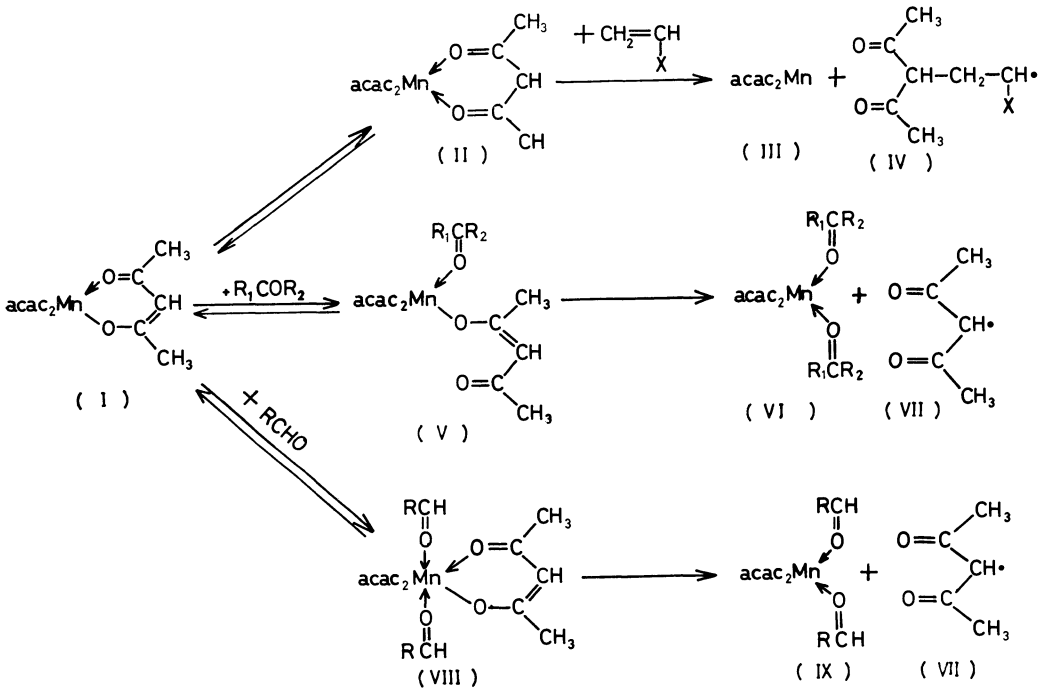
ketone interacts with the chelate and accelerates the polymerization. Ketones are arranged in the order of nucleophilic tendency. Figure 7 shows the relation between the conversion and the O-D shift in IR spectra. The O-D shift of monodeuterated methanol, which is cited from the report of Tamres and Searles,[12] is due to a hydrogen bond with ketone and depends on the nucleophilicity of the ketone. Acetone deviates from the line. It also deviates from the linear relation between the O-D shift and the heat of mixing with chloroform because of association. The deviation of cycloheptanone can be interpreted in terms of the difference in bulkiness between methanol and the chelate molecule. Cycloheptanone deviates only in reaction with manganese chelate, which has a stronger interaction with the ketone. It appears from Fig. 7 that conversion is dependent on the nucleophilicity of ketone. These results and the spectral data suggest that ketone coordinates to the chelate in an activation state.

The initiation reactions can be summarized schematically as on the next page. Styrene does not coordinate to I judging from the spectra. I is activated into II, which reacts with the monomer to generate the radical IV. The mechanism shouldlead to an order of 1.5 with the monomer. The observed order of 1.64 can, therefore, not be explained. A possible explanation is to suppose another reaction in which II reacts with two molecules of monomer. In the presence of the ketone I reacts with the ketone to form an activated complex V, which in turn decomposes into VI and VII. The mechanism predicts the linear dependence on the monomer concentration. The observed order is attributable to the simultaneous reaction *via* II. The above explanation is consistent with the spectral data and the equimolar reaction of the chelate with ketone.

Otsu *et al.* reported that metal β-diketonates induced a coordination polymerization of aldehyde.[13] Chloral was most easily polymerized; when *n*-butyl aldehyde and chloral were copolymerized by Cu bis-(ethyl acetoacetate), a copolymer

13) T. Otsu, S. Watanuma and Y. Nishikawa, *Kogyo Kagaku Zasshi*, **72**, 1857 (1969); *Makromol. Chem.*, **115**, 278 (1968).



Scheme 1

containing a small amount of *n*-butyl aldehyde units was produced. They also reported that $Mnacac_3$ did not induce the polymerization of chloral. In the present study, no polymer of caproic aldehyde was detected by precipitation in benzene or methanol. No copolymerization of caproic aldehyde with styrene was deduced from the IR data. Although caproic aldehyde is not polymerized by $Mnacac_3$, it has a stronger interaction with the chelate than cyclohexanone. In the presence of caproic aldehyde, two aldehyde molecules coordinate to the chelate in the ground state and VIII is formed. The decomposition of VIII generates the radical VII. This route is compatible with the spectral data and with the optimum molar ratio of the reactants.

The bond between manganese and the acetylacetone ligand is weakened by the coordination of aldehyde, and a acetylacetone ligand in VIII reacts with the polymeric radical. This indicates that the chelate terminates the polymerization of styrene in the presence of caproic aldehyde, as has been described in the section on the dependence on the initiator concentration.

The polymers produced by the present initiator systems do not have stereoregularity, the IR data indicate.[14]

The author is grateful to Dr. M. Suzuki and Dr. A. Okada for their interest and encouragement during this work.

Rhodium Tolane Complex and Cyclotrimerization of Substituted Acetylenes Catalyzed by Transition Metal Complexes

Yuji IWASHITA and Fumihide TAMURA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

(Received October 25, 1969)

Cyclotrimerization of tolane and phenylacetylene has been studied from the viewpoint of the reaction intermediates and the composition of reaction products. $Rh_4(CO)_{12}$ and $Co_4(CO)_{12}$ have been found to catalyze the trimerization of tolane and phenylacetylene to yield some substituted benzenes. By the reaction of $Rh_4(CO)_{12}$ with tolane, an unknown complex was obtained. The triphenyl phosphine derivative of this complex has been determined to be $Rh_2(CO)_3$-$(C_6H_5C{\equiv}CC_6H_5)_2P(C_6H_5)_3$. From infrared spectroscopic study, it was concluded that the two tolane molecules in the complex are connected to rhodium atoms separately without completion of dimerization. On the basis of the ratio of 1,2,4-triphenylbenzene to 1,3,5-triphenylbenzene, the reaction course of trimerization is discussed.

Trimerization of acetylenes using transition metal catalysts has been studied by many investigators. Hübel and Krüerk[1] have described the cobalt complex in which three substituted acetylenes are involved. Hagihara and his coworker[2] have suggested a *cis*-butadiene type structure as an intermediate complex of cyclotrimerization reaction. However, evidence for the proposed structure of these intermediates does not seem to be conclusive. There remains the question whether acetylene completed trimerization in the complex or during the course of leaving the metal.

Rhodium Tolane Complex. Several rhodium complexes having acetylene as a ligand were obtained by the reaction of $Rh_4(CO)_{12}$ with acetylene in *n*-hexane. However, they were unstable even at low temperature and rapidly decomposed to give benzene. In order to obtain the stable complex, the reaction of $Rh_4(CO)_{12}$ with tolane was carried out at 50°C in *n*-hexane.

At the first stage of the reaction, the infrared spectrum of the solution (Fig. 1-I) was very similar to that of $CH{\equiv}CHCo_4(CO)_{10}$[1] (Fig. 2), and the formed complex is considered to be $(C_6H_5C{\equiv}CC_6H_5)$

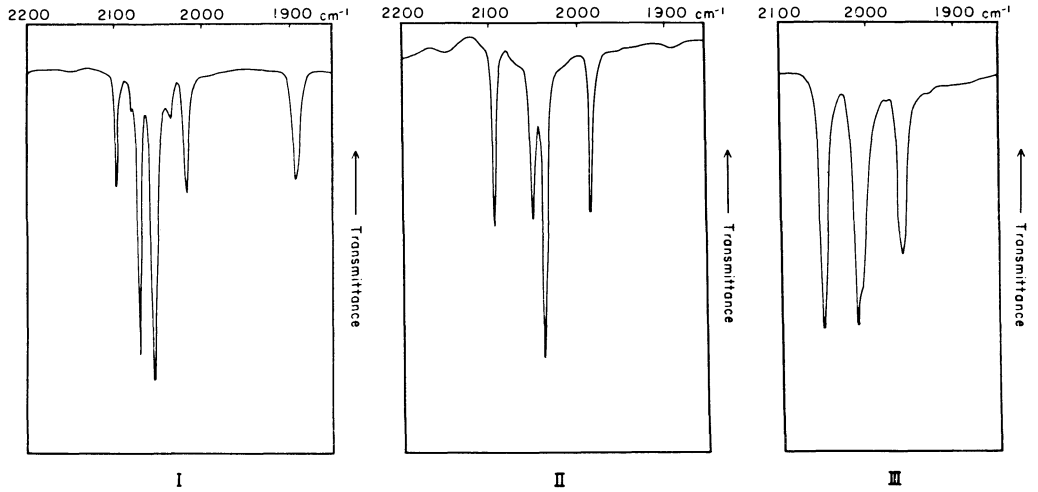

Fig. 1. Infrared spectra of reaction mixture: $Rh_4(CO)_{12}$ and tolane in *n*-hexane.

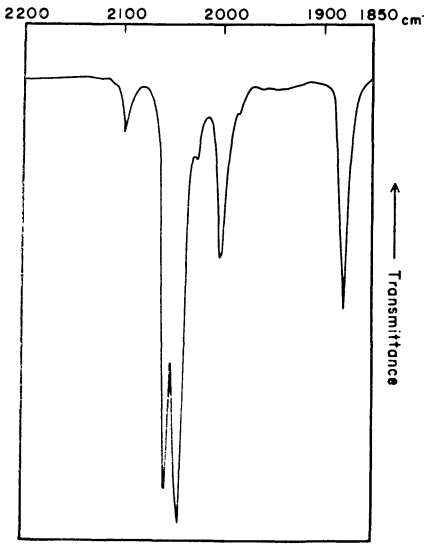

Fig. 2. Infrared spectrum of $CH{\equiv}CHCo_4(CO)_{10}$.

$Rh_4(CO)_{10}$.

After a while, the absorption due to the bridging carbonyls of the complex vanished (Fig. 1-II). When the reaction continued further at 50°C, the precipitation of hexaphenylbenzene was observed in the reaction vessel. Since the complex was too unstable to be isolated, it was transformed into a triphenylphosphine substituted complex. The same complex was also obtained from the reaction using aromatic solvents, although they show different powder X-ray patterns. When the formed complex was accompanied by some aromatic solvents such as benzene, toluene, *etc.*, the complex was washed by *n*-hexane, and recrystallized from ether. Thus, red-brown prisms decomposing at 115°C, were obtained.

The 100 MHz NMR spectrum of the complex shows the signals of triphenylphosphine protons[3] and tolane protons at separate positions in a perchloroethylene solution. The ratio of triphenylphos phine to tolane in the complex was then determined by the integration of spectrum. Molecular weight measurement failed because of decomposition. In the infrared spectrum of the complex, three strong bands at 2052.0, 2013.0 and 1954.5cm^{-1} were observed in terminal carbonyl stretching region (Fig. 1-III). The above-described spectroscopic data and elemental analysis are coincident with the molecular formula $Rh_2(CO)_3P(C_6H_5)_3(C_6H_5C{\equiv}CC_6H_5)_2$.

The course of the reaction may be expressed by the following equation :

$$Rh_4(CO)_{12} + C_6H_5C{\equiv}CC_6H_5 \rightarrow (C_6H_5C{\equiv}CC_6H_5)Rh_4(CO)_{10} + 2CO$$

$$(C_6H_5C{\equiv}CC_6H_5)Rh_4(CO)_{10} + 3C_6H_5C{\equiv}CC_6H_5 \rightarrow 2Rh_2(CO)_4(C_6H_5C{\equiv}CC_6H_5)_2 + 2CO$$

$$Rh_2(CO)_4(C_6H_5C{\equiv}CC_6H_5)_2 + P(C_6H_5)_3 \rightarrow Rh_2(CO)_3P(C_6H_5)_3(C_6H_5C{\equiv}CC_6H_5)_2 + CO$$

Infrared Spectra of the Coordinated Tolane. In order to separate the infrared absorption bands due to tolane from those due to triphenylphosphine moiety, the perdeuterio triphenylphosphine P-$(C_6D_5)_3$[4] substituted complex was prepared. Assignment of the infrared spectrum was done on the basis of a comparison with its deuterated compound (Table 1). In the region between 1600 cm^{-1} and 800 cm^{-1}, the bands attributed to the coordinated tolane have positions and intensities similar to those of free tolane molecule.

If the two coordinated tolane molecules take the form of *cis*-butadiene, the change of intensities and positions of absorptions should be observed.[5] Therefore, the two tolane molecules must be connected with the rhodium atoms independently. Several bands in far-infrared region which could not be assigned to tolane or triphenylphosphine may be due to rhodium-tolane[4] stretching, rhodium–(C≡O) stretching and Rh–(C≡O) bending vibrations. proposed structure of the complex is illustrated in Fig. 3.

Cyclotrimerization of Phenylacetylene. The $Rh_4(CO)_{12}$ or $Co_4(CO)_{12}$ catalyzed cyclotrimerization reaction of phenylacetylene was carried out in a benzene solution at 60°C. The products were identified by IR, E.A. and molecular weight measurements. The ratio of 1,2,4-triphenylbenzene to 1,3,5-triphenylbenzene was determined by gas chromatography. The results are given in Table 2. When $Co_4(CO)_{12}$ was used as a catalyst, the product was almost composed of 1,2,4-triphenylbenzene and when $Rh_4(CO)_{12}$ was used as a catalyst, the amount of 1,2,4-triphenylbenzene was twice as much as that of 1,3,5-triphenylbenzene.

In a transition state, three *cis*-butadiene type intermediates may be assumed (Fig. 4). Form III seems to be the most stable because of the lack of steric repulsion between phenyl groups and the metal carbonyl moiety. If the structure of the intermediate is supposed to be form III, the subsequent reaction to a phenylacetylene molecule should give 1,2,4-triphenylbenzene. In the $Rh_4(CO)_{12}$ catalyzed reaction, since rhodium atom has a larger covalent bond radii[6] than that of cobalt atom, the contribution of form II, which gives 1,3,5-triphenylbenzene, might be larger.

When the infrared spectra of the solution indicate the existence of $C_6H_5C{\equiv}CCHCo_4(CO)_{10}$ type complex only, half of triphenylbenzene is formed as a result of cyclotrimerization.

This means that not only $(C_6H_5C{\equiv}CH)_2M_2(CO)_4$ (M=Co or Rh) but also $(C_6H_5C{\equiv}CH)M_4(CO)_{10}$ has catalytic activity. Therefore these complexes must be transformed into *cis*-butadiene type structure in the transition state.

Experimental

Rhodium Tolane Complex. To a solution (50 m*l*) of $Rh_4(CO)_{12}$ (108 mg) in *n*-hexane, tolane (103 mg) was added and warmed at 50°C for 5 hr and then $P(C_6H_5)_3$ (62 mg) was added. The reaction product was chromatographed on alumina. From the eluted solution, red-brown prisms were obtained; yield 38%, mp 115°C (decomposed).

Found: C, 64.98; H, 4.36; Rh, 22.7%. Calcd for $C_{49}H_{35}O_3Rh_2P$: C, 64.77; H, 3.89; Rh, 22.65%.

The NMR spectrum was measured with a Varian HA-100 spectrometer in a tetrachloroethylene solution.

6) L. Pauling, " The Nature of the Chemical Bonds," 3rd Ed., Cornell University Press, Ithaca, New York (1960).

TMS was used as an internal reference. The multiplet at 725 Hz was assigned to phenyl protons of $P(C_6H_5)_3$ and the multiplet at 676 Hz was assigned to phenyl protons of tolane, respectively. Integration of the spectrum showed that this complex contained one $P(C_6H_5)_3$ and two tolane molecules.

The infrared spectra were measured with a Hitachi-225 spectrometer as paste and KBr pellets. The absorption was corrected by the known absorption of standard polystyrene film.

Cyclotrimerization of Tolane. A 200 m*l* Schlenk tube was charged with 130 mg of $Rh_4(CO)_{12}$, 620 mg of tolane and 100 m*l* of degassed benzene, and then heated to 60°C for 10 hr. The reaction mixture was chromatographed on alumina, and the eluted solution was condensed to dryness. The product was recrystallized by methanol and identified by means of IR spectrum. (Yield 28%)

Cyclotrimerization of Phenylacetylene. The reaction was carried out in a Schlenk tube under a nitrogen stream at 60°C, for 4 hr. The ratio of 1,2,4-triphenylbenzene to 1,3,5-triphenylbenzene was determined with a Shimadzu GC-2 gas chromatograph, operated with a 3.0 m column packed with 4% OV-1 coated on Diatoport at 245°C.

The authors wish to thank Dr. Asao Nakamura and Dr. Ryoji Iwanaga for their discussions and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1520—1523 (1970)

Reaction of Cobalt Hydrotetracarbonyl with Acetylene

Yuji IWASHITA, Fumihide TAMURA and Hachiro WAKAMATSU

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

(Received October 25, 1969)

The reaction of cobalt hydrotetracarbonyl with acetylene was carried out in methanol as a model of the carboxylation of acetylene. The complexes formed in this reaction were identified by means of IR, NMR, EA and molecular weight measurement. The main product was acetylene dicobalt hexacarbonyl. From the decomposition reaction of this complex in ethanol, ethyl acrylate, ethyl propionate and diethyl succinate were obtained. The yield of ethyl acrylate increased in the presence of carbon monoxide. The reaction course from acetylene to acrylate was examined.

Natta and Pino[1] reported that the carboxylation of acetylene catalyzed by cobaltcarbonyl gives fumaric, acrylic and succinic esters in the presence of hydrogen and carbon monoxide in alcohol. It was found that the rate of acrylate formation is accelerated by the presence of hydrogen.[2] The authors have intended to throw light on the reaction course of carboxylation of acetylene by studying the nature of the complexes obtained from the reaction of cobalt carbonyl with acetylene.

Wender and his colleagues[3] reported that the reaction of cobalt hydrotetracarbonyl with acetylene in gas phase gives propanal and acetylene dicobalt hexacarbonyl. However, the reaction in solutions has not been studied yet.

Reaction of Cobalt Hydrotetracarbonyl with Acetylene. Cobalt carbonyl is known to take the form of hydrotetracarbonyl in alcoholic solution under high pressure of carbon monoxide and hydrogen.[3]

$$Co_2(CO)_8 + H_2 \xrightarrow[ROH]{} 2HCo(CO)_4$$

Thus, the reaction of cobalt hydrotetracarbonyl with acetylene in methanol has been carried out either at $-10°C$ or at 25°C, as a model of the first step of acrylic ester synthesis. In order to compare the reaction products in methanol with those in a non-polar solvent, the same reaction using *n*-hexane as a solvent has also been carried out at $-10°C$ and 25°C.

Triphenylphosphine was added to the reaction mixture. The resulting solution was concentrated and chromatographed on alumina. The products thus isolated are listed in Table 1. Ether-insoluble products I, III, VI and X were identified to be $Co_2(CO)_6[P(C_6H_5)_3]_2$[4a] (I, III, VI) and $[Co(CO)_3$-

Methanol	−10°C	I	$Co_2(CO)_6[P(C_6H_5)_3]_2$
		II	$C_2H_2Co_2(CO)_5P(C_6H_5)_3$
	25°C	III	$Co_2(CO)_6[P(C_6H_5)_3]_2$
		IV	$C_2H_2Co_2(CO)_5P(C_6H_5)_3$
		V	$C_2H_2Co_2(CO)_4[P(C_6H_5)_3]_2$
n-Hexane	−10°C	VI	$Co_2(CO)_6[P(C_6H_5)_3]_2$
		VII	$C_2H_2Co_2(CO)_5P(C_6H_5)_3$
		VIII	$C_2H_2Co_4(CO)_8[P(C_6H_5)_3]_2$
		IX	$HCo(CO)_3P(C_6H_5)_3$
	25°C	X	$[Co(CO)_3(P(C_6H_5)_3)_2]^+[Co(CO)_4]^-$
		XI	$Co_2(CO)_6[P(C_6H_5)_3]_2$
		XII	$C_2H_2Co_2(CO)_5P(C_6H_5)_3$
		XIII	$C_2H_2Co_2(CO)_4[P(C_6H_5)_3]_2$

$(P(C_6H_5)_3)_2]^+[Co(CO)_4]^-$ (X) respectively, based on Vohler's studies.[4b] Complex IX, obtained from the reaction in *n*-hexane, was too unstable to be identified by means of IR and NMR, and rapidly decomposed to $Co_2(CO)_6[P(C_6H_5)_3]_2$. From the color and chemical behavior, complex IX was ascribed to $HCo(CO)_3P(C_6H_5)_3$, which Hieber has already reported.[5] Reddish brown crystals (II, IV, VII and XII) were obtained from the first eluted solution of *n*-hexane. All these components were proved to be identical, and this compound was the main product of the reaction not only in methanol but also in *n*-hexane. This complex shows four strong bands at 2065, 2011, 2001 and 1966 cm^{-1} in terminal carbonyl stretching region of the infrared spectrum. The NMR spectrum shows a doublet at $\delta = -5.03$ and a multiplet at $\delta = -7.3$ in a CS_2 solution. From elemental analysis and molecular weight measurement, the molecular formula was established to be $CH{\equiv}CHCo_2(CO)_5P(C_6H_5)_3$. The dark green complex (VIII) was obtained from the fraction eluted next to $CH{\equiv}CHCo_2(CO)_5P(C_6H_5)_3$. Complex VIII shows infrared bands at 2050.0 (s), 2015.0 (s), 1997.0 (m), 1982 (w), 1950 (m) and 1835.0 cm^{-1} in carbonyl stretching region. The NMR spectrum of complex VIII could not be observed, because of low solubility. The elemental analysis and molecular weight measurement have indicated the molecular formula of $C_2H_2Co_4(CO)_8[P(C_6H_5)_3]_2$. For the sake of comparison, the reaction of $Co_4(CO)_{12}$ with acetylene was carried out and the same complex as VIII was obtained.

The final component was isolated and determined to be $CH{\equiv}CHCo_2(CO)_4[P(C_6H_5)_3]_2$, from the infrared spectrum[6] and elemental analysis. The result is summarized in Table 1. The main product of the reaction of cobalt hydrotetracarbonyl with acetylene was established to be $CH{\equiv}CHCo_2(CO)_6$ in methanol and in *n*-hexane. The possibility of the association of cobalt hydrotetracarbonyl to form dicobalt octacarbonyl prior to the reaction was excluded for the reaction in methanol, because the former is considerably stable in methanol. The methanol solution of cobalt hydrotetracarbonyl shows only one broad infrared absorption at 1900 cm^{-1}, and this fact indicates that cobalt hydrotetracarbonyl dissociates into H^+ and $Co(CO)_4^-$. The reaction course is suggested as follows:

$$HCo(CO)_4 + CH{\equiv}CH \rightarrow HCo(CO)_3(CH{\equiv}CH) + CO$$

$$HCo(CO)_3(CH{\equiv}CH) + HCo(CO)_4 \rightarrow CH{\equiv}CHCo_2(CO)_6 + H_2 + CO$$

On the other hand, the reaction of sodium cobalt tetracarbonyl with acetylene has not given $CH{\equiv}CHCo_2(CO)_6$. This seems to be caused by the stability of $NaCo(CO)_4$ in a methanol solution. It is very interesting that all the complexes obtained from the reaction in methanol have the Co–Co covalent bond.

Decomposition Reaction of Acetylene Dicobalt Hexacarbonyl. Wender and his colleagues have reported that acetylene dicobalt hexacarbonyl catalyzes the polymerization of acetylene.[3] In order to investigate the role of $C_2H_2Co_2(CO)_6$ in acrylic ester formation, the decomposition reaction of this complex was carried out in the presence of ethanol and carbon monoxide.

Table 2. Products of decomposition reaction of $CH{\equiv}CHCo_2(CO)_6$

Complex (mM)	Temp. (°C)	CO (kg/cm^2)	Time (min)	Ethyl acrylate (%)	Ethyl propionate (%)	Diethyl succinate (%)
2.4	100	101	30	45	5	29
2.6	90	90	300	45	2	49
10.0	100	100	30	34	15	46
1.9	110	110	30	60	2	35
2.0	100	—	10	12	1	—
2.0	100	—	30	6	2	—
2.0	100	—	60	6	5	—
2.0	150	—	30	0	15	—

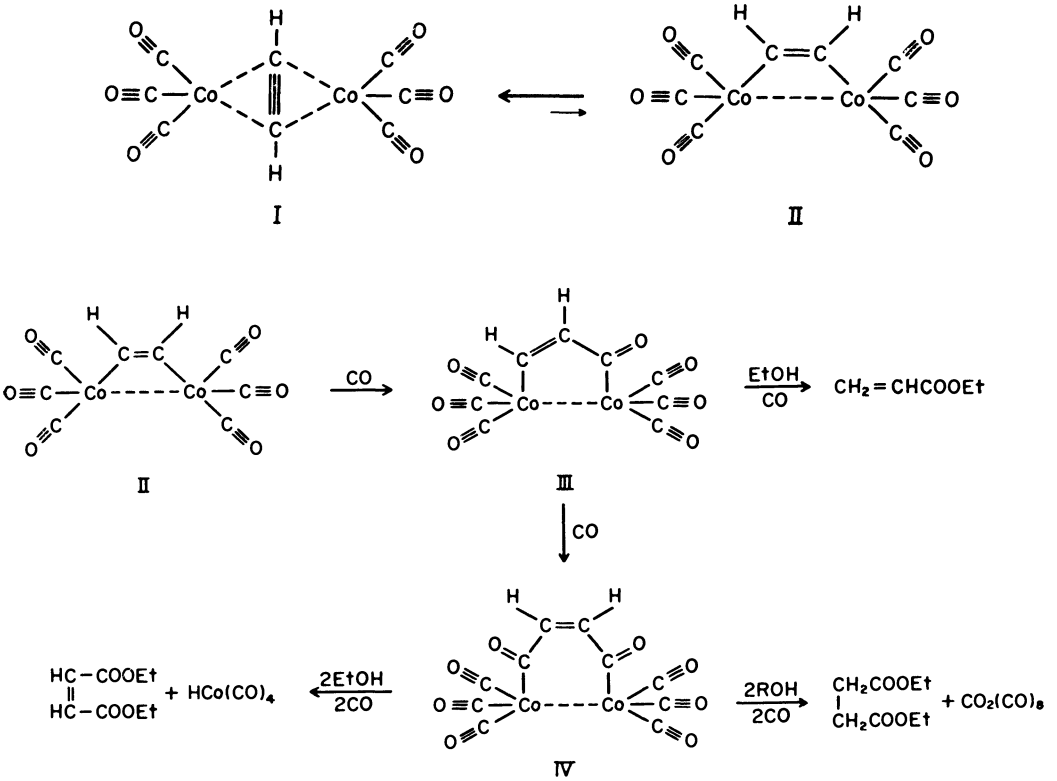
The reaction products were ethyl acrylate, ethyl propionate and diethyl succinate. In the absence of carbon monoxide the products were ethyl acrylate and ethyl propionate. The results are summarized in Table 2. The principal conclusions which emerge from a scrutiny of these data may be summarized as follows: (1) the presence of carbon monoxide increases the conversion ratio of $C_2H_2Co_2(CO)_6$ to ethyl acrylate, (2) diethyl succinate is not the secondary product from ethyl acrylate but is formed directly from $C_2H_2Co_2(CO)_6$, because the ratio of diethyl succinate to ethyl acrylate is almost constant during the course of reaction. (Table 2)

Reaction Course from Acetylene to Ethyl Acrylate. From the above-described experimental results and discussions, the following scheme can be suggested for the acrylate formation from acetylene under the pressure of carbon monoxide and hydrogen.

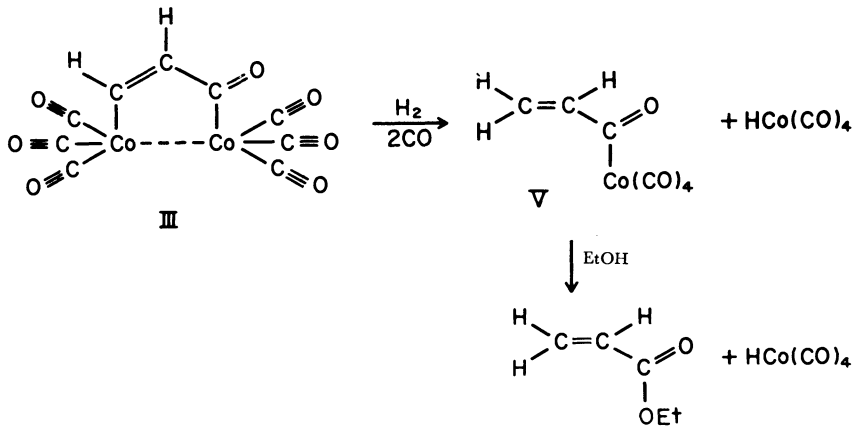
$$HC{\equiv}CH + 2HCo(CO)_4 \rightarrow HC{\equiv}CHCo_2(CO)_6 + H_2 + 2CO$$

$$HC{\equiv}CH + Co_2(CO)_8 \rightarrow HC{\equiv}CHCo_2(CO)_6 + 2CO$$

It has been suggested[7] that coordinated acetylene has C_{2v} symmetry and hybridization of this acetylene



7) Y. Iwashita, F. Tamura and A. Nakamura, *Inorg. Chem.*, **8**, 1179 (1969).



changes from *sp* to sp^2. The electrons in non-bonding orbital must occupy the two *cis*-positions of ethylene type structure. Therefore, the following isomerization may occur easily during the course of reaction. If the carbon monoxide or another Lewis base attacks isomer (II) the carbon monoxide can be inserted into the carbon-metal bond. This seems similar to the mechanism of butenolactone complex formation proposed by Heck.[8] The formation of other products (fumaric ester[1] and propanal) can be also explained on the basis of these assumed intermediates. Acetylene dicobalt hexacarbonyl has a considerable stability, and therefore, the rate determining step of acrylic ester formation from acetylene should be the transformation of this complex. The cobalt-carbon bond might be split by hydrogen as above. That the hydrogen can accelerate the rate of acrylate formation may be accounted for by these mechanisms.

Experimental

$HCo(CO)_4$ *n*-Hexane Solution. Thirteen grams of $Hg[Co(CO]_4]_2$ was dissolved into 200 m*l* of ether, and 200 g of Na-Hg was added to the solution. The ether solution was condensed after the color of $Hg[Co(CO)_4]_2$ had disappeared. $NaCo(CO)_4$ was obtained as white crystals. Five milliliters of concentrated hydrochloric acid was added to the aqueous $NaCo(CO)_4$ solution, and $HCo(CO)_4$ was extracted by *n*-hexane.

$HCo(CO)_4$ Methanol Solution. $HCo(CO)_4$ was generated from $Co(DMF)_6[Co(CO)_4]_2$ and concentrated HCl, and was absorbed by methanol.

Reaction of Acetylene with $HCo(CO)_4$. Acetylene purified by pyrogallol solution and dried by concentrated H_2SO_4, was admitted into $HCo(CO)_4$ solutions of methanol and *n*-hexane for 3 hr, and 10 g of $P(C_6H_5)_3$ was then added. The reaction mixture was condensed to dryness and extracted by ether. The ether layer was chromatographed on alumina. The main component of the ether soluble products was $C_2H_2Co_2(CO)_5P(C_6H_5)_3$ (yield about 45%). The yields of $C_2H_2Co_2(CO)_4[P(C_6H_5)_3]_2$ and $C_2H_2Co_4(CO)_8[P(C_6H_5)_3]_2$ were 5% and 3%, respectively (25°C, *n*-hexane solution). From ether-insoluble filtrate, $Co_2(CO)_6[P(C_6H_5)_3]_2$ and $[Co(CO)_3(P(C_6H_5)_3)_2]^+[Co(CO)_4]^-$ were obtained, but complete separation of these two species failed because of their sparing solubility in any solvent. (Yields of these two compounds were about 15%.)

Decomposition Reaction of $C_2H_2Co_2(CO)_6$ in Ethanol. $C_2H_2Co_2(CO)_6$ was thermally decomposed in ethanol under the pressure of CO in an autoclave. The reaction mixture was filtered and the filtrate was examined by gas chromatography (column PEG 400 with glycerine).

The authors wish to thank Dr. Asao Nakamura and Dr. Ryoji Iwanaga for their discussion and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1524—1529 (1970)

Synthetic Studies of the Flavone Derivatives. XVII.*[1] Synthesis of 5,7-Dihydroxy-6-methoxyflavone Derivatives[2]*

Kenji FUKUI and Mitsuru NAKAYAMA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

and Tokunaru HORIE

Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima

(Received October 28, 1969)

2,4-Dibenzyloxy-6-hydroxy-3-methoxyacetophenone was esterified with 3,4-disubstituted benzoyl chlorides, and the resulting esters were converted into 7-benzyloxy-5-hydroxy-6-methoxyflavone derivatives *via* the corresponding diketones. The catalytic hydrogenolysis of the benzyloxyflavones gave the desired 5,7-dihydroxy-6-methoxyflavones. Ethyl ethers of these flavones were also prepared from 2,4-diethoxy-3-methoxy-6-hydroxyacetophenone by an unambiguous method. 6,3′-Dimethoxy-5,7,4′-trihydroxyflavone, desmethoxycentaureidin (6,4′-dimethoxy-5,7,3′-trihydroxyflavone), and 6-methoxyluteolin (6-methoxy-5,7,3′,4′-tetrahydroxyflavone) were thus prepared.

Recently 6,3′-dimethoxy-5,7,4′-trihydroxyflavone (Ia) has been isolated from *Digitalis lanata* L.,[1] *Helichrysum visocum* var. *bracteatum* DC.,[2] and *Helenium alternifolium* (Spreng) Cabrera,[3] desmethoxycentaureidin (6.4′-dimethoxy-5,7,3′-trihydroxyflavone) (Ib) has been isolated from *Centaurea nigrescens* Willd,[4] and 6-methoxyluteolin[5] (nepetin[6]) (6-methoxy-5,7,3′,4′-tetrahydroxyflavone*[3]) (Ic) has been isolated from *Rosmarinus officinalis* L.[5] and *Nepeta hindostana*.[6]

This paper will report on the syntheses of these 5,7-dihydroxy-6-methoxyflavone derivatives (Ia-c) and will attempt to confirm the structure.

2,4-Dibenzyloxy-6-hydroxy-3-methoxyacetophenone (II)[7] was prepared from 3-methoxy-2,4,6-trihydroxyacetophenone[8] by partial benzylation, it was then esterified with 3,4-disubstituted benzoyl chlorides, such as 4-benzyloxy-3-disubstituted benzyloxy-4-methoxy-(b), and 3,4-dibenzyloxy-(c)-chloride, in the presence of anhydrous pyridine. The resulting esters were converted into ω-(3,4-disubstituted benzoyl)-2,4-dibenzyloxy-6-hydroxy-3-methoxyacetophenones (IIIa-c) by Baker-Venkataraman transformation.[9] The cyclodehydration of the acetophenones (IIIa-c) with anhydrous sodium acetate in acetic acid afforded flavones (IVa-c). The UV spectra of the flavones (IVa-c) showed the bathochromic shift of Bands I and II in the presence of aluminum chloride (Table 3). The NMR spectra*[4] of IIIa-c indicated the presence of a chelated phenolic group. The spectra exhibit, further, reasonable signals of the aromatic-, benzyloxy-, and methoxy-protons (Table 1).

These facts indicate that IVa-c were obtained from IIIa-c by the cyclodehydration with anhydrous

sodium acetate and by the subsequent partial debenzylation. The flavones, IVa-c, can thus be formulated as 7-benzyloxy-5-hydroxy-6-methoxyflavone derivatives. The catalytic hydrogenolysis of IVa-c over palladium charcoal gave the desired flavones (Ia-c), which were then converted into the corresponding acetates (Va-c) by the conventional method. The hydroxyflavones (Ia, b) gave the corresponding ethyl ether derivatives (VIa, b) upon complete ethylation with diethyl sulfate and anhydrous potassium carbonate.

In order to establish the structure of the hydroxyflavones (Ia-c), the ethyl ether derivatives (VIb, c) were prepared by the following unambiguous method. The esterification of 2,4-diethoxy-6-hydroxy-3-methoxyacetophenone (VII)[10] with 3-ethoxy-4-methoxy- or 3,4-diethoxy-benzoyl chloride yielded 6-(3-ethoxy-4-methoxybenzoyloxy)- (VIIIb) or 6-(3,4-diethoxy benzoyloxy)- (VIIIc) -2,4-di-

10) L. Farkas, L. Hörhammer, H. Wagner, H. Rösler and R. Gurniak, *Chem. Ber.*, **97**, 610 (1964).

ethoxy-5-methoxyacetophenone. The esters (VIIIb and VIIIc) gave 6,4′-dimethoxy-5,7,3′-triethoxy-(VIb) and 6-methoxy-5,7,3′,4′-tetraethoxy-(VIc)-flavone *via* the corresponding diketones (IXb and IXc) by a method similar to that described above. These flavones (VIa, b) were identified by direct comparisons with the ethyl derivatives obtained by the ethylation of the hydroxy-flavones (Ia, b).*5 Furthermore, the partial ethylation of the hydroxy-flavones (Ib, c) gave the 5-hydroxyflavone derivatives (Xb, c), which were then easily converted into monoacetates. Xb, c were also prepared from VIb, c by partial deethylation with anhydrous aluminum chloride. The hydroxyflavones (Ia-c) were now established to be 5,7-dihydroxy-6-methoxy-flavone derivatives.

Ia and Va were shown to be identical with the natural pigment and its acetate*6 by a mixed-melting-point determination and by NMR, IR and UV spectral comparisons.*7

On the other hand, the natural desmethoxycentaureidin and 6-methoxyluteolin were, unfortunately, could not be compared directly, but the properties of the synthetic samples of Ib and Ic were superimposable upon those recorded in the literature.[4-6]

Experimental*8

ω-(4-Benzyloxy-3-methoxybenzoyl)-(IIIa), ω-(3-benzyloxy-4-methoxybenzoyl)- (IIIb), and ω-(3,4-dibenzyloxybenzoyl) - (IIIc) - 2,4 - dibenzyloxy-6-hydroxy-3-methoxyacetophenone. A mixture of the crude dibenzyloxyacetophenone (II)[7] (2—2.5 g) and 3,4-disubstituted benzoyl chloride (2.5—3.0 g) in anhydrous pyridine (8.0 m*l*) was heated at 120°C for 2 hr. The cooled reaction mixture was poured into diluted hydrochloric acid, and then extracted with ether (the insoluble material was filtered off). The ether layer was washed with a sodium carbonate solution and water. The removal of the solvent gave a semi-solid, which was then dried in a desiccator.

A mixture of the crude ester, freshly-powdered potassium hydroxide (2.5 g), and pyridine (15—20 m*l*) was heated at 60°C for 4 hr with stirring. The reaction mixture was acidified with diluted hydrochloric acid, and then extracted with ether. The ether layer was washed with a sodium carbonate solution. The solvent was evaporated to 2—5 m*l* and then allowed to stand overnight. The separated crystals were collected and recrystallized to give III (Table 2), which gave a green color with ferric chloride in ethanol.

7,4′-Dibenzyloxy-6,3′-dimethoxy- (IVa), 7,3′-dibenzyloxy-6,4′-dimethoxy- (IVb) and 7,3′,4-tribenzyloxy-6-methoxy- (IVc)-5-hydroxyflavone. A mixture of III (500—700 mg) and anhydrous sodium acetate (2—4 g) in acetic acid (20—40 m*l*) was heated at 140°C for 4—5 hr. The reaction mixture was then diluted with water and extracted with ether. The ether layer was washed with a sodium carbonate solution and then allowed to stand overnight in a refrigerator. The combined precipitates were crystallized to give IV (Table 3), which gave a dark brown or dark greenish brown color with ferric chloride in ethanol and a red color with magnesium and hydrochloric acid.

6,3′-Dimethoxy-5,7,4′-tribenzyloxyflavone (5-O-Benzylether of IVa). A mixture of IVa (30 mg), benzyl chloride (0.1 m*l*), and anhydrous potassium carbonate (300 mg) in dimethylformamide (1.0 m*l*) was gently refluxed for 2 hr. The cooled reaction mixture was diluted with water and then extracted with ether. The ether layer was washed with diluted hydrochloric acid and water, and then subjected to evaporation under a vacuum. The oily residue was triturated with hexane and then treated with ether at 20—30°C. The separated crystals were recrystallized from methanol to give tribenzyloxyflavone as colorless needles; mp 127°C (115—116°C sinter); yield, 25 mg (71%). IR: 1638 cm^{-1} ($CHCl_3$). UV: λ_{max} mμ (log ε); 240_{sh}*9 (4.40), 264 (4.20), 330 (4.47).

Found: C, 76.05; H, 5.30%. Calcd for $C_{38}H_{32}O_7$: C, 75.98; H, 5.37%.

6,3′-Dimethoxy-5,7,4′-trihydroxyflavone (Ia), 6,4′-dimethoxy-5,7,3′-trihydroxyflavone (desmethoxycentaureidin) (Ib) and 6-methoxy-5,7,3′,4′-tetrahydroxyflavone (6-methoxyluteolin) (Ic). A solution of IV (350—400 mg) dissolved in a mixture of methanol and ethyl acetate (1:2: 80—100 m*l*) was shaken with palladium charcoal (10%: 200 mg) in an atmosphere of hydrogen for 3—4 hr. After the catalyst had been filtered, the filtrate was evaporated and the residue was recrystallized to give I (Table 4), which gave a dark brown or dark greenish brown color with ferric chloride in ethanol.

Ia was identified with a natural pigment*6 by a mixed-melting-point determination and by IR and UV spectral comparisons.

Acetates (Va–c) of I were synthesized by a hot acetic anhydride-pyridine method (Table 5). The NMR spectra of V were assigned as is shown in Table 6.

Va was found to be identical with the triacetate of the natural pigment by a mixed-melting-point determination and by NMR, IR, and UV spectral comparisons.

6-(3-Ethoxy-4-methoxybenzoyloxy)-(VIIIb) and 6-(3,4 - diethoxybenzoyloxy) - (VIIIc) - 2,4 - diethoxy-3-methoxyacetophenone. A mixture of VII[10] (2.0 g) and 3-ethoxy-4-methoxybenzoyl chloride (2.0 g) (or 3,4-diethoxybenzoyl chloride (2.1 g)) in anhydrous pyridine (5.0 g) was heated at 120°C for 2 hr. The reaction mixture was then treated by the usual method, and the crude product was recrystallized (Table 7).

ω-(3-Ethoxy-4-methoxybenzoyl)- (IXb) and ω-(3,4-diethoxybenzoyl)- (IXc)-2,4-diethoxy-6-hydroxy-3-methoxy-acetophenone. A mixture of VIII (1.5 g) and freshly-powdered potassium hydroxide (3.0 g) in anhydrous pyridine (15 g) was heated at 60°C for 4 hr with stirring. The reaction mixture was then treated by the method described in the case of III, and the crude

*5 The synthesis of VIa was previously reported by the present authors (T. Horie, M. Masumura, K. Fukui and M. Nakayama, This Bulletin, **41**, 1460 (1968)).

*6 The natural pigment was kindly supplied by Professor W. B. Whalley, University of London.

*7 Recently, Ia has also been synthesized from 3-methoxy-2,4,6-trihydroxyacetophenone by Drs. K. Y. Sim and R. Mukherjee (private communications).

*8 All the melting points are uncorrected; the UV spectra were measured in ethanol.

*9 sh=shoulder.

product was recrystallized (Table 7).

5,7-Diethoxy-6-methoxyflavone Derivatives (VIa–c).

a) From I. A mixture of I (20—30 mg), diethyl sulfate (0.2—0.3 m*l*), and anhydrous potassium carbonate (0.5—1.0 g) in anhydrous acetone (15—20 m*l*) was refluxed for 20—24 hr and then treated with aqueous methanol (10%: 15 m*l*). The solvent was distilled off. The resulting precipitate was collected and recrystallized to give VIa, b (Table 8).

b) From IX. Concentrated sulfuric acid (0.7 m*l*) was added to a solution of IX (700 mg) in acetic acid (7.0 m*l*) after which the mixture was heated at 70°C for 3 min. The reaction mixture was treated with hot water (30 m*l*), and then the separated precipitate was collected and washed with water. The recrystallization of the precipitate afforded VI, which was undepressed in melting point on admixture with the sample of a).

7-Ethoxy-5-hydroxy-6-methoxyflavone Derivatives (X).

a) From I. A mixture of I (30 mg), diethyl sulfate (0.2 m*l*), and anhydrous potassium carbonate (0.4 g) in acetone was refluxed for 6 hr and then treated by the method described in the case of VI. The crude product was recrystallized to give Xb, c (Table 8).

b) From VI. To a solution of VI (500 mg) in anhydrous nitrobenzene (6.0 g), a solution of anhydrous aluminum chloride (5.0 g) in absolute ether (15 m*l*) was added, and the mixture was heated at 47°C for 5 hr. After the mixture had been poured into 1% hydrochloric acid (250 m*l*), the solution was concentrated to 100 m*l* in a vacuum. The resulting precipitate was collected, washed with water, and recrystallized to give Xb, c; the melting point was undepressed on admixture with the sample of a).

Acetate of X. The acetate was prepared by a hot acetic anhydride-pyridine method (Table 8).

The authors are grateful to Professor W. B. Whalley, University of London, for supplying the 6,3′-dimethoxy-5,7,4′-trihydroxyflavone.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1530—1534 (1970)

Deamination of Methylenecyclopropylcarbinylamine. The Formation of a Vinyl Cation by Carbon–Carbon Bond Cleavage[1)]

Akio NISHIMURA and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

and Hiroshi KATO[2)]

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto

(Received October, 28, 1969)

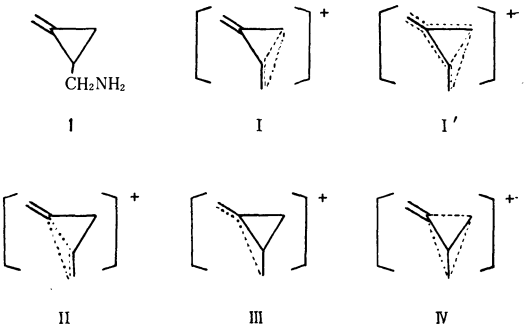
The deamination of methylenecyclopropylcarbinylamine, prepared from ethyl methylenecyclopropanecarboxylate *via* the corresponding amide, gave acetylcyclopropane, methylenecyclopropylcarbinol, and 3-methylenecyclobutanol. On the basis of these results and the deuterium distribution of the deamination products of methylenecyclopropylcarbinylamine-α,α-d_2, the homoallylic (III) and cyclopropylvinyl (VIII) cations are proposed as intermediates.

The deamination reactions of cyclopropylcarbinylamine derivatives have been very scrupulously investigated in connection with the problem of the structure of the intermediate cation.[3)] The deamination reaction of methylenecyclopropylcarbinylamine (**1**), which we wish to report on here, merits even further investigation because the introduction of an *exo*-methylene group leads to some stereochemical features which are absent in the heretofore-investigated cyclopropylcarbinyl systems.

Two bicyclobutonium intermediates, I and II, are possible for this ring system; of them, I may be further stabilized by two allylic resonances with the *exo*-methylene group (I′), though the stabilization by such an interaction would be decreased by an unfavorable configuration of the *exo*-methylene group and the cationic center at the transition state. On the other hand, the formation of II requires the loosening of a relatively strong sp^2–sp^3 carbon bond and it involves a contribution from a vinyl cation, which is generally considered to be formed only with difficulty.

Another possible intermediate, II, which is a homoallylic-type intermediate, may exist. Although stabilization by homoallylic resonance has been calculated to be less than that by bicyclobutonium resonance,[4)] in the particular case of III the scale model indicates that the cationic center is ideally situated for an effective (p-π type) interaction with the *exo*-methylene π-electrons.

A tricyclobutonium intermediate, IV, may also be considered although the possibility of the intermediacy of such a species has been eliminated in the case of the cyclopropylcarbinyl cation.[5,6)]



Results and Discussion

Methylenecyclopropylcarbinylamine (**1**) was prepared as is shown in Scheme 1. Ethyl methylenecyclopropanecarboxylate (**2**)[7)] was converted to methylenecyclopropanecarboxamide (**3**) by ammonolysis, or through the steps of the hydrolysis of

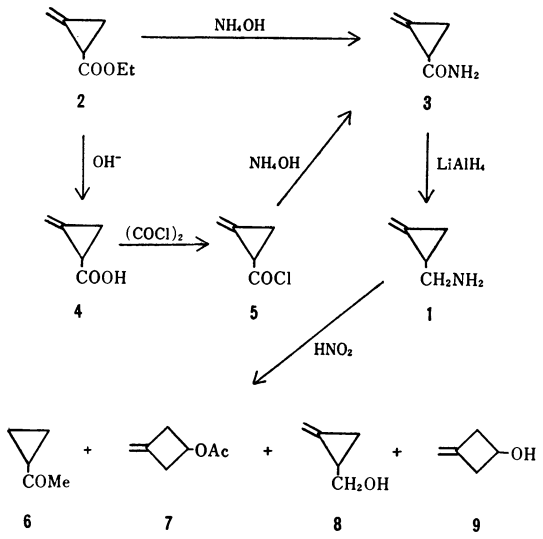
2 to the acid **4**, the conversion to acid chloride, **5**, with oxalyl chloride, and the treatment of **5** with ammonia. The amide, **3**, was converted to methylenecyclopropylcarbinylamine (**1**) by treatment with lithium aluminum hydride.



Scheme 1. Preparation and deamination of methylenecyclopropylcarbinylamine.

The deamination of **1** with nitrous acid in aqueous acetic acid gave four major products[8] (**A**—**D**) in a vpc-area ratio of 1.0 : 2.3 : 1.9 : 12.7 ; these products were separated by vpc and were identified as acetylcyclopropane (**6**), 3-methylenecyclobutyl acetate (**7**), methylenecyclopropylcarbinol (**8**), and 3-methylenecyclobutanol (**9**) respectively on the basis of the facts to be presented below.

The presence of an acetyl group in the component **A** could be detected by means of an NMR signal at τ 7.85 together with an infrared band at 1700 cm^{-1}, while a multiplet NMR signal at τ 9.0—9.4 was indicative of the presence of a cyclopropane ring. Its mass spectrum established its molecular weight and the presence of an acetyl group by peaks at *m/e* 84 and 43 (base peak). Its structure was confirmed to be **6** by a comparison of its spectral data and vpc retention times with those of authentic acetylcyclopropane.[9]

The infrared spectra of the component **C** suggested the presence of a hydroxyl group and of a terminal methylene group by bands at 3350, 3070, and 890 cm^{-1}. Its NMR spectrum displayed a broad two-proton singlet at τ 4.70 and a one-proton singlet at τ 7.09, supporting the idea of the presence of a terminal methylene group and of a hydroxyl group ; a two-proton doublet at τ 6.65 suggestive of a methylene group adjacent to the hydroxyl group, and a three-proton multiplet at τ 8.10—9.35 indicative of the presence of a cyclopropyl group. It was proved identical with methylenecyclopropylcarbinol, (**8**), prepared by the lithium aluminum hydride reduction of **2**.[7a]

The infrared spectrum of the component **D** showed absorption bands at 3320 and 1100 and at 3070, 1670, and 880 cm^{-1}, suggesting the presence of a secondary hydroxyl group and a terminal methylene group respectively. Its NMR spectrum indicated a terminal methylene proton by a two-proton quintet (J=2 Hz) at τ 5.23, a methine proton by a one-proton quintet (J=7 Hz) at τ 5.75, and a four-proton multiplet at τ 6.85—7.75. These spectral data are in accord with those of 3-methylenecyclobutanol (**9**).[10]

The NMR spectrum of the component **B** was similar to that of **9** except that the hydroxyl proton signal of **9** was replaced by a new three-proton singlet at τ 8.15,[11] and its infrared spectrum showed the bands of a terminal methylene group (3080, 1680 and 882 cm^{-1}) and bands at 1740 and 1240 cm^{-1} assignable to an ester group. These spectral data are consistent with 3-methylenecyclobutyl acetate (**7**) structure for the component **B**. This assignment was further corroborated by the fact that the acetylation of **9** gave **7**, and by the fact that the lithium aluminum hydride reduction converted **7** to **9**, as judged by their vpc retention times.

One of the components present in a minor proportion had, on a vpc column, a retention time identical with that of the acetylation product of methylenecyclopropylcarbinol, but it could neither be isolated nor further characterized.

The deamination, in aqueous acetic acid, of methylenecyclopropylcarbinylamine-α,α-d_2 (**1**-$\mathbf{d_2}$), itself prepared by the lithium aluminum deuteride reduction of **3**, gave α,α-dideuteriomethylenecyclopropylcarbinol and 2,2-dideuterio-3-methylenecyclobutanol (and its acetate). The quantity of deuterated acetylcyclopropane isolated in this experiment was too small to permit the determination of the position(s) of deuteration.

Among the reaction products, 3-methylenecyclobutanol (**9**) and acetylcyclopropane (**6**) deserve special consideration.

The bicyclobutonium intermediate I appears to be favored because of a possible stabilization of the cation I by allylic resonance (I′). Such an allylic resonance, however, should not be considered an efficacious one because the *exo*-methylene group cannot interact effectively with the cationic center at the transition state because of their unfavorable

8) These four components constituted 87% of the total products in the peak area, and most of other minor products had shorter retention times than those of **A**—**D**.

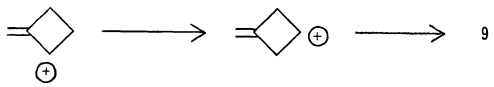
11) Other NMR signals (τ): 5.12—5.50 (3 H, m; $=CH_2$+H-C-O), 6.8—7.5 (4 H, m; ring protons).

configurations. Moreover, neither 2-methylenecyclobutanol nor 2-methylene-3-buten-1-ol was found to be formed in a detectable quantity, as would be the case with a reaction product arising from the intermediate I. Appelquist,[10,12] on the basis of the results of the deamination of spiropentylamine, suggested the rearrangement of the 2-methylenecyclobutyl cation (V) to the 3-methylenecyclobutyl cation (VI) by a hydride migration. The possibility of the formation of **9** in the present experiment by this mechanism can, however, be eliminated since, if **1** first formed the cation V and it was then rearranged to VI, then the alcohol, **9**, formed should be deuterated equally on the 1- and 2-positions. The 3-methylenecyclobutanol isolated from the present experiment, however, had all the deuterium atoms solely on the 2-position.



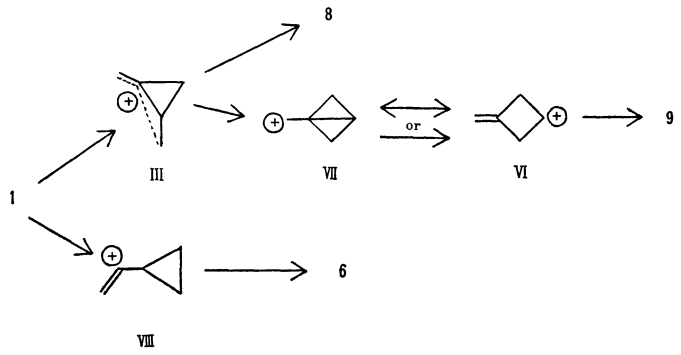
V VI

An alternative bicyclobutonium ion II[6] can structurally account for the formation of both methylenecyclopropylcarbinol (**8**) and 3-methylenecyclobutanol (**9**). However, methylenecyclopropylcarbinol was deuterated only on the α-methylene group. This means that the bicyclobutonium ion II is not in equilibrium with another bicyclobutonium ion of an identical structure. The presence of such an equilibirum has been established with the bicyclobutonium ion ;[5] thus, the intermediacy of II in this case is open to question.

Finally, the homoallylic intermediate, III, can be considered to be the precursor of the formation of both **8** and **9** if the isomerization of the intermediate III to VI is taken into account.

At present, it cannot be concluded whether or not the relief of strain in passing from the methylenecyclopropylcarbinyl to the 3-methylenecyclobutyl cation and the stabilization by conversion to a secondary cation is enough to compensate for the delocalization energy usually attainable by having a bicyclobutonium ion. Although it is generally accepted that a bicyclobutonium ion is, in general, capable of much more stabilization than a homoallyl cation, in the special case of III the conformation of III may favor the homoallylic cation by permitting an effective interaction of the cationic center with the *exo*-methylene π-electrons with a small entropy change, and/or the degree of stabilization of a bicyclobutonium ion may be lessened because of the extra strain imposed by the introduction of an *exo*-methylene group. In fact, the participation of the nitrogen atom to form an aza-bicyclobutonium ion, structurally analogous to III, in the solvolysis of both 1-*t*-butyl-3-azetidinyl- and 1-*t*-butyl-2-aziridinylcarbinyl derivatives has already been discussed.[13]

Considered in a classical way, the predominant formation of **9** rather than **8** may be considered to be a result of a vinyl group being a much better migrating group than a methyl group. Here, also, an intermediate similar to the homoallylic cation is considered to play an important role in creating this good migrating aptitude of a vinyl group.[14,15]



Scheme 2. Deamination pathway of methylenecyclopropylcarbinylamine.

12) This mechanism has been questioned: E. F. Kiefer and J. D. Roberts, *J. Amer. Chem. Soc.*, **84**, 784 (1962). See also: L. M. Konzelman and R. T. Conley, *J. Org. Chem.*, **33**, 3828 (1968).

13) V. R. Gaertner, *Tetrahedron Lett.*, **1968**, 5919; J. A. Deyrup and C. L. Moyer, *ibid.*, **1968**, 6179. An unpublished work of Martin and Anderson on the participation of sulfur atom in the solvolysis of 3-thietane derivative has been cited in these reports and in Ref. 10. These authors, however, also state that the ability of such a participation is poorer in the three-membered than in the four-membered ring, and absence of π-election participation in 3-methylene-cyclobutyl cation has been reported.[12]

14) W. Herz and G. Caple, *J. Org. Chem.*, **29**, 1691 (1964); R. S. Bly and R. T. Swindell, *ibid.*, **30**, 10 (1965), and references cited therein.

15) A completely different mode of ring cleavage has recently been reported with acid-catalyzed dehydration of phenyl-substituted methylenecyclopropylcarbinols. A. W. Herriott, E. P. Olavarria and W. M. Jones, *ibid.*, **33**, 3804 (1968).

The most unexpected result of the present work is the formation of acetylcyclopropane, albeit in a low yield. A tricyclobutonium intermediate, IV, may be considered to be an attractive candidate for the formation of **6**. The possibility of such a type of intermediate has, however, been denied with the cyclopropylcarbinyl system; also, the results of the labeling experiment with **1** is not in accord with this intermediate. The intermediate IV should give methylenecyclopropylcarbinol (**8**) with an equal deuterium distribution on the α-methylene and the cyclopropane ring.

Thus, the only remaining possible precursor for the formation of **6** is the cyclopropylvinyl cation (VIII). It is rather unexpected that a vinyl cation, which is generally believed to be obtainable only with difficulty, is formed even by the cleavage of a carbon-carbon bond, although there have recently been several examples of the formation of a vinyl cation intermediate by protonation and by π-electron migration.[16] The relief of strain in going from 1 to the cyclopropylvinyl cation, and the stabilization of the cationic center by the cyclopropane ring, probably accounts for this anomalous result.

To conclude, no adequate discussion is possible on the exact nature of the intermediate(s) or transition state(s) on the basis solely of the findings of a rather indiscriminate " hot cation " generated by deamination reaction. A solvolysis study of this and related systems would afford more fruitful information on this problem. Our preliminary attempt along this line, however, was unsuccessful because the reaction of methylenecyclopropylcarbinol with naphthalene-2-sulfonyl chloride gave a rearrangement product, 3-methylenecyclobutyl naphthalene-2-sulfonate.

Experimental[17]

Methylenecyclopropanecarboxylic Acid (4).[18] A solution of 5 g of ethyl methylenecyclopropanecarboxylate (**2**)[7] in 140 m*l* of methanol containing 4 g of potassium hydroxide was refluxed for one hour. The mixture was then diluted with 50 m*l* of water, acidified with hydrochloric acid, and extracted with ether. The extract was dried over magnesium sulfate and subsequently distilled to give 3.0 g (89% yield) of an acid, **4**, boiling at 101—103°C/17 mmHg; n_D^{25} 1.4660.

Methylenecyclopropanecarbonyl Chloride (5).[18] Oxalyl chloride (43 g) was added to 6.8 g of the acid, **4**, with external cooling, and then the resulting mixture was refluxed for two hours. Distillation gave 5.0 g (70% yield) of a liquid boiling at 42—43°C/19 mmHg; n_D^{25} 1.4695.

This substance, on treatment with methanol, was converted to methyl methylenecyclopropanecarboxylate.[19]

Methylenecyclopropanecarboxamide (3).

a). Into 10 m*l* of concentrated aqueous ammonia, 5 g of acid chloride **5** was added with stirring while the temperature was kept below 10°C. The mixture was concentrated under reduced pressure, and the residue was extracted with hot ethyl acetate. The extract, on cooling, afforded 2.4 g (62% yield) of **3** melting at 102.5—104°C. Its infrared spectrum was identical with, and its melting point was undepressed on admixture with, the specimen of **3** prepared by the procedure *b*.

b) A mixture of 14.2 g of the ester **2** and 50 m*l* of supersaturated aqueous ammonia was sealed in a pressure bottle and then allowed to stand for ten days. The residue which remained after the removal of the ammonia was recrystallized from benzene to give 7.8 g (71% yield) of **3** melting at 102—104°C.

Found: C, 62.16; H, 7.27; N, 14.16%. Calcd for C_5H_7NO: C, 61.84; H, 7.27; N, 14.42%.

Methylenecyclopropylcarbinylamine (1). To a stirred suspension of 4.5 g of lithium aluminum hydride in 120 m*l* of ether, 7.7 g of the amide **3** was added in portions, after which the resulting mixture was refluxed for eight hours. Aqueous sodium hydroxide (30%) was added to decompose the excess hydride, and the organic layer was decanted from the precipitate. The precipitate was washed with ether, and the combined extract was dried over magnesium sulfate and then distilled to give 2.8 g (42.5% yield) of a colorless liquid boiling at 105—115°C. Its purity was estimated to be *ca.* 90% by vpc (Carbo wax 20 M on Diasolid A). This crude product was used for the deamination study; the product composition was calibrated by the deamination of the vpc-purified sample of **1**. n_D^{25} 1.4725 (pure sample).

IR (cm^{-1}): 3360, 3295 (NH_2), 3065, 1745, 886 (=CH_2), 3040, 1019 (cyclopropane ring). NMR (τ): 4.90 (2H, m, =CH_2), 7.52 (2H, d, J=6 Hz; CH_2-N), 8.30—9.40 (3 H, m, ring protons), 9.02 (2 H, s, NH_2).

Phenyl isothiocyanate adduct: mp 70—71°C.

Found: C, 66.29; H, 6.68; N, 12.91%. Calcd for $C_{12}H_{14}N_2S$: C, 66.03; H, 6.47; N, 12.84%.

Methylenecyclopropylcarbinylamine-α,α-d_2 (1-d_2). This was prepared, by the method described above, from 3.0 g of the amide **3** and 2 g of lithium aluminum deuteride. A fraction distilling at 100—102°C was col-

16) M. Bertrand and M. Santelli, *Chem. Commun.*, **1968**, 718; D. S. Noyce and K. E. DeBruin, *J. Amer. Chem. Soc.*, **90**, 372 (1968); D. S. Noyce and M. D. Schiavelli, *ibid.*, **90**, 1020 (1968); M. Hanack, S. Bocher, K. Hummel and V. Vött, *Tetrahedron Lett.*, **1968**, 4613; M. Hanack and V. Vött, *ibid.*, **1968**, 4617; H. Fischer, K. Hummel, and M. Hanack, *ibid.*, **1969**, 2169; and references cited therein and in Ref. 1b.

17) All melting and boiling points are uncorrected, and the melting points were determined on a micro hot stage. The infrared spectra were recorded as neat liquid on a Hitachi model EPI-SII Spectrophotometer. The NMR spectra were determined using a JEOLCO C-60 (60 MHz) Spectrometer on solutions of carbon tetrachloride containing tetramethylsilane as internal standard, and the chemical shifts are reported by τ values. Mass spectra were taken on a Hitachi RMU-5 Spectrometer, and the vpc analyses were performed with a Shimadzu model GC-1B chromatograph.

18) For the preparation of **4** and **5**, *cf.* Ref. 7 b.

19) A. Nishimura, M. Ohta and H. Kato, This Bulletin, Manuscript under preparation. This compound was prepared by a base-catalyzed ester exchange of the corresponding ethyl ester **2**.

lected to give 1.0 g of **1-d_2**. The NMR peak at τ 7.52 of **1** completely vanished in this compound.

Deamination of the Amine 1. To a cooled and stirred solution of 2 g of **1** in 10 m*l* of 20% aqueous acetic acid, a solution of 3.6 g of sodium nitrite in 7 m*l* of water was added over a period of twenty minutes, after which the stirring was continued for seven hours. The mixture was then saturated with sodium chloride and extracted with ether. The extract was dried over sodium sulfate, and the ether was removed by fractional distillation. The residual oil was separated into four main components by vpc (Carbowax 20 M on Diasolid A). The product composition and pertinent spectral data, and the method used in identifying the products, have been described above.

Methylenecyclopropylcarbinol (8). To a stirred suspension of 3 g of lithium aluminum hydride in 100 m*l* of ether, 8.5 g of **2** was added slowly, and then the resulting mixture was stirred for three hours at room temperature. The mixture was decomposed by the addition of concentrated aqueous sodium hydroxide, the organic layer was separated, and the precipitate was washed with ether. The combined ether extract was dried over magnesium sulfate and subsequently distilled to give 3 g (45% yield) of a colorless liquid boiling at 142—146°C, n_D^{25} 1.4585.

Found: C, 71.06; H, 9.87%. Calcd for C_5H_8O: C, 71.39; H, 9.59%.

IR (cm^{-1}): 3340 (OH), 3070, 890 (=CH_2), 1015 (C–O). NMR (τ): 4.73 (2 H, m, =CH_2), 6.65 (2 H, d, J=7 Hz; -CH_2-O), 8.00 (1 H, s, -OH), 8.10—9.40 (3 H, m, ring protons).

p-Nitrobenzoate of **8:** mp 43.5—45°C.

Found: C, 61.57; H, 4.99; N, 6.29%. Calcd for $C_{12}H_{11}NO_4$: C, 61.80; H, 4.75; N, 6.01%.

Deamination of 1-d_2. The deuterated amine **1-d_2** (0.8 g) was treated with sodium nitrite by the method described above, and the products were separated by vpc.

The deuteriomethylenecyclopropylcarbinol obtained by this experiment showed no NMR peak at τ 6.6, and the NMR spectrum of deuteriomethylenecyclobutanol showed, among other signals, a two-proton triplet (J=2 Hz) at τ 5.28 and a two-proton multiplet centered at τ 7.3.

3-Methylenecyclobutyl Naphthalene-2-sulfonate. To a stirred solution of 1.0 g of **8** in 10 m*l* of 2,4,6-collidine, 3.0 g of 2-naphthalenesulfonyl chloride was added under cooling with an ice-salt bath; the mixture was kept at this temperature for two hours and then poured into 20 m*l* of 20% sulfuric acid containing ice. The resulting mixture was washed with aqueous sodium bicarbonate, dried over sodium sulfate, and concentrated under reduced pressure, and the residue was recrystallized from ether to give 1.0 g of crystals melting at 85—87°C.

Found: C, 65.86; H, 5.34%. Calcd for $C_{15}H_{14}O_3S$: C, 65.69; H, 5.15%.

NMR (τ; $CDCl_3$): 2.05 (1 H, m), 2.45—3.05 (6 H, m), 5.54 (1 H, t, J=6 Hz), 5.61 (2 H, pentuplet, J=2 Hz), 7.44 (4 H, d×t, J=6 and 2 Hz).

We are indebted to Miss Mizuko Yoshida for her measurement of the NMR spectra, to the microanalysis staff of this laboratory for the elemental analyses, and to Mr. Haruyoshi Sakurai for his measurement of the mass spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1535—1540 (1970)

Homolytic Chlorination of Aliphatic Compounds. IV.[1] Chlorination of Chloroalkanes by *t*-Butyl Hypochlorite

Masanori KOSUGI, Kohji TAKEUCHI and Toshihiko MIGITA

Department of Chemistry, Gunma University, Kiryu, Gunma

(Received November 7, 1969)

Chlorination of chloroalkanes by *t*-butyl hypochlorite was investigated by means of competitive experiment. Relative reactivities thus obtained were compared with those toward hydrogen abstraction by *t*-butoxy radicals derived from other sources. From the results it was concluded that a main chain carrier of this chlorination was a *t*-butoxy radical. Structure-reactivity relationships in *t*-butyl hypochlorite chlorination were also investigated. Linear free energy relationship was found to exist between the reactivities of methyl hydrogen of CH_3-X and Taft's σ^* constants for the substituent X, $\rho^* = -0.69$. α-Chlorine substituents were found always to enhance the rate of hydrogen abstraction of this position. Resonance effects of α-chlorine substituent is considered to be more important than in photochlorination with chlorine.

Chemistry of aliphatic chlorination by *t*-butyl hypochlorite has been extensively investigated by Walling and his co-workers.[2] They proposed a radical chain mechanism involving hydrogen abstraction by a *t*-butoxy radical, on the basis of the selectivity of the reaction being parallel to that of hydrogen abstraction by *t*-butoxy radicals derived from other sources.[3] Gilliom and Ward[4] reported ρ value (with σ) to be -0.75 for benzylic chlorination by *t*-butyl hypochlorite at 40°C. This value is quite different from that obtained by Sakurai and Hosomi[5] (with σ^+, -0.32 at 45°C) for benzylic hydrogen abstraction by *t*-butoxy radical derived from di-*t*-butyl peroxalate, and is rather similar to ρ value for chlorination by chlorine.[6] Thus it seems that benzylic chlorination by *t*-butyl hypochlorite involves a chlorine atom, rather than *t*-butoxy radical, as a chain carrier. Recently Walling and McGuiness[7] gave some evidence for the mechanism of benzylic chlorination by *t*-butyl hypochlorite.

We have been investigating substituent effects on the reactivities of aliphatic compound; toward a chlorine atom. A linear free energy relationship has been found to exist between the reactivity of CH_3-X and the σ^* value of X.[8] The study was extended to *t*-butyl hypochlorite chlorination. In this paper we wish to present an evidence which indicates that a main chain carrier of *t*-butyl hypochlorite chlorination of chloroalkanes is *t*-butoxy radical, in order to compare structure-reactivity relationship in this chlorination with that in photochlorination by chlorine.

Results and Discussion

t-Butoxy Radical as a Chain Carrier. Three possible chain carriers can be considered for the *t*-butyl hypochlorite chlorination.

scheme 1
$$t\text{-BuOCl} \xrightarrow{h\nu} t\text{-BuO}\cdot + \text{Cl}\cdot$$
$$t\text{-BuO}\cdot + \text{RH} \longrightarrow t\text{-BuOH} + \text{R}\cdot$$
$$\text{R}\cdot + t\text{-BuOCl} \longrightarrow \text{RCl} + t\text{-BuO}\cdot$$

scheme 2
$$t\text{-BuOCl} + \text{HCl} \rightleftharpoons \text{Cl}_2 + t\text{-BuOH}$$
$$\text{R}\cdot + \text{Cl}_2 \longrightarrow \text{RCl} + \text{Cl}\cdot$$
$$\text{Cl}\cdot + \text{RH} \longrightarrow \text{HCl} + \text{R}\cdot$$

scheme 3
$$t\text{-BuO}\cdot \longrightarrow \text{CH}_3\text{COCH}_3 + \text{CH}_3\cdot$$
$$\text{CH}_3\cdot + \text{RH} \longrightarrow \text{CH}_4 + \text{R}\cdot$$

Scheme 1 is a mechanism proposed originally by Walling,[2] which involves a *t*-butoxy radical as a chain carrier. In scheme 2, an actual chlorinating agent is chlorine molecule which is derived by a reversible reaction of *t*-butyl hypochlorite with hydrogen chloride formed through the subsequent chain steps involving a chlorine atom as a hydrogen abstracting species. The third possible chain carrier is a methyl radical which is formed by decomposition of *t*-butoxy radical (scheme 3). *t*-Butyl

5) H. Sakurai and A. Hosomi, *ibid.*, **89**, 458 (1967).

6) G. A. Russell and R. C. Williamson, *ibid.*, **86**, 2357 (1964).

7) C. Walling and J. A. McGuiness, *ibid.*, **91**, 2053 (1969).

8) T. Migita, M. Kosugi, Y. Tanaka and Y. Nagai, *Yuki Gosei Kagaku Kyokai Shi.*, **25**, 908 (1967).

hypochlorite reacted with chloroalkanes under irradiation by 500 W tungsten lamp, giving chlorinated products and *t*-butyl alcohol as main products. Relative amounts of these products are shown in Table 1. The results eliminate the possibility of scheme 3, since formation of *t*-butyl alcohol can not be expected from this mechanism.

Table 1. Ratio of chloride and *t*-butyl alcohol (40°)

(RH)	(RCl)/(*t*-BuOH)
CH_2ClCH_2Cl	1.05
$CHCl_3$	1.00
$(CH_3)_3CCl$	0.90
CH_2Cl_2	0.74
$(CH_3)_2CCl_2$	0.35

Table 1 shows that chlorination of 1,2-dichloroethane, chloroform gave the chlorinated product and *t*-butyl alcohol in equimolar amount. This is in agreement with the product pattern from the reaction schemes 1 and 2. However, less amounts of chlorinated products compared with *t*-butyl alcohol were formed from the chlorination of 2,2-dichloropropane and methylene chloride. In these cases, vapor-phase chromatographic analysis of the reaction mixtures showed the presence of considerable amounts of an additional common product, which was identified to be 1-chloro-2-methyl-2-propanol. Walling and Padwa[9] reported the formation of this compound in decomposition of *t*-butyl hypochlorite in carbon tetrachloride solution, and proposed the formation path way as follows:

$$t\text{-BuO}\cdot + Me_3COCl \longrightarrow t\text{-BuOH} + Me_2\overset{CH_2\cdot}{\overset{|}{C}}\text{-OCl}$$
$$\longrightarrow \quad \longrightarrow \quad Me_2\overset{OH}{\overset{|}{C}}\text{-}CH_2Cl$$

As will be seen later, while 1,2-dichloroethane and chloroform are relatively reactive substrates toward hydrogen abstraction by *t*-butoxy radical, 2,2-dichloropropane and methylene chloride are less reactive, so that *t*-butoxy radicals may abstract hydrogen atoms from *t*-butyl hypochlorite as well as from substrate molecules, forming *t*-butyl alcohol in a larger amount than chlorinated products.

In order to check the two possibilities of schemes 1 and 2, relative reactivities of several substrates towards the hypochlorite chlorination were compared with those towards hydrogen abstraction by *t*-butoxy radical derived from di-*t*-butyl peroxide.

Relative reactivities toward the chlorination were calculated from the relative yields of the chlorinated products from competitive reaction with binary mixtures of substrates. The relative reactivities towards *t*-butoxy radical formed by the photo-induced decomposition of di-*t*-butyl peroxide (high pressure mercury lamp) and *t*-butyl hypochlorite (tungsten lamp) were calculated from k_a/k_d derived from the relative yields of *t*-butyl alcohol and acetone formed by the following competition.[10]

$$t\text{-BuO}\cdot \begin{cases} \xrightarrow{k_d} CH_3COCH_3 + CH_3\cdot \longrightarrow CH_3Cl \\ \xrightarrow[k_a]{RH} t\text{-BuOH} + R\cdot \longrightarrow RCl \end{cases}$$

Relatively reactive chloroalkanes were chosen as substrates, in order to avoid the hydrogen abstraction from a *t*-butoxy radical sources, which would result in overestimation of the rates of hydrogen abstraction from substrate molecules. The results are shown in Table 2.

Apparently, relative reactivities obtained from competitive chlorination with *t*-butyl hypochlorite are very close to those from di-*t*-butyl peroxide and quite different from those for photochlorination by chlorine. We can conclude that *t*-butoxy radical is the most important chain carrier in *t*-butyl hypochlorite chlorination of chloroalkanes.

Relative Reactivities of Chloroalkanes. Relative reactivities of chloroalkanes toward *t*-butoxy radical were determined by competitive chlorination with *t*-butyl hypochlorite, and were formed as shown in Table 3.

As expected from the electron-seeking nature of *t*-butoxy radicals,[2] reaction rates are affected by the polar nature of the substituents in the substrates.

Table 2. Relative reactivities of chloroalkanes

Substrate	Reagents

	$-CH_2Cl$	74.2	0.78
	$-CHCl_2$	56.5	0.43

Logarithms of the relative reactivities for the methyl C–H bond are plotted against Taft's constants σ^* of the substituents in Fig. 1.

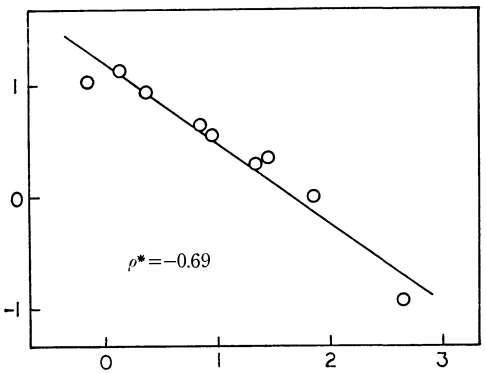

Fig. 1. Hammett plot for CH_3-*X*.

Good linear relationship was found to exist. The ρ^* value is −0.69, which is less negative than the value (−0.85) for chlorine atom reactions.[8] A similar trend of ρ values has been observed in the case of abstraction of benzylic hydrogen.[5,6] This indicates that *t*-butoxy radical is less electron-seeking than a chlorine atom.

Striking contrast to the chlorination with chlorine was observed in α-chlorine substituent effect. As was described previously,[11] a chlorine substituent will affect the reactivity of α-C–H bond in two ways. Its −I effect will deactivate the α-C–H bond. Contrarily the conjugative effect will accelerate the hydrogen abstraction from the C–H bond, since the stabilization of the incipient radical by the following resonance will diminish the dissociation energy of the C–H bond being reacted:

$$\dot{C}\text{-}\underline{\overline{Cl}}| \leftrightarrow \overset{(-)(+)}{\overline{C}\text{-}\dot{\underline{Cl}}}|$$

In photochlorination with chlorine, the following order of reactivities of C–H bonds were observed:

$H\text{-}CH_2CH_2Cl > H\text{-}CHClCH_2Cl > H\text{-}CCl_2CH_2Cl$

$H\text{-}CH_2CCl_3 > H\text{-}CHClCCl_3 < H\text{-}CCl_2CCl_3$

This indicates that the accelerating conjugative effect of α-chlorine substituent becomes more important than its inductive effect only when a strongly electron-withdrawing substituent like an trichloromethyl group is present in a substrate molecule.[11]

On the other hand, the present results for *t*-butyl hypochlorite chlorination show that an α-chlorine substituent always enhances the rate of hydrogen abstraction on this position. For example,

$H\text{-}CHClCH_2Cl < H\text{-}CCl_2CH_2Cl$

$H\text{-}CH_2CCl_3 < H\text{-}CHClCCl_3$

$H\text{-}CH_2CH_2CH_2Cl < H\text{-}CHClCH_2CH_2Cl$

This tendency indicates that electron-donating conjugative effect of a substituent is quite an important factor controlling the rate of hydrogen abstraction by a *t*-butoxy radical. It has been pointed out that concerning the radicals X which form the bond (X–H) of essentially equal bond energy, hydrogen abstraction from the side chains of toluenes by the less electron-seeking radical X· showed a less negative value of ρ and a greater isotope effect (k_H/k_D).[12] Thus compared with the reaction

* Relative to that of a C–H bond of the other substrate.

of a chlorine atom, hydrogen abstraction by the less electron-seeking *t*-butoxy radical would be influenced by a polar factor in a less extent (less ρ^* value), and by bond dissociation energy of substrate C–H in a greater extent. The tendencies are in agreement with this generalization.

Experimental

Materials. *t*-Butyl hypochlorite and di-*t*-butyl peroxide were prepared by the method of Teeter and Bell,[13]

13) H. M. Teeter and E. W. Bell, "Org. Syn"., Vol. 32, 20 (1952).

and Milas and Surgenor,[14] respectively. Dichloromethane, chloroform, 1,2-dichloroethane, 1,1,1-trichloroethane, 1,1,2-trichloroethane, 1,1,2,2-tetrachloroethane, pentachloroethane, neohexane, propylene chloride, 1,3-dichloropropane and 1,4-dichlorobutane were purified by fractionating commercial materials, and their purities were checked by means of v.p.c.

t-Butyl chloride, 2,2-dichloropropane and *n*-propyl chloride were prepared by the method previously described.[8,11] *n*-Butyl chloride and isopropyl chloride were prepared by a method analogous to the synthesis of *n*-propyl chloride.[15] 1,2-Dichloro-2-methylpropane was obtained by the chlorination of *t*-butyl chloride, bp 106°C[16] Among the authentic samples of chlorination products, 1,2,2-trichloropropane and 1-chloro-3,3-dimethylbutane have been identified previously.[8,11] 1,1,2-Trichloro-2-methylpropane and 1,2,3-trichloro-2-methylpropane were collected by v.p.c. from the reaction mixtures of chlorination of 1,2-dichloro-2-methylpropane by *t*-butyl hypochlorite, and identified on the basis of their NMR spectrum. (τ values).

$(CH_3^1)_2CClCH^2Cl_2$ 8.21 (H^1 singlet)
4.23 (H^2 singlet)

$CH_3^1CCl(CH_2^2Cl)_2$ 8.28 (H^1 singlet)
6.22 (H^2 singlet)

1,2,3-Trichloropropane was prepared by adding a chlorine to allyl chloride, bp 155—158°C.[17] 1,1-Dichlorobutane was prepared by treating *n*-butyraldehyde with phosphorus pentachloride, bp 114°C.[18] 1,1,4-Trichlorobutane was collected by v.p.c. from the chlorination mixture of 1,4-dichlorobutane and identified with its NMR spectrum (τ values).

CH^1Cl_2-CH_2^2-CH_2^3-CH_2^4Cl 4.17 (H^1 triplet)
7.3—8.2 (H^2, H^3 multiplet) 6.41 (H^4 triplet)

$(CH_3^1)_2COHCH_2^2Cl$ 8.74 (H^1 singlet)
6.56 (H^2 singlet)

1-Chloro-2-methyl-2-propanol was collected by v.p.c. from the reaction mixture of chlorination of 2,2-dichloropropane by *t*-butyl hypochlorite, and identified by comparing its NMR spectrum and v.p.c. retention time (X.F. 1105, P.E.G. 6000 and D.O.S. column) with that of an authentic sample (τ values).[19]

Determination of the Ratio of Chloride and *t*-Butyl Alcohol. A mixture of chloride and *t*-butyl hypochlorite (*ca.* 10: 1 molar ratios) was placed in a reaction tube. After the mixture was degassed in a dark place, the tube was sealed and immersed in a thermostat (40°C $\pm$0.1) and irradiated with 500 W tungsten lamp until the color of chlorine in the mixture disappeared. Analysis of the products was carried out by v.p.c. method employing 1.5 m column of P.E.G. 6000.

Determination of Relative Reactivities. Reactions were carried out in sealed, degassed tubes as described above. For the decomposition of di-*t*-butyl peroxide, pyrex tubes were used and irradiated for 24 hr with 300 W high pressure mercury lamp. Analysis of the acetone and the *t*-butyl alcohol was carried out by v.p.c. method employing 2.0 m column of D.O.P. Relative values of k_a/k_d were calculated by the amounts of acetone and *t*-butyl alcohol.[10] Average values of three runs are presented in Table 2.

Competitive reactions were carried out with mixtures of two chloroalkanes and *t*-butyl hypochlorite (*ca.* 10: 1 molar ratios). Relative reactivities were calculated by the ratio of the chlorination products and the substrates. Analysis of the chlorination products was carried out by v.p.c. Table 4 shows the results. From these values, reactivities of C–H bonds of chloroalkanes relative to that of 2,2-dichloropropane were calculated as shown in Table 3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1541—1544 (1970)

New Method for the Separation of Diastereomeric Mixtures of β-Methylnorleucine and β-Methylleucine

Kazuo Ōkubo and Yoshiharu Izumi

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received November 8, 1969)

β-Methylnorleucine and β-methylleucine were synthesized, separated into diastereomers and optically resolved. The configurational assignments of these isomers and the determinations of the optically active isomers were achieved by means of NMR spectroscopy and the enzymatic method respectively.

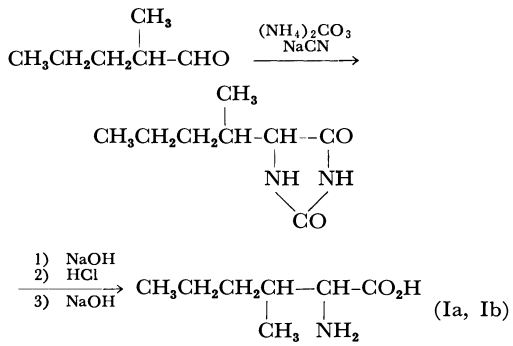
The present authors previously discovered the asymmetric hydrogenation catalyst, which is obtained by the modification of the Raney nickel catalyst with optically active α-amino or α-hydroxy acid, and found an experimental rule on the relation between the asymmetric activity of the catalyst and the structures of the modifying reagent.[1]

The syntheses, the separations in to diastereomers, and the optical resolutions of β-methylnorleucine and β-methylleucine were performed in order to study the effect of the β-asymmetric center of the α-amino acid on the asymmetric activity of the modified Raney nickel catalyst.

β-Methylnorleucine and β-methylleucine have β-asymmetric carbons in addition to α-asymmetric carbons and each has two diastereomers.

β-Methylnorleucine and β-methylleucine are not naturally occurring amino acids. For β-methylnorleucine, no descriptions of the synthesis, the diastereomers, or the optically active isomers have yet been published.

β-Methylleucine has been synthesized as the intermediate of the *N*,β-dimethylleucine, which is a component of antibiotic Ethamycin, and its four optically active isomers have been obtained by Kotake *et al.* and one of the present authors.[2]



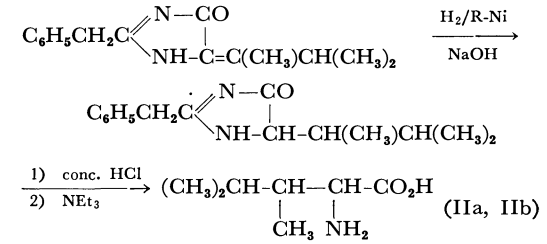
Scheme 1

In the present work, β-methylnorleucine was synthesized starting from α-methylvaleraldehyde by the general method developed by Bucherer and Steiner; it is described in Scheme 1.

The fine crystalline hydantoin derivative, obtained from the reaction of α-methylvaleraldehyde, ammonium carbonate, and sodium cyanide, was hydrolyzed with alkali in the autoclave; subsequent acidification with concentrated hydrochloric acid afforded an excellent yield of β-methylnorleucine hydrochloride.

β-Methylleucine was synthesized by a modification of the procedure developed by Kotake *et al.* The modification was based on catalytic hydrogenation with a Raney nickel catalyst of the α-methylisobutylidene derivative of the 2-benzyl-4-(5*H*)-imidazolone in a sodium hydroxide solution and successive treatment with concentrated hydrochloric acid.

By this method, β-methylleucine, which is a mixture of threo and erythro isomers in the molar ratio of 2 : 1, was directly obtained in a 87% yield (based on the α-methylisobutylidene derivative). (Scheme 2)



Scheme 2

Diastereomeric mixtures of β-methylnorleucine and β-methylleucine were crystallized from the concentrated hydrochloric acid, and the threo isomers (Ia and IIa) were obtained as the less soluble hydrochloride salts.

1) Part XII of the series: Y. Izumi, S. Tatsumi and M. Imaida, This Bulletin, **42**, 2373 (1969).

2) H. Kotake, T. Saito and K. Ōkubo, *ibid.*, **42**, 1367 (1969).

The erythro isomers (Ib and IIb) of these amino acids were purified as the less soluble copper salts in a hot 1% aqueous solution of cupric sulfate.

The extraction of the copper salt of the threo isomer with a hot 1% aqueous solution of cupric sulfate is a new, quite convenient method for the purification of the erythro isomers of these amino acids.

The relative configurational assignments of these amino acids were performed by the acylase resolution and the NMR spectroscopy. The stereochemically pure racemates, Ia, Ib, IIa, and IIb, were each *N*-acetylated and then resolved with acylase by the ordinary method to afford L-amino acids.

Recently Ōtsuka *et al.* introduced the use of NMR spectroscopy to elucidate the relative configurations at the α- aud β-carbon atoms of *N*,β-dimethylleucine diastereomers, which have $\rangle\underset{\alpha}{CH}-\underset{\beta}{CH}\langle$ structures, compared with the similar known compounds, the *N*-methylisoleucine diastereomers.[3] They proved that the threo form has a smaller coupling constant, $J_{\alpha,\beta}$.

Since the Karplud equation could be applied to β-methylnorleucine, (Ia and Ib) and β-methylleucine (IIa and IIb), although these amino acids were not *N*-methylated, we extended that theory, in the present work, to these amino acids. The observed coupling constants obtained from the doublet signals of the α-protons of the L-isoleucine, L-alloisoleucine, β-methyl-L-norleucine (Ia-L), β-methyl-L-norleucine (Ib-L), β-methyl-L-leucine (IIa-L), and β-methyl-L-leucine (IIb-L) are shown in Table 1.

Table 1. $J_{\alpha,\beta}$ Values obtained from the doublet signal of the α-proton

	$J_{\alpha,\beta}$ (Hz)
L-Alloisoleucine (*threo*)	3.6±0.1
L-Isoleucine (*erythro*)	4.1±0.1
β-Methyl-L-norleucine (Ia-L)	3.5±0.1
β-Methyl-L-norleucine (Ib-L)	4.0±0.1
β-Methyl-L-leucine (IIa-L)	3.5±0.1
β-Methyl-L-leucine (IIb-L)	5.2±0.1

As could be expected, L-alloisoleucine (*threo*) has a smaller coupling constant, $J_{\alpha,\beta}$, than L-isoleucine (*erythro*). For β-methylnorleucine and β-methylleucine, Ia and IIa have smaller coupling constants than Ib andIIb. From these results, Ia and IIa are said to be of the threo form, and Ib and IIb of the erythro form.

Additionally, this result coincides with the experimental rule that, in the asymmetric hydrogenation of methyl acetoacetate to methyl 3-hyoroxybutyrate, a Raney nickel catalyst modified with the optically active threo form has a stronger asymmetric activity than the optically active erythro form.*1

Experimental

Preparation of α-Methylvaleraldehyde (2-Methylpentanal). Two hundred and fifty-five grams of 2-methyl-2-pentenal were hydrogenated with a catalyst prepared from 4 g of $PdCl_3$ by Willstätter's method, at 90 atm and at 70°C. The hydrogenation product was distilled fractionally to yield 200 g (77.4%) of α-methylvaleraldehyde; bp 110—120°C.

Preparation of 5-(1-Methylbutyl)-hydantoin. A solution consisting of 125 g of sodium cyanide, 550 g of commercial ammonium carbonate, 1500 m*l* of methanol, and 1500 m*l* of water was placed in a 5-*l* four-necked, round-bottomed flask fitted with a mechanical stirrer, a dropping funnel, a reflux condenser, and a thermometer; the flask was then kept at 40°C in a water bath. Through the dropping funnel we stirred in 106 g of α-methylvaleraldehyde, drop by drop, where upon a vigorous reaction took place. After this vigorous reaction had ceased, the reaction mixture was stirred continuously at 55°C for 6 hr. When the resulting solution was concentrated to about one-half volume under reduced pressure, it became a sludge with crystals. The residual solution was boiled with 800 m*l* of concentrated hydrochloric acid for 1 hr in a draft chamber and then kept in a refrigerator. The precipitated crystals were collected, washed with water, and dried in air. The yield was 180 g (100%) of a practically pure material; mp 122°C.

Found: C, 56.25; H, 8.54; N, 16.55%. Calcd for $C_8H_{14}O_2N_2$: C, 56.45; H, 8.29; N, 16.46%.

Preparation of β-Methylnorleucine (Ia, Ib). In an autoclave, 170 g of 5-(1-methylbutyl)-hydantoin was hydrolyzed with 800 m*l* of aqueous sodium hydroxide containing 380 g of sodium hydroxide at 140°C for 5 hr. After removing the ammonia by boiling, the reaction mixture was neutralized with hydrochloric acid and treated with charcoal. Then, the solution was sufficiently acidified with hydrochloric acid and dried *in vacuo*, and the residue was extracted with 500 m*l* of methanol. The extract was dried *in vacuo*, and the residue was taken up with 300 m*l* of water and adjusted to pH 6.0 with aqueous sodium hydroxide to afford 136 g of β-methylnorleucine; another 9 g of the product were obtained from the mother liquid. Total yield, 145 g (100%).

A part of the product was recrystallized from 10% ethanol for the elemental analysis.

Separation and Purification of β-Methylnorleucine. One hundred and seventeen grams of the crude β-methylnorleucine (Ia+Ib) were recrystallized twice from 400 m*l* of concentrated hydrochloric acid; crystalline hydrochloride salt was collected and thoroughly washed with concentrated hydrochloric acid. Yield, 57 g (Ia·HCl).

The mother liquor obtained from the recrystallization was combined and concentrated to dryness under reduced pressure, and the residue was recrystallized twice from concentrated hydrochloric acid; another 17 g of β-

*1 These results will be reported fully in the near future in this Bulletin.

methylleucine hydrochloride were thus recovered. Yield, 74 g (50.8%).

The mother liquor and washings obtained by the above treatment were combined and evaporated to dryness, and the residue was taken up with 50 ml of water. The solution was neutralized to pH 6.5 with 20% sodium hydroxide to afford 32 g of crude β-methylnorleucine (Ib).

β-Methylnorleucine cupper salt was instantly precipitated from a solution containing 23 g of the crude β-methylnorleucine (Ib) and 6.5 g of sodium hydroxide in 300 ml of water, by the addition of 20 g of cupric sulfate. After heating the sluggish mixture, with occasional stirring, in a boiling-water bath for 1 hr, the precipitated cupper salt of β-methylnorleucine was collected from the hot, sluggish mixture and washed with methanol. The crude cupper salt was treated with 600 ml of a 1% cupric sulfate solution during heating on the water bath for 20 min with occasional stirring. An insoluble cupper salt was then collected from the hot mixture. This treatment with 1% cupric sulfate solution was repeated twice. The pure cupper salt obtained in this manner was dissolved in 10% hydrochloric acid and treated with hydrogen sulfide. After the cupric sulfide was filtered off, the filtrate was evaporated to dryness *in vacuo* to afford stereochemically pure β-methylnorleucine hydrochloride (Ib·HCl). The residue was recrystallized from hot acetone. Yield, 15 g (10.3%).

One portion of the hydrochloride salt was dissolved in a small amount of water and neutralized to pH 6.0 with aqueous hydroxide. The amino acid (Ib) thus precipitated was collected and washed with water.

Preparation of 2-Benzyl-5-(α-methylisobutylidene)-4-imidazolone. This material was prepared

from 2-benzyl-5(*H*)-imidazolone and methylisopropylketone according to the procedure of Kotake *et al.* The crude product was recrystallized from ether-hexane for elemental analysis.

Found: C, 74.33; H, 7.49; N, 11.64%. Calcd for $C_{15}H_{20}ON_2$: C, 74.35; H, 7.49; N, 11.56%. Mp 134—136°C.

Preparation of β-Methylleucine (IIa, IIb). One hundred and ninety grams of an imidazolone derivative were dissolved in a solution of 80 g of sodium hydroxide in 100 m*l* of methanol and 220 m*l* of water; this was followed by hydrogenation in the presence of a Raney nickel catalysts from 25 g of the alloy at 100°C and at an initial pressure of 90 kg/cm².

After the removal of the catalyst by filtration, the filtrate was concentrated to about 200 m*l* *in vacuo* and then boiled with 100 m*l* of concentrated hydrochloric acid for 10 hr. After cooling, the phenyl acetic acid thus precipitated was removed by filtration; the filtrate was washed with ether and evaporated *in vacuo* to a syrup, and the residue was taken up in water and again evaporated. The residue was dissolved in 400 m*l* of ethanol, and the insoluble material was removed by filtration. Into the cooled ethanol solution, triethylamine was added cautiously with gentle stirring; then the resultant crystals were collected, washed with a large amount of ethanol, and dried in air. A small amount of the crude product was then recrystallized from water. Yield, 102 g (80%).

Found: C, 10.68; H, 57.46; N, 9.46%. Calcd for $C_7H_{15}O_2N$: C, 10.41; H, 57.90; N, 9.65%.

Separation and Purification of β-Methylleucine. The crude β-methylleucine (IIa+IIb), 102 g was recrystallized twice from 200 m*l* of concentrated hydrochloric acid. The crystalline hydrochloride salt (IIa·HCl) was collected by filtration and washed thoroughly with concentrated hydrochloric acid. Yield, 85 g (67%).

One portion of the hydrochloride salt was dissolved in ethanol and neutralized with triethylamine to afford an amino acid (IIa).

The mother liquor and washings were combined and adjusted to pH 6.8 with an aqueous hydroxide solution, and then 30 g of cupric sulfate were added to the solution. The resultant blue-purple solution was gently heated on the water bath, allowed to cool, and then carefully neutralized with 20 g of sodium bicarbonate. The crystalline cupper salt of the amino acid was collected by vacuum filtration and washed repeatedly with water and then with methanol. The crude cupper salt was suspended in a 1% solution of cupric sulfate, and the mixture was slightly heated. Insoluble crystals were collected by filtration under reduced pressure and then washed with methanol. This treatment was repeated twice, and then the crystals were dried in air. Yield, 56 g.

The pure copper salt obtained in this manner was dissolved in 10% hydrochloric acid and treated with hydrogen sulfide. The cupric sulfide thus precipitated was removed. The filtrate and washings were combined and evaporated *in vacuo* to afford stereochemically-pure β-methylleucine hydrochloride (IIb·HCl). Yield, 27 g (21.2%).

Resolution of the Amino Acid (Ia, Ib, IIa, IIb). IIa·HCl was acetylated with 2 N sodium hydroxide and acetic anhydride by the ordinary method. Fifty-six grams of the acetyl derivative of IIa were dissolved in 1.5 *l* of water, and the pH was adjusted to 6.8 with 2 N sodium hydroxide. To this solution, 3 g of prozyme acylase were then added, after which the mixture was allowed to stand for 50 hr at 42°C. After 50 hr, the pH of the solution was again adjusted to 6.8 with 2 N NaOH, and the hydrolysis was continued. Then, the solution was evaporated to 100 m*l* *in vacuo*; the crystals of the L-amino acid were subsequently collected by filtration and washed with a small amount of water. The crude L-amino acid was purified by recrystallization from the water by treatment with charcoal. Yield, 12 g (55.3%). $[\alpha]_D^{33}$ +40.6 (*c* 1, 6N HCl).

The mother liquor was acidified with 6 N hydrochloric acid. The *N*-acetyl-D-amino acid thus precipitated was collected and washed with dilute hydrochloric acid and then water. Yield, 24 g (85.7%). $[\alpha]_D^{25}$ −2.3 (*c* 8.3 EtOH).

One portion of the *N*-acetyl-D-amino acid was refluxed with 10% hydrochloric acid; the solution was then neutralized with triethylamine to afford, quantitatively, D-amino acid. $[\alpha]_D^{25}$ −39.9 (*c* 1.2, 6 N HCl).

The other amino acids, Ia, Ib, and IIb were resolved by a procedure similar to that used for IIa.

The authors wish to express their sincere thanks to Miss Kiku Koike and Miss Nobuko Ōya of this Institute for the elemental analyses. They are also indebted to the Kyowa Fermentation Co., Ltd., for the gift of PROZYME.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1545—1553 (1970)

The Retentive Solvolysis. VII. Structural Effect of the Leaving Group on the Steric Course of the S_N1 Phenolysis of 1-Phenylethyl Systems*1

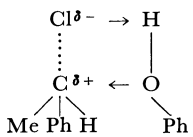
Kunio OKAMOTO, Tomomi KINOSHITA and Haruo SHINGU

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received November 12, 1969)

A series of optically active 1-phenylethyl systems with various leaving groups has been phenolyzed in the phenolic solvents. The 1-phenylethyl systems with a negative leaving group (*i.e.*, 1-phenylethyl chloride, bromide, 3,5-dinitrobenzoate, and tosylate) afforded 1-phenylethyl phenyl ether with a net retained configuration. In contrast, the 1-phenylethyl systems with a positively-charged leaving group (*i.e.*, the 1-phenylethyldiazonium ion, the diethyl-(1-phenylethyl)-oxonium ion, and the protonated 2,6-di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexadien-1-one) gave the 1-phenylethyl phenyl ether with a net inverted configuration. These results provide further support for the view that the retentive S_N1 phenolysis proceeds *via* a four-center transition state between the phenol molecule and the ion-pair intermediate. Besides the phenolic ether, the *o*- and *p*-(1-phenylethyl)-phenols with net inverted configurations were obtained from all optically active substrates except 1-phenylethyl 3,5-dinitrobenzoate and the 1-phenylethyldiazonium ion. The 3,5-dinitrobenzoate gave the completely racemic *o*-alkylated phenol, along with the inverted *p*-alkylated phenol, whereas the diazonium ion afforded the *o*-alkylated phenol with a net retained configuration, together with the inverted *p*-alkylated phenol. The stereochemical and mechanistic implications of the *C*-alkylation are also discussed on the basis of the results of the acidic rearrangement of the phenolic ether under the S_N1 phenolysis conditions.

Some years ago investigations in this laboratory showed that the S_N1 phenolysis of optically active 1-phenylethyl chloride occurs with a net retention (20—50%) of configuration to give 1-phenylethyl phenyl ether in the presence of aniline or triethylamine;[1] in order to account for these results, we offered the explanation that the ether with the retained configuration was probably formed from an ion-pair and a phenol molecule *via* a four-centered transition state as follows:[1b,2]



If this role of the phenol molecule were predominant in the retentive phenolysis of the chloride, we should observe the retention course in all 1-phenylethyl systems with a negative group such as the chlorine group. In contrast, for the case of the system with a positively-charged leaving group, the S_N1 phenolysis might proceed with a predominant inversion of configuration, as is typically observed in the other S_N1 solvolysis, since the positively-charged leaving group is conceivably unable to form such a specified transition state (*vide supura*) as the chlorine group does.

In order to ascertain these anticipations, we carried out the S_N1 phenolysis of several optically active 1-phenylethyl systems and examined the leaving-group influence. We chose 1-phenylethyl chloride, bromide, 3,5-dinitrobenzoate, and *p*-toluenesulfonate as the substrates with a negative leaving group; we also selected the 1-phenylethyldiazonium ion, the diethyl-(1-phenylethyl)-oxonium ion, and the protonated 2,6-di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexan-1-one as the systems with a positively-charged leaving group.

Results

Phenolysis of the 1-Phenylethyl System with a Negative Leaving Group. The results of the phenolysis of a familiar set of substrates with a negative leaving group are presented in Table 1, along with the respective first-order rate constants.

a) Calculated taking into account lack of optical purity of the starting substrate; the rotations of the optically pure materials are taken to be 125° (H. M. R. Hoffmann and E. D. Hughes, *J. Chem. Soc.*, **1964**, 1244) for R-(+)-1-phenylethyl chloride, 170° (H. M. R. Hoffmann and E. D. Hughes, *loc. cit.*) for R-(+)-1-phenylethyl bromide, 50.7° ($[\alpha]_D$, see Experimental section) for R-(+)-1-phenylethyl 3,5-dinitrobenzoate (RODNB), and 46.6° (Ref. 1b) for S-(+)-1-phenylethyl phenyl ether.

b) Prepared *in situ* from 1-phenylethyl chloride, α_D^{18} −57.1° (1 dm, neat), and silver *p*-toluenesulfonate (see text).

c) Calculated on the basis of the rotation of 1-phenylethyl chloride used for the preparation of the tosylate.

d) Cited from Ref. 1b.

Optically active 1-phenylethyl chloride and bromide were subjected to phenolysis in the presence of three molar equivalents of triethylamine in a 1 : 1 (by wt.) mixture of phenol and acetonitrile at 40.0°C. As anticipated, satisfactory first-order kinetic behavior was titrimetrically observed for each halide (Fig. 1); product analysis by chromatography showed that both halides gave 1-phenylethyl phenyl ether with a net retained configuration (Table 1),

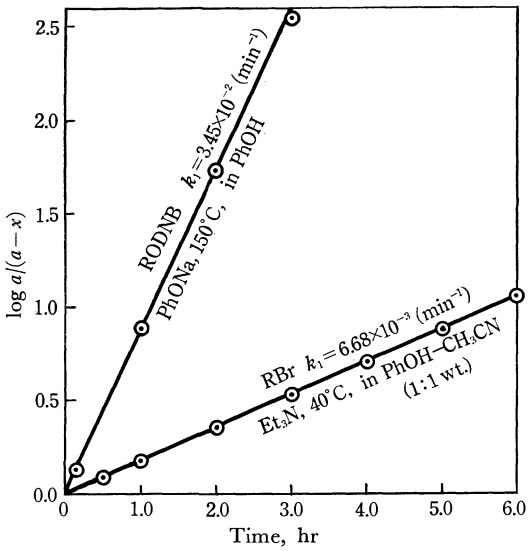

Fig. 1. The first-order plots for the phenolysis of the 1-phenylethyl system.

along with net inverted *o*- and *p*-(1-phenylethyl)-phenols (Table 3).

Optically active 1-phenylethyl 3,5-dinitrobenzoate was phenolized in the presence of one molar equivalent of sodium phenoxide in the phenol solvent. Because of the sluggishness of this phenolysis at the temperature (40°C) employed for the halides, the phenolysis was carried out at an elevated temperature (150°C). The decrease in the quantity of sodium phenoxide, followed titrimetrically, obeyed good first-order kinetics (Fig. 1). When chromatographed, the reaction mixture gave 1-phenylethyl phenyl ether with a 28% retained configuration (Table 1), along with completely racemized *o*-(1-phenylethyl)-phenol and 12% inverted *p*-(1-phenylethyl)-phenol (Table 3).

By modifying the method described by Hoffmann,[3] optically active 1-phenylethyl *p*-toluenesulfonate was prepared *in situ* from optically active S-(−)-1-phenylethyl chloride and silver *p*-toluenesulfonate in the acetonitrile solvent at 20°C. In order to determine the configuration of the tosylate thus formed, the concentrated solution of the tosylate was subjected to the reductive cleavage with sodium-naphthalene in tetrahydrofuran.[4] From the reaction mixture, R-(+)-1-phenylethyl alcohol was isolated by chromatography (see Experimental section). This indicates that the tosyl-

3) H. M. Hoffmann, *Chem. Ind.* (London), **1963**, 336.

4) W. D. Closson, P. Wriede and S. Bank, *J. Amer. Chem. Soc.*, **88**, 1581 (1966).

ate was formed with a net inversion of configuration, since it has been confirmed, for the other tosylates, that, in this reductive fission, no alkyl-oxygen bond, but only a sulfur-oxygen bond, is cleaved.[4]

$$\text{S-(}-\text{)-RCl} \xrightarrow[\text{in } CH_3CN]{\text{AgOTs}} \text{R-(?)-RO-Ts} \xrightarrow[\text{in THF}]{\text{Na-Naph.}} \text{R-(}+\text{)-RO-H}$$

When hydrolyzed, the tosylate gave S-(−)-1-phenylethyl alcohol, along with styrene (see Experimental section). This also indicates the inversive steric course for the formation of the tosylate, since, for the hydrolysis of the 1-phenylethyl system, a net inversion of configuration is typically observed.[5]

$$\text{S-(}-\text{)-RCl} \xrightarrow[\text{in } CH_3CN]{\text{AgOTs}} \text{R-(?)-ROTs} \xrightarrow{H_2O} \text{S-(}-\text{)-ROH}$$

To the acetonitrile solution of R-1-phenylethyl *p*-toluenesulfonate so prepared, we added a phenol solvent which contained about two molar equivalents of urea as a weak base.[6] After a rapid phenolysis at 20–35°C, R-(−)-1-phenylethyl phenyl ether, with a retained configuration, was isolated by chromatography, along with S-(−)-*o*-(1-phenylethyl)-phenol and S-(+)-*p*-(1-phenylethyl)-phenol (Tables 1 and 3).

Thus, in the phenolysis of the 1-phenylethyl system with a negative leaving group in the presence of a base, a net retention for the formation of the phenolic ether is the standard result, rather than a net inversion, this being shown in the following scheme:

$$\text{R-RCl} \xrightarrow[\text{in PhOH-CH}_3\text{CN}]{\text{Et}_3\text{N, 40°C}} \text{R-ROPh}$$

$$\text{S-RBr} \xrightarrow[\text{in PhOH-CH}_3\text{CN}_3]{\text{Et}_3\text{N, 40°C}} \text{S-ROPh}$$

$$\text{S-RODNB} \xrightarrow[\text{in PhOH}]{\text{PhONa, 150°C}} \text{S-ROPh}$$

(ODNB=3,5-dinitrobenzoate)

$$\text{R-ROTs} \xrightarrow[\text{in PhOH-CH}_3\text{CN}]{\text{CO(NH}_2\text{)}_2\text{, 20—35°C}} \text{R-ROPh}$$

The S_N1 Phenolysis of the 1-Phenylethyl System with a Positively-charged Leaving Group. The S_N1 phenolysis of this type can be classified as an S_N1 substitution of the missing-charge type.[7] As a representative S_N1 phenolysis of the missing-charge type, the phenolysis of the optically active 1-phenylethyldiazonium ion was conducted in a mixture of phenol and water. The diazonium was prepared *in situ* by adding concentrated hydrochloric acid to the mixture of optically active R-(+)-1-phenylethylamine and sodium nitrite in a 4 : 1 mixture of phenol and water at −8—+2°C. The diazotization and the succeeding nucleophilic reaction proceeded rapidly, with the evolution of nitrogen. From the reaction mixtures, a small amount of 1-phenylethyl phenyl ether with a net inverted configuration was isolated by chromatography (Table 2). In addition, *o*-(1-phenylethyl)-phenol with a net retained configuration and *p*-(1-phenylethyl)-phenol with a net inverted configuration were isolated (Table 3). In view of the poor yield (total 10.0%) of the substitution products and the 55% recovery of the starting amine, under these reaction conditions most of the nitrous acid was probably consumed by the phenol solvent to give the nitrosophenol. Besides the phenolic products, 1-phenylethyl alcohol with a 34.2% retained configuration was also isolated in a 5.30% yield. This retained alcohol seems to be formed from the diazonium hydroxide by a kind of S_Ni mechanism.[8]

As another example of the S_N1 phenolysis of a missing-charge type, we undertook the phenolysis of the diethyl-(1-phenylethyl)-oxonium ion. Optically active diethyl-(1-phenylethyl)-oxonium fluoroborate was prepared *in situ* in 1,2-dichloroethane from ethyl fluoroborate and S-(−)-1-phenylethyl ethyl ether.

$$\text{S-ROEt} + \text{EtBF}_4 \xrightarrow[\text{in ClCH}_2\text{CH}_2\text{Cl}]{} \text{S-R}\overset{+}{\text{O}}\text{Et}_2\text{BF}_4^-$$

The oxonium ion in 1,2-dichloroethane was subjected to phenolysis by addition of a mixture of phenol and 1,2-dichloroethane (*ca.* 10 : 1 by wt.) at 16—25°C. After the usual working-up, *o*- and *p*-(1-phenylethyl)-phenols with net inverted configurations were obtained (Tables 2 and 3); no phenolic ether was found in the products. This is most probably because of the rapid rearrangement of the *inverted* phenyl ether, initially formed, to the *inverted* *o*-(1-phenylethyl)-phenol, with a net retention of configuration, under the acidic reaction conditions. In fact, we confirmed that optically active 1-phenylethyl phenyl ether rapidly rearranges into *o*-(1-phenylethyl)-phenol, with a 35% retention of configuration, in the presence of hydrochloric acid in a 1 : 1 mixture of phenol and 1,2-dichloroethane (see Experimental section).

As has previously been reported,[9] the acidic cleavage of 2,6-di-*t*-butyl-4-methyl-4-(1-phenyl-

a) See the footnote a of Table 1.
b) The composition of the mixture was changed from 79 : 21 to 66 : 34 during the reaction (see Experimental section).
c) Prepared from 1-phenylethylamine, α_D^{17} +14.0° (1 dm, neat); the rotation of the optically pure amine was taken to be 38.88° (1 dm, neat) (W. Leithe, *Monatsh. Chem.*, **51**, 385 (1929)).
d) Prepared from 1-phenylethyl ethyl ether, $\alpha_D^{21.5}$ −7.18° (1 dm, neat), and ethyl fluoroborate; the rotation of the optically pure ether was taken to be 94.8° (1 dm. neat) (K. Mislow, *J. Amer. Chem. Soc.*, **73**, 4043 (1951)).
e) The protonated 2,6-di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexan-1-one.
f) 1-Phenylethylamine (55.0%) was recovered; 1-phenylethyl alcohol (5.3% yield) with 34.2% retention of configuration was obtained besides the phenolic products, illustrated in Tables 2 and 3.

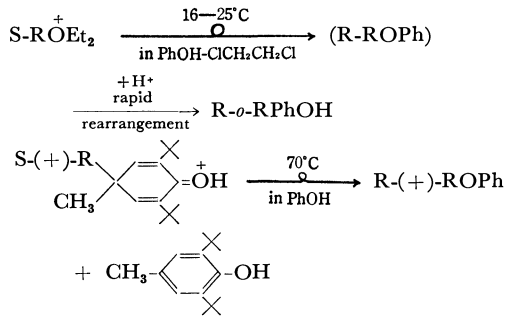
a) See the footnotes in Tables 1 and 2.
b) Cited from Ref. 9.
c) Calculated on the basis of the rotations of the starting 1-phenylethyl chloride, amine, and ethyl ether, respectively; see the footnotes in Table 2.
d) The rotations of optically pure samples were taken to be 27.85° (1 dm, neat) for R-(+)-*o*-(1-phenylethyl)-phenol and 10.26° ($[\alpha]_D$) for S-(+)-*p*-(1-phenylethyl)-phenol (see Ref. 13).
e) See the footnote f in Table 1.

ethyl)-cyclohexadien-1-one into a 1-phenylethyl compound and 2,6-di-*t*-butyl-4-methylphenol is also considered to be a typical S_Ni reaction of the missing-charge type for the protonated dienone; this optically active dienone in the phenol solvent gives 1-phenylethyl phenyl ether with a net inverted configuration, along with *o*- and *p*-(1-phenylethyl)-phenols with net inverted configurations (Tables 2 and 3).

Thus, contrary to the cases of the negative leaving groups, in the phenolysis of the 1-phenylethyl system with a positively-charged leaving group, a net inversion of configuration is standard for the formation of the phenolic ether, as is typically observed in the usual S_Ni reactions. This is illustrated in the following scheme:

$$R\text{-}RN_2^+ \xrightarrow[\text{in PhOH-H}_2\text{O}]{-8—+2°C} S\text{-ROPh}$$



Discussion

The Steric Course of the Formation of the Phenyl Ether. All the results presented above are consistent with the expected results as regards the steric courses of the formation of the phenolic ether; consequently, they lend support to the previous suggestion that the phenol molecule acts as a component of the four-center transition state which leads to the retentive phenolysis.

However, it has been established that, in the acrylonitrile solvent which does not solvate the negative leaving group but the positively-charged carbonium ion, 1-phenylethyl chloride is hydrolyzed to the unusual retentive course when it is conducted in the 97% aqueous acrylonitrile solvent.[10] This most probably indicates that the specific solvation, or coordination,[5] of acrylonitrile on the back-side of the cationic component of the ion-pair intermediate can cause the retentive hydrolysis. In other words, a sort of back-side shielding[5,11] of the ion-pair intermediate may operate in the acrylonitrile solvent. Considering this factor, therefore, we can not exclude the possibility that the phenol molecule also acts as a back-side shielder just as the acrylonitrile molecule does, although its role may be minor in comparison with the concomitant front-side four-center attack of the phenol molecule.

The Steric Course of the Formation of the Alkylated Phenol. As illustrated in Table 3, in the phenol-acetonitrile solvent the formation of *o*- and *p*-(1-phenylethyl)-phenols proceeds with a predominant inversion of configuration; in the other phenolic solvents, inverted 1-phenylethylphenols are also obtained, irrespective of the charge-type of the leaving group (Table 3). These results can be explained as a consequence of the back-side attack of the phenoxide ion (or the phenol molecule) on the ion-pair intermediate.

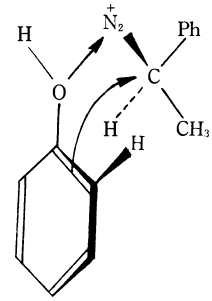
Andreades, *ibid.*, **80**, 6553 (1958); d) H. Weiner and R. A. Sneen, *ibid.*, **87**, 287, 292 (1965); e) N. Kornblum and D. E. Hardies, *ibid.*, **88**, 1707 (1966).

As an exception to the general trend, 1-phenylethyl 3,5-dinitrobenzoate afforded a racemic *o*-(1-phenylethyl)-phenol in the phenolic solvent. Since, in view of the facile acidic rearrangement with retention of configuration in the phenol-acetonitrile solvent at 40°C (see Experimental section), the retentive rearrangement of 1-phenylethyl phenyl ether to *o*-(1-phenylethyl)-phenol would proceed rather rapidly, even in the absence of a strong acid, at such an elevated temperature as 150°C, the formation of the racemic *o*-(1-phenylethyl)-phenol may be explained as the result of the fortuitous compensation of retention and inversion, caused by the concurrence of the retentive rearrangement and the inversive direct alkylations.

As another exceptional case of especial interest, the 1-phenylethyldiazonium ion gave a *retained* *o*-(1-phenylethyl)-phenol in the aqueous phenol solvent. Under similar acidic conditions, the rearrangement of 1-phenylethyl phenyl ether to *o*-(1-phenylethyl)-phenol was found to be comparatively slow (see Experimental section); moreover, any rearrangement should give an *inverted* *o*-(1-phenylethyl)-phenol, since, in the case of the diazonium ion, the *inverted* phenyl ether is formed and its rearrangement proceeds with a retention of configuration (*vide supra*) (Table 2). Therefore, the formation of the *o*-(1-phenylethyl)-phenol is probably caused by the "direct" and *retentive* *C*-alkylation of the phenol molecule; this is illustrated in the following scheme:



Hart and his collaborators[12] found that *o*-(1-phenylethyl)-phenol with a retained configuration is formed from 1-phenylethyl chloride in the phenol solvent in the absence of a base; they suggested that this is a direct and retentive alkylation with a four-center transition state. However, this result, at least partly, may stem from the rearrangement of the initially-formed phenyl ether with a retained configuration:

$$\text{R-RCl} + \text{PhOH} \xrightarrow[\text{in PhOH}]{} \text{(R-ROPh)} \xrightarrow[\text{rapid}]{\text{H}^+} \text{R-}o\text{-RPhOH}$$

$$\text{R-RCl} + \text{PhOH} \xrightarrow{\text{in the absence of a base}} \text{R-}o\text{-RPhOH (Hart } et\ al.^{12})$$

12) H. Hart, W. L. Spliethoff and H. S. Eleuterio, *ibid.*, **76**, 4547 (1954).

In fact, we confirmed that when the phenolysis of 1-phenylethyl chloride was conducted in the absence of the amine, no phenolic ether was obtained, while the retained *o*-(1-phenylethyl)-phenol, along with the inverted *p*-(1-phenylethyl)-phenol, was obtained in a 1 : 1 mixture of phenol and acetonitrile, and that under the same reaction conditions the phenolic ether undergoes a rapid rearrangement to give *o*-(1-phenylethyl)-phenol with a 74% retention of the configuration (see Experimental section).

Experimental

Materials. The R-(+)-1-phenylethyl chloride was prepared by the reaction of R-(+)-1-phenylethyl alcohol with thionyl chloride in a manner previously described.[13] The S-(−)-1-phenylethyl bromide was prepared by the reaction of R-(+)-1-phenylethyl alcohol with phosphorous tribromide after the method described by Hoffmann and Hughes.[14] The S-(−)-1-phenylethyl 3,5-dinitrobenzoate ($[\alpha]_D^{24}$ −23.7° (*c* 5.4, benzene), mp 101.5—103.4°C (corr.)) was synthesized by the reaction of S-(−)-1-phenylethyl alcohol, α_D^{22} +20.64° (1 dm, neat), with 3,5-dinitrobenzoyl chloride according to the method of Buckles and Maurer.[15] On the basis of this result, the value for the maximum rotation of the 3,5-dinitrobenzoate was calculated to be 50.7° ($[\alpha]_D$), using 44.2°[16] as the value for the maximum rotation of 1-phenylethyl alcohol. 1-Phenylethylamine was resolved according to the method of Theilacker and Winkler.[17] S-(−)-1-Phenylethyl ethyl ether, $\alpha_D^{21.5}$ −7.18° (1 dm, neat), was prepared by the reaction of R-(+)-1-phenylethyl chloride, α_D^{15} +22.3° (1 dm, neat), with potassium carbonate in ethanol after the method described by Kenyon and Phillips.[18] The silver *p*-toluenesulfonate was prepared from silver oxide and *p*-toluenesulfonic acid. All the other reagents employed were of an analytical reagent grade and were purified by fractional distillation.

The Isolation of the Reaction Products (General Procedure). A flask containing a reaction mixture was placed in a constant-temperature bath for at least ten half-lives. The reaction mixture was cooled at 0°C; then, after the addition of water (100 cc), the mixture was extracted with ether (4×100 cc). The combined extracts were washed successively with 10% aqueous sodium hydroxide (4×100 cc) and 10% aqueous sodium chloride (several 100-cc portions) until the washings became neutral to pH indicator paper. The ethereal solution, dried with anhydrous magnesium sulfate, was concentrated; the residual oil was chromatographed using an elution column packed with silica gel, 50-cc portions being taken out. The combined alkaline extracts were acidified with hydrochloric acid, and the resulting oil was extracted with ether; the dried ether extracts were concentrated and the residual oil was distilled *in vacuo* in order to recover some phenol. This residual oil was added to the sample (*vide supra*) for the chromatography.

The Phenolysis of Optically Active 1-Phenylethyl Chloride in the Phenol-Acetonitrile (1: 1 by Wt.) Solvent at 40°C. A mixture of phenol (42.8 g), acetonitrile (42.8 g), and triethylamine (6.09 cc; 0.424 M, as determined by titration) was prepared. To a 77.9-cc portion of the mixture, we added optically active 1-phenylethyl chloride (1.50 cc, 0.0113 mol; bp 56.0—58.0°C/4.0 mmHg; $\alpha_D^{31.2}$ +22.09±0.03°, 1 dm, neat). The reaction mixture so prepared was kept at 40.0±0.1°C for 97 hr. After the working-up described above, an oily material (2.12 g) was chromatographed over silica gel (80 g; Nakarai, No. 11-A, 100—200 mesh). The column was eluted successively with *n*-hexane-benzene (1: 1 by vol.), benzene, benzene-ether (97: 3 by vol.), ether, and ethanol, 50-cc portions being taken out. Fractions 4—9, obtained using *n*-hexane - benzene (1: 1 by vol.), gave 1-phenylethyl phenyl ether (1.284 g; 58.1% yield; the infrared spectrum was the same as that of an authentic sample; $\alpha_D^{27.5}$ −0.455±0.015°, 0.5 dm, neat). Fractions 15—21, obtained using benzene, gave *o*-(1-phenylethyl)-phenol (0.376 g; bp 140—145°C/4.0 mmHg; 17.0% yield; the infrared spectrum was the same as that of an authentic sample: $\alpha_D^{28.4}$ −1.015±0.015°, 0.5 dm, neat). Fractions 26—31, obtained using benzene-ether (97: 3 by vol.), gave *p*-(1-phenylethyl)-phenol (0.278 g; bp 150—156°C/4.0 mmHg; 12.6% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{28.5}$ +0.12±0.02° (*c* 27.3, benzene)).

The Phenolysis of Optically Active 1-Phenylethyl Bromide in the Phenol-Acetonitrile (1: 1 by Wt.) Solvent at 40°C. A mixture of phenol (42.8 g), acetonitrile (42.8 g), and triethylamine (5.85-cc, 0.419 M) was prepared. To a 90.0-cc portion of the mixture, we added optically active 1-phenylethyl bromide (2.00 cc, 0.0145 mol; bp 48.0—53.8°C/0.7 mmHg; $\alpha_D^{23.2}$ −33.15±0.04°, 0.5 dm, neat). The reaction mixture so prepared was maintained at 40.0±0.1°C for 19 hr. After the working-up described above, an oily material (2.550 g) was chromatographed over silica gel (80 g). Fractions 7—15, obtained using *n*-hexane - benzene (1: 1 by vol.), gave 1-phenylethyl phenyl ether (1.448 g; 55.7% yield; the infrared spectrum was the same as that of an authentic sample; $\alpha_D^{22.6}$ −1.475±0.045°, 0.5 dm, neat). Fractions 19—29, obtained using benzene, gave *o*-(1-phenylethyl) phenol (0.420 g; bp 125—130°C/3.0 mmHg; 16.2% yield; the infrared spectrum was the same as that of an authentic sample; $\alpha_D^{25.6}$ +2.90±0.05°, 0.5 dm, neat). Fractions 35—45, obtained using benzene-ether (97: 3 by vol.), gave *p*-(1-phenylethyl)-phenol (0.288 g; bp 140—150°C/4.0 mmHg; 11.1% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{22.4}$ −0.70±0.04° (*c* 69.4, benzene)).

The Phenolysis of Optically Active 1-Phenylethyl 3,5-Dinitrobenzoate in the Phenol Solvent at 150°C. To a mixture of phenol (40 cc) and sodium phenoxide (0.4490 g, 0.00386 mol; 0.0933 M), we added optically active 1-phenylethyl 3,5-dinitrobenzoate (1.0952 g, 0.00386 mol; mp 98.6—100.5°C (corr.); $[\alpha]_D^{25.9}$ −21.0±0.28° (*c* 5.32, benzene)). The reaction

mixture was kept at 150.0±0.1°C for 4.3 hr. After the working-up described above, an oily material (0.5067 g) was chromatographed over silica gel (40 g). Fractions 2—4, obtained using *n*-hexane - benzene (1: 1 by vol.), gave 1-phenylethyl phenyl ehter (0.305 g; bp 140—141°C/4.0 mmHg; 40.0% yield; the infrared spectrum was the same as that of an authentic sample; $\alpha_D^{26.7}$ −3.045±0.025°, 0.5 dm, heat). Fractions 8—11, obtained using benzene, gave *o*-(1-phenylethyl)-phenol (0.0872 g; bp 148—149°C/4.0 mmHg; 11.4% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{26.7}$ 0.00±0.06° (*c* 23.6, benzene)). Fractions 16—19, obtained using benzene-ether (97: 3 by vol.), gave *p*-(1-phenylethyl)-phenol (0.0627 g; bp 150—155°C/4.0 mmHg; 8.22% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{27.4}$ +0.554±0.262° (*c* 34.3, benzene)).

The Phenolysis of Optically Active 1-Phenylethyl *p*-Toluenesulfonate in the Phenol-Acetonitrile (1: 1 by Wt.) Solvent at from 20°C to 35°C. A solution (75 cc) of silver *p*-toluenesulfonate (4.221 g, 0.01508 mol in acetonitrile was prepared and kept at 20.0±0.1°C). When optically active 1-phenylethyl chloride (2.00 cc, 0.0148 mol; bp 45.0—46.1°C/1.0 mmHg; $\alpha_D^{18.2}$ −57.105±0.035°, 1 dm, neat) was then added to the solution, the precipitates of silver chloride appeared immediately. To the mixture, there was added a solution (85 cc) of urea (2.140 g, 0.0356 mol) in a mixture of phenol and acetonitrile (5.5: 1.0 by wt.). The reaction mixture so prepared was maintained at from 20.0°C to 35.0°C for 2.17 hr. The mixture was then cooled at 0°C and poured onto a mixture of ether and water (1: 1 by vol.; 200 cc). The precipitates of silver chloride were separated by filtration. After the working-up described above, an oily material (1.7820 g) was chromatographed over silica gel (50 g). Fractions 7—10, obtained using *n*-hexane - benzene (1: 1 by vol.), gave 1-phenylethyl phenyl ether (0.6008 g; 20.5% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{19.6}$ −0.43±0.20° (*c* 42.1, benzene)). Fractions 14—17, obtained using benzene, gave *o*-(1-phenylethyl)-phenol (0.1831 g; bp 135—140°C/3.0 mmHg; 6.24% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{20.4}$ −1.0;±0.85° (*c* 38.2, benzene)). Fractions 19—27, obtained using benzene and benzene-ether (97: 3 by vol.), gave *p*-(1-phenylethyl)-phenol (0.3604 g; bp 145—160°C/5.0 mmHg; 12.3% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{24.1}$ +0.733±0.221° (*c* 58.7, benzene)).

The Reductive Cleavage of Optically Active 1-Phenylethyl *p*-Toluenesulfonate with Sodium-Naphthalene. Into a solution of silver *p*-toluenesulfonate (12.40 g, 0.0444 mol) in acetonitrile (32 cc), we added optically active 1-phenylethyl chloride (2.00 cc, 0.0148 mol; bp 45.0—46.1°C/1.0 mmHg; $\alpha_D^{18.2}$ −57.105±0.035°, 1 dm, neat). The flask was kept at 20.0±0.1°C for 3 hr. The reaction mixture was then cooled at 0°C, and burnt sodium chloride (5.50 g, 0.0942 mol) and ether (15 cc) were added successively. Precipitates of silver chloride (13.27 g) was separated by filtration. The filtrate was concentrated to about 20 cc by a rotary-evaporator at room temperature. To the concentrated solution, tetrahydrofuran (5 cc) was added. After the separation of the additional precipitates of silver chloride (2.08 g) by filtration, the filtrate was concentrated to about 10 cc. From the concentrated solution, 0.5 cc of an aliquot was pipetted, after which the solvent was removed by distillation *in vacuo* (at room temperature) to give white crystals, which rapidly became reddish violet when exposed to air. The crystals showed IR absorption (in CCl_4) at 3070, 2950, 1600, 1495, 1450, and 700 cm^{-1}. Following the method described by Closson *et al.*,[4] a concentrated solution of 1-phenylethyl *p*-toluenesulfonate was added, drop by drop, into a tetrahydrofuran solution (150 cc) of sodium (1.23 g, 0.0535 mol) and naphthalene (7.00 g, 0.0547 mol) at −3.0°C under nitrogen; the color of the mixture was dark green. After the addition of the tosylate, there was immediately added, drop by drop, a mixture of tetrahydrofuran (15 cc) and distilled water (5 cc) at from 4.0°C to 7.0°C; the color become grey. After the addition of distilled water (10 cc), the reaction mixture was poured onto water (150 cc); sodium chloride (50 g) was then added, and the mixture was extracted with ether (four 50-cc portions). After the combined extracts had then been dried with anhydrous magnesium sulfate, the solution was concentrated to about 10 cc. The white crystals were separated by filtration; the crystals were washed with ethanol (two 5-cc portions); the filtrate was combined with washings and concentrated to about 10 cc. The second crop was filtered and washed with ethanol. The procedure was repeated seven times. The combined white crystals were characterized as naphthalene (5.78 g, 82.6% recov.; the infrared spectrum was the same as that of an authentic sample; mp 79.0—79.8°C). The residual material (2.30 g), concentrated from the final filtrate, was chromatographed over silica gel (50 g). Fractions 1—8, obtained using *n*-hexane, gave naphthalene (0.7795 g; the infrared spectrum was the same as that of an authentic sample; mp 79.5—80.0°C). Fractions 9—13, obtained using benzene, gave slightly yellow crystals (0.3091 g). Fractions 19—28, obtained using successively benzene, benzene-ether (1: 1 by vol.), and ether, gave 1-phenylethyl alcohol (0.6184 g; bp 75.0—80.0°C/4.0 mmHg; 11.3% yield; the infrared spectrum was the same as that of an authentic sample; $\alpha_D^{19.8}$ +0.248±0.107°, 1 dm, neat).

The Hydrolysis of Optically Active 1-Phenylethyl *p*-Toluenesulfonate in the Aqueous Acetonitrile. A solution of silver *p*-toluenesulfonate (6.5226 g, 0.0234 mol) and optically active 1-phenylethyl chloride (2.00 cc, 0.0148 mol; bp 47.5—49.6°C/2.0 mmHg; $\alpha_D^{15.0}$ −56.42±0.04°, 1 dm, neat) in acetonitrile (70.0 cc) was kept at 19.8±0.1°C for 23.7 hr. Precipitates of silver chloride were separated by filtration. The filtrate was treated with water (10 cc), dried with anhydrous magnesium sulfate, and concentrated by distillation. The distillation of the residual material (0.7700 g) under reduced pressure afforded 1-phenylethyl alcohol (0.5121 g; bp 66.5—67.0°C/2.5 mmHg; 28.2% yield; the infrared spectrum was the same as that of an authentic sample; $\alpha_D^{19.2}$ −0.31±0.10°, 0.5 dm, neat), along with styrene (0.3070 g; 19.9% yield; the infrared spectrum was the same as that of an authentic sample).

The Phenolysis of Optically Active 1-Phenylethyldiazonium Salt in a Mixture of Phenol and Water (79: 21 to 66: 34 by Vol.) at from −8°C to +2°C. A mixture of phenol (44.20 g), distilled water (12.00 g), sodium nitrite (13.00 g, 0.1885 mol), and optically active 1-phenylethylamine (22.90 g, 0.1884 mol; bp 64.0—64.5°C/10.0 mmHg; $\alpha_D^{17.0}$ +13.96±

0.04°, 1 dm, neat) was prepared in a flask cooled in an ice-salt bath. To the mixture so prepared, we added concentrated hydrochloric acid (16.56 cc, 0.0113 mol), drop by drop, at from −8.0°C to +2.4°C. The reaction proceeded very fast, with the evolution of nitrogen. The volume of nitrogen was measured with a gas burette (708 cc). The reaction mixture was treated according to the above procedures; the unchanged amine was recovered from the acidic extracts. An oily material (7.5026 g) was chromatographed over silica gel (180 g). Fractions 10—13, obtained using *n*-hexane - benzene (1: 1 by vol.), gave an oily material (0.1961 g) containing 1-phenylethyl phenyl ether; this material was rechromatographed over basic alumina (15 g; Nakarai, Alumina Activated 200, *ca.* 200 mesh) to give 1-phenylethyl phenyl ether (0.0566 g; bp 141—146°C/4.0 mmHg; 0.152% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{18.8}+1.40\pm0.22°$ (*c* 40.7, racemic 1-phenylethyl alcohol)). Fractions 18—25, obtained using benzene, gave an oily material (0.7125 g) containing *o*-(1-phenylethyl)-phenol; this material was rechromatographed over basic alumina (30 g) to give *o*-(1-phenylethyl)-phenol (0.4428 g; bp 145—150°C/4.0 mmHg; 1.19% yield; the infrared spectrum was the same as that of an authentic sample; $\alpha_D^{22.8}+0.065\pm0.015°$, 0.5 dm, neat). Fractions 28—43, obtained using benzene and benzene-ether (97: 3 by vol.), gave *p*-(1-phenylethyl)-phenol (1.2094 g; bp 150—155°C/4.0 mmHg; 3.24% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{19.0}+1.07\pm0.09°$ (*c* 65.1, benzene)). Fractions 46—59, obtained using ether, gave 1-phenylethyl alcohol (1.2191 g; bp 90—95°C/10.0 mmHg; 5.30% yield; the infrared spectrum was the same as that of an authentic sample; $\alpha_D^{20.5}+2.69\pm0.02°$, 0.5 dm, neat). The combined acidic solution was made alkaline with 30% aqueous sodium hydroxide; the resulting oil was worked-up in the usual manner, and distilled under reduced pressure to give 1-phenylethylamine (12.60 g; bp 68.5—70.5°C/10.0 mmHg; 55.0% recov.; $\alpha_D^{20.7}+13.59\pm0.015°$, 1 dm, neat).

The Phenolysis of Optically Active Diethyl-(1-phenylethyl)-oxonium Fluoroborate in the Phenol-1,2-Dichloroethane (1: 1 by Wt.) Solvent at from 16°C to 25°C. Optically active diethyl-(1-phenylethyl)-oxonium fluoroborate was prepared by a modification of Meerwein's procedure;[19] all the operations were carried out under a nitrogen atmosphere. Silver fluoroborate (1.93 g, 0.00991 mol) was dissolved in 1,2-dichloroethane (20 cc); to the solution, ethyl iodide (1.54 g, 0.00991 mol) was then added. The yellow precipitate was filtered; to the filtrate, optically active 1-phenylethyl ethyl ether (1.49 g, 0.00991 mol; bp 71.0—73.2°C/10.0 mmHg; $\alpha_D^{21.5}-7.18\pm0.02°$, 1 dm, neat) was then added. To the mixture so prepared, a mixture of phenol (28.5 g) and 1,2-dichloroethane (3.44 g) was added. The mixture was kept at room temperature (16.0°C to 24.5°C) with stirring. After the working-up described above, an oily material (1.5921 g) was chromatographed over silica gel (70 g). Fractions 1—3, obtained using *n*-hexane - benzene (1: 1 by vol.), gave polystyrene (0.0437 g; 4.24% yield; the infrared spectrum was the same as that of an authentic sample). Fractions 6—9, obtained using benzene, gave *o*-(1-phenylethyl)-phenol (0.6834 g; bp 145—150°C/4.0 mmHg; 34.8% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{17.5}+0.19\pm0.03°$ (*c* 58.0, benzene)). Fractions 11—19, obtained using benzene and benzene-ether (97: 3 by vol.), gave *p*-(1-phenylethyl)-phenol (1.0810 g; bp 150—153°C/4.0 mmHg; 55.2% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{17.9}-0.146\pm0.048°$ (*c* 41.0, benzene)).

The Phenolysis of Optically Active 1-Phenylethyl Chloride in the Absence of a Base in the Phenol-Acetonitrile (1: 1 by Wt.) Solvent. A mixture of phenol (41.8 g) and acetonitrile (41.8 g) was prepared. To 78.4 cc of the mixture, we then added optically active 1-phenylethyl chloride (2.00 cc, 0.0148 mol; bp 39.8—40.2°C/2.5 mmHg; $\alpha_D^{16.8}-53.32\pm0.02°$, 1 dm, neat). The reaction mixture so prepared was kept at 40.0±0.1°C for 73 hr. After the working-up described above, an oily material (3.1180 g) was chromatographed over silica gel (90 g). Fractions 7—14, obtained using benzene, gave *o*-(1-phenylethyl)-phenol (1.0032 g; bp 145—150°C/4.0 mmHg; 34.9% yield; the infrared spectrum was the same as that of an authentic sample; $\alpha_D^{21.6}-0.455\pm0.045°$, 0.5 dm, neat). Fractions 17—24, obtained using benzene-ether (97: 3 by vol.), gave *p*-(1-phenylethyl-)phenol (1.8583 g; bp 151—158°C/4.0 mmHg; 62.8% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{20.8}-0.532\pm0.223°$ (*c* 39.5, benzene)).

The Acidic Rearrangement of Optically Active 1-Phenylethyl Phenyl Ether in the Phenol-Acetonitrile (1: 1 by Wt.) Solvent at 40°C. Into 5 cc of a mixture containing phenol and acetonitrile (1: 1 ratio by wt.), anhydrous hydrogen chloride was bubbled for about 10 min. The acidic mixture was then diluted with the 1: 1 mixture of phenol and acetonitrile to make a solvent with the desired hydrogen chloride concentration. The exact normality (0.0234 N) was determined by titration with standard 0.05 N sodium acetate in acetic acid (crystal violet). A mixture of optically active 1-phenylethyl phenyl ether (0.8163 g, 0.00411 mol; bp 135—139°C/4.0 mmHg; $\alpha_D^{23.7}-6.41\pm0.02°$, 1 dm, neat) and the acidic solvent (41.7 cc) was maintained at 40.0±0.1°C for 5 hr. After the working-up described above, an oily material (1.2839 g) was chromatographed over basic alumina (40 g; Nakarai, Alumina Activated 200, *ca.* 200 mesh). Fractions 4—6, obtained using *n*-hexane - benzene (1: 1 by vol.), gave 2,3-diphenylbutane (0.0084 g; 1.94% yield). Fractions 8—11, obtained using *n*-hexane-benzene (1: 1 by vol.), gave *o*-(1-phenylethyl)-phenol (0.1908 g; bp 145—150°C/4.0 mmHg; 23.4% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{22.4}+2.85\pm0.32°$ (*c* 53.1, benzene)). Fractions 14—20, obtained using benzene, gave *p*-(1-phenylethyl)-phenol (0.6163 g; bp 155—158°C/5.0 mmHg; 75.8% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{22.3}+1.21\pm0.09°$ (*c* 73.6, benzene)).

The Acidic Rearrangement of Optically Active 1-Phenylethyl Phenyl Ether in the Phenol-1,2-Dichloroethane (1: 1 by Wt.) Solvent at 21°C. A mixture of phenol - 1,2-dichloroethane (1: 1 by wt.) containing the desired concentration of anhydrous hydrogen chloride (0.145 N, as determined by titration)

19) H. Meerwein, in Houben-Weyl, "Methoden der organischen Chemie," Georg Thieme Verlag, Stuttgart, (1965) Bd. VI/3, p. 338.

was prepared in a manner similar to that described above. To the acidic solvent (20.2 cc), optically active 1-phenylethyl phenyl ether (0.5871 g, 0.00298 mol; bp 140—145°C/4.0 mmHg; $\alpha_D^{19.2}$ −1.29±0.03°, 0.5 dm, neat) was added. The reaction mixture so prepared was allowed to stand at room temperature (21.0°C) for 0.5 hr. After the working-up described above, an oily material (0.5782 g) was chromatographed over silica gel (20 g). Fractions 2—5, obtained using *n*-hexane - benzene (1: 1 by vol.) and benzene, gave *o*-(1-phenylethyl)-phenol (0.2854 g; bp 145—151°C/4.0 mmHg; 48.6% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{22.0}$ +0.54± 0.06° (*c* 66.4, benzene)). Fractions 7—11, obtained using benzene and benzene - ether (97: 3 by vol.), gave *p*-(1-phenylethyl)-phenol (0.2069 g; bp 155—158°C/4.0 mmHg; 35.3% yield; the infrared spectrum was the same as that of an authentic sample; $[\alpha]_D^{22.0}$ −0.91±0.066° (*c* 45.2, benzene)).

The Acidic Rearrangement of Racemic 1-Phenylethyl Phenyl Ether in a Mixture of Phenol and Water (79: 21 to 66: 34 by Wt.) at from −6°C to +2°C. A mixture of phenol (37.6 g) and distilled water (10.0 g) was prepared. To 30 cc of the mixture, racemic 1-phenylethyl phenyl ether (0.9731 g; bp 140—145°C/4.0 mHg) was added. To the stirred mixture, concentrated hydrochloric acid (6.90 cc; Nakarai, reagent-grade quality, min. 35.5%) was added, drop by drop, over a 2-hr period at from −6.0°C to +2.0°C. After the working-up described above, an oily material (0.8975 g) was chromatographed over silica gel (30 g). Fractions 1—4, obtained using *n*-hexane - benzene (1: 1 by vol.), gave 1-phenylethyl phenyl ether (0.8751 g; 90.0% recov.; the infrared spectrum was the same as that of an authentic sample). Fractions 9—11, obtained using benzene, gave *o*-(1-phenylethyl)-phenol (0.0124 g; 0.0128% yield; the infrared spectrum was the same as that of an authentic sample). Fractions 14—17, obtained using benzene-ether (97: 3 by vol.), gave *p*-(1-phenylethyl)-phenol (0.0139 g; 0.0143% yield; the infrared spectrum was the same as that of an authentic sample).

Kinetic Measurements. The previous procedure[1] was followed; the usual sealed-ampoule (1.000 cc) technique was employed. The diminution of base concentrations was followed by titration with standard perchloric acid (0.05 N) in acetic acid, using crystal violet as the indicator. All the data were treated graphically by a plot of log $a/(a-x)$ against the time. In each case, the reaction was followed to at least 80% conversion; a smooth linear relationship was thus obtained. Infinity titers were determined after at least ten half-lives. The rate data are shown in Fig. 1 and Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1553—1556 (1970)

Reaction of *p*-Nitrophenyl Sulfate with Thiophenol

Takehiko KURUSU, Waichiro TAGAKI and Shigeru OAE

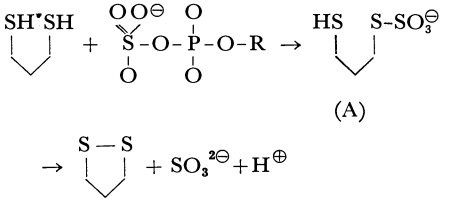
Department of Applied Chemistry, Faculty of Engineering Osaka City University, Sugimoto-cho, Sumiyoshiku, Osaka

(Received November 19, 1969)

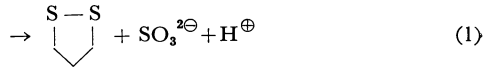
The reaction of *p*-nitrophenyl sulfate with *p*-substituted thiophenols were carried out in aqueous dimethylformamide under varying conditions. The rate was found to be independent of the concentration of thiophenolate, and to vary very little with the change of substituent. The Hammett correlation with σ value gives $\rho=0.12$. There was no rate-change in the pH range 6—12. Those observations seem to suggest the reaction to be of A-1 type.

Oxidation and reduction of organic sulfur compounds are important reactions in the metabolic pathway of living organisms.[1] However, the chemistry of these enzymatic processes, especially the reduction process, has not been investigated thoroughly.

An interesting model reaction for this enzymic reduction is that between organic sulfates and thiols. Hilz and Kittler[2] studied the reduction of sulfate ion to sulfite ion by lipoic acid, and suggested the following mechanism.



(A)



(1)

The reaction is actually a S_N2 type displacement reaction at a sulfur atom as shown by (A). It has to compete with the hydrolysis of the sulfate in aqueous media, especially in a high pH region,

1) F. Challenger, "Aspects of the Organic Chemistry of Sulfur," Academic Press, New York (1959). N. Kharasch, "The Chemistry of Organic Sulfur Compounds," Vol. 2, Pergamon Press, London, New York (1966).

2) H. Hilz. M. Kittler, *Biochem. Biophys. Res. Commun.*, **3**, 140 (1960).

since organic sulfates are considered to be hard acids[3] and hence would readily be attacked by hard bases, *i.e.*, $OH^{\ominus}$ ion in this case.

Thus, in order to understand the nature of oxidation and reduction on the sulfur atom of organic sulfur compounds, one should investigate the relative rates of alkaline hydrolysis and nucleophilic substitution of organic sulfates, as in the cases of aryl thiosulfonates,[4] aryl thiosulfate and aryl thiosulfonate.[5]

Hydrolysis of aryl sulfates has been studied considerably.[6] The mechanism suggested for the acid-catalyzed hydrolysis of alkyl sulfates involves the A-1 type cleavage of S–O bond.[7]

Kice and Anderson[8] studied the reaction in detail and concluded that the mechanism of the acid hydrolysis of sodium aryl sulfates is of A-1 type as shown by

$$ArOSO_3^{\ominus} + H^{\oplus} \overset{\text{fast}}{\rightleftarrows} Ar\text{-}\overset{\oplus}{O}(H)\text{-}SO_3^{\ominus} \xrightarrow{\text{slow}} ArOH + SO_3 \xrightarrow{\text{fast},\ H_2O} H_2SO_4 \qquad (2)$$

Benkovic[9] studied the pH-rate profile for the spontaneous hydrolysis of *p*-nitrophenyl sulfate and observed that the k_{obs} values are essentially independent of pH in the range 7—12, but change linearly with hydroxide ion concentration at higher pH values.

Thus, the spontaneous hydrolysis of *p*-nitrophenyl sulfate has been discussed in terms of a possible elimination of sulfur trioxide analogous to the monomeric metaphosphate formation in the hydrolysis of certain phosphate dianions. We have investigated the reaction of *p*-nitrophenyl sulfate with thiophenolate expecting it to result in the reduction of sulfate through nucleophilic substitution by thiol group.

Result and Discussion

An equimolar mixture of *p*-nitrophenyl sulfate and thiophenolate was heated in DMF in N_2 atmosphere in sealed tubes for 18 hr at 90°C. The products isolated were characterized by comparing the IR spectra, UV spectra and mps with those of the authentic samples. The products and yields are listed in Table 1.

Table 1. Product analysis of the reaction of *p*-nitrophenyl sulfate with thiophenolate[a]

Product		Yields[b] (%)
	(I)	94
	(II)	90
	(III)	5

a) In DMF 90°C, 18 hr in sealed tubes under nitrogen atmosphere.
b) Based on the ester used.
c) X=H

Two conceivable mechanisms for the reaction obtained from analysis of products are shown below. According to the mechanism of A-1 type, Eq. (3), the initial step of the reaction is S–O bond fission. Sulfur trioxide thus formed reacts immediately with thiophenolate to yield a Bunte salt (IV). In this case, the rate-determining step appears to be the elimination of sulfur trioxide. This seems to be analogous to the mechanism suggested for the solvolysis of phosphate esters which proceeds by way of monomeric metaphosphate intermediate.[7,10]

Sulfur trioxide thus formed incipiently can function as the sulfate donor in the synthesis of various biologically important organic sulfates.[11] Another possible path, shown as A-2 type,. is essentially a SN2-type reaction involving the nucleophilic replacement of *p*-nitrophenyl sulfate by thiophenolate. Reaction (a) is a simple synchronous SN2-type displacement reaction on sulfur atom, while reaction (b) proceeds *via* the initial addition of nucleophile to the benzene ring (bond making), followed by the leaving of sulfate group (bond breaking) to give *p*-nitrophenyl aryl sulfide.

The kinetics of the reaction of *p*-nitrophenyl sulfate with thiophenolate was studied spectrophotometrically by following the rate of formation of *p*-nitrophenolate (I).

A-1 type

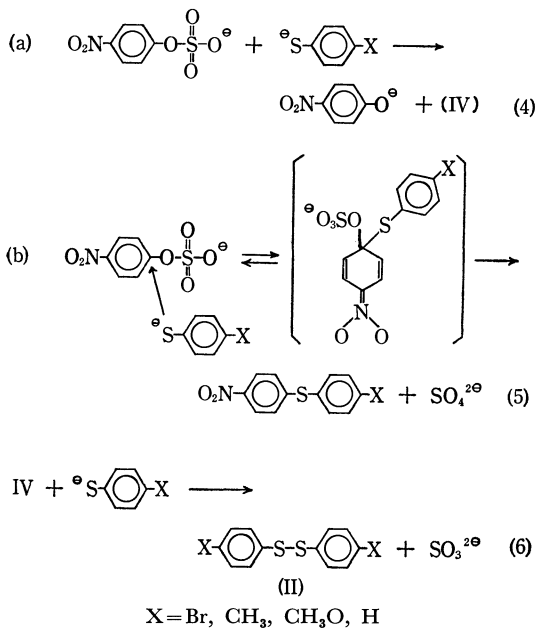
A-2 type



(4)

(5)

(6)

(II)

X=Br, CH_3, CH_3O, H

In order to avoid any complication due to possible side reactions, such as shown in Eq. (6), only the initial rate was used for calculation of the rate constants.

The pseudo-first-order constants of the reaction with substituted thiophenolate, k_{obs}, are listed in Table 2.

Table 2. Pseudo-first-order rate constants of the reaction of *p*-nitrophenyl sulfate with *p*-substituted thiophenols
(in DMF at 90°C)

X-	$k_{obs}\times10^6$ (sec^{-1})
p-Br	5.82
H	5.90
p-CH_3	6.14
p-CH_3O	6.40

It is apparent that the presence of electron-donor substituents in aromatic ring leads to only a very slight increase in the rate. From a good correlation with σ values, one can calculate the Hammett ρ value as +0.12. This means that the participation of nucleophilic attack by thiophenolate is very small at the transition state of the rate-determining step of this reaction. Therefore, the observed substituent effect seems to provide significant support for possible occurrence of an A-1 type pathway in (3).

The pH-rate profile for the reaction of *p*-nitrophenyl sulfate with thiophenol is shown in Fig. 1.

The k_{obs} values are independent of pH change in the range 6—12. Evidence supporting the A-1 type mechanism may be found in the pH-rate profile of the reaction, since the rate of A-2 type process varies with thiophilicity of thiophenol which in turn

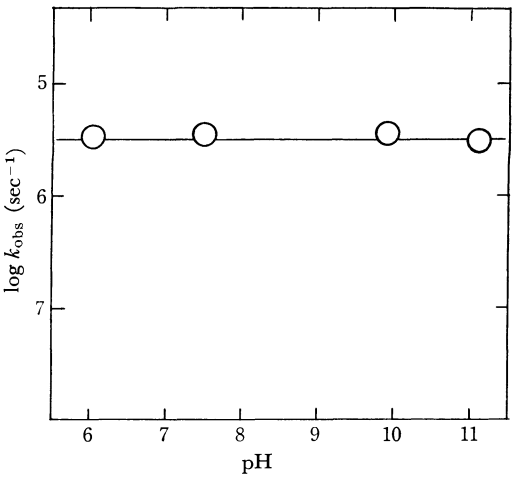


Fig. 1. The pH-rate profile for the reaction of *p*-nitrophenyl sulfate with thiophenyl (at 90°C, in 40% DMF-H_2O)

changes with pH of the reaction mixture. However, as Fig. 1 indicates, the difference in the rate is hardly discernible in the pH range 6—12. The mechanism of this reaction must be identical in this pH range and is very likely the A-1 type. Only at higher pH values or in the alkaline hydrolysis of *p*-nitrophenyl sulfate, the mechanism of A-1 type which depends on the first-power of hydroxide ion concentration may prevail. Thus, all these observations strongly suggest that the reaction of *p*-nitrophenyl sulfate with thiophenol proceeds by way of the A-1 type process.

Experimental

Reagents. *Potassium p-Nitrophenyl Sulfate.* This was prepared by a modification of procedure of Burkhardt and Lapworth.[12]

Chlorosulfonic acid (12 g) was slowly added pyridine (16 g) with stirring and cooling with ice-salt mixture. Benzene (100 cc) was then added, and the mixture was heated to 70°C. *p*-Nitrophenol (12 g) was then added, and the mixture was boiled for 4 hr, during which the pyridinium *p*-nitrophenyl sulfate crystallized out. The salt was then collected and poured into a slight excess of aqueous potassium hydroxide. After unchanged nitrophenol was extracted with ether, then water and pyridine were evaporated off *in vacuo*, potassium *p*-nitrophenol sulfate was obtained. It was purified by repeated recrystallization by dissolution in water and subsequent trituration with ethanol. The salt was dried under reduced pressure over calcium chloride, mp 203°C.

Found: C, 28.00; H, 1.60%. Calcd for $C_6H_4NO_6SK$: C, 28.01; H. 1.57%.

Solvent. *Buffer Solution.* 40% DMF-H_2O solvent was used in all pH solutions. At pH 6–8, KH_2PO_4–Na_2HPO_4 buffer was employed. pH~10 Na_2CO_3–$Na_2B_4O_7$ $10H_2O$, pH 11, NaOH (N/10)–Na_2HPO_4(M/

12) G. N. Burkhardt and A. Lapworth, *J. Chem. Soc.*, **1926**, 684.

10). The pH of the reaction mixtures were measured at 25°C by pH-meter (Horiba, Model-p, No. 17317).

Procedure for Kinetic Runs. Each kinetic run was carried out by monitoring the UV absorbance of *p*-nitrophenolate liberated during the reaction at 400 mμ. At first the solution of *p*-nitrophenyl sulfate (0.01 M 10 m*l*) in DMF was placed in a reaction vessel and immersed in a constant temperature bath which was kept at 90±0.05°C. 10 m*l* of thiophenoxide solution was then added to the ester solution. The reaction was followed by taking out 1 m*l* aliquots at suitable time intervals, diluting these aliquots with 25 m*l* of 0.01 N KOH–ethanol solution, and finally subjecting the solution for measurement of the optical density of the resulting solution at 400 mμ ($\varepsilon=18000$). The calculation of the rate constants was described in detail in earlier studies on the reaction of *p*-nitrophenyl benzenesulfonate with thiophenol.[3]

The Reaction of *p*-Nitrophenyl Sulfate with Thiophenolate. *p*-Nitrophenyl sulfate (4.8 g) and thiophenolate (2.6 g) were dissolved in DMF (20 cc) in an ampoule. The ampoule was sealed under N_2 atmosphere and then kept at 90°C for 18 hr. The solvent of the reaction mixture was evaporated off *in vacuo* and the residue was poured into water and extracted with ether. Work up of the ether layer gave (6.9 g) a mixture of *p*-nitrophenol, diphenyl disulfide and *p*-nitrophenyl phenyl sulfide. They were isolated by chromatography on alumina. The yield of *p*-nitrophenol could also be obtained spectrophotometrically in alkaline solution. The products and yields are listed in Table 1.

Ribonuclease T_1 Peptides. IV. Synthesis of a Protected Heptapeptide Corresponding to Sequence 17—23

Nobuo MITSUYASU, Michinori WAKI, Tetsuo KATO, Satoru MAKISUMI and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received December 8, 1969)

A protected heptapeptide corresponding to sequence 17—23 of ribonuclease T_1, namely benzyloxycarbonyl-L-seryl-L-threonyl-L-alanyl-L-glutaminyl-L-alanyl-L-alanyl-glycine ethyl ester (XIV), was synthesized by two routes. One consisted of the coupling of benzyloxycarbonyl-seryl-threonine azide with a pentapeptide ester, alanyl-glutaminyl-alanyl-alanyl-glycine ethyl ester. The other consisted of the coupling of benzyloxycarbonyl-seryl-threonyl-alanine azide with a tetrapeptide ester, glutaminyl-alanyl-alanyl-glycine ethyl ester. These four peptide segments were built up by the method of stepwise synthesis. Optical rotations, melting points and chromatographic behavior of XIV prepared by these two routes were found to be identical. Stereochemical homogeneity of the protected heptapeptide ester XIV was established by the digestion of the deblocked heptapeptide ester with leucine aminopeptidase.

Syntheses of the protected *N*-terminal undecapeptide (1—11) of ribonuclease T_1 containing asparagine residue in the 3rd position,[1] the protected pentapeptide (12—16)[2] and the heptapeptide (24—30)[3] were previously reported. In the present paper, we will describe the synthesis of the protected heptapeptide corresponding to the sequence 17—23, that is Z-Ser-Thr-Ala-Gln-Ala-Ala-Gly-OEt (XIV).[4] This heptapeptide sequence contains several functional groups, two hydroxys of serine and threonine and an acid amide of glutamine, in a rather short peptide, so the preparation of this compound seems to be interesting as an object of organic synthesis of a peptide.

The sequence of reaction for the synthesis of the desired compound XIV is shown in Fig. 1. The syntheses of the two C-terminal peptide segments, H-Gln-Ala-Ala-Gly-OEt·HCl (VI) and H-Ala-Gln-Ala-Ala-Gly-OEt·HCl (VIII), were achieved follows. Z-Ala-Ala-Gly-OEt (III) was prepared by coupling of H-Ala-Gly-OEt[5] with benzyloxycarbonyl-alanine *p*-nitrophenyl ester or a mixed

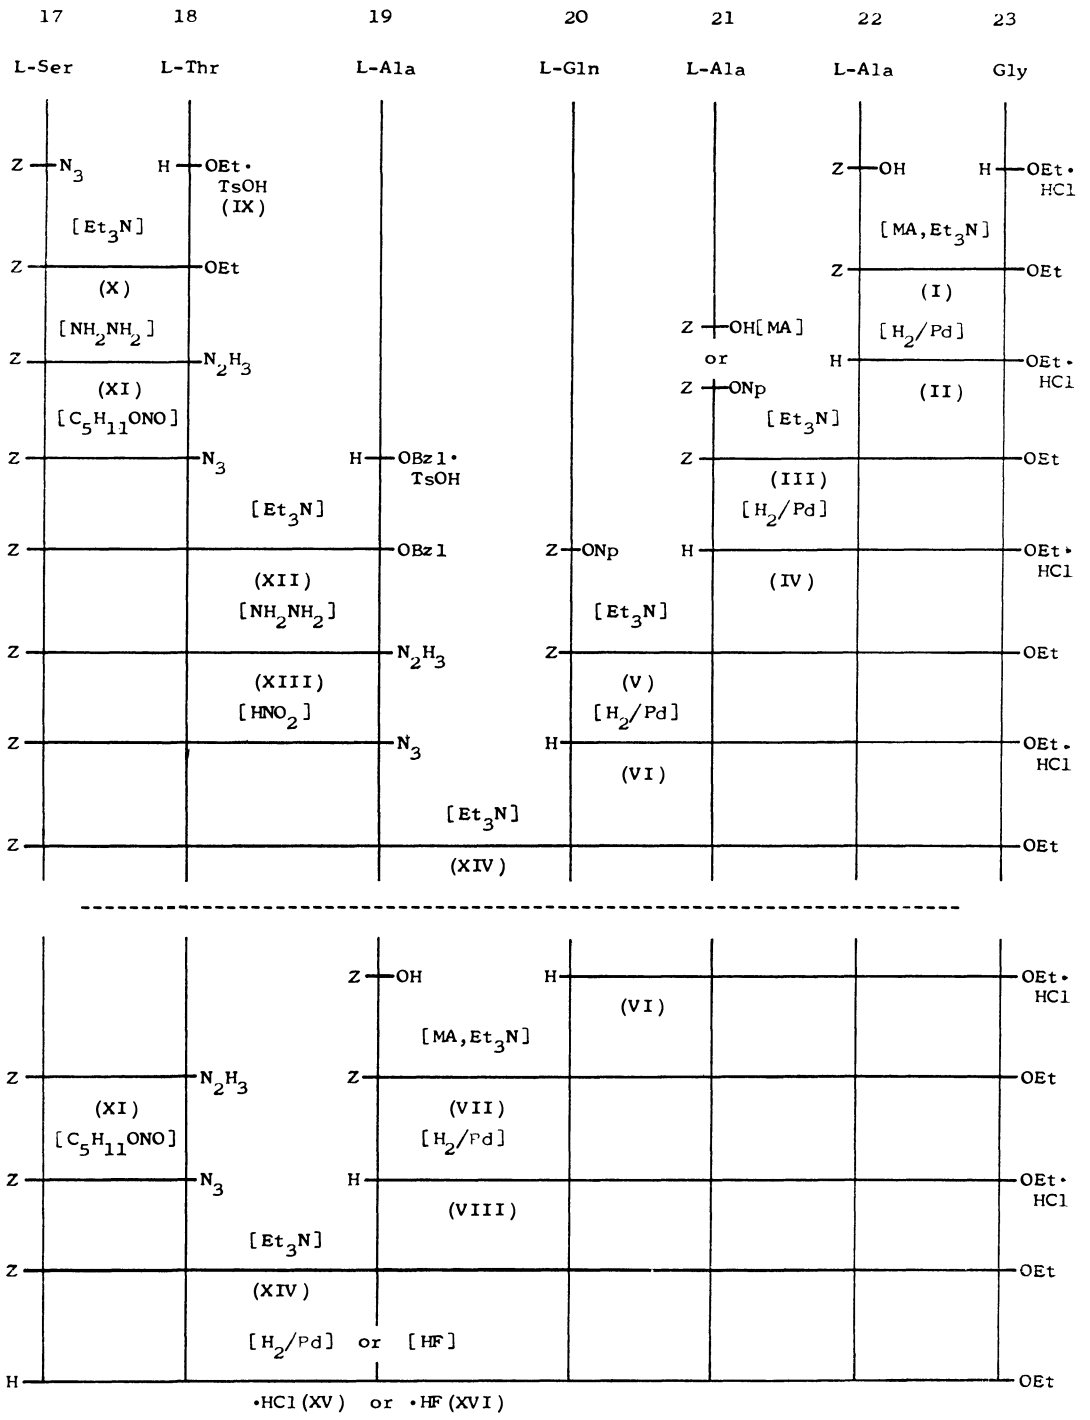

Fig. 1. Schematic diagram of synthesis of the heptapeptide ester.

anhydride[6] of benzyloxycarbonyl-alanine. The compound III was catalytically hydrogenated to yield the tripeptide ester hydrochloride (IV), which was then coupled with benzyloxycarbonyl-glutamine *p*-nitrophenyl ester. The protected tetrapeptide (V) obtained was suspended in methanol containing an equivalent hydrogen chloride and then hydrogenated to afford the tetrapeptide ester hydrochloride (VI) in a good yield. Z–Ala–Gln–

6) J. R. Vaughan, Jr. and R. L. Osato, *J. Amer. Chem. Soc.*, **73**, 5553 (1951).

Ala–Ala–Gly–OEt (VII) was prepared by coupling of benzyloxycarbonyl-alanine with VI by the mixed anhydride method in DMF because of poor solubility of VII. Compound VII thus obtained was hydrogenated as described for the preparation of VI to give the pentapeptide ester hydrochloride (VIII).

Synthesis of Z–Ser–Thr–N_2H_3 (XI) was reported previously.[7] Another *N*-terminal peptide segment, Z–Ser–Thr–Ala–N_2H_3 (XIII) was prepared as follows. The azide derived from the corresponding hydrazide XI was coupled with alanine benzyl ester to afford the acyl tripeptide ester, Z–Ser–Thr–Ala–OBzl (XII). The product obtained was converted to the hydrazide (XIII) by treatment with 2 equivalent of hydrazine.

For the synthesis of the desired protected heptapeptide ester, Z–Ser–Thr–Ala–Gln–Ala–Ala–Gly–OEt (XIV), two routes were developed (Fig. 1). The acyldipeptide azide derived from XI using isoamyl nitrite[8] was allowed to react with the pentapeptide ester (VIII) in DMF to give the desired protected heptapeptide ester (XIV) as a crystalline product. Compound XIV was obtained by condensation of the acyltripeptide azide derived from XIII with the tetrapeptide ester (VI) in a solvent of DMF. The optical rotation, melting point and chromatographic behavior of XIV prepared by these two routes were found to be identical.

For decarbobenzoxylation of the protected heptapeptide ester XIV, an attempt was made to perform catalytic hydrogenation of XIV in the presence of an equivalent of hydrogen chloride in methanol or DMF, but pure heptapeptide ester could not be obtained because of the insoluble character of XIV in an ordinary solvent. When XIV was subjected to hydrogenolysis in the presence of an equivalent of ethanolic hydrogen chloride in hexamethyl phosphoramide,[9] pure crystalline heptapeptide ester hydrochloride (XV) could be obtained. Thus, it was found that hexamethyl phosphoramide was a useful solvent for the hydrogenation of a sparingly soluble compound. The decarbobenzoxylation of XIV was performed by treatment of anhydrous hydrogen fluoride,[10] and pure crystalline heptapeptide ester hydrofluoride (XVI) was isolated. Homogeneity of the peptides, XV and XVI, was ascertained by thin-layer chromatography and by amino acid analysis on the acid hydrolysates of XV and XVI. Stereospecific homogeneity of the peptide XV was ascertained by digestion with leucine aminopeptidase.

Experimental

Melting points were uncorrected. Most of the optical rotations were measured on a Yanagimoto Photometric Polarimeter, OR-20 type, and some on a JASCO Model DIP–SL. Prior to analysis, samples were dried over phosphorus pentoxide at 60°C and 2 mmHg to a constant weight. Paper chromatography was carried out on Toyo Roshi No. 52 chromatography paper with the following solvent systems; R_f^1, *n*-butanol–acetic acid–pyridine–water, 4: 1: 1: 2 v/v. Thin-layer chromatography was carried out on Merck silica gel G with the following solvent systems; R_f^1, *n*-butanol–acetic acid–pyridine–water, 4: 1: 1: 2 v/v; R_f^2, *s*-butanol–formic acid–water, 75: 15: 10 v/v; R_f^3, chloroform–methanol, 5: 1 v/v; R_f^4, *n*-butanol–acetic acid–water, 4: 1: 2 v/v. Spots of materials possessing a free amino group on chromatograms were detected by spraying ninhydrin, and those of the amino group-blocked materials, by spraying 47% hydrobromic acid and then ninhydrin.

Z-Ala-Ala-Gly-OEt (III). (*a*) *Mixed Acid Anhydride Method.*[6] To a chilled solution of benzyloxycarbonyl-alanine (4.68 g, 21 mmol) and triethylamine (2.94 m*l*, 21 mmol) in tetrahydrofuran (40 m*l*), isobutyl chloroformate (2.75 m*l*, 21 mmol) was added. After 15 min, a chilled mixture of H–Ala–Gly–OEt·HCl[5] (II) (4.42 g, 21 mmol), triethylamine (2.94 m*l*, 21 mmol) and chloroform (40 m*l*) was added to the solution. The reaction mixture was stirred for one hour at 0°C, allowed to stand overnight at room temperature, and then evaporated to dryness *in vacuo*. The residual oil was extracted with ethyl acetate, and the solution was washed successively with a 3% sodium bicarbonate solution, 0.5 M citric acid and water, and dried over sodium sulfate. The filtered solution was concentrated *in vacuo* and the residual oil was crystallized after addition of ether and petroleum ether (5.0 g). It was recrystallized from ethanol–ether. Yield, 4.42 g (55%); mp 174—177°C; R_f^1 0.85; $[\alpha]_D^{15}$ −5.6° (*c* 2, DMF).

Found: C, 57.08; H, 6.43; N, 11.17%. Calcd for $C_{18}H_{25}O_6N_3$: C, 56.98; H, 6.64; N, 11.08%.

(*b*) *Active Ester Method.*[11] To a solution of II (0.84 g, 4 mmol) in a mixture of triethylamine (0.62 m*l*, 4 mmol) and DMF (5 m*l*), a solution of benzyloxycarbonyl-alanine *p*-nitrophenyl ester (1.38 g, 4 mmol) in DMF (5 m*l*) was added. The reaction mixture was allowed to stand overnight at room temperature, evaporated *in vacuo* and then extracted with ethyl acetate. The solution was treated by the same procedure as described above. Yield, 1.00 g (66%); mp 176—177°C; R_f^1 0.87; $[\alpha]_D^{15}$ −5.2° (*c* 2, DMF).

H-Ala-Ala-Gly-OEt·HCl (IV). A solution of III (2.66 g, 7 mmol) in a mixture of 0.52 N ethanolic hydrogen chloride (14.8 m*l*, 7.7 mmol) and ethanol (80 m*l*) was hydrogenated in the presence of palladium black. After 5 hr the filtrate from the catalyst was evaporated *in vacuo* and the residual oil was crystallized after addition

of ethyl acetate and ether. Yield, 1.88 g (95%); mp 187—188°C; R_f^1 0.57; R_f^I 0.70; $[\alpha]_D^{20}$ −2.8° (*c* 1, DMF).

Found: C, 42.58; H, 7.13; N, 14.60%. Calcd for $C_{10}H_{19}O_4N_3 \cdot HCl$: C, 42.63; H, 7.16; N, 14.91%.

Z-Gln-Ala-Ala-Gly-OEt (V). To a solution of IV (3.10 g, 11 mmol) in a mixture of triethylamine (1.68 m*l*, 12 mmol) and DMF (15 m*l*), was added a solution of benzyloxycarbonyl-glutamine *p*-nitrophenyl ester (4.42 g, 11 mmol) in DMF (5 m*l*). After it had been stood overnight at room temperature, the reaction mixture was diluted with 200 m*l* of water. The crystalline product deposited was collected by filtration and washed successively with a 3% sodium bicarbonate solution, 0.5 M citric acid and water (4.12 g). It was recrystallized from DMF-ethanol-ether. Yield, 4.04 g (73%); mp 223—225°C; R_f^1 0.75; $[\alpha]_D^{15}$ −18.0° (*c* 1, DMSO).

Found: C, 54.66; H, 6.64; N, 13.71%. Calcd for $C_{23}H_{33}O_8N_5$: C, 54.43; H, 6.55; N, 13.80%.

H-Gln-Ala-Ala-Gly-OEt·HCl (VI). A suspension of V (2.54 g, 5 mmol) in a mixture of methanol (75 m*l*) and 0.48 N methanolic hydrogen chloride (11.7 m*l*, 5.5 mmol) was hydrogenated in the presence of palladium black. After 7 hr the filtrate from the catalyst was concentrated *in vacuo* and the residual oil was crystallized after addition of ether. Yield, 1.82 g (89%); mp 176—179°C; R_f^1 0.56; R_f^I 0.58; $[\alpha]_D^{15}$ −6.3° (*c* 0.24, DMF).

Found: C, 43.44; H, 6.92; N, 16.62%. Calcd for $C_{15}H_{27}O_6N_5 \cdot HCl \cdot 1/2H_2O$: C, 43.01; H, 6.98; N, 16.72%.

Z-Ala-Gln-Ala-Ala-Gly-OEt (VII). To a chilled solution of benzyloxycarbonyl-alanine (0.89 g, 4 mmol) and triethylamine (0.56 m*l*) in tetrahydrofuran (5 m*l*), isobutyl chloroformate (0.52 m*l*, 4 mmol) was added. After 15 min, a precooled solution of VI (1.64 g, 4 mmol) in a mixture of triethylamine (0.56 m*l*) and DMF (25 m*l*) was added to the above solution. The reaction mixture was stirred for one hour at 0°C, allowed to stand overnight at room temperature and then concentrated *in vacuo*. Water (100 m*l*) was added to the residual oil and the crystalline product deposited was collected by filtration and washed as described for V (1.58 g). It was recrystallized from DMF-methanol-ether. Yield, 1.47 g (62%); mp 254—255°C; R_f^1 0.78; R_f^2 0.68; $[\alpha]_D^{15}$ −20.0° (*c* 1, DMSO).

Found: C, 53.38: H, 6.85; N, 14.50%. Calcd for $C_{26}H_{38}O_9N_6 \cdot 1/2H_2O$: C, 53.14; H, 6.69; N, 14.30%.

H-Ala-Gln-Ala-Ala-Gly-OEt·HCl (VIII). A suspension of VII (0.29 g, 0.5 mmol) in a mixture of DMF (10 m*l*) and 0.48 N methanolic hydrogen chloride (1.14 m*l*, 0.55 mmol) was hydrogenated in the presence of palladium black. After 6 hr the filtrate from the catalyst was evaporated *in vacuo* and the residual oil was crystallized after the addition of ethanol and ether. Yield, 0.23 g (97%); mp 206—208°C; R_f^1 0.52; $[\alpha]_D^{15}$ −17.0° (*c* 1, DMSO).

Found: C, 43.46; H, 7.16; N, 16.80%. Calcd for $C_{18}H_{32}O_7N_6 \cdot HCl \cdot H_2O$: C, 43.33; H, 7.07; N, 16.84%.

Z-Ser-Thr-Ala-OBzl (XII). To a chilled (−5°C) solution of Z-Ser-Thr-N_2H_3[7] (XI) (6.74 g, 19 mmol) in a mixture of 2 N hydrochloric acid (35 m*l*) and DMF (15 m*l*), N sodium nitrite (20 m*l*) was added. After it had been stood for 10 min, the precipitated azide was extracted with ethyl acetate (200 m*l*), washed with a 3% sodium bicarbonate solution and water, and then dried over sodium sulfate at 0°C. To the filtrate from the desiccant was added a precooled mixture of alanine benzyl ester *p*-toluenesulfonate[12] (8.08 g, 23 mmol) and triethylamine (3.22 m*l*, 23 mmol) in ethyl acetate (60 m*l*). After the reaction mixture had been stirred for 2 days at 0°C, it was washed successively with a 3% sodium bicarbonate solution, 0.5 M citric acid and water, dried over sodium sulfate, and then evaporated *in vacuo*. The residual oil was crystallized by the addition of ether and petroleum ether and the crystals were collected by filtration (5.11 g). It was recrystallized from ethanol-ether-petroleum ether. Yield, 4.82 g (51%); mp 149—150°C; R_f^1 0.87; R_f^3 0.49; R_f^4 0.95, $[\alpha]_D^{15}$ −7.0° (*c* 1, DMF).

Found: C, 59.47; H, 6.31; N, 8.28%. Calcd for $C_{25}H_{31}O_8N_3$: C, 59.84; H, 6.23; N, 8.38%.

Z-Ser-Thr-Ala-N_2H_3 (XIII). A solution of XII (2.50 g, 5 mmol) and hydrazine hydrate (0.485 m*l*, 10 mmol) in DMF (20 m*l*) was allowed to stand overnight at room temperature, and the reaction mixture was evaporated *in vacuo*. The residual oil was solidified by the addition of ether, and the crystals were collected by filtration (2.12 g). It was recrystallized from hot water. Yield, 1.17 g (60%); mp 212—214°C; R_f^1 0.77; R_f^3 0.36; R_f^4 0.77; $[\alpha]_D^{15}$ −9.5° (*c* 1, DMSO).

Found: C, 49.88; H, 6.48; N, 16.29%. Calcd for $C_{18}H_{27}O_7N_5 \cdot 1/2H_2O$: C, 49.76; H, 6.50; N, 16.12%.

Z-Ser-Thr-Ala-Gln-Ala-Ala-Gly-OEt (XIV). (*a*) *Condensation of Z-Ser-Thr-N_3 and H-Ala-Gln-Ala-Ala-Gly-OEt·HCl. (VIII).* To a chilled (−5°C) solution of XI (142 mg, 0.4 mmol) in a mixture of DMF (4 m*l*) and 0.45 N hydrogen chloride-tetrahydrofuran (1.79 m*l*) was added isoamyl nitrite[8] (0.054 m*l*, 0.4 mmol). After 10 min, triethylamine (0.112 m*l*, 0.8 mmol) was added. To the solution was added a precooled mixture of VIII (192 mg, 0.4 mmol), triethylamine (0.056 m*l*, 0.4 mmol) and DMF (10 m*l*). The reaction mixture was then stirred for 2 days at 0°C and then evaporated *in vacuo*. The residual oil was crystallized by the addition of water. The crystals were collected by filtration and washed as described for V (153 mg). It was recrystallized from DMSO-ethanol-ether. Yield, 138 mg (45%); mp 251—253°C; R_f^1 0.82; R_f^2 0.79; R_f^3 0.65; $[\alpha]_D^{20}$ −15.8° (*c* 1, DMSO).

Found: C, 50.46; H, 6.69; N, 14.15%. Calcd for $C_{33}H_{50}O_{13}N_8 \cdot H_2O$: C, 50.25; H, 6.55; N, 14.21%.

(*b*) *Condensation of Z-Ser-Thr-Ala-N_3 and H-Gln-Ala-Ala-Gly-OEt (VI).* To a chilled solution of XIII (213 mg, 0.5 mmol) in a mixture of acetic acid (0.5 m*l*), water (2 m*l*) and N hydrochloric acid (0.6 m*l*) was added N sodium nitrite (0.6 m*l*). After 10 min, the reaction mixture was diluted with water (20 m*l*). The precipitated azide was collected by filtration, washed with a 3% sodium bicarbonate solution and water, and then dried *in vacuo* at 0°C. To a chilled solution of VI (205 mg, 0.5 mmol) dissolved in a mixture of DMF (10 m*l*) and triethylamine (0.07 m*l*, 0.5 mmol) was added the azide prepared before. The solution was stirred for 2 days at 0°C and then diluted with water (30 m*l*). The precipitate was collected by filtration and washed as described for V (211 mg). It was recrystallized from DMSO-ethanol-ether. Yield, 196 mg (51%); mp 251—252°C; R_f^1 0.83; $[\alpha]_D^{20}$ −15.6° (*c* 1, DMSO).

Found: C, 50.34; H, 6.63; N, 14.11%. Calcd for $C_{33}H_{50}O_{13}N_8 \cdot H_2O$: C, 50.25; H, 6.65; N, 14.21%.

H-Ser-Thr-Ala-Gln-Ala-Ala-Gly-OEt·HCl (XV). A solution of XIV (39 mg, 50 μmol) dissolved in hexamethyl phosphoramide[9] (6 ml) containing 3.4 N ethanolic hydrogen chloride (0.018 ml, 60 μmol) was hydrogenated in the presence of palladium black. After 24 hr, the solution was diluted with petroleum ether (50 ml) and an oil was precipitated. In order to remove hexamethyl phosphoramide completely, the resulting oil was washed twice with petroleum ether by decantation and then triturated with ethanol and ether to afford powder (32 mg). It was recrystallized from DMSO-ethanol-ether. Yield, 28 mg (83%); mp 220—225°C (decomp.); R_f^1 0.55; amino acid ratios in acid hydrolysate,[13] Thr 0.90, Ser 0.86, Glu 1.00, Gly 1.00, Ala, 3.33.

In order to establish the stereochemical homogeneity of XV, a small amount of XV was digested by leucine aminopeptidase following essentially the same procedure as that of Hofmann and Yajima;[14] amino acid ratios[13] in the digest, Thr+Gln 1.78, Ser 1.11, Gly 0.80, Ala 3.31.

H-Ser-Thr-Ala-Gln-Ala-Ala-Gly-OEt·HF (XVI). Compound XIV (39 mg, 50 μmol) was placed in a vessel together with a drop of anisole.[10] HF (1 ml) was added into the vessel using an HF-reaction apparatus,[10] and the mixture was allowed to react at 0°C for 1 hr with stirring. Excess HF was removed under reduced pressure at 0°C, and the residue was kept at reduced pressure (3 mmHg) for 5 hr at room temperature over calcium chloride and sodium hydroxide. The oily residue was washed with ethanol by decantation and then dissolved in DMSO. After the insoluble material in small amount was filtered off, the filtrate was evaporated *in vacuo*. The residual oil was crystallized with the addition of ethanol and the crystals were collected by filtration. Yield, 29 mg (92%); mp 235—240°C (decomp.); R_f^1 0.50; amino acid ratios in acid hydrolysate,[13] Thr 0.93, Ser 0.93, Glu 0.99, Gly 1.00, Ala 3.21.

13) We are indebted to Mr. K. Noda in this laboratory for the amino acid analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1560—1563 (1970)

The Total Synthesis of (±)-Isoelliptone*1

Teruo HARANO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 10, 1969)

The condensation of 2′-hydroxy-4′,5′-dimethoxyfurano[3″,2″ : 6,7]isoflavone with ethyl bromoacetate in the presence of potassium carbonate gave the 2′-phenoxyacetate derivative. The subsequent treatment of this compound with dilute alkali gave isoelliptic acid. By the ring closure of the acid with acetic anhydride and anhydrous sodium acetate, or by the treatment of its ester with sodium methoxide, dehydroisoelliptone was obtained. The reduction of this compound with sodium borohydride, followed by Oppenauer oxidation, yielded isoelliptone, *via* a reduced compound, isoelliptol.

Isoelliptone[1] (erosone)[2] has been isolated, along with some rotenoids (*e.g.*, rotenone and pachyrrhizone), from yam beans (*Pachyrrhizus erosus*). Its chemical structure was shown to be an isomer of elliptone (I)[3] by Norton and Hansberry,[2] and has lately been identified as II on the basis of spectral studies by Ollis *et al.*[1,4] Derrisic acid derivatives are important intermediates in synthesizing some rotenoids (*e.g.*, munduserone,[5] rotenone,[6] deguelin[7] and elliptone[8]). These acids have been prepared from the corresponding phenols and ethyl (2-cyanomethyl-4,5-dimethoxyphenyl)acetate (III) by the Hoesch reaction. The preparation of the acetate III was, however, troublesome and did not give satisfactory results. Recntly, the present author has been reported a convenient method of synthesizing derrisic acid derivatives from the corresponding

2′-hydroxyisoflavone derivatives.[9,10] The present paper will describe the total syntehsis of (±)-II from 2′-hydroxy-4′,5′-dimethoxyfurano[3″,2″ : 6,7]-isoflavone (IV),[11,12] *via* isoelliptic acid (VI) or its methyl ester (VII).

The reaction of the 2′-hydroxyisoflavone (IV) with ethyl bromoacetate in the presence of anhydrous potassium carbonate in acetone gave a 2′-phenoxyacetate (V), mp 180—181°C, in a good yield. The treatment of V with alcoholic potassium hydroxide afforded an acid (VI), mp 216—217°C, which yielded its methyl ester (VII), mp 134—135°C, when treated with diazomethane in dioxane. The NMR spectrum*[2] of VII indicates the presence of a phenolic group at δ 12.36 ; this group is located at the position *ortho* to the carbonyl group and forms an intramolecular hydrogen bonding. Further, the signals of two methylene groups appear at δ 4.40 and 4.60 (Fig. 1). On the basis of these facts, the structure of VII was identified as 5-ω-(2-methoxycarbonylmethoxy - 4,5 - dimethoxyphenyl)acetyl - 6-hydroxycoumarone. The cyclization of the VI acid with acetic anhydride containing sodium acetate and a trace of acetic acid[13] gave dehydroisoelliptone (VIII), mp 266—268°C, in a poor yield (*ca.* 20%). The treatment of VII with sodium methoxide[14] was, however, found to be a suitable way to prepare it (yield: *ca.* 80%). The NMR spectrum of VIII exhibits the signals of olefinic protons at δ 6.95(1H, q, J=2.0 and 1.0 Hz, $C_{4'}$–H) and 7.77 (1H, d, J= 2.0 Hz, $C_{5'}$–H) due to a disubstituted furan ring. In addition, the signals of methoxyl, methylene, and aromatic protons are observed at δ 3.90_s, 4.00_s (each 3H, $OC\underline{H}_3$); 5.07_s (2H, $-C\underline{H}_2O-$); 6.59_s (1H, C_4–H), 7.59_s (1H, C_8–H), and 8.52_s and 8.59_s (each 1H, C_1– and C_{11}–H). According to the method of Miyano and Matsui,[15] VIII was reduced

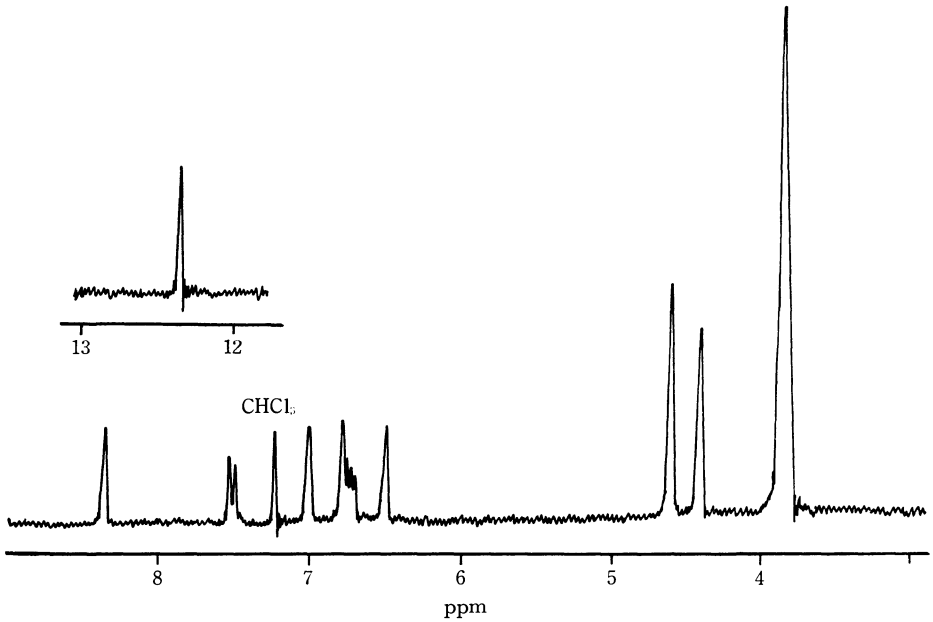

Fig. 1. The NMR spectrum of VII.

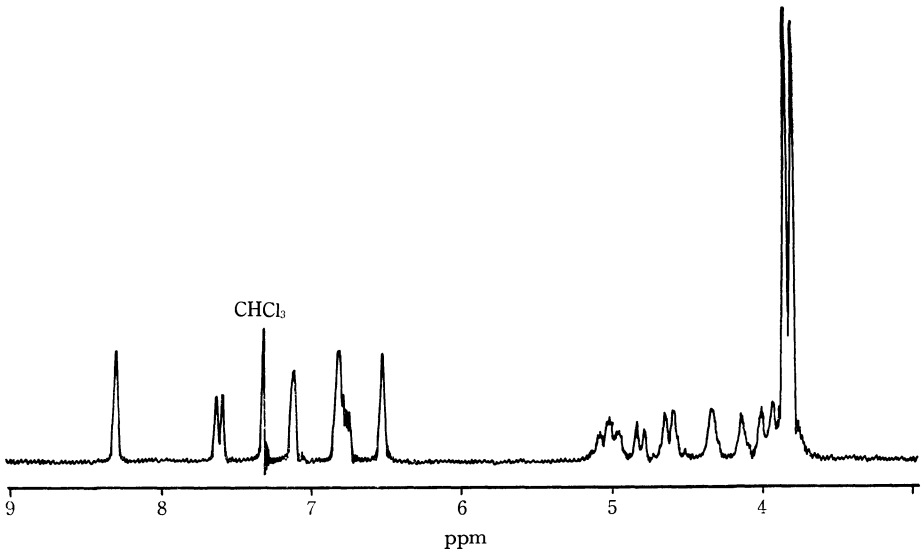

Fig. 2. The NMR spectrum of II.

with sodium borohydride in dioxane, subsequently, without any purification, Oppenauer oxidation gave (±)-isoelliptone (II), mp 215—216°C. The IR spectrum of II shows an absorption of the carbonyl at 1680 cm^{-1}. In the NMR spectrum of II, the signals due to the four protons in the positions 6, 6_a, and 12_a are observed at δ 3.9—5.2 as an ABCD system, and the signal of a proton in the position 1 shows an upper shift at δ 6.83 (Fig. 2).

These data are in accord with those reported by Ollis *et al.*[16] and by Crombie and Lown.[17] Furthermore, in the mass spectrum*3 of II the parent ion peak (M^+) appears at m/e=352 and the fragment ions are observed at 192, 191, 177, 161, 160, 149, 134, 131, 121, and 106. This mass spectrum is identical with that of natural isoelliptone, which has been previously reported by Reed and Wilson.[4]

Experimental*4

4′, 5′-Dimethoxy-2′-ethoxycarbonylmethoxyfurano[3″,2″: 6,7]isoflavone (V). A mixture of 4′,5′-dimethoxy-2′-hydroxyfurano[3″,2″:6,7]isoflavone (IV) (1.1 g), ethyl bromoacetate (700 mg), and anhydrous potassium carbonate (4.0 g) in acetone (80 m*l*) was refluxed for 24 hr. After the inorganic precipitates had been filtered off, the solvent was condensed to 10 m*l* and the residual solution was diluted with water. The separated solid was collected, washed with water, and then crystallized from ethanol to give V as colorless needless; mp 180—181°C; yield, 1.1 g. IR: 1725, 1653 cm^{-1} (C=O); UV: λ_{max}^{EtOH} mμ (log ε): 237 (4.54) 297 (4.10).

Found: C, 65.02; H, 4.70%. Calcd for $C_{23}H_{20}O_8$: C, 65.09; H, 4.75%.

Isoelliptic Acid (5-ω-(2-Carboxymethoxy-4,5-dimethoxyphenyl)acetyl-6-hydroxycoumarone) (VI). A mixture of V (1.0 g) and a 10% potassium hydroxide solution (40 m*l*) in ethanol (100 m*l*) was refluxed on an oil bath for 2 hr. The solvent was then removed as much as possible and acidified with 10% hydrochloric acid. After the separated solid had been extracted with ethyl acetate, the extract was washed with water and dried on sodium sulfate. The solvent was removed and the residual solid was crystallized from ethanol to give VI as yellow prisms; mp 216—217°C; yield, 800 mg. This substance gave a green color with alcoholic ferric chloride. IR: 3250 (OH), 1730, 1640 cm^{-1} (C=O); UV: λ_{max}^{EtOH} mμ (log ε): 233 (4.56), 278 (4.02), 340 (3.81).

Found: C, 62.04; H, 4.83%. Calcd for $C_{20}H_{18}O_8$: C, 62.17; H, 4.70%.

Methyl Ester (VII) of VI. To a solution of VI (1.0 g) in refreshed dioxane (100 m*l*), the ethereal diazomethane was added; the mixture was then allowed to stand overnight. The solvent was removed under reduced pressure to dryness, and the residue was crystallized from ethanol to give VII as light yellow needles; mp 134—135°C; yield, 950 mg. This substance gave a green color with alcoholic ferric chloride. IR: 1760, 1640 cm^{-1} (C=O); UV: λ_{max}^{EtOH} mμ (log ε): 236 (4.52), 264_i*5 (3.83), 281 (4.03), 334 (3.83). NMR: 383_s (9H), 6.51_s, 6.80_s, 7.01_s, 8.37_s (each 1 H), 6.75_q (1 H, J=2.0 and 1.0 Hz), 7.52_d (1 H, J=2.0 Hz).

Found: C, 62.96; H, 5.20%. Calcd for $C_{21}H_{20}O_8$: C, 62.99; H, 5.04%.

Dehydroisoelliptone (VIII). *a) With Acetic Anhydride-Anhydrous Sodium Acetate.* A mixture of VI (700 mg), acetic anhydride (15 m*l*), anhydrous sodium acetate (450 mg), and acetic acid (0.7 m*l*) was warmed at 120°C for 20 min. After the reaction mixture had been cooled, it was poured into ice water. The separated solid was then collected, washed with water, a large amount of a saturated sodium bicarbonate solution, and water again, and then dried under reduced pressure. The solid was chromatographed on silica gel (*ca.* 10 g) in dichloromethane and crystallized from dichloromethane-ethanol (1: 1 v/v) to give VIII as light yellow microneedles; mp 266—268°C; yield, 200 mg. IR: 1633 cm^{-1} (C=O); UV: λ_{max}^{EtOH} mμ (log ε): 237.5 (4.51), 273 (4.39), 307 (4.30).

Found: C, 68.40; H, 4.09%. Calcd for $C_{20}H_{14}O_6$: C, 68.57; H, 4.03%.

b) With Sodium Methoxide. To a refluxing solution of VII (0.9 g) in anhydrous methanol (90 m*l*), a sodium methoxide solution (prepared from 50 mg of Na and 5 m*l* of anhydrous methanol) was added dropwise for 30 min period. The mixture was refluxed for 3 hr and then allowed to stand overnight. The crystals which had been deposited were dissolved in dichloromethane, passed through a short column of silica gel (*ca.* 10 g), and crystallized from dichloromethane-ethanol (1: 1 v/v) to give VIII as light yellow needles; mp 265—267°C; yield, 750 mg. This compound was identical in all respects with the sample described above a).

Isoelliptone (II). A solution of sodium borohydride (100 mg) in absolute ethanol (10 m*l*) was added to a solution of VIII (200 mg) in dioxane (10 m*l*). The mixture was warmed at 50—60°C for 30 min and then allowed to stand overnight at room temperature. Acetone (20 m*l*) was added to the reaction mixture to decompose the excess reducing agent, and the solvent was removed under reduced pressure to dryness. The residual solid was dissolved in chloroform, washed with water, and dried on calcium chloride. The evaporation of chloroform under reduced pressure furnished crude isoelliptol; without any purification, this product was employed in the next reaction. Aluminum isopropoxide (4.0 g) was added to a solution of the crude isoelliptol in absolute benzene (40 m*l*) and refreshed acetone (30 m*l*), after which the mixture was gently refluxed for 12 hr. The reaction mixture was cooled, diluted with benzene (200 m*l*), washed with diluted sulfuric acid and water, and then dried on calcium chloride. After the solvent had then been removed under reduced pressure to dryness, the solid was chromatographed on silica gel (*ca.* 5 g) in dichloromethane and then crystallized from dichloromethane-ethanol (1: 1 v/v) to give II as colorless needles; mp 215—216°C; yield, 90 mg. IR: 1680 cm^{-1} (C=O); UV: λ_{max}^{EtOH} mμ (log ε): 236 (4.59), 254.5 (4.09), 276 (4.01), 300_s*6 (3.80), 335 (3.55); $\lambda_{max}^{CHCl_3}$ mμ (log ε): 280 (4.03), 344 (3.55). NMR: 3.78_s, 3.82_s (each 3 H), 6.54_s, 6.83_s, 7.12_s, 8.30_s (each 1 H), 6.80_q (1 H, J=2.0 and 1.0 Hz), 7.61_d (1 H, J=2.0 Hz).

Found: C, 68.14; H, 4.73%. Calcd for $C_{20}H_{16}O_6$: C, 68.18; H, 4.58%.

The author wishes to express his deep thanks to Professor Kenji Fukui, Hiroshima University, for his encouragement throughout the course of this work.

*4 All the melting points are uncorrected. The infrared spectra were measured in nujol, while the ultraviolet spectra were measured in an ethanol and a chloroform solution.

*5 i=inflection.

Synthetic Studies of Bacitracin. VI.[1] Synthesis of Unprotected Thiazoline Peptides

Yoshihiro HIROTSU, Tetsuo SHIBA*1 and Takeo KANEKO*1

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received December 11, 1969)

For a total synthesis of bacitracian A, a synthetic method to secure unprotected thiazoline peptides must be established. 2-Aminomethyl-R-Δ^2-thiazoline-4-carboxamide, 2-aminomethyl-R-Δ^2-thiazoline-4-carboxylic acid, 2-aminomethyl-R-Δ^2-thiazoline-4-carbonyl-L-leucine were synthesized by either the iminoether coupling method or by the dehydration method using *N*-benzyloxycarbonyl group and benzyl ester as protecting groups.

In the previous papers,[1,2] the syntheses of protected thiazoline peptides by either the iminoether coupling method, or by dehydration of cysteine peptide in nonaqueous medium were described. Saponification of methyl or ethyl ester of thiazoline peptide was accompanied by racemization of cysteine residue and cleavage of thiazoline ring,[2] while the thiazoline ring was stable in strong acidic condition.[3] In order to obtain the unprotected thiazoline peptide, therefore, use of *N*-benzyloxycarbonyl group and benzyl ester group, both being cleavable by hydrogen bromide in acetic acid, is required. Based on this principle, a synthetic method of the unprotected thiazoline peptide was established.

A thiazoline derivative of a dipeptide derived from L-cysteinamide was prepared as shown in Fig. 1. *N,N'*-Bisbenzyloxycarbonyl-L-cystine[4] was converted to *N,N'*-bisbenzyloxycarbonyl-L-cystinyl dichloride[5] by treatment with phosphorus pentachloride. The acid chloride was treated with ammonia to afford *N,N'*-bisbenzyloxycarbonyl-L-cystine diamide (I), which was then reduced to benzyloxycarbonyl-L-cysteinamide (II) with zinc dust and hydrochloric acid. Amide II was treated with 30% hydrogen bromide in acetic acid to give L-cysteinamide hydrobromide (III).

Coupling of III with benzyloxycarbonylaminoacetimino ethyl ether[2] gave 2-benzyloxycarbonylaminomethyl-R-Δ^2-thiazoline-4-carboxamide (IV), which was then treated with 30% hydrogen bromide in acetic acid to afford 2-aminomethyl-R-Δ^2-thiazoline-4-carboxamide (V). Product V was very hygroscopic solid and gave L-cystine by hydrolysis with hydrochloric acid followed by oxidation.

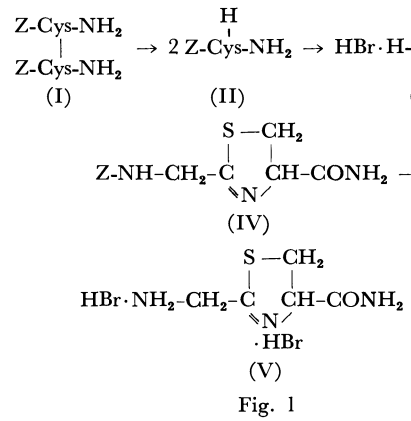

Fig. 1

$Z = C_6H_5CH_2OCO$

Cystine used is of L-configuration.

Unprotected thiazoline peptides were synthesized from di- or tripeptide involving cysteine residue by the dehydration method according to the scheme shown in Fig. 2. Coupling of benzyloxycarbonylglycine with dibenzyl L-cystinate dihydrochloride[6]

using *N,N'*-dicyclohexylcarbodiimide gave *N,N'*-bisbenzyloxycarbonylglycyl-L-cystine dibenzyl ester (IV), which was then converted to benzyloxycarbonylglycyl-L-cysteine benzyl ester (VII) by reduction with zinc dust and hydrochloric acid.

A ring closure of dipeptide VII through dehydration by hydrogen chloride in chloroform afforded benzyl 2-benzyloxycarbonylaminomethyl-R-Δ^2-thiazoline-4-carboxylate hydrochloride, from which the benzyloxycarbonyl thiazoline derivative (VIII) was obtained in crystalline state by removal of hydrogen chloride by treatment with an aqueous concentrated potassium carbonate solution.

Compound VIII was treated with 30% hydrogen bromide in acetic acid at 40°C for 3 hr to give a very hygroscopic solid of 2-aminomethyl-R-Δ^2-thiazoline-4-carboxylic acid dihydrobromide (IX).

Trt=$(C_6H_5)_3C$
Cysteine and leucine used are of L-configuration.

A tripeptide containing the thiazoline ring was also prepared as follows. Condensation of *N,S*-ditrityl-L-cysteine diethylamine salt[7] with benzyl L-leucinate *p*-toluenesulfonate[8] by the carbodiimide method gave *N,S*-ditrityl-L-cysteinyl-L-leucine benzyl ester (X), which was then treated with hydrochloric acid in acetone to give benzyl *S*-trityl-L-cysteinyl-L-leucinate hydrochloride (XI). Coupling of XI with benzyloxycarbonylglycine by carbodiimide method gave benzyloxycarbonylglycyl-*S*-trityl-L-cysteinyl-L-leucine benzyl ester (XII). The *S*-trityl tripeptide XII was converted to the silver mercaptide by treatment with silver nitrate and pyridine. Removal of silver from the mercaptide by hydrochloric acid gave benzyloxycarbonylglycyl-L-cysteinyl-L-leucine benzyl ester (XIII). Compound XIII was cyclized to the thiazoline derivative by the action of hydrogen chloride in chloroform. Treatment of the product with potassium carbonate gave 2-benzyloxycarbonylaminomethyl-R-Δ^2-thiazoline-4-carbonyl-L-leucine benzyl ester (XIV), which was then treated with 30% hydrogen bromide in acetic acid to afford 2-aminomethyl-R-Δ^2-thiazoline-4-carbonyl-L-leucine dihydrobromide (XV). Purification of hydrobromide XV, obtained as a very hygroscopic solid, was difficult by recrystallization or by reprecipitation.

The procedure described here will open the way to prepare other unprotected thiazoline peptides like bacitracin A.

Experimental

All melting points are uncorrected. Ultraviolet spectra were obtained in 95% ethanol and 12 N hydrochloric acid—95% ethanol (1: 1) with a Hitachi EPS-3 spectrophotometer.

***N,N'*-Bisbenzyloxycarbonyl-L-cystine Diamide (I).** To a suspension of 25.0 g (0.05 mol) of *N,N'*-bisbenzyloxycarbonyl-L-cystine[4] in 150 m*l* of anhydrous ether was added 25.0 g (0.12 mol) of phosphorus pentachloride on cooling at 0°C. After the reaction mixture had been shaken for 30 min, *N,N'*-bisbenzyloxycarbonyl-L-cystinyl dichloride[5] formed was filtered off and washed with anhydrous ether. The acid chloride was added to a mixture of 300 m*l* of anhydrous ether and 200 m*l* of tetrahydrofuran, which was saturated with ammonia gas at 0°C, with cooling in an ice bath. The reaction mixture was stirred for 3 hr and then concentrated *in vacuo*. Crystals formed upon addition of water were filtered off. Recrystallization from ethanol gave 21.5 g (85%) of I; mp 188—190°C, $[\alpha]_D^{14}$ −177° (*c* 1.10, dimethylformamide).

Found: C, 51.85; H, 5.21; N, 10.94; S, 12.56%. Calcd for $C_{22}H_{26}O_6N_4S_2$: C, 52.16; H, 5.17; N, 11.06; S, 12.66%.

Benzyloxycarbonyl-L-cysteinamide (II). To a solution of 5.1 g (0.01 mol) of I in a mixture of 50 m*l* of

7) G. Amiard, R. Heymes and L. Velluz, *Bull. Soc. Chim. Fr.*, **1956**, 698.

8) N. Izumiya and S. Makisumi, *Nippon Kagaku Zasshi*, **78**, 662 (1957).

dimethylformamide and 6.5 m*l* of concentrated hydrochloric acid was added 3.0 g of zinc dust in small portions over a period of 15 min with vigorous stirring on cooling in an ice bath. The mixture was stirred for an additional 30 min at room temperature and then filtered. Precipitate was formed upon addition of water to the filtrate. It was filtered off and washed with water. Recrystallization from ethanol-water gave 4.1 g (80%) of II; mp 136—138°C, $[\alpha]_D^{14}$ +7.7° (*c* 2.28, dimethylformamide).

Found: C, 51.90; H, 5.55; N, 10.95; S, 12.56%. Calcd for $C_{11}H_{14}O_3N_2S$: C, 51.95; H, 5.55; N, 11.01; S, 12.61%.

L-Cysteinamide Hydrobromide (III). To a mixture of 10.0 g (0.04 mol) of II and 4.0 g of anisole was added 40 m*l* of 30% hydrogen bromide in acetic acid, and the reaction mixture was kept at room temperature for 3 hr with occasional swirling. To the reaction mixture was added 150 m*l* of anhydrous ether, and the precipitate formed was filtered off. Recrystallization from anhydrous methanol-anhydrous ether gave 6.5 g (81%) of III; mp 178—180°C (decomp.), $[\alpha]_D^{16}$ +8.2° (*c* 2.91, anhydrous methanol).

Found: C, 18.30; H, 4.59; N, 13.78%. Calcd for $C_3H_9ON_2SBr_2$: C, 17.92; H, 4.51; N, 13.93%.

2-Benzyloxycarbonylaminomethyl-R-Δ^2-thiazoline-4-carboxamide (IV). To a solution of 10.1 g (0.05 mol) of III in a mixture of 50 m*l* of anhydrous tetrahydrofuran and 10 m*l* of anhydrous methanol was added 11.8 g (0.05 mol) of benzyloxycarbonylaminoacetimino ethyl ether.[2] After the reaction mixture had been kept at room temperature for 3 hr, ammonium bromide was deposited. The reaction mixture was concentrated *in vacuo*. The residue obtained was dissolved in ethyl acetate. The solution was washed with water, dried with sodium sulfate, and then evaporated *in vacuo* to give crystals. Recrystallization from ethyl acetate-petroleum ether gave 13.0 g (89%) of IV; mp 110—112°C, $[\alpha]_D^{17}$ +46.5° (*c* 2.98, dimethylformamide), λ_{max}^{EtOH} 235 mμ (ε 2300), 252 mμ (ε 2800), $\lambda_{max}^{EtOH\cdot HCl}$ 268 mμ (ε 5900).

Found: C, 53.15; H, 5.19; N, 14.38; S, 10.67%. Calcd for $C_{13}H_{15}O_3N_3S$: C, 53.23; H, 5.15; N, 14.32; S, 10.93%.

2-Aminomethyl-R-Δ^2-thiazoline-4-carboxamide Dihydrobromide (V). To a solution of 11.6 g (0.04 mol) of IV in 100 m*l* of acetic acid was added 40 m*l* of 30% hydrogen bromide in acetic acid. The reaction mixture was kept at room temperature for 2 hr. To the mixture was added 200 m*l* of anhydrous ether. The precipitate formed was filtered off and washed with methylene chloride and acetone; wt of V: 10.8 g (84%), mp 100—105°C (decomp.), $[\alpha]_D^{25}$ +3.3° (*c* 1.05, anhydrous methanol), $\lambda_{max}^{abs\ MeOH}$ 234 mμ (ε 2400), 250 mμ (ε 2000). $\lambda_{max}^{12N\ HCl}$ 277 mμ (ε 3400). It was reprecipitated from anhydrous methanol—anhydrous ether; mp 100—105°C (decomp., sintered at 90°C).

Found: C, 20.25; H, 4.14; N, 11.99%. Calcd for $C_5H_{11}ON_3SBr\cdot CH_3OH$: C, 20.41; H, 4.28; N, 11.90%.

Isolation of L-Cystine from Acid Hydrolyzate of V. A solution of 3.1 g (0.01 mol) of V in 100 ml of 6 N hydrochloric acid was refluxed for 3 hr on addition of 1.1 g of anisole. The reaction mixture was cooled and then extracted with ether. The aqueous layer was concentrated *in vacuo* to dryness. The residue obtained was dissolved in 50 ml of water, and evaporation *in vacuo* was repeated. pH of a solution of the residue in 50 ml of water was adjusted to about 8.5 with 28% aqueous ammonia. Air was bubbled through the solution until the nitroprusside reaction became negative by a spot test. After the addition of a drop of acetic acid, the reaction mixture was allowed to stand at 0°C for 2 days. The precipitate thus formed was filtered off and then dissolved in 30 m*l* of N hydrochloric acid. Undissolved substance was removed by filtration and the filtrate was adjusted to pH 5.5—6.0 by the addition of an aqueous sodium acetate solution. After standing at 0°C for 2 days, the precipitate formed was filtered off and dried at 80°C *in vacuo* for 4 hr to give 0.78 g (65%) of L-cystine; $[\alpha]_D^{19}$ −217° (*c* 1.03, N HCl).

Found: C, 29.80; H, 5.02; N, 11.77; S, 26.42%. Calcd for $C_6H_{12}O_4N_2S_2$: C, 29.99; H, 5.04; N, 11.66; S, 26.69%.

***N,N'*-Bisbenzyloxycarbonylglycyl-L-cystine Dibenzyl Ester (VI).** To a suspension of 30.7 g (0.05 mol) of dibenzyl L-cystinate dihydrochloride[6] in 300 m*l* of methylene chloride was added 10.1 g (0.1 mol) of triethylamine. After the reaction mixture had been stirred for 1 hr, 100 ml of ether was added. The precipitate formed was filtered off, and the filtrate was concentrated *in vacuo*. To the solution of the residue thus obtained in 300 m*l* of tetrahydrofuran, 20.9 g (0.1 mol) of benzyloxycarbonylglycine and 22.7 g (0.11 mol) of *N,N'*-dicyclohexylcarbodiimide were added. After the reaction mixture had been stirred for several hours, 2 m*l* of acetic acid was added to it. *N,N'*-Dicyclohexylurea formed was filtered off, and the filtrate was evaporated *in vacuo* to dryness. The residue was dissolved in ethyl acetate and the solution was washed successively with 0.5 N hydrochloric acid, water, a 5% aqueous sodium hydrogencarbonate solution, and water. Upon evaporation *in vacuo* after drying with sodium sulfate and recrystallization of the residue from methanol—water, 35.0 g (78%) of crystals of VI were obtained; mp 118—119°C, $[\alpha]_D^{24}$ −45.5° (*c* 3.49, dimethylformamide).

Found: C, 59.91; H, 5.48; N, 6.99; S, 7.88%. Calcd for $C_{40}H_{42}O_{10}N_4S_2$: C, 59.83; H, 5.27; N, 6.98; S, 7.99%.

Benzyloxycarbonylglycyl-L-cysteine Benzyl Ester (VII). To a mixture of 10.0 g (0.0125 mol) of VI and 3.5 g of zinc dust in 200 m*l* of acetone was added 8.3 m*l* of concentrated hydrochloric acid with vigorous stirring on cooling at 0°C within a period of 20 min. The mixture was stirred for an additional 10 min, and then filtered. The filtrate was concentrated *in vacuo* at 30°C. An oily product separated out on addition of water was extracted with ethyl acetate. The extract was washed with water, dried with sodium sulfate and then evaporated *in vacuo*. Recrystallization of the residual solid from ethyl acetate—petroleum ether gave 7.5 g (75%) of crystals of VII; mp 76—77.5°C, $[\alpha]_D^{25}$ −13.5° (*c* 5.30, dimethylformamide).

Found: C, 59.87; H, 5.59; N, 6.97; S, 7.79%. Calcd for $C_{20}H_{22}O_5N_2S$: C, 59.68; H, 5.51; N, 6.96; S, 7.97%.

Benzyl 2-Benzyloxycarbonylaminomethyl-R-Δ^2-thiazoline-4-carboxylate (VIII). A solution of 4.0 g (0.01 mol) of VII in 50 m*l* of chloroform was saturated with dry hydrogen chloride gas on cooling in an ice bath. The mixture was allowed to stand at room temperature overnight, and then concentrated *in vacuo*. To the residue was added 100 m*l* of ethyl acetate, and the mixture

was treated with a concentrated potassium carbonate solution. The ethyl acetate layer was washed with water, dried with sodium sulfate and then evaporated to dryness to give crystals. Recrystallization from ethyl acetate—petroleum ether gave 2.1 g of VIII; mp 86—87.5°C, $[\alpha]_D^{19}$ +84.0° (*c* 2.13, dimethylformamide), λ_{max}^{EtOH} 235 mμ (ε 2300), 252 mμ (ε 3000), $\lambda_{max}^{EtOH\text{-}HCl}$ 264 mμ (ε 5000).

Found: C, 62.43; H, 5.31; N, 7.23; S, 8.29%. Calcd for $C_{20}H_{20}O_4N_2S$: C, 62.48; H, 5.24; N, 7.29; S, 8.34%.

2-Aminomethyl-R-Δ^2-thiazoline-4-carboxylic Acid Dihydrobromide (IX). To a mixture of 1.2 g (0.003 mol) of VIII and 1.0 g of anisole was added 20 m*l* of 30% hydrogen bromide in acetic acid, and the mixture was kept at 40°C for 3 hr with occasional swirling. To the reaction mixture was added 100 m*l* of anhydrous ether. The precipitate formed was filtered off, and washed with anhydrous ether; wt of IX: 0.70 g (73%), mp 177—182°C (decomp.), $[\alpha]_D^{14}$ +30.7° (*c* 1.01, anhydrous ethanol), $\lambda_{max}^{abs\ EtOH}$ 235 mμ (ε 2900), 250 mμ (ε 2600), $\lambda_{max}^{12N\ HCl}$ 276 mμ (ε 4100).

Found: C, 18.98; H, 3.38; N, 8.50%. Calcd for $C_5H_{10}O_2N_2SBr_2$: C, 18.65; H, 3.13; N, 8.70%.

***N*-*S*-Dityrityl-L-cysteinyl-L-leucine Benzyl Ester (X).** To a solution of 13.6 g (0.02 mol) of *N*,*S*-dityrityl-L-cysteine diethylamine salt[7] and 7.9 g (0.02 mol) of benzyl L-leucinate *p*-toluenesulfonate[8] in 150 m*l* of methylenechloride was added 4.6 g (0.022 mol) of *N*,*N'*-dicyclohexylcarbodiimide. After the reaction mixture had been stirred for several hours, 1 m*l* of acetic acid was added, and the urea derivative formed was filtered off. The filtrate was washed with water and dried with sodium sulfate. Upon concentration of the solution *in vacuo* an amorphous powder was obtained.

Benzyl *S*-Trity-L-cysteinyl-L-leucinate Hydrochloride (XI). To a solution of 16.2 g (0.02 mol) of X in 100 m*l* of acetone was added 10 m*l* of 6 N hydrochloric acid. After the reaction mixture was stirred for 1 hr, the resulting clear solution was evaporated to dryness at 30°C. The residue was triturated with ether. The precipitate was filtered off, and washed with ether. Recrystallization from ethyl acetate gave 6.8 g (56%) of crystals of XI; mp 182—184°C, $[\alpha]_D^{23}$ +13.3° (*c* 5.06, ethanol).

Found: C, 69.64; H, 6.51; N, 4.64%. Calcd for $C_{35}H_{39}O_3N_2SCl$: C, 69.69; H, 6.52; N, 4.65%.

Benzyloxycarbonylglycyl-*S*-trityl-L-cysteinyl-L-leucine Benzyl Ester (XII). To a suspension of 12.1 g (0.02 mol) of XI in 50 m*l* of chloroform was added 2.0 g (0.02 mol) of triethylamine. The precipitate formed on addition of 100 m*l* of ether was filtered off, and the filtrate was evaporated *in vacuo*. To the solution of the residue obtained in 100 m*l* of tetrahydrofuran, 4.2 g (0.02 mol) of benzyloxycarbonylglycine and 4.6 g (0.022 mol) of *N*,*N'*-dicyclohexylcarbodiimide were added. The mixture was stirred for several hours, and then 1 m*l* of acetic acid was added. The urea derivative precipitated was removed by filtration, and the filtrate was concentrated *in vacuo*. The residue was dissolved in ethyl acetate, and the solution was washed as usual. Evaporation of the solvent *in vacuo* and then recrystallization of the residue from ethanol—water gave 13.2 g (87%) of XII; mp 114—116°C, $[\alpha]_D^{23}$ −11.4° (*c* 4.30, dimethylformamide).

Found: C, 71.62; H, 6.26; N, 5.53; S, 4.16%. Calcd for $C_{45}H_{47}O_6N_3S$: C, 71.31; H, 6.25; N, 5.54; S, 4.23%.

Benzyloxycarbonylglycyl-L-cysteinyl-L-leucine Benzyl Ester (XIII). A hot solution of 1.7 g (0.01 mol) of silver nitrate and 0.95 m*l* of pyridine in 20 m*l* of ethanol was added to a warm solution of 7.6 g (0.01 mol) of XII in 40 m*l* of ethanol. After the mixture was refluxed for 30 min, the silver mercaptide of XIII was separated out; after standing for 2 hr at room temperature under nitrogen, it was filtered off and washed with ethanol and then dried; wt 5.6 g (90%).

To a suspension of 5.6 g of the mercaptide in 50 m*l* dimethylformamide, 1.3 m*l* of concentrated hydrochloric acid was added. The mixture was shaken for 2 hr at room temperature and then heated on a boiling water bath for 1 min. The precipitate of silver chloride formed was removed by filtration and washed with a small amount of dimethylformamide. After addition of chloroform to the filtrate, it was washed with water several times, dried with magnesium sulfate, and then evaporated *in vacuo*. Upon addition of water to the residue, crystals were separated out. Recrystallization from ethyl acetate—petroleum ether gave 4.0 g (78%) of XIII; mp 96—98°C, $[\alpha]_D^{26}$ −15.6° (*c* 4.24, dimethylformamide).

Found: C, 60.82; H, 6.59; N, 8.09; S, 5.95%. Calcd for $C_{26}H_{33}O_6N_3S$: C, 60.56; H, 6.45; N, 8.15; S, 6.22%.

Benzyl 2-Benzyloxycarbonylaminomethyl-R-Δ^2-thiazoline-4-carbonyl-L-leucinate (XIV). A solution of 5.2 g (0.01 mol) of XIII in 100 m*l* of chloroform was saturated with dry hydrogen chloride gas on cooling at 0°C. The mixture was allowed to stand at room temperature overnight, and then evaporated *in vacuo* to dryness. To the residue was added 100 ml of ether, and the mixture was treated with a concentrated potassium carbonate solution. The ether layer was separated, washed with water, dried with sodium sulfate and then evaporated to dryness to give a crude oil; wt 4.2 g. This was dissolved in a small amount of ether and subjected to the sillica gel column (Mallincrodt Chemical Works, 100 mesh, 50 g). Elution with petroleum ether—anhydrous ether gave 3.9 g (87%) of XIV; $[\alpha]_D^{26}$ +28.6° (*c* 2.70, ethanol), λ_{max}^{EtOH} 233 mμ (ε 2600), 252 mμ (ε 2700), $\lambda_{max}^{EtOH\text{-}HCl}$ 268 mμ (ε 4900).

Found: C, 62.26; H, 6.45; N, 8.37; S, 6.44%. Calcd for $C_{26}H_{31}O_5N_3S$: C, 62.75; H, 6.28; N, 8.44; S, 6.44%.

2-Aminomethyl-R-Δ^2-thiazoline-4-carbonyl-L-leucine Dihydrobromide (XV). To a mixture of 2.0 g (0.004 mol) of XIV and 1.0 g of anisole was added 30 m*l* of 30% hydrogen bromide in acetic acid and the reaction mixture was kept at 40°C for 3 hr with occasional swirling. To the mixture was added 100 m*l* of anhydrous ether, and the precipitate formed was filtered off and washed with anhydrous ether; wt of XV: 1.26 g (75%), mp 140—148°C (decomp.), $[\alpha]_D^{15}$ −4.1° (*c* 1.46, anhydrous ethanol), $\lambda_{max}^{abs\ EtOH}$ 230 mμ (ε 2900), 250 mμ (ε 2200), $\lambda_{max}^{12N\ HCl}$ 276 mμ (ε 3100).

Found: N, 9.56%. Calcd for $C_{11}H_{21}O_3N_3SBr_2$: N, 9.66%.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1568—1569 (1970)

The Chemical Behavior of Low Valence Sulfur Compounds. IV.*1 The Solubility of Ammonium Thiosulfate in Aqueous Ammonia

Kunishige NAITO, Masahito Yamada*2 and Taijiro Okabe

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

(Received August 1, 1969)

The solubility of ammonium thiosulfate in aqueous ammonia has been measured as an investigation concerning the preparation of ammonium sulfamate from ammonium thiosulfate by oxidation with compressed oxygen in aqueous ammonia solution. The solubility is not known except for the measurement at 15°C by E. Weitz.[1] The solubility in water has been measured by W. C. Zeise,[2] E. Terres and F. Overdick[3] and W. Klempt, F. Brodhobb and H. Erlbach,[4] but the data are fairly scanty.

Experimental

Crystals of ammonium thiosulfate recrystallized from a very diluted aqueous ammonia solution had a purity of 95.27 wt% with 4.17 wt% adhered water. The solubility was measured by cloud method as follows: The crystals was enclosed in a glass tube of 8 mmϕ × 150 mm with aqueous ammonia and a glass agitater. The tube was heated in a glass water bath to dissolve the crystals as a homogeneous solution. After the dissolution, it was carefully cooled, especially with the cooling speed of 0.05 to 0.1°C/min near the cloud point, and the temperature was measured at which the crystals appeared. When the cloud point was determined within 0.05 to 0.2°C after several measurements, it was decided as saturation temperature. A thermometer graduated at 0.01°C intervals was used. It was calibrated with a standard thermometer.

Results and Discussion

The solubility data measured are shown in Fig. 1. The isothermal curves shown in Fig. 2 were made by plotting the solubility against ammonia concentration in Fig. 1.

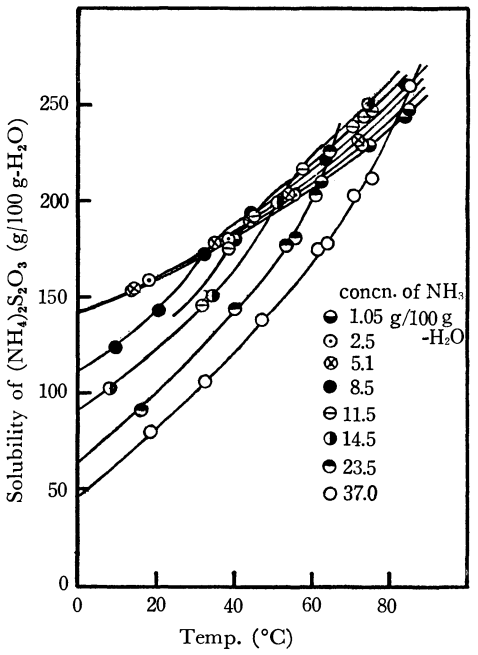

Fig. 1. Solubility of ammonium thiosulfate in aqueous ammonia (temperature-solubility curves).

As shown in Fig. 2, the solubility of ammonium thiosulfate increases with the increase of the ammonia concentration, reaches maximum and then decreases. The maximum point shifts toward the higher side of ammonia concentration with the rise in temperature. By means of X-ray diffraction it was observed that the bottom crystals in the low concentration of ammonia (undoubted ammonium thiosulfate) differ from those in the highly concentrated solution of aqueous ammonia should be an ammoniate of ammonium thiosulfate, because they decompose to ammonium thiosulfate on being stood in air for several hours.

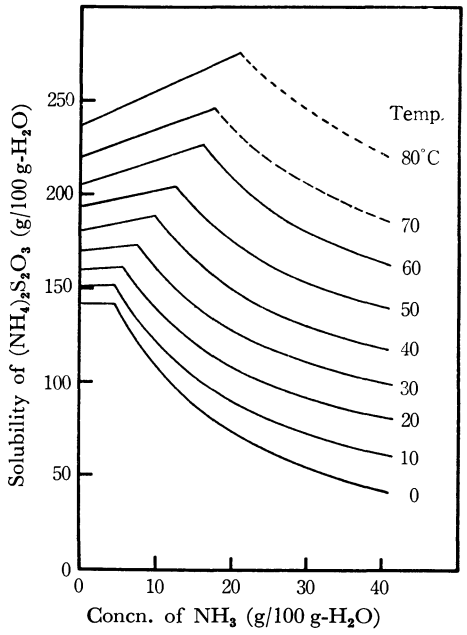

Fig. 2. Solubility of ammonium thiosulfate in aqueous ammonia (isothermal curves).

As elemental sulfur was liberated during the course of measurement at high temperature, the solubility of ammonium thiosulfate in pure water was estimated by extrapolating the solubility in aqueous ammonia to zero of ammonia concentration. The results are shown in Table 1 with those of the former investigators.

The Preparation of the Polyvinylmalachitegreen and Vinylcarbazole-Vinylmalachitegreen Copolymers and Their Absorption Spectra

Kenichi OKAMOTO, Yo HASEGAWA,*1) Shigekazu KUSABAYASHI and Hiroshi MIKAWA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Suita, Osaka

(Received August 28, 1969)

It is well known that triphenylmethane dyes are photoconductive and that the photoconductivity of such polymers as poly-*N*-vinylcarbazole (PVCz) is sensitized by mixing the dyes. The present authors have previously reported on the sensitization of the photoconductivity in the PVCz film by copolymerized malachite green molecules.[1] This note will deal with the preparation of the polyvinylmalachitegreen (PVMG) and *N*-vinylcarbazole (VCz)-vinylmalachitegreen (VMG) copolymers and with their absorption spectra.

Preparation of PVMG. The VMG carbinol was prepared by the method reported by Manecke and Kosmehl[2] and was recrystallized three times from benzene-methanol under nitrogen stream. The VMG carbinol was polymerized by azobisisobutyronitrile (AIBN) in a vacuum-sealed tube at 80°C for 10 hr (Table 1). The resulting white PVMG carbinol was purified by repeated reprecipitation from the benzene solution by methanol. The molecular weight was 13000 (as ascertained by means of a vapor-pressure osmometer).

Found: C, 80.99; H, 7.35; N, 7.46%. Calcd for $(C_{25}H_{28}N_2)_n$: C, 80.61; H, 7.58; N, 7.56%.

The PVMG carbinol was transformed into the chloride (PVMG) as will be described below. An amount 1.7 times the calculated amount of a 0.3 N dry HCl-THF solution was stirred into the benzene solution of PVMG carbinol, and the resulting precipitate (PVMG) was reprecipitated three times from the methanol solution by Bz–THF (1 : 10 : 7 in vol. ratio). The potentiometric titration by a 0.01 N $AgNO_3$ aqueous solution showed that the PVMG thus obtained was monocationic (Cl^- ion content; Found: 9.26, Cacld for the monocation: 9.08%). It should be noticed that

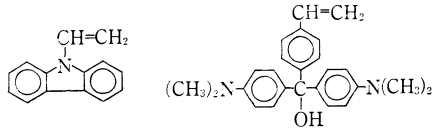
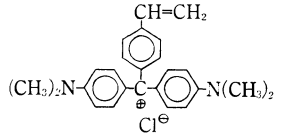
if a fairly large excess of a 0.3 N dry HCl–THF solution was added to the benzene solution of the PVMG carbinol, a fairly large proportion of the MG molecules were transformed into the dication.



VCz VMG carbinol



VMG

Preparation of the VCz-VMG Copolymer. The copolymerization of VCz with the VMG carbinol was carried out by means of AIBN in a vacuum-sealed tube at 80°C for 10 hr. The resultant VCz–VMG carbinol copolymer was purified by the repeated reprecipitation from the benzene solution by methanol. The VCz–VMG carbinol copolymer was then transformed into the VCz–VMG carbinol copolymer was then transformed into the VCz–VMG (HCl salt) copolymer and fractionated as follows. The 0.3 N dry HCl–THF solution (1.5-times the estimated MG dye content) was stirred into the benzene solution of the VCz–VMG carbinol copolymer, after which the precipitate was separated by the use of a centrifuge (Fraction I). A large amount of methanol was added to the filtrate, and the resultant precipitate was filtered (Fraction II). The filtrate was evaporated to dryness under reduced pressure (Fraction III). The VMG content of the copolymer was determined colorimetrically by use of the absorption maxima (626 and 452 mμ) of VMG, shown in Fig. 1. The results are shown in Table 1. The homopolymer of VCz is not contained in Fraction I, for PVCz is soluble in Bz–THF. Fraction II does not contain PVMG because of its insolubility in Bz–THF. Furthermore, Fraction I shows the same absorption spectrum as Fraction II and does not have the absorption peak characteristic

c) in 1×10^{-2} N HCl-THF-methanol solution (97 : 3 in volume ratio)

of PVMG at about 570 mμ. Fraction I, therefore, seems to consist of only the VCz–VMG copolymer. Fraction II will consist of the copolymer and PVCz (especially in the case of a low MG dye content). The molecular weight of the copolymer (Fraction II) is about 20000 (as determined by the use of the vapor pressure osmometer), a little lower than that of PVCz polymerized under the same conditions.

Absorption Spectra of the MG-dye Derivatives. Figure 1 shows the absorption spectra of PVMG, VMG, and the VCz–VMG copolymer in solution. The absorption maxima of these dye salts are listed in Table 2. The replacement of the 4-hydrogen of MG by the vinyl group or the main chain unit, $>CH-CH_2-$, causes the red shift of the visible absorption peaks.

It has been reported that MG has a small shoulder band at about 570 mμ in addition to its main peaks (426 and 618 mμ) and that this shoulder becomes larger with the increase in the concentration.[3)] Furthermore, Manabe *et al.*, have reported that the maximum extinction coefficient, ε_{max}, of the main peaks decrease with the increase in the dye concentration.[4)] These phenomena, which have also been observed in the spectra of such other cationic dyes as crystalviolet, have been attributed to the formation of the aggregate of the dye molecules, as is well known.[3-5)] A similar shoulder band was observed at about 570 mμ in the absorption spectra of VMG, the VCz–VMG copolymer and PVMG ;*2 it is also probably due to the formation of the aggregate. It should be noted that, in PVMG, the band attributed to the aggregation is larger than the main band and is not affected by either the temperature (0—50°C) or the concentration ($0.5—50\times10^{-5}$ mol/l). This suggests that the pendant MG group in the polymer chain aggregates much more easily than MG and VMG, and that most of the pendant dye molecules of PVMG exist in the aggregated form, even in a dilute solution.

It is well known that the aggregative cationic dyes show new peaks attributable to the aggregation, the so called methachromatic band, with the depression in the main band when they are adsorped on the anionic polymers and/or agar.[3)] In PVMG the distance between adjacent MG molecules is short, because each MG molecule is linked to a paraffinic polymer chain by a short covalent bond. The aggregation ability of the MG molecule will be enhanced by the short intermolecular distance in PVMG. No information on the aggregation state has been obtained for either MG or PVMG, however.

p-Brombenzolsulfonyloxyacetonitril als Cyanmethylierungsmittel der Carbonsäure

Kunihiro ICHIMURA

Institut für Polymer- und Faserforschung, Yokohama, Kanagawa-ku, Sawatari 4

(Eingegangen am 20. September, 1969)

Schweyzer und seine Mitarbeiter haben mitgeteilt, daß Cyanmethylester der Carbonsäure als aktiviertes Ester zur Peptidkondensation zweckmäßig dienen kann.[1,2] Die Herstellung des Cyanmethylesters wird von ihnen mittels Chloracetonitrils durchgeführt. Taschner und andere haben vor kurzem mitgeteilt, daß Bromacetonitril hinsichtlich der Herstellungsbedingungen des aktivierten Esters nützlicher als Chloracetonitril ist.[3]

Im Zusammenhang mit Darstellung des Aziridins hat der Autor einige α-Sulfonyloxynitrile synthetisiert,[4] und in dieser Arbeit wird die Umsetzung der Cyanmethylester der Arensulfonsäure mit Carbonsäure durchgeführt.

Der vor kurzem beschriebenen Prozedur nach werden *p*-Toluolsulfonyloxy- und *p*-Brombenzolsulfonyloxyacetonitril von Sulfonylchlorid, Formalin und Natriumcyanid aus in guten Ausbeuten dargestellt.

Wenn man *p*-Toluolsulfonyloxyacetonitril mit äquivalentem Phthaloylglycin in Gegenwart des Triäthylamins bei Raumtemperatur reagieren läßt, vollendet sich die Reaktion in 20 Std, und das Cyanmethylester wird in 88%-iger Ausbeute erhalten. Unter Benutzung des *p*-Brombenzolsulfonyloxyacetonitrils ist doch das Cyanmethylester in 4.5 Std bei Raumtemperatur in 88%-iger Ausbeute erhältlich. Es ist also zweckmäßiger als im Fall des Chloracetonitrils und Bromacetonitrils im Hinsicht der Darstellungsbedingungen. Die einige Ergebnisse sind in Tabelle zusammengefaßt.

Beschreibung der Versuche

***p*-Brombenzolsulfonyloxyacetonitril.** Man setzt 25 g *p*-Brombenzolsulfonylchlorid und 11 m*l* Formalin (etwa 37%) in 50 m*l* Acetonitril zu und fügt die konz. wäßr. Lösung des 5.50 g Natriumcyanids in das Gemisch unter gutem Rühren bei etwa 10°C langsam zu. Man setzt Äther zu und trennt die org. Schicht, die nach Waschen mit Wasser über Magnesiumsulfat abgetrocknet wird. Nach Eindampfen des Lösungsmittels löst man sofort den Rückstand in 7.5 m*l* *n*-Butanol und läßt die

Nach Versetzen mit Wasser und Ausziehen mit Äther wäscht man die äther. Lösung mit Wasser nach und eingedampft. 2.26 g (88% d. Th.) kristalliner Rückstand vom Schmp 80—88°C werden erhalten und aus Benzol/Ligroin umkristallisiert. Schmp 87—90°C (Ber Schmp[3] 87–88°C).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1573—1574 (1970)

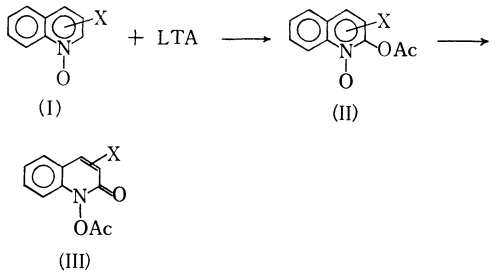
Rearrangements of Tertiary Amine *N*-Oxides. XXVI. Reactions of Arylnitrones with Lead Tetraacetate

Seizo TAMAGAKI and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received September 29, 1969)

Lead tetraacetate (LTA) has been used widely as a reagent for electron-oxidation of many organic compounds, for instance, the oxidation of alcohols or phenols to the corresponding ketones or quinones. An interesting example is the oxidation of quinoline *N*-oxide (I).[1] In this case, the heterocyclic carbon α to the *N*-oxide function is oxidized to afford the corresponding *N*-acetoxycarbostyril (III) which appears to be produced through the formation of α-acetoxyquinoline *N*-oxide(II) as shown below.



According to Ochiai and Ohta, electron-donating groups on the ring afford the corresponding carbostyrils in higher yields than electron-withdrawing groups.[1]

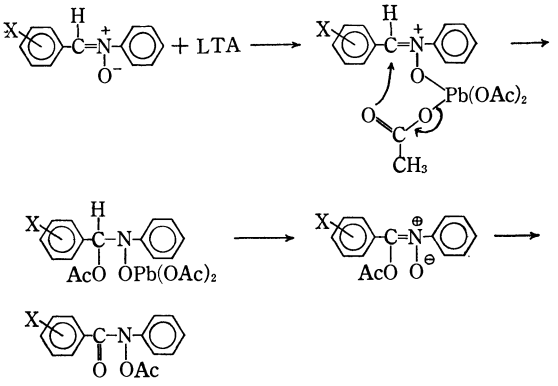
In extending this oxidation reaction by LTA to other tertiary amine *N*-oxides, we have examined the oxidation of arylnitrones which are considered to be the analogs of quinoline *N*-oxide.

When LTA was added portionwise into arylnitrones in dry benzene, the colorless powder precipitated immediately. When the precipitate was filtered off and benzene was removed from the filtrate by evaporation, either crystalline or oily products was obtained quantitatively irrespective of the nitrone employed. For instance, α,*N*-diphenylnitrone afforded *N*-acetoxy-*N*-benzoylaniline as the sole product.

Other examples of stoichiometries are tabulated in Table 1.

The structures of the products were determined by means of NMR, IR, elemental analysis as well as by chemical conversion to the corresponding *N*-hydroxybenzamides.

The reaction appears to proceed through the following scheme.



1) E. Ochiai and A. Ohta, *Chem. Pharm. Bull. (Tokyo)*, **10**, 1260 (1962). *ibid.*, **11**, 1586 (1963).

Table 1. Reaction of arylnitrones with lead tetraacetate in benzene

X-C6H4-C=N(O)-Ph	Mp (bp) (°C)	*N*-Oxide	Lead tetraacetate (g)	Product	Lead diacetate
p-Cl	108	2.0	4.0	2.15	2.17
H	(165—170/2 mmHg)	1.0	2.2	1.0	1.46
p-CH_3	95—96	0.75	1.6	0.90	1.12

The reaction of nitrones with LTA takes place very readily without heating the reaction mixture, whereas that of quinoline *N*-oxide requires refluxing of the solution. In the reaction with acylating agents also, nitrones are much more reactive than quinoline or pyridine *N*-oxide. Thus, we can conclude that nitrones are in general more reactive in oxidation than the aromatic *N*-oxides.

$$>C{=}N + LTA \xrightarrow[50°C]{CH_2Cl_2} >\overset{\overset{OAc^-}{\downarrow}}{C{=}N} \rightarrow >\overset{\overset{OAc}{|}}{C}{-}N{=}O$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1574—1577 (1970)

Studies of the Electric Discharge of Organic Compounds. I. The Decomposition of Toluene in 10-MHz and 2450-MHz Discharges

Ko Taki

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received October 16, 1969)

Extensive studies of the reactive species have been carried out with regard to the decomposition of inorganic and organic compounds in an electric discharge.[1-10]

In the present investigation, high-frequency electric discharges were used as the source for the formation of reactive species, and toluene was chosen as a representative substrate. Some comparisons of the reaction of toluene in a glow discharge produced by 10-MHz and by 2450-MHz fields will also be reported. The radical scavengers (such as NO, O_2, and C_2H_4) and the electron scavengers (such as N_2O) were used in both the discharges in order to ex-

amine the reaction mechanism. The mechanism is compared with that of the reactions by other energy sources (radiolysis,[11-15] photolysis,[16,17] and pyrolysis[18-20]). Also the formation of some reaction intermediates is discussed.

Experimental

All the runs were carried out in a flow system uing helium as the carried gas. The 10-MHz electric discharge was carried out in Pyrex tubing (1.3 cm od.) around which two 2.5-cm aluminum foil bands (3 cm apart) were fitted; the 10-MHz power of a few watts was generated by a hand-made Toshiba 2B29 valve generator. Microwave (2450-MHz) discharge was also carried out in Pyrex tubing (1.3 cm od.) using a cavity (2×1.4 cm); microwaves were fed into the cavity by means of a Raytheon PGM-10 magnetron (2450 MHz, 85 W). The experimental arrangement is shown in Fig. 1. All the products were analysed gas-chromatographically.

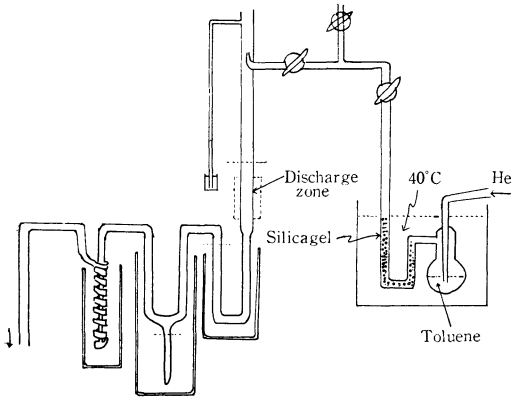

Fig. 1

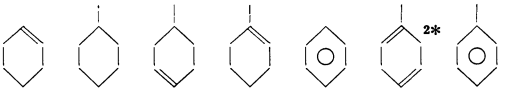
Results and Discussion

The relative product yields are shown in Table 1. The eluting order*1 of C_6 and C_7 compounds in gas chromatography using a polyethylene glycol column is as follows:



1-Methylcyclohexene and 4-methylcyclohexene, which are obtained in comparatively large yields, are the reduction products from toluene in the

electric discharge. Concerning the products, no difference in the reaction between 10 and 2450 MHz was found. Benzene and ethylbenzene were the main products in both the discharges. However, the variation in the product yields (based on the toluene consumed) with the concentration of the scavenger showed much difference between the 10- and 2450-MHz discharges, as is shown in Figs. 2, 3, and 4.

The Formation of Ethylbenzene. The main products are benzene and ethylbenzene. This experimental finding indicates that, in these discharges, phenyl radical are produced as well as benzyl radicals. Benzyl radicals have been reported to be commonly produced in the photolysis,[17] pyrolysis, and radiolysis of toluene. In the radiolysis[14] of liquid toluene, however, ethylbenzene is not the principal product. Cher[22] has found ethylbenzene, in the photolysis of gaseous toluene, to be a major non-gaseous product. Schüler and Stockburger[17] have also reported the formation of benzene and the benzyl radical in the discharge reaction of toluene and have pointed out, that in the electric discharge, the dissociation into H atoms is not a single process.

Effect of Scavenger. The fact that a small percentage of nitric oxide strongly inhibits the formation of ethylbenzene in the 10-MHz discharge, while nitrous oxide does not greatly inhibit it, suggests that the radical process is predominant in the reaction. On the other hand, in the 2450-MHz discharge about half of the ethylbenzene yield disappears in the presence of such radical scavengers as nitric oxide and ethylene. Moreover, the yield of ethylbenzene is also inhibited greatly in the presence of nitrous oxide. These experimental facts suggest that not only the radical but the ionic (not radical) process must be considered in the 2450-MHz discharge. This ionic process was also assumed by Streitwieser and Ward in the microwave discharge. However, these differences between the two discharge types are not yet clear.

Other Products. Benzaldehyde was found when nitric oxide and oxygen were used as scavengers in the 10-MHz discharge. One possible process of benzaldehyde formation may be shown as follows:

$$C_6H_5\text{-}CH_2\cdot + NO \rightarrow (C_6H_5\text{-}CH_2\text{-}NO) \rightarrow C_6H_5\text{-}COH + NH$$

In the 2450-MHz discharge, benzaldehyde was not detected in the presence of nitric oxide.

A small amount of nitrosobenzene was found in both the discharges; it may be produced by the reaction of the phenyl radical with nitric oxide. Phenylpropylene and phenylcyclopropane were not detected in these discharges when ethylene was used as a scavenger. Therefore, the formation of the benzal diradical[23] (C_6H_5-CH) was not confirmed. By using maleic anhydride, the formation of fulvene derivatives was not confirmed, either.

The author wishes to thank Professor S. Murahashi for his useful suggestions and encouragement, and Miss K. Motegi for her effort to the analyses of reaction products. He also thanks Dr. M. Imamura and Dr. M. Matsui for their helpful discussions and suggestions.

Studies of the Electric Discharge of Organic Compounds. II. The Decomposition of *o*-, *m*-, and *p*-Xylenes in 10-MHz and 2450-MHz Discharges

Ko Taki

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received October 16, 1969)

As has previously been shown[1] toluene gives benzene and ethylbenzene as the principal products in high-frequency electric discharges. The series of xylene isomers were chosen as the higher methyl-substituted benzene homologues in order to get further information on high-frequency electric discharges. Radical and electron scavengers were also used as additives in order to examine the reaction processes. The electric discharge assembly and the procedure of handling of the product were essentially the same as in previous studies. Product analyses were carried out by gas chromatography. The xylenes (Wako Pure Chemical Industries, Ltd.) were purified by repeated distillation or by recrystallization.

Results and Discussion

The major products from *p*-xylene decomposition were benzene, toluene, 2,5-dihydroxylene,*1 and ethyltoluene. These products are similar to those from the toluene decomposition. The relative yields of these products are listed in Tables 1, 2, and 3.

Table 2. The relative yields of the products based on *m*-xylene consumed

Residence time *m*-Xylene %	10-MHz discharge 0.12 sec 9.5% in He	2450-MHz discharge 0.008 sec 9.2% in He

Table 3. The relative yields of the products based on *o*-xylene consumed

Residence time *o*-Xylene %	10-MHz discharge 0.18 sec 3.1% in He	2450-MHz discharge 0.01 sec 3.5% in He
Benzene	0.2	0.1
Toluene	1.00	1.00
2-Ethyltoluene	1.8	1.0
Ethane	0.5	2.0
Polymer	12.6	2.3

The effects of the scavengers may be summarized as follows: the formations of ethyltoluene, toluene, and ethane are not affected by N_2O in the 10-MHz discharge, but the yields of toluene and ethyltoluene are inhibited to about half in the 2450-MHz discharge. On the other hand, while O_2 inhibits the

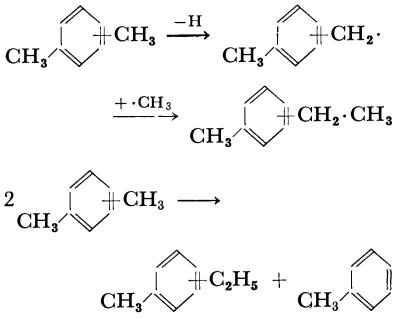
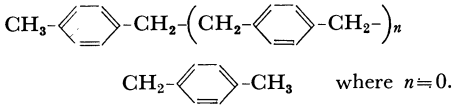
Fig. 2. 10-MHz discharge of *p*-xylene.

yield of products in both the discharges, as is shown in Figs. 1 and 2. From the above results, both the radical and ionic (not radical) processes may be considered to be present in the 2450-MHz discharge and the radical process is predominant in the formation of products in the 10-MHz discharge as well as in the toluene decomposition.*2 In the 2450-MHz discharge, however, the inhibition of the product yields by O_2 is relatively higher in *p*-xylene than in toluene and the inhibition of the product by N_2O is smaller in *p*-xylene than in toluene. The difference in the effects of the scavengers between *p*-xylene and toluene may be considered to be the effects of the substituted methyl group. The ionic process is not more important than that of toluene decomposition. The process may be described as follows:



The High-boiling Fraction, Oligomer from *p*-Xylene. The IR spectra of the polymers from *p*-xylene showed the presence of an aliphatic methylene group at 2910 cm^{-1} and 2850 cm^{-1}, and a methyl group at 2950 cm^{-1} and 2875 cm^{-1}. The presence of the methylene group was also confirmed by another band at 1445 cm^{-1} (methylene skeleton vibration), and that of the *C*-methyl group, by a weak band at 1380 cm^{-1}. The presence of an aromatic ring was confirmed by the characteristic vibrations at 1510 cm^{-1} and 1605 cm^{-1}. In the 600—900 cm^{-1} region, the strong band at 815 cm^{-1} showed clearly the presence of *p*-substitution of the benzene ring. The band of double-bond stretching (1640 cm^{-1}) was not observed.

The NMR spectra of the polymers were determined in carbon tetrachloride, using tetramethylsilane (at τ value 10.0) as an internal standard. The chemical shifts were measured relative to the standard. The spectra involve three single bands, at τ 3.03, 7.15, and 7.67, having area ratios of 4.0 : 1.3 : 3.0 in both the 2450-MHz and 10-MHz discharge polymers. These protons are, respectively, those of *p*-substituted benzene, *p*-substituted methylene, and *p*-substituted methyl with IR data. From the area ratio of the protons, the number of *p*-substituted methylene ($\langle\bigcirc\rangle$-CH_2-CH_2-$\langle\bigcirc\rangle$) can be said to be small. However, it can not be monomethylene ($\langle\bigcirc\rangle$-CH_2-$\langle\bigcirc\rangle$) because the chemical shift of the proton of monomethylene is measured at τ 6.15. From these results, the structure of oligomer may be represented as:



The presence of xylylene (CH_2=$\bigcirc$=CH_2) and its dimers could not be confirmed in these discharge reactions. The fraction of oligomers among the products was larger in the 10-MHz discharge than in the 2450-MHz, while the total conversion of *p*-xylene was higher in the 2450-MHz than in the 10-MHz discharge. The fraction of oligomer production may be considered to depend on the time of

*2 The photolysis of *o*-xylene gives ethyltoluene as the major product.[2]

Studies of the Electric Discharge of Organic Compounds. III. The Decomposition of Methylcyclohexane in 10-MHz and 2450-MHz Discharges

Ko Taki

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received October 16, 1969)

In the electric discharge of the methyl-substituted benzene homologue,[1,2] methyl migration has been found to be a main process. In this paper the methyl-group migration on methylcyclohexane in the high-frequency electric discharge was examined. Methylcyclohexane was chosen as a representative of saturated hydrocarbons. As has been shown previously,[1] radical and electron scavengers were used to investigate the reaction process, and the product distributions were described. Methylcyclohexane (Tokyo Kasei Kogyo Co., Ltd.) was purified by repeated distillation so as to make it gas-chromatographically pure.

Results and Discussion

The gaseous products were methane, ethane, ethylene, acetylene, propane, methylacetylene, allene, isobutane, butadiene, and seven unidentified products, while the liquid products were 1-methylcyclohexene, 4-methylcyclohexene, cyclohexane, and ten unidentified products. It was confirmed that ethylcyclohexane*1 is not formed in the present work, while in the case of toluene ethylbenzene is one of the major products. The yields of the products are shown in Table 1. Figures 1 and 2 show the effects of added oxygen and nitrous oxide on the yields of 1-methylcyclohexene and 4-methylcyclohexene.

From these data, the effects of additives can be summarized as follows: The yields of 1-methylcyclohexene and 4-methylcyclohexene decrease with an increase in the quantity of O_2 and N_2O scavengers in both the discharges, but the effect seems to be a little larger in the case of the O_2 scavenger. Moreover, the formation of ethane is inhibited by O_2, but not by N_2O, in both the discharges. The formation of cyclohexane is inhibited by both the scavengers; no striking difference in effect between the two additives is observed. The main products, 1- and 4-methylcyclohexenes, may be formed by the dehydrogenation, of the cyclohexane ring. Arnold[3] reported that the decomposition of cyclohexane in an electric discharge can be explained quantitatively by a radical mechanism.

The formation of cyclohexane and ethylcyclohexane involves the cleavage and recombination of the methyl group from methylcyclohexane, but ethylcyclohexane was not obtained in the discharges. The migration of the methyl group is quite different from that of toluene and xylene. The reason for this is not clear, but it may be explained by the stability of the benzene ring. Moreover, the fact that nitrous oxide does not inhibit the formation of 1- and 4-methylcyclohexenes so greatly as toluene decomposition[1] may be explained by assuming that the compounds having an electron network, such as toluene, behave differently from the saturated counterparts, such as methylcyclohexane, in the electron bombardment of an electric discharge.

The decomposition of methylcyclohexane gives many fragmented products in the discharges; this fact coincides with the result reported by Streitwieser and Ward.[4] The differences between the

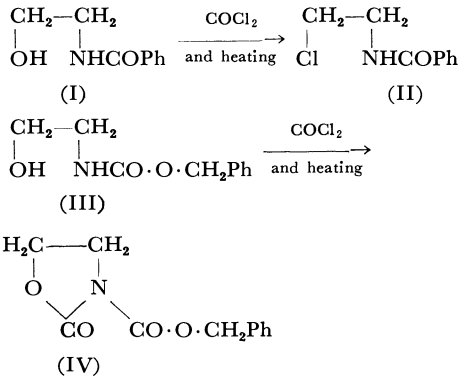
Oxazolidone Derivatives of Hydroxyamino Acid. VI.[1] Reactions of Phosgene on *N*-Acylserine Esters

Toshishige INUI, Shigeo TANAKA and Masakatsu TAKINO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

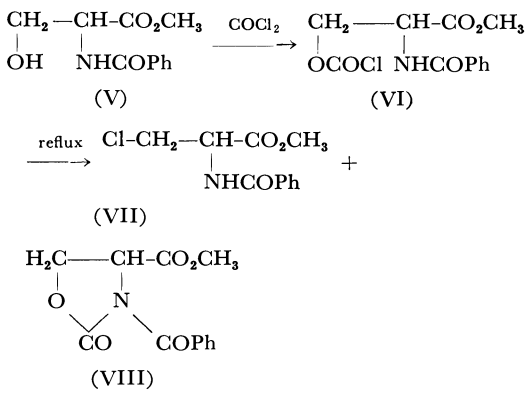
(Received October 20, 1969)

Treatment of *N*-(β-hydroxyethyl)-benzamide (I), *i.e.* *N*-benzoyl derivative of β-hydroxyethylamine, with phosgene and subsequent heating afforded *N*-(β-chloroethyl)-benzamide (II) through the corresponding *O*-chlorocarbonyl derivative. However, under the same condition, benzyl *N*-(β-hydroxyethyl)-carbamate (III) yielded only 3-benzyloxy-



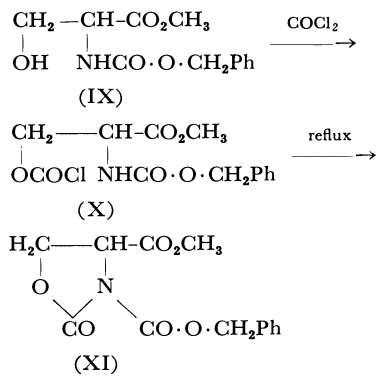
carbonyl(cbz)-2-oxo-oxazolidine (IV).[2] The present paper is concerned with the reactions of phosgene with *N*-benzoyl- and *N*-cbz-derivatives of methyl L-serinate (V and IX), having structures similar to those of I and III respectively.

Bergel reported that the reaction of benzyl *N*-cbz-DL-serinate with phosgene in benzene gave benzyl *N*-cbz-*O*-chlorocarbonyl-DL-serinate.[3] In the present study, methyl *N*-benzoyl-L-serinate (V), obtained from methyl L-serinate and benzoyl chloride, was converted with phosgene to the *O*-chlorocarbonyl derivative (VI). Reflux of VI in xylene provided a crystalline product, which was shown to be a mixture of methyl L-2-benzamido-3-chloropropionate (VII) and methyl 3-benzoyl-L-2-oxo-oxazolidine-4-carboxylate (VIII) by means of thin-layer chromatography with silica gel G (TLC). Separation of VII from VIII was achieved by using a column with silica gel, and by eluting it with a mixture of chloroform and ethyl acetate (9 : 1, v/v). The structures of compounds, VII and VIII, were



confirmed by their infrared spectra and nuclear magnetic resonance (NMR) spectra.

In a similar manner, the oily methyl *N*-cbz-L-serinate (IX) was converted with phosgene to the corresponding *O*-chlorocarbonyl compound (X). In this case, methyl 3-cbz-L-2-oxo-oxazolidine-4-carboxylate (XI) was obtained as the sole product by heating X in xylene. The structure of XI was also confirmed by elemental analysis and by a study of its



NMR spectra. Catalytic hydrogenation and subsequent hydrolysis of XI gave L-2-oxo-oxazolidine-4-carboxylic acid (XII). The properties tested on XII were identical with those of the authentic sample[4,5].

Experimental*1

Methyl *N*-Benzoyl-L-serinate (V). To a cold solution of methyl L-serinate hydrochloride (15.6 g, 0.1 mol) in water (225 m*l*), sodium hydrogen carbonate (25.2 g, 0.3 mol) and benzoyl chloride (16.0 m*l*, 0.13 mol) were added in succession. The reaction mixture was stirred for 2—3 hr at room temperature, and the resulting clear solution was extracted twice with ethyl acetate. Evaporation of the dried extract provided V as crystals. Yield, 18.0 g (81%), mp 85—86°C after recrystallization from benzene, $[\alpha]_D^{20}$ +16.0° (*c* 1.25, 95% ethanol); lit,[6] mp 84—86°C, $[\alpha]_D^{26}$ +17.7° (*c* 1, 95% ethanol).

Found: C, 59.27; H, 5.95; N, 6.34%. Calcd for $C_{11}H_{13}NO_4$: C, 59.19; H, 5.87; N, 6.27%.

Methyl *N*-Benzoyl-*O*-chlorocarbonyl-L-serinate (VI). Phosgene was passed through a solution of V (13.4 g, 0.06 mol) and *N*,*N*-dimethylaniline (7.3 g, 0.06 mol) in benzene (240 m*l*) at 5—10°C for 20 min, and the mixture was stirred for 2—3 hr below 20°C. Nitrogen was passed through the solution to remove the excess phosgene. The benzene solution was washed with dilute hydrochloric acid. The dried solution was evaporated *in vacuo* to give VI. Yield, 15.1 g (88%), mp 95—96°C (decomp.) after recrystallization from benzene.

Found: C, 50.28; H, 3.86; N, 4.85%. Calcd for $C_{12}H_{12}NO_5Cl$: C, 50.46; H, 4.23; N, 4.90%.

Treatment of a solution of VI in benzene with an etheral solution of aniline gave methyl *N*-benzoyl-*O*-(*N*-phenylcarbamoyl)-L-serinate; mp 134°C, $[\alpha]_D^{20}$ −24.1° (*c* 2.36, *N*,*N*-dimethylformamide).

Found: C, 63.16; H, 5.22; N, 7.76%. Calcd for $C_{18}H_{18}N_2O_5$: C, 63.15; H, 5.30; N, 8.18%.

Methyl L-2-Benzamido-3-chloropropionate (VII) and Methyl 3-Benzoyl-L-2-oxo-oxazolidine-4-carboxylate (VIII). A solution of VI (2.86 g, 0.01 mol) in xylene (60 m*l*) was refluxed for 4.5 hr. The solution was evaporated *in vacuo* to give an oil which was solidified by seeding (wt, 2.44 g). It gave a strong positive Beilstein's test and exhibited two spots on TLC. The product in a minimum amount of chloroform was adsorbed on a column (diameter 1.6 cm) of silica gel (50 g) and eluted with a mixture of chloroform and ethyl acetate (9: 1, v/v). Aliquots of the effluent fractions were subjected to TLC.

The fractions, exhibiting a single spot (R_f~0.50)*2 on TLC, were combined and evaporated *in vacuo* to give VII as crystals. Yield, 0.62 g (25.6%) mp 112—114°C. Recrystallization from petroleum ether raised the melting point to 114—116°C, $[\alpha]_D^{20}$ −12.9° (*c* 1.67, 95% ethanol); lit,[6] mp 114—115.5°C,$[\alpha]_D^{23}$ −14° (*c* 1, 95% ethanol).

IR (Nujol mull): 3280, 1635, 1540 (–CONH– in the amide group), 1735 cm^{-1} (C=O in the ester group).

NMR (Deuterochloroform solution, 60 MHz): 3.84 (singlet, CH_3– peak in the ester group), 4.03 (doublet, J=3.2 Hz, $-CH_2-$ peak in the Cl–CH_2–CH group), 5.16 (quintet, >CH peak in the $-CH_2-CH-NH-$ group), 6.85—7.20 (broad, NH peak), 7.25—7.90 ppm (multiplet, C_6H_5– peak).

Found: C, 54.46; H, 4.70; N, 5.50%. Calcd for $C_{11}H_{12}NO_3Cl$: C, 54.67; H, 5.00; N, 5.80%.

The other fractions exhibiting a single spot (R_f~0.25)*2 on TLC, were also combined and evaporated *in vacuo* to obtain VIII as prisms. Yield, 0.25 g (10.0%), mp 123—124°C. For analysis, it was recrystallized from benzene-petroleum ether (2: 1), mp 124.0—124.5°C, $[\alpha]_D^{23}$ −10.6° (*c* 2.08, methanol).

IR (Nujol mull): 1790 (C=O in the oxazolidone ring), 1750, 1730 (C=O in the ester group), 1680 cm^{-1} (C=O in the benzoyl group).

NMR (Deuterochloroform solution, 60 MHz): 3.80 (singlet, CH_3– peak in the ester group), 4.17—5.15 (multiplet, $-CH_2-CH$ peak in the oxazolidone ring), 7.35—7.75 ppm (multiplet, C_6H_5– peak).

Found: C, 57.58; H, 4.40; N, 5.89%. Calcd for $C_{12}H_{11}NO_5$: C, 57.83; H, 4.45; N, 5.62%.

Methyl *N*-Cbz-L-serinate (IX). Applying the method for the preparation of dimethyl *N*,*N*′-biscbz-L-cystinate by Zervas[7], a solution of methyl L-serinate hydrochloride (3.1 g, 0.02 mol) in a mixture of 30% aqueous potassium hydrogen carbonate solution (30 m*l*) and chloroform (30 m*l*) was treated with cbz-chloride (4.0 m*l*) at 5°C for 1 hr. The chloroform layer was treated with pyridine (1.0 m*l*) at 5°C for 10 hr and then washed successively with dilute sulfric acid, water and dilute aqueous potassium hydrogen carbonate solution. Evaporation of the dried solution gave IX as syrup. Yield, 4.3 g (85%).

Methyl *N*-Cbz-*O*-chlorocarbonyl-L-serinate (X). In a way similar to that described for the preparation of VI, phosgene was passed through a solution of IX (5.0 g, 0.02 mol) and *N*,*N*-dimethylaniline (2.4 g, 0.02 mol) in benzene (80 m*l*) for 20 min at 5—10°C. From the reaction mixture, X was obtained as white crystals. Yield, 5.1 g (82%), mp 65—67°C.

Found: C, 49.98; H, 4.33; N, 3.85%. Calcd for $C_{13}H_{14}NO_6Cl$: C, 49.46; H, 4.47; N, 4.44%.

Methyl *N*-cbz-*O*-(*N*-phenylcarbamoyl)-L-serinate was obtained by treatment of aniline on X, mp 127—128°C and 128—129°C after recrystallization from benzene, $[\alpha]_D^{20}$ −23.6° (*c* 1.25, *N*,*N*-dimethylformamide).

Found: C, 61.08; H, 5.39; N, 7.40%. Calcd for $C_{19}H_{20}N_2O_6$: C, 61.28; H, 5.41; N, 7.52%.

Methyl 3-Cbz-L-2-oxo-oxazolidine-4-carboxylate (XI). A solution of X (2.5 g, 0.008 mol) in xylene (50 m*l*) was refluxed for 5 hr. The solution was evaporated *in vacuo* to leave crystals exhibiting a single spot (R_f~0.45)*2 on TLC. Yield, 1.6 g (72%), mp 63—64°C and 64—65°C after recrystallization from ether, $[\alpha]_D^{20}$ −80.1° (*c* 3.39, methanol).

IR (Nujol mull): 1810 (C=O in the oxazolidone ring), 1745 (C=O in the ester group), 1730 cm^{-1} (C=O in the cbz group).

*1 All melting points are uncorrected.

6) E. M. Fry, *J. Org. Chem.*, **15**, 438 (1950).

*2 The R_f values refer to TLC with the chloroform-ethyl acetate (9: 1, v/v) as solvent system.

7) L. Zervas and L. Photaki, *J. Amer. Chem. Soc.*, **84**, 3887 (1962).

NMR (Deuterochloroform solution, 60 MHz): 3.73 (singlet, CH_3– peak in the ester group), 4.14—4.94 (multiplet, $-CH_2-\underset{|}{CH}-$ peak in the oxazolidone ring), 5.30 (slightly split singlet, $-CH_2-$ peak in the cbz group) 7.35 ppm (singlet, C_6H_5– peak).

Found: C, 56.01; H, 4.62; N, 5.12%. Calcd for $C_{13}H_{13}NO_6$: C, 55.92; H, 4.69; N, 5.02%.

L-2-Oxo-oxazolidine-4-carboxylic Acid (XII). A stream of hydrogen was passed through a solution of XI (4.2 g, 0.015 mol) in a mixture of methanol (50 m*l*) and water (10 m*l*) for 3 hr in the presence of 10% palladium on carbon (1.0 g). After the catalysts had been removed by filtration, the filtrate was evaporated *in vacuo* to provide an oil (wt, 1.4 g). Into a solution of the oil in methanol (35 m*l*), 1 N potassium hydroxide (9.5 m*l*, 0.0095 mol) was added and the mixture was stirred for 1.5 hr at room temperature. The solvent was evaporated *in vacuo* to a small volume, and the residual solution was diluted with water. The aqueous solution was extracted with ethyl acetate and acidified with 1 N hydrochloric acid (10 m*l*). The acidic solution was evaporated *in vacuo* to dryness and the residue was extracted three times with hot ethyl acetate. The dried extract was evaporated *in vacuo* to give XII as crystals. Yield, 1.0 g (51%), mp 114—117°C and 118—119°C after recrystallization from ethyl acetate-petroleum ether, $[\alpha]_D^{20}$ −18.2° (*c* 2.23, water); lit,[4] mp 118.5—120°C, $[\alpha]_D^{22.5}$ −17.7° (*c* 3.44, water).

The mixed melting point with an authentic sample was not depressed. The results obtained by means of infrared spectra were also identical with those of an authentic sample.

The authors wish to express their thanks to Professor T. Kaneko of Faculty of Science, Osaka University, for his valuable discussions, and to the Ajinomoto Co., Inc., for supplying the amino acids.

Absolute Configuration of Menthenone Oxide

Jun KATSUHARA, Hisaichi YAMASAKI and Noriyuki YAMAMOTO

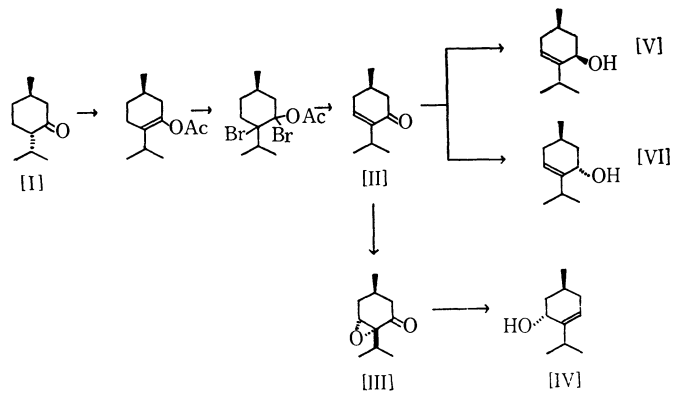
Sun Star Dentifrice Company, Research Laboratory, Takatsuki, Osaka

(Received October 25, 1969)

One[1] of the authors (J.K.) has recently discussed the epoxidation mechanism of endocyclic α,β-unsaturated terpene ketones, and, on the basis of orbital-overlap concept,[2] has concluded that the oxirane group is stereoselectively introduced to the double bond so as to sterically enable the most favored transition state conformation to be stabilized by an effective and concomitant orbital-overlap stabilization. When this generalization is applied to (1R)-4-menthene-3-one (II), the exclusive formation of 4-menthen-3-one oxide (III) having the (1R : 4R : 5R)-configuration may be predicted.

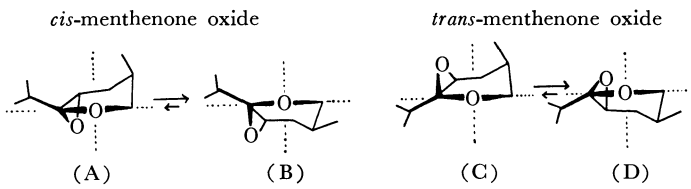
We wish in this paper to describe the determination of the absolute configuration of (+)-menthenone oxide (III) by an unequivocal chemical transformation into known derivative (+)-*trans*-menthenol (IV) of the well-defined configuration (1 S : 3 R) by the following scheme.

The results unambiguously demonstrate that the absolute configuration of (+)-menthenone oxide



Scheme 1

1) J. Katsuhara, This Bulletin, **42**, 2391 (1969).
2) H. E. Zimmerman, L. Singer and B. S. Thyagaraja, *J. Amer. Chem. Soc.*, **81**, 108 (1959).



Scheme 2

(III) is *cis*-(1 R : 4 R : 5 R). This is what was predicted previously.[1]

Octant projection diagrams, when conformational generalization is applied to the present *cis*- and *trans*-menthenone oxide systems, are shown in Scheme 2. It can be seen that, of the four conceivable conformations A, B, C and D, B and D are conformationally more favored than the respective counterpart. The diagrams show that in the ORD-measurement, *cis*-menthenone oxide should exhibit a high positive [ϕ] value whereas the *trans*-oxide a low negative [ϕ] value. This is also in good agreement[3] with the ORD data found for the (+)-menthenone oxide (a=+25), cogently supporting the configuration of *cis*-(+)-III as assigned above.

Experimental

Preparation of Menthenone Oxide (III). (−)-Menthenone (II)[4] 7.0 g, $[\alpha]_D^{20}$ −52.2° (c 0.6, ethanol), UV; $\lambda_{max}^{methanol}$ 236 mμ (ε, 7240), II-2,4-dinitrophenylhydrazone mp 142°C (lit,[4] mp 143°C), yield 87.0%, derived from (−)-menthone (I), $[\alpha]_D^{20}$ −22.1° (c 0.6, ethanol) was epoxidized with 26 m*l* of 30% hydrogen peroxide and 3.5 g of sodium in 140 m*l* of methanol for 5 hr at −30°C to menthenone oxide (III). The crude III indicated a single product by VPC analysis. Further purification on a preparative VPC gave pure III, $[\alpha]_D^{20}$ +61.5° (c 1.0, methanol), UV; $\lambda_{max}^{methanol}$ 299 mμ (ε, 20), 288 mμ (ε, 19), CD; mμ ([θ]) in methanol, 350 (0), 308 (+2035), 245 (0), 205 (+6460), ORD; mμ ([ϕ]) in methanol, 400 (+392), 355 (+1632), 292 (−849), 250 (+554), 220 (+3589), 210 (+979), yield 63.5%.

Found: C, 71.26; H, 9.65%. Calcd for $C_{10}H_{16}O_2$: C, 71.44; H, 9.60%.

Preperation of (+)-*trans*-Menthenol. By means of the Wharton reaction[5] technique, the oxide III has been converted into crude (+)-*trans*-menthenol (IV), $[\alpha]_D^{20}$ +69.1° (c 0.6, ethanol), yield 87.0%, IV-*p*-nitrobenzoate mp 54°C (lit,[6] mp 55°C), $[\alpha]_D^{20}$ −197° (c 0.1, chloroform).

Reduction of Menthenone (II). (−)-Menthenone (II) was reduced with lithium aluminum hydride in ether to give a mixture (yield 80.0%) of (−)-*cis*-menthenol (V), $[\alpha]_D^{24}$ −32.0° (c 1.0, ethanol), V-*p*-nitrobenzoate mp 38°C, $[\alpha]_D^{24}$ −10.4° (c 0.1, chloroform), and (−)-*trans*-menthenol (VI), the ratio of formation V: VI was 93: 7 as determined by VPC analysis. The epimeric (−)-VI was identified to be (+)-IV by comparison of each R_t of VPC.

The author wishes to thank Professor Tamon Matsuura of Hiroshima University, Professor Yuzo Inouye of Kyoto University, and Dr. Hitoshi Minato and Dr. Kaoru Kuriyama of Shionogi Research Laboratory for many helpful discussions during the course of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1586—1588 (1970)

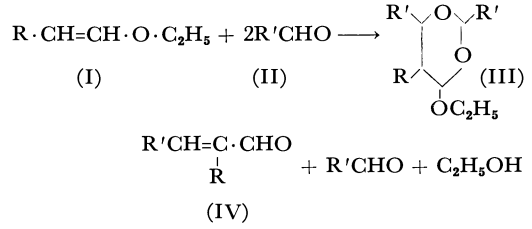
Preparation of Some α,β-Unsaturated Aldehydes

Sadayoshi SATSUMABAYASHI, Kiyoshi NAKAJO, Ryuichi SONEDA and Shinichi MOTOKI

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received November 5, 1969)

Copenhaver[1] and Hoaglin[2] reported that α,β-unsaturated ethers reacted with saturated aldehydes to form unsaturated aldehydes having two more carbon atoms than the starting aldehydes. However, the works were limited to the reactions of vinyl alkyl ethers with aldehydes except for the reaction of 1-butenyl methyl ether with butyraldehyde. If β-substituted vinyl alkyl ethers were used in addition to vinyl alkyl ethers in these reactions, they could be generalized as a preparative method for α,β-unsaturated aldehydes.



(I) (II) (III)

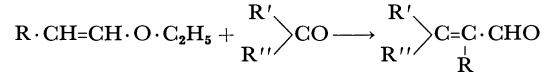
(IV)

In the present study, 1-propenyl ethyl ether (Ia), 1-butenyl ethyl ether (Ib) and 3-cyano-1-propenyl ethyl ether (Ic) were used as the alkenyl alkyl ether component (I), and acetaldehyde (IIa), propionaldehyde (IIb), butyraldehyde (IIc), benzaldehyde (IId) and β-cyanopropionaldehyde (IIe) were used as the aldehyde component (II). All the reactions of I with II were carried out according to Hoaglin's method, and the results obtained are presented in Table 1.

Hoaglin and Hirsch reported that the intermediate of the reaction was 1,3-dioxane (III), an addition product of one molecule of I and two of II, but gave no experimental details on the isolation and identification of III.[2]

When the catalyst was neutralized with sodium carbonate prior to hydrolysis, a colorless compound was isolated by distillation in a fairly good yield. The analytical values and molecular weight of this compound were very close to those of III, and the IR spectrum exhibited strong doublet peaks in the region 1150—1080 corresponding to those of 1,3-dioxane. This compound was readily converted to the unsaturated aldehyde (IV) by means of hydrolysis with dilute acid. From these facts, it may be concluded that the product is III. The results are summarized in Table 2.

The reaction was also extended to ketones. In a similar manner to that with aldehydes, the reaction of I with acetone (Va) as well as methyl ethyl ketone (Vb) was carried out. Although the yields of VI were lower than those of IV, the expected α,β-unsaturated aldehydes (VI) were also obtained as shown in Table 3. The intermediates were not isolated in this case.



(I) (V) (VI)

The advantage of this method, in comparison with aldol condensation, lies in the preparation of the optional α-substituted-α,β-unsaturated aldehydes and the ease of isolation of the product. Condensation of aldehyde with ketone has a significant limitation. Self-condensation of aldehyde or condensation at the α-carbon atom of ketone takes place and ketone does not condense at the α-carbon atom of aldehyde to form unsaturated aldehyde with simple basic or acid catalysts. Thus, the present reaction to yield VI is regarded as a reaction of wide utility.

Experimental

Materials. 1-Propenyl ethyl ether (Ia) and 1-butenyl ethyl ether (Ib) were obtained by catalytic decomposition of the corresponding aldehyde diethyl acetals.[3]

3-Cyano-1-propenyl ethyl ether (Ic) was prepared from β-cyanopropionaldehyde diethyl acetal.[4]

α-Substituted-α,β-unsaturated Aldehydes (IV). To a mixture of 0.1 mol of unsaturated ether (I) and 0.3 mol of aldehyde (II), 0.5 g of boron trifluoride etherate in 5 m*l* of diethyl ether was added with good agitation under an anhydrous condition. The temperature of the content was maintained at about 30°C by regulating the rate of addition of catalyst and by external cooling with water. After the mixture was stirred for 4 hr at room temperature, the reaction mixture was directly hydrolyzed by refluxing with 50 m*l* of 10% hydrochloric acid for 6 hr. The oily product was ex-

tracted with ether and dried over anhydrous sodium sulfate. Distillation of the extract gave the results shown in Table 1.

In the case of the use of acetaldehyde, the reaction temperature was maintained at about 10°C on account of the low boiling point of the aldehyde.

1,3-Dioxane Derivatives (III). After stirring the reaction mixture of I and II for 4 hr as in the preceding experiment, 5 g of powdered anhydrous sodium carbonate was added to the mixture in order to neutralyze the catalyst. The mixture was well agitated for 3 hr and then filtered. Fractional distillation of the filtrate gave III. The results are summarized in Table 2.

Hydrolysis of III with 10% hydrochloric acid gave IV, yield *ca.* 90%.

2-Ethyl-2-butenal-(1) (IVf) was obtained from IIIa. bp 55—56°C/50 mmHg. Found: C, 73.14; H, 10.31%, Calcd for $C_6H_{10}O$: C, 73.43; H, 10.27%.

2-Ethyl-2-hexenal-(1) (IVh) from IIIb, bp 54—56°C/7 mmHg. Found: C, 76.28; H, 11.10%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%.

2-Ethyl-3-phenyl-2-propenal-(1) (IVi) from IIIc, bp 102—104°C/3 mmHg. Found: C, 82.20; H, 7.78%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%.

α-Substituted-α,β-unsaturated Aldehydes (VI). A mixture of 0.1 mol of I and 0.3 mol of the ketone (V) was treated with boron trifluoride in the same manner as for IV. After stirring for 6 hr, the mixture was hydrolyzed for 10 hr. The results are summarized in Table 3.

The authors wish to thank Professor Yojiro Tsuzuki for his helpful advice and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1588—1589 (1970)

Preparation of Tricarbonyliron-μ-Carbonyl-μ-Diphenylphosphido-π-Cyclopentadienylnickel*[1]

Katsutoshi YASUFUKU and Hiroshi YAMAZAKI

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received November 17, 1969)

Since hexacarbonyl-π-cyclopentadienylmolybdenum-π-cyclopentadienyltungsten was reported by Abel,[1] many efforts have been made for the preparation of mixed transition-metal complexes with metal-metal bond.[2] The complexes were mostly mixed metal carbonyls in which metals are bonded only with a metal-metal bond. Tricarbonyl-π-cyclopentadienyliron-π-cyclopentadienylnickel[3] and monocarbonyl-π-cyclopentadienyliron-μ-dicarbonyl-tricarbonylcobalt[4] belong to a few complexes which consist of a metal-metal bond and

bridged carbonyls. Recently, Thompson[5] reported the synthesis of a new class of heterodinuclear transition-metal complexes joined by a metal-metal bond and a single phosphorus bridge by the reaction of tetracarbonyldiphenylphosphineiron with π-allyltricarbonylmanganese, -cobalt and π-allylpalladium chloride dimer.

In the present paper, we wish to report the preparation of a new mixed transition-metal complex consisting of iron and nickel which are bonded with a metal-metal bond, and with a bridged phosphido and a bridged carbonyl groups.

Experimental and Results

π-Cyclopentadienyltriphenylphosphinenickel chloride (1 g)[6] and 0.8 g of tetracarbonyldiphenylphosphineiron (I)[7] were allowed to react with excess diethylamine in methylene chloride at room temperature for two days. The reaction mixture was concentrated and subjected to chromatography on alumina with hexane-methylene chloride mixture as an eluent. Concentration of the brown eluate gave 0.41 g of brown cyrstals, mp*2 150—152°C, (Yield 45%. Found: C, 52.93; 3.30%. Calcd for $C_{21}H_{15}O_4PFeNi$: C, 52.90; H, 3.17%) The X-ray emission spectrum*3 indicated bands corresponding to NiKα at 51°34′, to FeKα at 61°08′ and PKα at 54°54′.

The same product was obtained in 25% yield by a similar treatment from π-cyclopentadienylcarbonylnickel iodide (prepared by method of Schropp[8]) and I in benzene with excess diethylamine at 0°C for four hours and at room temperature for two days.

$$\pi\text{-}C_5H_5Ni(PPh_3)Cl \text{ or } \pi\text{-}C_5H_5Ni(CO)I + HPh_2PFe(CO)_4 \rightarrow C_{21}H_{15}O_4PFeNi \quad (I)$$
$$\text{or } (\pi\text{-}C_5H_5)_2Ni$$

IR spectrum of the product showed the presence of terminal carbonyls and a bridged carbonyl both in KBr disk and in solutions as shown in Table 1. NMR spectrum (in $CDCl_3$) indicated signals of phenyl protons at 2.2—2.8τ and of cyclopentadienyl protons at 4.58τ. In mass spectrum,*4 the molecular peak consisting of ^{58}Ni and ^{56}Fe (which are the most abundant isotopic combination) appeared at m/e 476 (Calcd Mol Wt, 476) followed by peaks corresponding to successive loss of carbonyls as shown in Table 2. The peak at m/e 364 ($C_5H_5NiPPh_2Fe^+$) was the most abundant.

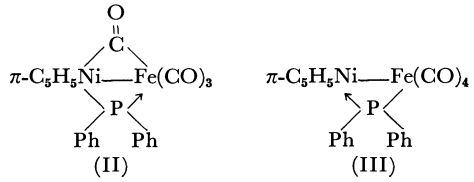
Table 1. IR spectrum of II in the ν_{CO} region

Solvent	ν_{CO} cm^{-1} terminal CO				bridged CO
KBr	2025	2018 s	1977 s	1956 s	1814 s
Hexane	2035 s	1990 s	1978 s		1840 s
CH_2Cl_2	2030 s	1985 s	1970 s		1820 s
CS_2	2032 s	1986 s	1972 s		1830 s
THF	2030 s	1965 s	broad		1825 s

Table 2. Mass spectrum of II
(only peaks consisting of ^{58}Ni and ^{56}Fe)

Fragment	m/e	Relative intensity
M^+	476	24
$(M-2CO)^+$	420	22
$(M-3CO)^+$	392	11
$(M-4CO)^+$	364	100
$(M-4CO-C_6H_6)^+$	286	22
$(M-4CO-C_6H_6-H_2)^+$	284	20

These spectral data suggest structure II for the present complex. It had been noted that the infrared spectra of octacarbonyldicobalt[9] and dicarbonyl-π-cyclopentadienyliron dimer[10] are markedly dependent on solvent in the ν_{CO} region and the structure in solution differs from that in crystalline state. Although the other structure III seems to be plausible as seen in the complexes obtained by Thompson,[5] the IR spectra in various solvents indicated no serious transformation in the ν_{CO} region showing the absence of any contribution of structure III even in solution.



II was also obtained in 35% yield by the reaction of I with nickelocene in tetrahydrofuran at room temperature for a week. The reaction did not occur in benzene or in methylene chloride solutions. In contrast to the high reactivity of the π-allyl complexes of cobalt, manganese and palladium with I,[5] π-allyl-π-cyclopentadienylnickel was much less reactive and gave II only in a low yield (<2%).

II is very stable in air, especially in solid state and is soluble in most organic solvents.

We thank Dr. Yasuo Takahashi and Mr. Sakae Satooka for measurement of the X-ray emission spectrum and the mass spectrum.

Coumarin-4-carboxylic Acids from Coumaran-2,3-diones

Masao KAWAI, Teruo MATSUURA and Ruka NAKASHIMA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received November 18, 1969)

The synthesis of coumarin-4-carboxylic acids (I) reported so far consists of condensation of phenols with phenols with oxalacetic acid or its equivalent.[1-3] During the course of our studies[4] on the structure and reactions of 4,7-dimethyl-5-ethylcoumaran-2,3-dione (IIg), a pyrolysis product of tetrahydrophysalin A,[5] we found that coumaran-2,3-diones (II) gave coumarin-4-carboxylic acids (I) under reflux in acetic anhydride containing catalytic amount of pyridine. The results are given in Table 1. This reaction is considered useful for the preparation of I with $R_1=R_4=CH_3$, because, by the earlier method, condensation of 2,5-xylenol with oxalacetate occurred mainly at 4-position of xylenol, affording the maleic acid derivative (III).

Table 1. Results of the formation of I from II

Starting material	Coumarin-4-carboxylic acids obtained (Yield %)	Recovery (%)
IIa[6]	Ia (12)	5
IIb[4]	Ib (14)	20
IIc[7]	Ic (7)	45
IId[7]	Id (8)	8
IIe[4]	Ie (12)	43
IIf[4]	If (19)	50

The mass spectra of I are summarized in Table 2. Compounds I with $R_1=CH_3$ gave a strong peak at *m/e* *M*-18 as well as at *m/e* *M*-44 and *m/e* *M*-45. In contrast to this, I with $R_1=H$ showed no significant peak at *m/e* *M*-18, suggesting that in the case of I with $R_1=CH_3$ the ion corresponding to *m/e* *M*-18 has mainly structure IV. From this observation, the mass spectra of various monomethyl derivatives of 1-naphthoic acid were examined. As expected only 8-methyl derivative gave a strong peak at *m/e* 168 (*M*-18). In other cases the peak at *m/e* 169 (*M*–OH) was stronger than that at *m/e* 168 (*M*-H_2O). The results are summarized in Table 3.

Experimental

Melting points were uncorrected. IR spectra were measured in KBr. Mass spectra were obtained using a Hitachi RMS-4 mass spectrometer with ionizing voltage of 70 eV.

General Procedure. Coumaran-2,3-dione (II) (*ca.* 400 mg) was refluxed in acetic anhydride (40 ml) containing a few drops of pyridine for 7—8 hr. The reaction mixture was evaporated *in vacuo* and the residual mass was triturated with water. The crude product was chromatographed on silica gel (3.0 g). First, elution with 5% acetone-light petroleum gave starting material (II), and then with 15% acetone-light petroleum, mainly cou-

marin-4-carboxylic acid (I). When necessary, this fraction was rechromatographed on silica gel (2.0 g) using 10% ether-light petroleum as eluent. Melting points and the results of elementary analysis of I are given in Table 4. The IR spectra of Ia and Ib were identical with those of authentic samples synthesized.[1,3]

Condensation of 2,5-Xylenol with Sodium Diethyl Oxalacetate. Intimate mixture of 2,5-xylenol (3.97 g) and sodium diethyl oxalacetate (5.25 g) was added into the ice-cooled concd. H_2SO_4 (25 m*l*). After 7 hr the reaction mixture was poured into ice-water. The solid separated was dissolved in NaOH aq. solution and carbon dioxide was introduced into it to remove unreacted xylenol by filtration. HCl aq. solution was added to the filtrate and the crude product separated was recrystallized from acetone giving 650 mg of III, mp 165—70°C.

IR spectrum: 1730, 1690, 1620 and 1575 cm^{-1}.

Found: C, 60.73; H, 5.20%. Calcd for $C_{12}H_{12}O_5$: C, 61.01; H, 5.12%.

Sublimation of III gave an anhydride (mp 169°C). IR spectrum: 1820, 1750, 1615 and 1565 cm^{-1}. (Found: C, 65.87; H, 4.68%).

On thin layer chromatography the mother liquor of III showed no spot corresponding to Ic.

The authors wish to thank Drs. T. Fujita and M. Utaka for the supply of 3-, 4-, 5-, 6-, 7- and 8-methyl-1-naphathoic acids.

Polymeric Structure in *N*-Picolinoyl-1,3-propanolaminatocopper(II) Dihydrate

Motomichi INOUE,* Heijirō OJIMA,** Kiyoko YAMADA,** and Masaji KUBO*

* *Department of Chemistry, Nagoya University, Chikusa, Nagoya*

** *Department of Chemistry, Aichi University of Education, Okazaki*

(Received November 19, 1969)

A number of copper(II) complexes have been synthesized with terdentate ligands. Magnetic measurements have indicated the presence of dimeric molecules in the crystals of these compounds.[1] Subsequently, the binuclear structure of acetylacetonemono(*o*-hydroxyanil)copper(II) has been established by X-ray crystal analysis.[2] The compound presents a typical example of binuclear structure in which copper atoms are bridged by two oxygen atoms. Its magnetic susceptibility conforms to the Bleaney-Bowers equation. On the other hand, the magnetic property of *N*-[2-(2-hydroxyethylthio) phenyl] arenesulfoamidatocopper-(II) obeys a theoretical equation for isolated ternuclear rings.[3] Ojima[4] has synthesized *N*-picolinoyl-1,3-propanolaminatocopper(II) dihydrate, which presents a new type of copper (II) complexes having terdentate ligands. Since the complex is prepared in basic solutions as described below, the nitrogen atom of the amide group coordinates to the metal ion as shown in Fig. 1.[5] In order to obtain some information about the structure of the copper(II) complex, we have determined the magnetic susceptibility in a temperature range of 80–300°K, using a Gouy magnetic balance described in previous papers.[3,6]

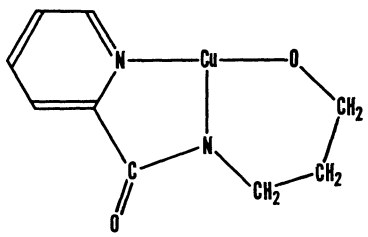

Fig. 1. Coordination of *N*-picolinoyl-1,3-propanolamine to a copper ion.

The material was prepared by a method described in a previous paper.[4] A mixture of methyl picolinate (1 mol) and 1,3-propanolamine (1 mol) was heated at 180—200°C for 8 hr. When the reaction product was diluted with water (1 : 2) and a saturated solution of copper(II) sulfate (1/2 mol) was added to it, the solution turned deep blue with heat evolution. On adding ethanol to the hot solution, blue crystals separated on cooling. When the crystals were left to stand in a desiccator over calcium chloride, $Cu(C_9H_{12}N_2O_2)_2SO_4 \cdot 2.5H_2O$ was obtained. Found: Cu, 11.45; N, 9.70; H_2O, 7.91%. Calcd for $Cu(C_9H_{12}N_2O_2)_2SO_4 \cdot 2.5H_2O$: Cu, 11.25; N, 9.92; H_2O, 7.97%. On adding sodium hydroxide solution (2 mol) to a concentrated aqueous solution of $Cu(C_9H_{12}N_2O_2)_2SO_4 \cdot 2.5H_2O$ (1 mol), *N*-picolinoylpropanolaminatocopper(II) dihydrate was obtained. It was recyrstallized from hot water. Found: Cu, 22.86; C, 38.86; H, 5.20; N, 10.20; H_2O, 12.99%. Calcd for $CuC_9H_{10}N_2O_2 \cdot 2H_2O$: Cu, 22.87; C, 38.92; H, 5.08; N, 10.09; H_2O, 12.97%.

The dihydrate was dehydrated in a vacuum desiccator over phosphorus pentoxide at about 100°C. Found: Cu, 26.28; C, 44,56; H, 4.22; N, 11.44%. Calcd for $CuC_9H_{10}N_2O_2$: Cu, 26.45; C, 44.72; H, 4.18; N, 11.59%.

The molar magnetic susceptibilities of the dihydrate and the anhydrous complex were determined as $0.77_8 \times 10^{-3}$ emu/mol (25°C) and 0.254×10^{-3} emu/mol (31°C), respectively. Corrections were made for diamagnetic contributions (in 10^{-6} emu/mol) from *N*-picolinoylpropanolamine (−120), water (−13),[7] and copper(II) ions (−11).[8] The value for the ligand was calculated from Pascal's constants.[7] The corrected molar susceptibilities are shown in Fig. 2 as functions of temperature.

Bleaney and Bowers[9] have proposed a theoretical

equation for the susceptibility, χ, of copper(II) complexes having a binuclear structure.

$$\chi = \frac{Ng^2\beta^2}{3kT}\left(1+\frac{1}{3}e^{2J/kT}\right)^{-1} + N\alpha \qquad (1)$$

where apart from obvious notations, J is the exchange integral and $N\alpha$ is the temperature-independent paramagnetism assumed to be equal to 60×10^{-6} emu/mol.[10] As shown in Fig. 2, the observed susceptibility of the anhydrous salt agrees well with the theoretical curve ($J/k=400$°K, $g=2.14$) above about 150°K, indicating the existence of dimer molecules in crystals. Presumably, the paramagnetic behavior below about 100°K is due to the presence of impurities and/or magnetically isolated copper(II) ions in small quantities.

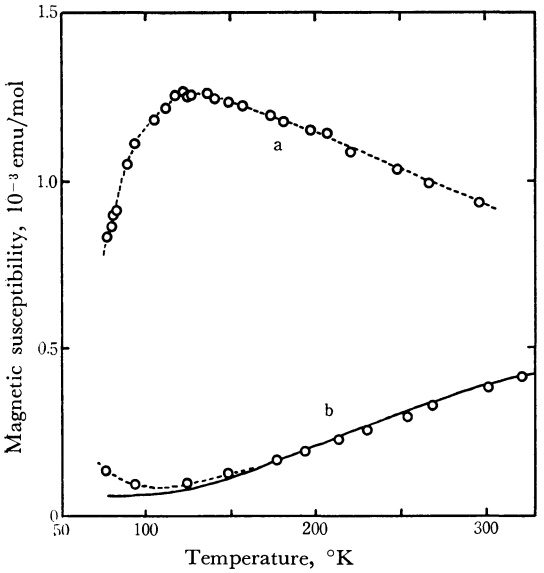

Fig. 2. Magnetic susceptibilities of *N*-picolinoyl-1,3-propanolaminatocopper(II) dihydrate (a) and the anhydrous salt (b). The solid curve represents the Bleaney-Bowers equation.

The magnetic susceptibility of the dihydrate cannot be fitted to the theoretical equation for isolated binuclear clusters. The magnetic susceptibilities for polymeric rings of spins have been calculated numerically by Bonner and Fisher[11] by use of the following Hamiltonian.

$$\mathcal{H} = -2J\sum_{i=1}^{n}\left(\boldsymbol{S}_i\boldsymbol{S}_{i+1}-\frac{1}{4}\right) \qquad (2)$$

where J is the exchange integral and $\boldsymbol{S}$ is the spin angular momentum ($\boldsymbol{S}_{n+1}=\boldsymbol{S}_1$). The theoretical curves are shown in Fig. 3. The observed susceptibility apparently fits the curve for a ring composed of even number of spins, especially that for a four-membered ring. The exchange integral, J, and g value were estimated as $|J|/k=92$°K and $g=2.08$, respectively. However, the observed values do not agree perfectly with the theoretical curve in the whole temperature range investigated. A conceivable reason for the discrepancy is the presence of two kinds of magnetic interaction in the cluster. Alternatively magnetic interaction might exist between clusters. In any case, polymeric structural units mostly containing even number of spins are formed in the crystal. The polymeric molecules in the dihydrate change to the binuclear clusters on dehydration. The important role of water molecules is open to speculation.

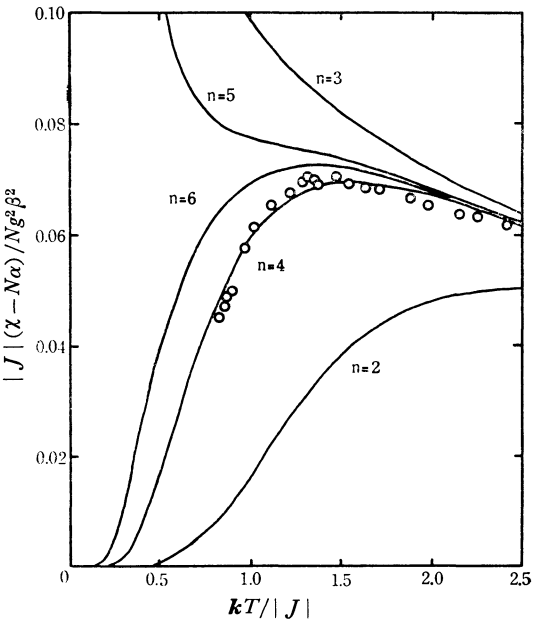

Fig. 3. Observed magnetic susceptibility of *N*-picolinoyl-1,3-propanolaminatocopper(II) dihydrate and theoretical curves calculated by Bonner and Fisher with Eq. (2). For a binuclear cluster ($n=2$), the exchange integral is equal to one fourth of the energy separation between the singlet and triplet states.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1594—1596 (1970)

The Kinetics of the Electrophilic Substitution Reaction of the *trans*-1,2-Cyclohexanediaminetetraacetatocadmate(II) Complex with Copper(II) Ion

Masaru KIMURA*[1]

Department of Applied Chemistry, Yamagata University, Yonezawa

(Received May 29, 1969)

The kinetics and the mechanisms of the electrophilic substitution reaction of the metal-ethylenediaminetetraacetate(EDTA) complex have been studied for several different reaction systems.[1-9] These metal-ion exchange reactions are all shown to proceed through the reaction of the entering metal ion with the EDTA complex and through that of the dissociated EDTA anion with the entering metal ion. Recently, similar electrophilic substitution reactions have been studied with *trans*-1,2-cyclohexanediaminetetraacetic acid (CyDTA) in place of EDTA.[2,10-12] In this case, there was no direct reaction between the entering metal ion and the CyDTA complex. This behavior was confirmed in the present study. In most cases, a metal-CyDTA complex has a larger stability constant (from 1 to 3 larger in the logarithm scale) than the corresponding EDTA complex.[13] Therefore, the dissociation reaction of CyDTA complexes may be expected to be considerably slower than that of the corresponding EDTA complexes. This expectation was also examined in this study.

Experimental

The solutions of disodium CyDTA and copper(II) nitrate were the same as those described in previous papers.[14,15] The cadmium(II) nitrate solution was prepared by dissolving pure cadmium metal in nitric acid: it was standardized against a standard CyDTA solution by amperometric titration.

The apparatus and procedure were also the same in principle as those described in the previous papers.[14,15]

Results

The overall reaction in acetate media is represented by:

$$\left\{\begin{matrix}Cu^{2+}\\ \uparrow\downarrow\\ CuOAc^{+}\\ \uparrow\downarrow\\ Cu(OAc)_2\end{matrix}\right\} + CdCy^{2-} \overset{V_i^+}{\rightleftharpoons} CuCy^{2-} + \left\{\begin{matrix}CdOAc^{+}\\ \uparrow\downarrow\\ Cd^{2+}\end{matrix}\right\} \quad (1)$$

Where Cy^{4-} denotes a tetravalent CyDTA anion. The forward reaction rate was obtained by the polarographic measurements of the copper(II)-ion concentration with the time. The copper-ion concentration that can be determined is an apparent concentration, *i.e.*, $[Cu^{2+}]_{app}=[Cu^{2+}]+[CuOAc^{+}]+[Cu(OAc)_2]$. Under the present experimental conditions, the forward reaction of Eq. (1) was so sluggish that the initial rate could be determined accurately. When the copper ion is present in a large excess over the cadmium ion, the initial rate was independent of the copper-ion concentrations, but it was proportional to the concentrations of the Cd(II)-CyDTA complex and the hydrogen ion (see Figs. 1, 2, and 3) On the other hand, when the cadmium ion is present in a large excess over the copper ion, the rate

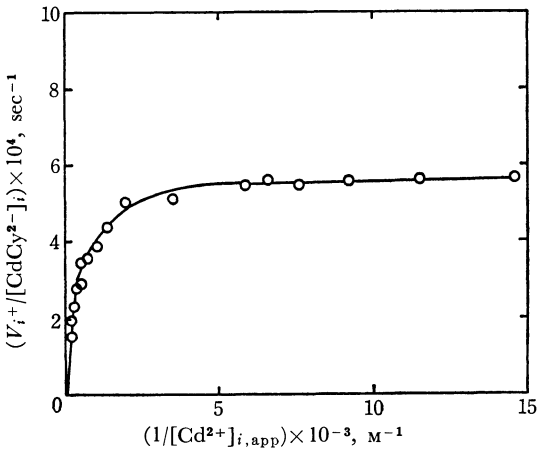

Fig. 1. $V_i^+/[CdCy^{2-}]_i$ as a function of the reciprocal cadmium concentration at ionic strength 0.2 and 25°C.
Initial concentrations are 1.12 mM and 5.03×10^{-1} mM for $[CdCy^{2-}]_i$ and $[Cu^{2+}]_{i,app}$ respectively, pH 4.90.

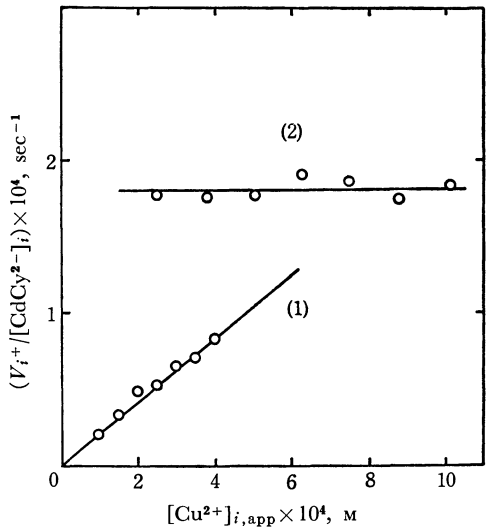

Fig. 2. $V_i^+/[CdCy^{2-}]_i$ as a function of the concentration of copper ion at ionic strength 0.2 and 25°C.
Initial concentrations are $[CdCy^{2-}]_i=2.25$ mM, $[Cd^{2+}]_{i,app}=6.3$ mM and pH 4.95 for curve 1, and $[CdCy^{2-}]_i=1.12$ mM, $[Cd^{2+}]_{i,app}=3.3\times 10^{-2}$ mM and pH 5.42 for curve 2.

was proportional to the concentrations of the copper ion as well as those of the Cd(II)-CyDTA complex and the hydrogen ion, and the rate was inversely proportional to the concentrations of the cadmium ion (Figs. 1, 2, and 4). These results indicate that the reaction between the copper(II) ion and the cadmium(II)-CyDTA complex proceeds through the following reaction paths;

$$CdCy^{2-} + H^+ \underset{k^{HCy}_{Cd}}{\overset{k^{H}_{CdCy}}{\rightleftharpoons}} HCy^{3-} + Cd^{2+} \qquad (2)$$

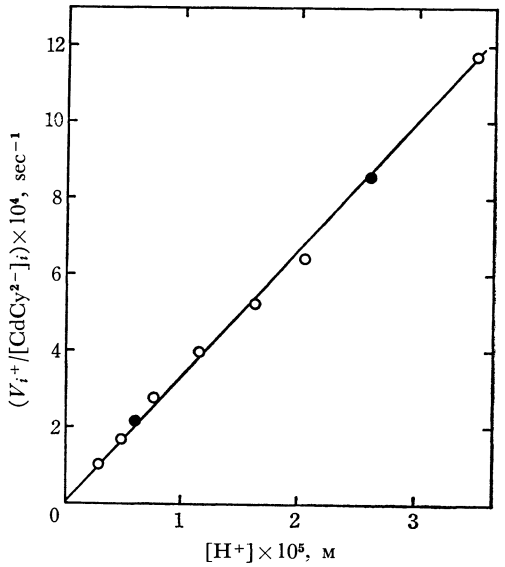

Fig. 3. $V_i^+/[CdCy^{2-}]_i$ as a function of the hydrogen ion concentration at ionic strength 0.2 and 25°C.
Initial concentrations are $[CdCy^{2-}]_i=1.12$ mM and $[Cd^{2+}]_{i,app}=3.3\times 10^{-2}$ mM for ○, $[CdCy^{2-}]_i=2.25$ mM and $[Cd^{2+}]_{i,app}=6.6\times 10^{-2}$ mM for ●, and $[Cu^{2+}]_{i,app}=5.03\times 10^{-1}$ mM for ○ and ●.

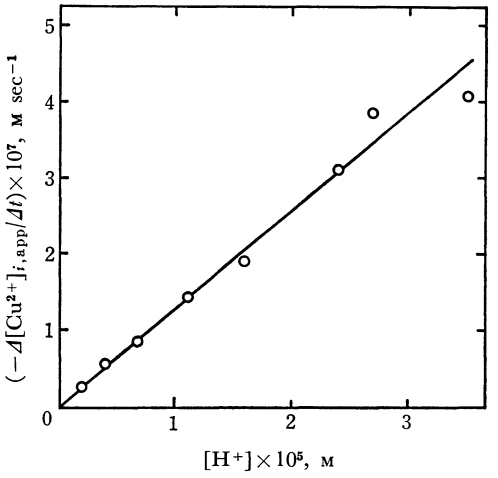

Fig. 4. Initial rate as a function of the hydrogen ion concentration at ionic strength 0.2 and 25°C.
Initial concentrations are 2.25 mM, 5.38 mM and 2.50×10^{-1} mM for $[CdCy^{2-}]_i$, $[Cd^{2+}]_{i,app}$ and $[Cu^{2+}]_{i,app}$ respectively.

$$Cu^{2+} + HCy^{3-} \underset{k^{H}_{CuCy}}{\overset{k^{HCy}_{Cu}}{\rightleftharpoons}} CuCy^{2-} + H^+ \qquad (3)$$

Determination of the Rate Constant of the Dissociation Reaction of the Cadmium(II)-CyDTA Complex. When the copper ion is present in a large excess over the cadmium ion, the

Cd-CyDTA	0.2	1.1×10^9*	32.8	Pol	The present study
Cu-CyDTA	0.2	3.3×10^9	2.1*	Pol	The present study

* Calculated by the author using the relation of $k_f/k_b=K_{MY}K_{HY}$.
$E_{1/2}$ refers to the analysis of the half wave potential of polarograph, ϕ, the phase angle behavior, NMR, to the nuclear magnetic resonance, Pol, to the polarographic diffusion current measurement, and Sp, to the spectrophotometry.

rate-determining step is the dissociation reaction of the Cd(II)-CyDTA complex. Therefore, the rate is expressed as Eq. (4);

$$-\frac{\Delta[Cu^{2+}]_{i,app}}{\Delta t} = V_i^+ = k^H_{CdCy}[CdCy^{2-}]_i[H^+] \quad (4)$$

where the i subscript indicates the initial state. The initial rate was obtained as a function of the hydrogen-ion concentration at two different concentrations of both the cadmium-CyDTA complex and the cadmium ion. The results are given in Fig. 3. Figure 3 clearly indicates that the value of k^H_{CdCy} can be determined from the slope. The value of k^H_{CdCy} was 32.8 l mol^{-1}sec^{-1}.

Determination of the Rate Constant of the Complex-forming Reaction between the Hydrated Copper(II) Ion and the CyDTA Anion. When the cadmium ion is present in a large excess over the copper ion, the relation of $k^{HCy}_{Cu}[Cu^{2+}] \ll k^{HCy}_{Cd}[Cd^{2+}]$ is satisfied. The following rate equation can then be deduced:

$$-\frac{\Delta[Cu^{2+}]_{i,app}}{\Delta t} = V_i^+ = k^{HCy}_{Cu}[Cu^{2+}]_i[HCy^{3-}]_i$$
$$= k_1\frac{[CdCy^{2-}]_i[Cu^{2+}]_{i,app}}{[Cd^{2+}]_{i,app}}[H^+] \quad (5)$$

$$k_1 = k^{HCy}_{Cu} \times \frac{1+\beta_{CdOAc}[OAc^-]}{K_{CdCy}K_{HCy}(1+\beta_{CuOAc}[OAc^-]+\beta_{Cu(OAc)_2}[OAc^-]^2)}$$
$$= k^{HCy}_{Cu}\frac{1+16\times0.04}{10^{19.23}\times10^{-11.70}(1+52\times0.04+93\times0.04^2)}$$
$$= k^{HCy}_{Cu}\times1.37\times10^{-8} \quad (5')$$

The initial rate was obtained as a function of the hydrogen-ion concentration(Fig. 4) and also as a function of the concentrations of the copper ion (Curve 1 in Fig. 2). The rate constant, k^{HCy}_{Cu}, was determined to be 8.0×10^9 l mol^{-1}sec^{-1} from Fig. 2, and to be 8.7×10^9 l mol^{-1}sec^{-1} from Fig. 4.

Discussion

Several workers have studied the kinetics of the dissociation or formation reactions of copper-EDTA[3a,c,d,f] and cadmium-EDTA[16] complexes. A few of their representative data are given in Table 1, together with the present results on the CyDTA complexes. The rate constant of the complex-forming reaction does not show any large differences between EDTA and CyDTA, nor between cadmium and copper. However, the dissociation reactions of CyDTA complexes are much slower than those of the corresponding EDTA complexes, and the dissociation-rate constants of the cadmium-CyDTA and -EDTA complexes are, respectively, 16 and about 1000 times larger than those of the copper-CyDTA and EDTA complexes. These facts indicate that the rate of the dissociation of these complexes is dependent on the stability of the complex. In the present case, the ratios of the stability constants are;

$$K_{Cu(cydta)}/K_{Cu(edta)} = 10^{21.3}/10^{18.7} = 10^{1.6} \text{ and}$$
$$K_{Cd(cydta)}/K_{Cd(edta)} = 10^{19.2}/10^{16.4} = 10^{2.8}$$

There were two noticeable conclusions for comparing the kinetic behavior of the CyDTA complex with that of the EDTA complex; (1) although are direct reactions between the copper ion and EDTA complex, there were on appreciable direct reactions between the copper ion and the CyDTA complex, and (2) there was a close similarity between the hydrogen-ion reaction with the two complexes. This kinetic behavior is consistent with that of the other metal-CyDTA and -EDTA complexes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1597—1598 (1970)

On the Valence State Energy of the Carbon and Nitrogen Atoms

Hideyuki NARUMI and Kimio OHNO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received December 5, 1969)

Several years ago, one of the present authors (K.O.) reported calculations on the energies of the carbon and nitrogen atoms in their valence states.[1] The valence state energies were those defined by Van Vleck.[2] A single Slater-type orbital (STO) was used for each atomic orbital (AO) and orbital exponents δ of the $1s$, $2s$, $2p\sigma$, and $2p\pi$ AO's were varied to make the energy minimum. It turned out that this approximation is especially inadequate for negative ions. Calculated electron affinities for carbon and pyridine-type nitrogen were -4.3 and -5.2 eV, respectively. A semi-empirical estimate[3] gives the value of 0.03 eV for C and 1.8 eV for N. The reason for this failure is probably that a single STO is not adequate for describing the long tail of the charge distribution of a negative ion, especially of the $2p\pi$ orbital.

In this note, results obtained by using two STO's to express the $2p\pi$ AO, instead of one STO, are reported. A very similar calculation was carried out on C by Silverstone and Joy,[4] namely Basis III calculation given in their Table III. However, their valence state was defined for hydrocarbon whose π-electrons were described in terms of molecular orbitals. Thus their energies differ from ours by an extra term, that is one fourth of the π Coulomb integral. Orloff and Sinanoğlu[5] have performed very extensive calculations on the valence state of C. Although their sets of basic orbitals are much bigger than ours, our calculations differ from theirs in that the $2p\sigma$ and $2p\pi$ AO's are allowed to differ. On pyridine-type and pyrrole-type nitrogens, there seems to be no calculation more detailed than our previous one.[1]

Results and Discussion

The numerical results are collected in Table 1. The coefficients and orbital exponents of the two STO's in the $2p\pi$ orbital are denoted as C_1, C_2, δ_1 $(2p\pi)$ and $\delta_2(2p\pi)$. The π one-electron energy W is defined by

$$W(n, q) \equiv \langle 2p\pi(q)\left|-\frac{1}{2}\Delta+V(n, q)\right|2p\pi(q)\rangle,$$

where V is the potential due to the σ-core, n is the

Table 2. Pi-electron ionization potential (in eV)

	C	Pyridine-type N	Pyrrole-type N	
			First	Second
Calculated with one STO for π AO	8.69	10.87	7.62	26.43
Calculated with two STO for π AO	9.29	11.87	9.52	27.00
Semi-empirical estimate[3,6]	11.16	14.12	11.96	28.71

difference between the nuclear charge and the number of σ-electrons (*e.g.* $n=1$ for C and pyridine-type N, and $n=2$ for pyrrole-type N) and q is the π-electon charge on the atom ($q=1$ for C, 2 for C^-).

These results show that the effect of q on W is not very big, less than 1.2 eV. The usual assumption in the Pariser-Parr-Pople method

$$W(n, 1)=W(n, 2)=-I_n$$

is valid within an error of about 2 eV. These general conclusions were reached in the previous treatment[1] and do not change under the extended calculations.

On the other hand, the use of two STO's for the π orbital improved somewhat the calculated π-electron affinities. They are -2.0 eV for C and -2.1 eV for pyridine-type N. The errors were reduced to about one half but still the correct sign could not be obtained.

The calculated and semi-empirically estimated π-ionization potentials are compared in Table 2. Here again, by using a better approximation, the calculated values come closer to the semi-empirical estimate but the differences could still be as large as 2.5 eV.

In conclusion, these simple variational calculations of valence state energies show that the deformation of the σ and π orbitals due to the change in the number of π electrons is considerable, but their effects on W apparently cancel each other and the net effect is not large. On the other hand, using two STO's for the π orbital is not good enough for calculating the π-electron ionization potentials and electron affinities for C and N more accurately than 2—3 eV.

The authors are grateful to Dr. J. H. Gallagher and Professor R. McWeeny for reading the manuscript.

SHORT COMMUNICATIONS

trans- and *cis*-Yabunikkeol, New Monoterpene Alcohols Isolated from the Essential Oils of *Cinnamomum japonicum* Sieb.

Yasuji FUJITA, Shin-ichi FUJITA and Hisashi YOSHIKAWA

Government Industrial Research Institute, Osaka; Midorigaoka, Ikeda-shi, Osaka

(Received February 23, 1970)

We have examined the essential oils of *Cinnamomum japonicum* Sieb. (Japanese name, "Yabunikkei"); we could isolate two new monoterpene alcohols, named *trans*-yabunikkeol (I) and *cis*-yabunikkeol (II).

The essential oil was obtained by the steam distillation of twigs (yield: 0.75% of the fresh material as a case). The monoterpene alcohols were separated by activated-alumina-column chromatography using the fraction with a bp of 129—132°C/20 mmHg which resulted from the fractional distillation of the oil; they well purified finally by preparative GLC. (Yields: I, 1.0%, and II, 1.5% of the original oil).

These alcohols all have the same molecular formula, $C_{10}H_{16}O$ (mol. wt 152 by MS spectra). The IR and UV spectra show the presence of a secondary hydroxy group, terminal methylene linkage, an isopropyl group, and conjugated double bonds. The UV spectra show a close resemblance to that of β-phellandrene.[1]

On dehydrogenation with selenium, both alcohols gave small amounts of carvacrol. Furthermore, by isomerization with sulfuric acid in an ethanol solution, they were converted to carvotanacetone easily. The IR spectrum of the carvotanacetone obtained was quite identical with that of an authentic sample[2] prepared from carvone.

These evidences show that both alcohols are *p*-mentha-1(7),5-dien-2-ol. The *cis-trans* assignments were made chiefly by means of comparing the retention times of the GLC and IR spectra with those of *cis*- and *trans-p*-menth-1(7)-en-2-ol.[3,4]

trans-Yabunikkeol (I) (*trans-p*-mentha-1(7),5-dien-2-ol) is a colorless oil; bp 226°C/760 mmHg, d_4^{30} 0.9335, n_D^{30} 1.4988, α_D^{22} −17.80°. UV spectrum: λ_{max}^{EtOH} 232 mμ (ε=15700), 239 mμ (ε=11200). The IR spectrum is shown in Fig. 1.

cis-Yabunikkeol (II) (*cis-p*-mentha-1(7),5-dien-2-ol) has the following properties: mp 34°C, bp 228°C/760 mmHg, d_4^{30} 0.9503, n_D^{30} 1.5036, α_D^{22} +41.20°. UV spectrum: λ_{max}^{EtOH} 230 mμ (ε=16400), 238 mμ (ε=11000). The IR spectrum is shown in Fig. 2.

The specific retention times of GLC against α-terpineol (PEG 6000, 175°C) are 1.53 for I and 2.10 for II.

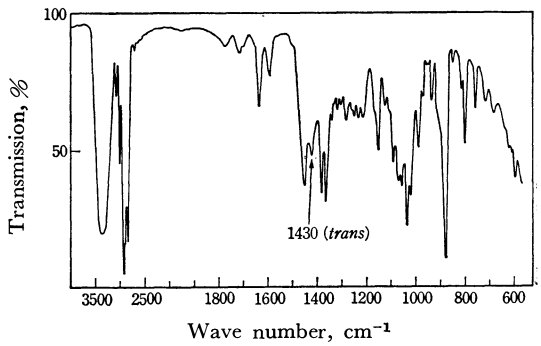

Fig. 1 IR spectrum of I.

Polymorphism of Inosine

Yoshihisa SUZUKI and Nobuya NAGASHIMA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

(Received December 2, 1969)

Two different forms of anhydrous inosine crystals have been found during the course of studies on the crystallization and purification of inosine. The crystal data of inosine dihydrate were reported by Bugg, Thewalt and Marsh,[1] but there is no report on the crystal data of anhydrous inosine. One inosine in orthorhombic system is usually crystallized with ease from aqueous solution above 20°C, as needles or long prisms elongated along the *b* axis. The other in the monoclinic system is crystallized as plates from the aqueous dimethylsulfoxide solution (about 70 v/v%). We call the former modification the α-form, and the latter the β-form.

X-ray diffraction studies were carried out on the two crystalline forms with CuK_α radiation. The space groups were obtained from equi-inclination Weissenberg photographs of zero and first layers about axes *a* and *b*. The unit-cell dimensions determined from precession photographs are shown in Table 1, with other data. Density was measured by flotation in a chloroform-tetrabromoethane mixture.

An interesting feature of the polymorphism is relatively large difference in density. A larger difference in density in the polymorphs was reported by Bugg & Marsh[2] in cytydilic acid b.

New-Type of Copper(II) Complexes with a Subnormal Magnetic Moment Derived from *N,N'*-Bis(2-carboxyethyl)oxamide

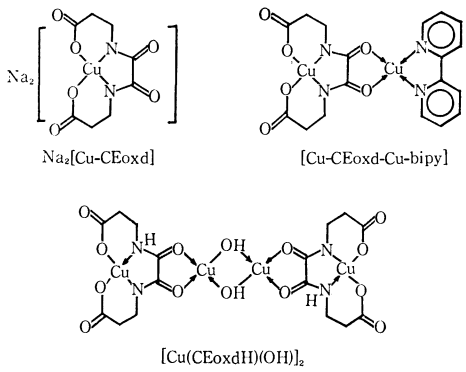
Heijiro OJIMA and Kiyoko YAMADA

Department of Chemistry, Aichi Kyoiku University, Kariya, Aichi

(Received February 12, 1970)

The present authors are continuing their syntheses and characterization of metal complexes coordinating negative amide nitrogen.[1] This paper will report that the *N,N'*-bis-substituted-oxamidato copper(II) acts as a bidentate ligand to afford new-type copper(II) complexes with a subnormal magnetic moment: that is, a new ligand, *N,N'*-bis(2-carboxyethyl)oxamide, has been synthesized, and then three kinds of copper(II) complexes with this ligand (abbreviated, Na_2[Cu–CEoxd], [Cu–CEoxd–Cu–bipy], and [Cu(CEoxdH)(OH)]$_2$) have been isolated.

The [Cu–CEoxd–Cu-bipy] was obtained as yellowish-green fine crystals by mixing one mole of the Na_2[Cu–CEoxd] and one mole of mono-(2,2'-bipyridyl)-copper(II) nitrate in a water solution in which the pH value had been adjusted at 9. Found for the tetra-hydrate, Cu, 21.50%; N, 9.99%; H_2O, 12.66%. Calcd for $C_{18}H_{16}O_6N_4Cu_2 \cdot 4H_2O$, Cu, 21.78%; N, 9.60%; H_2O, 12.35%. Found for the anhydrous salt, Cu, 24.85%. Calcd for anhydrous salt, Cu, 24.85%.



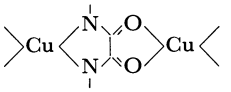
Na_2[Cu-CEoxd] [Cu-CEoxd-Cu-bipy]

[Cu(CEoxdH)(OH)]$_2$

Fig. 1. Copper (II) complexes isolated.

The [Cu(CEoxdH)(OH)]$_2$ was obtained as green fine crystals by the reaction of one mole of Na_2[Cu–CEoxd] with one mole of copper(II) salt in a water solution at room temperature. Found for deca-hydrate, Cu, 27.38%; N, 6.18%; H_2O, 19.59%. Calcd for $C_{16}H_{20}O_{14}N_4Cu_4 \cdot 10H_2O$, Cu, 27.43%; N, 6.05%; H_2O, 19.44%. Found for anhydrous salt, Cu, 34.12%; N, 7.59%. Calcd for anhydrous salt, Cu, 34.05%; N, 7.51%.

The values of the magnetic moment for the [Cu–CEoxd–Cu-bipy] and [Cu(CEoxdH)(OH)]$_2$ are obviously subnormal. This suggests that the mutual interaction between the two copper(II) ions must take place through the partial structure:



and that they belong to the category of "super exchange interaction."[2] Putting it concretely, the interaction may take place through a π-path way (Cu–N–C–C–O–Cu) set up by using $3d_{yz}$ (or $3d_{xz}$) orbitals of the cupric ions and $2p_\pi$ orbitals of the bridging oxamide group. These two complexes are new-type complexes with a subnormal magnetic moment.

TABLE 1. SOME PROPERTIES OF COPPER (II) COMPLEXES ISOLATED.

Ligand and its complex	Magnetic data				IR-spectra[c]			
	$10^6\chi_g$	$10^6\chi_M$	μ_{eff} (BM)	T°K	ν_{N-H}	COOH	COO–Cu	amide I
Ligand $CE_{oxd}H_4$	—	—	—	—	3310	1700	d)	1645
Na_2[Cu-CE_{oxd}]·$4H_2O$	2.86	1173.5	1.78	287				
anhydrous salt	3.44	1160.6	1.79	300	d)	d)	1630	1585[b]
[Cu-CE_{oxd}-Cu-bipy]·$4H_2O$	1.32	385.4	1.10	287				
anhydrous salt	1.73	442.4	1.13	287	d)	d)	1654	1619

A New Method for the Protection of *trans*-Diequatorial Amino and Hydroxyl Groups in Aminosugars and Aminocyclitols

Sumio UMEZAWA, Tsutomu TSUCHIYA and Yasushi TAKAGI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi Tokyo

(Received March 16, 1970)

The combined protection of vicinally situated *trans*-diequatorial amino and hydroxyl groups of pyranoside type aminosugars or inosamines is sometimes necessary in preparing their derivatives. However, contrary to the case of *cis* amino and hydroxyl groups, this kind of protection has not been achieved satisfactorily. Very recently, Miyai and Gross[1] prepared the 2,3-carbamate derivative of benzyl 2-amino-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside with the use of *N,N'*-carbonyldiimidazole in absolute tetrahydrofuran.

We wish to report that the protection was successfully performed by utilizing *p*-nitrophenoxycarbonyl chloride; a characteristic feature of this method is that the products are prepared by a one-step procedure in good yields and the reaction proceeds in a medium containing water, which is necessary in dealing with water-soluble compounds. As an example, the preparation of 2-deoxystreptamine 1,6;3,4-dicarbamate (I) and methyl 2-amino-2-deoxy-α-D-glucopyranoside 2,3-carbamate (II) is described.

To an aqueous solution of 2-deoxystreptamine (DST), Dowex 1×2 resin (OH form) was added, and an excess *p*-nitrophenoxycarbonyl chloride in acetone was added with stirring. A cyclic dicarbamate I was obtained in 73% yield; mp >285°C; IR spectrum: 1760 and 1735 cm^{-1} (C=O); no peak near 1550 cm^{-1} (amide II) was observed indicating I to be a cyclic amide. The 5-*O*-acetyl derivative of I was prepared from I with pyridine-acetic anhydride; mp 276°C (decomp.); molecular weight: 256 (mass spectrum); IR spectrum: 3300 (NH), 1770, 1735 cm^{-1}; NMR (dimethyl sulfoxide-d_6): τ: 4.45 (1-proton triplet, J 9.4 Hz, H-5), 5.91 (2-proton quartet, $J_{4,5}=J_{5,6}$ 9.4 Hz, $J_{3,4}=J_{1,6}$ 11.2 Hz, H-4,6), 6.30 (2-proton double triplets, $J_{3,4}=J_{1,6}$ $J_{1,2_a}=J_{3,2_a}$ 11.2 Hz, $J_{1,2_e}=J_{3,2_e}$ 3.2 Hz, H-1,3), 7.85 (1-proton double triplets, J 3.2 and 11 Hz, H-2_e), 8.40 (1-proton quartet, J 11 Hz, H-2_a). The results support the structure for I.

On alkaline hydrolysis I gave DST, and on ethanolysis in the presence of sodium ethoxide, I gave *N,N'*-diethoxycarbonyldeoxystreptamine (III); mp 225°C (decomp.); IR spectrum: 1695 (NH*COO*), 1545 (amide II) cm^{-1}.

Methyl 2-amino-2-deoxy-α-D-glucopyranoside was treated similarly to give the corresponding 2,3-carbamate derivative (II) in 70% yield; hygroscopic solid, $[\alpha]_D^{21}$ +110° (*c* 0.5, water); IR spectrum: 1760 cm^{-1} (C=O); NMR (deuterium oxide): τ: 4.86 (1-proton doublet, $J_{1,2}$ 3 Hz, H-1), 5.40 (1-proton quartet, $J_{2,3}$ 12 Hz, $J_{3,4}$ 9.3 Hz, H-3), 5.93 (1-proton triplet, $J\sim9$ Hz, H-4), 6.22 (1-proton quartet, J 3 and 12 Hz, H-2), 6.5 (3-proton singlet, OMe). A similar acetylation of II gave the 4,6-di-*O*-acetyl derivative; amorphous solid, $[\alpha]_D^{21}$ +94° (*c* 0.5, chloroform); NMR (deuteriochloroform): τ: 4.67 (1-proton quartet, $J_{4,5}$ 9.2, $J_{3,4}$ 10 Hz, H-4), 4.96 (1-proton doublet, $J_{1,2}$ 3 Hz, H-1), 5.33 (1-proton quartet, $J_{3,4}$ 10, $J_{2,3}$ 11.8 Hz, H-3), 6.5 (3-proton singlet, OMe), 7.88 and 7.90 (each 3-proton singlet, OAc). These results indicate the CI conformation of II.

Redox Reactions on the Lithiated Nickel Oxide Electrode

Hiroshi YONEYAMA and Hideo TAMURA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received April 14, 1969)

The redox reactions of the Ce^{3+}/Ce^{4+}, Fe^{2+}/Fe^{3+} and $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ systems on lithiated nickel oxide electrodes in a H_2SO_4 medium were studied. For the Fe^{2+}/Fe^{3+} and $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ systems, the reactions were controlled by an activation process when the electrode was polarized anodically, while the current tended to saturation as the current was increased in the cathodic direction. The apparent exchange current densities of these systems were distinctly dependent on the resistivity of the electrode. These phenomena were discussed qualitatively from a consideration of the energy states of the charge carriers in the electrode and redox systems, and it was concluded that all the reactions had proceeded through only hole transfer.

A large number of metallic oxides exhibit semiconductivity. For a catalytic reaction which proceeds in the presence of such kinds of oxides, it has often been found that the reactivity is affected by their semiconducting character. In such a case, the chemical reaction is supposed to be controlled by the behavior of the charge carriers in the oxides. More particularly, for the electrode of a semiconductor such as Ge it has been found that the behavior of the charge carriers clearly controls an electrochemical reaction.[1,2] Recently, studies of electrode reactions on semiconductors have been developed to cover oxide semiconductors.[3,4] Almost all of the semiconductors on which electrode reactions have been studied have, though, been ones with a clear energy-band scheme. In these electrodes, the current-potential curves are often affected by the behavior of the minority carrier in the electrode, and from these curves it is possible to estimate which carrier, electron or hole, participates in the reaction. This estimation is also possible from the study of the reactions of redox systems having various standard electrode potentials,[5,6] because the density of the electron or hole in the electrode-surface region is adjusted in accordance with the redox potential of the redox system.

In contrast to a usual band-type semiconductor such as Ge and ZnO, a hopping-type semiconductor is normally considered to have a different energy-band structure,[7] although this question has not yet been completely clarified. However, the kind of charge carrier participating in an electrode reaction on a hopping-type semiconductor electrode may be estimated by means of the experimental technique used in the study of the electrode reaction on usual band-type semiconductors, because a reaction should also proceed when the energy state of the charge carrier in the semiconductor almost coincides with that of ions in an electrolyte. Recently, Yohe and his co-workers studied the redox reactions on a lithiated nickel oxide electrode[8], which is classified as a typical hopping-type semiconductor.[7,9] However, they examined the behavior of the electrode over a wide pH range, and so the condition of the electrode surface may not have been always the same[10]; moreover, the effect of the resistivity of the electrode on the reactivity is not clear, either. Therefore, we studied the reactivity of the redox reactions on this electrode as a function of its resistivity. Experiments were carried out in an acid medium so as always to establish the same surface condition of the electrode.

Experimental

Electrode. High-purity Ni powder (99.99%) was dissolved in a H_2SO_4 solution, and $NiCO_3$ was precipitated by the addition of $NaHCO_3$ to the solution.

10) M. Pourbaix, "Atlas of Electrochemical Equilibra in Aqueous Solution," Pergamon Press, New York (1966), p. 330.

After several decantations, the precipitate was filtrated, washed thoroughly by de-ionized water, and then evaporated to dryness. It was finally decomposed to NiO by heating at 600°C for 4 hr in the air. The NiO powder prepared in this way was spectroscopically pure. Using this NiO powder, an electode was prepared by a method descirbed previously.[11] This electrode showed P-type semiconductivity when examined by the thermo-electromotive-force measurements.

Specific Resistivity. The specific resistivity of the electrode was measured by the four-probe method[12] at 25°C after completing the measurements of the polarization curves in various redox solutions. The electrode had a specific resistivity of 1.9—193 Ω-cm. The electrodes had the Li contents shown in Table 1. The Li contents in Table 1 were estimated from the relationship between the Li content and the resistivity, which had been obtained beforehand for various NiO's. In the previous investigation we estimated the resistivity from the voltage drop between platinum contacts on both faces of a disk-shaped electrode. The value estimated before was somewhat larger than that obtained by the four-probe method. Even if this difference had been caused by bringing Pt into contact with the lithiated NiO, Pt contact on the lithiated NiO did not have any serious effect on the electric conduction as will be discussed below.

TABLE 1. Li CONTENT IN TEST ELECTRODES

Resistivity at 25°C (Ω-cm)	1.9	5.0	13.3	44.0	192
Li content (atom %)	7.0	2.4	0.80	0.23	0.054

Electrode Area. The effective area of the electrode was estimated by a method described previously.[11] The area was fixed in a small part of the face of the disk-shaped electrode by covering it with epoxy resin in order to eliminate the voltage drop in the electrode, which would make the current-potential curves more complex. In the estimation of the surface area, the resistivity estimated by the method reported previously[11] was used, because the electrode always had Pt contact on the lithiated NiO.

Cell Equipment. Connection between the reference electrode (SCE) and the solution was made by an agar bridge containing a saturated KCl solution, but the agar bridge was not inserted directly into the electrolytic cell. The cell was convered with aluminum foils so as to shut off the light.

Current-potential Relation. Steady-state current-potential (*I-V*) curves were obtained potentiostatically by means of an electronic potentiostat. Electrodes were conditioned by successive pre-electrolysis in 0.1N H_2SO_4 at 1.6 V and −1.2 V each 10 min and finally at 0V for 5 min. Before and during measurements N_2 gas was bubbled into the electrolyte so as to remove any dissolved oxygen and stir the solution. All the measurements were carried out at 25±0.5°C.

Chemicals. All the chemicals used in this study were of a G.R. grade. Three kinds of redox systems were used in this study. They are indicated in Table 2. The concentrations of the ions were determined by analysis, if necessary. The Fe^{2+}/Fe^{3+} and Ce^{3+}/Ce^{4+} systems were prepared by their sulfates, while potassium salts were used to prepare the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ system.

TABLE 2. REDOX SYSTEMS STUDIED

System	Medium
5 mM Ce^{3+} 5 mM Ce^{4+}	0.17N H_2SO_4
5 mM Fe^{2+} 5 mM Fe^{3+}	0.1N H_2SO_4
5 mM $Fe(CN)_6^{4-}$ 5 mM $Fe(CN)_6^{3-}$	0.1N H_2SO_4

Results

Steady-state *I-V* curves in 0.1N H_2SO_4 are shown in Fig. 1 for 1.9, 5.0, 13.3, 44, and 192Ω-cm electrodes. *I-V* curves for $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$, Fe^{2+}/Fe^{3+}, and Ce^{3+}/Ce^{4+} systems are shown in Figs. 2, 3, and 4 respectively. For the Ce^{3+}/Ce^{4+} system, a saturation current was observed when the anodic

polarization was increased to about 1.5 V, and with a further increase in polarization beyond 1.6 V the current increased again, supposedly because of commencement of the oxygen-evolution reaction. In these figures, the following facts can be noticed: (a) In a cathodic polarization the current tends to become saturated in the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ and Fe^{2+}/Fe^{3+} systems, this phenomena appearing more distinctly in the former. (b) In the anodic polarization, the electrode reaction seems to proceed by an activation process. (c) The current in Figs. 2—4 is considered to be related to the reaction of the redox system itself, since this current is over 10 times that in Fig. 1. (d) The reactivity of the redox system was much influenced by the resistivity of the electrode. To make clear the nature of the cathodic current for the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ and Fe^{2+}/Fe^{3+} systems, which showed a tendency toward saturation, the dependence of this current on the concentration of the oxidant was obtained. One typical result is shown in Fig. 5 for the reduction of Fe^{3+}.

Discussion

When a metal comes in contact with a P-type semiconductor, a barrier layer may be formed on the contact surface between them. If this layer exists, the current is hindered by this layer when a metal is biased positively against the P-type semiconductor. As is shown above, however, the current flowed more easily in the anodic polarization and a Tafel slope was observed. Therefore, the contact between the Pt and the lithiated NiO can be considered not to have caused any serious problem if it existed at all.

The (a) fact in the previous section conceivably does not indicate the character of the redox system itself, but that of the redox reaction restricted by the behavior of the charge carrier participating in the reaction, because the *I-V* curves of the same redox system were quite different on an N-type semiconductor electrode of αFe_2O_3 doped with titanium.[13] Therefore, the *I-V* curves of the various redox systems can be reasonably explained if it is assumed that the flow of the cathodic current was hindered by the potential barrier formed on the electrode surface as a result of the polarization. As the flat-band potential of the lithiated NiO is 0.65 V *vs.* SCE in 0.1N H_2SO_4 and 0.76 V in 0.17N H_2SO_4,[14] the energy levels of the electron and positive hole of the electrode were lowered in the electrode surface region for the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ and Fe^{2+}/Fe^{3+} systems because the redox potentials of these systems are lower than the flat-band potential; hence, the Fermi level of the

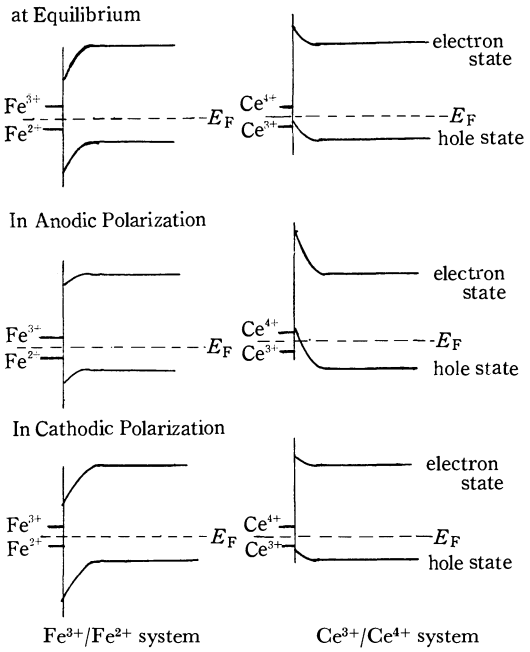

Fig. 6. Schematic representation of energy profile at the interface of electrode and redox electrolyte.

electrode surface is apparently shifted toward a higher energy state compared to the inside of the electrode. The hole concentration in the surface region of the electrode will then decrease, while electron density will increase if it is present at all. This situation is strengthened by the cathodic polarization. Such a energy scheme of the electrode and the electrolyte is represented in Fig. 6 using a band model, though it may not precisely represent the energy structure of 3*d* transition metal oxide.[15] In Fig. 6, each energy state pictured by a solid line in the electrode part indicate the localized energy level at which a positive hole and a localized free electron exist. According to Fig. 6, the electron exchange may occur in the cathodic polarization if the energy state of the electron in the electrode is higher than that of the oxidant of the redox system, that is, $Fe(CN)_6^{3-}$ or Fe^{3+}. However, if electron transfer had occurred, the tendency of the current toward saturation with an increase in the cathodic polarization would not have been observed because the electron transfer from the electrode into the electrolyte could not possibly have been hindered. The only exceptional case is when the current had been hindered by the deficiency of the electron on the electrode surface, but if this were true in this case, no dependence of the cathodic current on the Fe^{3+} concentration would have been observed. The electron transfer mechanism can be eliminated from such a consideration, though Bosman and Crevecouer[16] reported the existence of an electron in the lithiated NiO. On the contrary, the hole-transfer mechanism is reasonable for the following reasons. The height of the potential barrier over which the hole should jump into the electrode under the reaction increases with an increase in the cathodic polarization. The cathodic current would then show a tendency toward saturation. The dependence of the cathodic current on the concentration of Fe^{3+} shown in Fig. 5 means that the probability function of the electron state in the electrolyte[17] was almost proportional to the concentration of Fe^{3+}. In the anodic polarization of $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ and Fe^{2+}/Fe^{3+} systems, hole transfer would more easily occur, since the barrier height for the hole transfer into the electrode decreases with a rise in the anodic potential; thus the Tafel slope was observed. One possible explanation[18] for the mechanism in which the reaction proceeds only through hole transfer is that the energy state of the electron is separate from that of the hole state even if free electron exists in the lithiated NiO.[16] According to Houten's calculation,[19] the energy level of the electron denoted as Ni^+ is located about 5.4 eV above the acceptor level of Ni^{3+} next to a substitutional Li^+.

The situation is very different for the Ce^{3+}/Ce^{4+} system, which has a higher redox potential, that is, 1.36 V *vs.* SCE.[20] The energy levels occupied by charge carriers are raised; this causes the hole concentration in the electrode surface to increase. Such a situation is also represented in Fig. 6. The potential barrier for hole transfer into the electrode will decrease with polarization in the cathodic direction. Thus, the cathodic current would apparently not be suppressed by this potential barrier. On the other hand, hole transfer from the electrode into the electrolyte would occur in the anodic polarization, and no potential barrier would exist in this pathway. The Tafel relation conceivably appears because of such a condition. The *I-V* curves of the Ce^{3+}/Ce^{4+} system possibly indicate

15) F. J. Morin, *Phys. Rev.*, **93**, 1195 (1954); *ibid.*, **93**, 1204 (1954). Bosman *et al.* claimed that application of band model is larther erasonable (see Ref. 16). Yu. M. Ksendzov and I. A. Darbkin also support existence of a band for the energy state of Ni^+ (*Soviet Physics-Solid State*, **7**, 1519 (1965)).

—○— Fe^{2+}/Fe^{3+}
—◆— Ce^{3+}/Ce^{4+}

the reaction patterns of this redox system itself.

The apparent exchange current density, i_0, was estimated by extraporation of the anodic Tafel slope to the measured open-circuited potential of each redox system; it is plotted against the resistivity of the electrode in Fig. 7. The i_0 value increases with a lowering of the resistivity of the electrode, and nearly a linear relationship exists between these two values. From this result, it is obvious that i_0, and, accordingly, the rate of the electrochemical reaction is determined by the charge carrier density in the electrode. This is a reasonable result, since the charge carrier density on the surface of the electrode is larger for the electrode with the lower resistivity.

In conclusion, we can state that the charge carrier density in the lithiated NiO is the most important factor in determining the reaction rate for the electrochemical reaction which proceeds on this electrode. The reaction potential is another important factor in controlling the reaction rate in either oxidation or reduction. The present studies may give instructive information on the rate of some electrochemical reactions on the Ni electrode, since the Ni electrode in solution usually forms a passivated or oxide film in the specified potential region and the flat-band potential of this film coincides with that of the lithiated NiO.[21]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1607—1610 (1970)

Magnetic Susceptibilities of Chloroform Mixtures

R. GOPALAKRISHNAN

Sri Venkateswara University, College of Engineering, Tirupati, India

(Received January 7, 1969)

Magnetic susceptibilities of nine typical liquid mixtures were determined as a function of concentration. Deviations from an additive law were observed for these mixtures of chloroform with triethylamine, aniline, pyridine, α-picoline, 2,4-lutidine, diphenyl ether, toluene, nitrobenzene and chlorobenzene. The observed deviations are explained on the basis of hydrogen bond formation.

Early experimental work regarding the effect of hydrogen bond formation on magnetic susceptibility has been done by Angus and Hill,[1] Venkataramaiah,[2] Varadachari,[3] and Rumpf and Seguin.[4] Milligan and Whitehurst[5] reviewed the work up to 1952, and interpreted their own measurements of magnetic properties of hydrogen-bonding substances namely, water, propanol and acetic acid absorbed on silica gel with the assumption that hydrogen bonding decreases diamagnetism. Recent studies of Venkateswarlu and Sriraman[6] and

G, toluene	H, nitrobenzene	I, chlorobenzene

Deshpande and Pathki[7] confirm the above view.

Experimental

Mixtures were prepared by mixing weighed amounts of pure components. Pure components were previously distilled in an all-glass apparatus. The specific susceptibilities were measured using a standard Gouy balance. The Gouy force ranged from 20 to 30 mg and the accuracy of its determination was estimated to be 0.05 mg. The magnetic susceptibilities of standard liquids were determined as a check and results were in good agreement with the accepted values. Water was used as a reference liquid in all measurements with $\chi=-0.720\times10^{-6}$. Densities were determined by the pycnometer method.

Results and Discussion

The results are presented in the figure where the excess susceptibility, χ^E, defined as the difference between the experimental value and linear law value, is represented as a function of molecular concentration x_B of the second component, the concentration of the first component (chloroform) being x_A.

Before a discussion of the results in the light of hydrogen bond formation it is necessary to find whether there would be any effect of hydrogen bond on susceptibility. For this, we use the explanations given by Pople, Bernstein and Schneider.[8]

In the electrostatic picture of hydrogen bond[9] of the type X–H---Y, Y system is superposed on the X–H bond to produce a strong electric field which attracts the partially screened proton of the X–H bond. Consequently, the proton of the hydrogen bond will be drawn away from its own bonding electrons. This produces a distortion in the charge distribution round H. The screening, not being spherically symmetrical, has to be expressed in terms of an appropriate tensor. The components of this tensor will then affect the values of magnetic susceptibility of the hydrogen and endow it with an anisotropic character. The principal components of susceptibility parallel and perpendicular to the bond can be written as

$$\chi_{\parallel}=\chi_0+\eta_{\parallel}E^2$$
$$\chi_{\perp}=\chi_0+\eta_{\perp}E^2$$

where χ_0 is the value of the susceptibility in the free state, E is the electric field at the hydrogen due to the donor electrons. The values of η's are given by

$$\eta_{\parallel}=-\frac{159a^6}{16mc^2};\quad \eta_{\perp}=-\frac{797a^6}{48mc^2}$$

where a is the radius of the Bohr orbit. The mean susceptibility value is given by

$$\chi=\chi_0+\frac{1}{3}(\eta_{\parallel}+2\eta_{\perp})E^2$$

Therefore, the fractional change in susceptibility per hydrogen atom is

$$\left|\frac{\chi-\chi_0}{\chi_0}\right|=\left|\frac{\Delta\chi_0}{\chi_0}\right|=28.76\ \frac{a^4}{c^2}E^2=28.76\times E_{au}^2$$

where E_{au} is the value of electric field expressed in atomic units. A rough estimate of this change can be made by considering a O–H---O bond. Calculations carried out by Pople[10] show that $E=4\times10^5$ e.s.u. or 0.024 au. It therefore leads to a value of (-0.017) for $\left|\frac{\Delta\chi}{\chi_0}\right|$ *i. e.*, a lowering of roughly 2%. In the present investigations, values of χ^E of this order of magnitude have been observed.

There is still another aspect of the hydrogen bonding refered to as "ring effect" which arises in the case of mixtures of chloroform with certain aromatic compounds (Pople,[11] Reeves and Schneider[12]).

The mixtures of chloroform with different liquids are discussed one by one. In the case of triethylamine the electronegative 'N' leads to the formation of C–H---N bond with chloroform. There is considerable evidence in support of this based on PMR and infrared absorption[13,14] studies of these mixtures. Such a hydrogen bond formation usually results in large negative excess function. Our observations are consistent with this.

The nitrogen in aniline has two attached hydrogen atoms and by itself is an electron donor. There is a possibility of bonding between N and C–H bond of the chloroform. This is consistent with evidence from infrared absorption studies.[15,16] Our measurements show a large negative value for χ^E.

Consider the solution of chloroform with pyridine. There is evidence for hydrogen bond formation between chloroform and this strong base.[17] The nitrogen is highly electronegative. Consistent with

this we obtain a large negative value for χ^E.

α-Picoline molecule can be considered to be arising out of the attachment of a methyl group to the pyridine ring in its α-position. In this case also there is evidence from IR studies[18] in favour of hydrogen bonding. The excess value, χ^E is small in our studies, which does not enable us to lay any great stress on it.

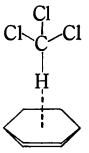
Similar is the case with 2,4-lutidine. There seems to be no chemical or other evidence in support of hydrogen bonding. The possibility of such a bonding is small because of disubstitution by methyl groups in 2 and 4 positions of the pyridine ring. In our studies, we find very small, irregular positive and negative values of χ^E.

In diphenyl ether solutions, we find small progressive deviation and this is attributable to hydrogen bonding. The ether oxygen is highly electronegative and because of this there is a possibility of hydrogen bond formation (type C–H---O). Deviations, however, are small. In the absence of any conclusive evidence, we feel that this may be taken to be a case where there is a large dipolar interaction.

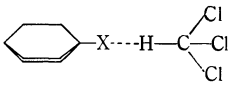
The small negative value of χ^E in the case of 2,4-lutidine, and diphenyl ether mixtures can be explained by invoking a relaxation mechanism associated with hydrogen bonding as has been done by Reddy.[19] Hydrogen bonds are formed and broken in such quick succession that on a macroscopic scale their effect is not perceptible particularly, if the effect is sought to be measured employing a static method of measurement.

Toluene mixtures show a positive deviation, nitrobenzene an almost zero or slight positive deviation, and chlorobenzene a negative deviation. These substances are built round the benzene ring. NMR studies[12] of their mixtures with chloroform show evidence of "ring effect". Taking this "ring effect" into account it is possible to explain the observed trends in χ^E.

The electrons circulating in the aromatic ring have a donor character. The hydrogen in chloroform has an acceptor character. In the mixtures of chloroform with aromatic compounds, chloroform attaches itself to the aromatic ring and forms a bonded complex. There are two positions for such a bonding. The C–H bond in chloroform standing perpendicular to the plane of the ring is called π-bonding and its orientation parallel to the plane of the ring leads to the formation of *n*-bonding.



(π-type)



(*n*-type)

The aromatic ring, unless hindered, orients itself with its plane perpendicular to an external magnetic field. Therefore, the π bonding produces a paramagnetic effect and an *n*-bond which is a normal hydrogen bond produces a diamagnetic effect. The effects of these bondings contribute a corresponding term to the diamagnetic susceptibility of the mixture. The NMR studies cited above show that there is a strong π interaction with toluene, a relatively weak π interaction nitrobenzene and a still weaker one with chlorobenzene.

In the case of toluene mixtures, there is only π interaction and no *n*-interaction because of preferential orientation of chloroform proton above or below the ring. This introduces a paramagnetic contribution and therefore leads to a positive χ^E as observed in these investigations.

Nitrobenzene is a relatively poor π donor and a better *n*-donor. As a result the net deviation (χ^E) is almost zero in the case of nitrobenzene. In the case of chlorobenzene the *n*-interactions are preponderant leading to a negative χ^E.

I thank Professor J. Bhimasenachar for his guidance and inspiration throughout the progress of this work. Thanks are also due to the authorities of Sri Venkateswara University for offering me the facilities to carry out the present invesgitation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1611—1614 (1970)

Charge Transfer Interaction between 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone and Substituted Benzenes

R. D. SRIVASTAVA and G. PRASAD

Chemical Laboratories, University of Lucknow, Lucknow, India

(Received February 21, 1969)

Charge transfer complexes between 2,3-dichloro-5,6-dicyano-*p*-benzoquinone and various methyl and phenyl substituted benzenes have been studied. The spectral characteristics and equilibrium constants of *o*-, *m*-, and *p*-xylenes and those of *o*-, *m*-, and *p*- terphenyls are reported. The results have been interpreted in terms of Mulliken's charge transfer theory. From the spectral data, the electron affinity of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone has been estimated to be 1.974 eV. The energy of the first CT band has been found to be related to the ionization potential of the donors by the expression $h\vartheta_{CT}=0.7I_D-3.86$.

In a previous communication[1] we have reported some of the studies on the charge transfer complexes of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) with aromatic hydrocarbons. The studies have now been extended to substituted benzenes with a view to get a more clear picture of the interactions and to test the characteristic regularities of the charge transfer complexes. The reported results have been used in estimating the electron affinity of DDQ.

Experimental

Pure 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) was obtained from Light & Co. It was further purified by crystallizing from chloroform. Xylenes (B.D.H.) were distilled before use while terphenyls (Light & Co.) were crystallized from carbon tetrachloride or chloroform.

Spectrophotometric studies were carried out on a Unicam SP-500 spectrophotometer using 1.00 cm matched silica cells. The measurements were made at room temperature 25°C±2.0. Stock solutions for each of the donors were prepared separately which were mixed and diluted to required concentrations just before use. Optical density measurements have a maximum error of 1 percent. Equilibrium constants K_c (l mol^{-1}) and extinction coefficient, ε (l mol$^{-1}\cdot$cm^{-1}) were calculated graphically, using the appropriate forms of the Ketelaar's equation.[2] The following two equations served the purpose:

$$\frac{q}{A-A_q}=\frac{1}{(\varepsilon-\varepsilon_q)K_c}\cdot\frac{1}{D}+\frac{1}{\varepsilon-\varepsilon_q} \quad (1)$$

$$\frac{q}{A}=\frac{1}{\varepsilon K_c}\cdot\frac{1}{D}+\frac{1}{\varepsilon} \quad (2)$$

Equation (1) was used in cases where the absorption due to the acceptor molecules could not be neglected, while Eq. (2) was used when the acceptor and donor molecules did not have appreciable absorption at the λ_{max}. In the above equations, q represents the acceptor concentration, D the concentration of the donor, both in mol/l. A is the optical density, ε is the extinction coefficient at the maximum of the charge transfer band λ_{max}, and the subscript q represents the contribution in the property due to the presence of the acceptor in the system. In cases where the optical density of the quinone could not be neglected, its appropriate concentration was taken in the reference cell.

Results and Discussion

The yellow colour of DDQ turned to deep red on addition of xylenes and to amethyst or apple green on addition of terphenyls. Spectroscopic investigations in the region 400 to 700 mμ revealed in each case band characteristics of charge transfer complexes of the stoichiometric ratio of 1 : 1. In the case of xylenes one charge transfer band was obtained, but in the case of terphenyls two charge transfer bands were noted. It may be pointed out that xylenes are expected to show two bands but these could not be resolved in our experiments. Hammond[3] using 10 cm silica cells isolated the second CT band of *o*- and *m*-xylenses in dichloromethane, which are found to occur at 452 mμ and 451 mμ respectively. From the shape of the curves it is apparent that second CT and of *p*-xylene should appear somewhere around 460 and 470 mμ.

Ionization Potential and Energy of CT Band. The energy of the CT band is approximately related to the parameters of the components by the equation

$$h\vartheta_{CT}=I_D-E_A-W \quad (3)$$

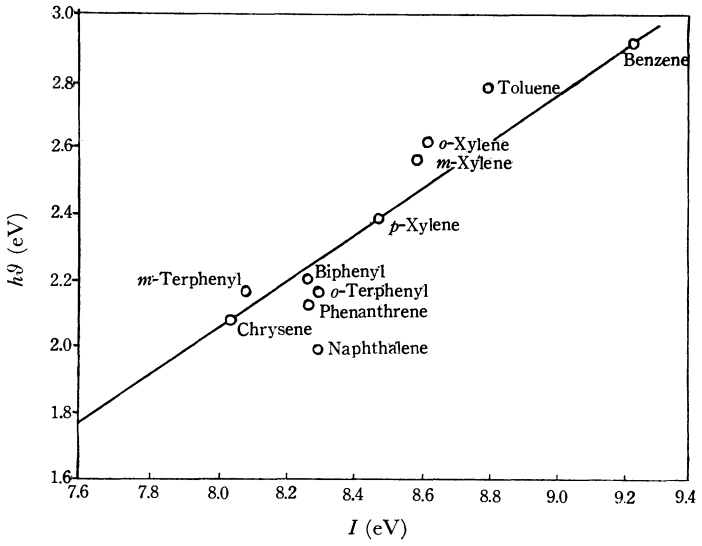

Fig. 1. Relationship between ionization potential (I) and energy of the charge-transfer band ($h\vartheta_{CT}$)

TABLE 1. EQUILIBRIUM CONSTANTS OF THE COMPLEXES WITH DDQ

Donor	$q\times10^3$ mol/l	D range mol/l	λ_{max} mμ	($1\ mol^{-1}\ cm^{-1}$) ε_c	K_c ($1\ mol^{-1}$)
o-Xylene	0.348	0.248 to 2.08	480	3480	2.60
m-Xylene	0.351	0.245 to 1.75	480	3636	2.50
p-Xylene	3.810	0.245 to 1.65	520	3540	3.00
o-Terphenyl	1.960	0.213 to 0.48	580	1000	0.83
m-Terphenyl	1.870	0.068 to 0.18	574	900	2.70
p-Terphenyl	6.000	0.019 to 0.05	635	1000	5.00

where ϑ_{CT} is the frequency of the CT band, I_D is the ionization potential of the donor, E_A is the electron affinity of the acceptor and W is the difference in the stablization energy of the ground and excited state. From the data given in Tables 1 and 2 we find that a plot of $h\vartheta_{CT}$ *versus* I_D gives a straight line of the form (see Fig. 1)

$$h\vartheta_{CT} = 0.7I_D - 3.86 \quad (4)$$

Orgel[4] explains the appearance of more than one CT band in the substituted benzenes on the basis that degeneracy of $^2E_{1g}$ ground state of benzene positive ion is removed by suitably arranged substitution. The two orbitals now split to an extent depending on the number of substituents, their nature and relative positions on the ring. The resultant two electronic states have two different ionization energies. The following are the expressions for the energy difference between the ionisation potential, I_B of benzene itself and the two ionisation potentials, I_1 and I_{11} of the substituted molecules.

$$I_1 = I_B - n\vartheta_s - p_1\varepsilon_s \quad (5)$$
$$I_{11} = I_B - n\vartheta_s - p_{11}\varepsilon_s \quad (6)$$

Here n is the number of the substituents S in the benzene ring; ε_S and ϑ_S are parameters arising from perturbation by S and depend on the nature of the substituent. ε_S relates to the total interaction of S with the π-electron system of the ring, while ϑ_S describes the interaction of S with the σ-system of the ring. p_1 and p_{11} are constants depending on both n and the relative position of the substituents; these values were calculated by Orgel,[4] which are shown below for 0, 1, 1-2, 1-3, and 1-4, substituents.

Position substituent	0	1	1-2	1-3	1-4
p_1	0	1	3/2	3/2	2
p_{11}	0	0	1/2	1/2	0

If $p_1 \neq p_{11}$, two charge transfer bands will result for all substitutions; for $p_1 = p_{11}$ only one band will be observed. When $p_1 = p_{11} = 0$, the charge-transfer energy will be fairly close to that of the benzene complex, since ϑ_S turns out to be rather small compared to ε_S. The band separation $h\vartheta_{11,1} \simeq I_{11} - I_1 = \Delta p_{11,1}\varepsilon_S$ will be very significant in the case of *p*-disubstituted and symmetrically tetra substituted benzenes. Therefore for *o*- and *m*-substituents of benzene, the two ionization potentials would be

4) L. E. Orgel, *J. Chem. Phys.*, **23**, 1352 (1955).

Table 2. Spectral characteristics of DDQ complexes

Table 3. Separation of the first CT band of methyl derivatives with respect to benzene

Separation in	Calculated	Observed $\Delta\vartheta_{max}$
Benzene and toluene	$\vartheta_s+\varepsilon_s$	1200cm^{-1}
Benzene and *o*-xylene	$2\vartheta_s+3/2\ \varepsilon_s$	2600cm^{-1}
Benzene and *m*-xylene	$2\vartheta_s+3/2\ \varepsilon_s$	2600cm^{-1}
Benzene and *p*-xylene	$2\vartheta_s+2\ \varepsilon_s$	4200cm^{-1}

Table 4. Separation of the first CT band of phenyl derivatives with respect to benzene

Separation in	Calculated	Observed $\Delta\vartheta_{max}$
Benzene and biphenyl	$\vartheta_s+\varepsilon_s$	5700cm^{-1}
Benzene and *o*-terphenyl	$2\vartheta_s+3/2\ \varepsilon_s$	6100cm^{-1}
Benzene and *m*-terphenyl	$2\vartheta_s+3/2\ \varepsilon_s$	6000cm^{-1}
Benzene and *p*-terphenyl	$2\vartheta_s+2\ \varepsilon_s$	7700cm^{-1}

equal to each other. This would mean that corresponding CT bands should occur with equal energy and in fact this has been found to be the case in the present investigations. (Tables 3 and 4).

The band separations, $\Delta\vartheta_{max}$ (11-1) observed on varying the number and positions of donor substitutent are *p*-disubstituted$>$*o*- and *m*-disubstituted donors$\geq$mono substituted donor. Again this agreed with what is predicted from the difference Δp (11-1): *p*-disubstituted$>$*o*- and *m*-disubstituted$=$mono substituted donor.

In fact, numerically, the charge-transfer band for a *p*-(1-4) substituted isomer corresponding to a fixed arbitrary value of ϑ_S and ε_S has to be separated from the bands of benzene with an energy interval twice that of corresponding separation between the

Table 5. Separation of the second CT band of phenyl derivatives with respect to benzene

Separation in	Calculated	Observed $\Delta\vartheta_{max}$
Benzene and biphenyl	ϑ_s	600cm^{-1}
Benzene and *p*-terphenyl	$2\vartheta_s$	≈000cm^{-1}

second CT bands of mono substituted benzenes. This has not been found to be true. The reported separations as given in Tables 3—5 do not support the above prediction.

Electron Affinity of DDQ. Another consequence of Eq. (3) is that the CT spectra of a single donor with various closely related acceptors should be displaced with an energy interval corresponding to the difference in the electron affinities of the two acceptors. Also if the electron affinity of one of the acceptors is known and the spectra shift is studied, the electron affinity of an acceptor can be estimated from this shift. As pointed out in Ref. 1, the CT band of DDQ complexes with various hydrocarbons shifts to the red region with respect to the corresponding CT band of chloranil. This shift is 4870 cm^{-1} or equivalent to 0.604 eV.

The electron affinity of chloranil is 1.37 eV.[5] Hence the electron affinity of DDQ should be

$$h\vartheta_{CT}(\text{chloranil}) - h\vartheta_{CT}(\text{DDQ})$$

$$= E_A(\text{DDQ}) - E_A(\text{chloranil}) = 0.604\ \text{eV}$$

$$\therefore\ E_A(\text{DDQ}) = 1.37 + 0.604 = 1.974\ \text{eV}$$

Stability of the Complex and the Ionization Potential. The main stablization energy[6] for the charge transfer complex arises from the resonance energy between the no bond state (A–D) and the ionic stage (A^-D^+) of the complex configurations. Thus, the lower the ionization potential, the higher should be the stability of the complex. This preposition has been found to be true. If the K_c values of Ref. 1 and of the present investigations are considered, it is seen that in general the complexes of donors of comparatively lower ionisation potentials have greater values of equilibrium constants than the complexes of donors of comparatively higher ionization potentials. One must however be careful to choose donors which are similar. For instance, the three separate groups of methyl substituted, the phenyl substituted and the polynuclear hydrocarbon donors should be considered separately. When this is done regularity in regard to complex stability is observed.

Benzene $<$ toluene $<$ xylene

Benzene $<$ biphenyl $<$ terphenyl

Benzene $<$ naphthalene $<$ phenanthrene $<$ chrysene $<$ pyrene

Intensity and Stability. According to Mulliken[6] the intensity of the charge transfer band μ_{1n} should be directly proportional to the stability or the equilibrium constant of the complex. The intensity is related to oscillator strength by the equation

$$f = 4.704 \times 10^{-7} \vartheta_{mesc} \times \mu_{1n} \quad (7)$$

The oscillator strength has been calculated using the equation of Briegleb[7] and is recorded in Table 2. The present investigations do not conform to the predicted relationship.

One of us (G. Prasad) is grateful to the Ministry of Education for the grant of research training Scholarship.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1614—1617 (1970)

Solvent Effect on the Dielectric Properties of Nitroalkanes

Suresh CHANDRA*[1] and Dina NATH

Physics Department, Allahabad University, Allahabad-2, India

(Received June 2, 1969)

Permittivity and dielectric loss of four nitroalkanes have been measured in solution in three solvents *viz.*, *n*-heptane, benzene and cyclohexane at 9.8 GHz and 30°C. The variation of the relaxation time calculated from the data, with the viscosity of the solutions has been discussed. It has been found that the results cannot be explained on the basis of known relations between relaxation time and viscosity. It is expected that some other interactions such as proton-proton interaction are responsible for the relaxation time in cyclohexane lower than in benzene. The loss tangents are found to vary linearly with the concentration of the solution. Dipole moments have also been evaluated in all the three solvents and are in good agreement with the values in literature within experimental error.

The measurement of dielectric relaxation time provides a means of studying the molecular interaction and intermolecular forces. Many papers have appeared in which the authors have given the relaxation time of polar molecules in non-polar solvents. They have tried to correlate the relaxation time with some molecular model but with only partial success. Most of the work has been done to prove or disprove the theory given by Debye.[1] The Debye theory considers the molecule as a sphere embedded in a continuous viscous fluid with inner friction coefficient ζ which is related to the relaxation time τ by

$$\tau = \zeta/2kT.$$

Using Stokes' law, Debye identifies the inner friction coefficient with the viscosity η of the fluid by

$$\zeta = 8\pi\eta a^3,$$

where a is the radius of the sphere. Thus the Debye equation becomes

$$\tau = \frac{4\pi\eta a^3}{kT}.$$

Several empirical and semi-empirical formulae have been suggested to modify the Debye equation. On the basis of the present theories, it is expected that the relation between ln τ and ln η will be linear. It has been found that this is not true for the case of nitroalkanes when τ is measured in solvents of different viscosity *viz.*, *n*-heptane, benzene and cyclohexane.

Experimental

Measurements have been made at 9.8 GHz and at 30°C. The permittivity and dielectric loss (ε' and ε'') have been determined using Smyth's method[2] and short wave technique. The relaxation time τ and the dipole moment μ were then determined by the Gopal

Krishna method.[3] Viscosities of the solutions were determined by an Ostwald viscometer. All the chemicals were distilled twice before use.

Results

The experimental data and results are presented in Tables 1 and 2 respectively.

Discussion

The relaxation times τ for nitroalkanes have been determined from the data obtained with dilute solution of these compounds in *n*-heptane, benzene and cyclohexane. The values of relaxation times obtained in solutions are lower than the values obtained in pure liquids. In *n*-heptane the lower values of relaxation time can be explained on the basis of the low viscosity value of the solvent because the viscosity of *n*-heptane at 30°C is 0.390 cp whereas the viscosities of the nitro compounds are 0.617, 0.644, 0.759 and 0.718 cp respectively. The viscosity of benzene is 0.564 cp which is again less than the viscosities of the solute molecules at the same temperature. The values of relaxation times in benzene are greater than the values obtained in *n*-heptane. This seems reasonable due to the difference in viscosities of the two solvents. The other reason is the hindrance of molecular rotation by dipole-dipole interaction which is present in the pure liquid and mostly absent in dilute solutions. Since the polar molecules used in the present investigation are not quite spherical, viscosity of the surrounding medium should have considerable effect on the dielectric relaxation time. Such results have already been reported by others.[4,5] However, in the case of cyclohexane the values of τ obtained are smaller than the values of relaxation time in benzene, although the viscosity of cyclohexane is about one and a half times that of benzene and three times that of *n*-heptane. This cannot be explained on the basis of the effect of viscosity. The relation between τ and η given recently by Krishnaji and Mansingh[6,7] requires that at constant temperature the plots of $\ln\tau$ *vs.* $\ln\eta$ should be linear. Such plots for four nitroalkanes have been made, but the curves are not linear, the values of relaxation time in cyclohexane being less than the values obtained in benzene. Data of other workers[8-11] give straight lines for $\ln\tau$ *vs.* $\ln\eta$ because they have used a single solvent and have changed the viscosity by varying the temperature. By varying the temperature the viscosity changes but the interactions of solute and the solvent molecules remain the same. They used the same concentration at a single frequency, but in the present investigation the concentration variation at a single frequency method has been used. The viscosity has been varied by using different solvents. The behaviour of $\ln\tau$ *vs.* $\ln\eta$ plots in this case cannot be explained in the light of existing theories. The dependence of $\ln\tau$ upon $\ln\eta$ cannot be explained on the basis of the viscoelastic relaxation time. Such results, however, giving smaller relaxation times in solvents of higher viscosity than in the solvent of lower viscosity have been reported by Higasi[12,13] and Walker *et al.*[14] Walker has also obtained lower values of relaxation time in benzene and carbon tetrachloride for chloroform and has suggested that this might be due to hydrogen bonding of the hydrogen atom in chloroform to the π-electrons. Higasi,[12] on the other hand, has explained the difference in relaxation times as due to the solvent effect. The relaxation time is a physical quantity which is easily affected by the surroundings. The relaxation times and the dipole moments in aromatic solvents are greater than those in aliphatic solvents. There is a possibility of complex formation due to hydrogen bonding or a large interaction energy due to proton-proton interactions. It is possible that the molecule goes into a different isomeric configuration because of these short range interactions. Such an effect has been observed by Higasi[13] in 1,2-dichloroethane.

The relaxation times in each solvent increase with the increase in the number of carbon atoms and molecular size. This is in accordance with the Debye relationship relating the relaxation time τ with the molecular radius, a. The dependence of relaxation time τ on the chain length can be explained on the basis of Fröhlich's equation[15]

$$\tau = AE^{nH/kT}$$

where H is the energy required to lift a link of the

chain over the potential barrier. Experimental values of log τ have been plotted against the number of carbon atoms and they are found to be straight lines satisfying the above relationship.

From the plots of $\tan\delta$ *vs.* concentration it is seen that the loss tangent varies linearly with concentration for all the four liquids in all the three solvents. The rates of variation of the loss tangents, $\tan\delta$, with concentration, c, are given in Table 2 and it is found that the rate of variation of $\tan\delta$ with c in a particular solvent increases with increase in the number of carbon atoms.

The dipole moment values obtained are in agreement, within experimental error, with the solution values given in literature. The values are slightly lower than those reported, and this is in agreement with the apparent tendency to obtain slightly lower moments by the microwave method.

The authors are grateful to Professor Krishnaji for his valuable suggestions and kind interest in the present work.

Reaction Intermediates in γ-Irradiated Mercaptans at 77°K

Ayako TORIKAI, Shuzo SAWADA, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received September 11, 1969)

Elementary processes in the radiolysis of ethyl mercaptan has been investigated by both spectrophotometric and electron spin resonance (ESR) methods. Ethyl mercaptan (C_2H_5SH) forms a glassy solid at 77°K, and when irradiated with γ-rays from Co-60, it develops a deep orange color; this color fades upon illumination with visible light, leaving a clear yellow color. The ESR spectrum of γ-irradiated C_2H_5SH at 77°K consists of two components; one is a complex spectrum which has been identified with the spectrum of $C_2H_5S\cdot$, while the other is a photo-bleachable broad singlet which has been assigned to the ionic species. The $C_2H_5S\cdot$ radical shows an absorption spectrum with $\lambda_{max}=405$ nm. The *G*-values for the formation of the radicals and the ionic species were 0.5 and 2.9 respectively. Studies of 2-methyltetrahydrofuran and butyl chloride solutions of C_2H_5SH were performed to identify these ionic species. Some significant elementary processes will be discussed on the basis of these results.

The reaction intermediates in the radiolysis of organic compounds have recently been studied in order to elucidate the elementary processes in the radiation chemistry using spectrophotometric and ESR methods. Much information about the ionic species and radicals produced by the γ-irradiation of organic glasses has been given by these techniques.

Ethyl mercaptan forms a clear glass at 77°K, so it is easy to measure the reaction intermediates by an optical method. In the case of sulfur-containing compounds, molecular ions have been expected as intermediates of γ-radiolysis.[1-3] Hitherto, there have been only a few ESR studies of the intermediates in the radiolysis of mercaptans and other organic compounds containing sulfur atoms in the solid state.[4-9] The assignment of free radicals has been established in these studies, while the broad ESR singlet observed in ethyl mercaptan has been attributed to ionic species without conclusive evidence.[5,8,9]

In the present study, the ionic intermediates and radicals produced by the γ-irradiation of pure ethyl mercaptan and by those in 2-methyltetrahydrofuran (MTHF) or butyl chloride glasses at 77°K have been investigated in detail by both spectrophoto-

metric and ESR methods. Studies of several alkyl mercaptans have also been performed.

Experimental

Materials. Extra-pure-grade ethyl, *n*-propyl, isopropyl, and *n*-butyl mercaptans were distilled several times on a vacuum line and then stored in a vessel containing calcium hydride. MTHF (supplied by K & K Co.) was purified by passing it through an alumina column after having been fractionally distilled and dried with calcium hydride. Butyl chloride was purified by passing it through a silica gel column, after which it was distilled under vacuum and stored in a vessel containing calcium hydride.

Procedure. Sample tubes for ESR measurements were 4 mm in i.d. and were made of high-purity quartz; the quartz cells with a rectangular cross-section ($1\times 1\times 4$ cm) were used for spectrophotometric measurements. The degassing of the purified samples was accomplished by repeated freeze-pump-thaw cycles. Irradiations were made with γ-rays from Co-60 at 77°K, and in most cases at a dose rate of 6.3×10^{18} eV/g·hr. After γ-irradiation, ESR and optical absorption spectra measurements were carried out at 77°K on a Japan Electron JES-3BX spectrometer and a Hitachi EPU-2-type or Hitachi-Perkin Elmer 139 type spectrophotometer respectively.

Results

Pure Ethyl Mercaptan. Ethyl mercaptan is a glassy solid at 77°K; when irradiated with γ-rays, it develops a deep orange color and gives the ESR spectrum shown in Fig. 1a. This spectrum consists of two components. When γ-irradiated ethyl mercaptan glass is photobleached with visible light ($\lambda>325$ nm), the broad singlet ($\Delta H_{msl}=30$ gauss) centered at $g=2.010$ gradually decreases and there remains a complicated radical spectrum (Fig. 1c).

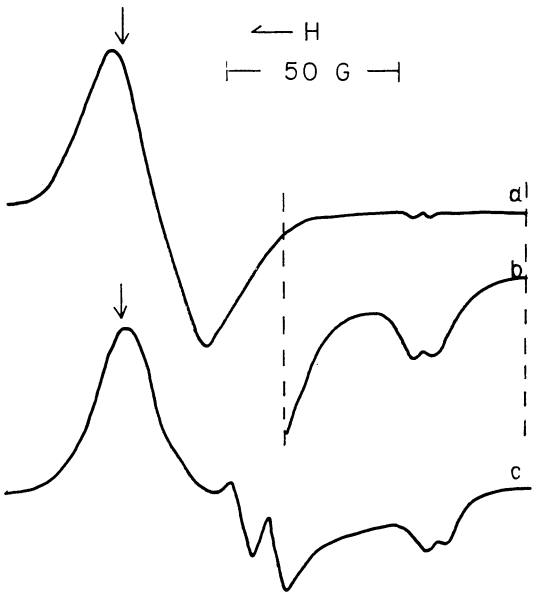

Fig. 1. ESR spectra of γ-irradiated ethyl mercaptan at 77°K.
a: before photobleaching (40db), b: the same spectrum with a greater sensitivity (80db), c: after photobleaching with light of $\lambda>325$ nm (80db) irradiation dose: 3.7×10^{19} eV/g

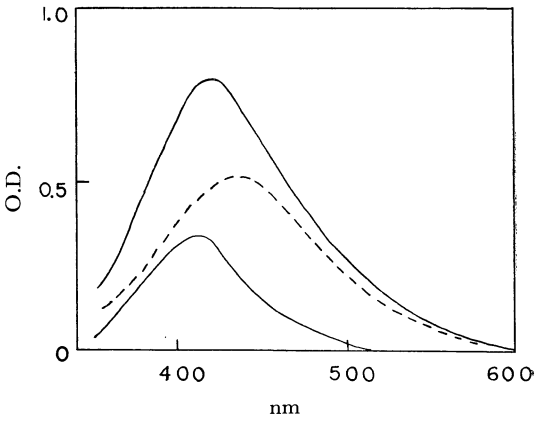

Fig. 2. Absorption spectra of γ-irradiated ethyl mercaptan at 77°K.
a: before photobleaching, b: after photobleaching with light of $\lambda>325$ nm, c: photobleached species, irradiation dose: 2.5×10^{18} eV/g

The absorption spectrum of a glassy ethyl mercaptan at 77°K is shown in Fig. 2. γ-Irradiation produces a broad band centered about 430 nm. This band is bleached with visible light and is responsible for the deep orange color. When bleached with visible light, there remains a band centered at 405 nm which is responsible for the yellow color.

When pure ethyl mercaptan is irradiated with light from a low-pressure mercury lamp at 77°K, it develops a clear yellow color and gives an absorption spectrum with $\lambda_{max}=405$ nm (Fig. 3). The ESR spectrum of UV-irradiated pure ethyl mercaptan is shown in Fig. 4. This spectrum is identical with that in Fig. 1c and is assigned to the $C_2H_5S\cdot$ radical, because its g-tensor agrees with

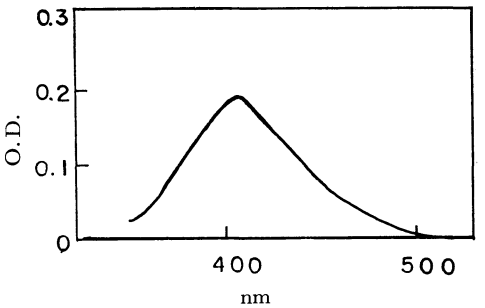

Fig. 3. Absorption spectrum of UV-irradiated ethyl mercaptan at 77°K.

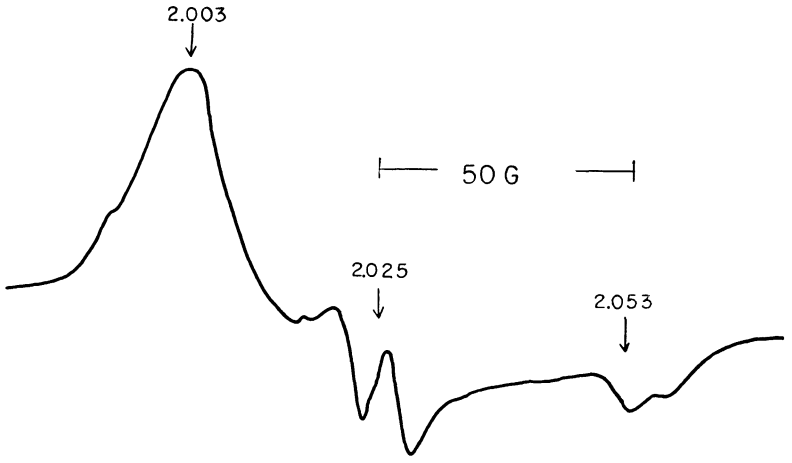

Fig. 4. ESR spectrum of UV-irradiated ethyl mercaptan at 77°K.

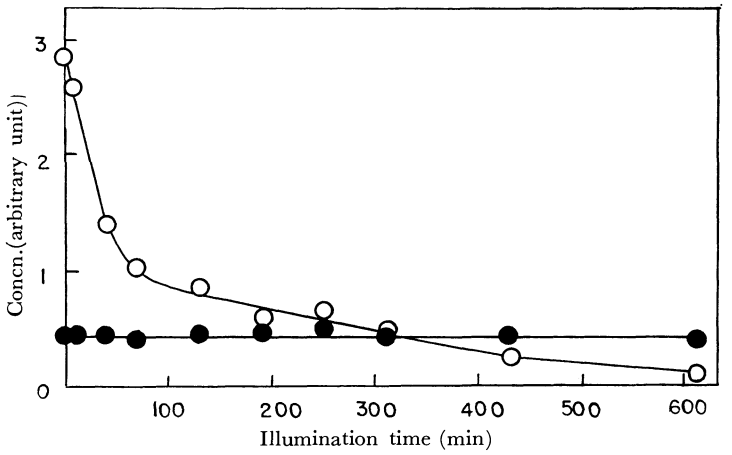

Fig. 5. Photobleaching of ionic species in γ-irradiated ethyl mercaptan at 77°K.
○: ionic species, ●: $C_2H_5S\cdot$ radicals

that of the cystein radical,[4] $HOOC(NH_2)CHCH_2S\cdot$.

The broad singlet which gives $\lambda_{max}=430$ nm is tentatively assigned to an ionic species, and the complicated ESR spectrum which gives $\lambda_{max}=405$ nm is assigned to the $C_2H_5S\cdot$ radical.

The effect of the time of photobleaching on the ionic species and the radicals is shown in Fig. 5. The ionic species decayed rapidly in the initial period and then slowly at 77°K, while the amounts of $C_2H_5S\cdot$ radicals did not change significantly between before and after photobleaching. It was also confirmed that the ionic species decayed relatively rapidly in the initial stage and then very slowly at 77°K in the dark, and no increase was observed in the quantity of $C_2H_5S\cdot$ radicals.

The concentrations of ionic species and of $C_2H_5S\cdot$ radicals increases with an increase in the irradiation dose in the range studied.

The *G*-values for the formation of the ionic species and the radicals were 2.9 and 0.5 respectively. The latter value agrees with the radical yield of hexyl mercaptan, $G(\text{radical})=0.4$ at -150°C,[10] within the limits of experimental error.

Ethyl Mercaptan in MTHF. When a MTHF solution containing 5 mol% of ethyl mercaptan is irradiated at 77°K with γ-rays, it develops a yellowish green color. The ESR spectrum is shown in Fig. 6, superimposed on the seven-line spectrum due to the MTHF radical. This broad singlet spectrum is the same as that observed in γ-irradiated pure ethyl mercaptan. Small amounts of the ethyl radical are also seen in Fig. 6. The narrow singlet due to the trapped electron of MTHF was not observed in this case.

The optical absorption spectrum of the MTHF solution of ethyl mercaptan is essentially the same as that of Fig. 2, although some shift in λ_{max} is

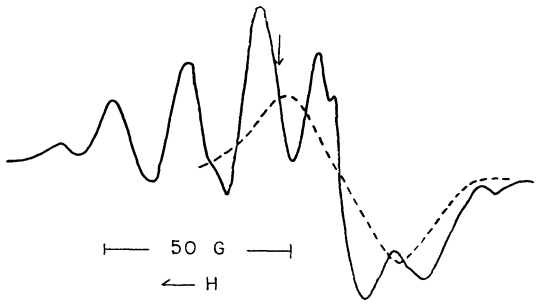

Fig. 6. ESR spectra of γ-irradiated MTHF solutions containing 5 mol% of ethyl mercaptan at 77°K.
irradiation dose: 8.7×10^{18} eV/g

seen in this case. Upon the illumination of this sample with light of $\lambda>325$ nm, the band centered at 410 nm was bleached. This band is also reduced by the addition of carbon tetrachloride as an electron scavenger.

Ethyl Mercaptan in Butyl Chloride. The ESR spectrum of γ-irradiated butyl chloride containing 5 mol% of ethyl mercaptan consists of two components; one is assigned to the butyl radicals, and the other is the same broad singlet as that observed in γ-irradiated pure ethyl mercaptan.

The general features of the optical absorption spectrum of γ-irradiated BuCl solution of ethyl mercaptan are like those of γ-irradiated pure ethyl mercaptan.

Other Alkyl Mercaptans in MTHF. The optical absorption spectra of γ-irradiated MTHF solutions of *n*-propyl, isopropyl, and *n*-butyl mercaptans give broad bands centered at about 410 nm and develop a deep orange color. They are also photobleached with visible light ($\lambda>325$ nm) leaving a yellow color.

Discussion

The species responsible for the ESR singlet and the 430 nm band observed in γ-irradiated ethyl mercaptan may be attributable to ionic species, because they can be photobleached and considerably reduced in the presence of iodine.

Truby *et al.*[1] have extensively studied the intermediates in the solid state radiolysis of disulfides and have concluded that electron ejected by the radiation are captured by the sulfur group of disulfide, that positive charges are also localized at the sulfur group, and that these processes do not lead to molecular dissociation. In the case of the solid state radiolysis of ethyl mercaptan, it also seems reasonable to consider that the mercaptan positive ion remains in the form of $C_2H_5SH^+$ and that ejected electrons are captured to form a molecular anion, $C_2H_5SH^-$. The results obtained from the ESR and optical absorption spectra of γ-irradiated ethyl mercaptan in MTHF solutions essentially coincide with those of γ-irradiated pure ethyl mercaptan. The bond dissociation energy of $C_2H_5{}^-SH$ (69 ± 5 kcal/mol) is greater than its electron affinity (60 kcal/mol); the dissociative electron capture, $C_2H_5SH+e^-\rightarrow C_2H_5\cdot+SH^-$, can, therefore, not be expected in this case. These facts indicate that $C_2H_5SH^-$ is involved in the spectrum of γ-irradiated pure ethyl mercaptan.

The ethyl radicals observed in γ-irradiated ethyl mercaptan in MTHF solutions may arise from the decomposition of directly excited C_2H_5SH. The fact that the ethyl radical was not observed in an appreciable amount in pure ethyl mercaptan can be explained by assuming that the $C_2H_5\cdot+C_2H_5$-$SH\rightarrow C_2H_6+C_2H_5S\cdot$ reaction takes place in this case, although the activation energy of this reaction has not been established. This assumption seems reasonable, because diethyl disulfide has been found among the radiolysis products of liquid ethyl mercaptan.[8]

The following interpretations of the broad ESR singlet and the optical absorption band in the 430 nm region observed in γ-irradiated ethyl mercaptan in BuCl glasses may be derived from the experimental results:

It is well known that butyl chloride forms a glass at 77°K and that radiation ejected electrons in the chloride are scavenged by the matrix itself,

$$BuCl + e^- \rightarrow Bu\cdot + Cl^-{}^{11)} \quad (1)$$

The positive hole is mobile at an early stage but is then trapped by the matrix, giving rise to a broad band at 400—600 nm.

In the case of the γ-irradiated ethyl mercaptan in BuCl glasses, the BuCl cation band disappeared. The 430 nm band is similar to that of the anion band in its position, but considering the efficient scavenging reaction (1), this species may be attributable to the $C_2H_5SH^+$ produced instead of $BuCl^+$.

Another possible species is $C_2H_5SH^-$, which is produced by the competivie reaction between (1) and

$$C_2H_5SH + e^- \longrightarrow C_2H_5SH^- \quad (2)$$

for the following reasons: 1) The rate constants of hydrated electrons at room temperature are of the order of $\sim5\times10^{18}M^{-1}\,sec^{-1}$ for butyl chloride and of $\sim2\times10^{10}M^{-1}$ for methyl mercaptan. The efficiency of the electron capture of mercaptan in an aqueous solution is roughly 40 times that of BuCl, so the competition between (1) and (2) seems conceivable under the present experimental conditions (the concentration of ethyl mercaptan in BuCl is 5 mol% in this case) and 2) The fact that $C_2H_5SH^+$ and $C_2H_5SH^-$ have the same posi-

tion in λ_{max} is not acceptable in view of the general features of the optical absorption measurements of many other linear organic compounds.

If the 430 nm band or the broad ESR singlet is assigned to an anionic species, $C_2H_5SH^+$ should be found, because the BuCl cation band disappears upon the addition of ethyl mercaptan.

The cationic species of disulfides have been found to have absorption maxima between 700—900 nm.[3,12] The absorption spectra of ethyl mercaptan in the BuCl matrix and the 3-methylpentane matrix were measured over the range of 700—1000 nm in order to identify $C_2H_5SH^+$. However, no species other than the 430 nm band was found in this case. This fact seems to indicate that $C_2H_5SH^+$ has an absorption maximum at a wavelength longer than 1000 nm or that the extinction coefficient of C_2H_5-SH^+ band is too small to be found in the visible region of the absorption spectrum under the present experimental conditions. Another possibility is that the 430 nm band includes some cationic species other than $C_2H_5SH^+$.

It is difficult to identify the 430 nm band in the BuCl matrix with either cationic or anionic ones. Further study is required to establish the assignment of this band.

The following elementary processes for γ-irradiated ethyl mercaptan can be considered on the basis of these results, although cationic species have not yet been clearly identified:

$$C_2H_5SH \rightsquigarrow \begin{cases} C_2H_5SH^+ + e^- \\ C_2H_5SH^* \end{cases}$$

$$C_2H_5SH + e^- \longrightarrow C_2H_5SH^-$$

$$C_2H_5SH^* \longrightarrow C_2H_5S\cdot + H$$

$$\searrow \text{ or } C_2H_5\cdot + \cdot SH$$

$$C_2H_5\cdot + C_2H_5SH \longrightarrow C_2H_6 + C_2H_5S\cdot$$

Photobleaching

$$C_2H_5SH^- \longrightarrow C_2H_5SH + e^-$$

$$C_2H_5SH^+ + e^- \longrightarrow C_2H_5SH$$

The optical absorption spectra of γ-irradiated MTHF solutions of *n*-propyl, isopropyl, and *n*-butyl mercaptans give broad bands centered about 410 nm and develop a deep orange color. They are also photobleached with visible light ($\lambda > 325$ nm) leaving a yellow color. The photobleachable species may be attributable to a molecular anion, RSH^-, and unbleachable parts, to the radicals, RS··.

Hydrogen-bonding Effects on the Electron Spin Resonance Spectra of the Anion Radicals of Several Aromatic Amine *N*-Oxides

Tanekazu KUBOTA, Yoshiko ŌISHI, Koichi NISHIKIDA and Hiroshi MIYAZAKI

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received November 10, 1969)

The hydrogen-bonding effects of ethanol, phenol, and water on the electron-spin-resonance spectra of the anion radicals of 4-nitro- and 4-cyano-pyridine *N*-oxides, pyrazine mono- and di-*N*-oxides, and 4-nitropyridine electrochemically generated in dimethylformamide have been studied quantitatively. The equilibrium constant, *K*, pertinent to the hydrogen-bonding systems was determined on the basis of analyses of the variation in the hyperfine coupling constant caused by the addition of a proton donor. The active site in a radical anion participating in the hydrogen-bonding interaction and the *K* values were then discussed on the basis of the theoretical calculation of the spin density and the coupling constant of the radicals in the hydrogen-bonding interaction. It has been pointed out that this sort of experiment in hydrogen bonding interaction is also useful for assigning the hyperfine coupling constant to a definite atom in a radical. Last, these *K* values are used to explain the mechanism of radical formation by the controlled potential electrolysis at different reduction potentials of pyrazine mono- and di-*N*-oxides in dimethylformamide-ethanol mixed solvents.

Since the first finding in 1962 by Deguchi,[1] Stone and Maki,[2] Piette *et al.*,[3] and other workers[4] regarding the quite large solvent dependence of the isotropic hyperfine coupling (hfc) constant of some organic free radicals, the study of the mechanism of solvent effects on electron spin resonance (ESR) spectra has attracted the attention of many workers. The theoretical considerations for explaining these solvent effects have been presented by Gendell, Freed, and Fraenkel (GFF),[5] who applied the mass-action-law, which describes the solvent dependence in terms of radical-solvent of molecular-complex formation, and who pointed out that the change in hfc constant arises from the redistribution of an unpaired electron due to the variation in the electronic state of free radicals with the complex formation. Later, this GFF theory was supported by experimental studies,[6,7] where mixed solvents consisting of water or alcohol and acetonitrile (AN) or dimethylformamide were frequently used. However, a successful quantitative examination of the GFF theory has been reported only by Stone and Maki.[8] In those studies, however, one component in the mixed solvents was a well-known proton donor, water, appearing in hydrogen-bonding complexes which seem to play an important role in the solvent effects.

Aside from the studies mentioned above, Deguchi *et al.*[1,9,10] also studied in detail the solvent effects on the ESR spectra of several organic free radicals; they showed that electrostatic interaction and charge transfer (CT) interaction, such as hydrogen bonding[9] or usual CT complex formation,[10,11] are the two main factors in the solvent effects. Including the studies mentioned above, a survey of the investigations reported thus far of solvent effects on the hfc constant or on the *g*-value of ESR spec-

tra[12],*1 clearly tells us that the hydrogen-bonding effect plays an important role in the case of solvents having O–H or N–H groups. However, only a few quantitative studies of the equilibrium system have been reported thus far.

In the foregoing paper[13] we reported in detail on the ESR spectra the anion radicals of many heterocyclic amine *N*-oxides, and also on the polarographic behavior of these radicals. During our studies we found that the hfc constants (absolute value) due to the nitrogen atom $|a_N|$ or ring hydrogen $|a_H|$ show quite a large solvent dependence with the addition of a proton donor. In this paper quantitative data on the equilibrium constant, K, for the hydrogen-bonding systems composed of some heterocyclic amine *N*-oxide anion radicals and several proton donors will be reported on the basis of the different formulation in GFF's concept.[5] These K values, as well as the change in the hfc constants with hydrogen-bonding interaction, are then discussed theoretically from the viewpoint of the electronic structures of these radical anions, and are also used to explain the mechanism of radical formation by controlled potential electrolysis at the different reduction potentials observed in non-aqueous polarograms of some amine *N*-oxides.

Experimental

Methods and Measurements. Anion radicals were generated electrochemically using the controlled-potential electrolysis cell reported in a previous paper.[13] The potential for the electrolysis was determined by using the polarographic data. The electrolysis cell for nonaqueous polarography has also been previously reported in detail.[13] The ESR spectra were measured under almost the same conditions as in the polarographic measurement. A 0.1M solution of tetra-*n*-propylammonium perchlorate was employed as a supporting electrolyte throughout the experiments. It has been reported[14] that this kind of bulky ammonium salt has almost no concentration effect on the hfc constants of free radicals. The instruments used for recording the ESR spectra were a Varian V-4502-15 X-band spectrometer with a 100 KHz magnetic field modulation, the magnetic field being monitored with a Varian F-8 nuclear fluxmeter and a Takeda Riken TR-5578 frequency counter. A Yanagimoto polarograph, Model PA-102, was used to record the DC and AC polarograms. The experimental conditions for operating these instruments and the cautions taken in obtaining the accurate observed values have already been described elsewhere.[13] All the measurements were made at ~25°C.

Samples and Solvent. 4-Nitropyridine *N*-oxide (4NPO), 4-cyanopyridine *N*-oxide (4CNPO), pyrazine mono- and di-*N*-oxides, and 4-nitropyridine (4NP) were adopted as the mother substances for producing the anion radicals. The methods of syntheses and purifications of these compounds, and also the ESR spectra, except for those of 4NP,[15] in a dimethylformamide (DMF) solvent have been reported in previous papers.[13,16] 4NP was yielded by the deoxygenation of the *N*-oxide-group oxygen atom of 4NPO by using the method reported by Hamana and Yoshimura,[15] it being repeatedly recrystallized from petroleum ether (mp 47.0—47.2°C). As to the proton donors, ethyl alcohol, water, and phenol were used. On the other hand, ethyl ether was used as a reference substance. 99.5% special-grade ethyl alcohol and special-grade ethyl ether were, respectively, dried sufficiently with $CuSO_4 \cdot H_2O$ (alcohol) or a molecular sieve (ether), and then rectified carefully. Phenol of a special pure grade was distilled two times under reduced pressure. The solvent DMF and the supporting electrolyte, tetra-*n*-propylammonium perchlorate, were of the same quality as in a previous report.[13]

compounds studied here moves toward a positive value (*i. e.*, these are a positive shift) upon the addition of proton donors into the DMF or acetonitrile solvent, the set potential for controlled potential electrolysis is also shifted to a positive potential. When the first and the second waves are obviously separated in the DMF solvent alone, just like the reduction wave of 4NPO,[13] as is shown in Fig. 1, the above-mentioned positive shift of $E_{1/2}$ is remarkable for the second wave. As a result, the coalescence of the first and the second waves occurs with an increase in the proton donor concentration, while the radical formed by the electrolysis simultaneously becomes unstable. a) Numbering of each ring atom in the radicalas is as follows:

course, the selection of the set-potential becomes difficult because of the above-mentioned coalescence of the first and the second reduction waves, the former being due to the anion-radical formation of mother compounds. Our hydrogen-bonding experiments were, thus, restricted within some limited concentrations of proton donors, as is shown in Table 1. Nevertheless, the anion radical of 4NPO was most stable, and it was possible to use some proton donors in making the hydrogen-bonding study. It should be now noted that even though ethyl ether of, for example, about 20% is added in a DMF solvent instead of ethyl alcohol, we observed almost no change in the polarogram of 4NPO or in the ESR spectrum of the 4NPO anion radical compared with those recorded in the DMF solvent alone, but that when ethyl alcohol is added the ESR spectra and polarograms undergo considerable change. These facts may support the evidence that the hydrogen-bonding effect is an important factor in bringing about the change in the ESR spectra and in the polarograms. As examples, the ESR spectral change in 4NPO and 4CNPO anion radicals arising from the addition of proton donors is shown in Figs. 2 and 3 respectively. Figures 4A and 4B show the variation in the hfc constants caused most predominantly by the addition of proton donors.

Evaluation of the Equilibrium Constant, *K*. According to the GFF concept, let us consider this hydrogen-bonding equilibrium:

$$RS + D \rightleftarrows RD + S \quad (1)$$

Here, RS, D, and RD stand for the assumed radical-solvent complex, the proton donor, and the radical-proton donor complex respectively. On the other hand, if no radical-solvent complex is assumed, the equilibrium may be written as:

$$R + D \rightleftarrows RD \quad (2)$$

this sort of expression being usually employed for the equilibrium study of various charge-transfer (CT) complexes, including hydrogen-bonding complexes. If the equilibrium in Eqs. (1) and (2) is

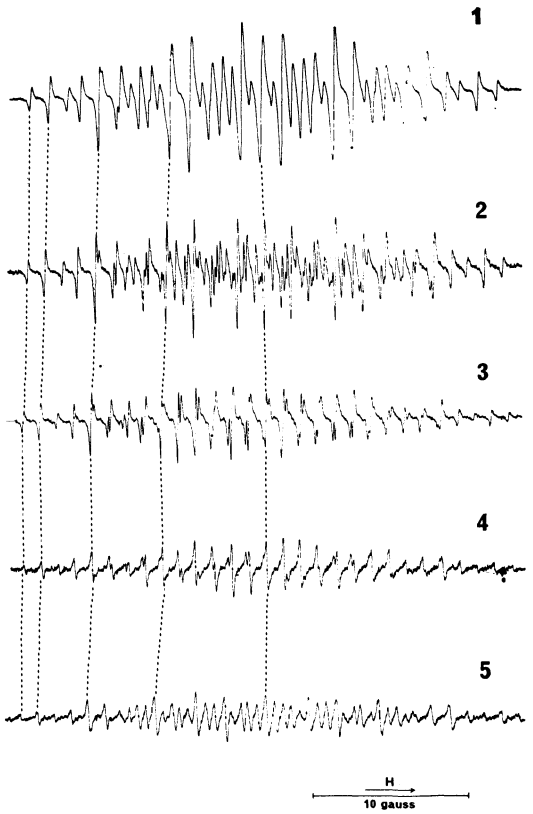

Fig. 2. ESR spectral change of 4-nitropyridine *N*-oxide anion radical in dimethylformamide with the addition of ethanol, the concentration of which is 0, 10, 30, 40 and 60 vol% for spectral No. 1, 2, 3, 4 and 5, respectively.

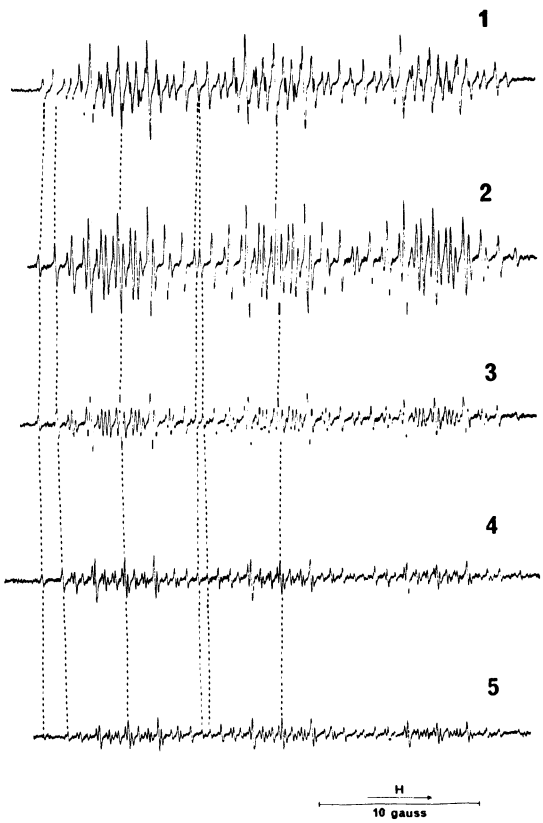

Fig. 3. ESR spectral change of 4-cyanopyridine *N*-oxide anion radical in dimethylformamide with the addition of ethanol, whose concentration is ~0, 2, 4, 10 and 16 vol% for spectral No. 1, 2, 3, 4 and 5, respectively.

very rapid,*2 the observable hfc constant, $\bar{a}$, is easily given by $\bar{a}=P_{RS}a_{RS}$(or P_Ra_R)$+P_{RD}a_{RD}$; for the case of hydrogen-bonding interaction, this expression for $\bar{a}$ would be correct because it is well known that the hydrogen-bonding equilibrium is very rapid.*2 Using the definition of $K=$(RD)·(S)/(RS)(D) for Eq. (1), P_{RS} and P_{RD} are now written as $P_{RS}=1/(1+K\alpha)$, $P_{RD}=K\alpha/(1+K\alpha)$, and $P_{RS}+P_{RD}=1$. Here, $\alpha=$(D)/(S). If Eq. (2) is applied, $K=$(RD)/(R)(D), $P_R=1/(1+K$(D)), and $P_{RD}=K$(D)$/(1+K$(D)). Now, by combining those equations we can get:

$$\bar{a} = a_{RD} - (1/K)(\bar{a}-a_{RS})/\alpha \quad (3)$$

and

$$\bar{a} = a_{RD} - (1/K)(\bar{a}-a_R)/(D) \quad (4)$$

from Eqs. (1) and (2) respectively. The concentrations (D) and (S) in Eqs. (3) and (4) are those in the equilibrium state, but the radical concentration is very small ($<10^{-4}$ mol/l), so that, in good approximation, (D)$\approx$(D)$_0$ and $\alpha\approx$(D)$_0$/(S)$_0$. The zero subscript means the initial concentration. It can easily be understood that the plot of $\bar{a}$ against $(\bar{a}-a_{RS})/\alpha$ or $(\bar{a}-a_R)/$(D) should satisfy the linear relation if Eq. (1) or (2) holds. Thus, from the slope and the intersection at the ordinate the $1/K$ (then K) and a_{RD} values can be directly obtained.*3

For the equilibrium system where 1 (radical) : 2 (proton donor) complex formation, such as

$$SRD + D \rightleftarrows DRD + S \quad (5)$$

has to be taken into consideration in addition to the 1 : 1 form (Eq. (1)), Stone and Maki[8] derived the equation:

*2 The recombination rate process in usual hydrogen bonding or proton addition equilibriums was reported to be in the order of $\sim 10^{10}$ (mol/l)$^{-1}$(sec)$^{-1}$. N. Mataga, Y. Torihashi and Y. Kaifu, *Z. Phys. Chem. N. F.*, **34**, 379 (1962); A. Weissberger (Editor), Technique of Organic Chemistry, Vol. 8, Part II, Chapters XV—XX "Very Rapid Reactions in Solution," p. 793, Interscience Publishers Inc., New York (1963).

*3 From this viewpoint Eq. (3) seems to be more convenient than the equation, $\bar{a}=(1/2)(a_{RS}+a_{RD})+(1/2)[(a_{RD}-a_{RS})\times(K\alpha-1)]/(K\alpha+1)$, given in the GFF paper.[5]

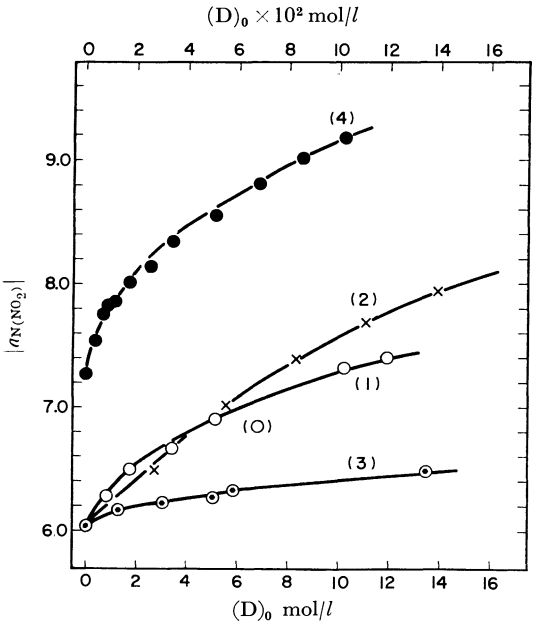

Fig. 4A. Variation of hfc constant due to the nitro group nitrogen atom of 4-nitropyridine *N*-oxide (curves 1, 2 and 3) and 4-nitropyridine (curve 4) with the addition of proton donor. Added proton donors are ethanol, water, and phenol for curves 1 and 4, 2, and 3, respectively. Upper abscissa should be referred only to curve 3. Here note that each curve is obtained theoretically by the method written in the text, but each point is the experimental value.

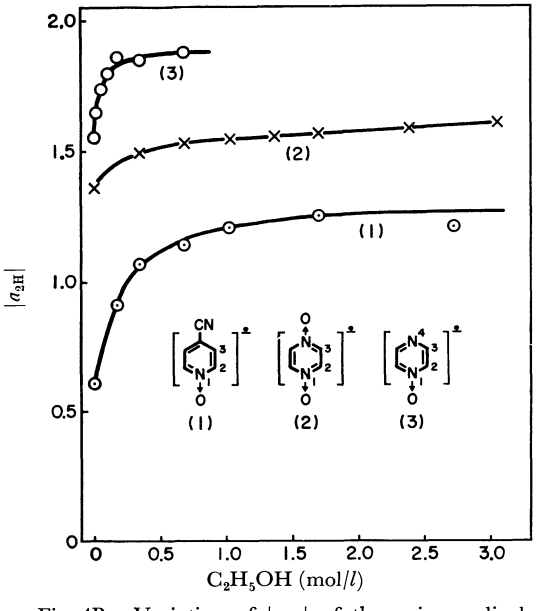

Fig. 4B. Variation of $|a_{2H}|$ of the anion radicals given in this figure with the addition of ethanol. Each curve is obtained theoretically (see text), but each point is the observed one.

$$a = \frac{a_{SRS} + K\alpha a_{SRD} + KK'\alpha^2 a_{DRD}}{1 + K\alpha + KK'\alpha^2} \quad (6)$$

K' represents the equilibrium constant corresponding to Eq. (5), while a_{SRS}, a_{SRD}, and a_{DRD} are, respectively, the hfc constants pertinent to the SRS, SRD, and DRD complexes. Note that, in this case, the radical has two or more effective active sites in a molecule for hydrogen-bonding interaction. Usually $K' < K$, and K is not so large in the present experiment (see Table 2). In addition, if the experiment is made under the conditions where $\alpha \ll 1$, if, that is, the concentration of the proton donor (D) is much smaller than that (S) of the solvent, the $KK'\alpha^2$ and $KK'\alpha^2 a_{DRD}$ terms may be neglected in Eq. (6). Then, Eq. (6) is easily reduced to Eq. (3), from which the values of K and a_{SRD} are determined. Eq. (6) is now modified as follows:

$$\bar{a} = a_{DRD} - \frac{1}{K'}\left[\frac{(\bar{a} - a_{SRS}) + K\alpha(\bar{a} - a_{SRD})}{K\alpha^2}\right] \quad (7)$$

The plotting of $\bar{a}$ *vs.* "the quantity in the brackets" on the right-hand side of Eq. (7) makes it possible to evaluate the values of K' and a_{DRD} separately. Thus, we tried the above-mentioned linear plots using Eqs. (3), (4), and (7), and also using the

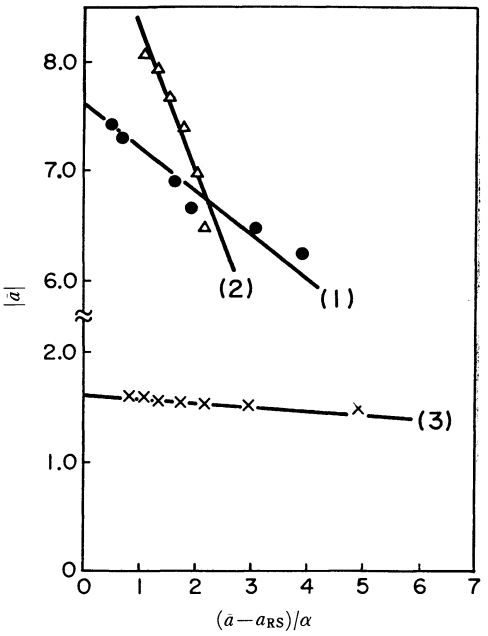

Fig. 5. Some examples of the linear relation of Eq. (3) (see text). The straight lines 1 and 2 are for the change of $|a_{N(NO_2)}|$ of 4-nitropyridine *N*-oxide anion radical with the addition of ethanol (line 1) and water (line 2), respectively. Line 3 is for the $|a_H|$ of the system: pyrazine di-*N*-oxide anion radical + ethanol. Solvent is dimethylformamide.

TABLE 2. EQUILIBRIUM CONSTANTS K'S AND HYPERFINE COUPLING CONSTANTS a'S (absolute value) PERTINENT TO THE HYDROGEN BONDING SYSTEMS OF THE ANION RADICALS STUDIED HERE

Anion radical of	Proton donor	K (dimensionless) by Eq. (3)	a_{RD}* by Eq. (3)	K (l/mol) by Eq. (4)	a_{RD}* by Eq. (4)
4 NPO	Water	0.72 ± 0.16	9.75 ± 0.54[a]	0.043 ± 0.016	10.96 ± 1.33[a]
4 NPO	Ethanol	3.39 ± 0.59	7.37 ± 0.11[a]	0.18 ± 0.04	7.83 ± 0.25[a]
4 NPO	Phenol	—	—	25.95 ± 11.56	6.51 ± 0.11[a]
4 CNPO	Ethanol	66.97 ± 10.18	1.29 ± 0.03[b]	5.05 ± 0.82	1.30 ± 0.03[b]
Pyrazine di-*N*-oxide	Ethanol	39.00 ± 7.02	1.61 ± 0.01[c]	3.00 ± 0.58	1.62 ± 0.01[c]
Pyrazine mono-*N*-oxide	Ethanol	301.57 ± 13.25	1.89 ± 0.01[b]	23.25 ± 1.03	1.89 ± 0.01[b]
4-Nitropyridine	Ethanol	$K=10.0\pm1.5$ $a_{SRD}=8.50\pm0.2$[a] $K'=0.49\pm0.02$ $a_{DRD}=10.00\pm0.05$[a] with Eqs. (5), (6) and (7).		—	—

* The value of hyperfine coupling constant is that of $a_{N(NO_2)}$, a_{2H} and a_H for the superscript a, b and c, respectively.

experimental data listed in Tables 1A—1E. Assuming the 1 : 1 interaction model, quite a good linear relation for Eq. (3) or (4) was then yielded for each system except for the case of the 4NP anion radical plus ethanol, where the 1 : 2 model was much better (see below). In Fig. 5 these linear plottings for Eq. (3) are illustrated as examples.

The values of the equilibrium constant, K, and the hfc constants in the hydrogen-bonding state thus evaluated are shown in Table 2. Also, the solid curves given in Figs. 4A—4B were theoretically obtained using the values listed in Table 2. We see that there is quite a good agreement of the proton-donor dependence of $\bar{a}$ yielded experimentally with the corresponding curve obtained theoretically. The behaviour of the $|a_N|$ of the 4NP anion radical upon the addition of ethanol may be interpreted by assuming the 1 : 2 model. In small ethanol concentrations Eq. (3) or (4) is well satisfied, but the linear relation of Eq. (7) is again fulfilled in the region of relatively high ethanol concentrations. The values of K, K', a_{SRD}, and a_{DRD} were thus determined; they are included in Table 2. As may be seen in Fig. 4A, the experimental values of $\bar{a}$ were reproduced by the theoretical $\bar{a}$ curve drawn by employing the above-mentioned K and K' values.

Discussion

Active Site for Hydrogen-bonding Interaction. The compounds used in this study have, in a molecule, more active atoms than the one for hydrogen-bonding interaction. From the viewpoint of the electronic structures of the present anion radicals, it is important and interesting to examine which atom in a molecule enters into hydrogen-bond formation with proton donors. The studies reported thus far suggest that the intermolecular charge transfer of a lone-pair electron, belonging to the active-atom, non-bonding orbital which enters into hydrogen bonding to, for example, the O–H antibonding orbital of proton donors, is the most important mechanism in hydrogen-bond formation.[17] Of course, there is also electrostatic force. Now, note that the charge-transfer mechanism and the electrostatic interaction both bring about an increase in electronegativity at the atom in question. In other words, the Coulomb integral concerning the π-AO at the atom increases in magnitude in the HMO calculation, as was suggested by Frankel *et al.*[5] The change in the spin-density distribution arising from the perturbation due to hydrogen bonding can then be calculated. The parameter values in the HMO calculation, as modified by McLachlan's treatment (MHMO calculation),[18] have already been given for heterocyclic amine *N*-oxides and their derivatives, having NO_2, CN groups *etc.*, in order to interpret the hfc constants and, thus, the spin densities of these anion radicals in the free state.[13] The results agree well with the observed values.*4 Assuming some active sites,

18) A. D. McLachlan, *Mol. Phys.*, **3**, 233 (1960).

*4 Parameter values for the MHMO calculation of the anion radicals of *N*-oxide compounds are: $k_N^{\delta+}=1.0$ with inductive effect$=0.1$, $k_O=0.6$, and $\beta_{NO}=0.8$ for $\rangle N^{\delta+}\rightarrow O^{\delta-}$ group. See Fig. 7 in Ref. 13 for the parameter sets and their literature on the substituents NO_2 and C≡N, and ring nitrogen atom ($\rangle$N:). The hfc constants were theoretically calculated using the following equations[13] connecting spin density and σ-π interaction term: $a_{N(NO_2)}=99.0\rho_N-35.8(\rho_O+\rho_{O'})$; $a_{N(N\rightarrow O)}=42.57\rho_N-18.98\rho_O-6.66(\rho_C+\rho_{C'})$; $a_H=-25.67\rho_C$; $a_{N(C\equiv N)}=23.1\rho_N-6.8\rho_C$; $a_{N(\rangle N\cdot)}=27.3\rho_N-1.7$ $(\rho_C+\rho_{C'})$.

the spin density and the hfc constant in the hydrogen-bonding state can be calculated using many parameter sets which are reasonably selected by referring to the ones in the free state, and the calculated values are compared with the behavior of the hfc constants observed upon the addition of proton donors (see Table 1 and Fig. 4). This comparison may lead to the acceptable conclusion as to which atom in an anion radical mainly participates in the hydrogen-bond formation.

First, let us discuss the 4NPO anion radical. This radical has two active groups in the molecule; one is the NO_2 group, while the other is the *N*-oxide group. If the lone-pair orbital of the *N*-oxide-group oxygen atom enters into hydrogen bonding, the Coulomb integral of the oxygen atom in the MHMO calculation becomes larger than the standard value, $\delta\alpha_0=0.6\beta$.[13],*4 The hfc constants*4 obtained using the spin densities led from the calculation under the above boundary conditions are illustrated in Fig. 6. On the other hand, in Fig. 7 are shown the calculation results assuming that the nitro-group oxygen atom makes a hydrogen bond with the proton donors.*5,[19,20] Since the ESR spectrum in the hydrogen-bonding interaction of the 4NPO anion radical can be well interpreted as the radical is in C_{2v} molecular symmetry, the hydrogen-bonded hydrogen atom of proton donors should be rapidly exchanged between two oxygen atoms in the NO_2 group (*vide infra*). The same circumstances would also hold in the 1 : 1 hydrogen bonding system, consisting of a proton donor and pyrazine di-*N*-oxide, as will be discussed later.

Now, when we compare the theoretical values shown in Figs. 6 and 7 with the experimental results seen in Table 1A and Fig. 2, it seems certain that the active center partaining to the hydrogen-bonding interaction of the 4NPO anion radical with proton donors is the nitro group in the molecule, since the experimental and theoretical results are in quite good agreement in this case. This conclusion is in agreement with the conclusion that the hydrogen-bonding or alkali metal-complexing center of the anion radicals of nitrobenzene and related nitro-compounds is in the nitro group,[6,14,21]

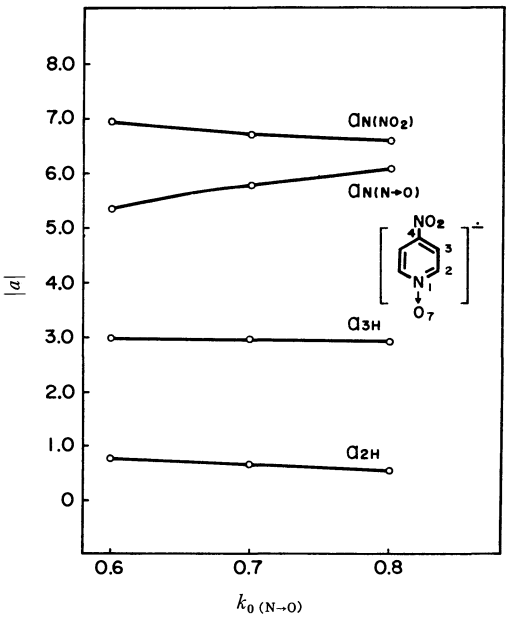

Fig. 6. The behavior of hfc constants theoretically estimated (see text for the method) assuming that the *N*-oxide oxygen atom of 4-nitropyridine *N*-oxide anion radical is the active site for hydrogen bonding interaction.

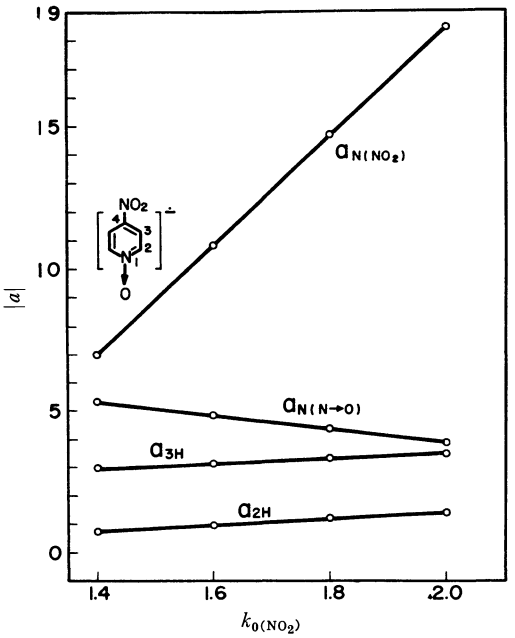

Fig. 7. The behavior of hfc constants theoretically estimated (see text for the method) assuming that the nitrogroup oxygen atom of 4-nitropyridine *N*-oxide anion radical is the active site for hydrogen bonding interaction.

*5 It should be noted that the MO calculation[13,15,19] leads to the conclusion that the $\rangle C{=}NO_2$ bond order in the anion radicals of 4NPO, nitrobenzene, *etc.* becomes larger than in the corresponding neutral molecules. The possibility of the twisting around the C–N bond due to the hydrogen bonding effect would be then rejected from the consideration unless bulky substituent at ortho position brings about the steric hidrance against the nitro group. This argument seems to be experimentally supported.[15b,6,20]

whose complexing ability is not so small in the anion radical. However, it should be recalled[22] that the protonation of the 4NPO neutral molecule in an aqueous solution occurs at the *N*-oxide group oxygen atom, and that the pK_a value is -1.7.[22] Therefore, we can say that the active center for the hydrogen-bonding or protoantion interaction of 4NPO is exactly reversed between the neutral molecule and the anion radical. There is much evidence supporting the idea that the intramolecular charge transfer (CT) from a *N*-oxide-group oxygen atom to a nitro group is an important factor in describing the nature of the ground state as well as the excited state of 4NPO, 4-nitroquinoline *N*-oxide, *etc.**6,22,23) For example, the $pK_a = -1.7$ of 4NPO is much smaller than the correspoding value, 0.78, of pyridine *N*-oxide.[22] The theoretical MO considerations[13,15,19] reported thus far on various aromatic nitro compounds including 4NPO suggest that the lowest vacant MO (LVMO) is mainly localized on the NO_2 group and that, thus, the unpaired π electron densitie on that group are very large. Also, an intramolecular CT absorption band pertinent to nitrobenzene, 4NPO, *etc.* may appear in the near ultraviolet region.[23,24] This result implies that the nitro-group oxygen lone-pair electrons become quite active for n-σ type intermolecular interaction when the species is in an anion radical or in an intramolecular CT excited state, although the above interaction is weak in the case of the neutral nitro compounds.[25] Our aforementioned conclusion on the active site of the 4NPO anion radical for hydrogen-bonding interaction seems, therefore, to be reasonable.

Next, let us discuss the hydrogen-bonding active site of the 4CNPO anion radical, which is of interest in comparison with that of the 4NPO anion radical discussed above. It is well known that the nitrile-group lone-pair electrons show a very weak n-σ-type intermolecular interaction ability,[26] so that the hydrogen-bonding power is also weak, and that the nitrogen hfc constant, $|a_N|$, due to the cyano group in the aromatic nitrile anion radicals is found only within 1—3 gauss.[13] In addition, the cyano group is a weak π substituent[27] and affects the near-UV spectra of aromatic substances weakly, and the intramolecular CT band partinent to benzonitrile has been reported not to be exhibited in the near-UV region.[27] In view of these facts, we may expect that the hydrogen-bonding ability of the nitrile group in π anion radicals is not large. In fact, MHMO spin-density calculations according to the procedure used in the case of 4NPO led to the finding that the stronger active site for the hydrogen-bond formation of the 4CNPO anion radical is the *N*-oxide group and not the cyano group, for, if we assume the latter case, the change in the calculated spin densities and hfc constants arising from hydrogen bonding does not reproduce the experimental results so well; however, the agreement between experiment and theory is good for the former case. Here, note that the hfc constant due to the hydrogen atom at the position 2, $|a_{2H}|$ (see Fig. 4B for numbering), increases in magnitude in the hydrogen-bonding complex, while $|a_{3H}|$ is relatively insensitive. These results are in good agreement with the calculation results. Conversely, this type of experiment on the solvent effect seems to be a useful technique for determining the assignment of the hfc constants.[13,16]

The calculation was next carried out on the anion radicals of pyrazine mono *N*-oxide and 4-nitropyridine. It was clearly concluded that, in the case of the former radical, the hydrogen-bonding interaction ability of the *N*-oxide group is stronger than that of the ring-nitrogen atom, but that the stronger active atom in the 4NP anion radical is, of course, the nitro-group oxygen atom, with the ring-nitrogen atom next. As may be understood from Table 1, the experimental values of $|a_{N(ring)}|$[13] and $|a_{2H}|$[13] for the case of the pyrazine mono-*N*-oxide anion radical are quite increased by the addition of ethanol, but the increase is small for the $|a_{N(N\to O)}|$ and $|a_{3H}|$ values. These results are satisfied by assuming the active site to be the *N*-oxide-group oxygen atom, and have confirmed the assignment of $|a_{3H}| > |a_{2H}|$ which was preferred in the previous paper.[13] In Fig. 8 are shown these calculated results. The calculation on the assumption that both the *N*-oxide-group oxygen atoms are the active centers of the hydrogen-bonding interaction for the pyrazine di-*N*-oxide anion radical

results in a good agreement with the experimental values listed in Table 1. Note also that the ESR spectrum observed in DMF-ethanol mixed solvents has a pattern corresponding to the V_h symmetry of the anion radical. This may be attributed to the rapid exchange of hydrogen-bonding interaction at the two oxygen atoms, just as in the case of the *p*-benzosemiquinone- 1-^{13}C molecule.[8]

Equilibrium Constants of Hydrogen Bond Formation. Let us first examine the values of the equilibrium constant, *K*, which are listed in Table 2. It is deemed that, except for pyrazine mono-*N*-oxide, the *K* values are not very large considering that the species are anion radicals; they are comparable to the corresponding *K* values of neutral pyridine *N*-oxide, quinoline *N*-oxide, *etc.*[28] However, it should be remembered that the compounds whose π-anion radicals are relatively stable are those which have electron-drawing substituents, like CN, COOR, NO_2, *etc.*, in a molecule and that these are conjugated with π-electron systems. In the present case, these substituents cause the decrease in the electron densities at the *N*-oxide oxygen atom, even in the anion radicals, as the calculation[13] of the spin densities shows. In turn, the nitro group in, for example, nitrobenzene is essentially a weak base. Pyrazine di-*N*-oxide may be also a weak base, as may be understood from the pK_a value (−1.62)[22] of phenazine di-*N*-oxide. This weak basicity of the above-mentioned functional groups might be one of reasons for the present, perhaps, small *K* values, except for the case of the pyrazine mono-*N*-oxide anion radical, which has rather large *K* value compared with those of the other radicals (see Table 2). The basicity of neutral pyrazine-mono-*N*-oxide may be not so different from, or only a little weaker than, that of pyridine *N*-oxide. This may be inferred from the fact[22] that the pK_a value (1.57) of acridine *N*-oxide is almost the same as that (1.32) of phena-

TABLE 3. ANION RADICALS PRODUCED BY THE CONTROLLED POTENTIAL ELECTROLYSIS OF PYRAZINE MONO- AND DI-*N*-OXIDES AT DIFFERENT POLAROGRAPHIC REDUCTION WAVES AND UNDER DIFFERENT ETHANOL CONCENTRATIONS ADDED IN DMF SOLVENT

Mother compound	Ethanol concentration	Anion radical species[a] (observed ESR spectra) produced at		
		First wave	Second wave	Third wave
Pyrazine mono-	~0	PMNO	Pyrazine	—
N-oxide	0.1	PMNO	Pyrazine	—
(PMNO)	0.3	PMNO	PMNO	—
	1.0	PMNO	PMNO	—
	>2.0	PMNO	PMNO	—
Pyrazine di-	~0	PDNO	PMNO	Pyrazine
N-oxide	<0.5	PDNO	PMNO	Pyrazine
(PDNO)	1.0	PDNO	PMNO	PMNO
	>2.0	PDNO	PDNO	PDNO

a) ESR spectum observed at the second or third reduction wave is sometimes contaminated more or less by the other spectra, but the main spectrum is the one shown in this Table.

zine mono-*N*-oxide. Keeping in mind this fact, we may expect that the *K* value (the active site is the *N*-oxide group) of the pyrazine mono-*N*-oxide anion radical for the hydrogen bonding with alcohol is larger than that (~15 *l*/mol in *n*-heptane, ~6—7 in CCl_4) of the corresponding equilibrium in the pyridine *N*-oxide, quinoline *N*-oxide, and acridine *N*-oxide neutral molecules, because the former is the anion radical with an extra electron in the molecule. In fact, this is actually the case, the *K* value (23.3 *l*/mol) obtained here being larger than that just mentioned above for the neutral species.

Now let us consider the hydrogen-bonding equilibrium constant, *K*'s, formed between the 4NPO anion radical and water, ethanol, and phenol. As Table 2 indicates, the *K* values are increased in the following order of proton donors: water<ethanol <phenol. This order seems to be in agreement with that of the proton-donating power for 1:1 hydrogen-bond formation studied by infrared spectral measurements.[29] In relation to these results, it is thought that, for the same hydrogen-bonding systems as the above, the $|a_{RD}^{N}|$ value (see Eqs. (3) and (4), and Table 2) of the 4NPO anion radical is in an order just the reverse of that of the *K* value, namely, water>ethanol>phenol. Remember that the *K* value for the 4NPO anion radical-water system is quite small. Much water is necessary to bring about the change in the hfc constant $|a_N|$, as may be seen in Table 1. In these mixed solvents with high values of $\alpha=(D)/(S)$ (see Eq. (3)), the nature of the mixed solvents is never the same as that of DMF itself in the present experiments. The dielectric constant of water is very large. The effect of electrostatic interaction, that is, the effect of the reaction field of the mixed solvent on the electronic state of radicals can not be ignored in these cases. In view of this, the thermodynamic and ESR data for the case of phenol as the proton donor might be attributed to the fact that the data are closer to hydrogen binding itself; since phenol is a strong donor, the phenol concentration added in the solvent system is small. The solvent character may be unchanged with the addition of such a small phenol concentration.*[7]

Relation of Equilibrium Constant Data to the Radical Species Produced by Controlled Potential Electrolysis. In the course of this experimental study, we observed that the polarograms of pyrazine di- and mono-*N*-oxides in a DMF solvent exhibit a slight increase in wave height at about −1.98 and −2.24 V for the former and the latter respectively (abbreviated henceforth as "the second wave; see Fig. 9). This observation seems to be attributable to the presence of a slight quantity of water[13] introduced into the solvent during the process to remove the dissolved oxygen with N_2 gas. The result in the case of pyrazine mono-*N*-oxide is illustrated in Fig. 9 as an example. The second wave obviously increases in wave height with the addition of a proton donor, ethanol. When controlled-potential electrolysis is carried out at the first and the second reduction waves, the recorded ESR spectra, *i.e.*, the anion radicals produced, are different and depend on the concentration of the proton donor. At any rate, the second wave would be due to the electrode reaction of radical species produced at the first wave, and the reaction is dependent on the proton-donor concentration. These

29) M. Tuboi, *Kagaku no Ryoiki* (in Japanese), **7** (No. 10), 611 (1953).

*7 The presence of supporting electrolyte, tetra-*n*-propylammonium perchlorate 0.1 mol/*l*, would render the system somewhat complicated.

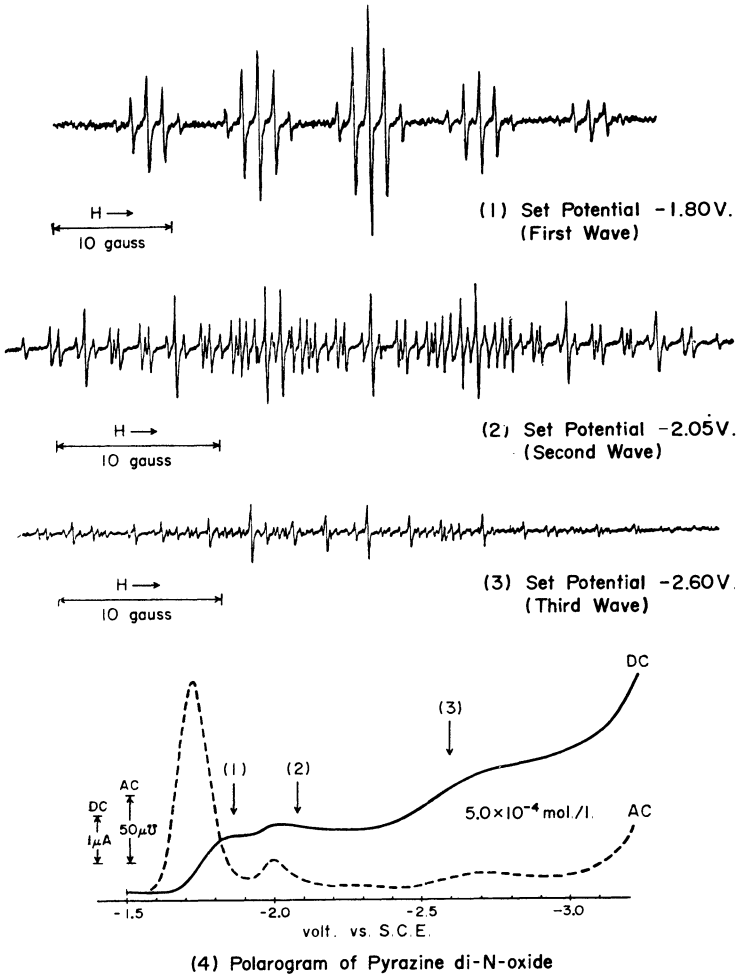

Fig. 10. ESR spectra observed by the controlled potential electrolysis of pyrazine di-*N*-oxide at the three different potentials shown in the polarogram (4) in this figure. ESR spectra (1), (2) and (3) are easily identified to the anion radical of pyrazine di-*N*-oxide, pyrazine mono-*N*-oxide, and pyrazine, respectively, by comparing with the data given in our foregoing paper.[13] But, note that the spectrum (3) is contaminated to some extent by the spectrum (2) of pyrazine mono *N*-oxide anion radical (see footnote of Table 3).

experimental results have been summarized in Table 3, while the ESR spectra observed at three different potentials, corresponding to the first, second, and third reduction waves, are exhibited in Fig. 10 for the case of pyrazine di-*N*-oxide itself without any proton donor. The identification of these spectra is easy,[13] as may be understood from the figure caption. It is understood that incresing the ethanol concentration makes the deoxygenation process of the *N*-oxides more difficult, and that, when the quantity of ethanol added is more than a suitable critical concentration, the ESR spectrum of the pyrazine mono- or di-*N*-oxide anion radical occures even in electrolysis at a more negative potential than that of the first reduction wave. This relation is depicted in Fig. 11, in which the C (~0.3%) and C′ (~2.6%) points, respectively, correspond to the above-mentioned critical concentrations of pyrazine mono- and di-*N*-oxides. These concentrations are almost in agreement with those where hydrogen-bonded and free species exist in an equal molar ratio. In other words, there is an intimate correlation between the hydrogen-bonding equilibrium constant, *K*, and the experimental results shown in Table 3 and Fig. 11. We also note that when ethyl ether instead of ethanol is added to the DMF system, the phenomenon seen in Fig. 11 and Table 3 is not observed. This result

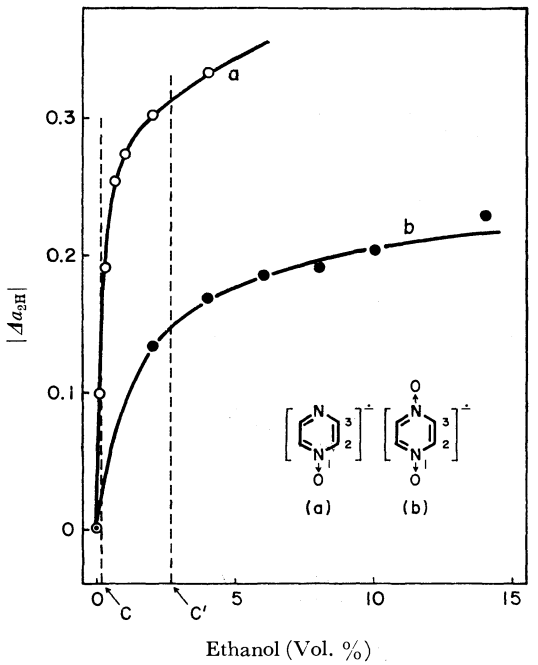

Fig. 11. Change (Δa_{2H}) in $|a_{2H}|$ of the anion radicals shown in this figure upon the addition of ethanol. See text for the meaning of the points C and C'. Solvent: dimethylformamide

suggests the importance of hydrogen-bonding interaction in relation to the experimental results presented above.

The reason for this phenomenon is not completely clear. One possibility is that the anion radical in hydrogen-bonding interaction is more stabilized than in the free radical itself, if no side chemical reaction occurs. Dianion or similar unstable chemical species of the mother compounds produced by the electrolysis at the second or third reduction waves*8 easily bring about electron transfer to the neutral molecule. Thus, the anion radical stabilized by hydrogen bonding has been observed at all reduction waves. If the anion radical is not stabilized, the deoxygenation reaction of the mother compound occurs in the higher-potential electrolysis. The ESR spectra corresponding to that of the anion radical of deoxygenated species have thus been observed.

The authors wish to express their thanks to Professor Saburo Nagakura of the Institute for Solid State Physics, the University of Tokyo and to Professor Yasuo Deguchi of the Department of Chemistry, the University of Kyoto for useful discussions.

*8 In this connection it is noted that the ESR spectrum of 4NPO anion radical is always observed by the electrolysis at the second reduction wave as well as the first wave regardless of the addition of ethanol in DMF solvent. 4NPO anion radical is quite stable, so that the equilibrium such as $(4NPO)^{=}+(4NPO) \leftrightarrows (4NPO)^{-}$ may occur easily whether or not the species is hydrogen bonded. That dianion $(4NPO)^{=}$ is formed at the second reduction wave was experimentally confirmed from the polarographic measurement of 4NPO anion radical itself.[30]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1634—1642 (1970)

Studies on Associated Solutions. I. Excess Volume of Binary Systems of Alcohols with Various Organic Liquids

Koichiro NAKANISHI and Hideko SHIRAI*

Department of Industrial Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received November 13, 1969)

Excess volumes of mixing have been determined at 25.00°C by pycnometry for eleven binary solutions of methanol and two binary solutions of ethanol with organic liquids. The second components include three aliphatic amines, *n*-butyraldehyde, ethyl acetate, isopropyl ether, anisol, chlorobenzene, acetonitrile, pyridine and nitromethane. The excess volumes of binary solutions containing aliphatic alcohols, which are evaluated from the available density data, were critically reviewed and compared with the present results.

The specific interaction due to the hydrogen bond between the polar groups of different components is primarily responsible for the non-ideal behaviors of binary associated solutions. In binary solutions containing alcohols, for example, the hydrogen bond energy between the hydroxyl group in the alcohol

* Tokyo College of Pharmacy, Shinjuku-ku, Tokyo.

molecules and the proton acceptor group in the other component is estimated to be more than 2 kcal/mol, while the interactions between the inert groups such as the aliphatic hydrocarbon portion of the molecules are almost negligible. This is why the simple lattice theory as proposed by Barker[1] proved considerably successful in interpreting the behavior of the excess functions of associated solutions such as benzene + methanol or chloroform + acetone.

When an alcohol is mixed with other organic compounds, part of alcohol molecules will tend to dissociate from the polymeric aggregates through the hydrogen bond to form other kinds of hydrogen bonds with different kinds of molecules. The degree of dissociation from polymeric species would be dependent on the proton accepting ability of the functional group in the molecule. As a rough first approximation, this may be the most decisive factor in determining the sign and magnitude of the deviation from the ideal solution law.[2]

It is the purpose of the present studies to investigate in detail the dependence of each thermodynamic property of the mixtures of polar and associated liquids including alcohols on the nature of component liquids. The present paper deals with the volume of mixing for thirteen binary solutions containing methanol or ethanol as one component. The results are discussed with available data.

Experimental

Purification of Liquids. Samples of alcohols and other organic liquids were the same as in our recent vapor-liquid equilibrium studies.[3,4] They were prepared as follows. Available reagents of the best grade were dried, whenever necessary, over dehydrating agents such as CaO, and then distilled with a 30 plates fractionating column under atmospheric or reduced nitrogen pressure. Only the middle fraction was used. When the liquids are highly hygroscopic, they are re-distilled immediately before use.

Density Measurement. The densities of pure liquids and solutions were determined with a bicapillary-type pycnometer.[5-7] The capacity of the pycnometer was 10 m*l*. All the measurements were carried out at 25.00°C in a thermostat. The temperature was controlled to ±0.005°C. The present density data seems to be accurate within ±0.00005 g/m*l*.

Results and Discussion

Density and Excess Volume Data. The density data d_{12} were converted to the excess volumes of mixing V^E by means of

$$V^E = \frac{x_1M_1 + x_2M_2}{d_{12}} - \left(x_1\frac{M_1}{d_1^0} + x_2\frac{M_2}{d_2^0}\right) \quad (1)$$

where x is mole fraction, M is molecular weight, d^0 is density of pure liquid, and subscript 1 refers to alcohols. V^E values for each solution were then fitted to the equation

$$V^E = x_1(1-x_1)\sum_{n=0}^{2}A_n(1-2x_1)^n \quad (2)$$

where constants A_n were determined by the method of least squares.*1

The density and excess volume data are presented in Table 1 and the latter is plotted in Fig. 1. The constants in Eq. (2) and the excess volume for equimolar mixture, $(V^E)_{x_1=x_2}$, are listed in Table 2. As is evident from Eq. (2), the values $(A_0+A_1+A_2)$ and $(A_0-A_1+A_2)$ represent the terminal values of V^E/x_1x_2 at $x_1=0.0$ and $x_1=1.0$. Thus, they are equivalent to $\bar{v}_1-v_1^0$, the difference between the molar volume of pure liquid and the partial molar volume of the same liquid at infinite dilution. They are also shown in Table 2.

The excess volumes of all the systems investigated are negative for the whole composition ranges. The only exception is the nitromethane-rich region of ethanol+nitromethane systems. As seen in Table 2, the largest volume contraction in methanol solutions is observed with *n*-butyraldehyde, which is followed by aliphatic amines (Et_2NH, Et_3N, and *n*-$BuNH_2$), isopropyl ether, pyridine in this order. Other polar liquids show smaller volume contraction. The volume contraction in ethanol solutions is smaller than that in corresponding methanol solutions. It should be remarked that constant A_1 is always negative, which means $\bar{v}_1-v_1^0$ is more positive than $\bar{v}_2-v_2^0$.

Literature Survey. In order to interpret the present data, we found it necessary to compare them with available data. Therefore, we have made an extensive literature survey and analyzed the density data of binary solutions containing methanol, ethanol, propanols, or butanols as a component. The results are summarized in Table A (see Appendix) by listing the value of $(V^E)_{x_1=x_2}$ $(=0.25\,A_0)$ for each system. Most of the data published be-

*1 As seen in Table 1 and Fig. 1, the precision with which the V^E values are established is sometimes not enough for evaluating three constants in Eq. (2). This is the case especially for the systems having small absolute values of V^E. However, it is revealed that the V^E/x_1x_2 *vs.* x_1 plot, though not shown here, cannot be approximated by a straight line. Thus, it is necessary to assign three constants for each system as in Table 1.

fore 1956 have been collected by Timmermans.[8] We have used his data and also the more recent ones as shown in the footnote of the table.

Dependence of V^E on Various Factors. We call attention to the following evidence obtained from the present work and literature survey.

1. As Fig. 2 illustrates, $(V^E)_{x_1=x_2}$ increases generally with the molar volume of primary normal alcohol. For *c*-C_6H_{12}, Et_2O, $CHCl_3$, and Et_3N, the dependence is somewhat irregular. Since the molar volume of the second component chosen is generally larger than 80 ml/mol, the results indicate that the empirical congruent principle proposed by Brönsted[9] cannot be applied to alcohol solutions.

2. As was shown by Brown,[10] the $(V^E)_{x_1=x_2}$ values for secondary and tertiary alcohols are larger than those for the corresponding normal alcohol. This can also be verified from the cases with acetone and *n*-heptane.

3. The $(V^E)_{x_1=x_2}$ value increases generally with tepmerature. There are some exceptional cases. An inverse dependence is observed with phenol, aniline, and formamide. Note that they are all associated liquids.

4. As regards to the symmetricity of the excess function, it appears that highly a symmetric V^E *vs.* x relation is observed for definite type of second component (*e. g.*, $CHCl_3$, CCl_4, toluene, *etc.*). As was discussed by Rowlinson[11] and van Ness,[12] these liquids have very weak interactions with hydroxyl group and break the alcohol hydrogen bond only insufficiently. However, such high asymmetry

[a] ml/mol

is not limited to the cases of practically nonpolar liquids. As an example, EtOH+dioxan or EtOH+nitromethane shows a similar trend. In the cases where the excess volume changes sign, there is always a volume contraction in alcohol-rich region.

5. There exists a sequence in the values of excess volumes of binaries with a given alcohol. The excess volume has an exceptionally large negative value of −2 to 5 ml/mol for the combination of alcohols with the liquids in which a chemical reaction might take place. Binary systems with aldehydes or acids are typical examples. Another group of binary systems which exhibit a large negative V^E is the mixture, aliphatic amine and alcohol. The V^E values are between −0.5 and −2.5 ml/mol. On the other hand, the V^E

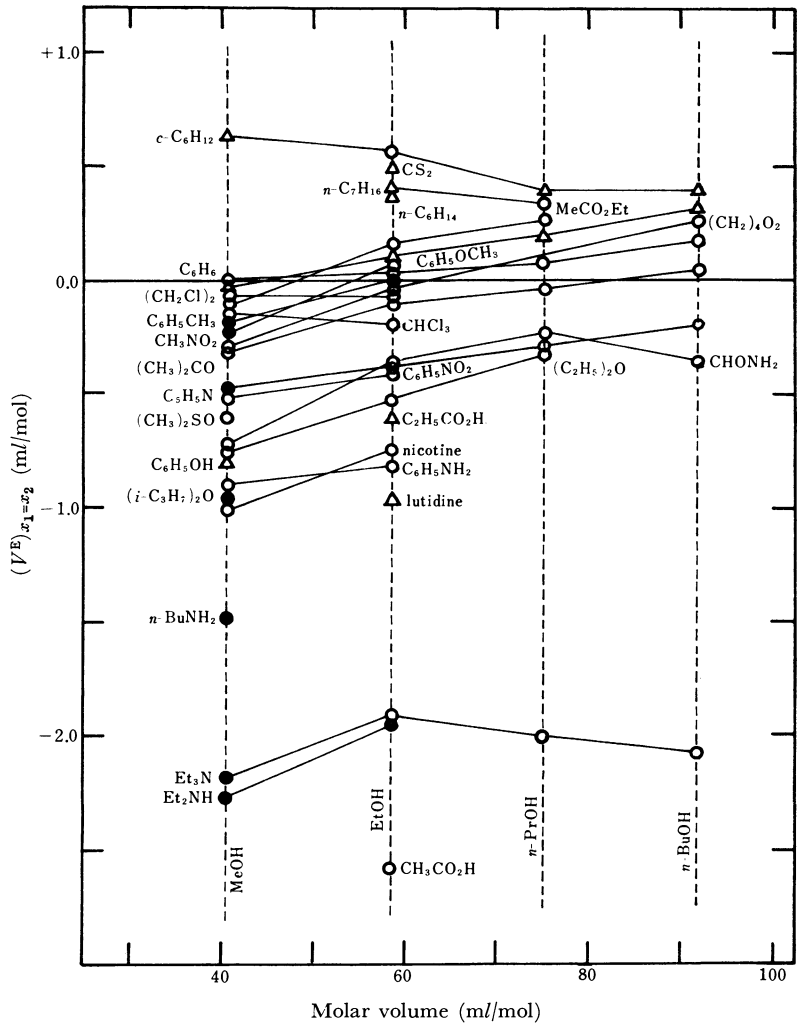

Fig. 2. Relation between excess volume at equimolar mixture and molar volume of alcohol. ● this work, ○ literature value, △ indicates the values at other temperatures than 25°C

values for the systems with paraffin hydrocarbons such as *c*-C_6H_{12}, *n*-C_6H_{14}, *etc.* are positive and usually larger than +0.3 ml/mol. The V^E values for aromatic hydrocarbons and weakly polar liquids are nearly equal to zero or slightly negative. Thus, an obvious relationship between the V^E and the proton affinity of the functional group in the second component is now widely confirmed. This sequence is also parallel with that observed in spectroscopic studies.[2,13] The variation in the values of V^E for aliphatic amines deserves attention. We will compare them with the heat of mixing data in a succeeding paper.[14]

Part of the above observations has been discussed by Brown *et al.*,[10,15] Paraskevopoulos and Missen[16] and Copp and Findlay.[17] The systems alcohol +nonpolar liquid were discussed extensively by Brown *et al.* in their recent paper.[15] We were able to reveal the V^E behaviors for a wide variety of binary solutions. Figure 1 of Ref, 15 shows the behaviors with higher alcohols in certain cases.

Qualitative Interpretation. In view of the present status of solution theories, our analysis is limited to a qualitative description, since the speci-

fic interactions in alcohol solutions are too complicated. Paraskevopoulos and Missen[16] have concluded in their analysis of V^E data for alcohol+CCl_4 solutions that there are two contributions to the total volume change on mixing, *viz*, the break-up of the alcohol structures and the geometrical fitting of the second component into the remaining alcohol structure. Since the alcohol structure has open cavities, the first contribution should be positive. On the other hand, the geometrical fitting leads to a negative contribution, as it is a process of co-operative accommodation of the second component into the alcohol structure which is accompanied by an interstitial dissolution. This interpretation seems to be valid also for various types of binary alcohol solutions. The fact that the V^E values are generally negative indicates that the second contribution is more important in determining the sign of V^E values. For the co-operative accommodation of the second component to be effective, the molecules should have higher proton accepting ability. The second contribution may then be roughly proportional to the proton accepting ability, though the geometrical characteristics of each molecule will produce an additional effect. A comparison of the V^E data with the spectroscopic data such as "hydrogen bond shift" indicates that this is the case for binary methanol solutions. Existence of a positive contribution reflects on the positive temperature coefficient of V^E. Relative easiness of the break-up of alcohol structure may be responsible for less negative value of secondary and tertiary alcohols than primary alcohols. This will be verified by a comparison with V^E data for alcohol-alcohol mixtures, which are positive with a combination of primary and secondary alcohols. The available data are as follows; The $(V^E)_{x_1=x_2}$ value is +0.005 for MeOH +EtOH (15°C), +0.045 for MeOH+*n*-PrOH (15°C), +0.07 for MeOH+*n*-BuOH (25°C), +0.09 for MeOH+*i*-BuOH (15°C), +0.01 for EtOH+*n*-BuOH (25°C), +0.045 for EtOH+*i*-BuOH (15°C) and 0.00 for *n*-PrOH+*n*-BuOH (15°C).[8,18]

In conclusion, the present data comprise a new and important addition to our knowlegde of excess volume behavior of binary methanol solutions, for which there are less data than for ethanol.

The authors thank K. Nakasato, S. Ichinose, R. Toba and T. Minamiyama for their assistance in experimental work. They also wish to thank Professor N. Watanabe and Mr. H. Touhara for their interest and discussions.

Appendix

The density data are available in literature. We summarize the present information on V^E for binary solutions containing five lower aliphatic alcohols in Table A by listing $(V^E)_{x_1=x_2}$ value.

Semi-Empirical SCF MO Method for Systems Including All Valence Electrons

Fumihiko HIROTA and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 18, 1969)

For the purpose of evaluating approximate SCF-MO's for systems including all valence electrons, two semi-empirical methods are presented. One of them (method I) uses non-empirical Coulomb integrals and the other (method II) empirical ones. The orbital energies, charge distributions, and excitation energies are calculated for ethylene, acetylene formaldehyde, carbon monoxide and hydrogen cyanide, and are compared with those obtained by the other semi-empirical and non-empirical calculations and also with the corresponding experimental values. The present methods are found to give rather satisfactory results. The calculated orbital energies are improved by the present methods compared with those by the CNDO type calculation. Calculated charge distributions are well coincident with those of the non-empirical SCF calculation. Calculated dipole moments change in parallel with experimental values from a molecule to another, though the former values are generally larger than the latter.

It is desirable to develop a theoretical method convenient for the quantitative or semi-quantitative treatment of all valence electrons of complex molecules. Yoshizumi[1] and also Hoffman[2] extended the simple Hückel method to σ-electron systems

1) H. Yoshizumi, *Trans. Faraday Soc.*, **53**, 125 (1957).

2) R. Hoffman, *J. Chem. Phys.*, **39**, 1397 (1963).

in spite of several difficulties[3] inherent to the method. More quantitative theories for all valence electrons analogous to the Pariser-Parr-Pople[4] method for π-electrons were developed.[5-13]

One of them is the CNDO (Complete Neglect of Differential Overlap) method developed by Pople, Santry and Segal.[8,9] This method, in spite of its simplicity, brought about much success in explaining several points such as the charge distributions of diatomic molecules and the bending force constants of AH_2 and AH_3 type molecules (A; C, N and O). It failed, however, in explaining several problems, for example, the streching force constants[9] or the charge densities at hydrogen atoms for a series of CH_4, C_2H_6, C_2H_4 and C_2H_2.[10]

Several other methods[14-16] are presented along the lines of considering all valence electrons and of evaluating semiempirically Coulomb integrals. Yonezawa *et al.*[16] obtained rather satisfactory results for charge distributions, ionization potentials and excitation energies by the aid of the method (called hereafter the Y-Y-K method) developed on this line. But in details there are still several difficulties; for example, the orbital energy separation is usually too small compared with those obtained by the exact non-empirical SCF calculation. This seems to be mainly due to the use of empirical Coulomb integrals. In this connection, the following points may be pointed out as the problem of the CNDO and Y-Y-K method. It may be expected[17] that σ-orbitals are more closely packed than π-orbitals and therefore that the Coulomb integrals are larger for σ-electrons than for π-electrons. In the CNDO method all one-center Coulomb integrals are taken to be equal to one another and two-center Coulomb integrals are independent of the character of atomic orbitals. In the Y-Y-K method, one-center Coulomb integrals are evaluated differently for s and p orbitals but the individuality of two-center Coulomb integrals is not considered except for the cases where one-center integrals are different. This effect is expected to be especially great for the molecules which have both σ- and π-electrons.

In this paper, we present improved semi-empirical methods suitable to the theoretical treatment of systems including all valence electrons and compare the results obtained for some small molecules with those by the other methods.

Theoretical

Roothaan's equation of LCAO SCF[18] is employed, the atomic integrals necessary for the calculation being evaluated by the following two methods. In method I, the integrals are evaluated approximately but non-empirically except for off-diagonal core integrals; in method II, the integrals are evaluated empirically. The essential points of our calculation are described below.

1. Molecular orbitals are expressed as linear combinations of all the valence atomic orbitals (AO's) centered on each atom except for the 1s orbitals of carbon, nitrogen and oxygen which are pushed into the cores. The Slater type AO's are taken, if necessary, the orbital exponent being determined by Slater's rule except for the hydrogen 1s AO, the effective nuclear charge of which is taken to be 1.2.

2. In Roothaan's equation,[18] the overlap integrals and two-electron integrals including two-center differential overlap are disregarded. This means that all the one-center integrals and the Coulomb type two-center integrals are taken into account in the present calculation.

3. The one-center core integrals are calculated non-empirically in method I with the core Hamiltonian H^{core};

$$H^{\text{core}} = \sum_{\mu} H_{\mu}^{\text{core}} = \sum_{\mu}\left[-\frac{1}{2}\Delta_{\mu} - \sum_{A}\frac{Z_A}{R_{A\mu}} \right] \qquad (1)$$

where Z_A is taken as the number of valence electrons in atom A and $R_{A\mu}$ is the distance between the μth electron and atom A. But for 2s orbital, a different method based on the experimental ionization potentials (I.P.) are used as follows;

$$\langle 2s|H^{\text{core}}|2s\rangle = \langle 2p|H^{\text{core}}|2p\rangle + (\text{I.P.}(2s) - \text{I.P.}(2p)) \qquad (2)$$

In method II, this integral for AO x is evaluated

$$\langle x|H^{\text{core}}|x\rangle = -\text{I.P.}(x) - \sum_{i\neq x} n_i\left\{(xx|ii) - \frac{1}{2}(ix|ix)\right\} \quad (3)$$

where n_i is the occupation number of the ith orbital and the summation is taken over all valence orbitals.

4. One-center Coulomb integrals are estimated non-empirically in method I by using the Slater type functions.

In method II, the Pariser approximation[19] is used for (pp|pp) type integral. Since the valence states of atoms, particularly of hetero-atoms can not be determined exactly, we assume the following valence states:*1 sp^3 for carbon, sp^4 for nitrogen and s^2p^4 for oxygen. The other one-center Coulomb integrals are estimated by making use of the Slater-Condon parameters[20] F_2^{pp} and G_1^{sp} obtained from atomic spectra of neutral atoms:*2

$$\begin{aligned}(pp|p'p') &= F_0^{pp} - 2F_2^{pp}\\ (sp|sp) &= G_1^{sp}\\ (pp'|pp') &= 3F_2^{pp}\end{aligned} \quad (4)$$

where p and p′ are orthogonal to each other and F_0^{pp} is estimated by using the Pariser approximation. The integral (ss|pp) is taken as the arithmetic mean of (ss|ss) and (pp|pp).

5. Two-center Coulomb integrals are evaluated by using the following approximate formulas of Roothaan's exact ones[21] for several sub-integrals.*3

$$\begin{aligned}[3S|3S] &= \frac{1}{\rho}\left[1 - S^2/\{(1-\tau^2)^7\cdot(1+0.465\rho)\}\right]\\ [3S|1S] &= \frac{1}{\rho}\left[1 - \frac{S^2}{-0.2 + (1-1.66\tau)\rho}\right]\\ [3S|3D\Sigma] &= \frac{1}{(1-\tau)^2\rho^3}[1-S^2\cdot(1+0.5\rho)]\\ [3S|3P\Sigma] &= \frac{1}{(1-\tau)\rho^2}[1-S\cdot(1+0.12\rho)]\end{aligned} \quad (5)$$

Here S means the overlap integral between two s type AO's, $\tau=(\zeta_a-\zeta_b)/(\zeta_a+\zeta_b)$, ζ_a and ζ_b being taken as the orbital exponents of two AO's, and $\rho=R_{AB}(\zeta_a+\zeta_b)/2$, R_{AB} being the distance between atoms A and B. The following more approximate formulas are employed for other smaller sub-integrals.

$$\begin{aligned}[3P\Sigma|3P\Sigma] &= \frac{2}{\rho^3}(1-2S^2)\\ [3P\pi|3P\pi] &= \frac{1}{\rho^3}\left(1-\frac{16}{\rho^3}\right)\\ [3D\Sigma|3D\Sigma] &= \frac{6}{\rho^5}\left(1-\frac{3.76}{\rho^4}\right)\\ [3D\Delta|3D\Delta] &= \frac{1}{\rho^5}\left(1-\frac{7.5}{\rho^2}\right)\end{aligned} \quad (6)$$

In method II, the semi-empirical values for these integrals are evaluated from the corresponding non-empirical values in method I by using the following formulas:

$$\begin{aligned}(s_As_A|p_Bp_B)^{emp} &= (s_As_A|p_Bp_B)^n\\ &\quad - \Big[\frac{1}{2}(s_A|s_B)^2\{(s_Bs_B|p_Bp_B)^n - (s_Bs_B|p_Bp_B)^{emp}\}\\ &\quad + (p_A|p_B)^2\{(s_As_A|p_Ap_A)^n - (s_As_A|p_Ap_A)^{emp}\}\\ &\quad + (s_A|p_B)^2\{(p_Bp_B|p_Bp_B)^n - (p_Bp_B|p_Bp_B)^{emp}\}\\ &\quad + (s_A|p_B)^2\{(s_As_A|s_As_A)^n - (s_As_A|s_As_A)^{emp}\}\Big]\\ (s_Ap_A|p_Bp_B)^{emp} &= (s_Ap_A|p_Bp_B)^n\\ &\quad - \Big[\frac{1}{2}(s_A|s_B)(p_A|s_B)\{(s_Bs_B|p_Bp_B)^n\\ &\quad - (s_Bs_B|p_Bp_B)^{emp}\}\\ &\quad + (s_A|p_B)(p_A|p_B)\{(p_Bp_B|p_Bp_B)^n\\ &\quad - (p_Bp_B|p_Bp_B)^{emp}\}\Big]\end{aligned} \quad (7)$$

Here superfixes emp and n mean empirical and non-empirical values, respectively. These formulas are obtained by expanding the AO of atom A with regard to the position of atom B.*4

6. The off-diagonal core integral (β_{ab}) between AO's a and b is evaluated by the following formula;

$$\beta_{ab} = C\cdot S_{ab}\left\{\left(a\left|\frac{Z_A}{R_{A\mu}}\right|a\right) + \left(b\left|\frac{Z_B}{R_{B\mu}}\right|b\right) - \left(a\left|\frac{Z_B}{R_{B\mu}}\right|a\right) - \left(b\left|\frac{Z_A}{R_{A\mu}}\right|b\right)\right\}\Big/4 \quad (8)$$

where C is an empirical parameter and is commonly taken $C=0.92$ for all molecules. S_{ab} is the overlap integral between AO's a and b. β_{ab} is taken for both neighboring and non-neighboring AO's.

Our treatment is similar to the NDDO (Neglect of Diatomic Differential Overlap) method of Pople *et al.*,[8] in the sense that the overlap integrals and the two-center differential overlaps are disregarded. The integrals of these two types may be expected to be cancelled out when Löwdin's orthogonalized

*1 The (pp|pp) type integrals are not so sensitive to the valence state of each atom.

*2 The use of F_2^{pp} and G_1^{sp} for neutral atoms seems to be incompatible with the fact that F_0 evaluated by the Pariser approximation is that of the corresponding anion. But F_2 and G_1 are so small that the difference between the neutral and anionic values may be safely disregarded.

$(\sigma\sigma\|\pi\pi)$	10.35	10.01
$(\pi\pi\|\pi\pi)$	9.35	9.13

* The estimation is made for the case of C_2H_4, the 1s orbital exponent of hydrogen being taken to be 1.0, and 2s and 2p orbital exponents for carbon to be 1.59. Superscript 0 means the one-center integrals.

orbitals (OAO's)[22] are taken as the basis AO's as was pointed out by Fischer-Hjalmars[23] for π-electron systems. This cancellation may be expected to be less perfect for σ-orbitals than for π-orbitals, but this approximation is essential for the simplification of the calculation. Furthermore, we neglect the changes of the remaining integrals (except for β) caused by the transformation of the basis set from the Slater AO's to the OAO's.*5 According to our estimation, they are larger for σ-orbitals than for π-orbitals, but are not fatal as is shown in Table 1.

Since the Slater type 2s orbital is not orthogonal to the inner 1s orbital, the direct calculation leads to a too large absolute value of the one-center core integral for this orbital. The ionization potential for an electron in orbital x can be obtained by Koopmans' theorem[24] as the sum of the core integrals and electron repulsion part. Therefore, if the repulsive part is considered to be equal to each other for 2s and 2p electrons, the difference in the core integrals for these orbitals may be thought to be equal to that in the ionization potentials. Thus we obtain Eq. (2).

The approximations adopted to the evaluation of the two-center Coulomb integrals are not always necessary. In view of computational convenience, however, the present formulas are satisfactory from the practical point of view. The present approximate formulas are applicable to the rather small region of orbital exponents and atomic distances. In the sub-integrals of Roothaan's formulas which are

$(\pi\pi\|\pi'\pi')$	10.03	10.10

a) Here, s, σ, π and π' mean 2s, $2p\sigma$, $2p\pi$ and $2p_y$ (y-axis is in the molecular plane) AO's, whose orbital exponents are determined following Slater's rule.

common to several atomic integrals, the term including $\exp(-2\rho)$ is approximated by the term including the square of overlap integrals for the first four formulas. For other small sub-integrals, the more approximate formulas are employed. These formulas give the resultant integrals different by less than 6% from the exact values as is shown in Table 2.

In the evaluation of the semi-empirical two-center Coulomb integrals in method II, the following three factors are considered. First the correlation effect discussed by many researchers,[25] second the effect of the reorganization of orbitals caused by the one-electron ionization or excitation,[26] and third the expansion of the excited orbitals.[27] These effects may affect two-center Coulomb integrals, even when overlap integrals are zero. By considering these effects we evaluated the integrals by Eq. (7) obtained by expanding the AO of atom A with regard to the position of atom B. When the same method is applied to π-electron systems, the evaluated values are somewhat larger than those obtained by the uniformly charged sphere model or by the Ohno approximation.[28]

The formula for the off-diagonal core integral is obtained by adopting the Mulliken approximation and by considering the effect of the orthogonalization to the first order of overlap integrals between

population of a certain AO is calculated as the sum of the square of the coefficients of the corresponding AO in the occupied MO's. This definition coincides with Mulliken's gross or net atomic population in this case in which overlap integrals are disregarded. Dipole moments are calculated by the method proposed by Pople and Segal.[9] Excitation energies are calculated by considering the configuration interaction among several singly excited configurations of lower energy.

Results and Discussion

In this section, we present the results obtained by applying the above-mentioned two methods to several small molecules and compare them with those of other calculations and also with the experimental results.

Orbital Energies. In Tables 3—6 are shown the occupied orbital energies calculated by the present authors. In these tables the results calculated by other theoretical methods are also shown for the purpose of comparison, together with the observed ionization potentials which correspond to the absolute values of orbital energies according to Koopmans' theorem.[24] Recently, the ionization potentials higher than the first one are measured by the photo-electron spectroscopy technique for various molecules.[29,30]

Concerning ethylene (Table 3), the original CNDO/2 parameters failed in giving the orbital energies in correct order. Modifying the parameters, Sichel and Whitehead[13] obtained by the CNDO method the results which are fairly in good agreement with the observed ionization potentials, but the separation between the highest and second highest occupied orbitals is still too small. In the result of the Y-Y-K method, the order of the second highest and third highest occupied orbitals is reverse to that obtained by the other methods. Either of the present results obtained by methods I and II is generally in rather good agreement with the result obtained by the non-empirical calculation and with the observed ionization potentials. In particular, it may be noticed that the present methods lead to better agreement with the ionization potentials for the higher three orbital energies than the other non-empirical or semi-empirical methods.

The result of ethylene obtained by method II shows rather smaller orbital energy separations compared with that of method I. This tendency holds for formaldehyde, carbon monoxide and hydrogen cyanide, too. Anyhow, from the results in Tables 3—6, it is revealed that both the empirical and non-empirical Coulomb integrals in the present methods are applicable to the theoretical prediction of ionization potentials.

Charge Density. The charge density on the hydrogen atom in several molecules are listed in Table 7. The present results as well as those by the other methods show that the positive charge on hydrogen increases in the order of $CH_4 < C_2H_4 < C_2H_2$. This is coincident with the fact that the hydrogen atom of acetylene is rather easily replaced by metal and also with the fact that the dipole moments of C–H bonds in these molecules estimated from the absolute intensities of the infrared absorption spectra[31] increase in the same order. Comparing the results of methods I and II with each other, the former gives a little smaller values for all molecules under consideration than the latter. The results of INDO[32] calculation give considerably large values compared with those by other methods.

In Table 8, the calculated atomic population of ethylene is shown. Our results show rather good agreement with those of the non-empirical calculation except for the population on the 2p orbital. The value calculated by the present method is smaller than that by the non-empirical one, but

not so extremely small as the result by Dewar and Klopman.[15]

In Table 9, the atomic population of formaldehyde is shown. According to our results the population on the $p\pi$ orbital is larger for oxygen than for carbon. This is reverse to the results by the non-empirical calculation. In the other points, the atomic populations of formaldehyde calculated by the present method are well coincident with those by the non-empirical calculation.

TABLE 11. DIPOLE MOMENTS OF SOME SIMPLE MOLECULES

Molecule	Method I	Method II	CNDO[a]	Exp.[b]

a) Ref. 9.
b) A.L. McClellan, "Tables of Experimental Dipole Moments," W. H. Freeman & Co., San Francisco, California (1963).

Now let us turn to the atomic population of carbon monoxide shown in Table 10. According to our calculation, the oxygen atom is negatively charged in accordence with the non-empirical calculation, while the CNDO method leads to the reverse result. Concerning the total electron density on the oxygen atom, the result of method I (6.15) is well coincident with that of the non-empirical calculation (6.10) and method II gives a little smaller value (6.02). Since the same tendency is also found for the result by the Y-Y-K method, this seems to be an intrinsic to the use of the empirical integral values.

As a general tendency found for the calculated atomic populations, method II gives the smaller value for the population of 2s orbital than the non-empirical calculation. This is probably because the diagonal core integrals for 2s are a little underestimated (in absolute values) in method II.

The calculated dipole moments of several mo-

lecules are shown in Table 11 compared with the experimental values. We can find a parallelism between the calculated and experimental values, though the former values are generally larger than the latter. Generally speaking, the dipole moment values calculated by method I are better coincident with experimental ones than those by method I.

Excitation Energies. In Table 12, the excitation energies calculated for ethylene, formaldehyde and carbon monoxide are listed. In the both methods the calculated energies are too high compared with the experimental results. This point may be improved by selecting the optimum β_{ab} value for the calculation of excited state quantities.

According to method I, the lowest singlet and triplet excited states of ethylene include σ—σ^* excited configurations by 30 and 22%, respectively, and the separation between them is a little improved by the configuration interaction compared with the single configuration picture. The separation is evaluated to be 4.16 and 3.39 eV by methods I and II, respectively. The latter is well coincident with the observed value (3.0 eV). The situation is the same for the separation between the singlet and triplet $n\rightarrow\pi^*$ states of formaldehyde. That is to say, the value calculated by method II agrees well with the observed one, though the value evaluated by method I is somewhat larger than the experimental value.

Concerning the orbital energies and atomic populations, the both methods give similarly good results, while method II is better for the excitation energies than method I. It may be noticed that method I gives fairly satisfactory results for the quantities of the ground state, in spite of its simplicity and the great reduction in the calculation time compared with the non-empirical calculation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1649—1656 (1970)

Measurement of Negative Ions Formed by Electron Impact. VI. Negative Ion Mass Spectra and Ionization Efficiency Curves of Negative Ion of *m/e* 35 from Alkyl Chlorides

Satoru TSUDA, Akira YOKOHATA and Michihiro KAWAI

Department of Chemistry, Faculty of Engineering, University of Hiroshima, Senda-machi, Hiroshima

(Received November 20, 1969)

The negative ion mass spectra of alkyl (methyl, ethyl, *n*- and *iso*-propyl) chlorides, with emphasis on their relative abundance to the positive ions under 80, 40, 20 and 15 eV electron energies, and the ionization efficiency (IE) curves of Cl^- ions to the extent of 30 eV electron energies were measured. In every sample, the electron impacts of 80 eV and 40 eV gave almost the same distribution of *m/e* for negative ion mass spectra, in which, besides the intense peaks of *m/e* 35 and 37 (Cl^-), a relatively strong peak of *m/e* 25 (C_2H^-) in ethyl chloride and *n*- and iso-propyl chlorides was characteristic. For 20 eV and 15 eV, Cl^- ions predominated other negative ions. The ratio of the abundance of negative ions to positive ions was the order 10^2—10^3 for CH_3Cl^+/Cl^-, $C_2H_5Cl^+/Cl^-$, $C_3H_6^+/Cl^-$ and $C_3H_7^+/Cl^-$ throughout the range of electron energies. Each onset value observed in IE curves was interpreted to correspond to the appearance of the following reactions, the reaction scheme for second process being tentative. For the first process $RCl+e^-\rightarrow R+Cl^-$, for the second process $CH_3Cl+e^-\rightarrow H+CH_2+Cl^-$, $C_2H_5Cl+e^-\rightarrow H_2+H+C_2H_2+Cl^-$, C_3H_7Cl(*n*- or iso-)$+e^-\rightarrow H+C_2H_4+CH_2+Cl^-$. For the third process the possibility of ion pair formation was pointed out. For the fourth process in ethyl chloride a brief discussion was made in view of the overlapping phenomena of a complicated dissociative electron capture process with an ion pair formation.

When molecules are bombarded with electrons in the ion source of a mass spectrometer, both positive and negative ions may be formed, the latter often several orders of magnitude less abundantly. If the energy of the ionizing electrons is greater than about 30 eV the relative abundance of the positive ions produced is generally independent of electron energy, and positive-ion mass spectral

data for many molecules are available.[1-3] However, only a few data have been reported[4-8] regarding the identity and distribution of the negative-ion species produced when molecules of chemical interest undergo electron bombardment. Data on the ionization efficiency (IE) curves of negative ions are very limited.[9-12]

There are mainly three mechanisms by which ion formation for negative ions may occur; at low electron energies by electron capture, at intermediate energies by a dissociative resonance process and at higher electron energies by ion-pair formation. Hence the ions observed and their abundance are markedly energy-dependent.

In the present stage when information on negative ion mass spectra is lacking, further work is needed. This work was extended to alkyl chlorides, emphasis being placed on the relative abundance of negative ions to the positive ions in relation to the electron energies and on the measurement of IE curves of Cl^- ions.*1

Experimental

Experiments were performed on a Hitachi RMU-6D mass spectrometer equipped with a T-2M ion source having a rhenium filament. The ion detection circuit consisted of a ten stage electron multiplier having Ag-Mg dynode and of a Faraday collector. All the spectra were measured with a total emission current of 20 μA, accelerating voltage of 3.6 kV and electron multiplier voltage 2.5 kV, under the ionizing energies of 80, 40, 20 and 15 eV and pressure $\sim 10^{-6}$ mmHg in the source. Ionizing current varied from 10.5 to 6.4 μA in the range from 10 to 3 eV, while it was constant in the range higher than 10 eV (Fig. 1).

The electron energy was always calibrated in every measurement by the vanishing current method as compared to the ionization potential of argon for the positive ions and to the appearance potential of *m/e* 16 (O^-) from carbon monoxide, carbon dioxide and oxygen[13] for the negative ions.[8] Repeller voltage was adjusted to the best condition to collect the ions for positive and negative ions. The chemicals used were of research grade.

Results and Discussion

Negative Ion Mass Spectra. *Methyl Chloride.* In 80 eV electron impact experiment, negative ions of *m/e* 35(Cl^-) and *m/e* 37(Cl^-) besides a small peak of *m/e* 12(C^-) ion have mainly been observed (Fig. 2a), the most intense peak *m/e* being 35 (Cl^-) ion. The relative abundance of *m/e* 37 ion shows an isotope ratio of chlorine atom. Comparison of the yield of Cl^- ion (*m/e* 35) with that of CH_3Cl^+ ion (*m/e* 50, the most intense peak among the positive ions) gave $\sim 2.7 \times 10^2$ for CH_3Cl^+/Cl^-.

For 40 eV electron energies (Fig. 2b) the pattern of the negative ions was the same as that for 80 eV except for a small change in the yield of minor ions, and the ratio of CH_3Cl^+ to Cl^- was $\sim 4.5 \times 10^2$.

For 20 and 15 eV electron energies (Fig. 2c and 2d) Cl^- ions predominated other negative ions. The values $CH_3Cl^+/Cl^- \simeq 5.1 \times 10^2$ and 4.1×10^3 were obtained.

Table 1 shows the yield of minor negative ions for 80, 40, 20 and 15 eV. For 80 and 40 eV, *m/e* 12 (C^-), *m/e* 13 (CH^-), *m/e* 14 (CH_2^-), *m/e* 47 (CCl^-), *m/e* 48 ($CHCl^-$), *m/e* 49 (CH_2Cl^- or CCl^-), *m/e* 50($CHCl^-$) and *m/e* 51 (CH_2Cl^-) ions were found. The result for 40 eV was almost consistent with

50 ($CHCl^-$)	0.06	0.12		
51 (CH_2Cl^-)	0.14	0.12	0.14	

that of MacNeil *et al.*[7] except that the relative intensity of *m/e* 12 (C^-) ion to *m/e* 14 (CH_2^-) ion was reversed. It is probable that differences in the source pressure and in the geometry of the ion source are responsible for the discrepancy, which emphasizes the much greater sensitivity of negative ion mass spectrometry toward the change in experimental conditions as compared with positive ion mass spectrometry.

Molecular ion (CH_3Cl^-) was not observed, contrary to the formation of $CH_3NO_2^-$ ion from nitromethane at 80 eV and 40 eV electron impacts.

Ethyl Chloride. For the electron impact of 80 eV (Fig. 3a) negative ions of *m/e* 13 (CH^-), *m/e* 24 (C_2^-), 25 (C_2H^-), 35 (Cl^-) and 37 (Cl^-) have been mainly observed. The peak of molecular ion ($C_2H_5Cl^-$) was not found. When the yield of Cl^- ion (*m/e* 35) is compared with that of $C_2H_5Cl^+$ ion (*m/e* 64, the most intense peak among the positive ions),

$C_2H_5Cl^+/Cl^-$ gave $\sim7.3\times10^2$. A relatively large peak of *m/e* 25 (C_2H^-) ion among the negative ions arising from the ethyl group is quite similar to the situations in ethane,[4] ethyl alcohol[4] and nitroethane.[8]

TABLE 2. MINOR NEGATIVE IONS FROM C_2H_5Cl
(Normalized to [*m/e* 35 (Cl^-)] = 100)

m/e (ions)	Relative abundances for electron energies of			
	80 eV	40 eV	20 eV	15 eV
12 (C^-)	0.71	trace		
13 (CH^-)	1.29	0.7		
14 (CH_2^-)		trace

25 (C_2H^-)	10.62	6.3		
35 (Cl^-)	100	100	100	100

Mass spectra for 40 eV (Fig. 3b) did not differ so much from those for 80 eV except for the decrement of peaks of *m/e* 13 (CH^-), 24 (C_2^-) and 25 (C_2H^-) ions. The ratio of $C_2H_5Cl^+/Cl^-$ gave $\sim1.1\times10^3$.

For 20 and 15 eV (Fig. 3c and 3d), *m/e* 35 (Cl^-) and 37 (Cl^-) ions predominated other negative ions. The values $\sim1.5\times10^3$ and $\sim1.3\times10^3$ for $C_2H_5Cl^+/Cl^-$ were obtained respectively.

Table 2 shows the yield of the minor negative ions in relation to electron energies. It should be noted that no ion is formed containing carbon, hydrogen and chlorine atoms, or carbon and chlorine atoms.

n- and Iso-propyl Chlorides. For the electron impacts of 80 eV and 40 eV, both samples gave almost the same negative ions except for a small change of minor ions (Figs. 4a, 5a and 4b, 5b). It is of great interest that a relatively strong peak of *m/e* 25 (C_2H^-) ion has been observed as one

of negative ions arising from the propyl group. This was consistent with the results in propyl alcohol[4] and nitropropane.[8]

Patterns obtained for 20 eV and 15 eV were quite similar in both samples (Figs. 4c, 5c and 4d, 5d). The most intense peak was always of Cl^- ions.

The values of $C_3H_6^+/Cl^-$ were $\sim1.8\times10^3$ at 80 eV, $\sim2.8\times10^3$ at 40 eV, $\sim3.0\times10^3$ at 20 eV and $\sim3.5\times10^3$ at 15 eV for n-propyl chloride and those of $C_3H_7^+/Cl^-$ were $\sim1.2\times10^3$, $\sim1.9\times10^3$, $\sim2.7\times10^3$ and $\sim3.0\times10^3$ for isopropyl chloride, respectively.

Tables 3 and 4 show the yield of minor negative ions for n- and iso-propyl chlorides in relation to the electron energies. It should be noted that neither ions containing carbon, hydrogen and chlorine, nor ions containing carbon and chlorine are observed. This is in sharp contrast with the observations for methyl chloride. This may be explained on the basis of the size, symmetry and bonding of the molecule or of the electron affinity of the radical,[7] but a quantitative explanation is not so easy in the present stage. Ferguson *et al.*[11] gave geometrical considerations for negative ion processes, but their discussions are limited to a few simple molecules.

IE Curves of Cl^- Ions. Figs. 6A-a, 6B-a, 6C-a and 6D-a show the ionization efficiency curves of Cl^- ions from methyl chloride, ethyl chloride, n- and iso-propyl chlorides, respectively. Figs. 6A-b, 6B-b, 6C-b and 6D-b show the same curves to the extent of electron energies of 30 eV on an enlarged scale. The result for ethyl chloride was consistent with that obtained by using the combined swarm-beam method by Christophorou *et al.*[10] In the three compounds except for ethyl chlrodie, the contributions of at least three processes can be observed. The first process appears at a considerably lower energy*[2] for all compounds, the second process at $\sim$3.2 eV for methyl chloride, at $\sim$3.5 eV for ethyl chloride, at $\sim$4.1 eV for

14) E. E. Ferguson, F. C. Fehsenfeld and A. L. Schmeltekopf, *J. Chem. Phys.*, **47**, 3085 (1967).

*2 Reliability of this work is restricted to electron energies above $\sim$3 eV because of instrumental difficulty.

n-propyl chloride and at ~4.3 eV for isopropyl chloride, and the third process at ~9.5, ~8.2, ~11.6 and ~11.8 respectively.*3

In ethyl chloride, the fourth process was observed at ~11.2 eV.*4 As discussed later, this may not correspond to a simple reaction but an overlapping of two different reactions.

The plausible reaction schemes expected to occur at each onset value observed were sought on the basis of appearance potentials calculated by using $\Delta H_f(CH_3Cl) = -0.90$ eV, $\Delta H_f(C_2H_5Cl) = -1.16$ eV, $\Delta H_f(n\text{-}C_3H_7Cl) = -1.38$ eV, $\Delta H_f(iso\text{-}C_3H_7Cl) = -1.50$ eV,[15] $\Delta H_f(Cl^-) = -2.35$ eV,*5 $\Delta H_f(CH_3) = 1.39$ eV, $\Delta H_f(CH_2) = 2.5$ eV, $\Delta H_f(CH) = 6.16$ eV, $\Delta H_f(C_2H_2) = 2.35$ eV, $\Delta H_f(H) = 2.26$ eV, $\Delta H_f(C_2H_5) = 1.1$ eV, $\Delta H_f(C_2H_4) = 0.54$ eV, $\Delta H_f(C_2H_3) = 2.8$ eV, $\Delta H_f(n\text{-}C_3H_7) = 0.96$ eV, $\Delta H_f(iso\text{-}C_3H_7) = 0.73$ eV, $\Delta H_f(CH_3^+) = 11.23$ eV, $\Delta H_f(C_2H_5^+) = 9.88$ eV, $\Delta H_f(n\text{-}C_3H_7^+) = 9.65$ eV and $\Delta H_f(iso\text{-}C_3H_7^+) = 8.65$ eV.[16]

For the first process

		AP_{calc} (eV)*6

For the third process

		AP_{calc} (eV)
$CH_3Cl + e^- \longrightarrow CH_3^+ + Cl^- + e^-$	(13)	(9.78)
$C_2H_5Cl + e^- \longrightarrow C_2H_5^+ + Cl^- + e^-$	(14)	(8.69)

*3 Since the tailing due to the 1st or 2nd process might be overlapped with the appearance of the 2nd or 3rd process, the exact determination of appearance potential of the 2nd or 3rd process is difficult. In this work, the minimum values in IE curves were taken as the subject of discussion. (G. J. Schulz, *Phys. Rev.*, **113**, 816 (1959)).

*4 The situation is the same as *3.

15) J. A. Kerr, *Chem. Rev.*, **66**, 465 (1966).

*5 To be estimated from $\Delta H_f(Cl) = 1.25$ eV (Refer 9) and $EA(Cl) = 3.6$ eV (J. M. Williams and W. H. Hamill, *J. Chem. Phys.*, **49**, 4467 (1968)).

16) R. R. Bernecker and F. A. Long, *J. Phys. Chem.*, **65**, 1565 (1961).

*6 For the estimation of AP_{calc}, the kinetic energies of fragment ions are ignored, and the ions are assumed to be formed in ground state.

n-$C_3H_7Cl + e^-$

$\longrightarrow n$-$C_3H_7^+ + Cl^- + e^-$ (15) (8.68)

$\longrightarrow C_2H_5^+ + CH_2 + Cl^- + e^-$ (16)(11.41)

iso-$C_3H_7Cl + e^-$

$\longrightarrow iso$-$C_3H_7^+ + Cl^- + e^-$ (17) (7.8)

$\longrightarrow C_2H_5^+ + CH_2 + Cl^- + e^-$ (18)(11.53)

The first process observed in a lower energy than $\sim$3 eV appears to correspond to the reactions (1)—(4) (the dissociative electron capture). The situation is similar to the reaction, $RNO_2 + e^- \rightarrow R + NO_2^-$ in nitroalkanes.[12]

As evident from Figs. 6A-a—6D-a, the second processes extend over the relatively broad range of electron energies and their dependence on electron energies is very small, especially near the onset. Although this makes it difficult to determine exactly each onset value, reactions (5), (7), (9) or (11) are likely to be assigned for each onset.

The third process seems to be more complicated. Although the simple ion pair formations such as (13), (14), (15) and (17) are expected, consistency of AP_{calc} with AP_{obs} is not so good. This is probably due to overlapping. In n- and iso-propyl chlorides, the possibility of reaction (16) or (18) is stronger than that of (15) or (17).

The fourth process in ethyl chloride might be also interpreted in terms of the overlapping of a complicated dissociative electron capture (for example, reaction (19)) and an ion pair formation (reaction (14)).

$C_2H_5Cl + e^- \rightarrow 3H + C_2H_2 + Cl^-$ (19) $AP_{calc} = 8.39$ eV

If each IE curve of reaction (19) and reaction (14) is expressed by curves (A) and (B) in Fig. 7, they would result in curve (C) which consists qualitatively of the last part (the part higher than 8.8 eV of IE curves in Fig. 6B-a). This is a tentative interpretation.

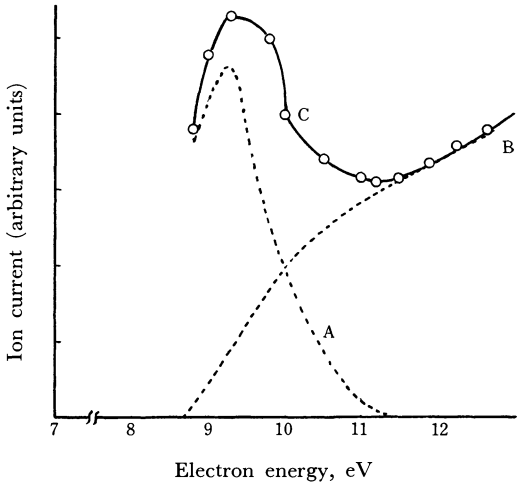

Fig. 7. An interpretation diagram for the fourth process in ethyl chloride.

It should be emphasized that (1) for ethyl chloride and n- or iso-propyl chlorides, neither ions containing carbon, hydrogen and chloride, nor ions containing carbon and chlorine are observed, (2) for all compounds the negative ions observed at electron energies lower than 20 eV are only Cl^- ion, and (3) for the Cl^- ion formation in the range of electron energies lower than about 12 eV the contribution of at least three different mechanisms are considered. The Cl^- ion yield increases monotonically with increasing electron energies in the range higher than about 12 eV.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1657—1661 (1970)

Hydrogen Formation in the Radiolysis of Saturated Hydrocarbons in the Liquid and Solid Phases. Effect of Temperature

Toyoaki KIMURA, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received November 24, 1969)

Hydrogen yields have been determined for thirteen saturated hydrocarbons (*n*-pentane, cyclopentane, methylcyclopentane, 3-methylpentane, *n*-hexane, cyclohexane, methylcyclohexane, *n*-heptane, *n*-octane, 2,2,4-trimethylpentane, *n*-nonane, *n*-decane and polyethylene) γ-irradiated at 20°C, −72°C and −196°C. The decrease in hydrogen yield with decreasing temperature from 20°C to −196°C has been correlated with the yield of thermal hydrogen atoms, which was obtained by adding ethylene as a scavenger at 20°C; the decrease in most cases was nearly equal to a half of the thermal hydrogen atom yield. Evidence of thermal hydrogen atom production at −196°C has also been demonstrated by ESR measurement. It has been concluded that thermal hydrogen atoms abstract hydrogen atoms from solvent molecules at 20°C, but they mostly recombine with each other to form hydrogen molecules at −196°C. An empirical formula based on the C–H bond parameter has been presented which is adapted for the hydrogen yield from normal alkanes.

One of the major products from γ-irradiated hydrocarbons is hydrogen and in most cases its yield depends upon the irradiation temperature. Dewhurst showed in the 800 Kvp electron radiolysis of *n*-hexane that the hydrogen yield was 5.0 (*G* unit) at 30°C and 3.0 (*G* unit) at −196°C.[1]

Recently we reported the hydrogen yield from γ-irradiated methylcyclohexane in the temperature range from 20°C to −196°C.[2] In contrast to Dewhurst's result, the decrease in hydrogen yield in our case was only 0.5 (*G* unit). Several workers[3-5] also reported results similar to those obtained by us; the decrements of hydrogen yield were lower than 1.0 (*G* unit). Only the result by Dewhurst is significantly different from the others. In this paper, we will report the hydrogen yields from thirteen γ-irradiated saturated hydrocarbons at 20°C, −72°C and −196°C and attempt to give a semiquantitative explanation for the yields.

A few studies have been made to explain the yields of products in the radiolysis of hydrocarbons from the view point of their chemical structure.[6-8] We will propose an empirical formula from which the hydrogen yield from *n*-alkanes can be evaluated fairly well.

Experimental

The experimental procedure was almost the same as that described earlier.[2] *n*-Pentane, cyclopentane, methylcyclopentane, *n*-hexane, cyclohexane, methylcyclohexane, *n*-heptane, and 2,2,4-trimethylpentane were Tokyo Kagaku Seiki 99.9% standard pure materials and used as received. Tokyo Kagaku Seiki 99.0% 3-methylpentane was shaken with concentrated sulfuric acid in a separating flask, washed with distillated water and dried over Galuber's salt. Passing through a silica gel column, 3-methylpentane was fractionally distillated. *n*-Octane, *n*-nonane and *n*-decane were Nakarai Kagaku 99% guaranteed reagents and purified in the same procedure as for 3-methylpentane. Polyethylene was "Takasen" made by ^{60}Co γ-irradiation at the Japan Atomic Energy Research Institute (Takasaki) and used without further purification.

Irradiations at −196°C were performed in a Dewar filled with liquid nitrogen and the absorbed dose was determined by correcting for the shielding effect of Dewar and liquid nitrogen. This shielding effect was measured with two Fricke dosimeters; one was settled in a position in the radiating field and the other in a Dewar filled with liquid ethanol, which has almost the same density as liquid nitrogen, in the same position as the first one. This shielding effect was 11.1%; the dose rate at −196°C decreased to 88.9% of that at 20°C.

The dose absorbed at −72°C was estimated assuming that the shielding effect of dry-ice is proportional to its density.

ESR measurements were performed using a JES 3BX ESR spectrometer.

Results

The hydrogen yields from thirteen hydrocarbons irradiated at 20°C, −72°C and −196°C are listed in Table 1. The doses were 2.28×10^{19}, 1.43×10^{20} and 1.62×10^{20} eV/g at the irradiation temperatures of 20, −72 and −196°C, respectively. From Table 1, the following three features can be pointed out: (1) the decrease in hydrogen yield $\{G(H_2)_{20°C}-G(H_2)_{-196°C}\}$ is low in the cases of *n*-pentane, methylcyclopentane and 3-methylpentane, (2) the hydrogen yield from 2,2,4-trimethylpentane increases at −196°C, although it decreases at −72°C, and (3) the decrease in hydrogen yield from the other hydrocarbons is $\lesssim 1$. The results differ considerably from those of Dewhurst.[1)]

Table 1. Hydrogen yields at each irradiation temperature

Substance	Temperature		
	20°C	−72°C	−196°C
n-Pentane	5.13	4.58	4.70
Cyclopentane	5.60	5.30	4.46
Methylcyclopentane	4.18	4.40	4.10
3-Methylpentane	4.25	4.40	3.90
n-Hexane	5.50	5.00	4.30
Cyclohexane	5.60	5.60	5.00
Methylcyclohexane	4.85	4.50	4.40
n-Heptane	5.45	4.70	4.40
n-Octane	5.36	5.26	4.36
2,2,4-Trimethylpentane	2.72	2.34	2.87
n-Nonane	5.30	4.80	4.40
n-Decane	5.20	5.20	4.25
Polyethylene	4.40	4.20	3.40

It seemed that the decrease in hydrogen yield could be explained in terms of "thermal" hydrogen atom, so we measured the yields of thermal hydrogen atoms from hydrocarbons excepting polyethylene. For this purpose, ethylene was added to the hydrocarbons, which were γ-irradiated at 20°C at a dose of 2.74×10^{20} eV/g. Figure 1 shows the effect of ethylene on the hydrogen yield from *n*-pentane. The curve was drawn to fit the experimental data. The hydrogen decrease is almost completed at about 0.3M. The limiting value of the decrement in hydrogen yield in Fig. 1 can be taken as the yield of thermal hydrogen atoms, $G(H_{thermal})$. In the same manner as for *n*-pentane, the yields

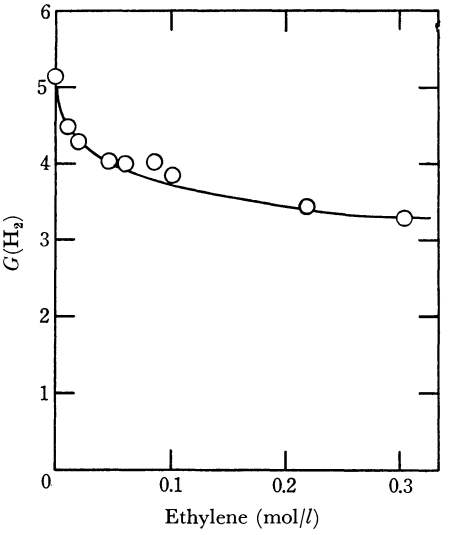

Fig. 1. Effect of ethylene on the hydrogen formation from γ-irradiated *n*-pentane at 20°C.

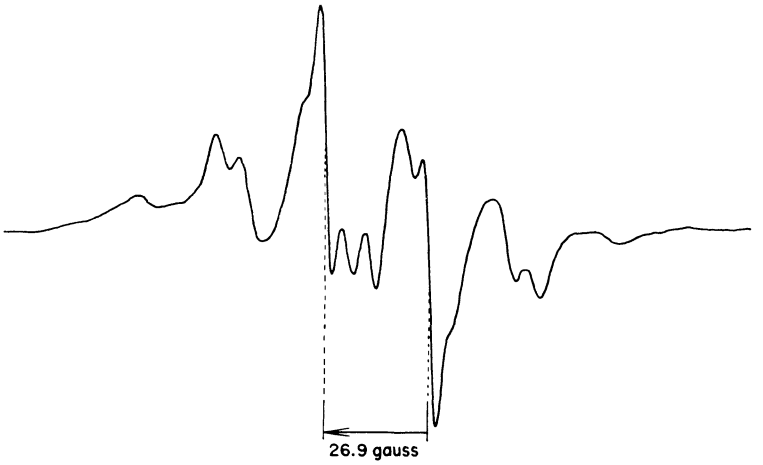

Fig. 2. ESR spectrum of γ-irradiated 3-methylpentane glass containing 3.73 mol% of ethylene at −196°C.

of thermal hydrogen atoms from the other hydrocarbons were obtained and are listed in Table 2. These thermal hydrogen atom yields are between 1 and 2 (G unit).

To ascertain whether thermal hydrogen atoms are produced at -196°C, ESR measurements were performed for γ-irradiated 3-methylpentane glass which contains 3.74 mol% of ethylene. In Fig. 2, we can see 3-methylphentyl radicals mixed with ethyl radicals the splitting constant of which is 26.9 gauss.

Discussion

The mechanism of hydrogen formation from γ-irradiated hydrocarbons has been investigated by many workers and are described as follows:

$$RH \rightsquigarrow \begin{cases} -RH^+ + e^- & (1) \\ -RH^* & (2) \end{cases}$$

$$\left.\begin{matrix} RH^+ + e^- \longrightarrow \\ RH^* \longrightarrow \end{matrix}\right\} \begin{cases} -H\ (\text{thermal}) + R\cdot & (3) \\ -H\ (\text{hot}) + R\cdot & (4) \\ -H_2 + \text{Olefin} & (5) \end{cases}$$

The molecular hydrogen detachment (Eq. (5)) needs a lower energy than that of atomic hydrogen detachment (Eqs. (3) and (4)).[9] Thus the molecular detachment process does not seem to be affected by temperature. Hot H atoms abstract hydrogen atoms from solvent molecules to form H_2 molecules and solvent radicals both at 20°C and -196°C.

$$H(\text{hot}) + RH \longrightarrow H_2 + R\cdot \quad (6)$$

Thermal H atoms abstract H atoms from solvent molecules to produce H_2 molecules at room temperature, but in the presence of an H atom scavenger such as olefin, they are scavenged and the total hydrogen yield decreases.[10-12]

$$H(\text{thermal}) + RH \longrightarrow H_2 + R\cdot \quad (7)$$

$$H(\text{thermal}) + C_2H_4 \longrightarrow C_2H_5\cdot \quad (8)$$

However, up to the present, the formation of thermal H atom in solid hydrocarbons at -196°C has not been confirmed.

We have reported the effect of ethylene on the hydrogen formation from γ-irradiated methylcyclohexane at -196°C as well as 20°C[13] and ascribed it to thermal H atom scavenging.

On the other hand, Timm *et al.*[14] have shown in the ESR measurements at 4°K that no thermal H atom can be observed in solid hydrocarbons except methane. However, as is shown in Fig. 2, H atoms are captured by ethylene to form ethyl radicals. Therefore it can be said that thermal H atoms are probably produced not only at room temperature, but also at liquid nitrogen temperature. The reason for the absence of H atoms in the ESR spectra may be that thermal H atoms cannot be trapped by solid hydrocarbons except methane, but recombine with each other to form hydrogen molecules, as was suggested previously.[13]

$$2H(\text{thermal}) \longrightarrow H_2 \quad (9)$$

Molecularly detached hydrogen and hot H atoms do not affect the total hydrogen yield when the irradiation temperature decreases from 20°C to -196°C. Only thermal H atoms can affect the total hydrogen yield. From Eqs. (7) and (9), it seems that the total hydrogen yield decreases by $0.5\,G(H_{thermal})$ when the irradiation temperature decreases from 20°C to -196°C. Thus we can describe the hydrogen yields at 20°C and -196°C as follows:

$$G(H_2)_{20°C} = G(H_2)_{molecular} + G(H)_{hot} + G(H)_{thermal} \quad (10)$$

$$G(H)_{-196°C} = G(H_2)_{molecular} + G(H)_{hot} + 0.5G(H)_{thermal} \quad (11)$$

Table 2. Yields of thermal H atoms in hydrocarbons irradiated at 20°C

	$G(H_{thermal})$
n-Pentane	1.8

n-Heptane	1.7
n-Octane	1.8
2,2,4-trimethylpentane	1.1
n-Nonane	1.7
n-Decane	1.4

Substracting Eq. (11) from Eq. (10), we obtain

$$\Delta G(H)_2 = G(H_2)_{20°C} - G(H_2)_{-196°C} = 0.5G(H)_{thermal} \quad (12)$$

To see if Eq. (12) holds for our results or not, we compared $\Delta G(H_2)$, obtained from Table 1, with $0.5\,G(H_{thermal})$ from Table 2. The results are listed in Table 3. Although $\Delta G(H_2)$ is not exactly equal to $0.5\,G(H_{thermal})$ because thermal H atoms cannot be completely scavenged by ethylene, the results shown in Table 3 illustrate the validity of Eq. (12) except in the cases of *n*-pentane, methyl-

cyclopentane, 3-methylpentane and 2,2,4-trimethylpentane. In the case of these four hydrocarbons, Eq. (12) does not hold and $\Delta G(H_2)$ is considerably less than $0.5\,G(H_{thermal})$ (2,2,4-trimethylpentane gives a negative value of $\Delta G(H_2)$).

It is not easy to explain the exceptions, but we might consider the difference in intramolecular energy partition in the liquid and solid states, which may change the relative contribution of the C–C and C–H bond cleavage.

To investigate the relation between the hydrogen yield and the chemical structure, we have made the following calculation. Denoting the number of hydrogen molecules formed per unit absorbed energy (eV), per 1 g of hydrocarbon, by P_i, we can express the G value of hydrogen as

$$G(H_2) = 100P_i \tag{13}$$

Denoting the number of hydrogen molecules formed per 1 eV energy absorbed, per 1 molecule of hydrocarbon, by p_i, we can write as

$$p_i = P_i(M/N) \tag{14}$$

where M is the molecular weight of a hydrocarbon and N is the Avogadro number. Combining Eqs. (13) and (14), we obtain p_i as a function of $G(H_2)$;

$$p_i = \frac{M}{100N}G(H)_2 \tag{15}$$

Here we restrict our discussion to normal alkanes and make the following assumption; the number of hydrogen molecules per 1 eV, per 1 molecule of normal alkane is given by

$$p_i = n_pX_p + n_sX_s, \tag{16}$$

where n_p and n_s are the number of primary and secondary hydrogen atoms, respectively, and X_p X_s are parameters associated with the primary and secondary C–H bonds, respectively. From Eqs. (15) and (16), the hydrogen yield from each normal alkane is expressed as

$$G(H_2) = 100N\left(\frac{n_p}{M}X_p + \frac{n_s}{M}X_s\right) \tag{17}$$

If Eq. (17) holds, the hydrogen yield from a normal alkane can be calculated substituting the numbers of primary and secondary hydrogen atoms and the molecular weight into Eq. (17).

Using the data in Table 1, we obtain the values of X_p and X_s; $X_p=5.40\times10^{-25}$ and $X_s=5.78\times10^{-25}$ at 20°C, and $X_p=X_s=4.57\times10^{-25}$ at −196°C. Using these values, we calculated the hydrogen yields for normal alkanes. The calculated and observed yields at 20°C and −196°C are listed in Tables 4 and 5, respectively. The calculated values at

n-Pentane	4.57	4.70
n-Hexane	4.46	4 30
n-Heptane	4.39	4 40
n-Octane	4.33	4.36
n-Nonane	4.29	4.40
n-Decane	4.25	4.25

$X_p=X_s=4.57\times10^{-25}$

20°C (Table 4) are in good agreement with the observed values except for *n*-pentane. The observed hydrogen yield for *n*-pentane is somewhat lower than the calculated one. A possible reason for this is that the C–C bond cleavage in *n*-pentane is more favorable than that in higher normal alkanes, resulting in suppression of hydrogen formation to some extent. Equation (17) appears to be valid for normal alkanes which are larger than *n*-pentane. We also calculated the hydrogen yield from the normal alkane, whose C–C chain is infinitely long, which was 4.97 (G unit). The observed hydrogen yield from polyethylene was 4.40 (G unit). This difference between the calculated and the observed yield may be due to terminal double bonds or branching methyl (or other) groups in polyethylene which reduce the hydrogen yield.

Equation (17) also holds for non-branching cyclic alkanes, if we use $X_s=6.51\times10^{-25}$ which is higher than that for normal alkanes. We need more data

for further investigation on this class of hydrocarbons. Equation (17) does not hold for branching alkanes which involve the tertiary C–H bond. Taking 3-methylpentane as an example, Eq. (17) must be changed to

$$G(H_2) = 100N\left(\frac{n_p}{M}X_p + \frac{n_s}{M}X_s + \frac{n_t}{M}X_t\right) \qquad (17')$$

where subscript t is associated with the tertiary C–H bond.

Even if we use $X_t=0$, the calculated value is higher than the observed one.

It should be noted that the branching methyl group decreases the hydrogen yield which is easily recognizable if we compare the yield from cyclopentane with that from methylcyclopentane, and the yield from cyclohexane with that from methylcyclohexane.

The effect of this branching methyl group on the hydrogen yield will not be due to the increase in the fraction of primary H atoms, but the branching methyl group itself, which would affect the decomposition pattern of the molecule.

Polyethylene used in the present work has 2.1 methyl groups per 1000 units of $-CH_2-$, and the deviation of the hydrogen yield from the expected value may partly be due to these branching methyl groups.

We now consider the physical meaning of the parameters, X_p and X_s. These are interpreted as representing contributions of a hydrogen atom at a specified position to the total hydrogen yield. In other words, these parameters indicate the overall probability of C–H bond cleavage, including detachment of H atom, H atom abstraction by the detached H atom, and molecular H_2 detachment. Since X_p and X_s do not differ very much from one another, the C–H bond cleavage seems to occur almost equally at the primary and secondary C–H bonds for normal alkanes. However, our results are not consistent with those of Gäumann,[15] who used isotopic compounds to determine the scission probability of bonds. This discrepancy might be ascribed to the isotope effect.

The Crystal and Molecular Structure of Dimethyltin Chloride *N,N*-Dimethyldithiocarbamate

Kenji FURUE, Toshihide KIMURA, Noritake YASUOKA, Nobutami KASAI*1 and Masao KAKUDO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received November 29, 1969)

The molecular structure of dimethyltin chloride *N,N*-dimethyldithiocarbamate, $[(CH_3)_2SnCl(S_2CN(CH_3)_2)]$, has been determined from three-dimensional X-ray diffraction data. The unit-cell dimensions are $a=12.67$, $b=7.64$, $c=12.11$ Å, and $\beta=110.3°$. The space group is $P2_1/c$. Four formula units are contained in a unit-cell. The structure was established by the heavy-atom method. The coordination around the tin atom is a distorted trigonal bipyramid with the following bond distances: Sn–C, 2.17(5) and 2.20(5) Å; Sn–Cl, 2.46(1) Å, and Sn–S, 2.48(1) and 2.79(1) Å. Two methyl groups are both in equatorial positions.

Recently, numerous studies have been reported on transition metal complexes of dialkyldithiocarbamates. The crystal structures of several complexes have also been determined; however, few structures of non-transition metal complexes have yet been reported.

Tanaka and his co-workers[1] reported on the preparation and properties of some organotin *N,N*-dimethyldithiocarbamates. According to the spectroscopic studies, the three configurations shown in Fig. 1 were proposed for a penta-coordinated complex, dimethyltin chloride *N,N*-dimethyldithio-

*1 To whom any correspondence should be addressed.

carbamate, $[(CH_3)_2SnCl(S_2CN(CH_3)_2)]$ (to be abbreviated as $Me_2SnCl(dtc)$ hereafter). Among these configurations, (3) is considered to be most likely; in it the two methyl groups are both in equatorial positions.

To determine the exact configuration, the crystal structure analysis has now been undertaken by means of X-ray diffraction.

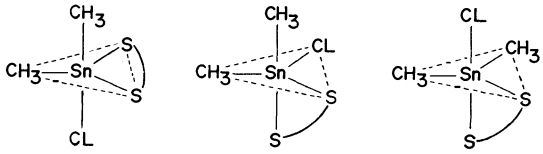

Fig. 1. Three possible configurations of Me_2SnCl-(dtc) molecule.

The purpose of this study is also to contribute to the understanding of the bonding nature of the tin atom in penta- and hexa-coordinated dimethyltin complexes, among which the crystal structures and molecular configurations of $[(CH_3)_2SnCl_2((CH_3)_2SO)_2]$,[2] $[(CH_3)_2Sn(C_9H_6NO)_2]$,[3] and $[((CH_3)_2$-SnCl, terpyridil)$^+\cdot((CH_3)_2SnCl_3)^-]$[4] have already been determined.

Experimental

The crystals of $Me_2SnCl(dtc)$ were recrystallized from a chloroform-ethanol solution. They belong to the monoclinic system, and the unit-cell dimensions are: $a=12.67\pm0.07$, $b=7.64\pm0.01$, $c=12.11\pm0.06$ Å, and $\beta=110.3\pm0.4°$. The unit-cell dimensions were determined from Weissenberg photographs taken around the b and c axes, on which Debye lines of aluminum were superposed for calibration. The observed density is 1.86 $g\cdot cm^{-3}$, while the calculated density, assuming four formula units per unit-cell, is 1.84 $g\cdot cm^{-3}$. From the systematic absences of reflections (l: odd for $h0l$ and k: odd for $0k0$), the space group was determined to be $P2_1/c$.

A set of three-dimensional intensity data was collected on multiple-film equi-inclination Weissenberg photographs with nickel-filtered Cu$K\alpha$ radiation. Layers from 0 through 5 were recorded around the b axis; layers from 0 through 5 around the c axis were also recorded, mainly for the purpose of inter-layer scaling. The intensities of 1968 independent reflections were estimated visually by using a calibrated standard scale. The intensities were corrected for the usual Lorentz and polarization factors. No absorption correction was made.

Determination and Refinement of the Structure

A three-dimensional Patterson function was computed; from it the location of the tin atom was easily determined. The chlorine and two sulfur atoms could also be located from the Patterson function, but the chlorine atom could not be distinguished from the sulfur atoms. Therefore, the first Fourier synthesis was computed with the phases based on the tin atom only, while the chlorine and two sulfur atoms were identified at the positions which had been suggested from the Patterson synthesis. The nitrogen and three carbon atoms were also found in the Fourier map. The remaining two carbon atoms were found in another Fourier map, with phases based on all the atoms which had already been located.

The structure factor calculation after a cycle of least-squares refinement gave a discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, of 0.27. Successive block-diagonal least-squares refinement was carried out on a HITAC 5020E computer at the University of Tokyo. In the refinement, the weight was taken as unity for all reflections. After five cycles of

isotropic refinement for all the atoms except hydrogen, the R factor was reduced to 0.156 non-zero reflections. Anisotropic temperature factors for all atoms were introduced at this stage and the refinement was continued; four subsequent cycles of refinement gave $R=0.137$. The atomic scattering factors used in the refinement were taken from those of Hanson and his co-workers.[5]

The final positional and thermal parameters are given in Table 1. The observed and calculated structure factors are given in Table 2.

Result and Discussion

The Geometry around the Tin Atom. The molecular structure and the numbering system of $Me_2SnCl(dtc)$ are shown in Fig. 2. The bond distances and angles in the environment of the tin atom are listed in Table 3. As can be seen in Fig. 2 and Table 3, the configuration about the tin atom is a penta-coordinated distorted trigonal bipyramid. The four atoms, S(1), C(4), C(5), and Sn, lie on the same plane, the equatorial plane of the bipyramid. The Cl and S(2) are at the tops of the bipyramid; the Sn–Cl and the Sn–S(2) bonds cross the equatorial plane at angles of 81.8° and 72.7° respectively. The methyl groups attached to the tin atom are both in the equatorial positions. This configuration

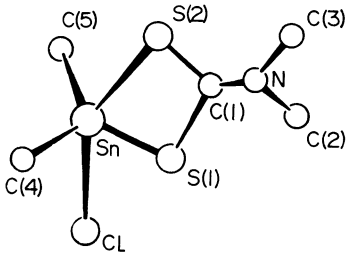

Fig. 2. The molecular structure and the numbering system of $Me_2SnCl(dtc)$.

Table 3. Geometry around the tin atom

(a) Bond distances and angles along with their estimated standard deviations in parentheses.

Bond distance (Å)		Bond angle (°)	
Sn-Cl	2.46 (1)	Cl-Sn-S (1)	86.4 (0.4)
Sn-S (1)	2.48 (1)	Cl-Sn-S (2)	154.5 (0.4)
Sn-S (2)	2.79 (1)	Cl-Sn-C(4)	99 (1)
Sn-C(4)	2.17 (5)	Cl-Sn-C(5)	98 (1)
Sn-C(5)	2.20 (5)	S (1)-Sn-S (2)	68.2 (0.3)
		S (1)-Sn-C(4)	113 (1)
		S (1)-Sn-C(5)	116 (1)
		S (2)-Sn-C(4)	91 (1)
		S (2)-Sn-C(5)	93 (1)
		C(4)-Sn-C(5)	128 (2)

b) The least-squares plane of four atoms, Sn, S (1), C(4), and C(5):

$-0.01339x - 0.52110y - 0.85339z + 2.15929\text{Å} = 0$,

Deviations from the least-squares plane(Å): Sn 0.15
S(1) −0.04
C(4) −0.05
C(5) −0.05

Angle between the least-squares plane and the Sn–Cl bond: 81.8°,

Angle between the least-squares plane and the Sn–S(2) bond: 72.7°.

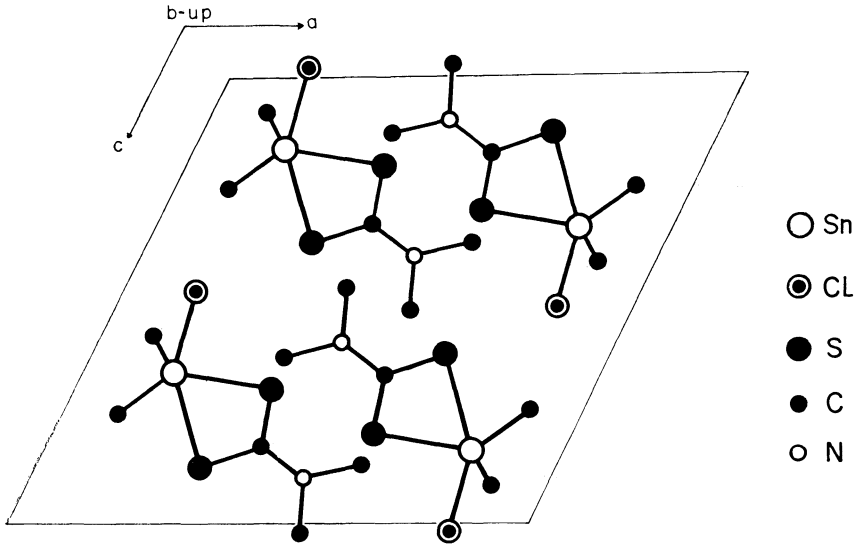

Fig. 3. The crystal structure of $Me_2SnCl(dtc)$ projected onto the (010) plane.

5) H. P. Hanson, F. Herman, J. D. Lea and S. S. Skillman, *Acta Crystallogr.*, **17**, 1040 (1964).

is in good agreement with the model (3) proposed in Fig. 1.

In tin compounds with coordination numbers greater than four, a qualitative MO approach to the bonding nature of the tin atom has been postulated in which no contribution of the 5*d*-orbital of a tin atom is considered.[6,7] In the case of the present complex, it may be assumed, in a way similar to that postulated by Schlemper,[3] that the bonding could also involve the sp^3 hybrid orbitals on the tin atom participating in normal covalent bonds with the two methyl groups and with the chlorine atom and in a three-centered bond with the ligand group. The M–Sn–C(4), M–Sn–C(5), and M–Sn–Cl angles, where M is the midpoint of the line connecting S(1) and S(2), are 104°, 107°, and 122° respectively. The C(4)–Sn–C(5) angle of 128(2°) is, however, considerably larger than the tetrahedral angle. Furthermore, as will be described later, the difference between the two Sn–S bond distances is significant (Table 3); it may be due to the difference in nature between the axial and equatorial bonds. From these facts and from the other angles around the tin atom listed in Table 3, it is better to consider that the configuration about the tin atom in the present complex is a distorted trigonal bipyramid similar to that of the $[(CH_3)_2SnCl_3]^-$ anion.[4]

The Sn–C bond distances, (2.17(5) and 2.20(5) Å), are in good agreement with the sum of the covalent radii of Sn and C, 2.17 Å. These observed values are, within the limits of experimental error, equal to those in $[(CH_3)_2SnCN]$,[8] $[CH_3SnH_3]$[9], and $[(CH_3)_2Sn(C_9H_6NO)_2]$;[3] in the first compound the tin atom takes a trigonal bipyramidal configuration, in the second, a tetrahedral one, and in the third, a hexa-coordination. On the other hand in $[(CH_3)_2SnF_2]$[10] a slightly shorter Sn–C distance (2.06 Å) is obtained.

The Sn–Cl distance, 2.46(1) Å, is slightly longer than the sum of the covalent radii, 2.39 Å. In the $[(CH_3)_2SnCl_3]^-$ ion,[3] the tin atom takes a pentacoordination, and the equatorial Sn–Cl bond distance, 2.32 Å, is shorter than the observed one, while the axial distance, 2.54 Å, is longer.

In the Sn–S distances, the equatorial one (Sn–S(1), 2.48(1) Å), is slightly longer than the sum of the covalent radii, 2.44 Å, but the axial one (Sn–S(2), 2.79(1) Å), is considerably longer. This may suggest that the Sn–S(2) is a weak coordination bond. Such a weak metal-sulfur bond as Sn–S(2) is also found in $[(C_6H_5)As(S_2CN(C_2H_5))_2]$[11] and in $[As(S_2CN(C_2H_5))_3]$.[12]

Table 4. Geometry of the ligand, *N,N*-dimethyldithiocarbamate group

a) Bond distances and angles along with their estimated standard deviations in parentheses.

Bond distance (Å)		Bond angle (°)

1.68(4) and 1.74(4) Å respectively, but the difference is not significant. The C(1)–N distance, 1.32(5) Å, is equal to those found *in other* dialkyldithiocarbamates;[11–19] this fact suggests that the carbon(sp^2)-nitrogen(sp^2) bond has a high double-bond character, as was to be expected on the basis of the IR studies. The N–C(2) and N–C(3) distances, 1.51(6) and 1.57(6) Å are equal; they are close to the N–C single bond distance (1.48 Å) within the limits of experimental error.

The ligand group is planar within ± 0.03 Å. Deviations from the least-squares plane are listed in Table 4(b).

Crystal Structure. The crystal structure projected along the *b* axis is shown in Fig. 3. The short intermolecular atomic contacts, less than 4.0 Å, are summarized in Table 5. None of them is short enough to suggest any significant deviation from the normal van der Waals interaction.

The authors wish to express their deep thanks to Professor Toshio Tanaka and to Professor Rokuro Okawara of this university for their kindness in supplying crystals and in engaging in helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1667—1670 (1970)

The Visible Spectra of Alizarine Saphirol SE in Water-Dioxane Mixtures

Masaru MITSUISHI, Mieko HASHIZUME, Akira KATAYAMA*1 and Nobuhiko KUROKI*1

Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano

(Received December 2, 1969)

The visible absorption spectra of Alizarine Saphirol SE in water-dioxane mixtures were obtained, and the spectral changes were considered on the basis of the results of the conductance measurements of the dye. In the spectra of the dye in the mixtures containing less than 60% dioxane, the absorption was found to increase with an increase in the dioxane content. This spectral change was attributed to the decrease in the tendency of the dye to aggregate. In the spectra of the dye in the mixtures containing more than 70% dioxane, however, the absorption found to decrease with an increase in the dioxane content, *i.e.*, with a reduction in the dielectric constant of the solvent. This spectral change was considered to be characteristic of the increase in the electrostatic interaction between the dye ion and the counter ion.

In a previous paper,[1] the ion-association constants were determined by means of Shedlovsky's treatment from the conductance behavior of Alizarine Saphirol SE in water-dioxane mixtures, and they were found to become enormously larger with an increase in the dioxane content of the mixtures, *i.e.*, with a lowering of the dielectric constant. In a solvent with a low dielectric constant, a spectrum characteristic of the ion association between the dye ion and the counter ion can be expected.

In water-organic solvent mixtures having a medium (*ca.* 20) or a low dielectric constant (*ca.* 5), however, no spectrum characteristic of the ion association of the aromatic sulfonate ion with the sodium ion has yet been reported. Therefore, it seems that it would be valuable to examine whether a characteristic spectrum of the interaction between the dye ion and the counter ion is found in the spectrum of Alizarine Saphirol in water-dioxane mixtures.

Experimental

The Alizarine Saphirol SE (sodium salt of 1,5-dihydroxy-4,8-diaminoanthraquinone-2-sulfonic acid) was

*1 College of Engineering, University of Osaka Prefecture, Sakai, Osaka.

1) M. Mitsuishi, Y. Funatsu and N. Kuroki, This Bulletin, **42**, 2384 (1969).

a laboratory stock used in a previous work.[2]

The dioxane was purified by the method described in the previous work.[1]

The visible absorption spectra of the dye were measured by the procedures described in another previous work.[2]

Results and Discussion

The spectra of Alizarine Saphirol in water-dioxane mixtures are shown in Figs. 1 and 2. The spectra of the dye in water and in water-dioxane mixtures containing less than 60% dioxane in Fig. 1 are quite similar to those in water-ethanol mixtures.[2]

The spectrum of Alizarine Saphirol in water is characterized by a prominent peak at about 590 mμ (α-band) and a shoulder at about 620 mμ (β-band). Both the α- and β- bands are intensified by increasing the dioxane content, the β -band is more intensified than the α-band in the solvents containing more than 10% dioxane, and the β-band becomes a prominent peak. The wavelengths of maximal absorption are found to shift towards longer wavelengths. This spectral behaviour is similar to that found in the spectra of the dye in water-ethanol mixtures.[2] The curves from III to VI in Fig. 1 and all of the curves in Fig. 2 have doublet peaks at about 590 and 630 mμ.

These doublet peaks in the main band are known to be characteristic of a monomeric dye with two electron-donating groups, such as hydroxyl or amino groups, in the 1- and 4- positions of an anthraquinone nucleus.[3,4] From the conductance data reported in a previous paper,[1] Alizarine Saphirol was supposed to be monomeric in mixtures containing more than 60% dioxane. Therefore, the spectral changes produced by increasing the dioxane in the mixtures containing less than 60% dioxane (in Fig. 1) may be supposed to come from the decrease in the tendency of the dye to aggregate.

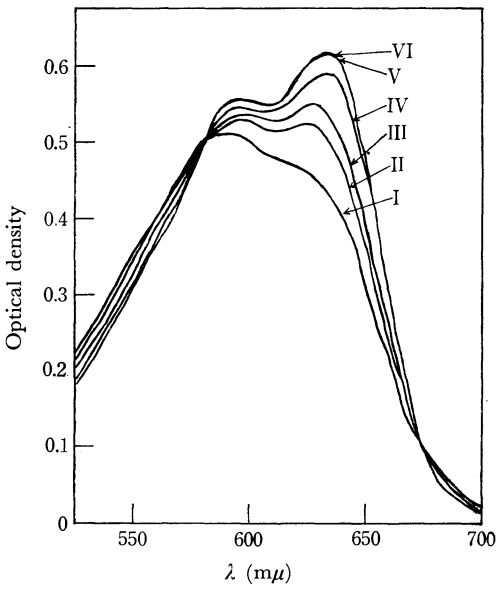

Fig. 1. Spectra of Alizarine Saphirol SE in water-dioxane mixtures at 25°C (3.79×10^{-5} mol/l, 10 mm cell), dioxane concentration; I, 0; II, 10%; III, 20%, IV, 45%; V, 60%; VI, 70%.

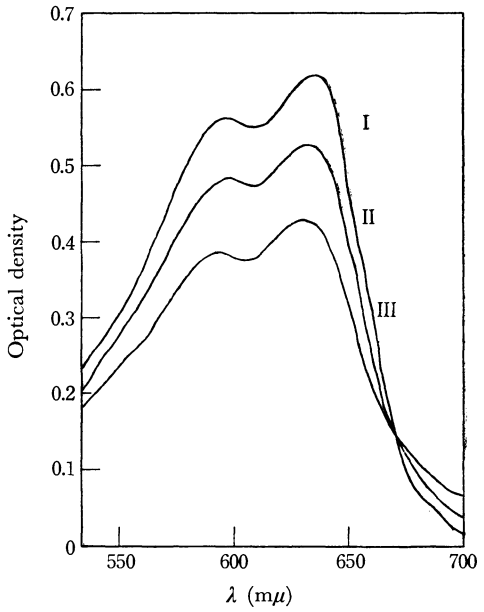

Fig. 2. Spectra of Alizarine Saphirol SE in water-dioxane mixtures at 25°C (3.79×10^{-5} mol/l, 10 mm cell), dioxane concentration; I, 70%; II, 82%; III, 85%.

In Fig. 2, the intensities of both the α- and β-bands are found to decrease progressively with an increase in the dioxane content in the mixtures containing more than 70% dioxane, and an isosbestic point is found at about 670 mμ. As no such spectral change in Alizarine Saphirol is found in water-ethanol mixtures, the spectral changes induced by an increase in the content may be supposed to be caused by the reduction of the dielectric constant of the mixtures to values lower than those of the water-ethanol mixtures.*2

The presence of an isosbestic point at about 670 mμ suggests that a certain equilibrium is set up in the mixtures.

Next, let us examine the cause of the spectral changes induced by increasing the dioxane content

*2 The dielectric constants of ethanol and of 70, 82, and 85% dioxane are 24.3, 17.7, 9.5, and 8.2 respectively.

in the mixtures. In previous papers,[1,5] the following equilibrium among the dye ion, the sodium ion, and the ionic associate of the dye was established in water-dioxane mixtures with a low dielectric constant;

$$D^- + Na^+ \rightleftarrows (D^-Na^+)^0 \quad (1)$$

where, D^- and $(D^- Na^+)^0$ are the dye ion and the ionic associate respectively.

The ion-association constant, K_A, was obtained by the equation;

$$K_A = \frac{1-2}{c\alpha^2 f_\pm^2} \quad (2)$$

where, α and $f_\pm$ are the degree of dissociation of the ionic associate and the mean activity coefficient of the ion at the dye concentration, C.

The electrostatic interaction between the dye ion and the counter ion was found to increase enormously with an increase in the dioxane content in the mixtures.[1],*3 Accordingly, the spectral changes seen in Fig. 2 may be produced when the ion-association constant of the dye increases enormously with an increase in the dioxane contents of the mixtures.

If the spectral changes in Alizarine Saphirol induced by an increase in the dioxane content are caused by the increase in the electrostatic interaction between the dye ion and the counter ion, *i.e.*, by the increase in the concentration of the ionic associate, spectral changes similar to those shown in Fig. 2 must be observed under any condition that cause the equilibrium constant, K_A, of Eq. (2) to vary.

The ion-association constants of the dye in water-dioxane mixtures with a low dielectric constant and a constant composition were found to increase with a rise in the temperature of the solution.[5],*4 In water-dioxane mixtures of a constant composition, the degree of dissociation of the ionic associate obviously decreases with an increase in the dye concentration; that is the concentration of the ionic associate increase with an increase in the dye concentration.*5

Therefore, if the spectral changes induced by an increase in the dioxane content (Fig. 2) are similar to those spectral changes induced by raising the temperature of the solution and by increasing the dye concentration in the mixtures with a constant composition, the spectral changes shown in Fig. 2 may be concluded to be induced by the increase in the interaction between the dye ion and the counter ion.

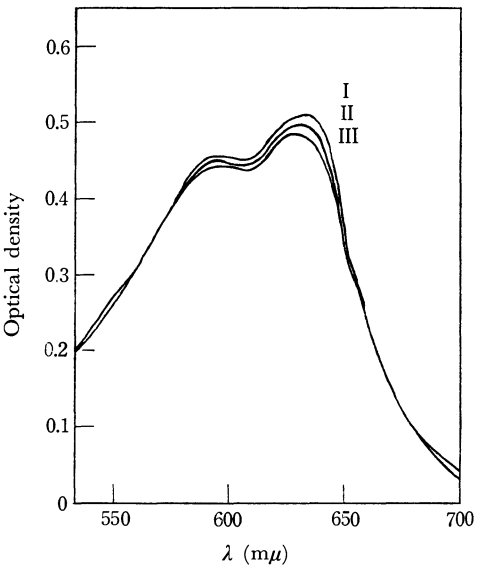

Fig. 3. Spectra of Alizarine Saphirol SE in 82% dioxane at various temperatures (3.79×10^{-5} mol/l, 10 mm cell); I at 16°C; II, 24°C; III, 35°C.

The effect of raising the temperature of the solution on the visible spectrum of Alizarine Saphirol in 82% dioxane is shown in Fig. 3. The intensities of both the α- and β-bands are found to decrease with a rise in the temperature of the solution, *i.e.*, with an increase in the ion-association constant, and an isosbestic point is found at about 670 mμ. The spectral change seen in Fig. 3 is found to be less than that seen in Fig. 2, but these spectral changes can be explained reasonably by taking into consideration the fact that the effect of the increase of dioxane content is larger than that of the elevation of the temperature of the solvent with a constant composition on the ion-association constant of the dye.*6

The visible spectrum of Alizarine Saphirol in 70% dioxane is shown in Fig. 4. The intensities of both the α and β-bands are found to decrease with an increase in the dye concentration, and an isosbestic point is found at about 670 mμ. The decrease in the intensities seen in Fig. 4 may be supposed to be induced by the decrease in the degree of dissociation of the ionic associate. The spectral change shown in Fig. 4 is less than that shown in Fig. 2, but these changes can be explained reasonably by taking into consideration the fact that the effect of the increase in the dioxane content is larger than that of the increase in the dye concentration in the solvent

5) M. Mitsuishi, M. Hashizume, A. Katayama and N. Kuroki, This Bulletin, **43**, 960 (1970).

*3 The ion association constants of the dye in 70, 82, and 85% dioxane at 25°C are 1.88×10^3, 9.86×10^3, and 3.46×10^4 respectively.

*4 For example, the ion association constants at 15, 25, and 35°C in 82% dioxane are 8.67×10^3, 9.86×10^3, and 1.30×10^4 respectively.

*5 For example, the degrees of the dissociation of the ionic associate at dye concentration of 0.79, 2.34, and 5.64×10^{-5} mol/l in 70% dioxane are estimated to be about 0.990, 0.970, and 0.935 respectively.

*6 *Cf.* footnotes *4 and *3.

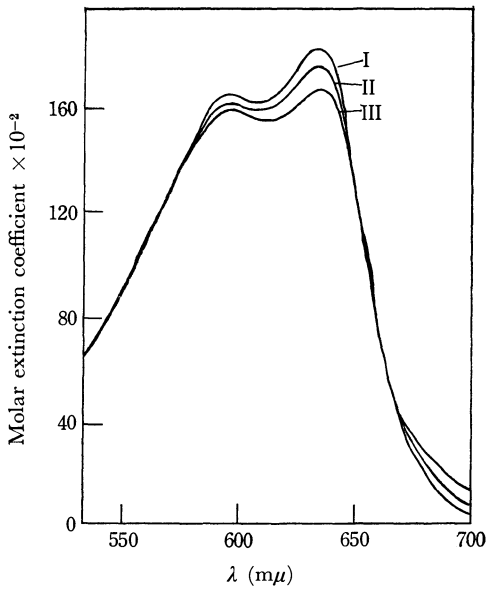

Fig. 4. Spectra of Alizarine Saphirol SE in 70% dioxane at 25°C, dye concentration; I, 0.179×10^{-5} mol/l; II, 2.34×10^{-5} mol/l; III, 5.64×10^{-5} mol/l.

of a constant composition on the degree of dissociation of the ion associate.*7

From the results noted above, the spectral changes in Alizarine Saphirol induced by increasing the dioxane content in mixtures containing more than 70% dioxane (Fig. 2) has been found to be quite similar to those changes induced by raising the temperature of the solution (Fig. 3) and those induced by increasing the dye concentration in mixtures with a constant composition (Fig. 4). That is to say, the intensities of the main band of the visible spectra of Alizarine Saphirol in water-dioxane mixtures with low dielectric constants are invariably found to decrease under any conditions where the interaction between the dye ion and the counter ion increases in the mixtures.

As has been described above, we can conclude that the changes in the spectra of Alizarine Saphirol induced by increasing the dioxane content in mixtures containing more than 70% dioxane are to be attributed to the increase in the interaction between the dye ion and the counter ion, and that such spectral changes are characteristic of the increase in the electrostatic interaction between the two ions.

The authors wish to thank Professor Haruo Gotoh for his helpful discussions.

*7 The values of α at a concentration of 3.79×10^{-5} mol/l in 70, 82, and 85% dioxane are estimated to be about 0.945, 0.750, and 0.640 respectively.

Photo-Ionization of Molecules in Solutions. VI. Studies on the Photocurrent Arising from the Flash-Excitation of Aromatics in Solutions

Takeshi IMURA,* Naoto YAMAMOTO and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received December 13, 1969)

A technique is described for the study of the photocurrent due to the transient ionic species produced by the flash photolysis of aromatics in solutions at room temperature. The technique has proved to give valuable information in a way complementary to conventional flash spectrometry. The photo-ionization of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine was studied by this method in polar and non-polar solvents. The photocurrents of the solutions of some electron donor-acceptor systems were also measured, and the results were compared with that obtained from flash spectrometry. The recombination rate constants of the ionic species were estimated from the decay of transient photocurrents.

Flash spectroscopy is a powerful tool for studies of chemical reaction intermediates, including unstable ionic species.

The photo-ionization of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) has been studied extensively by steady state illumination in low-temperature matrices and by flash spectroscopy at room temperature. The photo-ionization was shown to

*1 Present address: Faculty of Engineering, Osaka University, Suita, Osaka

take place by the two-step process, with the triplet state as the intermediate.[1-5]

By flash spectrometry for the intermolecular electron-transfer processes between an electron donor (D) and acceptor (A), Leonhardt and Weller found that the cation (D^+) from a donor molecule and the anion (A^-) from an acceptor molecule were formed momentarily by photo-excitation in a polar solvent, and disappeared immediately by the recombination process.[6,7] This process is closely related with the mechanisms of fluorescence quenching in polar solutions. More evidence on the formation of ionic intermediates has been obtained recently by photo-excitation of donor-acceptor systems in polar solutions.[8]

However, the flash-spectroscopic technique has limitations: 1) Measurement of the spectra of the intermediates is difficult when they lie in the same region as that of the solvent or the original solute molecules. 2) It is often difficult to make the assignment of the transient spectrum. 3) The spectroscopic data cannot give information on whether there are loose associations between cations and anions (or solvated electrons).

We have attempted to extend information on the ionic intermediates formed by flash-illumination of aromatics in solutions at room temperature by measuring the transient photocurrent arising from these intermediates. In the present paper, some of the results are reported.

As an earlier photoconductivity work of the same kind, Jarnagin *et al.*,[9-11] studied photocurrents caused by the flash illumination of aromatic hydrocarbons in solutions which they attributed to a result of bimolecular triplet-triplet interaction of the aromatics. Recently, Pilloff and Albrecht have measured the photocurrent appearing in a non-polar solvent containing TMPD,[4] and found the photocurrent signal to be proportional to the square of the total intensity of flash light.

Experimental

Commercially-available TMPD dihydrochloride was neutralized in an aqueous solution with a little excess of ammonia. The precipitate of TMPD was washed slightly with water, dried, and sublimed twice in a vacuum. Anthracene and maleic anhydride were recrystallized from a benzene and a chloroform solution. *p*-Dimethoxybenzene and 1,3,5-trinitrobenzene were recrystallized from ethanol solutions and sublimed twice in a vacuum. Acetonitrile and ethanol were purified by methods described in an earlier paper.[1] G. P. grade formamide and spectro-grade dimethylformamide were used without further purification.

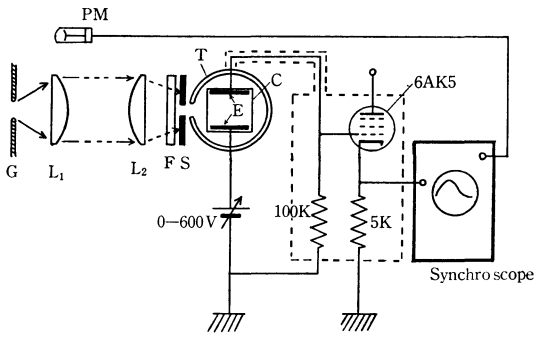

Fig. 1. Schematic diagram of the apparatus. G: tungsten gap. L_1 and L_2: quartz lenses (ϕ=100 mm). F: filter. S: slit. T: copper shield tube. C: quartz sample cell. E: electrodes. PM: photomultiplier.

In Fig. 1, a schematic diagram of the apparatus is shown. Flash light was generated from the condenser discharge through a tungsten gap (G), initiated with a high voltage trigger pulse. In order to decrease the electrical noises due to the flash discharge, a distance of about 5 m was taken between quartz lenses L_1 and L_2. The quartz sample cell was put into a copper shield tube (T). The light comes into the cell through a slit 2 mm in width, so that direct irradiation on the two electrodes (spaced by approximately 9 mm) was avoided. The electrode was a plate having the dimensions 1 cm × 4 cm. Aluminum, nickel and platinum electrodes were tested and no substantial difference in the photocurrent response was found by use of any electrode, although the first two electrodes were somewhat stained gradually in the course of experiments. The photocurrents for the acetonitrile solutions containing TMPD were measured by the above mentioned procedure. As photocurrents were very weak in all other cases, the light source (G) was placed directly before the filter so as to increase the light intensity. The tungsten gap (G) used as the light source was fired at 250J (5 μF, 10 kV) in the case of the acetonitrile solution of TMPD and at 125J (2.5 μF, 10 kV) in other cases. The duration of the flash was less than 3 μsec.

The upper part of the sample cell (C) can be sealed with a ground glass stopper. Before each of the experiments a fine Teflon tube was inserted into the cell and commercial high-purity nitrogen was bubbled

through the solution.

The circuit rise time was less than 0.4 μsec. The d.c. dark current in the case of polar solvents was of the order of 10^{-4} A. An Iwasaki SS-5302 type synchroscope was used for measurements of the currents. A part of the flash light was received by a photomultiplier(PM) and the signal was used to trigger the synchroscope. Electrical noise resulting from flash-firing on the photocurrent signal disappeared within 20 μsec after the flash.

Results

Flash-excitation of TMPD. In Fig. 2 are shown the synchroscope tracings of the photocurrents produced by the flash irradiation of deoxygenated solutions containing TMPD. The lower straight lines indicate the dark current. Two maxima of the photocurrent were found for the acetonitrile solution. The first one appeared at about 0.2 msec, more accurately 170 μsec as found by magnifying the sweep velocity of the synchroscope. The second maximum was at about 50 msec under this applied electric field.

Flash light intensity was so weak in this experiment that the characteristic color of TMPD cation (Würster's blue) did not appear. But under the condition of very strong flash intensity the irradiated TMPD solution was colored and exhibited a large photocurrent signal having a prolonged tail measurable even at 60—90 sec after the flash.

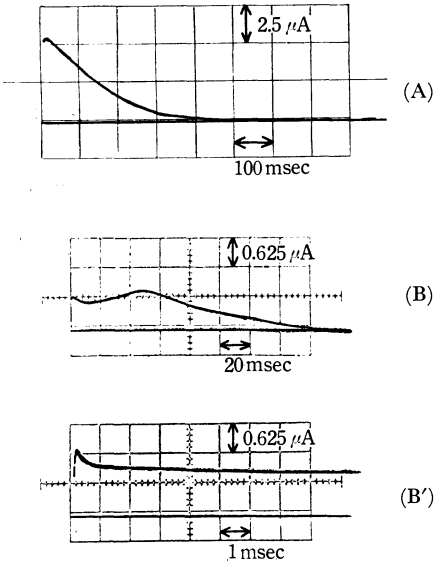

Fig. 2. The photocurrent of TMPD solution.
(A) In dimethylformamide, 1.5×10^{-4}M. Applied field: *ca.* 100 V cm^{-1}. 2.5×10^{-6} A/div, 100 msec/div.
(B), (B′) In acetonitrile, 3.7×10^{-3}M. Applied field: *ca.* 700 V cm^{-1}. 6.25×10^{-7} A/div., (B) 20 msec/div, (B′) 1 msec/div.

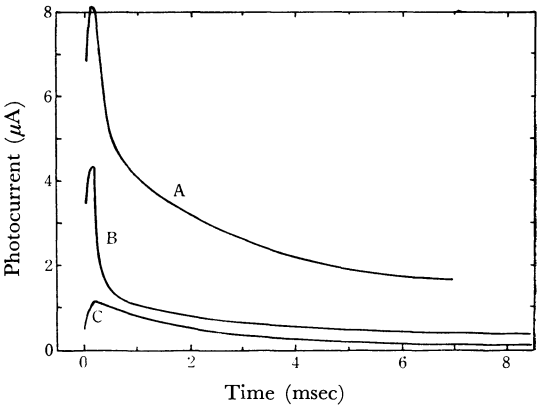

Fig. 3. The photocurrent of solution of DMB and TNB in acetonitrile. Applied field: *ca.* 100 V cm^{-1}. Concentration of DMB and TNB: both 1.5×10^{-3}M.
A: Deoxygenated. B: Not deoxygenated. C: Deoxygenated, and a 0.1M DMB solution was used as a filter.

Flash-excitation of Donor-Acceptor System. Figure 3 shows the photocurrent signals in an acetonitrile solution of *p*-dimethoxybenzene (DMB) and 1,3,5-trinitrobenzene (TNB). Curve A is the transient photocurrent signal for a deoxygenated solution, and curve B for an aerated solution. The difference between curve A and B indicates the effect of dissolved oxygen which seems to reduce the formation of charge carriers. Curve C indicates the photocurrent for the case where only 1,3,5-trinitrobenzene (acceptor) was selectively excited by the flash light through a filter solution of *p*-dimethoxybenzene (0.1M, 10 mm) in front of the sample cell. The photocurrents observed for these samples indicate only one maximum at 140 μsec. There is no such a maximum for the absorbance of the ionic species in the flash spectroscopic measurement of the same solution.[8] Assuming that the decay is second order, the rate constant is derived from curve C of Fig. 3 to be 9.2×10^{8}M^{-1}sec^{-1}. The value is about the same as that of the decay rate constant of *p*-dimethoxybenzene cation reported in a previous paper,[8] by taking the molar extinction coefficient of the cation to be about 3×10^{3}. The initial concentration of the ions interpolated to zero time becomes $\sim10^{-5}$M.

The photocurrent of a dimethylformamide solution containing *p*-dimethoxybenzene and 1,3,5-trinitrobenzene (both 1.4×10^{-3}M) was also measured. Its shape was essentially the same as that of the acetonitrile solution, but the photocurrent at the maximum was only one half. The maximum comes later and the decay is slower than for the acetonitrile solution.

In Fig. 4, curve A shows the photocurrent of an acetonitrile solution containing 1.1×10^{-3}M anthracence and 1.4×10^{-3}M maleic anhydride. Curve

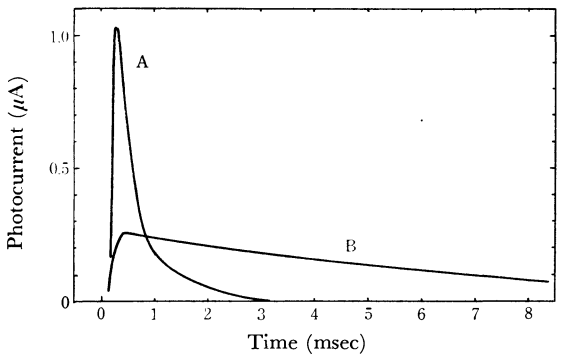

Fig. 4. The photocurrent of solution of anthracene and maleic anhydride in acetonitrile. Filter: UV-35.
A: anthracene (1.1×10^{-3}M), maleic anhydride (1.4×10^{-3}M). Applied field: *ca.* 100 V cm^{-1}.
B: anthracene alone (1.1×10^{-3}M). Applied field: *ca.* 600 V cm^{-1}.

B shows the photocurrent of anthracene alone (1.1×10^{-3}M) in the same solvent. A filter (Toshiba UV-35) was used to excite selectively the first bands (^1L_a) of anthracene. The recombination rate constants were calculated from the decay of the photocurrents to be $\sim10^{10}$M^{-1} sec^{-1} from both curves A and B, if the effective volume where the ions were generated was taken to be 0.1 cm^3. The schematic aspect of curve B resembles that obtained by Kawada and Jarnagin.[9] When dissolved oxygen was not removed by bubbling with pure nitrogen gas, the photocurrent for curve B was so weak that the measurements were almost impossible.

After more than ten flashes, it was found that the ^1L_a absorption bands of anthracene in the sample solution decreased, indicating that the concentration of anthrancene was reduced. This seems to be most probably due to the Diels-Alder type addition reaction between anthracene and maleic anhydride. Attempts to detect the absorption spectra of intermediates from this donor-acceptor system by means of the flash spectrometry[12] were made. But no spectrum of ionic species was obtained in the wavelength range from 300 to 650 mμ, though transient T–T′ absorption bands of anthracene were found near 420 mμ.

Discussion

The photocurrent density is given by

$$i(t) = \sum_j Z_j e n_j(t) \mu_j E,$$

in which e represents the charge of the electron, E the applied electric field and μ_j the carrier mobility. $n_j(t)$ represents the number of positive and negative charge carriers in unit volume which changes with time by reactions between the carrier and solvent (or impurities), by the recombination reaction, or by the electrical discharge at the electrodes when E or μ is very large.

The lower limit C_l (mol/l) of the concentration of ions produced by a flash irradiation in the sample solution, is expressed by

$$C_l \sim (1/VF)\int_0^\infty i(t)\mathrm{d}t,$$

where V is the volume of the sample solution in liter and F Faraday constant. C_l is calculated to be less than 10^{-9}M for the acetonitrile solution of TMPD. Lower values, 10^{-10}M, are obtained for the donor-acceptor systems.

The behavior of the photocurrents may be classified into three types as shown below, where τ is the lifetime of charge carriers or ionic species, and t_t the time required for the charge carriers produced near the center of two electrodes to arrive at the electrode, *i. e.* the 'transit time' which depends upon E and μ:

(1) $t_t \gg \tau$: In this case, the velocity of the charge carriers in the electric field is negligibly small, and the behavior of the photocurrent may be explained only by taking account of the reactions of the ionic species, *i. e.*, the charge neutralization or the electron transfer reactions;

(2) $t_t \ll \tau$: In this case, the ionic species remain stable enough until they arrive at the electrodes. This case is suitable for the study of the electrical transfer phenomena in solutions;

(3) $t_t \simeq \tau$: This is an intermediate case of the former two.

It is generally stated that the mobilities of inorganic ions in aqueous solutions are of the order of 10^{-4} cm^2 V^{-1} sec^{-1}, and those of organic ions in organic solutions may also be roughly estimated at the same order.[6,7] Taking the mobility to be this order of magnitude, the distance between the electrodes to be 1 cm, and the applied electric field to be 10^2 V cm^{-1}, the drift velocity of ions and the transit time become the order of 10^{-2} cm sec^{-1} and 50 sec, respectively. As all samples, except TMPD solution, examined in the present work have decay times of the order of 1 msec to 10 msec, they fall into the above-mentioned case (1). As the lifetime of TMPD cation is exceptionally long, estimated at 10^2—10^3 sec from the decay of its absorption spectrum in flash photolysis,[1] the photocurrent for this case falls into case (3).

Without exception, the photocurrent measured showed an initial rise to a maximum, which is attained at about 100 μsec. This behavior is contrary to the results of transient absorption spectra obtained from the flash spectrometry of donor-acceptor systems.[8] This delayed photocurrent was also found for the flash illumination of anthracene *etc.* in tetrahydrofuran by Jarnagin *et al.*[9–11] who regarded it as evidence for the 'delayed

12) The apparatus used here was the same as described in Ref. 3.

ionization' through the triplet-triplet interaction of the aromatics. Our results in an acetonitrile solution of anthracene closely resembled theirs. This interpretation does not apply, however, to the donor-acceptor systems or to the photo-ionization of TMPD in solutions. The fact that the rise time of the photocurrent gets longer for the more viscous solvent favors the interpretation that the photochemically produced ions initially exist in the form of loose ion-pairs,[13,14] which do not contribute to the electric current, and then seperate into free ions by the thermal motion of surrounding solvent molecules. The fact that the photocurrents reach maxima at about 100 μsec, however, seems too long for such diffusional processes.[15] Therefore, the explanation for the appearance of the maxima of the photocurrents is difficult at present.

TMPD Solutions. In previous papers,[1-3] it was found by means of flash spectrometry that TMPD in polar solvents is photo-ionized by biphotonic process *via* the triplet state as the intermediate. The fact that photocurrent has been detected for the irradiated solution certainly indicates that ions are generated and are present rather as separate positive and negative ions (or solvated electrons) than in the form of ion-pairs.

It has already been stated in the early part of this paper that the photocurrent in an acetonitrile solution of TMPD has two maxima (at 170 μsec and at about 50 msec). This behavior of the photocurrent was not found in formamide, dimethylformamide and *n*-hexane and for all other solutes examined in this work. Kawada and Jarnagin had found two maxima in a tetrahydrofuran solution of anthracene or phenanthrene and considered the second maximum to be due to impurities.[9] The second maximum of the photocurrent in this work suggests the existence of a different kind of charge carrier (Q_2). If the recombination rate of the charge carrier corresponding to the first maximum (Q_1) is larger than that of Q_2 and the mobility of Q_2 is larger than that of Q_1, it is possible that the photocurrent has double maxima. The dark reaction of Q_1 with the surrounding solvent molecules or impurities might form Q_2. The carrier, Q_2 might be cyanide anion (CN^-), methylene cyanide anion (CH_2CN^-) or $CH_3\underset{\displaystyle CH_2CN}{\underset{|}{C}}=N^-$ as conjectured from the reaction of acetonitrile with sodium metal. Cationic intermediates will not be concerned with the second maximum, since TMPD cation is rather stable.

The position of the second maximum was found to be proportional to the reciprocal of the applied voltage. This fact suggests that the time of the appearance of the maximum, t_m is of the same order of magnitude as t_t, because if t_m is much smaller than t_t, t_m should be determined mainly by the charge annihilation processes in the solution and not by the change with applied voltage.

The influence of some macroscopic properties of solvents on the photocurrent for TMPD is listed in Table 1. In ethanol the photocurrent was hardly detectable though the transient electronic spectrum of the TMPD cation appeared after flash illumination. This seems to imply that the ionic species produced by the photo-ionization in ethanol is in the form of ion-pairs.[16] In *n*-hexane a weak photocurrent (less than 6×10^{-8} A) having the decay time of a few milli-seconds was observed. Further, it appears from Table 1 that the photocurrent depends both on the dielectric constant and on the viscosity, and not on the refractive index. This is a reasonable result, because (1) the ion-pair may be

TABLE 1. PHOTOCURRENT OF TMPD SOLUTION

dissociated into free ions the more easily, the higher the dielectric constant, and (2) the mobility of the charge carrier becomes the smaller, the more viscous the solvent.

Donor-Acceptor Systems. It has been fairly well established by means of the flash spectrometry that the flash excitation of a donor-acceptor system in polar solvents produces transient cations and anions through excited charge transfer states, as described below,[6-8]

$$A+D+h\nu \longrightarrow A^*+D \text{ (or } A+D^*) \rightleftarrows (A\cdots D)^*$$
$$(A\cdots D)^* \longrightarrow (A^-\cdots D^+)_{solv} \longrightarrow A^-_{solv}+D^+_{solv} \longrightarrow A+D,$$

where $(A\cdots D)^*$ means the charge transfer state and $(A^-\cdots D^+)_{solv}$ the ion-pair. The existence of the photocurrent for the system of *p*-dimethoxybenzene-1,3,5-trinitrobenzene in acetonitrile as revealed in the present research confirmed the formation of free ions in the solution. This may be taken as a supplementary evidence for the electron transfer process of the same system observed by flash spectroscopy.[8]

For the system of anthracene-maleic anhydride-acetonitrile, no flash-spectrum of the ionic species was found. The reason for this may probably be the insensitivity of the photographic film used here at the near infrared region where the anthracene cation is expected to have the absorption spectrum. The weak absorption bands of this cation to be present in the visible and ultraviolet region should also overlap with those of the orginal solutes. The observation of photocurrent in this system, therefore, shows the superiority in the sensitivity of detection of ionic species by the present photocurrent method over the spectroscopic method.

As described in the Results, the flash irradiation of an acetonitrile solution of anthracene alone showed a photocurrent. But the intensity of the photocurrent was much weaker than that for the solution containing both anthracene and maleic anhydride. It seems reasonable, therefore, to attribute the photocurrent for anthracene (An)-maleic anhydride (Ma) system to the formation of An^+ and Ma^- through the charge transfer excited state, similar to the *p*-dimethoxybenzene-1,3,5-trinitrobenzene system. The photocurrent observed for the former is much weaker compared with that for the latter, although the experimental conditions for both cases are about the same. The main reason for this may be attributed to the difference in the strengths of the acceptors. Thus, 1,3,5-trinitrobenzene, with larger electron affinity than maleic anhydride may produce more free ionic species in the course of the reaction

$$(D^+\cdots A^-)_{solv} \longrightarrow D^+_{solv}+A^-_{solv}.$$

As is well known, anthracene and maleic anhydride form Diels-Alder type adducts by the effect of ultra-violet light. The quantum yield of this reaction in dioxane was determined to be 0.02.[17] This low value of the quantum yield seems to show that most of the 'encounter complex' of excited anthracene and maleic anhydride ($An^*\cdots Ma$) will transfer to the charge transfer state $(An\cdots Ma)^*$ which should be lower in energy than the former, and then to free ions and a small part of the encounter complex will undergo addition reaction.

$$\begin{array}{ccccc} {}^1An^* + Ma & \longrightarrow & (An^* \cdots Ma) & \dashrightarrow & \text{adduct} \\ \uparrow & & \downarrow & & \\ h\nu & & (An \cdots Ma)^*_{solv} & & \\ \downarrow & & \downarrow & & \\ An + Ma & & An^+_{solv} + Ma^-_{solv} & & \end{array}$$

Some Semi-Empirical SCF MO Calculations on Norbornadiene, Norbornene, and Their 7-Cations

Hideyuki KONISHI, Hiroshi KATO*1 and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received December 13, 1969)

Using a semi-empirical SCF MO method for valence electron systems proposed previously by the present authors, the electronic structures of norbornadiene (NBD), norbornene (NBE), and their 7-cations are discussed, together with the configurational problem of the 7-cations. In NBE and NBD, the interaction between the π AO's in the double bond and the AO's of the other parts of the molecules is made clear by the charge densities and the bond orders. For the first electronic transition assigned to a π–σ^* or σ–π^* in NBD, the present calcuation gives a rather larger excitation energy than does the experiment. For 7-norbornenyl and 7-norbornadienyl cations, the presence of structures distorted from NBE and NBD respectively can theoretically be concluded. The delocalization of the positive charge and the bonding interaction between the bridged carbon atom and the double bond carbon atoms support the concept of the so-called non-classical carbonium ions.

Norbornadiene (NBD), norbornene (NBE), and related compounds have been investigated from many points of view, such as reaction mechanisms,[1] electronic transitions,[2,3] and other physicochemical properties.[1] The first electronic band of NBD, which was identified as a forbidden π–π^* one,[4-6] has recently been pointed out to be a π–σ^* or σ–π^* one by Robin and Kuebler.[3] It seems interesting to include σ electrons in our theoretical studies in order to compare the electronic structures of NBD with earlier π-electron calculations.[4-6] An investigation of the σ electronic structures of NBD as well as of the π electronic structures is an aim of the present calculations, made by the semi-empirical SCF MO method for valence electron systems previously presented by the present authors.[7]

The carbonium ions of NBD and NBE have been discussed as so called non-classical carbonium ions.[1] In our study of the 7-carbonium ions of NBD and NBE, we have focussed our attention on the following four points: the distortion of the valence angle and the alternation of the bond length with reference to the neutral molecules, the migration of charges, and the non-bonding interactions in these ions.

Method and Parameters

The present calculations were performed by means of our previously-reported semi-empirical SCF MO method, using the zero-differential overlap approximation except for the one-center exchange integrals.[7] All the core-resonance integrals are taken into account in estimating the non-bonding interactions of atoms as:

$$H_{rs} = -KS_{rs}(I_r+I_s)$$

where K is a constant which will be described in a later part of this section, where S_{rs} is the overlap integral between the rth and the sth atomic orbitals (AO's), and where I_r denotes the valence-state ionization potential of the rth AO. The other parts of the present method and the basic integral values are the same as in our previous paper.[7]

For the geometry of NBD, the gas-electron diffraction datum reported by Morino *et al.*[8] is adopted. (All the skeletal carbon atoms for the compounds treated in the present paper are numbered as is shown in Fig. 1.) For the 5- and 6-carbon skeletal structures of NBE, the datum of norbornane[8] is used, while for the residual part,

that of NBD is adopted. In the 7-Norbornenyl and 7-norbornadienyl cations (7-NBEI and 7-NBDI), the sp^2 hybridization of the 7-carbon atoms is assumed, along with the same C–H bond distances as in the neutral molecules. The distortion of 7-NBEI and 7-NBDI is also investigated by moving the C_5, C_6, and C_7's, with their hydrogens, on arcs determined by fixing the plane formed by C_1, C_2, C_3, and C_4 carbon atoms and by keeping the C_s symmetry of the compounds and all the bond lengths unchanged. The distortion is indicated by the θ angle (illustrated in Fig. 1), which represents the displacement of the C_1, C_7, C_4-plane from its positions in the parent neutral molecule. The displacement of the C_1, C_4, C_5, C_6-plane is also tentatively taken to be $\theta/2$ in the same direction as the C_1, C_7, C_4-plane so as to reduce the strain on the compound.

The parameter, K, is taken to be 1.05, so that the calculated value of the lowest singlet transition energy of NBE may fit the observed value. The parameter dependence of several calculated quantities is presented in Table 1, together with the observed values. From this table, it may be noticed that the transition energies depend remarkably on the values of K, while the ionization potentials and the charge distributions are almost independent of the K values.

Results and Discussions

NBE and NBD. The charge distribution of NBE and NBD is recorded in Table 2. The π-charge densities on the unsaturated carbons are also shown, together with the other AO's.[10] The calculated charge densities on the π AO's of NBE and NBD are larger than unity. This indicates the presence of electron delocalization due to interaction between the π AO's and the residual parts of the molecules. This can also be seen in the fact that the values of the π-bond orders, such as the $P_{\pi_2\pi_3}$ in both NBE and NBD, are less than unity.

The π AO coefficients[10] of some of the MO's of NBE and NBD in Table 3 represent a measure of the localization of the MO's in the π AO's. For this purpose, the D quantity is defined as:

$$D(\text{NBE}) = 2\{C(\pi_2)\}^2$$
$$D(\text{7-NBEI}) = 2\{C(\pi_2)\}^2 + \{C(\pi_7)\}^2$$
$$D(\text{NBD}) = 4\{C(\pi_2)\}^2$$
$$D(\text{7-NBDI}) = 2\{C(\pi_2)\}^2 + 2\{C(\pi_5)\}^2 + \{C(\pi_7)\}^2$$

where $C(\pi)$ is the transformed π-AO coefficient of an MO. A large D value denotes the localization of electrons occupying the MO. The highest occupied (HO) MO's of NBE and NBD are least localized, as is indicated by the D values in Table 3.

The transition energies of NBE are presented in Table 4, together with the experimental values measured in an ultraviolet vacuum by Stokes and Pickett.[2] The calculated values are obtained

9) R. Hoffmann, *J. Chem. Phys.*, **40**, 2480 (1964); *J. Amer. Chem. Soc.*, **86**, 1259 (1964).

10) The π-AO coefficients can be defined at every sp^2 carbon atom by transforming the MO coefficients to those of the p AO perpendicular to a local molecular plane. Therefore, in 7-NBDI the π AO's of the 2,5 and 7 carbon atoms are not parallel to one another.

by taking account of the configuration interactions among a limited number of singly-excited configurations. The notation, f_π, is the oscillator strength contributed by all kinds of π AO's. The difference between f_{total} and f_π for the lowest transition of NBE can be attributed to the σ AO's participation.

All previous theoretical treatments of the electronic transition of NBD have been carried out for π-electrons.[4-6] In these treatments the first transition is forbidden, whereas the second one is

allowed. Robin and Kuebler,[3] however, assigned the first transition to a $^1A_1 \rightarrow {}^1A_1$ species (corresponding to a π–σ^* or σ–π^* transition) on the basis of a vibrational analysis in the vapor phase.

The $^1A_1 \rightarrow {}^1A_1$ transition energy calculated by the present method (in Table 4 (b)) is considerably larger than the experimental energy. For the $^1A_1 \rightarrow {}^1B_2$ transition energy, the calculated value does not agree with the experimental finding. In view of these defects, there seems to be some room for improvements in the present theory.[11]

7-NBEI and -NBDI. The non-classical structures of the carbonium ions derived from NBE and NBD have been discussed previously.[1] The electron delocalization of the 5-norbornenyl cation by means of Hückel MO calculations was made by Simonetta and Winstein.[12] 7-NBEI was treated as a bishomocyclopropenyl cation by Woods, Carboni, and Roberts.[13] These treatments shows the stabilizing energies of the non-classical models due to electron delocalization, though they are estimated by means of Hückel MO calculations and empirical calculations of the strain energy. All the valence electrons of NBEI and NBDI were treated with an extended Hückel theory by Hoffmann,[9] who also discussed the charge distribution and the stable conformation of NBEI and NBDI. Recently, a more quantitative treatment for NBEI has been performed by Ohorodnyk and Santry using the CNDO method.[14]

The experimental evidence on 7-NBDI was obtained from the NMR spectra by Story *et al.*,[15] The signals for four kinds of protons in 7-NBDI show a structure with a C_s, not a C_{2v}, symmetry. Recently, the bridge flipping of 7-NBDI was detected also from the NMR spectra by Brookhart, Lustgarten, and Winstein.[16] Further, the existence of 7-NBEI was proposed by Winstein *et al.*[17] on the basis of the unusual reactivity and complete retention of configuration in the acetolysis of aniti-7-norbornenyl tosylate. In the present paper, the configuration and the electronic structures of 7-NBEI and 7-NBDI will be discussed.

To deal with a configurational problem, the total energy is obtained as a sum of the total electronic energy of the valence electrons and the repulsion energy between cores:

$$E_{total} = E_{electronic} + E_{core}$$

The E_{core} is approximated by a point-charge model as follows:[18]

$$E_{core} = \sum_{A<B} \sum Z_A Z_B e^2 / R_{AB}$$

where Z_A is the core charge of the atom A and where R_{AB} is the internuclear distance between the atoms A and B.

The calculated potential energy curves are plotted in Fig. 2 for 7-NBDI and 7-NBEI using the distortion described in the previous section. In 7-NBEI, the positive θ corresponds to the motion of the C_7 toward the double bond. The existence of the calculated potential minima at the angles different from zero for 7-NBDI and 7-NBEI in Fig. 2 supports

11) In the present paper, the parameter, K, in the equation of the core-resonance integral is taken to be 1.05, whereas the value of 0.8 for benzene, pyridine, and so on (Ref. 7), and that of 0.9 for ethylene, have been adopted. The different values taken for K may suggest defects in the evaluation of the integrals, *e.g.*, the core-resonance integral and the Coulomb repulsion integrals.

18) If the total energy difference between a neutral molecule and its dehydrated cation (or between a neutral molecule and its protonated cation) is calculated on the basis of the point-charge model, the ionization energy (or proton affinity) becomes too small. In the present paper, where the E_{core} is used mainly in the distortion problem, this approximation can be used.

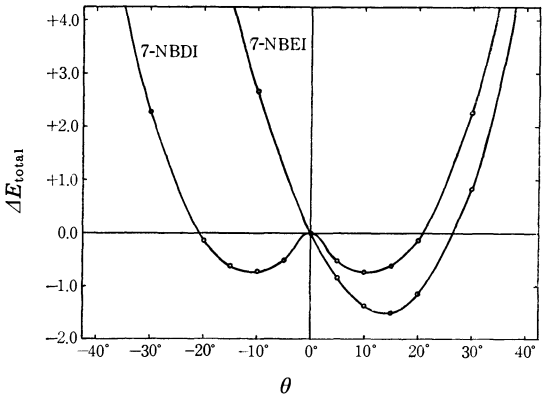

Fig. 2. Potential energy curves for distortion of the bridge in 7-NBEI and 7-NBDI.

the idea of non-classical structures of them. These results are also supported by Hoffmann[9,19] and Ohorodnyk and Santry,[14] though the angles of the potential minima differ among these treatments. The conclusion of Story *et al.*[15] obtained by means of NMR is also substantiated. The calculated potential minimum for 7-NBDI is obtained at $\theta=10°$, with the stabilization energy of 0.75 eV referred to the energy at $\theta=0°$. The present value of the stabilization energy is close to the values estimated by Brookhart, Lustgarten, and Winstein[16] by means of NMR spectroscopy ($\geq$0.85 eV). The calculated energy minimum for 7-NBEI is found at $\theta=15°$. In order to discuss the electronic structures of these ions with variable θ angles, we will hereafter use the following abbreviations: 7-NBDI I ($\theta=0°$), 7-NBDI II ($\theta=10°$), 7-NBEI I ($\theta=0°$), and 7-NBEI II ($\theta=15°$).

The charge distribution of the cations is presented in Table 2. The remarkable migration of the positive charge in the molecule may be a characteristic of a non-classical structure. The positive charge on C_7 is not so large as those found by Hoffmann using the extended Hückel method.[9] In 7-NBEI II and 7-NBDI II, the $2p_\pi$ AO's of the C_2's lost a little charge compared with those in their neutral molecules, whereas the $2p_\pi$ AO's of the C_7's gained somewhat. This trend and the fairly large values of the $P_{\pi_2\pi_7}$'s support our ideas as to the features of the nonclassical carbonium ion. (A more detailed discussion will be given below.)

In our previous paper,[7,20] we used a semiempirical relation between the bond length and the E_{AB}^1 value of the AB bond, which corresponds to the bond energy, in estimating unknown bond lengths. In the

a) the pair in the parenthesis is non-bonding one.

19) The extended Hückel theory, which is not recklessly applicable to charged compounds,[9] can probably be applied to the distortion problem in the present case because the main contribution is by the electronic terms rather than by the Coulombic terms, as will be discussed later in terms of E_{AB}^1 and E_{AB}^2.

20) In Ref. 7, the E_{AB} notation is adopted instead of E_{AB}^1 in the present paper.

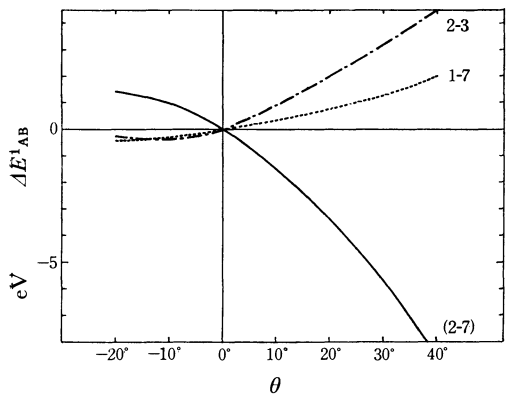

Fig. 3. Variation of E^1_{AB} values for 7-NBEI according to the distortion.

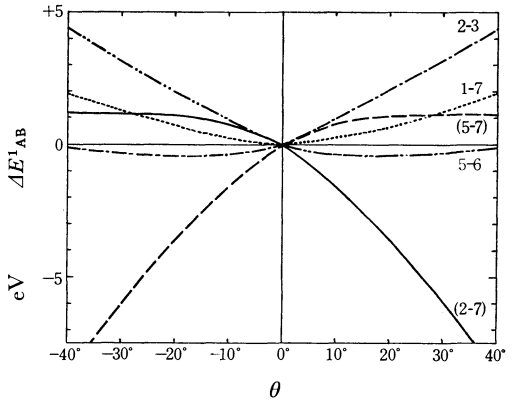

Fig. 4. Variation of E^1_{AB} values for 7-NBDI according to the distortion.

present paper, another index, $E_{AB}{}^2$, is introduced to discuss the strength of the heteropolan bond. The value of E_{AB}, which consists of $E_{AB}{}^1$ and $E_{AB}{}^2$ terms, can be used as a measure of the strength of a bond, where a stronger bond has a smaller value (see Appendix).[21]

In Table 5, the changes in the values of $E_{AB}{}^1$ and $E_{AB}{}^2$ for 7-NBEI and 7-NBDI, referred to NBE and NBD respectively, are tabulated. Based on these values for 7-NBEI I, which is assumed to have the same carbon skeleton as NBE, the trend of the alternation of the bond length can be confirmed. That is, all of the bonds in NBEI I, except for the 1–7 and 4–7 bonds, must be longer than those of NBE. Moreover, the non-bonding atomic distance between C_2 and C_7 (C_3 and C_7) can be predicted to become shorter than that of the neutral molecule. A similar trend can also be pointed out for 7-NBDI I. The $\Delta E_{AB}{}^1$'s of the non-bonding pairs of C_2 and C_7 for 7-NBEI II and 7-NBDI II have quite large absolute values, with a minus sign, though their $\Delta E_{AB}{}^2$'s also have large positive values. These facts indicate a partial bond characteristic of the so-called non-classical carbonium ions.

The variation in $E_{AB}{}^1$ values for 7-NBEI and 7-NBDI according to their distortion is illustrated in Figs. 3 and 4. For both cations, the interaction between C_2 and C_7 becomes stronger as θ increases, whereas the double bond (2–3) becomes weaker. The course of yielding the tricyclo-isomers[22] through

21) This point is connected with the relation between the values of E_{AB} and the experimental bonding energy attributed to the AB bond of a molecule (*cf.* a paper to be published).

22) H. C. Brown and H. M. Bell, *J. Org. Chem.*, **27**, 1928 (1962); *J. Amer. Chem. Soc.*, **85**, 2324 (1963).

the carbonium ions can theoretically be expected, though there is a high potential barrier, accompanied by an alternation in the bond length and a variation in the valence angle.

The absorption spectra of these cations have been reported on only a little. The absorption band at 350 mμ (3.54 eV), which is assigned to an electronic transition in 7-NBDI by Winstein and Ordronneau,[23] is not compatible with the finding of Stofy and Saunders,[15] who found no absorption sbove 330 mμ (3.76 eV). The transition energies characteristic of the carbonium ions[24] are calculated to be slightly less than 3 eV for 7-NBDI (2.85 eV for I and 2.98 eV for II): these and the other results are presented in Table 6. Since we lack experimental data comparable with the present results, further experiments on the present problem must be undertaken.

In conclusion, the distorted configurations of 7-NBEI and 7-NBDI have been theoretically indicated. The delocalization of the positive charge and the bonding interaction between the bridged carbon atom and the double-bond carbon atoms, measured with E^1_{AB} and E^2_{AB} values, have been pointed out as the features of the so-called non-classical carbonium ions.

The calculations were carried out at the computation centers of both Tokyo University (HITAC 5020E) and Kyoto University (HITAC 5020).

Appendix

The total electronic energy of the valence electrons is:

$$E_{\text{electoronic}} = \frac{1}{2}\sum_r\sum_s P_{rs}(H_{rs}+F_{rs}) \qquad \text{(A-1)}$$

where $\sum_r$ denotes the summation of all the valence AO's considered, and where P_{rs}, H_{rs}, and F_{rs} are, respectively, the bond order, the core-resonance integral, and Fock's operator between the rth and sth AO's. With the choice of a point-charge model for the repulsion energy between cores, the total energy of the molecule can be represented as follows:
where I_r is the valence-state ionization potential of the

$$E_{\text{total}} = \frac{1}{2}\sum_r\sum_s P_{rs}(H_{rs}+F_{rs}) + \sum_{A<B}\sum Z_A Z_B e^2/R_{AB} \qquad \text{(A-2)}$$

The substitution of the one-center integrals presented in our previous paper[7] into Eq. (A-2) leads to the following expression:

$$E_{\text{total}} = \sum_A E_A + \sum_{A<B}\sum E_{AB}$$
$$= \sum_A E_A + \sum_{A<B}\sum (E^1_{AB}+E^2_{AB}) \qquad \text{(A-3)}$$

Here, the monoatomic part, E_A, and the diatomic parts, E^1_{AB} and E^2_{AB}, are:

$$E_A = \sum_r^{\text{on A}} P_{rr}\left[-I_r-\left(N_r-1-\frac{1}{4}P_{rr}\right)(rr|rr)\right]$$
$$-\sum_r^{\text{on A}}\sum_{r'<r}^{\text{on A}}\left[P_{rr}(2N_{r'}-P_{r'r'})\left\{(rr|r'r')-\frac{1}{2}(rr'|rr')\right\}\right.$$
$$\left.+\frac{1}{2}P^2_{rr'}\{(rr|r'r')-3(rr'|rr')\}\right] \qquad \text{(A-4)}$$

$$E^1_{AB} = \sum_r^{\text{on A}}\sum_s^{\text{on B}} P_{rs}(H_{rs}+F_{rs}) \qquad \text{(A-5)}$$

$$E^2_{AB} = \sum_r^{\text{on A}}\sum_s^{\text{on B}}(P_{rr}P_{ss}-P_{rr}N_s-P_{ss}N_r)(rr|ss)$$
$$+ Z_A Z_B e^2/R_{AB} \qquad \text{(A-6)}$$

rth AO, where N_r is the number of valence electrons occupying the rth AO in the valence state, and where $(rr|ss)$ and $(rr'|rr')$ are the two-center Coulomb and one-center exchange repulsion integrals respectively. The relation between the E_{AB} and the experimental bonding energy attributed to the AB bond of a molecule is shown graphically. This will be presented in detail in a following paper. By the use of the positive hole approximation[25,26] instead of the point-charge model for the repulison energy between cores, E^2_{AB} can be expressed as follows:

$$E^2_{AB} = \sum_r^{\text{on A}}\sum_s^{\text{on B}}(N_r-P_{rr})(N_s-P_{ss})(rr|ss) \qquad \text{(A-7)}$$

Thus, for two neutral atoms with P_{rr} equal to N_r, E_{AB} consists of only E^1_{AB}. However for charged species, it should be necessary to take into account E^2_{AB} terms because of their large contributions, as is shown in Table 5.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1683—1686 (1970)

Temperature Dependence of the Heats of Solution of Poly(ethylene glycol) and of Related Compounds

Haruo NAKAYAMA

Department of Chemistry, Faculty of Engineering, Yokohama National University, Ooka-machi, Minami-ku, Yokohama

(Received December 18, 1969)

The heats of solution of poly(ethylene glycol) and of related compounds (1,4-dioxane, tetrahydrofuran, ethylene glycol, diethylene glycol, and several ethyl ethers of ethylene glycol and of diethylene glycol) have been measured as a function of the temperature. The change in the partial molar heat capacity of the solute molecule in the dissolution process, $\Delta\bar{C}_{p2}$, is obtained from the temperature coefficient of the heat of solution. The $\Delta\bar{C}_{p2}$ for poly(ethylene glycol) is 15 cal/deg per $-CH_2CH_2O-$ chain unit. This value is in good agreement with those obtained for other low-molecular-weight compounds. The effect of the polar groups (the ethereal oxygen atom and the hydroxyl group) on the iceberg formation around the nonpolar residues has been discussed. From the results obtained, it seems likely that the iceberg formation around the $-CH_2-CH_2O-$ group is somewhat suppressed by the orientation-dependent interactions (hydrogen bond formation) between the ethereal oxygen atom and the water molecule.

As a typical solvent, water has many unique properties which depend on the nature of the molecules dissolved in it. When a compound containing a nonpolar group only (such as hydrocarbon) is introduced into an aqueous solution, an ice-like structure is stabilized in the neighborhood of the solute (the iceberg formation[1]). On the other hand, in aqueous solutions of substances having not only nonpolar residues, but also functional groups which may participate in hydrogen bonding, the situation becomes much more complex and their thermodynamic functions are apparently governed to a considerable extent by the relative strengths of the two types of interactions: nonpolar group-water (such as the iceberg formation) and polar group-water (such as the hydrogen-bond formation).

In the present investigation, we have been concerned with the aqueous-solution properties of the latter compounds, that is, the molecules having both nonpolar residues and polar groups, in order to ascertain how the hydrogen-bond formation influences the water structure around the nonpolar groups which are located near or adjacent to the functional groups. It is obvious from several investigations[2-6] that the ions with large nonpolar groups promote the water structure by increasing its likeness to ice. However, so far little is known about the structure-making effect of relatively small nonpolar residues which are directly connected with the functional groups. As a typical example of such a characteristic compound, we have chosen poly(ethylene glycol), in which each ethylene group is hemmed in by ethereal oxygen atoms.

The partial molar heat capacities of solutes in aqueous solutions make them suitable for studying the influence of the solutes on the structural modifications of water.[6] Therefore, we have determined the change in the heat capacity for the dissolution process by measuring the temperature dependence of the heats of solution. The heats of solution at infinite dilution, ΔH_s°, are simply expressed as:

$$\Delta H_s^\circ = n_2(\bar{H}_2^\circ - H_2), \tag{1}$$

where $\bar{H}_2^\circ$ is the partial molar-heat content of the solute at an infinite dilution, $\bar{H}_2$ is the molar-heat content of the pure solute, and n_2 is the number of moles of the solute. The temperature coefficient of Eq. (1) gives the change in the heat capacity for the dissolution process, $\Delta\bar{C}_{p2}$:

$$\frac{\mathrm{d}(\Delta H_s^0)}{\mathrm{d}T} = n_2(\bar{C}_{p2}^0 - C_{p2}) = n_2\Delta\bar{C}_{p2} \tag{2}$$

in which $\bar{C}_{p2}$ is the partial molar-heat capacity of the solute at an infinite dilution, while C_{p2} is the molar-heat capacity of the pure solute.

Experimental

Materials. The poly(ethylene glycol) was obtained from the Wako Pure Chemicals Company and was purified by recrystallization from a hot methyl-ethyl ketone solution. The melting point was 61.5—62.3°C, and its molecular weight was about 1.4×10^4, as was estimated from the intrinsic viscosity measurements (0.224 cc/g in water at 25°C). The ethylene glycol, the diethylene glycol, the mono- and di-ethyl ethers of these glycols, the 1,4-dioxane, and the tetrahydrofuran were of a reagent grade and were purified by vacuum distillation just before use. The 1,4-butanediol was of a reagent grade and was used without further purification.

Calorimetric Measurements. The calorimeter employed in this study was a twin-type micro-calorimeter manufactured by Oyodenki Kenkyujo (CM-502).[7] Each sample (about 0.5 g or less), sealed in an ampoule, was dissolved into 50 m*l* of redistilled water whose temperature was kept constant. The measured values of the heat of solution may be in error by as much as 4% at worst. The results shown in Figs. 1 and 2 and tabulated in Table 1 are averages of three or four determinations.

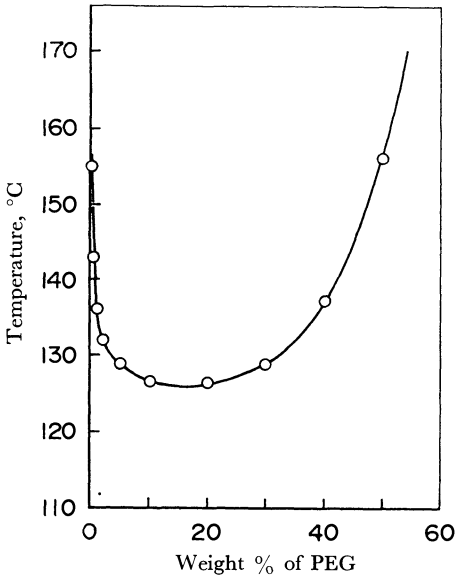

Fig. 1. The liquid-liquid phase diagram for the H_2O-PEG system.

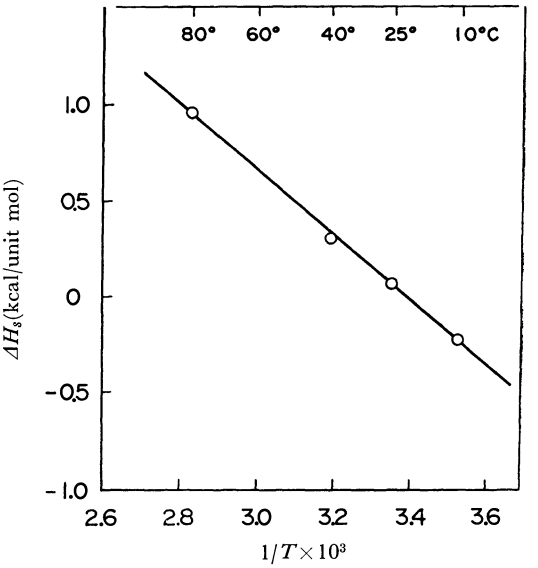

Fig. 2. Temperature dependence of the heats of solution of PEG in H_2O.

Results

The liquid-liquid phase diagram for the water-poly(ethylene glycol) (which we will denote by PEG hereafter) system is shown in Fig. 1. This system has a lower critical solution temperature. The critical solution temperature and critical concentration are about 126°C and 15 wt% respectively. At 160°C, for example, a very dilute solution (less than 0.1%) is in equilibrium with a fairly concentrated solution (*ca.* 50%); the latter corresponds to the solution in which there are 2.5 water molecules per $-CH_2CH_2O-$ group.

The temperature dependence of the heats of solution of solid PEG, ΔH_s, is shown in Fig. 2. The final concentration is about 1%. The heat of solution at 80.3°C (which is higher than the melting point) is obtained by adding the heat of fusion of PEG (2.07 kcal/unit mol[8,9]) to the heat of soultion of liquid PEG at 80.3°C, which has been measured by Rowlinson *et al.*[10] It may be seen from Fig. 2

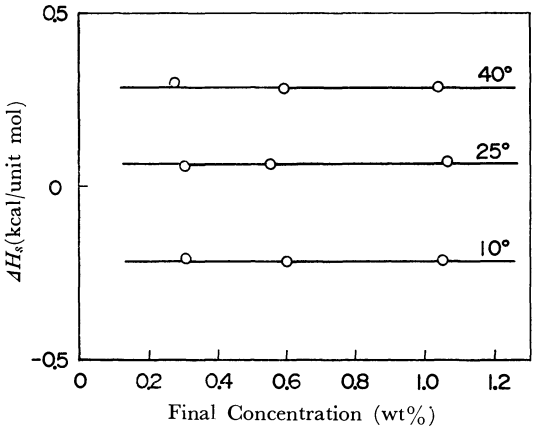

Fig. 3. Concentration dependence of the heats of solution of PEG in H_2O.

that, over the temperature intervals examined, the heat of solution of PEG is approximately a linear function of the reciprocal of the absolute temperature. Obviously, the decrease in exothermicity with rise in the temperature causes phase separation at high temperatures, as is shown in Fig. 1.

In Fig. 3 the concentration dependence of the heats of solution of PEG in dilute regions is shown. As is evident from this figure, the heat of solution is almost independent of the concentration if the final concentration is less than 1%. Therefore, we may safely conclude that the observed heats of solution of PEG (in about a 1% solution, Fig. 2) may be regarded as the heats of solution at an infinite dilution. Thus, from Eq. (2) and Fig. 2, the $\Delta\bar{C}_{p2}$ for PEG can be calculated to be 15 cal/deg. unit-mol around 25°C.

The heats of solution of various low-molecular-weight compounds containing an ethereal oxygen atom and/or a hydroxyl group at 25 and 40°C are listed in Table 1. The final concentration is about 1% or less. For these compounds the values of $\Delta\bar{C}_{p2}$, which are calculated from the temperature coefficients over the 25—40°C temperature range, are also included in Table 1.

Discussion

The heat of solution of solid PEG is slightly endothermic at 25°C (0.07 kcal/unit-mol, as is seen from Fig. 2 or Table 1). This means that the heat of fusion of solid PEG (2.07 kcal/unit-mol[8,9]) is almost canceled out by the exothermic heat of solution of liquid PEG (2.00 kcal/unit-mol). The fact that the introduction of liquid PEG into water leads to a large evolution of heat indicates that the exothermic heat of solution due to a specific interaction between PEG and water exceeds the endothermic heat of solution due to the difference in the cohesive energy densities of the two substances.[11]

The main factors which lead to an exothermic heat of mixing are, presumably: (1) the hydrogen-bond formation between the ethereal oxygen atom of PEG and the hydrogen atom of water, and (2) the structural modifications (the iceberg formation) of water around the hydrocarbon portions of PEG. These interactions will also be reflected in the temperature dependence of the heat of solution. However, we have no quantitative information concerning the effect of the hydrogen-bond formation upon the value of $\Delta\bar{C}_{p2}$. Regarding the latter effect, however, it has been established that the $\Delta\bar{C}_{p2}$ increases about 10 cal/deg·mol[12,13] per $-CH_2-$ group. In any case, we may reasonably expect a value of more than 20 cal/deg-mol for the $\Delta\bar{C}_{p2}$ of the $-CH_2CH_2O-$ group if a stable, ice-like structure is formed in the immediate neighborhood of the $-CH_2CH_2O-$ chain. However, the observed value of $\Delta\bar{C}_{p2}$ for the $-CH_2CH_2O-$ group is 15 cal/deg·mol, as has been mentioned above. This suggests, convincingly but not conclusively, that the iceberg formation around the $-CH_2CH_2O-$ chain is somewhat suppressed by the orientation-dependent interactions (*i. e.*, the hydrogen-bond formation) between ethereal oxygen atoms and water molecules. We believe much more work needs to be done before anything can be said conclusively about the behavior of water molecules in the neighborhood of the $-CH_2CH_2O-$ group.

In Table 1 we may derive some interesting observations about the $\Delta\bar{C}_{p2}$ in relation to the molecular structure:

(1) The $\Delta\bar{C}_{p2}$ for 1,4-dioxane, which is a cyclic dimer of the $-CH_2CH_2O-$ group, is somewhat smaller than twice the $\Delta\bar{C}_{p2}$ for the $-CH_2CH_2O-$ group. On the other hand, for tetrahydrofuran the $\Delta\bar{C}_{p2}$ value is considerably greater than that to be expected from the values of $\Delta\bar{C}_{p2}$ for one $-CH_2-CH_2O-$ group and two methylene groups. These discrepancies are probably due to the difference in structure-making ability between the small cyclic molecule and the linear molecule.

(2) The heat of solution of ethylene glycol is almost independent of the temperature around 25°C. This fact suggests that the strong hydrogen-bond formation between the hydroxyl group and the water molecule causes a disruption of the water structure so striking that the structure-making capacity of the methylene group adjacent to the hydroxyl group is considerably lowered. As has

been mentioned above, the occurrence of a similar phenomenon can also be expected in the case of poly (ethylene glycol), though the effect there is not so marked. However, as the $\Delta\bar{C}_{p2}$ of 1,4-butanediol shows (Table 1), the structural modifications of water occur around the methylene groups, remote from the hydroxyl group. An analogous effect has also been observed in the aqueous solutions of alkylhexaoxyethylene glycol monoethers.[14]

(3) The differences in the $\Delta\bar{C}_{p2}$'s between diethylene glycol and ethylene glycol, between diethylene glycol monomethyl ether and ethylene glycol monoethyl ether, and between diethylene glycol diethyl ether and ethylene glycol diethyl ether are 15, 14, and 16 cal/deg·mol respectively. These differences may be ascribed to the cntribution of the $-CH_2CH_2O-$ group to the $\Delta\bar{C}_{p2}$. It is interesting that they are in very good agreement with the $\Delta\bar{C}_{p2}$ observed for the $-CH_2CH_2O-$ group in PEG (15 cal/deg·mol).

(4) If we assign 15 cal/deg·mol to the $\Delta\bar{C}_{p2}$ for the $-CH_2CH_2O-$ group, 22 cal/deg·mol to that for the $-CH_2OC_2H_5$ group, and 0 cal/deg·mol to that for the $-CH_2OH$ group, the $\Delta\bar{C}_{p2}$ values for ethylene glycol, diethylene glycol, and their various ethyl ethers can be reasonably estimated. In Table 1, these calculated values are also listed (in parentheses). They are in good agreement with the observed values.

The author wishes to thank Dr. Kōzō Shinoda for his helpful criticisms and suggestions.

Hydrogen Ion Titration of Poly-S-carboxymethyl-L-cysteine

Shoichi IKEDA*1

Department of Biology, Osaka University, Toyonaka and Department of Chemistry, Nagoya University, Nagoya

(Received December 25, 1969)

Potentiometric titration curves have been determined for aqueous solutions of poly-S-carboxymethyl-L-cysteine. A pH-induced transition of the polymer conformation is manifest from the occurrence of a transition region around pH 5, where the solution has an essentially infinite buffer action. The titration curve at higher ionization corresponds to that of a random coil. At lower ionization the polymer is associated to form a β-structure and its titration behavior is qualitatively accounted for by the Gouy model for a uniformly charged sheet. Deviation from the model would partly be ascribed to the aggregation of sheets in the β-form. The standard free energy of transition from random coil to β-form has been estimated for the unchanged polymer and is found to depend on the molecular weight of polymer. It is suggested that fine structure of the β-form and its mode of aggregation vary with polymer chain length.

It has been accepted that some synthetic polypeptides, which exist as the β-conformation in solid, can retain the β-structure even in solution, if some specific solvent systems are chosen,[1-3] However, most of these polypeptides are insoluble in aqueous media and thus have been examined in mixtures of organic solvents. A conformational transition takes place from random coil to β-form at a certain solvent composition, as the solvent mixture becomes less polar. Evidence for the coil-β transition and the formation of the β-form was mainly derived from measurements of optical rotation and infrared spectrum. However, thermally induced formation of β-form of poyl-L-lysine in water was elaborated by two groups of workers.[4-6]

Recently, pH-induced coil-β transition was found for a water-soluble polypeptide, poly-S-carboxymethyl-L-cysteine.[7,8] The transition was observed as large changes in optical rotation, intrinsic viscosity and infrared spectrum around pH 5. The polymer is associated into an intermolecular β-conformation upon lowering pH, while it is in a random coil conformation at higher pH. Its ultraviolet rotatory properties were also investigated as a function of pH and correlated with the conformational transition.[9] .Is can be expected that the transition is also observed on potentiometric titration curves of the polymer, provided that ionized carboxyl groups in the β-form have different affinity or electrostatic interaction with hydrogen ions from those in the random coil. The pH titration method would provide another useful approach to elucidate the detailed structure of the β-form and its transition to random coil. Preliminary titration curves have already published.[7,8]

The helix-coil transition of poly-L-glutamic acid in aqueous meida was successfully investigated by means of the titration method.[10-13] The results clearly showed the presence of three regions on a titration curve, each corresponding to the pure helix, the pure coil and the intervened transition region, and made it possible to estimate the standard free energy of transition.

Experimental

Materials. Poly-S-carboxymethyl-L-cysteine used was the same samples as described previously.[8] The intrinsic viscosities (in $dl\ g^{-1}$) of the three samples were 0.230 for E602, 0.089 for E527 and 0.041 for E515, in 0.2M NaCl at pH 7, 25°C. Most experiments were performed on the highest molecular weight sample, E602.

Carbonate-free 1N NaOH was standardized against potassium acid phthalate, and 1N HCl was standardized against Na_2CO_3 and checked against the NaOH. Glass-redistilled CO_2-free water was used to make up all the solutions.

pH Measurements. A Horiba Model P pH-meter of a potentiometric type, accurate to ± 0.003 pH unit, was used with a Horiba standard buffer (pH 6.86 at 25°C).

Hydrogen Ion Titration. Titrants were delivered from calibrated micrometer syringes with 0.5 ml capacities. All the measurements were carried out under nitrogen flushing. Temperature was 25°C, unless otherwise stated. A specially designed titration vessel with three necks, two of which were installed with a glass electrode and a reference electrode, respectively, and the other was fitted with a syringe, thermometer and nitrogen inlet, was placed on a magnetic stirrer which was grounded to the earth.

To a weighed amount of sample was added 10 ml of solvent with appropriate ionic strength of NaCl. The suspension was first titrated with 1N NaOH up to pH 11.5, when the sample had been in solution at about pH 6. Then the alkaline solution was back-titrated with 1N HCl. Each addition of HCl yielded white gel upon the tip of the syringe needle but the gel redissolved within a few minutes. However, below about pH 4, the solution was so viscous and turbid that observed pH values were unreliable.

The degree of ionization, α, was calculated from the difference between total and free concentrations of hydrogen ions. Free hydrogen ion concentration was computed by assuming that liquid junction potentials and mean activity coefficients of the solution were the same as those of solution containing no polymer.

Results

The titration curves in a forward direction, *i. e.*, from acid to alkaline, and those in a backward direction were not necessarily conicident with each other. The forward curve generally shifted to slightly more alkaline side than the backward curve. This would be caused mostly by the different rates of reactions in suspension and in homogeneous solution. The suspension became clear when its pH was raised to 5 or higher. The homogeneous solution could be kept clear down to pH 4 or even lower during the beckward titration, which was more reproducible. The backward titration may be regarded as closer to the equilibrium titration

behavior of the system. All the results presented below are concerned with those of the backward titration process, which moves from the alkaline to the acid side, using acid titer.

A characteristic feature common to all the titration curves should be noted. As the titration proceeds from alkaline to acid side, a region always appears where the solution exhibits an essentially infinite buffer action or where the pH of solution remains unaltered upon addition of some amount of acid. This is illustrated in Fig. 1. The location of this particular region is slightly dependent on polymer concentration and temperature and is markedly dependent on ionic strength. The characteristic region is located around pH 5 or slightly lower. Previous results[7-9] have shown that various properties suddenly change around pH 5 and conformational change from coil to β-from takes place here. Thus the characteristic pH titration curve may be reasonably identified with the pH where the polymer undergoes a conformational change. In this sense, the specific pH region will be referred to as the transition pH or the transition region. At pH higher than this, the polymer is in a randomly coiled form, but at lower pH it is in an intermolceular β-conformation. Occurrence of such a transition region during the titration would imply that the affinity of hydrogen ions with ionized carboxyl groups is higher in the coil form than in the β-form. The observed sharpness of the transition would be related to the cooperative formation of hydrogen bonds upon lowering pH.

The titration curve slightly shifted to higher pH with increasing polymer concentration. The transition pH in 0.2M NaCl was 4.64 for 0.154 g dl^{-1}, 4.68 for 0.295 g dl^{-1} and 4.72 for 0.608 g dl^{-1}. The last pH value is in complete agreement with that found previously[8] for the titration. As the concentration was as high as 0.5 g dl^{-1}, gelation occurred at the transition pH and made it difficult to obtain reliable values at lower pH. The concentration dependence would be ascribed to stronger electrostatic interaction between ionized groups at higher concentrations or in larger aggregates. Most experiments were, therefore, performed at polymer concentrations around 0.150 g·dl^{-1} or 0.0093N.

Typical titration curves at different ionic strengths are shown in Fig. 1. As the ionic strength is higher, more carboxyl groups are ionized at a given pH, and the transition pH is more acid but the degree of ionization is higher. The latter indicates that the β-form is stabilized by the ionic atmosphere formed around charged groups, which is in accord with the previous results.[8,9]

The effect of temperature on the titration in 0.2M NaCl is shown in Fig. 2. The observed shift of the titration curve indicates that at higher temperature the β-form is less stable owing to the increased ionization.

Discussion

Electrostatic Free Energy and Polymer Conformation. Potentiometric titration of polyelectrolytes having a uniform distribution of ionizable groups can be described by the expression[14-16]

$$\mathrm{pH} - \log \frac{\alpha}{1-\alpha} = \mathrm{p}K_{\mathrm{int}} + \frac{0.434}{ZkT}\frac{\partial G_{\mathrm{el}}}{\partial \alpha} \qquad (1)$$

where $\mathrm{p}K_{\mathrm{int}}$ is the negative logarithm of intrinsic dissociation constant, Z the total number of ionizable groups in a molecule (or its associated from), and G_{el} is the electrostatic free energy of the molecule (or its associated form) with $Z\alpha$ ionized groups. Since the last term, $\partial G_{\mathrm{el}}/\partial(Z\alpha)$, represents the work necessary to remove a hydrogen ion from the molecule (or its associated form) with $Z\alpha$ charges, Eq. 1 may be written[17,18]

$$\mathrm{pH} - \log \frac{\alpha}{1-\alpha} = \mathrm{p}K_{\mathrm{int}} - 0.434\frac{\varepsilon\psi_0}{kT} \qquad (2)$$

where ε is the elementary charge and ψ_0 is the electrostatic potential at the molecular surface.

Figure 3 shows the modified plots, $\mathrm{pH} - \log \alpha/(1-\alpha)$ *vs.* α, at various ionic strengths. As was also noted in Fig. 1, each of the curves in Fig. 3 can be separated into at least three regions, corresponding to the random coil at higher α, the β-

form at lower, α, and the intermediate transition region. The portion of curves at very low α could not be traced down to $\alpha=0$, owing to its large curvature, to determine the pK_{int} value. However, the pK_{int} value seems to be considerably lower than that ($pK_{int}=4.5$) for poly-L-glutamic acid.[12,13] In fact, the δ-carboxyl group of the monomer, S-carboxymethyl-L-cysteine, has a pK value, 3.12, in 0.2M NaCl, as will be seen in Fig. 6 below. As there is no way for the extrapolation to $\alpha=0$, the pK_{int} value is assumed to be 3.00 for both random coil and β-form, irrespective of the ionic strength. Then the specific titration behavior of the polymer in each region may be accounted for by different electrostatic interactions, each characteristic of the conformation in that region. The electrostatic interaction or the electrostatic free energy has been evaluated for various systems, either analytically or numerically, using idealized model appropriate to the system.

Although a detailed structure of the β-form in solution is not known yet, its fundamental structure may be sheet-like, as in the solid, in which polypeptide chains are aligned and held together by inter- or intra-molecular hydrogen bonds. The two-dimensional hydrogen bonded structure can stack together through side chain interactions to form intersheet aggregates. To the first approximation or at some stage of its formation, the β-structure would have the sheet-like structure in solution. Then the β-form of ionized polypeptides in solution would be most adequately represented by a uniformyl charged plane, *i. e.*, by the Gouy model. The electrostatic potential at a charged plane dipped in an electrolyte solution is given by[19,20]

$$\psi_0 = \frac{2kT}{\varepsilon}\sinh^{-1}\frac{\kappa\sigma}{4n\varepsilon} \tag{3}$$

where σ is the surface charge density, n is the number concentration of salt, and κ is the Debye-Hückel parameter.

Charged groups in the present polymer are side chain carboxyls and they are directed to both sides of the molecular sheet alternately along with polypeptide chains or hydrogen bonds in the β-structure. Thus an electric double layer is formed at each side of the molecular sheet, and the area assigned to a charge should be twice as large as the area occupied by an amino acid residue, A_0. The surface charge density may be given by

$$\sigma = -(\varepsilon/2A_0)\,\alpha \tag{4}$$

Substitution of Eq. (4) into Eq. (3) leads to an expression for the surface potential of a charged β-form

$$\psi_0 = -\frac{2kT}{\varepsilon}\sinh^{-1}\frac{125\pi}{DN_AkT}\frac{\varepsilon\alpha}{A_0\sqrt{C_s}} \tag{5}$$

where C_s is the molar concentration of salt, D the dielectric constant of solvent, and N_A the Avog-

20) E J. W. Verwey and J. Th. G. Overbeek, "Theory of the Stability of Lyophobic Colloids," Elsevier Publishing Co., Inc., New York (1948).

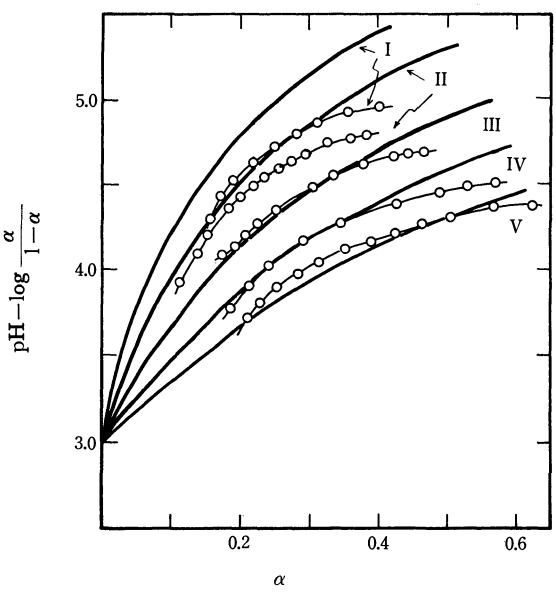

Fig. 4. Calculated and experimental titration curves of the β-form.
Thick curves are calculated by Eq. (6) with $pK_{int}=3.00$ and $A_0=16.8$ A². Circles show experimental values. NaCl concentrations (in M) are:

	I	II	III	IV	V	
C_s	0.01	0.02	0.05	0.10	0.20	(Calcd)
Initial	0.00	0.01	0.05	0.10	0.20	(Exp.)

adro number.

Thus the potentiometric equation for the charged β-form is obtained as

$$\mathrm{pH}-\log\frac{\alpha}{1-\alpha}=\mathrm{p}K_{\mathrm{int}}+0.868\sinh^{-1}\frac{125\pi}{DN_AkT}\frac{\varepsilon\alpha}{A_0\sqrt{C_s}} \quad (6)$$

This can be brought to direct comparison with experimental results. Assuming that pK_{int} is 3.00 and the area per residue, A_0, is 16.8 A², theoretical curves can be obtained for different C_s values. Figure 4 shows the calculated curves together with the experimental plots in the region of the β-form.

Agreement is rather good, except for the lowest ionic strength, if the use of the idealized model and the assumed values for the parameters are taken into account. At low ionic strengths, the effect of increase in ionic strength during the titration is considerably high. While the β-structure has not been well defined, the sheet-like structure postulated above would stack into a larger aggregate owing to the side-chain interaction. Only at the initial stage of its formation, *i. e.*, at pH far from the transition pH, the β-structure would be more like a sheet. Upon lowering pH, the intersheet aggregation would become predominant and cause the β-form to deviate from the sheet-like structure. In this sense, the agreement mentioned above appears to be fortuitous, and in fact, deviation is noticed in different curvatures between experimental and calculated curves.

Randomly coiled polyelectrolytes have been treated on the basis of various models, and the Poisson-Boltzmann equations have been solved by means of the Debye-Hückel approximation or electronic computors. Among them, Kotin and Nasasawa[21] obtained computor solutions, postulating a rod-like model for a charged random coil, and found that the titration data of polyacrylic acid and polymethacrylic acid could be described by these solutions.[21,22] Although no precise comparison has been made, the present titration data at higher ionization appear to conform to the Kotin-Nagasawa solution, if the pK_{int} value is assumed to be 3.00 and the molecular dimension is properly chosen.

Standard Free Energy for the Coil-β Transition. The pH-induced transition of the polymer is of electrostatic one, and the process bringing polymer molecules from an uncharged β-form to fully charged random coils can be divided into two steps: first, transforming the uncharged molecules from β-form to random coils and secondly, charging up the random coil molecules. More significant in the discussion of conformational change is the free energy charge accompanying the first step, *i. e.*, the charge-independent part, which will be denoted by $-\Delta G^0_{c\to\beta}$ per residue.

The second step, during which random coils are being charged, yields a free energy change per residue

$$dG^{(c)}=2.30\,kT\left(pK^{(c)}-pH^{(c)}+\log\frac{\alpha}{1-\alpha}\right)d\alpha \quad (7)$$

where $pK^{(C)}$ is the pK in the random coil form and $pH^{(C)}$ is the pH of the hypothetical random coil solution. The free energy change per residue accompanying the ionization process through the actual titration course can be expressed by

$$dG=2.30kT\left(pK-pH+\log\frac{\alpha}{1-\alpha}\right)d\alpha \quad (8)$$

where pK is the apparent pK in the actual polymer. In equilibria, Eqs. (7) and (8) lead to the Henderson–Hasselbach equations, respectively, which permit the calculation of the pK values from titration data.

It follows from an earlier statement that a thermodynamic relation

$$\Delta G=-\Delta G^0_{c\to\beta}+\Delta G^{(c)} \quad (9)$$

holds for integrated values of the above quantities. Equation (9) can be written as

21) L. Kotin and M. Nagasawa, *J. Chem. Phys.*, **36**, 873 (1962).
22) M. Nagasawa, T. Murase and K. Kondo, *J. Phys. Chem.*, **69**, 4005 (1965).

$$\Delta G^0_{c\to\beta} = 2.30\,kT\int_0^1 (pK^{(c)} - pK)\,d\alpha \qquad (10)$$

$$= 2.30\,kT\int_0^1 (pH^{(c)} - pH)\,d\alpha \qquad (11)$$

Equations (10) and (11) provide methods of evaluating charge-independent part of the free energy of transition.

The methods of evaluating the transition free energy have been presented by Zimm and Rice,[11] Nagasawa and Holtzer,[14] and Leyte and Mandel.[23] The helix-coil transitions of poly-L-glutaimc acid,[14,14-26] poly-L-lysine,[25] and copolymers of L-leucine and L-glutamic acid[24] were treated by these methods, and an undefined conformational transition of polymethacrylic acid[23] was also examined in the same way. From the method of derivation it is clear that Eqs. (10) and (11) have a general validity for any conformational change, even if it accompanies an association-dissociation equilibrium.

Equation (10) was applied to the present coil-β transition to estimate the charge-independent part of transition free energy. Graphical integration was performed on the modified titration curve such as shown in Fig. 3, after both coil and β-form regions, drawn in solid curves, were extrapolated to lower ionization in such a way to give an identical pK_{int} value (3.00) at $\alpha=0$. The values of $\Delta G^0_{c\to\beta}$ obtained

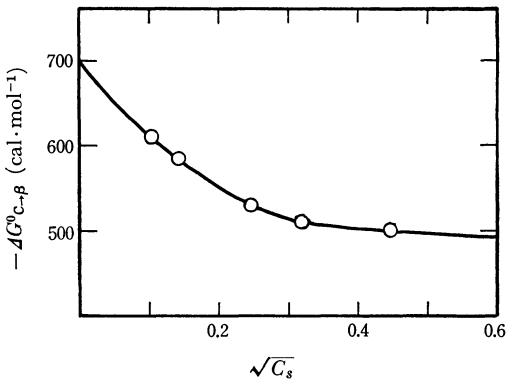

Fig. 5. Dependence of $-\Delta G^0_{c\to\beta}$ on the square root of ionic strength.

are plotted against the square root of ionic strength in Fig. 5. The charge-independent part of transition free energy is still dependent on the ionic strength, as was also observed in the helix-coil of transition, of poly-L-glutamic acid,[14] and varies from -700 cal mol^{-1} in water to -480 cal mol^{-1} at higher ionic strength. These values suggest that the β-form of unionized poly-S-carboxymethyl-L-cysteine is generally much more stable than the

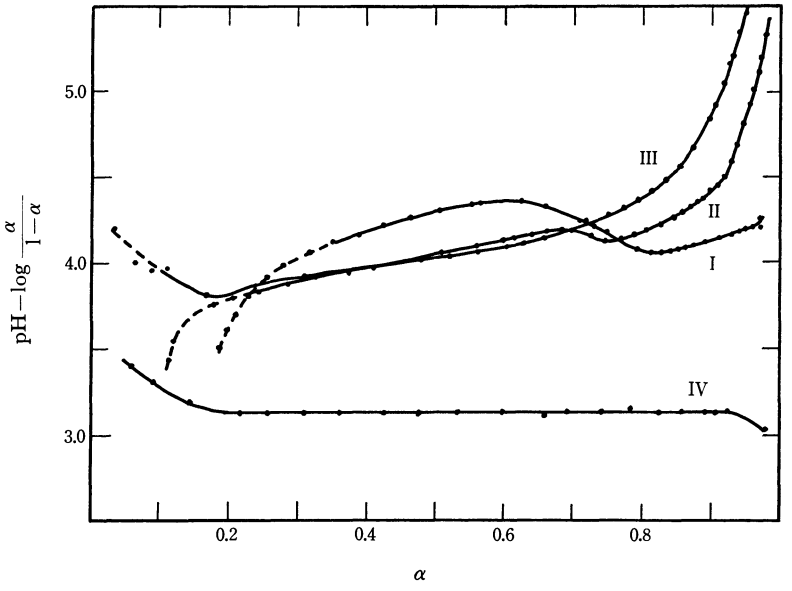

Fig. 6. Modified titration curves for different samples in 0.2M NaCl.

α-helix of unionized poly-L-glutamic acid,[14,24-26] relative to their random coil forms. However, this conclusion can not be extended to the other poly-S-carboxymethyl-L-cysteine samples, because of marked molecular weight dependence of $\Delta G^{2}_{C\to\beta}$, as will be shown below.

The coil-β transition of the polymer in 0.2M NaCl was also examined at different temperatures, as illustrated in Fig. 2, and the charge-independent transition free energy was estimated at each temperature. Rough estimates lead to a corresponding transition enthalpy of about -2.4 kcal mol^{-1} and a transtion entropy of -6.5 e.u., giving a transition temperature around 100°C. Both negative values obtained would reflect the nature of hydrogen bonding and hydrophobic interaction.

The Effect of Molecular Weight upon the Titration Behavior. Figure 6 shows modified plots of titration curves for three samples of poly-S-carboxymethyl-L-cysteine in 0.2M NaCl, together with that for δ-carboxyl group of its monomer, S-carboxymethyl-L-cysteine, in 0.2M NaCl. The three polymer samples differ from one another in their molecular weight, as revealed in their intrinsic viscosity of random coil form.

It can be seen that the δ-carboxyl group of the monomer has a constant pK value, 3.12, reasonably close to the pK_{int} value assumed for the polymers. The lowest molecular weight sample, E515, does not show any sharp transition region on its titration curve. Its rotatory properties have shown only trivial changes with pH,[9,10] in accordance with the titration result. Berger, Noguchi and Katchalski[27] have reported that titration curves of poly-S-carboxymethylcysteine prepared by other synthetic methods can be described by the Linderstrøm-Lang equation, suggesting the absence of clear transition region.

With increasing molecular weight, the transition region becomes more distinct. The molecular weight dependence of titration behavior is considerably stronger at higher ionization, where random coil forms are predominant. At lower ionization, however, no such regular dependence is observed. If the charged β-form could be represented by the Gouy model, in which hydrogen-bonded polypeptide chains would form an infinitely extended sheet, its titration behavior would not depend on the molecular weight of constituent polymer. Thus the observed molecular weight dependence indicates deviation of the β-structure from an infintely extended sheet model. The sheet structure of the β-form would have a finite size with appreciable edge effect, which would depend on the chain length of polymer. More possibly, the sheet-like structures would form a globular aggregate by side chain interaction.

The charge-independent transition free energy of these three polymer samples was estimated by Eq. (10) and found to be -80 ± 80 cal mol^{-1} for E515, -180 cal mol^{-1} for E527, and -500 cal mol^{-1} for E602, in 0.2M NaCl at 25°C. The uncharged β-form is less stable as the molecular weight becomes smaller. It is not yet known whether such dependence of stability of β-form is extended to a higher molecular weight range. However, it is conceivable that the dependence reflects variations of a detailed structure of the β-form and its mode of aggregation with polymer chain length and is closely related with the intermolecularly associated structure of the β-form.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1693—1703 (1970)

Determination of the Molecular Structures of AsF_3 and $AsCl_3$ by Gas Electron Diffraction*1

Shigehiro KONAKA and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received January 8, 1970)

The thermal-average distances and mean amplitudes of $AsCl_3$ and AsF_3 have been determined by gas electron diffraction. The sources of experimental errors have been discussed in detail. The observed molecular parameters are r_g(As–Cl)$=2.1621\pm0.0033$ Å, θ_g(ClAsCl)$=98°\ 34'\pm34'$, l(As–Cl)$=0.0470\pm0.0024$ Å, l(Cl–Cl)$=0.0945\pm0.0063$ Å, r_g(As–F)$=1.7089\pm0.0016$ Å, θ_g(FAsF)$=95°53'\pm22'$, l(As–F)$=0.0433\pm0.0022$ Å, and l(F–F)$=0.0689\pm0.0044$ Å. The results have been compared with the structures of other trihalides of the Vb-group elements.

The interatomic distances of AsF_3 and $AsCl_3$ were first observed by the visual method of electron diffraction. Those previous results are summarized in Table 1. The bond angle of AsF_3 was not determined. Kisliuk and Townes[4] measured the rotational constants of $As^{35}Cl_3$ and $As^{37}Cl_3$ by microwave spectroscopy and obtained the r_s(As–Cl) distance of 2.161 ± 0.004 Å and the bond angle of $98°25'\pm30'$.

TABLE 1. MOLECULAR STRUCTURES OF $AsCl_3$ AND AsF_3 DETERMINED BY THE VISUAL METHOD OF ELECTRON DIFFRACTION

r (As–Cl)	∠ ClAsCl	r (As–F)	Ref.
2.18 ± 0.03 Å	$101°\pm40'$		1
2.16 ± 0.03 Å	$103°\pm3°$	1.72 ± 0.02 Å	2
2.17 ± 0.02 Å	$99°\pm2°$		3

The molecular structure of AsF_3, however, could not be determined uniquely from the rotational constant observed in the microwave study of Kisliuk and Geschwind,[5] for no isotope of the fluorine atom was present. They estimated the bond angle of AsF_3 to be $102\pm2°$ by a comparison of the observed quadrupole interaction constant of AsF_3 with that of $AsCl_3$, and determined the r_0(As–F) distance to be 1.712 ± 0.005 Å.

Recently, Mirri[6] obtained the centrifugal distortion constants, D_j and D_{jk}, as well as the rotational constant, B_0, his values agreeing with the results of Kisliuk and Geschwind, by an analysis of the millimeter-wave rotational spectrum of AsF_3. She determined the quadratic potential constants of AsF_3 from the observed centrifugal distortion constants and the four observed vibrational frequencies. Then, she calculated the Coriolis coupling constant, ζ_4, from the potential constants and compared it with those determined by studies of the band envelope of infrared spectra.[7,8] It was found that the calculated and the observed values of ζ_4 did not agree well unless the bond angle of AsF_3 was in the range of $99\pm1°$. Mirri assumed the angle to be 98° by referring to the 98.5° of $AsCl_3$,[4] and she obtained 1.708 Å for the As–F distance. However, it is most desirable to determine the molecular structure of AsF_3 directly; her method is still indirect.

The molecular structures derived directly from the observed rotational constants, B_0, include the effect of the interaction of the vibration and the rotation, so they have no definite physical meaning. Although this effect is not large, it can not be neglected in determining molecular structures in the order of one-thousandth of an Angstrom. On the other hand, the interatomic distances obtained by gas electron diffraction are the thermal averages of instantaneous interatomic distances. It is the principal purpose of the present study to determine the accurate structures of AsF_3 and $AsCl_3$ by gas electron diffraction.

Experimental

The diffraction apparatus used in the present study was designed and constructed by Murata, Kuchitsu, and Kimura.[9] The camera length was fixed at 10.930 cm. In order to measure the accurate value of the scale factor, the diffraction patterns of CS_2 molecules, the precise structure of which had been given by spectroscopy,[10,11] were taken just before or after those of the samples.

Research-grade arsenic trichloride (above 99% pure) obtained from the Yamanaka Chemical Industry, Inc., was used as the sample. The experimental conditions were as follows: accelerating voltage, about 45 kV; sample pressure, about 4 mmHg; exposure time, 3—4 minutes; electron-beam current, about 0.15 μA, and nozzle temperature, about 18°C. The vacuum in the diffraction chamber was about 6×10^{-5} mmHg during exposures.

A sample of arsenic trifluoride in a polyethylene bottle was obtained from the K and K Laboratories, Inc., of the United States. It was transferred into a sample holder made of glass just before taking photographs. Since arsenic trifluoride (mp −6°C) reacts to some extent with glass, the sample was solidified at about −10°C and evacuated by a rotary pump to eliminate any possible impurities such as SiF_4 (mp −90°C). The experimental conditions were as follows; accelerating voltage, about 52.5 kV; sample pressure, about 10mmHg; exposure time, 70—100 sec; electron-beam current, about 0.15 μA, and nozzle temperature, about 19°C. The vacuum pressure was about 8×10^{-5} mmHg during exposures.

Photographs taken on Fuji-Process Hard plates were developed at 20°C for five minutes with an FD-131 developer diluted twice in volume.

The plates were spun rapidly about the centers of the diffraction patterns, while optical densities were measured with an NLM-VII microphotometer. In the case of $AsCl_3$, the densities were read out at integral q values from 20 to 130 from the density curves recorded on charts. A value taken from one side and the corresponding value from the other side were averaged, point by point, in order to diminish the errors due to the uncertainty as to the center position of the chart.

In the case of AsF_3, the densities were measured with a digital microphotometer*2 at intervals of $\Delta R=1/3$ mm along the diameters of the concentric patterns. The q value corresponding to the distance, R, on a plate from its center was calculated as:

$$q = \left(\frac{40}{\lambda}\right)\sin\left(\frac{1}{2}\tan^{-1}\left(\frac{R}{L}\right)\right) \qquad (1)$$

where λ is the wavelength of the incident electron beam and where L is the camera length. The two sides of the photometer curve were analyzed independently.

The relation between the optical densities and the scattering intensities of the electrons was investigated by the use of two selected plates of AsF_3. The ratio of the densities for the same q value of the two plates was about 1.5. The density-intensity curve obtained by Karle's method[13] fit the $E=D\ (1+0.03D)$ relation with a good approximation. A linear relation between the density and the intensity was assumed for the case of $AsCl_3$. The systematic errors caused by this assumption will be discussed in a later section.

The intensities were corrected for the deviation of the rotating sector from the ideal r^3-shape.

Five plates for $AsCl_3$ and six plates for AsF_3 were selected for analysis. The number of CS_2 plates used for determination of the scale factors were four and five for $AsCl_3$ and AsF_3 respectively.

Analysis of Data

The intensities were levelled by smooth functions based on the theoretical backgrounds. Smooth background curves, I_B, were first drawn arbitrarily through the total intensity curves, I_T, thus obtained. The molecular intensities, $qM(q)$, were calculated as $q(I_T-I_B)/I_B$. The theoretical expression of $qM(q)$ may be written, with notations of the usual significance,[14] as follows:

$$qM(q) = k\sum_{i\neq j} A_{ij}\mu_{ij}\cos\Delta\eta_{ij} \times\sin\left\{\frac{\pi}{10}q\left(r_{aij}-\left(\frac{\pi}{10}q\right)^2\kappa_{ij}\right)\right\} \times\exp\left\{-\frac{1}{2}\left(\frac{\pi}{10}q\right)^2 l_{ij}^2\right\}. \qquad (2)$$

The r_a distance is an apparent interatomic distance; it can easily be converted into the thermal-average distance, r_g, as follows:[15]

$$r_g = r_a + \frac{l^2}{r_a}. \qquad (3)$$

The elastic scattering factors were calculated by the partial-waves method from the Hartree-Fock potentials.[16] The inelastic scattering factors, also based on the Hartree-Fock potentials, were taken from the table presented by Tavard *et al.*[17] They were used to compute $\mu_{ij}\cos\Delta\eta_{ij}$ and the theoretical

backgrounds. In order to revise the background curves, radial distribution curves (RD curves) were calculated as the following Fourier integral:

$$f(r) = \int_0^{q_{max}} (qM(q)_{obs} + \Delta qM(q)) \sin\left(\frac{\pi}{10} qr\right) \times \exp(-bq^2)\, dq. \quad (4)$$

The correction, $\Delta qM(q)$, was added to use the non-negativity criterion of the RD curves as:[13,18]

$$\Delta qM(q) = k \sum_{i \neq j} A_{ij}(g_{ij} - \mu_{ij} \cos \Delta\eta_{ij}) \times \sin\left\{\frac{\pi}{10} q \left(r_{aij} - \left(\frac{\pi}{10} q\right)^2 \kappa_{ij}\right)\right\} \times \exp\left\{-\frac{1}{2}\left(\frac{\pi}{10} q\right)^2 l_{ij}^2\right\}, \quad (5)$$

$$\begin{aligned} g_{As-Cl} &= \cos(0.0072\, q), \\ g_{Cl-Cl} &= 1.11, \\ g_{As-F} &= 0.7 \cos(0.0095q) + 0.5 \exp(-5 \times 10^{-4} q^2), \\ g_{F-F} &= 1.25 \exp(-3 \times 10^{-6} q^2) + 0.65 \exp(-10^{-3} q^2). \end{aligned} \quad (6)$$

The g functions were so chosen that the correction terms, $\Delta qM(q)$, were small compared with $qM(q)_{obs}$. In practice, the background curves were revised by the inverse Fourier transformation of $f(r)$ in the range of r ($r \leqq 1$ Å). At small q values where $qM(q)$ could not be observed, theoretical values were used. The artificial damping factor, b, was so chosen as to reduce the molecular intensity to one-tenth of the original value at q_{max}.

One of the I_T curves and its I_B curve thus obtained are shown in Fig. 1 for both $AsCl_3$ and AsF_3. The values of I_B express approximately the ratio between the observed and the theoretical background intensities. At small scattering angles, the ratio is smaller than unity. This is mainly due to the errors in the sector correction curve, and it has no effect on the molecular parameters. The gradual increase in the ratio at large scattering angles ($q \geqq 90$) is due to extraneous scattering. This may cause a slight increase in the observed values of mean amplitudes. The molecular intensities, $qM(q)_{obs}$, were then multiplied by the ratio in order to eliminate errors caused by the extraneous scattering.

The index of resolution, k, and the molecular parameters, r_{ij} and l_{ij}, were determined by the least-squares fitting of the observed $qM(q)$ to its theoretical expression. The anharmonicity parameters were fixed. The anharmonicity parameters for bonded pairs were estimated in the diatomic approximation as;[19]

$$\kappa_{As-Y} = \left(\frac{1}{6}\right) a_3 \left(1 + \frac{8\kappa}{(1+\kappa)^2}\right) l_{As-Y}^4, \quad (7)$$

where:

$$\chi = \exp\left(\frac{h\nu_{As-Y}}{kT}\right). \quad (8)$$

Here, the anharmonicity parameter of the Morse function, a_3, was assumed to be 2.0 Å^{-1} and the characteristic frequencies, ν_{As-Y}, were taken to be 400 and 721 cm^{-1} for $AsCl_3$ and AsF_3 respectively.[20,7] The estimated values were 3.6×10^{-6}

and 1.2×10^{-6} Å^3 for κ_{As-Cl} and κ_{As-F} respectively. The anharmonicity parameters, κ_{Y-Y}, for non-bonded paris were assumed to be zero, since no simple method of estimating them was available and since their values could be expected to be of the same order as κ_{As-Y} or less.

The weights of the observed values for least-squares fitting were reduced at small scattering angles because of the uncertainty in the correction curve for the sector shape; those at large scattering angles were also taken to be small because of extraneous scattering. The following from was assumed for AsF_3:

$$\begin{aligned} P(N) &= \exp(-a(N-N_1)^2), & 1\leqq N\leqq N_1 \\ P(N) &= 1.0, & N_1\leqq N\leqq N_2 \\ P(N) &= \exp(-b(N-N_2)^2), & N_2\leqq N \end{aligned} \quad (9)$$

where N shows the numbering of the observed data.

(b)

Fig. 2. Molecular intensities (dots for observed values and the solid curve for the best-fit theoretical intensity), the residuals and the weight function used.
(a) $AsCl_3$ and (b) AsF_3.

Errors due to the arbitrariness of the weights were estimated by using several sets of weight functions which had been obtained by changing the parameters, a, b, N_1, and N_2, in the least-squares treatment.

In the case of AsF_3, the analysis was repeated by correcting the positions of the centers of the photometer curves until the interatomic distances obtained from the two sides of each curve showed satisfactory agreement.

A program for the HITAC 5020E electronic computer was written which allowed for automatic computation from the density-intensity transformation to the least-squares fittings. The analysis for AsF_3 was made by using this program. The average time needed for one computation was about 7 sec. The theoretical values of the μ factors and the levelling function were calculated for the observed points by interpolation of the input data, which had been calculated beforehand for the integral values of q by another program.

Examples of the observed molecular intensities and their best-fit curves are shown in Fig. 2, along with the weight function used.

The analysis of the diffraction patterns for CS_2 was made according to the same procedure as that employed for the samples. Five plates for $AsCl_3$ were numbered from I to V, and six plates for AsF_3 were numbered from I to VI. The wavelength for each plate and the number of CS_2 plates employed were as follows: 0.05539 ± 0.00007 Å for the $AsCl_3$ plates I and II, two CS_2 plates; 0.05626 ± 0.00005 Å for the $AsCl_3$ plates from III to V, two CS_2 plates; 0.05217 ± 0.00003 Å for the AsF_3 plates from I to III, three CS_2 plates; 0.05214 ± 0.00004 Å for the AsF_3 plates from IV to VI, two CS_2 plates.

The above values of the wavelengths for the sample plates had, however, to be corrected if the accelerating voltage had drifted during the experimental sequence. The drift of the accelerating voltage was monitored throughout the experiment. Such corrections for the wavelengths were found unnecessary for the $AsCl_3$ plates I, II and IV, but those of about 0.26% and −0.05% were found necessary for the plates III and V respectively by measuring the load current of the high-voltage source. The drift for AsF_3 was confirmed to be less than 0.01% by measuring the voltage drops of the standard resistance in the high-voltage source by the use of a digital voltmeter. The results of the least-squares analyses, corrected for scale factors, are shown in Table 2, along with the averages of standard deviations, $\bar{\sigma}$.

The mean amplitudes and the shrinkage, δ_g, which is defined as $\delta_g=2r_g(\text{C-S})-r_g(\text{S-S})$,[21] observed for CS_2 are shown in Table 3, along with the errors. The method of estimating the errors will be described in a later section. The observed values are close to those calculated from the spectroscopic data.[11]

Error Analysis

1) Estimation of Random Errors. Experimental random errors are introduced mainly in the process of photographing, development, and photometry. Random errors can be estimated from the standard deviations in the least-squares treatment (σ_1) and from the fluctuation among the results on several plates (σ_2).[22] The standard deviations, σ_1,

21) Y. Morino, J. Nakamura and P. W. Moore, *J. Chem. Phys.*, **36**, 1050 (1962).

22) Y. Morino, K. Kuchitsu and Y. Murata, *Acta Crystallogr.*, **18**, 549 (1965).

associated with the average values in Table 2 were estimated to be $\bar{\sigma}/\sqrt{N}$, where N is the number of plates, since the individual standard deviations for all the plates were nearly equal. The standard deviations, σ_2, are defined by $\sqrt{\sum_{i=1}^{N}(x_i-\bar{x})^2/N(N-1)}$. Random errors corresponding to a 99% confidence interval have so far been taken to be 2.5 times the larger of σ_1 and σ_2.[14,22] It seems, however, more reasonable to estimate them from either 2.58 times σ_1, or 4.60 ($N=5$) or 4.03 ($N=6$) times σ_2, according to Student's t-distribution.[23] If σ_1 and σ_2 are of nearly equal magnitude, 2.58 σ_1 can be taken as the confidence interval, because all the observations on N plates are considered to belong to a single statistical population, as has been discussed by Morino *et al.*[22] When σ_2 is considerably larger than σ_1, the confidence interval should be estimated from σ_2 and the t-value depending on N. Since σ_2 is equal to, or slightly smaller than, σ_1 for almost all the parameters in the present analysis, 2.58 σ_1 was chosen as the random error corresponding to the 99% confidence interval.

2) Estimation of Systematic Errors for Interatomic Distances. The sources of systematic errors taken into consideration were as follows:

a) The Uncertainty in the Camera Length.

b) The Uncertainty in the Scale-magnification Ratio on the Microphotometer Trace.[24] The above two errors are, however, negligible because of the use of the reference sample (CS_2).

c) Errors in the Determination of the Center of the Microphotometer Trace. These errors are also negligible since, in the case of AsF_3, both sides of the photometer trace were analyzed and the results from both sides averaged, and in the case of $AsCl_3$ the corresponding densities of both sides were averaged.

d) The Finite Size of the Light Beam on Microphotometry. This effect was discussed by Kuchitsu.[24] In the present experiment, the size of the light beam was 0.03 mm × 0.1 mm. The inward shift of the halo of the radius, R (mm), is about $(0.1)^2/24R$ in mm units, which is about 0.001% of R even at $R=6$ mm. Thus, this effect is completely negligible.

e) Errors Due to Averaging Densities over a Scanning Length of About 0.1 mm on the Plate on Microphotometry. In the case of AsF_3, the optical density obtained on microphotometry is the average of densities over a range of about 0.1 mm on the plate.*3 The effect of such an averaging process on molecular-parameter values may be estimated as follows. The average of the molecular intensity is given by the following integration:

$$M=\frac{1}{2\Delta R}\int_{R_0-\Delta R}^{R_0+\Delta R}\exp\left(-\frac{1}{2}l^2s^2\right)\frac{\sin sr}{sr}\,dR \qquad (10)$$

Here s is a function of the scanning length, R, measured from the center of the photographic plate and ΔR is half of the range over which the average is taken. By noting that s is proportional to R in a good approximation, Eq. (10) can be transformed into the following equation by neglecting higher-order terms than $(\Delta R/R_0)^2$:

$$M=\exp\left(-\frac{1}{2}l^2s_0^2\right)\frac{\sin s_0r}{s_0r}\left[1+\frac{1}{6}\left(\frac{\Delta R}{R_0}\right)^2\times\{(ls_0)^4-(rs_0)^2-2(l^2s_0^2+1)s_0r\cot s_0r\}\right] \qquad (11)$$

This can be rewritten in the same order of approximation as follows:

$$M=(1+\Delta k)\exp\left\{-\frac{1}{2}(l+\Delta l)^2s_0^2\right\}\frac{\sin s_0(r+\Delta r)}{s_0(r+\Delta r)} \qquad (12)$$

where:

$$\Delta k=-\frac{1}{6}\left(\frac{\Delta R}{R_0}\right)^2(s_0r)^2, \qquad (13)$$

$$\frac{\Delta l}{l}=\frac{1}{6}\left(\frac{\Delta R}{R_0}\right)^2(s_0l)^2, \qquad (14)$$

and:

$$\frac{\Delta r}{r}=-\frac{1}{3}\left(\frac{\Delta R}{R_0}\right)^2((s_0l)^2+1). \qquad (15)$$

Since the value of $\Delta Rs_0/R_0(=\Delta s)$ is about 0.05 Å^{-1} for the accelerating voltage of 52.5 kV, the apparent decreases of interatomic distances are about 0.001% for both As–F and F–F distances; both are negligible.

f) Errors Involved in the Determination of the Scale Factors. They were estimated to be 0.14% and 0.07% for $AsCl_3$ and AsF_3 respectively from the standard errors corresponding to the 99% confidence interval of the C–S and S–S distances in the least-squares treatment of CS_2 and from the drift of the accelerating voltage while taking photographs of CS_2 and the samples.

g) Errors Due to Uncertainty in the Parameter, κ. The uncertainties for the κ values were estimated to be 1, 8, 0.6, and 4×10^{-6} Å^3 for As–Cl, Cl–Cl, As–F, and F–F respectively, values which correspond to uncertainties of 0.0004, 0.0016, 0.0002, and 0.0014 Å in the respective distances.

h) Errors Due to Uncertainty in the Correction Curve for the Sector Shape. They include errors due to small pieces of dust which might have been at the edge of the sector during the experiment. They were estimated by changing the sector correction curve over the range of small scattering angles ($q\leqq40$).

i) Errors Due to the Delocalization of the Sample

23) J. Bass, "Elements of Probability Theory," Academic Press Inc., New York (1966), p. 214.

24) K. Kuchitsu, This Bulletin, **32**, 748 (1959).

*3 In the microphotometry of AsF_3, photographing plates were moved at the speed of about 0.025 mm/sec, while the intensities of light passing through the plates were integrated for 4 seconds by using a digital voltmeter.[12]

Gas. Scattering from unlocalized gas causes an apparent increase in the interatomic distances.[25] If the decrease in the index of resolution from unity is assumed to be due completely to the samlpe delocalization in the diffraction chamber, the apparent increase in interatomic distances can be estimated as follows:[25]

$$\frac{\Delta r}{r} = \frac{[3(1-k)/k]}{[20+(sr)^2]} \tag{16}$$

By taking the effective value of s to be 15 $Å^{-1}$, the values listed in Table 4 were obtained for $AsCl_3$ and CS_2, and for AsF_3 and CS_2. The corrections for r_a distrances were estimated to be as shown in Table 9. The errors associated with this correction were taken to be 0.02%.

Table 4. Apparent increases of the interatomic distances ($\Delta r/r$) due to the delocalization of sample gas for $AsCl_3$ and CS_2, and AsF_3 and CS_2

r(As-Cl)	r(Cl-Cl)	r(C-S)	r(S-S)
0.04%	0.02%	0.06%	0.02%

r(As-F)	r(F-F)	r(C-S)	r(S-S)
0.04%	0.02%	0.05%	0.01%

Table 5. Estimation of errors for r_a distances (in 10^{-4} Å unit)

j) Errors Due to Arbitrariness of the Background Curves. The errors were estimated by changing the artificial damping factor and the range of the inverse Fourier transformation.

k) Errors Due to Arbitrariness of the Weight Function. They were estimated by changing weight functions.

The errors for interatomic distances are summarized, along with the total errors, in Table 5.

3) Estimation of Systematic Errors for Mean Amplitudes. *a) Effect of the Finite Sample Size.* The finite sample size causes an apparent increase in the mean amplitudes.[26] The distribution of gaseous molecules spouted from the nozzle depends mainly on the distance, a, from the top of the nozzle to the main beam, the diameter, b, of the nozzle aperture and the viscosity of the gas.

The distribution of silicon tetrachloride molecules jetted from the needle-type nozzle (a=0.41 mm and b=0.55 mm) was investigated by Morino and Murata.[26] The distribution function obtained by their experiments was:

$$f(x) = \left(\frac{2.74}{2}\right) \exp(-2.74\,|x|) \tag{17a}$$

for $|x| \leqq 0.7$, and:

$$f(x) = 0.356 \exp(-1.59x) \tag{17b}$$

for $|x| \geqq 0.7$, where x is the distance in millimeters measured from the center of the nozzle inlet along the direction of the beam. Since the nozzle type with a diameter of 0.2 mm was used at a=0.4 mm in the present experiment, more localization of gas molecules may be expected than in their experiment. The following distribution function was, therefore, tentatively assumed:

$$f(x) = 1.5 \exp(-3\,|x|). \tag{18}$$

The apparent increase in the mean amplitudes estimated from this distribution is:

$$\Delta l_{ij} = \frac{r_{ij}^2}{l_{ij}} \frac{1}{(3L)^2} \tag{19}$$

where L is the camera distance in millimeters. Numerical values of Δl_{ij} for $AsCl_3$, AsF_3, and CS_2 are tabulated in Table 6. The errors associated with this correction were taken to be 70% of the correction. The values of CS_2 corrected for this effect are shown in Table 3.

b) Errors for Density-Intensity Calibration. For AsF_3, they were estimated by changing the parameter c from 0 to 0.5 in the relation, $E/D=(1+cD)$.

25) L. S. Bartell, *J. Appl. Phys.*, **31**, 252 (1960).
26) Y. Morino and Y. Murata, This Bulletin, **38**, 114 (1965).

Because a linear relation ($c=0$) was assumed in the analysis of the $AsCl_3$ data, the effect of the parameter c on the mean amplitudes was examined by the reanalysis of the densest plate ($D_{max}=0.8$) of $AsCl_3$. By taking 70% of the correction for this plate as the average values of the mean amplitudes, they were estimated to be 0.0002 Å and 0.0001 Å for As–Cl and Cl–Cl respectively. The uncertainties of this correction were estimated to be as is shown in Table 7.

c) Errors for Averaging Densities over a Scanning Length of About 0.1 mm on the Plate on Microphotometry. This effect was considered in the previous section. The apparent increase in the mean amplitudes of AsF_3 is smaller than 0.0005%; this effect is thus found to be completely negligible.

d) Corrections for Extraneous Scattering. The correction was made in the analysis. The errors for this correction were estimated to be 70% of the correction.

e) Errors Due to the Uncertainty of the Atomic Scattering Factors. Since the complex scattering factors based on the Hartree-Fock atomic potentials were used, these errors would be small. Their estimated values are shown in Table 7.

f) The Drift of the Wavelength of the Incident Electron during Exposure for One Plate. For the plates III, IV, and V of $AsCl_3$, a slight drift of accelerating voltage was observed; its effect on the molecular parameters must be investigated. If the wavelength is assumed to have drifted from $\lambda_0-\Delta\lambda$ to $\lambda_0+\Delta\lambda$ during one exposure, the observed molecular intensity is given by;

$$M=\frac{1}{2\Delta\lambda}\int_{\lambda_0-\Delta\lambda}^{\lambda_0+\Delta\lambda}\exp\left(-\frac{1}{2}l^2s^2\right)\frac{\sin sr}{sr}\,d\lambda \qquad (20)$$

where s is a function of λ. By expanding this equation into the power series of $(\Delta\lambda/\lambda_0)$ and by neglecting the higher order terms than $(\Delta\lambda/\lambda_0)^2$, it can be rewritten in the following form;

$$M = \exp\left(-\frac{1}{2}l^2s_0^2\right)\frac{\sin s_0 r}{s_0 r}\left[1-\frac{1}{6}\left(\frac{\Delta\lambda}{\lambda_0}\right)^2 \times \{(s_0 l)^2+(s_0 l)^2\cot s_0 r+(s_0 r)^2-(s_0 l)^4\}\right] \quad (21)$$

Therefore, an apparent increase in the mean amplitude is given approximately as:

$$\Delta l = \frac{1}{6}\left(\frac{\Delta\lambda}{\lambda_0}\right)^2\frac{r^2}{l}. \quad (22)$$

Since the value of $\Delta\lambda/\lambda_0$ was 0.2% at most, the corrections for the mean amplitudes of $AsCl_3$ are 0.0001 Å or less. The effects on interatomic distances can also be completely ignored.

The following three kinds of systematic errors were estimated in the same way as has been described for the case of interatomic distances:

g) Errors Due to the imperfection of the correction curve for the sector shape.

h) Errors Due to the arbitrariness of the backgrounds.

i) Errors Due to the arbitrariness of the weight func-

tion. The systematic errors for the mean amplitudes are summarized in Table 7, together with the total errors.

The systematic errors for the index of resolution were estimated to be as shown in Table 8. The deviation of the indices of resolution from unity is considered to be due mainly to the extraneous scattering, which raises the background intensities uniformly over the whole observed range of scattering angles. This extraneous scattering is certainly caused partly by the delocalization of the sample gas in the diffraction chamber and partly by the reflection of scattered electrons by the chamber walls.

Results and Discussion

The corrections necessary for obtaining thermal average distances from the interatomic distances given in Table 2 are listed in Table 9. The final values of the r_g distances, the mean amplitudes, and the indices of resolution are tabulated in Table 10. The θ_g(YAsY) bond angles were calculated by the relation:*4

$$\sin\left(\frac{\theta_g}{2}\right) = \frac{r_g(\text{Y-Y})}{2r_g(\text{As-Y})} \tag{23}$$

The bond angle of $AsCl_3$ is close to the microwave value, but that of AsF_3 is about 6° smaller than Kisliuk's value and 2° smaller than Mirri's value.*5 The molecular structures are compared with those of other arsenic trihalides in Table 11.[28-36] They vary gradually with the atomic numbers of halogens.

The molecular structures of the other trihalides of the Vb-group elements XY_3 are also shown in Table 11. The bond distances, r_{X-Y}, are shorter than the sum of the covalent radii*6 (r_X+r_Y) in almost all cases. Figure 3 shows the shortenings $(r_X+r_Y-r_{X-Y})$ plotted against the differences in electronegativities $|x_X-x_Y|$ taken from the literature.[38] The curve can be roughly expressed by the $(r_X+r_Y-r_{X-Y})=0.06\,(x_X-x_Y)^2$ relation. Aside from the causes of these bond shortenings, this relation shows that the bond shortening varies rather regularly with the difference in electronegativity.

(a) $AsCl_3$ 45 keV and (b) AsF_3 52.5 keV.

*4 Strictly speaking, the bond angles thus obtained are not necessarily equal to the thermal average of the bond angles. It is likely, however, that the difference is, in the present case, much smaller than the experimental uncertainty. K. Kuchitsu, private communication.

*5 The present finding for the structure of AsF_3 is consistent with the recent gas electron diffraction finding obtained independently by Clippard and Bartell.[27]

The bond angles decrease with the increase in the electronegativity of halogens relative to Vb-group atoms as is shown in Fig. 4. This is in accordance with the valence-shell electron-pair repulsion theory of Gillespie,[39] as discussed by Morino *et al.*[29]

The values of the parameters listed in Table 10 were obtained by using the Hartree-Fock scattering factors ($f_{H.F.}$), which are better than the Thomas-Fermi-Dirac scattering factors ($f_{T.F.D}$).[16] Since $f_{H.F.}$ factors are not available for atoms heavier than krypton, it is worthwhile looking at the changes in the results given rise to by the use of $f_{T.F.D}$ factors instead of $f_{H.F.}$ factors for arsenic. The two scattering factors are compared in Fig. 5, while the corresponding μ factors are shown in Fig. 6. Table 12 shows that, although the changes in parameter values are apparent, they are smaller than the experimental errors. Slight increases in the standard deviations were found, as was expected.

The molecular structures and mean amplitudes obtained here will be combined with the spectroscopic data to determine harmonic potential constants and more accurate molecular structures in a succeeding paper.[40]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1703—1707 (1970)

Location of Gadolinium Ions in Hydrated Oxalate by ESR

Hsiu CHI

Department of Chemistry, New Asia College, The Chinese University of Hong Kong, Hong Kong

(Received April 30, 1969)

Gadolinium oxalate hydrate crystallizes isomorphously as $La_2(C_2O_4)_3 \cdot 10H_2O$, with two molecules in a unit cell of dimensions: $a_0 = 11.61 + 0.05$, $b_0 = 9.656 + 0.020$, $c_0 = 10.22 + 0.05$ Å and $\beta = 119.0 + 0.1°$. A detailed study of the *d*-spacings for the coprecipitates of varying composition in the La-Gd oxalate system was made, and 46 nearest-neighbor pairs were selected for Van Vleck second moment calculation. Agreement of the results of the calculation with those of the experiment justifies the suggested model representing the location of the gadolinium ions in the hydrated oxalate salt.

During the course of investigation of the coprecipitated phases of calcium-gadolinium oxalate system[1] the author found it desirable to know the relative positions of gadolinium ions in the lattice of the hydrated salt. However, no such information is available in literature. In the work of Gilpin and

1) H. Chi and K. Nagashima, This Bulletin, **41**, 2054 (1968).

McCrone[2,3] concerning the crystallographic data of hydrated lanthanum oxalate, the authors did not seem to pay attention to the structural refinements or to the location of ions in such a specified lattice. Studies on the single crystal X-ray data of oxalates of rare-earths other than lanthanum cannot be carried out easily. This is because most of these salts, prepared from their aqueous solutions, can be obtained only in the form of a fine powder.

In this article a new result is presented. Even when direct crystallographic data are lacking or a well-resolved Fourier projection has not been examined, recent refinements of ESR measurements enable one to obtain detailed information for the distribution of paramagnetic ions in solids.[4,5] In favorable cases, we can solve problems concerning the exact location of each kind of paramagnetic ions in their respective crystals.

Since the gadolinium ion has no resultant orbital momentum, it is very active to ESR at room temperature.[6] The author has therefore worked on the following presumption: ESR may offer excellent opportunities of providing exact knowledge of the location of lanthanide ions in crystals. The only necessary condition is that they are similarly located to gadolinium ions in their respective crystals. Thus, gadolinium ions may be regarded as a guide in ESR experiments for determining the exact positions of other allied lanthanide ions, either less active to ESR or perfectly inert, in many kinds of isomorphous salts.

The Van Vleck calculation of the magnetic second moment for a polycrystalline sample usually gives good results which are valuable for the verification of ESR experimental data.[7] However, in order to use the Van Vleck equation for this purpose, we need a fixed model in which the distances between the nearest neighboring paramagnetic ions are precisely known. In the present study, the process is reversed. The Van Vleck calculation is used as an independent means to determine whether or not the positions of the paramagnetic ions are crystallographically well fitted.

Experimental

Reagents and Procedure. Lanthanum oxide was dissolved in nitric acid and heated on a water bath until crystallization took place. The resulting lanthanum nitrate was dissolved and diluted. Gadolinium oxide was treated in the same way. The two solutions were then mixed in various proportions. A total of 200 m*l* each of the resulting solutions contained 1.25 mM of tripositive ions. The pH value of the solutions was adjusted to near 1.5. Three series of the specimens were prepared. To each of them was added 50 m*l* of water containing 1 g of oxalic acid or dimethyl oxalate, the latter being used to effect homogeneous precipitation. In the first series, oxalic acid was added as a precipitant at room temperature. In the second, dimethyl oxalate was added at room temperature. In the last, dimethyl oxalate was added and the temperature was held at about 80°C. In the first instance, the mixtures turned turbid at once. However, in the case of homogeneous precipitation, the reaction proceeded very slowly and lasted from 8 to 16 hr. Generally, the smaller the content of gadolinium in the solution, the slower was the rate of precipitation. All the precipitates were allowed to settle overnight, filtered, washed and air-dried. One part from each of the precipitates was taken for X-ray powder study, and the remaining was used for ESR spectrometry.

Apparatus. Measurement for electron spin resonance was carried out at room temperature swept both increasingly from 250 up to 10000 gauss and decreasingly from 10000 down to 250 gauss with a JES-3BS-X ESR spectrometer, manufactured by the Japan Electron Optics Laboratory. The X-ray measurement was carried out with a Rigaku-Denki X-ray diffractometer operated at 30 KV and 15 mA, using a copper target.

Results and Discussion

A. X-Ray Diffractometry. The author studied carefully the *d*-spacings for each of the coprecipitates of varying composition in the lanthanum-gadolinium oxalate system. The coprecipitates were prepared by three different procedures. It was observed that in each case the *d*-spacings, except for d_{020}, changed slightly and regularly with composition. Three typical and strong diffraction data together with the corresponding axial lengths were selected. They are listed in Table 1 for comparison.

In Table 1, the values of each of the cell dimensions were calculated from the general relation: Monoclinic: $a : 1 : c$, $\alpha=\gamma=90°$, $\beta \neq 90°$

TABLE 1. SHRINKAGE ALONG *a* AND *c* AXES OF LANTHANUM OXALATE DECAHYDRATE

Spacing and Axis	Alteration of the lattice of Hydrated La-Gd Oxalate (Å) Mole Fraction of Gadolinium					
	0	0.20	0.40	0.60	0.80	1.00
(1) d_{100}	10.40	10.36	10.30	10.25	10.20	10.16
a_0	11.91	11.86	11.78	11.72	11.66	11.61
(2) d_{011}	6.66	6.63	6.60	6.58	6.57	6.56
c_0	10.47	10.41	10.35	10.30	10.26	10.22

$$d_{hkl} = \frac{b_0}{\sqrt{\dfrac{(h/a)^2 + (1/c)^2 - \dfrac{2hl}{ac}\cos\beta}{\sin^2\beta} + k^2}} \quad (1)$$

where $a=a_0/b_0$, $c=c_0/b_0$.

The results indicate that with the replacement of lanthanum ions by smaller gadolinium ions, the angle β remains unchanged in all cases, and most of the shrinkage occurs along a and c axes in the proportion of 1 : 0.88 which is approximately equal to the axial ratio of pure lanthanum oxalate decahydrate. Although a_0 and c_0 in this coprecipitated system vary linearly with the mole fraction of gadolinium, the shortest b-axis only shows little variation to the extent of 0.02 Å with change of composition.

In order to ascertain whether the mole number of hydration was altered the author analyzed both the pure precipitates and the coprecipitates. All gave the same result, with the mole number lying around 10. Analysis of pure lanthanum oxalate and pure gadolinium oxalate precipitated by the three procedures described above, gave the average mole number as 10.58 and 10.49, respectively. The calculated density of the latter 2.514 g/cm^3 for the two formula weights in a unit cell agreed with that obtained (2.49±0.01 g/cm^3 at 28°) by means of flotation and pyconometry.

B. Validity of the Van Vleck Equation. The Van Vleck equation in a general form[8] is expressed as

$$\langle \Delta\nu^2 \rangle = \frac{3}{4} g^4 \mu_B^4 h^{-2} s(s+1) \sum_j r_{jk}^{-6} (3\cos^2\theta - 1)^2 \quad (2)$$

Under the present experimental conditions of varying external magnetic field for a fixed frequency, an equivalent magnetic field second moment $\langle \Delta H^2 \rangle$ is conveniently computed instead of $\langle \Delta\nu^2 \rangle$ for very fine polycrystalline specimens, like those used in this experiment, the powers of the direction cosines can be replaced by their average over a sphere. Neglecting surface effect, equation (2) may be transformed into a precise and useful equation as

$$\langle \Delta H^2 \rangle_{calc} = \frac{3}{5} g^2 \mu_B^2 s(s+1) \sum_j r_{jk}^{-6} \quad (3)$$

The theoretical values can be readily calculated by means of (3) on the basis of X-ray diffraction data. For the present purpose, g is taken to be 2.0023 and s to be 7/2 for free Gd^{3+}. The Bohr magneton μ_B has its usual value 9.2732×10^{-21} erg/gauss. The Van Vleck equation may be rewritten for this special case in a very simple form:

$$\langle \Delta H^2 \rangle_{calc} = 3.258 \times 10^9 \sum_j r_{jk}^{-6} \quad (4)$$

In this equation r and $\langle \Delta H^2 \rangle_{calc}$ are given in Ångstroms and gauss^2 respectively.

We come now to the point in question: How will gadolinium ions orient themselves so as to provide a proper summation term as shown in Eq. (4). In this summation term, every r-value must satisfy theoretically probable conditions; the total amount of the negative sixth power of every r-value must also give a correct answer for the $\langle \Delta H^2 \rangle_{calc}$ in coincidence with the result obtained from the ESR measurements.

The theoretically probable conditions are not restricted to the verification based on d-spacing data. The following aspects have also been noted.

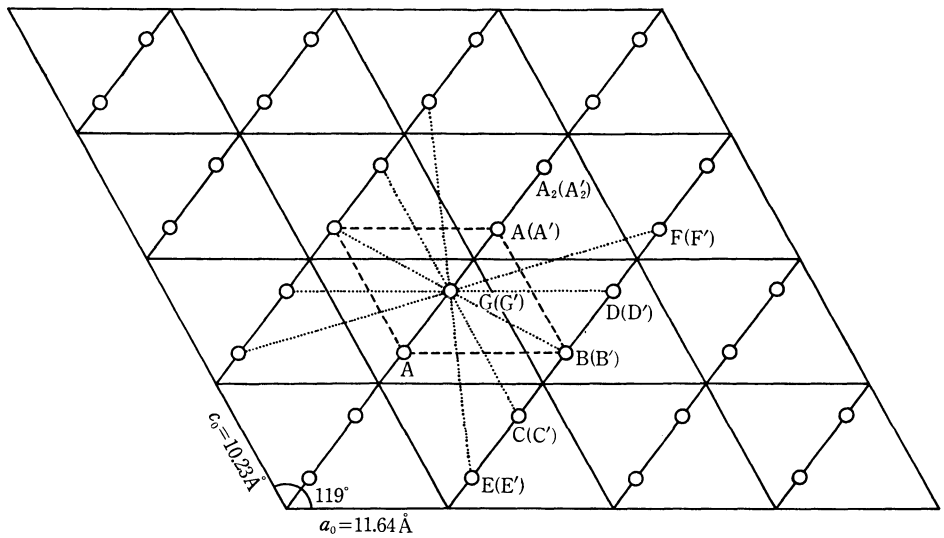

Fig. 1. Location of Gadolinium Ions on the a—c Plane.

** Every single primed letter indicates the same position of Gd^{3+} on the upper or lower adjoining plane, and the double primed letter indicates the plane next to the adjoining plane. GA$_2$′ represents a distance twice as long as GA′.

Firstly, every tripositive ion should settle in an electrostatic balancing position. Secondly, the closest arrangement of the heaviest gadolinium ion should reflect the most intensive X-ray diffraction. Lastly, the hydrogen bonding between oxalate ions and water molecules would as usual have a habit of forming the framework of a monoclinic cell.[9,10] The locations of 46 nearest neighboring ion pairs of gadolinium are shown in Figure 1, and the r-values of each of the ion pairs are summarized in Table 2. In providing these locations and r-values, due consideration has been given and a geometrical allowance has also been made.

The sum of the summation terms in Eq. (4) gives the value 264.9×10^{-6}, from which the theoretical value $\langle \Delta H^2 \rangle$ is calculated to be 8.630×10^5 gauss^2.

$$\langle \Delta H^2 \rangle_{\text{calc}} = 3.258 \times 10^9 \times 264.9 \times 10^{-6} = 8.630 \times 10^5 \text{ gauss}^2$$

The experimental value of the equivalent magnetic field second moment is computed by referring to the corresponding ESR differential curve. The width between the points of maximum slope is measured and calculated to be 1850 gauss (average). The value for $\langle \Delta H^2 \rangle$ thus obtained is 8.626×10^5 gauss^2. Since a good agreement exists between the observed second moment and that calculated theoretically, the validity of the suggested model representing the location of gadolinium ions in the hydrated gadolinium oxalate is well justified.

C. Location Diagram. Referring to Fig. 1, we see that each pair of the gadolinium ions lies on the diagonal of a parallelogram in the a—c plane. Each ion rides on the head of the other, and a total of four gadolinium ions in a unit cell with the coordinates (¼ 0 ¼), (¾ 0 ¾), (¼ ½ ¼), and (¾ ½ ¾) constitute the $\bar{1}01$ plane. One of the densest packed planes with gadolinium ions is 020 plane, which gives rise to the strongest diffractions throughout the experiment. Another characteristic of the packing is that each gadolinium ion is located at the center of gravity of a parallelogram. Both the upper and lower planes are similarly packed, hence the ions coexist centrosymmetrically around G.

The method for locating ions in salts in this experiment has one great advantage, *viz.*, exchange interactions contribute nothing to the second moment. Moreover, this method reveals immediately whether the assumption is correct. Decision is very easy owing to the extreme sensitiveness of the summation term of r^{-6}. If 1 per cent error was made in estimating the smallest r-value, such as r_1 in Table 2, the error of the result would be over 5 per cent. If an incorrect position was so assigned that in the unit cell of gadolinium oxalate decahydrate two Gd^{3+} ions were located on the longer diagonal at (¼ 0 ¾) and (¾ 0 ¼), and the other two on the shorter at (¼ ½ ¼) and (¾ ½ ¾), the calculated second moment compared with the experimental result would have been too low, with a discrepancy of more than 30 per cent. Another remarkable feature of this method is that the smallest r-value has a decisive influence on the second moment. It is readily seen from Table 2: the shortest distance r_1 (2 ions) has an effect as much as 60 per cent; the next two distances r_2 and r_3 (6 ions) 34 per cent; whereas all the others, from r_4 to r_{15} (38 ions), only 6 per cent of the grand total. Such a characteristic may serve as a convenient guide leading to the right assignment of location of ions in a crystal.

The author expresses his sincere thanks to Professor Kozo Nagashima, Tokyo Kyoiku University, and Professor Shizuo Fujiwara, the University of Tokyo, for their constructive guidance and advice throughout this study. Professor Nagashima made all facilities of his research laboratory available for three successive summers since 1966, where all the fundamental work, including sample preparation and X-ray diffraction measurement, was successfully performed. The important data for the computation of magnetic second moment could not have been obtained without the high precision JES-3BS-X ESR spectrometer, which was made available by Professor Fujiwara from the summer of 1967 onward. During the same period, the author benifited from stimulating discussion with Mr. Yoshinori Sugitani, Tokyo Kyoiku University. The author is also indebted to Dr. Tokuko Watanabe, the University of Tokyo, for her skilled technical assistance in the ESR spectrometry.

This research was supported in part by a grant from The Chinese University of Hong Kong through the recommendation of New Asia College, for which the author expresses his appreciation.

Polarography of Halides in Dimethylformamide. II. The Iodide Ion, the Triiodomercurate Ion, and Mercuric Iodide

Yoshihisa MATSUI, Yukio KUROSAKI*1 and Yoshio DATE

Department of Agricultural Chemistry, Faculty of Agriculture, Shimane University, Nishikawazu-cho, Matsue

(Received July 28, 1969)

The polarographic behavior of the iodide ion, the triiodomercurate ion, and mercuric iodide at the dropping mercury electrode was investigated in dimethylformamide, using d.c. polarography, controlled potential electrolysis, and oscillographic polarography with a multi-triangular voltage sweep. The iodide ion gives two well-defined anodic waves: the first wave corresponds to the reversible oxidation of mercury to the triiodomercurate ion, and the second, to the reversible oxidation of mercury to mercuric iodide. A maximum arises on the reduction wave of the triiodomercurate ion, but it is suppressed by the addition of a small amount of polyvinyl chloride. The oscillographic polarograms and electrocapillary curves suggested that the iodide ion, like the triiodomercurate ion and mercuric iodide, is strongly adsorbed on the dropping mercury electrode. The maximum on the wave due to the reduction of the triiodomercurate ion to mercury and the iodide ion was ascribed to the convection of the mercury drop, which was itself probably caused by the abrupt desorption of the iodide ion formed successively with an increase in the negative potentials. The adsorption phenomena of the corresponding bromides and chlorides are also discussed.

In a previous paper,[1] the electrode reaction mechanism of the bromide ion, the tribromomercurate ion, and mercuric bromide in dimethylformamide (DMF) was studied with the dropping mercury electrode. The results of d.c. polarography and large-scale electrolysis at a controlled potential indicated that two well-defined anodic waves given by the bromide ion can be attributed to the formation of the tribromomercurate ion and mercuric bromide by this reaction sequence:

$$2Hg + 6Br^- \rightleftharpoons 2HgBr_3^- + 4e \quad (1)$$

$$Hg + 2HgBr_3^- \rightleftharpoons 3HgBr_2 + 2e \quad (2)$$

The present study was undertaken in order to extend the previous study of the bromides to the corresponding iodides, namely, the iodide ion, the triiodomercurate ion, and mercuric iodide. Also, the adsorption phenomena of these depolarizers on the electrode surface were studied by the measurements of the oscillographic polarograms with a multi-triangular voltage sweep and of the electrocapillary curves. The adsorption phenomena of halide ions on the surface of the dropping mercury electrode have been extensively studied in aqueous

solution,[2-6] but scarecely studied at all in non-aqueous solutions. The adsorption of the bromide ion on the electrode surface has been suggested[1] on the basis of the partial deviation from linearity of the log plot of the more negative wave, but the phenomenon has not been studied in detail.

Experimental

Materials. The DMF was purified as has been described previously,[1] except that distillation was carried out in the presence of a few lumps of calcium hydride. The tetraethylammonium perchlorate, used as a supporting electrolyte, was prepared as has been described by Fujinaga *et al.*[7] The tetraethylammonium iodide was prepared according to the directions of Given, Peover, and Schoen.[8] The tetraethylammonium bromide was prepared as has been described in a previous paper.[1] The tetraethylammonium chloride was prepared by neutralizing an aqueous solution of tetraethylammonium hydroxide with an equivalent quantity of hydrochloric acid. Mercuric iodide, bromide, and chloride obtained commercially were purified by recrystallizing them from ethanol. The polyvinyl chloride (PVC), used as a maximum suppressor, was obtained commercially. The degree of polymerization was about 1000.

Apparatus. D.c. polarography, large-scale electrolysis at a controlled potential, and conductivity measurements were carried out as have been described previously.[1] Likewise, all the potential measurements were referred to the aqueous saturated calomel electrode connected with the test solution by a DMF-agar salt bridge.[9] The dropping mercury electrodes used had the following characteristics in a 0.10M solution of tetraethylammonium perchlorate in DMF (open circuit): (1) $m=1.165$ mg/sec, $t=5.60$ sec for $h=66.0$ cm, (2) $m=1.540$ mg/sec, $t=4.50$ sec for $h=66.0$ cm.

The oscillographic polarograms were obtained using an apparatus similar in construction to that of Shinagawa *et al.*[10] An isosceles triangular voltage sweep obtained by integrating a square-wave voltage was amplified and then applied to the electrode alternatively. The polarographic cell used was the same as that used for d.c. polarography. In order to minimize the iR drop yielded across the cell, a fairly concentrated electrolyte solution (0.50M of tetraethylammonium perchlorate) was used. No test solutions were degassed. The two-electrode system with the dropping mercury electrode and the mercury pool electrode was used. The mercury pool electrode in 0.50M of tetraethylammonium perchlorate did not always provide a stable reference potential, but the variation in the reference potential was so small that it did not prevent us from observing electrochemical phenomena. The current-potential curves were observed on a dual-beam cathode-ray oscilloscope VC-6 of the Nihon Kohden Kogyo Co., which had a relatively high sensitivity up to 1.0 mV/cm. The horizontal sweep of the cathode-ray oscilloscope was synchronized with the frequency of an applied potential. The vertical deflection was proportional to the current flowing through the polarographic cell, so that the resulting trace had an i-E relationship. The oscillographic pattern of the trace was recorded on Fuji Neopan SS film using a Canon Pellix camera. The sweep frequency used for the oscillographic polarography was kept constant at 20 Hz.

Results and Discussion

Complex Formation between Tetraethylammonium Iodide and Mercuric Iodide in DMF. In order to elucidate the anodic dissolution mechanism of mercury in the presence of the halide ion, it is necessary to know what kinds of mercury complexes are formed between the mercuric or mercurous cation and the halide ion in solution. For example, it has been reported that, in an aqueous solution, the bromide ion depolarizes the dropping mercury electrode with the formation of mercurous bromide,[11] which is the most stable species in water. In DMF, however, mercurous bromide is less stable than either the tribromomercurate ion or mercuric bromide, so in DMF the bromide ion gives two anodic waves which correspond to the formation of the latter.[1]

Mercuric iodide is extremely soluble in DMF (*ca.* 4M at 20°C[12]) and stable in the solution. On the other hand, mercurous iodide is essentially insoluble in DMF and decomposes in part to mercury and mercuric iodide. Accordingly, when a dilute solution of the iodide ion is polarographically studied in DMF, it is not necessary to consider the formation of mercurous iodide.

Mercuric iodide has been reported to form a complex ion with the iodide ion in DMF.[12,13] The resulting complex ion has been thought to be the tetraiodomercurate ion (HgI_4^{2-}), formed from one mole of mercuric iodide and two moles of the iodide ion. However, in the case of the corresponding bromides it has been shown,[1] by means of conductometric titration, that the complex ion formed

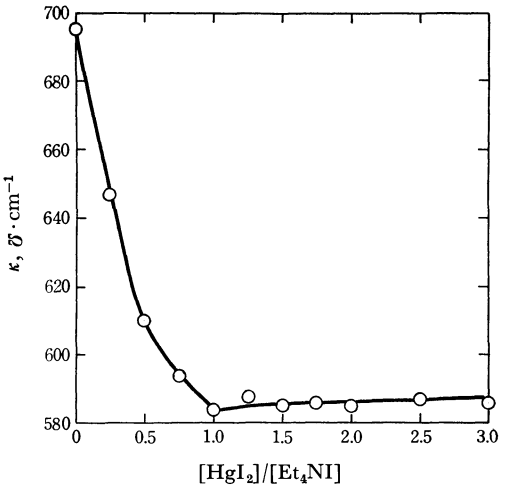

Fig. 1. Effect of HgI_2 on specific conductance of 10 mM Et_4NI in DMF at 25°C.

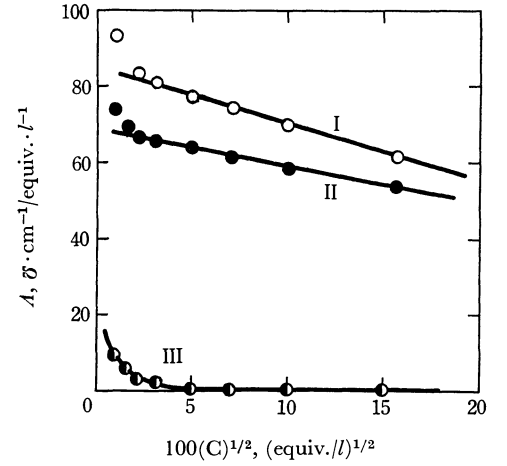

Fig. 2. Equivalent conductivities of Et_4NI (I), Et_4NHgI_3 (II), and HgI_2 (III) *vs.* square root of concentration in DMF at 25°C.

from mercuric bromide and the bromide ion was the tribromomercurate ion ($HgBr_3^-$) rather than the tetrabromomercurate ion ($HgBr_4^{2-}$). Consequently, the composition of the complex ion between mercuric iodide and the iodide ion was reexamined by the same method. The results are given in Fig. 1.

The addition of mercuric iodide to the solution of tetraethylammonium iodide in DMF lowered the specific conductivity, which reached the minimum value when the mole-ratio became equal to one. This obviously suggests that the complex formation occurs in solution and that the resulting complex ion is the triiodomercurate ion (HgI_3^-). The line in Fig. 1 curves also at the point where the mole-ratio is equal to 0.5. This suggests that the tetraiodomercurate ion may be formed in solution when the concentration of the iodide ion is more than double that of mercuric iodide.

The complex formation between mercuric iodide and the iodide ion can be confirmed by the data from the UV spectrum, too. The spectrum of the mixture of the iodide ion and the mercuric iodide equivalent in concentration has a strong absorption maximum at 304 mμ ($\varepsilon = 1.1 \times 10^5$), while neither mercuric iodide nor tetraethylammonium iodide shows such a maximum in the same wavelength region.

The equivalent conductivities of tetraethylammonium iodide, tetraethylammonium triiodomercurate, and mercuric iodide are plotted as a function of the square root of the concentration in Fig. 2. The data for tetraethylammonium iodide and tetraethylammonium triiodomercurate fit the Onsager equation, indicating that these salts behave as strong electrolytes in DMF. The equivalent conductivity of mercuric iodide is very low and does not fit the Onsager equation, showing that it is a weak electrolyte in DMF.

D. c. Polarography. A. Tetraethylammonium Iodide as Depolarizer. Using anhydrous DMF as a solvent, with 0.10M tetraethylammonium perchlorate as a supporting electrolyte, the d.c. polarographic behavior of tetraethylammonium iodide was investigated. This depolarizer gave two well-defined anodic waves (Fig. 3). The ratio between the heights of these waves was approximately 2 : 1, as was observed for tetraethylammonium bromide. The half-wave potentials ($E_{1/2}$) and the diffusion current constants (I_d) in various concentrations are given in Table 1. The I_d's of both the waves were practically constant over the concentration range studied. The limiting currents

74.3	0.430	1.06	0.050	0.123
64.3	0.425	1.01	0.053	0.126
54.3	0.395	0.90	0.053	0.122
44.3	0.345	0.83	0.052	0.123
38.3	0.325	0.77	0.052	0.124

for 0.50 mM of the depolarizer were found to be proportional to the square root of the effective pressure of mercury applied to the dropping mercury electrode (Table 2). These results indicate that the limiting currents of the two waves are diffusion-controlled.

The polarographic waves of the iodide ion are so similar to those of the bromide ion that the electrode-reaction mechanism proposed for the latter may also be presumed to hold for the former (Eqs. (3) and (4)):

$$2Hg + 6I^- \rightleftharpoons 2HgI_3^- + 4e \quad (3)$$

$$Hg + 2HgI_3^- \rightleftharpoons 3HgI_2 + 2e \quad (4)$$

This mechanism was substantiated by analyzing the polarographic waves as follows. If the electrode reactions (3) and (4) are reversible, the equations of the waves are expressed by:

$$E_n = C_n + (\boldsymbol{RT}/2\boldsymbol{F}) \ln i/(i_d - i)^3 \quad (5)$$

$$E_p = C_p + (\boldsymbol{RT}/2\boldsymbol{F}) \ln i^3/(i_d - i)^2 \quad (6)$$

where E_n and E_p denote the potential of the electrode for the more negative and the more positive waves respectively, and where C_n and C_p are constant. These equations show that the half-wave potentials should change with i_d or with the concentration of the iodide ion according to:

$$E_{n,1/2} = C'_n - (\boldsymbol{RT}/\boldsymbol{F}) \ln i_d \quad (7)$$

$$E_{p,1/2} = C'_p + (\boldsymbol{RT}/2\boldsymbol{F}) \ln i_d \quad (8)$$

The results of the analysis of the waves are given in Fig. 4. The log plot for the more positive wave was a fairly good straight line, with a slope equal to 0.032 V, which is in fair agreement with the theoretical value of 0.030 V. The log plot for the more negative wave was also linear, with a slope equal to 0.030 V, over the greater part of the potential range. However, it became somewhat curved in the more negative region of potential, just as was observed in the case of the bromide ion.[1] As was suggested in the previous paper, this is probably due to the adsorption of the iodide ion on the surface of the dropping mercury electrode before depolarizing. The deviation can also be considered to be due in part to the formation of the tetraiodomercurate ion in the more negative part of the wave, where the concentration of the iodide ion on the mercury drop is much higher than that of mercuric

Slope: (I) 0.032; (II) 0.030

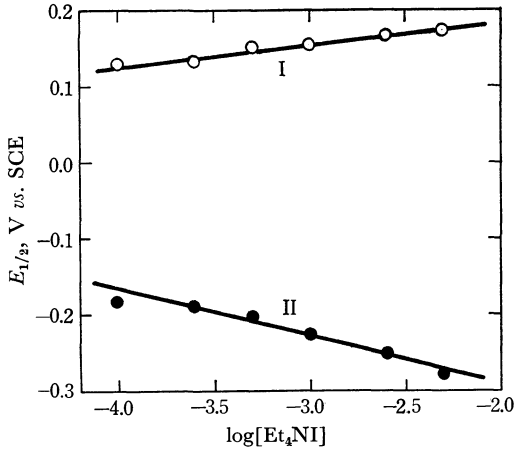

Fig. 5. Effect of concentration of Et_4NI on its half-wave potential.
Slope: (I), 0.030; (II), −0.060

ion dissolved.

The relation between the half-wave potential and the concentration of the depolarizer is plotted in Fig. 5. Straight-line relations were obtained for the waves with slopes equal to −0.060 V for the more negative wave (calculated for Eq. (7): −0.059 V) and 0.030 V for the more positive wave (calculated for Eq. (8): 0.030 V). All these results indicate that Eqs. (3) and (4) are both valid.

B. Mercuric Iodide. If Eqs. (3) and (4) are both valid, mercuric iodide should give two cathodic waves according to the following reactions:

$$3HgI_2 + 2e \rightleftharpoons Hg + 2HgI_3^- \quad (9)$$

$$2HgI_3^- + 4e \rightleftharpoons 2Hg + 6I^- \quad (10)$$

Actually, mercuric iodide gave two cathodic waves, though a maximum appeared on the more negative one (Fig. 6-I). In order to suppress the maximum, a small amount of PVC was dissolved in the test solution. PVC was reported to suppress all the maximum waves of thallium(I), lead(II), cadmium(II), and zinc(II) in *N*,*N*-dimethylacetamide.[14] As is shown in Fig. 6-II, PVC was found to suppress the maximum of mercuric iodide very effectively. In the concentration range from 0.003 to 0.007%, PVC acted as a satisfactory suppressor and had no effect on either the half-wave potential or the diffusion-current constant. At concentrations lower than 0.002% as well as higher than 0.010%, the effect of PVC became weak.

44.3	0.65	1.50	0.097	0.224
38.3	0.58	1.40	0.094	0.226

The polarographic characteristics of mercuric iodide at various concentrations in the presence of 0.005% of PVC are given in Table 3. The limiting currents of both the waves were proportional to the concentration and to the square root of the effective pressure of mercury applied to the dropping mercury electrode (Table 4), indicating that they are diffusion-controlled.

The waves of mercuric iodide were analyzed in the same way as those of tetraethylammonium iodide. The results showed that the waves are in fair agreement with those given theoretically by Eqs. (11) and (12).

$$E'_p = C''_p - (\boldsymbol{R}T/2\boldsymbol{F}) \ln i^2/(i_d - i)^3 \quad (11)$$

$$E'_n = C''_n - (\boldsymbol{R}T/2\boldsymbol{F}) \ln i^3/(i_d - i) \quad (12)$$

The shift of the half-wave potential with i_d is given by Eqs. (7) and (8), which were accepted to hold as is shown by the results in Table 3.

C. Tetraethylammonium Triiodomercurate. As was to be expected from Eqs. (4) and (10), tetraethylammonium triiodomercurate gives two waves, anodic and cathodic, and on the latter a maximum arises (Fig. 7-I). The maximum was also suppressed by the addition of 0.005% of PVC (Fig. 7-II). The polarographic behavior is summarized in Table 5. Analysis of the current-voltage curves showed that the anodic wave is ex-

pressed by Eq. (6), and the cathodic wave, by Eq. (12).

Controlled Potential Electrolysis of Mercuric Iodide. Further evidence for the electrode-reaction mechanism postulated above was obtained by a large-scale electrolysis of mercuric iodide at a mercury pool cathode with a controlled potential. Electrolytic reduction at a potential of the plateau of the more positive wave yielded tetraethylammonium triiodomercurate, the formation of which was confirmed by measuring the polarogram and the UV spectrum of the catholyte. The quantity of electricity transferred per mole of the depolarizer (n=0.64 F) virtually agreed with that calculated for Eq. (9) (n=0.67 F). As was expected from Eq. (10), tetraethylammonium iodide, identified by the polarogram of the catholyte, was obtained by the electroreduction of mercuric iodide at a potential of the plateau of the more negative wave. The value of n (n=2.21 F) also agreed with that calculated for Eqs. (9) and (10) (n=2.00 F).

Oscillographic Polarography of Tetraethylammonium Iodide. In order to investigate the polarographic behavior of tetraethylammonium iodide in more detail, an isosceles-triangular voltage sweep was applied to polarize the dropping mercury electrode alternatively. A current-potential curve obtained on a cathode-ray oscilloscope is shown in Fig. 8-I. It may be inferred at sight that the anodic peaks, A and B, are due to the step-by-step oxidation of mercury to the triiodomercurate ion and to mercuric iodide respectively. The cathodic peaks, C and D, probably correspond to the step-by-step re-reduction of mercuric iodide to the triiodomercurate ion and to the iodide ion respectively.

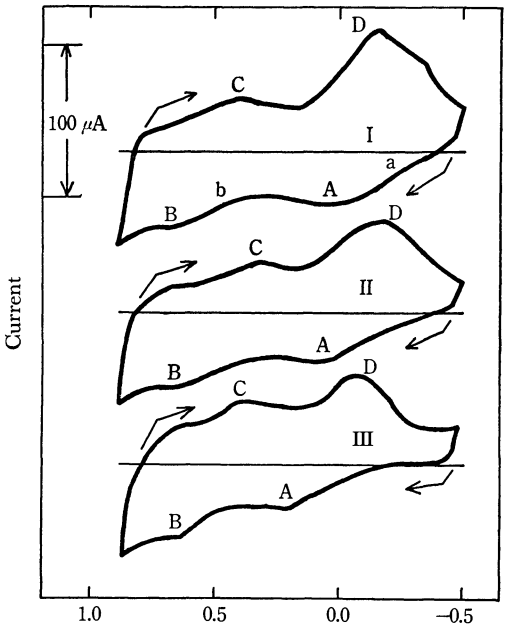

Fig. 8. Oscillographic polarograms of Et_4NI (I), Et_4NBr (II), and Et_4NCl (III) in DMF.

It is noticeable that the base line of the anodic peaks goes down as the positive potential increases, whereas that of the cathodic peaks remains essentially the same. Furthermore, it is remarkable that the peak D is exceptionally higher than the other peaks, A, B, and C. The peak D is so high that it cannot be considered that the whole current is due only to the re-reduction of the triiodomercurate ion formed in the preceeding electrooxidation and re-reduction processes. These results indicate that not only the electron transfer process, but also the adsorption-desorption process, occurs on the electrode surface.

The species which can be adsorbed on the elec-

trode are the iodide ion, the triiodomercurate ion, and mercuric iodide. In the anodic scan, the adsorption of these depolarizers may cause the increase in the anodic charging current. Since the iodide ion is the only depolarizer existing in the solution before electrolysis, the moderate increase in the charging current shown by the curve a may be due to the successive adsorption of the iodide ion on the electrode surface. At the potential close to the peak A, the iodide ion adsorbed is converted into the triiodomercurate ion as a result of its reaction with the mercuric ion formed by the electrooxidation of mercury. The resulting triiodomercurate ion may also be adsorbed on the electrode surface, so the double-layer capacity may gradually increase with an increase in the amount of the adsorbate during electrolysis (curve b). At the potential near the peak B, the triiodomercurate ion adsorbed is further converted into mercuric iodide, which may also be adsorbed on the electrode surface, and a considerable charging current flows consecutively.

In the cathodic scan, on the other hand, the desorption of the depolarizers can cause an increase in the cathodic charging current. However, when mercuric iodide is re-reduced to mercury and the triiodomercurate ion at the potential close to the peak C, both mercuric iodide and the triiodomercurate ion may be strongly adsorbed on the electrode surface. Consequently, the double-layer capacity may scarcely change, and the base line of the cathodic scan remains essentially the same. At the potential near the peak D, the triiodomercurate ion is reduced to mercury and the iodide ion. The resulting iodide ion may be abruptly desorbed from the electrode surface with an increase in the negative potential. As a result, a large quantity of charging current flows (the peak D).

Considering that the potential of the maximum, which arises on the reduction wave of the triiodomercurate ion, is close to that at which the iodide ion is abruptly desorbed, we might be able to relate the desorption phenomena to the appearance of the polarographic maximum as follows. It has been confirmed that the current density at the bottom of the mercury drop is greater than that at the top as a result of the screaning effect of the tip of the capillary.[15] If the iodide ion, which is formed by the reduction of the triiodomercurate ion adsorbed on the electrode surface, is abruptly desorbed from the electrode surface, the difference in current density must cause an unequal distribution of the triiodomercurate ion in the double layer at the bottom and at the top of the mercury drop, which may also cause a tangental potential gradient in the double layer around the mercury drop, as well as the difference in surface tension between that at the bottom and that at the top of the drop. Consequently, the interface is pulled from top to bottom. The resulting streaming of the double layer and mercury in the drop may be responsible for the polarographic maximum. The maximum may not disappear until the potential of the mercury electrode becomes too negative for the triiodomercurate ion to adsorb on the electrode surface. The PVC added to the solution as a maximum suppressor may be adsorbed on the electrode surface with the formation of a thin film, which may prevent the iodide ion from being abruptly desorbed from the electrode surface. In the case of the electrooxidation of mercury in the presence of the iodide ion, the iodide ion may be supplied to the electrode surface by diffusion, and so no convection of the electrode can occur. Although the above description of the cause of the polarographic maximum is plausible, it is no more than a speculation; further experimental data are necessary before we can discuss it conclusively.

The oscillographic polarograms of tetraethylammonium bromide and chloride (Fig. 8-II and -III) were very similar to those of the corresponding iodide, but with some differences. The most remarkable difference was that the heights of the peaks D of I^-, Br^-, and Cl^- decrease in that order. This clearly indicates that the peak D is due not only to the electron-transfer process, but also to the nonfaradic desorption process. Furthermore, it was ascertained that the adsorptive activities of the triiodomercurate ion, the tribromomercurate ion, and the trichloromercurate ion decrease in that order.

Electrocapillary Curve. The adsorption phenomena of the halides were also studied by the measurement of the electrocapillary curves. The

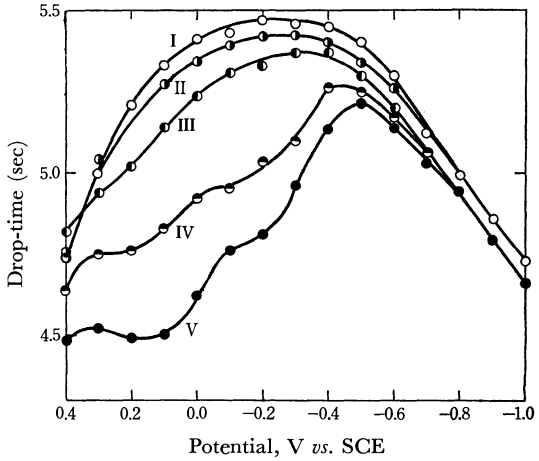

Fig. 9. Electrocapillary curves: (I), 0.1M Et_4NClO_4; (II), (I)+0.005% PVC; (III), (II)+1.0 mM $HgCl_2$; (IV), (II)+1.0 mM $HgBr_2$; (V), (II)+1.0 mM HgI_2.

15) I. M. Kolthoff and J. J. Lingane, "Polarography," 2nd ed., Vol. I, Interscience Publishers, New York (1952), p. 176.

effect of 1.0 mM of mercuric halide on the shape of the electrocapillary curve is shown in Fig. 9. The electrocapillary curve in the presence of 2.0 mM of tetraethylammonium iodide was essentially identical with that in the presence of 1.0 mM of mercuric iodide.

In the presence of mercuric iodide, a marked decrease in the surface tension was observed in the potential region between +0.4 and −0.8 V *vs.* SCE. Considering the electrode reaction mechanism elucidated above, it can be presumed that the decrease in the drop time in the potential region between +0.4 and +0.2 V *vs.* SCE is due to the adsorption of mercuric iodide. Similarly, the decrease in the surface tension in the potential range between +0.1 and −0.1 V *vs.* SCE and that between −0.3 and −0.8 V *vs.* SCE may correspond to the adsorption of the triiodomercurate ion and the iodide ion respectively on the electrode surface.

The results in Fig. 9 also reveal that the iodide ion and its mercuric complexes are the most capillary-active. The bromide ion and its mercuric complexes are less strongly adsorbed on the electrode surface. The chloride ion and its mercuric complexes are only slightly capillary-active.

The effect of PVC on the shape of the electrocapillary curve is also shown in Fig. 9. The addition of a small amount of PVC caused a slight decrease in the drop time of the mercury in the potential region more positive than −0.7 V *vs.* SCE. It is apparent that the adsorption of PVC on the electrode surface occurs, this may prevent the convection of the mercury drop and, consequently, the appearance of the maximum. All the results mentioned here are in fair agreement with those obtained by oscillographic polarography.

Lattice Constants of Tetragonal Sodium Potassium Tungsten Bronzes

Seiichiro UTSUMI and Shuko FUJIEDA*1

Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo

(Received October 30, 1969)

Sodium potassium tungsten bronzes, $Na_xK_yWO_3$, having various values of x and y were prepared by electrolytically treating a fused mixture of carbonates of the two alkali metals and tungsten-(VI) oxide. Lattice constants, a and c, of the tetragonal crystals were estimated by the X-ray powder method. Similarity of the crystal lattice of these bronzes to that of potassium tungsten bronzes, instead of to that of sodium tungsten bronzes, suggests that the lattice constants of the sodium potassium bronzes are by far more influenced by the potassium content than by the sodium content.

Tungsten bronzes are nonstoichiometric crystalline compounds represented by a general formula, Na_xWO_3, in which M is a metal ion and x has a value less than unity. Among them, sodium tungsten bronzes*2 Na_xWO_3 and potassium tungsten bronzes K_yWO_3, especially the former, are the most popular.

Sodium bronzes have been prepared with relative ease over a wide range of x value. Their color and crystal system vary with values of x, and the crystal surfaces exhibit a characteristic metallic luster. On the other hand, the crystals of the potassium bronzes show neither variety in color nor metallic luster as in of sodium bronzes.

The marked difference in appearance between the two series of bronzes might be clarified by investigating the crystals of sodium potassium bronzes, intermediate or mixed bronzes having a general formula $Na_xK_yWO_3$ where the sum of x and y is less than unity. Also the role of metal ions could be revealed by determining the color and structure of the crystals.

Several kinds of sodium potassium bronzes have been prepared and their crystals investigated,[1-3] but with little information. We prepared sodium potassium bronzes with a wider range of composition and higher purity. Tetragonal crystals were

subjected to X-ray diffraction in order to obtain their lattice constants.

Experimental

Materials. All chemicals used were of reagent grade. Tungsten rods supplied by Tokyo Tungsten Co., Ltd. were 2 mm in diameter and specified to be 99.98% pure.

Preparation. A powdered mixture consisting of anhydrous sodium, potassium carbonates and tungsten(VI) oxide $WO_3 \cdot H_2O$ (Table 1), was thoroughly melted in a porcelain crucible by heating at 800 ± 15°C in an electric furnace. Two tungsten rods were placed in the crucible as electrodes with one end of each rod immersed in the melted mixture. An electric voltage was applied between the two electrodes so that the voltage drop across the electrodes was 1.0—1.2 V. A direct current, 2—5 A, was supplied. Crystals were soon formed at the cathode. After carrying out electrolysis for several hours, the current was switched off and the electrodes were removed. The melted mixture, along with the crystals, was allowed to cool to room temperature, and the remaining mass was treated first with boiling water, then with a hot nitric acid solution and finally with a hot sodium hydroxide solution. Thus the remaining crystals could be obtained.

Analytical Procedure. A powdered and weighed sample was fused in a nickel crucible together with a mixture of sodium carbonate and sodium nitrate in the ratio of 1 to 3 by weight,[4] and the fused product was dissolved in water. In the first place, potassium was determined gravimetrically as potassium tetraphenylborate precipitate $KB(C_6H_5)_4$. Subsequently tungsten was oxidized completely to sexivalent state with nitric acid, precipitated with hydrochloric acid and cinchonine, and the precipitate was ignited and weighed as WO_3. If the two procedures of precipitation were carried out in reverse order, an erroneous value for the potassium content would result from to the presence of excessive cinchonine in the solution which is used for the determination of potassium. Values of x and y for sodium potassium bronzes were estimated assuming that the ratio of tungsten to oxygen was 1 : 3[5] in bronzes, and also that the remainder which was obtained by subtracting the contents of potassium, tungsten and oxygen from the initial weight of the sample was estimated as sodium content.

Lattice Constants. The diffraction pattern of the powder was obtained with an X-ray diffractometer, compact type from Rigaku Denki Co., Ltd., Tokyo, using Cu-Kα radiation, $\lambda = 1.5418$ Å. Values of lattice distance, d, calculated from the pattern of each sample were then used to determine the appropriate lattice constants a and c by the usual procedure. The values of a and c were accurate within the error ± 0.01 Å.

Density. The density of crystals was measured with a pycnometer using water as the immersion liquid. The values of density were reproducible within ± 0.03 g/cm^3. The accuracy of the data was proved by the density of metallic cadmium which was observed by the same procedure, the value 8.61 g/cm^3 being sufficiently close to the value 8.642 g/cm^3.[6]

Results and Discussion

Brimm *et al.*[3] prepared sodium potassium bronzes by merely fusing a mixture of Na_2WO_4, K_2WO_4, WO_3 and metallic tungsten. In the present work, however, carbonates were preferred to tungstates as starting materials on account of lower melting point and easier access. The bronzes produced by the process of Brimm *et al.* were by no means free from contamination, presumably of fine particles of metallic tungsten and some compounds of tungsten of lower oxidation states, as demonstrated by X-ray powder photography.[3,7] Thus we employed the electrolytic process of Knorre.[1] Sienko and Mazumder[8,9] prepared tungsten bronzes in an atmosphere of argon. In the present work materials were kept open to atmosphere without any difficulties. Crystals having uniform color and metallic luster were obtained.

The tetragonal crystals in square prisms of the sodium potassium bronzes are listed in Table 1. They are not exhaustive, but only those whose values of x and y and lattice constants were determined are shown. In Table 1 are shown, in successive columns, compositions of the starting materials, colors, compositions and the lattice constants a and c. Twenty one species of bronzes are arranged in the table in decreasing order of the alkali metal contents of the starting materials.

Crystals of tetragonal sodium bronzes were more or less bluish purple, probably because the tetragonal structure was limited to a narrow region of x. In the case of potassium bronzes, however, blue and reddish purple crystals were formed independent of the composition of the starting materials. In contrast, a variety of colors ranging from reddish purple to blue is covered by the group of tetragonal sodium potassium bronzes, as seen in the table. The crystal shown as No. 12 in Table 1 was the most reddish.

The ratios of Na to K in the bronzes were very nearly equal to the ratios of sodium carbonate to potassium carbonate in the composition of starting materials. But there were some exceptions. For instance, when the starting materials contained approximately ten times as much Na as K (Nos. 7, 8 and 9, Table 1), the product was a mixture of a small amount of needle-shaped blue crystals of

* expressed in molar ratio ** rp: reddish purple, p: purple, bp: bluish purple, b: blue

sodium potassium bronze and a large amount of cubic sodium bronze.

It is noteworthy that the color of crystals varies from blue to reddish purple in accordance with the increase of the y values instead of the sum of x and y. In other words, the color of the crystal with a small y value was blue and that with a large y value was reddish.

Magnéli[10] stated that the tungsten-oxygen octahedra in tetragonal tungsten bronzes join each other by sharing oxygen atoms at the corners so as to form a framework with the formula WO_3, where the lattice contains empty tunnels which run right through the structure whose projections on the 001 plane consist of triangle, square and pentagon. Alkali metal atoms in bronzes are considered to be accomodated in either of the square and pentagonal empty tunnels. Particularly, in the crystal structure of the bronzes $Na_xK_yWO_3$, the potassium ions which are larger than the sodium ions would be accomodated more easily in the pentagonal interstices. On the other hand, dimensional consideration concerning the W–O bond length in comparison with the ionic size of K suggests that the square tunnels, as well as the triangular ones, would be too small to accomodate potassium ions. Thus it seems that the potassium ions should exist only in pentagonal spaces. Referring to the structure of sodium potassium bronzes, Wadsley[11] proposed that the interstitial ions are assorted according to their size. The present interpretation is consistent with the opinion of Magnéli and Wadsley, and is further supported by the following experimental facts.

Current efficiency in the electrolytic preparation was much lower for preparing potassium bronzes than for sodium bronzes. The process in which potassium bronzes were formed from a starting material consisting of potassium carbonate and tungsten(VI) oxide hardly proceeded, but the presence of only a twentieth part of sodium carbonate in one part of potassium carbonate remarkably facilitated the preparation of bronze, a sodium potassium bronze in this case instead of a potassium bronze. For example, from a starting material mixture consisting of potassium carbonate and tungsten(VI) oxide in the ratio of 1 : 2 a potassium bronze $K_{0.41}WO_3$ was produced, while from a starting material containing potassium salt and tungsten oxide in approximately the same ratio as above and additional sodium carbonate in such a small amount as a twentieth of the amount of potassium

11) A. D. Wadsley, "Nonstoichiometric Compounds," ed. by L. Mandelcon, Academic Press, New York (1964), p. 98.

salt (No. 15, Table 1) a sodium potassium bronze $Na_{0.12}K_{0.43}WO_3$ was prepared in preference to the tetragonal potassium bronze. Brimm *et al.* similarly found that incorporation of any potassium into the structure of cubic sodium bronzes led exclusively to tetragonal bronzes. Therefore, it might be presumed that sodium ions were inserted into the K_yWO_3 host lattice which belonged to the tetragonal system, so that incorporation of sodium in the interstitial spaces existing in the host lattice stabilized the tetragonal crystal structure.

The lattice constant a of cubic sodium bronzes Na_xWO_3 is known to be linearly proportional to the x value as expressed by $a=0.0819x+3.7846$.[12] In other words, the WO_3 host lattice was expanded in accordance with the increase of the sodium concentration in the lattice. A similar result was observed with respect to potassium bronzes, because the reported y values of some tetragonal potassium bronzes K_yWO_3 proved to be in a parallel relation to the lattice constants of their crystals.[10,13]

It may be reasonable to presume that the potassium ions, larger than the sodium ions, in the crystal would influence more decisively the host lattice and might determine the size. The lattice constants, a and c, measured by the X-ray powder method are shown in Table 1. The value of c/a was unequivocally 0.312, so that, for the sake of simplicity, plotting in Fig. 1 was only for the constant a.

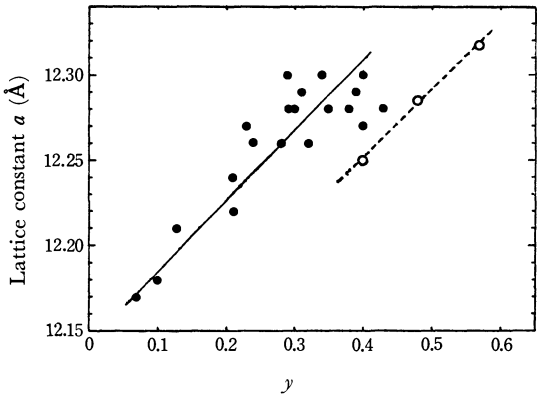

Fig. 1. Lattice constant a as a function of y.
● of tetragonal $Na_xK_yWO_3$
○ of tetragonal K_yWO_3[13,14]

The variation of the lattice constant a for $Na_xK_yWO_3$ crystal is shown as a function of y in Fig. 1. The lattice constant a reported of tetragonal potassium bronzes, K_yWO_3, for $y=0.40-0.57$[10,13] is also shown by open circles. The lattice constant for sodium potassium bronzes represented by solid circles, though it diverges more for larger values of y, seems to vary in the linear relation to y within the range in which measurement was made, as shown by the full line. The inclination of the line is approximately parallel to that of the broken line which shows the linear variation concerning potassium bronzes. For the same value of y, the lattice constant of a sodium potassium bronze is larger than that of a potassium bronze, presumably due to the sodium ions which are incorporated in the corresponding potassium bronze. Extrapolation of the full line to $y=0$ suggests that the extremity of sodium potassium bronze, where the potassium content diminishes to null, would have the lattice constant 12.14 Å. This value may be considered to be not inconsistent with 12.1 Å reported by Magnéli[14] for the lattice constant of a tetragonal sodium bronze because of larger error involved.

Although a linear relationship exists as stated above between the lattice constant a and y of the sodium potassium bronzes, no correlation was found between the lattice constant a and x. Therefore it may be concluded that, in determining the structure of sodium potassium bronzes, the role of y, or of the potassium content, is more important than that of x, or of the sodium content.

Crystals of tetragonal potassium bronzes K_yWO_3 are stable for y values larger than 0.14.[3] The y values with which crystals of sodium potassium bronzes are stable extend from over 0.4 to less than 0.1. In other words, a tetragonal form of potassium bronze crystals has been made stable for smaller y values by introducing sodium ions into the structure.

The color of crystals of sodium potassium bronzes can be related to their lattice constants. Thus, as seen in Table 1, it varies from reddish to bluish as the lattice constant a is decreased. The same inclination was observed with sodium bronzes, including cubic and tetragonal.[15,16] Color referred to in this paper involves the relevant regular reflectance spectrum, which will be discussed elsewhere in the near future.

The density of eleven samples of sodium potassium bronzes, whose x and y values varied from 0.22 to 0.58 and from 0.07 to 0.39, respectively, was 7.15 g/cm^3 within an error of 0.03. This value argees with the density of tetragonal potassium bronze, 7.18 ± 0.03 g /cm^3 for $K_{0.40}WO_3$, by Sienko and Morehouse.[13]

The number of $Na_xK_yWO_3$ unit included in a unit cell of the crystal can be calculated from the observed density and lattice constants. The calculated value of the number for eleven different sodium potassium bronzes was 10, which agrees with

that of the tetragonal potassium bronzes published by Magnéli[10] and by Brimm *et al.*[3]

In conclusion, the close resemblance of tetragonal sodium potassium bronzes as a whole to tetragonal potassium bronzes, instead of to sodium bronzes, with respect to color, lattice constants, density and the related quantity, has convenced us that the crystal lattices of the sodium potassium bronzes are mainly decided by the lattices of the corresponding potassium bronzes, and that the sodium ions are incorporated and play a less important role in determining the structure of the crystal.

Studies of the Alkaline Earth Complexes in Various Solutions. V. Calcium(II) and Strontium(II) Complexes with Carbonate Ions in 1M Sodium Chloride Media

Yuko HASEGAWA, Hiroshi KAWASHIMA and Tatsuya SEKINE

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received November 28, 1969)

The complex formation of calcium(II) and strontium(II) with carbonate ions in 1M sodium chloride media at 25°C has been determined by a liquid-liquid distribution method. The metal ions in the aqueous phase were extracted with a mixture of benzoylacetone and tributylphosphate in hexane as adduct chelate complexes. The distribution ratio was determined by radiometry as a function of the carbonate-ion concentration in the aqueous phase. The decrease in the metal distribution caused by the addition of carbonate ions to the aqueous phase has been explained in terms of the complex formation, and the stability constants have been determined from these data by a "curve-fitting" method. It has been concluded from the results that the stabilities of these complexes are about the same magnitude of those of the sulfate complexes of these metal ions and that the concentration of the carbonate complexes in usual natural waters is probably negligibly small.

The formation of calcium(II) and strontium(II) complexes with carbonate ions may influence the chemical behavior of these metal ions in various aqueous solutions in equilibrium with atmospheric carbon dioxide, such as in the sea or in living bodies. Since the chemical behavior of these ions, especially of calcium(II), has attracted the attention of many chemists for many years, the solubility or solubility products of these metal carbonates have been reported repeatedly by many authors, but only few of these investigators have determined the stability constants of carbonate complexes in aqueous solutions.[1] The present authors have studied the solvent extraction of calcium(II) and strontium(II) in 1 M sodium chloride media containing various amounts of carbonate ions, and have determined the distribution ratio as a function of the carbonate concentration.

For the solvent extraction of calcium(II) and strontium(II), 8-hydroxy-quinoline has very often been used.[2-4] However, the solvent extraction method with this reagent seems to be unsuitable for the determination of complexes in aqueous solutions because the distribution behavior of the 8-hydroxyquinolinates of these metal ions is complicated due to the formation of an aqueous chelate with this extractant.[4] The use of thenoyltrifluoroacetone (TTA) in methylisobutylketone(MIBK) has been also suggested for the extraction of these metal ions.[5-6] The extraction equilibria of calcium(II)

or strontium(II) with TTA in carbon tetrachloride containing MIBK, tributylphosphate(TBP), or trioctylphosphine oxide (TOPO) have been studied in detail,[7] and these adduct-chelate extraction systems have been used for the study of the oxalate and sulfate complexes of alkaline earth metal ions in previous papers of this series.[8-11]

In the present study, the hydrogen-ion concentration of the aqueous phase had to be kept much lower than in the previous studies because carbonic acid is a weaker acid (the pK_{a_1} and pK_{a_2} in 1M $Na(ClO_4)$ are 6.04 and 9.57 respectively[12]) than sulfuric or oxalic acid; thus, it was necessary to keep the $-\log[H^+]$ above 8.5 in order to prevent the dinegative carbonate ions from associating with protons.

However, if the $-\log[H^+]$ is kept high, a chelating acid of a higher dissociation constant, such as TTA (pK_a is 6.23[7]), in the organic phase will be distributed into the aqueous phase due to the acid dissociation;[7] it was, therefore, concluded that the use of TTA as the extractant was unsuitable for the present purpose. For this reason, benzoylacetone (BZA) (pK_a is 8.96[3]) was employed in conjunction with TBP, which was found to form adduct complexes with the BZA chelates in hexane and which enhances the extraction considerably. The ionic media used in the previous studies were 1M $Na(ClO_4)$. These media, however, were found to be unsuitable for the present work because of the extraction of the mixed chelate or the metal perchlorate at higher TBP concentrations, as has been pointed out previously,[13] and so the 1M Na(Cl) media were employed throughout this study instead of the perchlorate media. The distribution ratio was determined from the radioactivity in the two phases. A decrease in the distribution ratio of the metal ions was caused by the addition of carbonate ions to the aqueous phase; this decrease was explained in terms of the complex formation. The stability constants were determined graphically from these data by using a curve-fitting method. These complexes were then discussed.

Experimental

Tracers. The calcium-45 was obtained from the Nuclear Science and Engineering Co., U. S. A., as a hydrochloric acid solution. The strontium-85 was obtained from the New England Nuclear Corp. as a hydrochloric acid solution. They were both diluted with a 1M sodium chloride solution. The calcium stock solution thus prepared contained 1.5×10^{-5}M calcium, while the strontium stock solution contained 7.5×10^{-6}M strontium.

Reagents. All the reagents were of an analytical grade. The TBP and MIBK were obtained from the Tokyo Kasei Co. In order to remove impurities, they were washed successively with 0.1M perchloric acid, water, and a 0.1M sodium hydroxide solution, and then several more times with water. The other reagents were used without further purification.

Procedures. All the procedures were carried out in a thermostatted room at 25 ± 0.5°C. Hexane containing BZA and 0.6M TBP was used as the organic solvent. The concentrations of BZA were 0.1M and 0.2M for the calcium and the strontium extractions respectively. The two phases were equilibrated in stoppered glass tubes (volume 20 m*l*). Various amounts of a 0.5M sodium carbonate solution and/or a 1M sodium acid carbonate solution were placed in the tubes. When it was necessary, a small amount of sodium borate (0.0025M at initial) was added to the aqueous phase as a buffer. The tracer (calcium-45 or strontium-85) was then added to this solution, and finally the aqueous phase was made up to 5 m*l* with a 1M sodium chloride solution. A 5-m*l* portion of the organic phase was then placed in the tubes, and the two phases were agitated mechanically for 30 min and then centrifuged. After the two phases had then been separated, a small portion of the aqueous phases was transferred into a glass vessel and the hydrogen ion concentration was determined potentiometrically by using 1M sodium chloride containing 1.00×10^{-2}M hydrochloric acid as the standard of $-\log[H^+]$ 2.00.

The radioactivity in the two phases was determined as follows. Calcium: A 2-m*l* portion of the aqueous phase was transferred into another stoppered glass tube and agitated with 2 m*l* of MIBK containing 0.2M TTA in order to extract the calcium into the MIBK phase. A 1-milliliter portion of this MIBK solution was pipetted out, placed on a stainless steel dish, and then decomposed gradually on a hot plate under controlled heating. The β-radioactivity of the sample in the dish was measured with an end-window-type G. M. counter. The calcium in the organic phase containing TBP was first back-extracted into 4m*l* of 0.1M nitric acid, and then a 2-m*l* portion of this aqueous phase was transferred into another tube and 2-m*l* of 0.1M sodium hydroxide were added. The calcium in this aqueous solution was treated just as has been described above.

Strontium. A two-milliliter portion was pipetted from each phase; these portions were then transferred into small test tubes. The γ-radioactivity of the samples was then measured with a well-type (NaI) scintillation counter.

ion, M^{2+}, with dinegative ligand ions, L^{2-}, in the aqueous phase may be described as:

$$M^{2+} + nL^{2-} \rightleftarrows ML_n^{2-2n} \quad (1)$$

$$\beta_n = [ML_n^{2-2n}]/[M^{2+}][L^{2-}]^n \quad (2)$$

The extraction of this metal ion into an organic phase containing a chelating acid, HA, and an adduct-forming ligand, E, may be described as follows:

$$M^{2+} + 2HA(org) + eE(org) \rightleftarrows MA_2E_e(org) + 2H^+ \quad (3)$$

$$K = [MA_2E_e]_{org}[H^+]^2/[M^{2+}][HA]_{org}^2[E]_{org}^e \quad (4)$$

In the present study, the concentration of the adduct-forming ligand (TBP) is kept constant (0.6M) throughout the experiments, and so the terms of this adduct-forming ligand will not be presented in the equations. Thus, the organic metal species will be denoted by MA_2, and the extraction constant, K_{ex} will be defined and described as;

$$K_{ex} = [MA_2]_{org}[H^+]^2/[M^{2+}][HA]_{org}^2 \quad (5)$$

When no ligand exists in the aqueous phase, the distribution ratio is:

$$D_0 = [MA_2]_{org}/[M^{2+}] \quad (6)$$

Then, the K_{ex} in Eq. (4) can be described as:

$$K_{ex} = D_0[H^+]^2[HA]_{org}^{-2} \quad (7)$$

Here, this K_{ex} should give a constant value at a certain temperature.

When the complex-forming ligand is present in the aqueous phase and when the concentration is $[L^{2-}]$, the distribution ratio may be described from Eqs. (2) and (5) as:

$$D = [MA_2]_{org}/([M^{2+}] + [ML] + [ML_2^{2-}] + \cdots) = D_0/(1+\sum\beta_n[L^{2-}]^n) \quad (8)$$

From Eqs. (7) and (8), the following can be described:

$$D[H^+]^2[HA]_{org}^{-2}/K_{ex} = (1+\sum\beta_n[L^{2-}]^n)^{-1} \quad (9)$$

The dissociation constants of carbonic acid are described as follows:

$$H_2CO_3 \rightleftarrows H^+ + HCO_3^-$$

$$K_{a_1} = \frac{[H^+][HCO_3^-]}{[H_2CO_3]}$$

$$HCO_3^- \rightleftarrows H^+ + CO_3^{2-}$$

$$K_{a_2} = \frac{[H^+][CO_3^{2-}]}{[HCO_3^-]}$$

The values in 1M $NaClO_4$ at 25°C are 9.12×10^{-7} and 2.70×10^{-10} respectively for K_{a_1} and K_{a_2}.[12]

The total concentration of carbonate ions is, then;

$$[\text{carbonate}]_{\text{total}} = [H_2CO_3] + [HCO_3^-] + [CO_3^{2-}] = [CO_3^{2-}]\left(1 + \frac{[H^+]}{K_{a_2}} + \frac{[H^+]^2}{K_{a_1}\cdot K_{a_2}}\right) \quad (10)$$

The concentration of the dinegative carbonate ions at a certain hydrogen-ion and a certain total carbonate concentration can be calculated from Eq. (10), while the stability constants, β_n, can be determined from the distribution data by a curve-fitting method[7-10] using Eq. (9).

Results

Dependence of D on the Hydrogen-ion Concentration. In order to determine the extraction constant, K_{ex}, in Eq. (5), the distribution ratio of the metal ions between 1M NaCl containing no carbonate ions and hexane containing 0.6M TBP and 0.1M BZA (extraction of Ca(II)) or 0.2M BZA (extraction of Sr(II)) was determined as a function of $-\log[H^+]$. The results are shown in Fig. 1. We can see from Fig. 1 that the plots of both the calcium(II) and strontium(II) extractions have a slope of +2. Thus, the extraction equilibria can be represented by Eq. (4); that is, neither the aqueous chelate formation nor the decrease in the $[HA]_{org}$ occurs in the hydrogen-ion concentration

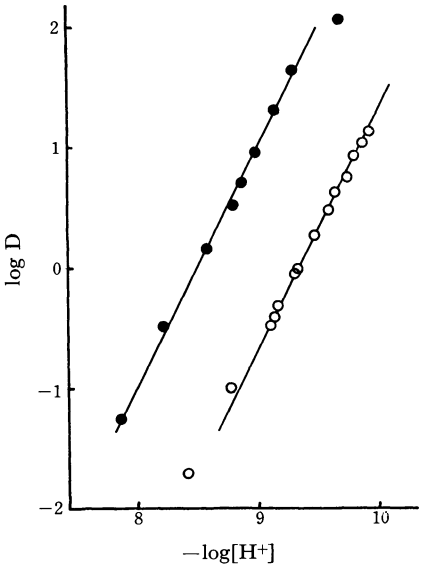

Fig. 1. Distribution ratio of calcium(II) (closed circles) and strontium(II) (open circles) as a function of the hydrogen ion concentrations.
Aqueous phase: 1M Na(Cl).
Organic phase: Ca(II), 0.1M BZA+0.6M TBP in hexane.
Sr(II), 0.2M BZA+0.6M TBP in hexane.
The straight lines give $\log D = -2\log[H^+] - 17.04$ ··· (Ca(II)) and $\log D = -2\log[H^+] - 18.75$ ··· (Sr(II))

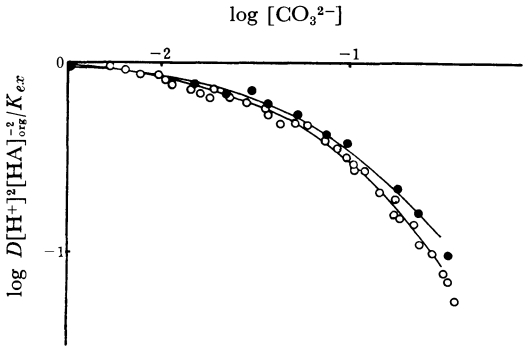

Fig. 2. Decrease in the calcium(II) (closed circles) and strontium(II) (open circles) extraction as a function of the carbonate ion concentration. The solid lines represent the followings;

$Ca(II): \log D[H^+]^2[HA]_{org}^{-2}/K_{ex} = -\log(1+10^{1.22}[CO_3^{2-}]+10^{1.38}[CO_3^{2-}]^2)$

$Sr(II): \log D[H^+]^2[HA]_{org}^{-2}/K_{ex} = -\log(1+10^{1.28}[CO_3^{2-}]+10^{1.60}[CO_3^{2-}]^2+10^{1.70}[CO_3^{2-}]^3)$

range studied in Fig. 1. The decrease in the extraction of metal ions by the addition of carbonate ions into the aqueous phase is given in Fig. 2. The results in Fig. 2 were analyzed by the curve-fitting method. The extraction curve of calcium(II) (closed circles) was found to fit with a standard curve by assuming the first and the second complexes. From the parameters of this best-fit standard curve, the stability constants were obtained as shown in Table 1. The extraction curve of strontium(II) (open circles), on the other hand, could be fitted to none of the standard curves drawn by assuming the formation of the first and the second complexes. Therefore, the curve-fitting was further carried out by assuming the formation of the third complex, and finally the best-fit standard curve was found. The three stability constants determined from the parameters of the standard curve for the strontium extraction are given in Table 1. Table 1 also gives the stability constants previously obtained in this series to facilitate comparison with the present results.

Discussion

From the present results, it may be concluded that the complexes containing the acid carbonate ion, HCO_3^-, are negligible within the limits of experimental accuracy. The data in Fig. 2 were plotted against the carbonate concentration disregarding the acid carbonate ions, but this seems to have caused no systematic deviation.

The stability constants of calcium(II) and strontium(II) carbonate complexes in Table 1 are rather similar to each other, except for the third complex of strontium(II), which has not been observed in calcium(II). Such similarity in the magnitude of the constants——in other words, the small difference in the stability constants among the complexes of metal ions of different ionic sizes——can also be seen in the sulfate complexes of alkaline earth ions given in Table 1. Although no direct evidence showing the nature of the interactions between the metal and the ligand ion could be obtained from only these distribution data, we might assume the following. Among these, the oxalate complexes should be the inner-sphere chelate complexes. On the other hand, the sulfate complexes should be mainly outer-sphere complexes (ion-pairs), as has been suggested by the kinetic data.[14] The similarity in the stabilities of sulfate and carbonate complexes can be explained if we assume that the carbonate complexes are also outer-sphere complexes.

The stability constants of carbonate complexes in Table 1 seem to show that the contribution of carbonate complexes to the total concentrations of these metal ions in usual natural water is negligibly small. For example, in a 1 M aqueous sodium chloride solution at pH 8, the total carbonate concentration necessary to convert a 1% portion of the total calcium(II) into carbonate complexes can be calculated from these data as about 2×10^{-2} M; this is about ten times larger than the carbonate con-

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1722—1728 (1970)

An NMR Study of Metal Complexes Containing Acetylacetone and Related Compounds. I. The Preparation, Halogenation and NMR Spectra of Cobalt(III) Complexes Containing Acetylacetone and Bis(acetylacetone)ethylenediimine

Yuki Fujii

Department of Chemistry, Ibaraki University, Bunkyo-cho, Mito, Ibaraki

(Received December 1, 1969)

A mixed cobalt(III) complex containing both bis(acetylacetone)ethylenediimine and acetylacetone anions, [Co(bean)(acac)] (bean=dianion of bis(acetylacetone)ethylenediimine, acac=anion of acetylacetone), was newly prepared and its electrophilic substitution reaction at the chelate ring protone was studied by means of NCS, NBS, and NIS (NCS, NBS and NIS are the abbreviated forms of *N*-chloro-, *N*-bromo- and *N*-iodosuccinimide). The structures of this complex, [Co(baen)-(acac)], and of the halogenated complex were both determined to be of the β-form (*cis* with respect to the coordinated two oxygen atoms of baen) on the basis of their NMR spectra. The ring protons of the imine chelates were found to be more reactive than that of the acetylacetone chelate in the chlorination reaction. Then, a bi-substituted complex, [Co(baen-Cl_2)(acac)], in which two chlorine atomes were attached to the two imine chelate rings, was prepared. Tri-substituted complexes, [Co(baen-X_2)(acac-X)] (X=Cl, Br and I), were also prepared. The quasiaromaticity of both the acetylacetone and imine rings was considered on the basis of their NMR spectra. A new complex, [Co(baen)(OH)(H_2O)], was also prepared in order to assign the NMR spectrum of the complex, [Co(baen)(acac)]. The IR, UV, and visible absorption spectra were also considered.

The quasiaromaticity of the metal-acetylacetonate is quite interesting and has been discussed by several authors. On the basis of their reactivity for the electrophilic substitution reaction, characteristic of aromatic compounds, Collman pointed out that metal-acetylacetonates had an aromatic character.[1,2] He also pointed out that imine complexes of β-diketone underwent electrophilic substitution reactions at the chelate-ring protons, as did acetylacetone complexes.[3] For the imine chelate, however, not such a large benzenoid resonance is expected as for the acetylacetone chelate because of the asymmetric property of the imine chelate.[4] Therefore, the quasiaromaticity of the imine chelate is quite an interesting question.

Under these circumstances, it seemed that it would be worthwhile to study the reactivity of the imine chelate ring towards the electrophilic substitution reaction and to compare the reactivity of the imine chelate ring with that of the acetylacetone chelate ring. Mixed cobalt(III) complex containing both the bis(acetylacetone)ethylenediimine anion (baen) and the acetylacetone anion (acac) was prepared and the halogenation reaction on the chelate ring was examined.

Experimental

Preparation of the Complexes. *1) Bis(acetylacetone)ethylenediiminatohydroxoaquocobalt(III)*, [Co(baen)(OH)(H_2O)] (I). Bis(acetylacetone)ethylenediiminatodiaquocobalt(II)[5] (12.5 g, 0.04 mol) was dissolved in 200 m*l* of methanol, 4.0 g of potassium hydroxide in 20 m*l* of water was then added, and the resulting solution was oxidized by sucking air through the solution for 4 to 5 hr. When the solution was allowed to stand overnight, reddish crystals were separated out in a low yield. They were subsequently recrystallized from methanol. Found: C, 45.69; H, 6.34; N, 8.65%. Calcd for $C_{12}H_{21}CoN_2O_4$: C, 45.58; H, 6.70; N, 8.86%.

When the filtrate of the complex I was further concentrated by allowing it to stand for 2 or 3 days in an atmosphere, dark green crystals were separated out. They were subsequently recrystallized from methanol. This dark green complex was assigned to the complex II on the basis of its NMR spectrum.

2) Bis(acetylacetone)ethylenediiminatoacetylacetonatocobalt(III), [Co(baen)(acac)] (II). Bis(acetylacetone)ethylenediiminatodiaquocobalt(II) (25 g, 0.079 mol) was dissolved in 200 m*l* of methanol. Acetylacetone (7.8 g, 0.078 mol) neutralized with potassium hydroxide (10 g) in 100 m*l* of water was then added. The resulting solution was oxidized by sucking air through the solution for 4 to 5 hr. After oxidation was completed, the solution was concentrated under a reduced pressure to a volume of about 200 m*l*. During the course of the concentration, a small amount of bisacetylacetonatocobalt(II) was isolated and filtered off. When the solution was allowed to stand for two days, dark green crystals were separated out. They were subsequently recrystallized from methanol. The yield was about 55%. Found: C, 53.68; H, 6.80; N, 7.36%. Calcd for $C_{17}H_{25}CoN_2O_4$: C, 53.55; H, 6.63; N, 7.35%.

Halogenation of the Complex II. *1) Bis(3-chloroacetylacetone)ethylenediiminatoacetylacetonatocobalt(III)*, [Co(baen-Cl_2)(acac)] (III). The methanol solution (40 m*l*) of NCS (2.0 g, 0.015 mol) was added slowly to the methanol solution (40 m*l*) of the complex II (3.8 g, 0.01 mol) at 40°C. After five minutes' stirring, about 100 m*l* of water was added. When the resulting solution was allowed to stand for a day at room temperature, light green crystals were separated out. They were subsequently recrystallized from methanol-water. Yield, about 1.2 g (27%). Found: C, 45.55; H, 5.25; N, 6.25%. Calcd for $C_{17}H_{23}CoCl_2N_2O_4$: C, 45.45; H, 5.16; N, 6.24%.

2) Bis(3-chloroacetylacetone)ethylenediiminato-3-chloroacetylacetonatocobalt(III), [Co(baen-Cl_2)(acac-Cl)] (IV). Method 1. A methanol solution (40 m*l*) of NCS (4.0 g, 0.03 mol) was slowly added to a methanol solution (40 m*l*) of the complex II (3.8 g, 0.01 mol) at about 50°C. The solution was stirred for five minutes and then treated with about 100 m*l* of water, and allowed to stand for a day at room temperature. This gave light green crystals and they were then washed with methanol. Yield, about 3.8 g (79%). Found: C, 42.65; H, 4.54; N, 5.44%. Calcd for $C_{17}H_{22}CoCl_3N_2O_4$: C, 42.22; H, 4.58; N, 5.79%.

Method 2. To a methanol solution (20 m*l*) of the complex III (0.54 g, 0.0012 mol), a methanol solution (10 m*l*) of NCS (0.2 g, 0.0015 mol) was added at 50°C. After five minutes, 50 m*l* of water were added and the solution was allowed to stand for a day. This gave light green crystals, which were subsequently washed with methanol. Yield, about 0.4 g (70%). Found: C, 42.36; H, 4.38; N, 5.52%. Calcd for $C_{17}H_{22}CoCl_3N_2O_4$: C, 42.22; H, 4.58; N, 5.79%.

3) Bis(3-chloroacetylacetone)ethylenediiminato-3-bromoacetylacetonatocobalt(III), [Co(baen-Cl_2)(acac-Br)] (V). To a methanol solution (20 m*l*) of the complex III (0.54 g, 0.0012 mol), a methanol solution (10 m*l*) of NBS (0.3 g, 0.0017 mol) was added at 50°C. After five minutes' stirring, about 50 m*l* of water was added to it. The resulting solution was allowed to stand for a day to give light green crystals, which were subsequently washed with methanol. Yield, about 0.4 g (63%). Found: C, 38.55; H, 4.36; N, 5.29%. Calcd for $C_{17}H_{22}CoBrCl_2N_2O_4$: C, 38.66; H, 4.20; N, 5.30%.

4) Bis(3-bromoacetylacetone)ethylenediiminatoacetylacetonatocobalt(III), [Co(baen-Br_2)(acac)] (VI). This compound was prepared from the complex II and NBS in methanol by the same method as in the case of the dichlorination described in *1)*. Yield, about 4.0 g (71%). Found: C, 36.88; H, 4.24; N, 5.07%. Calcd for $C_{17}H_{23}CoBr_2N_2O_4$: C, 37.94; H, 4.31; N, 5.21%.

5) Bis(3-bromoacetylacetone)ethylenediiminato-3-bromoacetylacetonatocobalt(III), [Co(baen-Br_2)(acac-Br)] (VII). This compound was prepared from the complex II (or the complex VI) and NBS in methanol in the way as described above *2)*. Yield, about 4.5 g (74%) for the method 1 and about 0.5 g (82%) for the method 2. Found for the method 1: C, 33.94; H, 3.55; N, 4.73%. Found for the method 2: C, 33.88; H, 3.47; N, 4.69%. Calcd for $C_{17}H_{22}CoBr_3N_2O_4$: C, 33.64; H, 3.65; N, 4.61%.

6) Bis(3-iodoacetylacetone)ethylenediiminato-3-iodoacetylacetonatocobalt(III), [Co(baen-I_2)(acac-I)] (VIII). This compound was prepared from the complex II and NIS in methanol by the method used in the case of trichlorination. Yield, about 5.0 g (65%). Found: C, 27.21; H, 3.05; N, 3.58%. Calcd for $C_{17}H_{22}CoI_3N_2O_4$: C, 26.94; H, 2.93; N, 3.70%.

Measurements. All the NMR spectra were recorded with a Hitachi R-20 spectrometer (60 MHz) at 35°C. The spectra were measured with about a 5—10% solution of deuterochloroform and/or carbontetrachloride. As the internal reference, chloroform (2.74 τ) (when deuterochloroform was used as the solvent) and tetramethylsilane (when carbontetrachloride was used as the solvent) were used. The infrared absorption spectra were taken on potassium bromide disks with a Hitachi EPI-S2 spectrophotometer. All the visible and ultraviolet absorption spectra were recorded by a Hitachi EPS-3 spectrophotometer, with methanol as the solvent.

Results and Discussion

Synthesis and Halogenation Reaction. The complex II was successfully prepared in a yield of about 55% by oxidizing an alkaline methanol solution containing both bis(acetylacetone)ethylenediiminatodiaquocobalt(II), [Co(baen)(H_2O)$_2$], and acetylacetone. Although the yield was low, it could also be prepared by oxidizing an alkaline

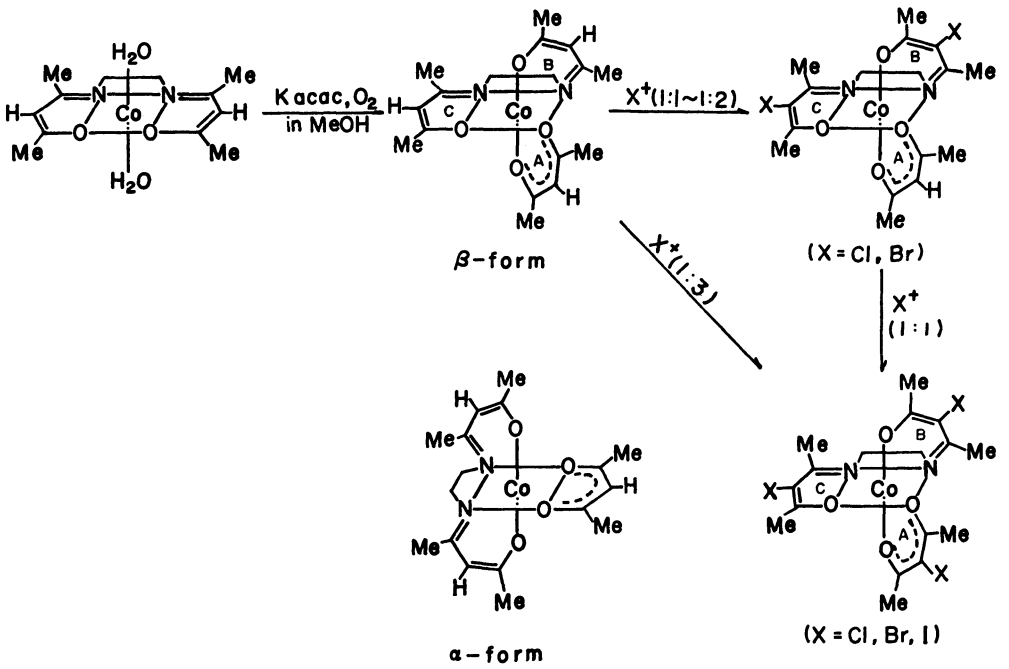

Fig. 1. The preparative scheme and the two geometrical isomers of the complex, [Co(baen)(acac)].

methanol solution containing only the complex, [Co(baen)$(H_2O)_2$]. With both procedures, only the β-form complex was isolated. Therefore, it may be presumed that the β-form may be preferred in this reaction, for the starting material, [Co(baen)-$(H_2O)_2$], takes a planer structure with respect to the two nitrogen atoms and the two oxygen atoms of the coordinated baen. Then, for the two oxygen atoms of baen to coordinate *trans* (α-form), two oxygen atoms of baen should move from the *cis* position to the *trans* position. However, only one oxygen atom should move when the β-form is taken.

Two dihalogenated complexes, III and VI, were obtained whenever the complex II was treated with NCS and NBS in a molar ratio of the reactants of 1 : 1 or 1 : 2. However, no diiodinated complex could be isolated because of the contamination of the complex VIII. When iodine monochloride (ICl) was used as the iodinating reagent, the complex II decomposed instantaneously.

The trichloro- and tribromo-substituted complexes were obtained by the two methods shown in the preparative scheme (Fig. 1).

NMR Spectrum of the Complex I. The NMR spectra of the new complexes are shown in Figs. 2, 3, and 4. The numerical data are summarized in Table 1.

The NMR spectrum of the complex I in deuterochloroform exhibits three types of protons, at τ 5.10, 6.97, and 8.15, with the area ratio of 1 : 2 : 6. On the other hand, in carbon tetrachloride I exhibits four types of protons, at τ 5.26, 7.02, 8.20, and 8.25, with the area ratio of 1 : 2 : 3 : 3. Since these spectra resemble that of bis(acetylacetone)ethylenediiminatonickel(II), [Ni(baen)],[4] the peaks were assigned as is shown in Table 1. The difference between the methyl signals in deuterochloroform and in carbon tetrachloride is thought to be due to the difference in the solvation effect; a similar

( ) represents the spectra in $CDCl_3$. * shows the complicated band.

phenomenon has been reported for the NMR spectrum of [Ni(baen)].[4] The assignment of the methyl signals in carbon tetrachloride is as follows: the lower-field signal is due to the methyls adjacent to the C–O groups, and the higher-field signal, to the methyls near the C–N groups,[4] since the methyls adjacent to the C–O groups would be slightly less shielded than those near the C–N groups because of the lower electronegativity of nitrogen than of oxygen.

The peak positions of all the protons were scarcely changed by replacing the metal ion from Ni^{2+} to Co^{3+}. This may be due to the nearly identical ionic radii of the two metal ions.

Though there are four possible geometrical isomers for the complex I, the probable structure may be (a) or (b) in Fig. 5, since the resonance of the ethylene protons shows a single peak.

The coordinated OH and H_2O protons in the complex I did not appear in this measurement ($\tau - 10.0 \sim 10.0$), perhaps because of the broadening.

NMR Spectrum of the Complex II. The

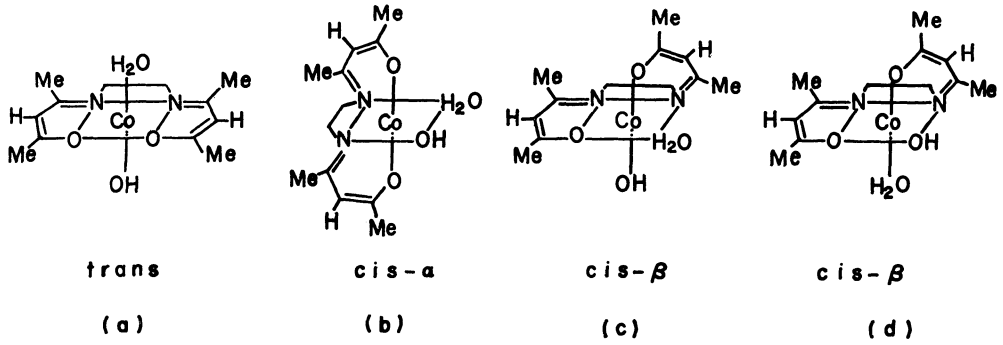

Fig. 5. The possible structures of the complex, [Co(baen)(OH)(H_2O)].

NMR spectrum of the complex II shows a rather more complex pattern than that of the complex I. Though two geometrical isomers are possible, as is shown in Fig. 1, this complicated pattern can be safely assigned to that of the β-form, for nine peaks with the area ratio of 1 : 1 : 1 : 4 : 6 : 3 : 3 : 3 : 3, in which the ethylene peak is splitted into the complex pattern, were observed in carbon tetrachloride. If the complex II took the α-form, six peaks, of which the ethylene peak consists of only one signal, should be observed. On the other hand, the β-form would give ten peaks, of which the ethylene peak would consist of more than one signal.

It is known that the signal of the ring proton of the trisacetylacetonatocobalt(II) complex appears at τ 4.63.[1] This position is apparently located at a field lower than that of the ring protons of imine chelates, such as are seen in the complex I. Therefore, the peak of τ 4.76 in carbon tetrachloride of the complex II may be assigned to the ring proton of the acetylacetone chelate, and the two peaks at τ 4.92 and 5.00 to the ring protons of the two imine chelates. The separation between the chemical shifts of the two imine ring protons is thought to be due to the differences in the solvation and ion-pair effects of the imine rings rather than to the differences in the diamagnetic shielding of the two imine ring protons by the ring-current of the acetylacetone chelate ring, for, from the molecular model, it is known that the ring proton of the B-ring in Fig. 1 is closer to the ethylene bridge than of the C-ring and only very small ring-current, if any, can be expected for the β-diketone complexes.[6] The separation between the chemical shifts of the ring protons of the acetylacetone ring (A-ring) and the ring protons of the imine rings (B- and C-rings) suggests that the electron density of the γ-position of the A-ring is a little smaller than those of the B- and C-rings and/or that the paramagnetic shielding for the A-ring proton by the ring-current of its own A-ring is a little larger than those in the case of the B- and C-rings. Experimentally, these separations were found to be due mainly to the differences in the electron density at the γ-position between the A-ring and the B- and C-rings, for the chlorination reaction at the imine ring (B- and C-rings) proton precedes the chlorination of the acetylacetone ring (A-ring). The details will be discussed in the next paragraph.

The peak of the ethylene-bridge protons is very complicated; such a complex pattern suggests that the configuration of the complex II is of a β-form, since only one peak is expected for that of the α-form on the basis of the symmetrical property.

The methyl protons show five peaks, with an area ratio of 6 : 3 : 3 : 3 : 3, but evidently the signal at τ 7.77 represents two methyl groups which have not been resolved.

The methyl signals of the complex II were assigned as follows, with the aid of the NMR spectra of the dichlorinated complex, III, and the trichlorinated complex, IV. The signals at τ 7.89 and 8.25 in the complex II were not shifted to the lower field even when the complex II was dichlorinated; they were shifted only when it was trichlorinated. Since the methyl signal of the acetylacetone chelate[1,2] and the imine chelate of β-diketone*1 is shifted to the lower field when the ring proton is halogenated, the two signals at τ 7.89 and 8.25 can be assigned to the two methyl groups of the acetylacetone ring. The two peaks, τ 7.79 and 8.18, can be assigned to the two methyl groups near the C–N groups, and the peak at τ 7.77, to the two methyl groups adjacent to the C–O groups of the imine rings, for the methyl protons near the C–N groups will appear at a higher field than that near the C–O groups.[4] The separation of the chemical shifts between the two methyl groups near the C–N groups is thought to be due to the difference in the steric strain between the two $-CH_2-N=$ groups. Since the steric strain in the C-ring is a little larger than that in the B-ring because of their steric requirement,[7] since, that is,

the C-ring takes the meridional form with respect to the two nitrogen atoms and one oxygen atom, while the B-ring takes the facial form, the signal at τ 7.79 can be assigned to the methyl group near the C–N group of the B-ring, and the signal at τ 8.18, to that of the C-ring.

If the ring-current of the β-diketone chelate compounds could be expected to be large enough to be detectable in the NMR spectra, the signals of the methyl groups of acetylacetone chelate should appear at a further lower field than those of the imine chelate of acetylacetone, for the benzenoid resonance of the imine chelate ring can be expected to be smaller than that of the β-diketone chelate ring because of the asymmetric property of the imine ring.[4] Therefore, the paramagnetic shielding of the methyl groups of the imine ring by the ring-current of its own ring is not expected to be larger than that of the acetylacetone ring. However, the peaks of the methyl groups of the acetylacetone ring evidently appear at a higher field than those of the imine rings in the complex II. Therefore, it may be concluded that the ring-current for the β-diketone chelate, if any, is very small, and that the ring-current for the imine chelate of β-diketone, if any, is very small, also. Here, again, the separation of the chemical shifts of the ring protons between the A-ring and the B- and C-ring is confirmed to be due mainly to the difference in the electron density at the γ-positions of the chelate rings.

NMR Spectra of the Complexes III, IV, and V. The dichlorinated complex, III, gives signals at τ 4.76, 6.34, 7.52, 7.57, 7.89, 7.99, and 8.25, with the area ratio of 1 : 4 : 6 : 3 : 3 : 3 : 3 in carbontetrachloride. Evidently, the two ring protons of the imine rings disappears upon dichlorination and only one peak, to be assigned to the ring protons of acetylacetone ring, remains at the same position as the ring proton of acetylacetone ring of the complex II. Therefore, it is clear that the dichlorination occurs at the two imine chelate rings. This means that the two imine-ring protons are more reactive than the acetylacetone-ring proton. This fact also indicates that the electron density at the γ-positions of the imine rings is slightly larger than that of the acetylacetone ring. Therefore, the difference in the chemical shifts of the ring protons between the imine and the acetylacetone rings can be concluded to be due mainly to the difference in the electron density of the carbon atoms (γ-position) where the ring proton is attached.

The methyl signals of the complex III are shifted to a lower field than those of the complex II except the two peaks at τ 7.89 and 8.25. As has been mentioned above, the shift of the methyl signals to the lower field is due to the halogen substitution at the γ-positions of their rings. Therefore, the methyl signals shifted to the lower field by dichlorination can be assigned to the methyl groups of the two imine rings, and the two peaks at τ 7.89 and 8.25, to the two methyl groups of the acetylacetone ring. These assignments are further supported by the NMR data of the trichlorinated complex, IV. The two peaks at τ 7.89 and 8.25 in the complex III are shifted to a lower field by trichlorination and the signal at τ 4.76 assigned to the ring proton of acetylacetone ring disappears.

The methyl protons of the imine rings of the complexes III and IV were also assigned in the same way described above for the complex II. Although the signal at τ 7.57 of the complex III in Fig. 3 seems to have the same intensity as that at τ 7.52, the integration of these peaks indicates that the intensity of the peak at τ 7.57 is half that of the peak at τ 7.52. This is due to the overlap of the skirts of these two peaks. The complex IV shows three methyl peaks, at τ 7.52, 7.62, and 7.98, with an area ratio of 9 : 3 : 6. It is estimated that the signal at τ 7.98 consists of the protons of the two methyl groups, of which one is the methyl group of the acetylacetone ring, and the other, the methyl group near the C–N group of the C-ring. Also, the signal at τ 7.52 is estimated to consist of three methyl groups; two of them are the methyl groups adjacent to the C–O groups of B- and C-rings, while the third is the methyl group near the C–N group of the B-ring.

In the NMR spectra of both complexes, III and IV, the signals of the ethylene-bridge protons are still complicated, as are those of the complex II. This indicates that the configuration of the β-form in the complex II holds also in the chlorinated complexes, III and IV.

The NMR spectrum of the complex V is nearly the same as that of the complex IV. This fact suggests that the substitution of the ring proton by chlorine or bromine atoms does not cause any remarkable change in their NMR spectra.

NMR Spectra of the Complexes VI, VII, and VIII. The NMR spectrum of the complex VI shows a very complicated pattern which is obviously different from that of the complex III. In spite of the dibromination, the signal at τ 5.00 remains, together with the peak at τ 4.76, in the complex VI, while the peak area also remains the same. Furthermore, many elemental analyses of the complex VI invariably showed that the complex VI has two bromines per mole. The possibility of the contamination of the tribrominated complex, VII, to the complex VI during the preparative procedure could thus be ruled out, since the former is less soluble in methanol than the latter and is easily separated from the reaction mixture. Since it has been reported that NBS is stronger than NCS as a halogenating reagent in methanol,[8] it is probable that the bromination occurs at the A-ring proton as well as the B- and

8) Y. Fujii, E. Kyuno and R. Tsuchiya, This Bulletin, **42**, 1301 (1969).

C-rings protons. Therefore, it can be estimated that the complex VI is a mixture of the three dibrominated compounds. This estimation is supported by the complicated methyl signals, that is, the peaks at τ 7.91 and 8.25 which are assigned to the two methyl groups of the unsubstituted acetylacetone ring exist together with the two peaks, at τ 7.54 and 7.91, which are assigned to the two methyl groups of the brominated acetylacetone ring by the aid of the NMR spectrum of the complex VII.

The tribrominated complex VII shows a spectrum very similar to that of the complex IV, though the positions of the peaks in the complex VII are shifted to a slightly lower field. Tribromination at γ-positions was confirmed by the disappearance of the three ring protons. The methyl peaks were assigned as in the case of the complex IV.

The triiodinated complex VIII showed a spectrum similar to those of the IV and VII complexes. Triiodination at the γ-positions is also confirmed by the disappearance of the signals of three ring protons. The peaks were assigned as in the case of the complexes IV and VII.

Table 2. IR spectra (in cm^{-1})

Complex	asym. $\nu_{C=C}$	asym. $\nu_{C=O}$ and $\nu_{C=N}$
(I)	1589	1511
(II)	1589	1515
(III)	1579	1520
(IV)	1570	—
(V)	1570	—
(VI)	1564	1515
(VII)	1561	—
(VIII)	1548	—

Infrared, Ultraviolet, and Visible Absorption Spectra. It has been established that the $\nu_{C=C}$ and $\nu_{C=O}$ bands in the region from 1600 to 1500 cm^{-1} of the trisacetylacetonatocobalt(III) complex are shifted to lower-energy site by the substitution at the γ-position and that only one band assigned to the $\nu_{C=C}$ remains in this region.[9]

The complex I shows two bands between 1600 and 1500 cm^{-1}, as is shown in Table 2. The band at the higher-energy site can be assigned to the $\nu_{C=C}$ band, and that at the lower-energy site, to the $\nu_{C=N}$ band.[10]

The complex II also shows two bands in this region. The band at 1589 cm^{-1} can be assigned to the $\nu_{C=C}$ bands of the acetylacetone ring and the imine ring, which overlap, and the band at 1515 cm^{-1}, to the overlapping bands of $\nu_{C=O}$ and $\nu_{C=N}$. The dihalogenated complexes, III and VI, show two bands in this region, though the intensity of the band at the lower-energy site is small. On the other hand, the trihalogenated complexes show only one band in this region. These bands were assigned as in the case of the trisacetylacetonatocobalt(III), as has been mentioned above. These IR spectra give strong evidence that the complex VI is a mixture of three dibrominated complexes.

The numerical data of the ultraviolet and visible absorption spectra of the new complexes are summarized in Table 3.

The first absorption band is shifted only a little by halogenation. On the other hand, the band near 340 mμ in the complex II is shifted to the lower-energy site by halogenation. The order of this red-shift is Cl<Br<I; this order is that expected for the order of the elongation of the π-system by introducing the halogen atom to the acetylacetone ring and its imine ring.[11]

The author wishes to express his deep thanks to Professor K. Yamamoto and Dr. M. Kodama of Ibaraki University for their encouragement. The author wishes also to express his deep thanks to Dr. M. Hirayama of Ibraraki University for his kind help in the measurements of the NMR spectra and to Professor S. Ito and his coworkers of Tohoku University for their kind help in the elemental analysis. He also wishes to thank Mr. A. Okada for his helpful assistance in the measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1729—1733 (1970)

Macro Chelate Rings. III.*1 Syntheses and Configurations of Complexes of New Ligands, 4,4′-Dimethyl-2,2′-bis(salicylideneaminomethyl)-diphenyl Ether and 4,4′-Dimethyl-2,2′-bis(salicylidene-aminomethyl)diphenylamine

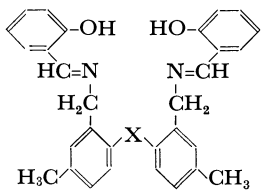
Hisashi Okawa, Hiroyuki Koyama, Takahiko Inazu and Tamotsu Yoshino

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received December 3, 1969)

Two quadridentate chelating agents, 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenyl ether and 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenylamine, which may form a metal complex with a ten-membered chelate ring, were synthesized by a sequence of steps. The cobalt(II), nickel(II), copper(II), and zinc(II) complexes could be derived from the ligands. Their configurations around the central divalent metal ion were explored on the basis of the absorption in the ligand field in a solution. A tetrahedral configuration for cobalt(II) complexes as well as the zinc(II) complexes, and a pseudo-tetrahedral configuration for the nickel(II) and copper(II) complexes, were concluded.

There have already been reports upon complexes derived from 2,7-dimethyl-4,5-bis(salicylideneaminomethyl)acridone[1] and 2,7-dimethyl-4,5-bis(salicylideneaminomethyl)xanthone,[2] which are sterically-controlled ligands and which form a non-planar metal complex with a ten-membered chelate ring with a divalent metal ion. They are rather favorable for a complex formation in that the two salicylideneaminomethyl groups are oriented in the same direction. If the carbonyl group in the acridone or the xanthone nucleus is eliminated from the ligand in each case, the new ligands thus made, which are 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenylamine and 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenyl ether (Fig. 1)



(X = O and NH)

I

Fig. 1. Structures of the ligands.

respectively, may be quite flexible and may form a metal complex different from the complex of the parent ligands. Out of our interest in the configuration of the complex with a macro chelate ring, we attempted to prepare the new chelating agents 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenyl ether and 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenylamine, shown in Fig. 1. It is, of course, one of the objects of this work to determine if a stable monomeric complex can be made from these ligands.

Experimental

Syntheses of Ligands. The synthetic schemes of the ligands are shown in Fig. 2. All the melting points are uncorrected.

2,2′-Dibromo-4,4′-dimethyldiphenyl Ether (II, X=O). To a solution of 4,4′-dimethyldiphenyl ether (40 g) in chloroform (100 m*l*), bromine (66.2 g) was added in the course of an hour's stirring, while the temperature was maintained at 60°C. The reaction mixture was then poured into water to give a pale-colored mass, which was collected and crystallized from alcohol as colorless prisms with a mp of 79—80°C. The yield was above 80%.

Found: C, 47.28; H, 3.51%. Calcd for $C_{14}H_{12}OBr_2$: C, 47.23; H, 3.68%.

2,2′-Dicyano-4,4′-dimethyldiphenyl Ether (III, X=O). A mixture of 2,2′-dibromo-4,4′-dimethyldiphenyl ether (30 g) and cuprous cyanide (15 g) in *N,N*-dimethylformamide (200 m*l*) was refluxed on an oil bath for six hours. Cuprous cyanide was then dissolved into a solution gradually. The reaction mixture was once filtered when hot and then poured into a hot solution of ferric chloride ($FeCl_3 \cdot 6H_2O$ 50 g, water 200 m*l*) to give a pale-colored mass of the nitrile, which

2) H. Okawa and T. Yoshino, *ibid.*, **43**, 805 (1970).

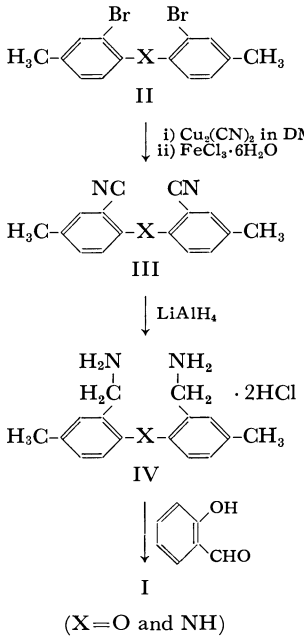

Fig. 2. The synthetic scheme of the ligands.

was collected, washed with water, and crystallized from ethanol as colorless needles with a mp of 131—132°C. The weight of the pure product was 16 g.

Found: C, 77.22; H, 4.77; N, 11.29%. Calcd for $C_{16}H_{12}N_2O$: C, 77.40; H, 4.87; N, 11.28%.

2,2′-Di(aminomethyl)-4,4′-dimethyldiphenyl Ether Dihydrochloride (IV, X=O). 2,2′-Dicyano-4,4′-dimethyldiphenyl ether (2.0 g) was reduced with lithium aluminum hydride (1 g) in tetrahydrofuran (50 m*l*). The mixture was then stirred for 5 hr at the boiling point of the solvent. After the reaction mixture had been decomposed with water (20 m*l*), the pH of the solution was adjusted to 8 and the inorganic substance which separated out was eliminated by filtration. The pale brown, oily substance which remained after the evaporation of the solvent was suspended in ether (150 m*l*), and to it we introduced a dry hydrogen chloride gas to give colorless needles of the diamine dihydrochloride. It was recrystallized from 95% ethanol.

Found: C, 58.31; H, 6.83; N, 8.33%. Calcd for $C_{16}H_{22}N_2OCl_2$: C, 58.26; H, 6.73; N, 8.51%.

4,4′-Dimethyl-2,2′-bis(salicylideneaminomethyl)-diphenyl Ether (I, X=O). 2,2′-Di(aminomethyl)-4,4′-dimethyldiphenyl ether dihydrochloride (0.6 g) and salicylaldehyde (1 g) were dissolved into 50% ethanol (150 m*l*), and then to the solution was added a 10% sodium bicarbonate solution until it was neutralized to give yellow needles; these needles were collected and recrystallized from ethanol as yellow needles with a mp of 92°C.

Found: C, 77.53; H, 6.03; N, 6.14%. Calcd for $C_{30}H_{28}N_2O_3$: C, 77.56; H, 6.08; N, 6.03%.

2, 2′-Dibromo-4, 4′-dimethyldiphenylamine (II, X=NH). To a solution of 4,4′-dimethyldiphenylamine (39.4 g) in chloroform (200 m*l*) we added bromine (35 g) over the course of one hour. After all of the bromine had been added, the stirring was continued for one more hour at the boiling point of chloroform. The reaction mixture was poured into water, and the organic layer was separated, washed with water, and dried over calcium chloride. When the solvent was evaporated, there remained an oily liquid, which soon solidified. It was crystallized from methanol as colorless needles with a mp of 61—63°C. The yield was 76%.

Found: C, 47.22; H, 3.66; N, 3.99%. Calcd for $C_{14}H_{13}NBr_2$: C, 47.36; H, 3.69; N, 3.94%.

2, 2′-Dicyano-4, 4′-dimethyldiphenylamine (III, X=NH). A solution of 2,2′-dibromo-4,4′-dimethyldiphenylamine (35.5 g) and cuprous cyanide (19.0 g) in *N,N*-dimethylformamide (200 m*l*) was heated on an oil bath for five hours. The reaction mixture was once filtered when hot, and then poured into a hot ferric chloride solution ($FeCl_3 \cdot 6H_2O$ 50 g, water 200 m*l*), to give a dark-colored, oily substance which solidified when cooled. It was collected, washed with water, and crystallized from methanol as colorless needles (17 g) with a mp of 151°C.

Found: C, 77.48; H, 5.26; N, 16.78%. Calcd for $C_{16}H_{13}N_3$: C, 77.71; H, 5.30; N, 16.99%.

2,2′-Di(aminomethyl)-4,4′-dimethyldiphenylamine Dihydrochloride (IV, X=NH). To a solution of 2,2′-dicyano-4,4′-dimethyldiphenylamine (2 g) in tetrahydrofuran (50 m*l*), we added powdered lithium aluminum hydride (1 g). After the mixture had then been heated at the boiling point of the solvent for seven hours under stirring, the reaction mixture was decomposed with water and the pH of the solution was adjusted to 8. After any inorganic substances had been eliminated by filtration, the solvent was evaporated. There remained a viscous oily liquid. It was then treated in the same way as 2,2′-di(aminomethyl)-4,4′-dimethyldiphenyl ether, and the reduced product was isolated as dihydrochloride in the solid state. It was recrystallized from 95% ethanol as colorless needles.

Found: C, 55.83; H, 7.35; N, 12.36%. Calcd for $C_{16}H_{23}N_3Cl_2 \cdot H_2O$: C, 55.49; H, 7.28; N, 12.13%.

4,4′-Dimethyl-2,2′-bis(salicylideneaminomethyl)-diphenylamine (I, X=NH). To a solution of 2,2′-di(aminomethyl)-4,4′-dimethyldiphenylamine dihydrochloride (0.6 g) and salicylaldehyde (1 g) in 50% ethanol (150 m*l*), we added a 10% sodium bicarbonate solution until neutralization had been effected. A yellow precipitate which separated was collected and crystallized from ethanol as yellow prisms or needles with a mp of 130—131°C. The yield was quantitative.

Found: C, 77.70; H, 6.32; N, 8.97%. Calcd for $C_{30}H_{29}N_3O_2$: C, 77.73; H, 6.31; N, 9.06%.

Syntheses of Complexes. Cobalt(II), nickel(II), copper(II), and zinc(II) complexes could be made from the ligands. However, we were not successful in preparing palladium(II) and platinum(II) complexes. The methods of synthesizing the complexes were almost all the same; a typical procedure is given below. A slight excess of a metal acetate and a ligand (Schiff base) were treated in warm ethanol. The solution was kept at 60—70°C for about half an hour and then allowed to stand until its temperature went down to room temperature. The product which separated was collected and washed with a small amount of ethanol.

The cobalt(II) complexes are orange prisms, and the nickel(II) and copper(II) complexes were green and black prisms respectively. On the other hand, the zinc(II) complexes were almost colorless prisms. Although the molecular weights of these complexes are not

measured, they are surely monomeric. The results of elementary analyses of these complexes are given in Table 1.

Measurements. The electronic absorption spectra of the complexes in solution were determined with a Hitachi EPS-3T spectrophotometer in the near-infrared and visible regions at room temperature. Wako spectrograde pyridine was used in some measurements. The infrared spectra were measured with a Hitachi EPI-S2 spectophotometer in the region from 4000—650 cm^{-1} on a KBr disk.

Results and Discussion

Infrared Spectra of Complexes. Some main infrared absorption bands of complexes of 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenyl ether are given in Table 2. When a complex was formed, a red shift of from 10 to 25 cm^{-1} in the C=N stretching vibration was observed and a new absorption band appeared at 1535 cm^{-1}; this band being constant when the metal was changed. On the other hand, the C–O stretching vibration due to diphenyl ether did not appreciably shift upon complex formation; this demonstrates that the possibility of interaction as well as of bonding between the central metal ion and the oxygen in diphenyl ether can be eliminated and that the ligand acts as a quadridentate chelating agent, forming a metal complex with a ten-membered chelate ring.

Cu	3370	1615	1535	1325
Zn	3325	1620	1535	1320

Data from the infrared absorption spectra of the complexes derived from 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenylamine are given in Table 3. By a complex formation, a red shift by 10 to 20 cm^{-1} in the C=N stretching vibration was found and a new absorption band appeared at 1535 cm^{-1}; this band remained constant even when the metal was exchanged. Although the N–H stretching vibration shifted toward a lower wave number, the possibility of a direct interaction or bonding between the metal ion and the nitrogen atom in diphenylamine was also eliminated by the fact that the C–N stretching vibration of diphenylamine did not considerably shift upon complex formation. Thus, it can also be concluded that this compound is a quadridentate ligand which forms a complex with a ten-membered chelate ring.

The Electronic Absorption Spectra and Configurations of Complexes. The electronic absorption spectra of the cobalt(II) complex of 4, 4′-dimethyl-2, 2′-bis (salicylideneaminomethyl) diphenyl ether clearly showed that the configuration of the complex was always tetrahedral in chloroform as well as in pyridine (Fig. 3). As it is well known that a tetrahedral cobalt(II) complex, which is made from *N*-substituted salicylideneimine, changes to an octahedral complex in a donor solvent pyridine,[3] the steric condition of 4,4′-dimethyl-2,2′-

3) H. Nishikawa and S. Yamada, This Bulletin, **37**, 8 (1964); **38**, 1506 (1965); E. Yoshida and S. Yamada, *ibid.*, **40**, 1395 (1967).

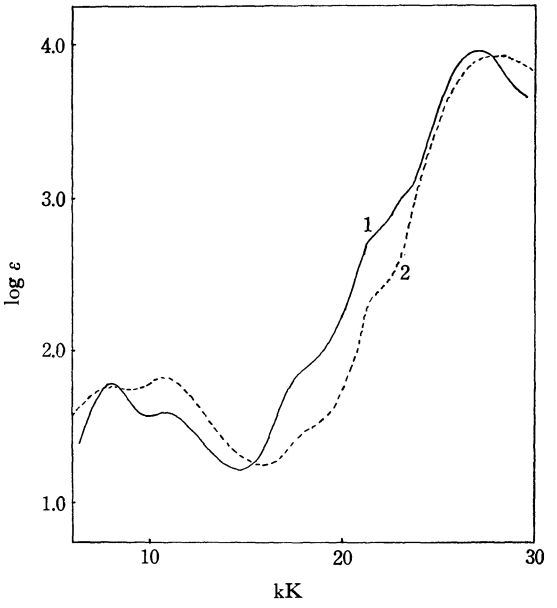

Fig. 3. Electronic absorption spectra of the cobalt(II) complex of 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenyl ether in chloroform (1) and pyridine(2).

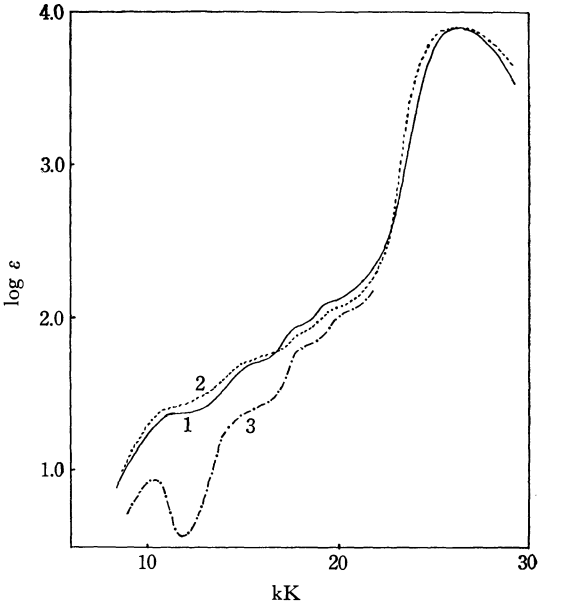

Fig. 4. Electronic absorption spectra of the nickel(II) complexes of 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenyl ether (1) and 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenylamine (2) in pyridine, and bis(*N*-isopropylsalicylideneiminato)nickel(II) in chloroform (3).

bis(salicylideneaminomethyl)diphenyl ether may be quite unfavorable for an octahedral configuration around the cobalt(II) ion. On the other hand, the cobalt(II) complex of 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenylamine was very unstable in solution, and we were unsuccessful in measuring the ligand-field band of the complex. However, it was supposed that the complex also had a tetrahedral structure because of the close resemblance of its infrared spectrum to that of the zinc(II) complex of 4,4′-dimethyl-2,2′-bis(salicylideneaminomethyl)diphenylamine.

The ligand-field bands of the nickel(II) complexes were measured in pyridine. They are given in Fig. 4. The appearance of the d-d transition bands in the region from 10—15 kK precluded a planar configuration around the nickel(II) ion, as it had been well established that a square-planar configurational nickel(II) complex of *N*-substituted salicylideneimine showed two d-d transition bands at 16—18 and 20—24 kK.[4] Although the measurements were done in pyridine, the possibility of an octahedral configuration around the nickel(II) ion could also be rejected; two d-d transition bands, at 9—10 and at 15—17 kK, were found in an octahedral nickel(II) complex of *N*-substituted salicylideneimines.[4,5] Judging from these facts and from the resemblance of the spectra of the nickel(II) complexes to that of a nearly tetrahedral nickel(II) complex bis(*N*-isopropylsalicylideneiminato)nickel(II), in which the angle between the planes containing the coordinating atoms of the chelate group and the nickel(II) atom is 81°,[6] it is quite natural to say that these nickel(II) complexes possess a tetrahedral configuration. The small shift in the ligand-field bands of our complexes from bis(*N*-isopropylsalicylideneiminato)nickel(II) may be caused by a distortion of a configuration around the nickel(II) ion.

The electronic absorption spectra of the copper(II) complexes measured in chloroform are given in Fig. 5. The d-d transition bands of the complexes shifted toward a considerably lower wave number than with a normal square-planar copper(II) complex, which had a d-d transition band at 17.5—17.7 kK. As it has been well established that this shift is caused by the distortion of the configuration around the copper(II) ion from coplanarity,[7] our complexes can be effected to be fairly much distorted. Yamada and Nishikawa[8] measured

the ligand-field bands of copper(II) complexes of *N*-R-substituted salicylideneimines in chloroform and found a band at 13 kK for R=*t*-butyl and one at 15.7 kK for R=isopropyl, *s*-butyl, 1-ethylpropyl or cyclohexyl; They decided that all of these are not planar but tetrahedral. On the other hand, Cheesemann *et al.*[9] studied several copper(II) complexes by X-ray analyses and found that the angle between the planes containing the coordinating atoms in the ligand and the central copper(II) ion in bis(*N*-*t*-butylsalicylideneiminato)copper(II) was only 54°. They also found that the angle in bis(*N*-ethylsalicylideneiminato)copper(II), which had been thought, from its absorption spectrum in solution, to be a planar complex, was unexpectedly, 36°. The drastic red shift in the d-d transition was, thus, caused by the fact that the angle between the planes containing the coordinating atoms and the central copper atom altered by only 18°. As the copper(II) complexes in this work had a ligand-field band at 14.7 kK, they must have an intermediate configuration. Insofar as their spectra are concerned, it is, however, reasonable to interpret the copper(II) complexes as exhibiting a pseudo-tetrahedral configuration.

The zinc(II) complexes must also have a tetrahedral configuration, judging from the steric requirements of the ligands, which inhibit a square-planar configuration, as well as from the tendency for a zinc(II) ion to take a tetrahedral configuration.

Metal Halide Complexes with Trimethylstibine Sulfide

Takayuki SAITO, Junzo OTERA and Rokuro OKAWARA

Department of Applied Chemistry, Osaka University, Yamadakami, Suita, Osaka

(Received December 23, 1969)

2:1 complexes of trimethylstibine sulfide (TMSS) with zinc(II), cadmium(II), mercury(II) and cobalt(II) halides were prepared. 1:1 complexes were also obtained with cadmium bromide and mercuric iodide. On the basis of infrared spectra, it was found that TMSS coordinates to the metal through the sulfur atom and that $Hg(TMSS)I_2$ has a sulfur-bridged structure. The electronic spectral parameters of the tetrahedral $Co(TMSS)_2X_2$ (X=Cl, Br and I) complexes are quite close to those of trimethyl-phosphine and -arsine sulfide complexes. These results indicate that for Co–S interactions, polarizability of the thioxo ligand is more important than polarity.

In previous papers, we reported the electronic character of the Sb–S bond in tertiary stibine sulfide[1] and the unique behavior of the bond towards organotin halides.[2]

Recently, various metal complexes with tertiary

phosphine[3-10] and arsine[11-14] sulfide were prepared and their properties were discussed in relation to the nature of the P–S or As–S bond. However, only a few investigations have been reported[2,8] on the metal complexes of tertiary stibine sulfide.

In the present paper, we describe the preparation and properties of the complexes of zinc(II), cadmium(II), mercury(II) and cobalt(II) halides with trimethylstibine sulfide (TMSS).

Experimental

Preparation of the Complexes. *Zinc and Cadmium Complexes.* These complexes were obtained by mixing the methanol solutions of the ligand and metal halides in stoichiometric ratios, followed by evaporation of the solvent. The complexes obtained were washed with methanol and dichloromethane. In the treatment of the ligand with cadmium bromide, the 1 : 1 complex was precipitated from the solution (yield 38%) and the 2 : 1 complex was obtained from the filtrate after evaporating the solvent under reduced pressure (yield 60%). When a large excess of the ligand was employed, only the 2 : 1 complex was obtained in a good yield.

$Hg(TMSS)_2Br_2$. On adding methanol solution of the ligand to mercuric bromide in methanol, yellow powder precipitated, which soon decomposed after separation from the solvent and could not be confirmed. From the filtrate the 2 : 1 complex was obtained. This complex decomposes slowly by heating and on exposure to light.

$Hg(TMSS)I_2$ and $Hg(TMSS)_2I_2$. To a suspension of mercuric iodide in methanol was added a slight excess of the ligand. The color of mercuric iodide gradually changed to pale yellow. Washing the obtained powder with dichloromethane gave the 1 : 1 complex. When a large excess of the ligand and mercuric iodide in chloroform were stirred until the color of mercuric iodide disappeared, white precipitates of the 2:1 complex were obtained.

$Co(TMSS)_2X_2$. The methanol solutions of trimethylstibine sulfide and cobalt halides were combined in 2:1 molar ratio. Evaporation of methanol under reduced pressure and washing the resulting precipitates with methanol and dichloromethane gave the corresponding complexes. The chloride complex, however was contaminated with a small amount of black precipitates which seemed to be CoS. The precipitates obtained by evaporating methanol were therefore quickly recrystallized from a large amount of dichloromethane-

methanol. The complexes decompose slowly in air in the solid state, and a little more rapidly in solution.

Sulfur-halogen Exchange Reaction. Trimethylstibine sulfide in methanol was added to an equimolar amount of mercuric chloride in the same solvent at room temperature. Black powder of mercuric sulfide was filtered off, and the filtrate gave trimethylantimony dichloride almost quantitatively. When trimethylstibine sulfide and mercuric bromide were mixed in hot methanol, a similar exchange reaction occurred, yielding trimethylantimony dibromide.

Analytical data of these complexes, together with their molar conductivities, are summarized in Table 1.

Physical Measurements. The infrared spectra in Nujol mulls were recorded with a Hitachi EPI-L grating spectrophotometer. Measurements of the electronic spectra were carried out by a Hitachi EPS-3 spectrophotometer. Molar conductivities were measured using a Yokogawa Universal Bridge (Bv-Z 13 C).

Results and Discussion

As shown in Table 1, trimethylstibine sulfide usually forms 2 : 1 complexes with the metal halides employed and also 1 : 1 complexes with cadmium bromide and mercuric iodide. No complex*1 can be obtained with mercuric chloride. However, sulfur-halogen exchange reaction (1) takes place, similar to that reported[2] for some organotin halides.

$$(CH_3)_3SbS + HgCl_2 \longrightarrow (CH_3)_3SbCl_2 + HgS \quad (1)$$

The infrared frequency of the ν(Sb–S) band in all the complexes, as listed in Table 2, shifts to a lower frequency by 25—55 cm^{-1} from that of the free ligand, indicating coordination through the sulfur atom. These ν(Sb–S) frequencies are comparable with, or a little higher than those (357—381 cm^{-1}) in trimethylantimony halide thiocarboxylates.[15] Thus, the Sb–S bond in the complexes seems to exist almost in the form of the semipolar structure, [I], although slight $d\pi$-$p\pi$ bonding might still remain in this bond.

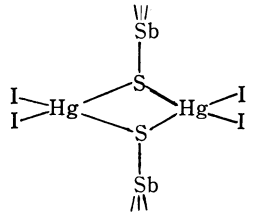
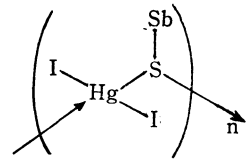
$$[(CH_3)_3\overset{+}{S}b\text{–}\overset{-}{S}]_2\cdot MX_2$$
[I]

The molar conductivities (Table 1) suggest weak dissociation of the halide anion in the zinc and cadmium complexes in acetonitrile. However, both ν(M–S) and ν(M–Cl) (or ν(M–Br)) bands can be observed in some of their infrared spectra in Nujol mulls so that the complexes appear to have a non-ionic tetrahedral structure in the solid state.

The 1 : 1 complex, $Cd(TMSS)Br_2$, is less soluble than the corresponding 2 : 1 complex, $Cd(TMSS)_2Br_2$. The molar conductivity (22.2 cm^2/ohm·mol) seems to be too small to assume the ionic structure, $[Cd(TMSS)Br]^+Br^-$. The associated structure may be presumed in the solid state for the tetrahedral arrangement around the cadmium atom, but the present data are not sufficient to give a more detailed structure. The 1 : 1 complex, $Hg(TMSS)I_2$, shows the marked lower shift of the ν(Sb–S) frequency as compared with the 2 : 1 complex, $Hg(TMSS)_2I_2$. This is interpreted as suggesting that the sulfur-bridged structure [II] or [III] is more probable than the halogen-bridged structure. The latter



(II)



(III)

structure is suggested for the 1 : 1 complex of mercuric bromide with tris(dimethylamino)phosphine sulfide on the basis of the infrared spectrum.[10]

From the low molar conductivities as given in Table 1, ionic formulations are ruled out for the cobalt complexes in dichloromethane. In accordance with these results, the electronic spectra of the complexes (Table 3) give two structured bands characteristic of tetrahedral coordination (ν_3, $^4A_2$–$^4T_1$(P) and ν_2, $^4A_2$–$^4T_1$(F)). As presented in Table 4, the ligand field splitting energies, Δ, and the β values calculated from the above data fall in quite

*1 It has been reported[5,7] that with mercuric chloride, trimethyl- and triphenyl-phosphine sulfide give 2 : 1 and 1 : 1 complexes, respectively.

close values to those obtained for trimethyl-phosphine and -arsine sulfide complexes. In the series of these three ligands, the basicity of the sulfur atom is likely to increase from phosphorus to antimony, because the size difference between the central atom and the sulfur atom becomes larger and the extent of $d\pi$-$p\pi$ bonding should decrease in this order. The close similarity of the electronic spectral parameters of the cobalt complexes indicates that the interaction of the cobalt atom with ligand is not affected by polarity of the ligand. It is apparent from the low β values that a considerably large covalency is implied in the Co–S bond. Thus, polarizability (or covalent-bonding character) of the ligand seems to have a primary effect on Co–S interactions. This is consistent with the results reported for the relations between the trimethylphosphine and -arsine sulfide complexes.[9]

(Received January 8, 1970)

Eight new complexes, *trans*(*N*) or *cis*(*N*) isomers of (L- or D-alaninate-*N,N*-diacetato) (amino-acidato)cobaltate(III) ions, have been synthesized as their potassium salts, where the amino acids are glycine, L-alanine and L-proline. Stereoselective formation of a limited number of the isomers with respect to the geometrical arrangement of the coordinated nitrogen and oxygen atoms and with respect to the position of the chelate ring containing the methyl group of the coodinated alaninate-*N,N*-diacetate ion, were confirmd from the results of the studies by ion-exchange column chromatography, proton magnetic resonance and circular dichroism spectra. The additivity of vicinal circular dichroism contributions from the two different optically active ligands in a complex has been discussed for the complexes without the configurational chirality.

There have been many studies[1,2] concerning the so-called vicinal contribution to circular dichroism (CD) spectra of Co(III) complexes containing optically active ligands; in most of these complexes,[1] however, the "vicinal" effect is combined with the "configurational" CD contribution due to a chiral configuration around the central Co(III) ion. Therefore, it was inevitable to separate the two kinds of contribution from each other on the CD curves. In a previous paper,[3] we reported the CD spectra of *trans*(*N*)- and *cis*(*N*)-(ammoniatriacetato)(L-amino-acidato)cobaltate(III) ions, [Co(ata)(L-am)]$^-$, in which the configuration around the central Co(III) ion is not chiral, and the coordinated chelate ligand has a chiral configuration. In the present paper,*1 the preparation and the CD curves of *trans*(*N*)- and *cis*(*N*)-(L- or D-alaninate-*N,N*-diacetato) (L-amino-acidato) cobaltate(III), [Co(L- or D-alada)(L-am)]$^-$, will be reported. These have no chiral configuration around the central Co(III) ion in a first approximation but have two kinds of optically active ligand in their coordination sphere, the one being bidentate and the other quadridentate. The electronic absorption spectra, CD and PMR spectra of these complexes will be discussed mainly in relation to their geometrical structures.

Experimental

Preparation of L- or D-Alanine-*N,N*-diacetic Acid. To a solution of 8.9 g of L- or D-alanine in 25 m*l* of 4N lithium hydroxide, a solution of 20.8 g of monochloroacetic acid in 30 m*l* of 4N lithium hydroxide and 80 m*l* of 4N lithium hydroxide were added simultaneously over a period of about 2 hr with vigorous stirring at 70°C, the pH of the reaction mixture being adjusted in a range of 9—10 all over the reaction time. At the end of the reaction, the mixture was heated at 90°C for about 10 min. After the reaction mixture had been cooled to room temperature, 25 m*l* of concentrated hydrochloric acid was added to it. The solution was concentrated as far as possible in a vacuum evaporator. When about 300 m*l* of absolute ethanol was added to the residue, insoluble crystals separated out, which were collected by filtration and then washed well warm ethanol. The white crystals were lithium salt of the desired acid, which was contaminated with a small amount of lithium chloride. It was recrystallized from 35 m*l* of 2N hydrochloric acid and then from 50 m*l* of 0.2N hydrochloric acid. The yield was approximately 10 g. L-aladaH$_3$: mp 199—200°C (decomp.), $[\alpha]_D^{25}$ −41.5° (*c* 4.0, water).

Preparation and Separation of Potassium (L- or D-Alaninate-*N*,*N*-diacetato)(amino-acidato)-cobaltate(III). *1) Trans(N)- and cis(N)-K[Co(L-alada)(gly)].* A solution of 7.5 g of cobalt(II) acetate tetrahydrate in 20 m*l* of water was added to a solution containing 6.2 g of L-aladaH$_3$ in 15 m*l* of 2N potassium hydroxide. To this solution was added gradually 4.0 g of lead dioxide and the mixture was warmed at 60°C on a water bath for about 40 min. After the mixture had been filtered, 2.3 g of glycine was dissolved in the blue-violet filtrate. When the solution was concentrated almost to dryness at 60°C on a water bath, the color of the reaction mixture changed from blue-violet to red-violet. To the residue was added a saturated aqueous solution of 2.6 g of potassium sulfate in order to eliminate the lead ion. The precipitate was filtered off. The filtrate was evaporated in a vacuum evaporator to a fourth of its original volume. When about 30 m*l* of methanol was added to the concentrated solution, the crude *trans*(*N*) isomer crystallized out. After cooling in an ice bath, the crude product was filtered out and recrystallized from water-methanol (1 : 2) mixture. This isomer was confirmed to be pure *trans*(*N*) isomer by ion-exchange column chromatography.[3] To the filtrate was added a large amount of ethanol and ether. The precipitated crude *cis*(*N*) isomer was filtered off and purified by ion-exchange column chromatographic method.[3] Recrystallization was achieved from water-methanol (1 : 1).

2) Trans(N)- and cis(N)-K[Co(L- or D-alada)(L-ala)]. The L-alada complexes were prepared and separated by a similar procedure to that of the corresponding glycinato complexes, using L-alanine instead of glycine. The D-alada complexes were prepared by the same way as that of L-alada complexes, using D-alada instead of L-alada.

In preparation 1) and 2), the *trans*(*N*) isomer can be also easily separated and purified from the original reaction mixture by ion-exchange column chromatography as in preparation 3) of L-prolinato complex.

3) Trans(N)-K[Co(L-alada)(L-pro)]·H_2O. To a solution containing 8.2 g of L-aladaH$_3$ in 20 m*l* of 2N potassium hydroxide was added a solution of 10.0 g of cobalt(II) acetate tetrahydrate in 30 m*l* of water. To the solution 5.3 g of lead dioxide was gradually added and the resulting mixture was warmed at 60°C on a water bath for 40 min. After the insoluble materials had been filtered off, 4.6 g of L-proline was dissolved in the filtrate and the solution was added to a saturated aqueous solution containing 3.5 g of potassium sulfate and the resulting precipitate was filtered off. A large amount of ethanol and ether was added to the filtrate. The crude product precipitated was purified by ion-exchange column chromatographic method.[3] The complex was recrystallized from water-methanol (1 : 5). The column chromatographic investigation indicated that no *cis*(*N*) isomer arose in this preparation.

4) Trans(N)-K[Co(D-alada)(L-pro)]·$2H_2O$. This complex was prepared and separated in a similar way to that of L-alada complex, using D-alada instead of L-alada. The *cis*(*N*) isomer was not formed in this preparation. Recrystallization was achieved from methanol containing a small amount of water.

In the preparation of each isomer, the solid complex finally isolated was more than 80% of the isomer separated by column chromatography.

The results of the chemical analysis for the complexes obtained are shown in Table 1.

Measurements. The electronic absorption spectra of the complexes were measured with a Shimadzu QV-50 spectrophotometer. The CD spectra were recorded with a Rousel-Jouan dichrograph. All the measurements were made in aqueous solution at room temperature.

The proton magnetic resonance (PMR) spectra of the complexes were recorded with a Japan Electron Optics JNM-4H-100 spectrometer operating at 100 MHz, in D_2O solutions. The spectra for the *trans*(*N*) complexes were measured after adding a few drops of 20% DCl to the D_2O solution to avoid the overlap of the signals of the complex and of HOD. No significant variation of the general pattern on the spectra was observed by the addition of the acid. Measurements were carried out using *t*-butanol as an internal standard. All the signals lie at a lower field than that of the standard. The chemical shifts are referred to NaTMS (sodium trimethylsilylpropanesulfonate) as zero; *t*-butanol resonates at 1.234 ppm downfield of NaTMS.

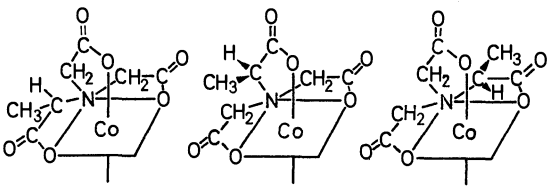

Fig. 1. Three geometrical isomers with respect to the methyl group of the coordinated L-alada.

Results and Discussion

Stereoselectivity. Complete stereoselective formation of the *trans*(*N*) isomer was observed in the preparation of (L- or D-alanine-*N*,*N*-diacetato)(L-prolinato)cobaltate(III) ion as in the case of (ammoniatriacetato)(L-prolinato)cobaltate(III) ion.[3] On the column chromatographic investigation of the reacted solutions, it was confirmed that for all of the present complexes the *trans*(*N*) isomers are dominantly formed in comparison with the corresponding *cis*(*N*) ones. This fact coincides with the results of the corresponding ata complexes.[3]

In the case of L- or D-alada complexes, three geometrical isomers due to the difference in the position of the chelate ring containing a methyl group are possible for each of the *trans*(*N*) and *cis*(*N*) isomer as shown in Fig. 1. It is reasonable to expect that these isomers concerning the methyl group are separable by ion-exchange column chromatographic method. For each of the present complexes, however, all the fractions by solubility difference or by ion-exchange chromatography showed a constant CD spectrum. All the *trans*(*N*) and *cis*(*N*) isomers were obtained in good isolation yields (more than 80% of the yields estimated by absorbance measurements). These results suggest that each of the complexes obtained is not a mixture of the isomers concerning the methyl group but only one type of isomer, and that the present complexes were stereoselectively formed. This consideration is strongly supported from the results of PMR and CD spectra of the complexes.

Proton Magnetic Resonance Spectra. It can

*2 This complex was prepared by mixing equivalent amounts of (L-alada)- and (D-alada)-complexes.

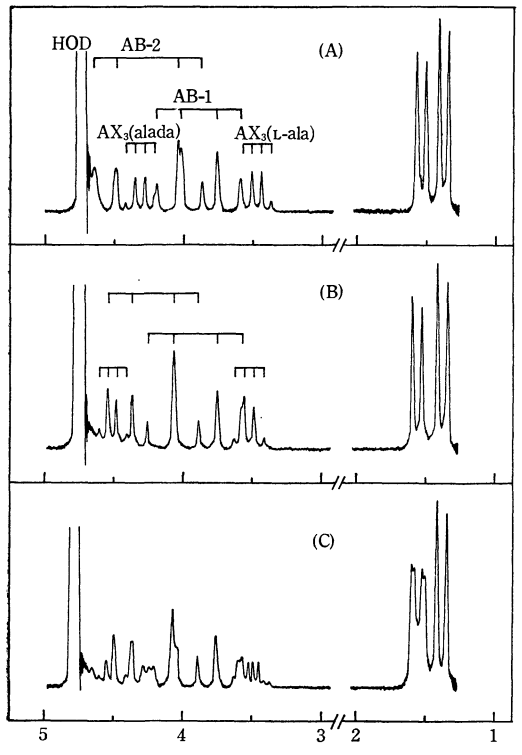

Fig. 6 PMR spectra of (A) *cis*(*N*)-K[Co(L-alada)(L-ala)]·$3H_2O$, (B) *cis*(*N*)-K[Co(D-alada)(L-ala)]·$3H_2O$ and (C) *cis*(*N*)-K[Co(DL-alada)(L-ala)]*[2] in D_2O solution.

be expected that the three geometrical isomers concerning the methyl group show a difference in their PMR spectra due to the protons of the coordinated alada or amino acid.

The PMR spectra of the complexes are shown in Figs. 2—6 and the assignments of the signals are summarized in Tables 2 and 3 with the coupling constants. For all the complexes, the signals for the protons of the alada consist of one AX_3 pattern due to the $>CH-CH_3$ and two AB pattern (AB-1 and AB-2) of equal intensities due to the two $-CH_2-$ groups. The molecular model indicates that the two $-CH_2-$ groups of the alada are in different environments; furthermore, the geminate protons in each the group are also in different environments. The appearance of two AB patterns due to the protons of L-alada coincides well with this topological consideration. This result indicates that the complexes obtained here are just one of the three isomers concerning the methyl group of alada.

The spectra of the alada complexes with L-alaninate exhibit another AX_3 pattern due to the metal-L-alaninate ring protons; the doublet and the quartet are at a fairly higher field than that of the protons of alada (Tables 2 and 3). This is justified by the chemical shifts of the corresponding ata complexes. Namely, the chemical shifts of the signals assigned to AX_3 pattern of L-alaninate protons in *trans*(*N*)-[Co(L- or D-alada)(L-ala)]$^-$ ion are quite similar to those (1.59 ppm for the doublet and 3.90 ppm for the quartet) of L-alaninate protons in *trans*(*N*)-[Co(ata)(L-ala)]$^-$ ion.*[3]

The complexes with L-prolinato ligand show very complicated spectra because of the many spin-spin couplings between the protons in pyrrolidine ring. Judging from the integrations and chemical shifts, however, it is possible to point out that the multiple signals at the region from 1.83—2.73 ppm are assigned to four ethylenic protons ($-CH_2CH_2-$) which are not adjacent to nitrogen atom and the

TABLE 2. PMR SPECTRAL DATA OF *trans*(*N*)-K[Co(L- or D-alada)(am)] COMPLEXES IN ACID D_2O SOLUTION

Assignment	Chemical shifts(ppm from NaTMS) (L-alada)-(gly)	(L-alada)-(L-ala)	(D-alada)-(L-ala)	(L-alada)-(L-pro)	(D-alada)-(L-pro)	Coupling constant(Hz)*

	4.32	4.31	4.32	4.34	4.32	
$-CH_2-$(AB-2)	4.31	4.34	4.33	4.34	4.32	16
	4.68	4.71	4.72	4.73	4.68	

* The values are common for all of the complexes.

*[3] Only one AB pattern and one singlet for the protons of the coordinated ata was observed in the spectrum of *trans*(*N*)-[Co(ata)(L-ala)]$^-$ ion.[3] From more detailed measurements, however, it was confirmed that the AB pattern splits into two as expected theoretically. Thus the two signals at the lower field in the AB quartet are somewhat broad, while each one at the higher field splits further into two signals of equal intensities separated by 1.0 Hz.

	61.0	(+0.37)		

The frequencies, ν_{ext}, are given in 10^{13} sec^{-1}.

signals at 3.03—3.93 ppm to the remaining two protons ($-CH_2-$). Consequently, the weak signals at 4.22, 4.30 and 4.37 ppm for the L-alada complex and the signals at 4.30 and 4.37 ppm for the D-alada complex will be assigned to the methine protons.

In conclusion, all the signals observed for each of the present complexes can be assigned without considering the existence of more than one isomer. Therefore, it is reasonable to consider that each of the complexes obtained consists of only one species of the three possible isomers concerning the methyl group of alada.

Circular Dichroism and Absorption Spectra. The visible absorption data of the complex ions are summarized in Table 4 and the representative curves are shown in Figs. 7 and 8. The absorption spectra are very similar to those of the corresponding ata complexes.[3] The geometrical structures with respect to the two coordinated nitrogen atoms were confirmed from the splitting pattern of the so-called first absorption band and from the ion-exchange column chromatographic behavior.[3-5] The CD data and curves of the complexes are shown in Table 5, and Figs. 7 and 8. The observed CD curve of the *trans*(*N*)-[Co(L-alada)(L-ala)]$^-$ and the *trans*(*N*)-[Co(D-alada)(L-ala)]$^-$ ion agrees quite well with the CD curve calculated from those of the *trans*(*N*)-[Co(ata)(L-ala)]$^-$ and *trans*(*N*)-[Co(L-alada)(gly)]$^-$ ions, on the basis of the following additivity formulas;[4]

$$\text{CD(L-alada, L-ala)} = \text{CD(L-alada, gly)} + \text{CD(ata, L-ala)} \quad (1)$$

$$\text{CD(D-alada, L-ala)} = \text{CD(D-alada, gly)} + \text{CD(ata, L-ala)} = -\text{CD(L-alada, gly)} + \text{CD(ata, L-ala)} \quad (2)$$

Similar good agreement of the observed CD curves with the calculated ones is also realized for the two *trans*(*N*) complexes with L-prolinate and for one of the two *cis*(*N*) complexes, *cis*(*N*)-[Co(L-alada)-(L-ala)]$^-$ (Figs. 7 and 8). These facts indicate that the additivity of the two vicinal contributions is perfect and each of the asymmetric carbon atoms of the two optically active ligands in a complex contribute independently to the optical activity of the complex ion. This agreement will show that the complexes obtained have commonly only one type of geometrical structure concerning the methyl group of the quadridentate ligand alada.

As an exception, the observed CD curve of *cis*(*N*)-[Co(D-alada)(L-ala)]$^-$ deviates considerably from the calculated one derived from the observed CD curves of *cis*(*N*)-[Co(L-alada)(gly)]$^-$ and *cis*(*N*)-[Co(ata)(L-ala)]$^-$ (Fig. 8). This deviation suggests that the position of the chelate ring containing the methyl group of the D-alada in this *cis*(*N*)-[Co(D-alada)(L-ala)]$^-$ complex obtained here differs from that of the other complexes, since from their PMR data we confirmed that the complex obtained is not a mixture of the possible isomers.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1744—1746 (1970)

Gold Complexes of Schiff Bases obtained from Salicylaldehyde Derivatives and Alkyl Amines*1

Shoichiro YAMADA and Kuniko YAMANOUCHI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received January 16, 1970)

Gold complexes (abbreviated as $[Au^{III}(X\text{-}SAL\cdot alkyl)_2][Au^{I}Cl_2]$) with salicylideneimine derivatives were prepared as red-brown crystals, where X denotes H, 5,6-benzo and 5-Cl. Since all these complexes are diamagnetic and exhibit similar electronic absorption spectra, the complexes of the $[Au(X\text{-}SAL\cdot R)_2]^+$ type are considered to have a similar configuration, namely a square-planar one. It should be noted that the complexes of the $[Au(X\text{-}SAL\cdot i\text{-}C_3H_7)_2]^+$ type are also planar. The result is found to be similar to that for the palladium(II) and platinum(II) complexes, but different from that for the nickel(II) complexes.

In previous papers, we reported palladium(II) and platinum(II) complexes with salicylideneimine derivatives,[1-3] in order to compare the results with those of the corresponding nickel(II) complexes, which had been studied extensively.[4,5] It seems to be of interest to extend a similar study to gold(III) having a $5d^8$ configuration and to compare the results with those of the corresponding complexes of nickel(II), palladium(II) and platinum(II), which also have a d^8 configuration. No systematic study has ever been carried out on the gold(III) complexes (Fig. 1)*2 with the Schiff bases, except for a small number of examples.[6] The present paper deals with the results of a study on these gold(III) complexes.

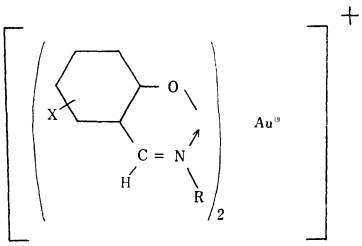

Fig. 1. $[Au^{III}(X\text{-}SAL\cdot R)_2]^+$.

Experimental

Materials. The complexes of the type $[Au^{III}(X\text{-}SAL\cdot R)_2][Au^{I}Cl_2]$ were prepared as red-brown crystals according to the following method.

To an aqueous solution of sodium tetrachloroaurate(III) dihydrate (0.01 mol) were added a solution of salicylaldehyde or its derivative (0.018 mol) in ethanol and a solution of an appropriate amine (0.02 mol) in ethanol. The resulting solution was warmed at about 40°C for about one hour. A brown precipitate formed in the solution was filtered off and recrystallized from suitable organic solvents.

Analytical data of the gold complexes obtained are shown in Table 1. Any attempt to isolate the complexes of the $[Au(X\text{-}SAL\cdot t\text{-}C_4H_9)_2][AuCl_2]$ type according to the method described above has so far been unsuccessful. In this case, the colour change of the solution immediately

took place, but crystals of the desirable complexes could not be isolated from the solution.

These gold complexes are soluble in acetone, chloroform and ethanol, but insoluble in water. The solubility, however, varies from compound to compound and from solvent to solvent. They are stable to the atmosphere, and do not undergo decomposition when stored in an ordinary sample-tube.

Measurements. Electronic absorption spectra of the gold complexes were determined with a Shimadzu MPS-50L spectrophotometer and a Shimadzu QR-50 spectrophotometer. The solution spectra were determined with ethanol or acetone as a solvent according to the solubility of the complex. The spectrum of the ethanolic solution was found to be nearly the same as that of the acetone solution, when the determination of the spectrum was possible with both solvents.

Diamagnetism of the complexes was detected by the Gouy method.

Electric conductivities of the complexes in acetone were determined with a Toadempakogyo CM-1 conductance bridge.

Results and Discussion

The gold complexes, $[Au(X\text{-}SAL\cdot R)_2][AuCl_2]$, obtained in the present work, which are shown in Table 1, are found to correspond to the empirical formula, Au(X-SAL·R)Cl. The oxidation state of gold in this formula might apparently be plus two. This, however, proves to be incorrect, since these complexes are all diamagnetic; the gold(II) complex, having a d^9 configuration, would be expected to be paramagnetic with one spin-free electron. Thus, we might assume that the complex with the composition Au(X-SAL·R)Cl be formulated as $[Au^{III}(X\text{-}SAL\cdot R)_2][Au^{I}Cl_2]$, which involves one gold ion in the tervalent and the other in the univalent state. It seems difficult to tell exactly how the reduction of gold(III) to gold(I) has taken place. However, gold complexes of this sort, containing $[Au^{I}Cl_2]^-$ or $[Au^{III}Cl_4]^-$ as a counter-anion, have often been reported in literature;[6,7] the syntheses of the complexes in these reports were also carried out using reactions of a type somewhat similar to those employed in the present work. Electric conductivities of some of the complexes in solution were determined. The values for the acetone solutions, which are shown in Table 2, seem to correspond to the values expected for uni-uni-electrolytes, in agreement with the formulation proposed above for these gold complexes.[7]

Since it is known that the gold(III) ion generally requires a quadri-coordinate planar configuration, the complexes of the $[Au(X\text{-}SAL\cdot n\text{-}alkyl)_2]^+$ may reasonably be considered to be planar, no steric hindrance being expected, in this case, against the planar configuration.

Table 2. Molecular conductivities(Λ) of gold complexes of the $[Au(X\text{-}SAL\cdot R)_2]\cdot[AuCl_2]$ type in acetone at 25°C

Compound		Conc.(mol/l)	Λ (mho)
H	n-C_3H_7	5.15×10^{-4}	144
	i-C_3H_7	6.12×10^{-4}	134
5,6-Benzo	i-C_3H_7	6.50×10^{-4}	132
	n-C_4H_9	7.75×10^{-4}	131
5-Cl	CH_3	5.91×10^{-4}	126

The complexes of the $[Au(X\text{-}SAL\cdot n\text{-}alkyl)_2][AuCl_2]$ type in solution show electronic spectra which are similar to each other. Some of the representative spectra are shown in Fig. 2.*3 In the region shown in Fig. 2, the ion $[AuCl_2]^-$ exhibits almost no absorption, so that the spectra in Fig. 2 may be considered to represent those due to the complexes $[Au(X\text{-}SAL\cdot n\text{-}alkyl)_2]^+$. That the spectra are similar to each other indicates that the complexes of the $[Au(X\text{-}SAL\cdot n\text{-}alkyl)_2]^+$ type have a similar configuration, namely a square-planar one. The broad absorption band which appears in the region between about 17 and 24 kK may be considered to arise principally from spin-allowed *d-d* transitions in the planar complexes $[Au(X\text{-}SAL\cdot n\text{-}alkyl)_2]^+$. The broadness of the band indicates that this band consists of a few components. The intensity of this band seems to be a little too high for the transitions of the pure *d-d* origin, but this finding may be interpreted as due to the considerably high mixing-in of the ligand π-orbitals with the metal *d*-orbitals, as has often been observed with most transition metal complexes with Schiff bases of a similar type. An intense absorption band with its maximum at about 26.7 kK may be considered as due to the internal transitions within the ligands under the influence of the gold(III) ion.

Since Beer's law holds for all these complexes in solution, no association of the planar gold(III) complexes is found to take place. This result is similar to that for the corresponding palladium(II) or platinum(II) complexes,[1-3] but different from that for the nickel(II) complexes, in agreement with the current view that the gold(III) ion, like the palladium(II) or platinum(II) ion, has a high tendency to take a quadri-coordinate planar configuration.

For the complexes of the $[Au(X\text{-}SAL\cdot i\text{-}C_3H_7)_2]^+$ type, steric hindrance may be expected to be considerably high against the planar configuration of the complexes. It should be remembered that the corresponding nickel(II) and copper(II) complexes of the $[M(X\text{-}SAL\cdot i\text{-}C_3H_7)_2]$ type were previously

*3 It was confirmed that the spectra of these complexes in the solid state are essentially similar to their solution spectra.

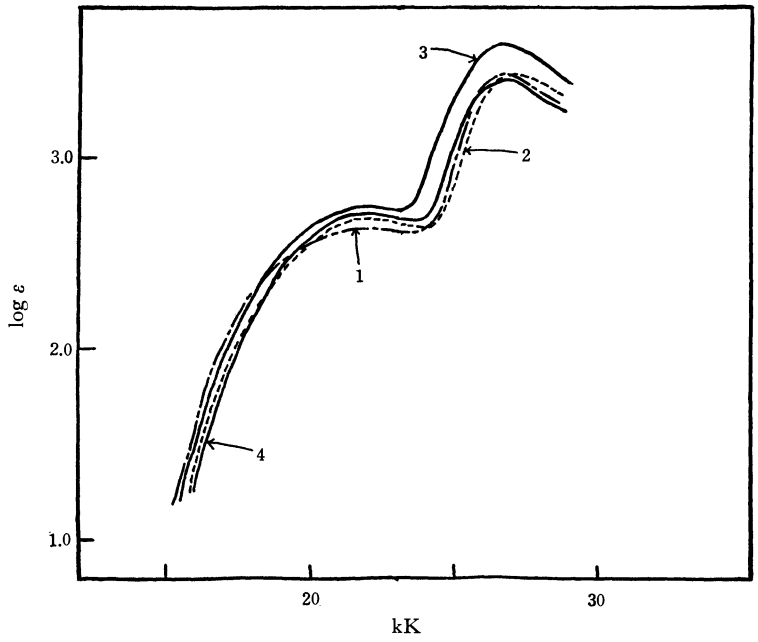

Fig. 2. Electronic absorption spectra of $[Au(X\text{-}SAL\cdot R)_2][AuCl_2]$. 1, X=H, R=*n*-$C_3H_7$, in chloroform; 2, X=H, R=*i*-C_3H_7, in acetone; 3, X=5,6-benzo, R=*i*-C_3H_7, in acetone; 4, X=5-Cl, R=CH_3, in acetone.

concluded to be tetrahedral or planar, depending upon X; they are tetrahedral for X=H[8,9] and planar for X=5-Cl and 5,6-benzo.[9] It is considered that the gold(III) complexes of the $[Au(X\text{-}SAL\cdot i\text{-}C_3H_7)_2]^+$ type have a planar configuration, since their spectra are similar to those of the complexes of the $[Au(X\text{-}SAL\cdot n\text{-alkyl})_2]^+$ type. This result with the gold(III) complexes is evidently different from that with the corresponding nickel(II) complexes, both metal ions having a d^8 configuration. This difference between the gold(III) and the nickel(II) complexes may be ascribed principally to the two factors, which are related with the bonding nature and the size of the metal ions, in quite the same way as was previously discussed in the case of the corresponding palladium(II) and platinum(II) complexes.[1-3]

The Transformation of the Triphenylmethyl Radical into the Triphenylmethyl Cation in the Sulfur Dioxide - Oxygen System

Hiroshi TAKEUCHI, Toshikazu NAGAI and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received May 10, 1969)

The decomposition of phenylazotriphenylmethane (I) in the presence of SO_2 and O_2 in benzene at 60°C gives *p*-hydroxytetraphenylmethane (II) by the reaction of the trityl cation and the phenol formed in the reaction system. However, in the absence of O_2 or SO_2, the above-mentioned reaction produces trityl phenyl sulfone (III) or bistrityl peroxide (IV), without forming any II. Also, 1-diphenylmethylene-4-trityl-2,5-cyclohexadiene (Gomberg's trityl) (V) has been chosen as the trityl radical source, and reacted with phenol in the presence of SO_2 and O_2 to give II as the product. However, in the absence of SO_2, IV and a trace of II are formed. Moreover, in the absence of O_2 in the above system, *p*-benzhydryltetraphenylmethane (VI) and a small amount of II are formed. The benzene solution of VI is stable on exposure to air at 60°C. Further, the UV spectrum of V in the liquid SO_2-O_2 system shows λ_{max} at 405 mμ (log ε 4.1) and 434 mμ (log ε 4.1) (trityl chloride in 98% H_2SO_4: λ_{max} 430 mμ (log ε 4.58)). However, the UV spectrum of VI in the liquid SO_2-O_2 system has no absorption in this range. The NMR spectrum in the liquid SO_2-O_2 system of V exhibits only aromatic protons (2.6—3.1 τ). These facts indicate that the trityl radical generated from V is transformed into the trityl cation in the SO_2-O_2 system at room temperature, whereas VI does not dissociate into the trityl radical even at 60°C in benzene.

We have previously established[1] the reaction of SO_2 with a radical source such as phenylazotriphenylmethane (I) which is able to liberate both the π- and the σ-character radicals[2,3] (the trityl and phenyl radicals). The nearly-quantitative formation of trityl phenyl sulfone (III) in the above reaction could be considered to be the result of the intramolecular radical recombination of the radical pairs (the phenylsulfonyl and trityl radicals) surrounded by SO_2 molecules.

On the other hand, the reaction of I with SO_2 in the presence of O_2 gave *p*-hydroxytetraphenylmethane (II) and benzenesulfonic acid, but neither III nor bistrityl peroxide (IV). Busch and Knoll have reported[4] the formation of II from the ionic reaction of Ph_3CCl with PhOH. Therefore, the formation of II from I in the presence of SO_2 and O_2 was expected to result by means of the trityl cation formed from the trityl radical. The thermal electron-transfer reaction[5] in the presence of SO_2 and O_2 has been recongnized as reasonable in the polymerization of *N*-vinylcarbazole.

The present study was concerned with the ionic behavior of the trityl radical in the SO_2-O_2 system by using I and using 1-diphenylmethylene-4-trityl-2,5-cyclohexadiene (V) as the trityl radical source. Phenol was used as a trapping reagent of the trityl cation.

Further, the transformation of the trityl radical into the tritvl cation in the liquid SO_2-O_2 system was proved by a study of the UV and NMR spectra. This fact arouses our interest in the field of polymerization.

Results and Discussion

The Effect of Oxygen - Sulfur Dioxide in the Reaction of Phenylazotriphenylmethane (I) with Phenol. In a previous paper,[1] we reported that the reaction of I with SO_2 in benzene or *n*-heptane gave trityl phenyl sulfone (III) in a good yield:

$$\underset{\text{(I)}}{Ph\text{-}N{=}N\text{-}CPh_3} + SO_2 \xrightarrow[\text{in benzene or } n\text{-heptane}]{-N_2} \underset{\text{(III)}}{Ph\text{-}SO_2\text{-}CPh_3}$$

In the presence of O_2, the above reaction gave *p*-hydroxytetraphenylmethane (II), benzenesulfonic acid, and a small amount of phenol, but neither III nor bistrityl peroxide (IV) was found, although the reaction of I with only O_2 gave IV, without

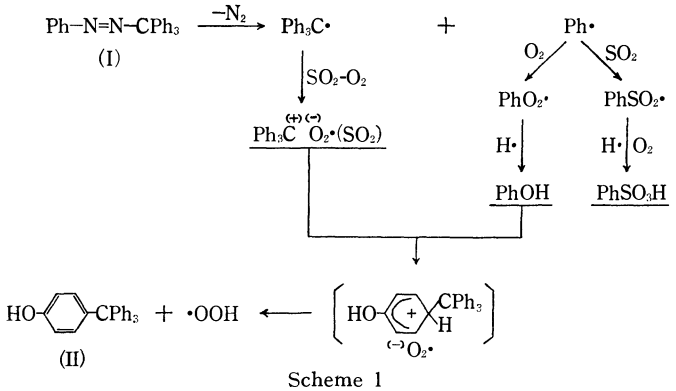
any II. These facts suggest that the reaction in the presence of SO_2 and O_2 is ionic. Actually, Busch and Knoll[4] reported a 98% yield of II from the reaction of Ph_3CCl with PhOH. Therefore, it was expected that II was formed by the reaction of the trityl cation with phenol.

Then, phenol (five equivalents to I) was added to the system (Exp. 1). In this reaction, the yield (58%) of II increased in comparison with the yield (18—24%) of II in the reaction without phenol. However, in the absence of O_2 in Exp. 1, III was formed without giving II (*cf.* Exp. 2). These facts suggest the formation of II by the reaction of the trityl cation with phenol, as in Scheme 1:

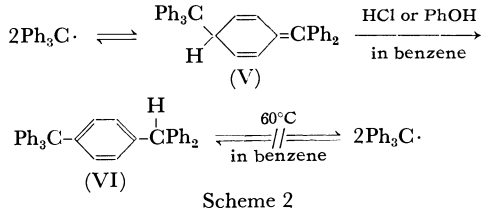


Scheme 1

The Effect of Oxygen - Sulfur Dioxide in the Reaction of 1-Diphenylmethylene-4-trityl-2,5-cyclohexadiene (V) with Phenol. The reaction of V with phenol in the presence of SO_2 and O_2 in benzene at 60°C gave II (52%) (*cf.* Exp. 3). However, in the absence of SO_2, IV (41%) and II (trace) were formed in Exp. 4. Moreover, in the absence of the O_2 of Exp. 3, *p*-benzhydryltetraphenylmethane (VI) (45%) and a small amount of II were formed (*cf.* Exp. 5).

These observations support the idea that the transformation of the trityl radical into the trityl cation in the SO_2-O_2 system occurs as Scheme 1 shows.

The Formation of *p*-Benzhydryltetraphenylmethane (VI). As is indicated in Exp. 6, VI was obtained by the reaction of V with phenol under Ar gas. When HCl was used in place of phenol, VI was also produced (Exp. 7).



Scheme 2

It has been reported by Lankamp, Nauta and MacLean[6] that Gomberg's trityl has a cyclohexadiene structure, as is shown in Scheme 2. Gomberg *et al.*[7,8] have reported that the reaction of V with HCl or CH_3COOH gives hexaphenylethane. However, it was found that the product was not hexaphenylethane, but VI, on the basis of the IR, NMR and mass spectral data (*cf.* Exp. 5). The details of the reaction mechanism of the formation of VI will be reported in the near future.*1

The UV spectrum of VI has $\lambda_{max}^{cyclohexane}$ at 263 mμ (log ε 3.11). The NMR spectrum of VI shows aromatic protons (2.6—3.1 τ) and a methine proton (4.6 τ) in CCl_4. The mp (225—227°C) of VI is higher than the mp (145—147°C) of V. Further,

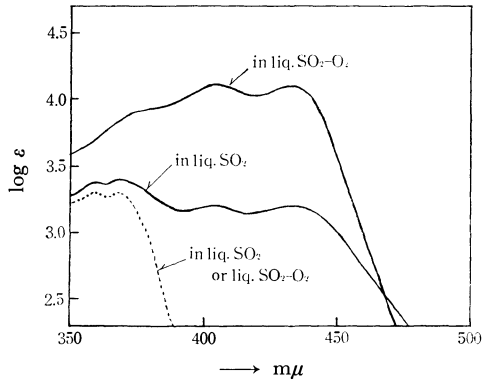


Fig. 1. The electronic spectra of Gomberg's trityl (V).
—— Gomberg's trityl (V)
---- *p*-Benzhydryltetraphenylmethane (VI)

6) H. Lankamp, W. Th. Nauta and C. MacLean, *Tetrahedron Lett.*, **1968**, 249.
7) M. Gomberg, *Ber.*, **35**, 2877 (1902).
8) F. Ullmann and W. Borsum, *ibid.*, **35**, 3914 (1902).

*1 In the experiment using I in place of the V of Exp. 3, VI was never found. Similarly, the treatment of 1-(phenyl-*p*-tolylmethylene)-4-(diphenyl-*p*-tolylmethyl)-2,5-cyclohexadiene with HCl in benzene afforded α,α,α′-triphenyl-α,α′-ditolyl-*p*-xylene by the isomerization of the cyclohexadiene structure.

Table 1. The UV spectra of V in liquid SO_2 and liquid SO_2-O_2

Average	3.4	3.4	3.2	3.2	3.9	4.1	4.1

This transformation is shown as Fig. 1.

the benzene solution of VI is stable on exposure to air, even at 60°C.

The Transformation of the Trityl Radical into the Trityl Cation in the Liquid SO_2-O_2 System. The UV spectra of Compound V were measured in liquid SO_2 and liquid SO_2-O_2 systems at room temperature. The results are summarized in Table 1.

This transformation is shown as Fig. 1.

In the liquid SO_2-O_2 system, no absorption corresponding to the trityl radical[9] appears. The values of log ε at 405 and at 434 mμ in liquid SO_2 were 3.2,*2 whereas those in the liquid SO_2-O_2 system were 4.1. The UV spectra of the trityl cation have been established to be as follows:

Trityl chloride[10]: $\lambda_{max}^{98\%\ H_2SO_4}$ 430 mμ (log ε 4.58).

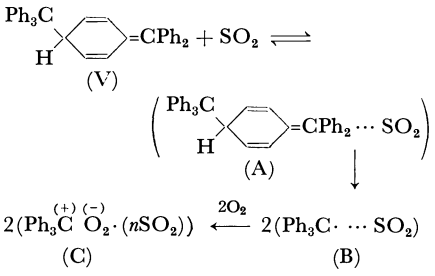
Compound V[11]: $\lambda_{max}^{H_3PO_4}$ 400 mμ and 440 mμ (log ε 4.5).

Compound V[11]: $\lambda_{max}^{POCl_3}$ 420 mμ and 440 mμ (log ε 4.2).

Therefore, the peaks at 405 and 434 mμ in the liquid SO_2-O_2 system may be said to correspond to the absorptions of the trityl cation.

The absorption with $\lambda_{max}^{SO_2}$ at 360 and 368 mμ is observed characteristically in liquid SO_2. Also, the UV spectrum of VI was measured as: $\lambda_{max}^{SO_2\ or\ SO_2\text{-}O_2}$ 360 mμ (log ε 3.3) and 368 mμ (log ε 3.3). The UV spectrum of VI does not have the absorption corresponding to the trityl cation in the liquid SO_2-O_2 system, indicating that the dissociation of VI into the trityl radical does not occur as in Scheme 2, since the trityl radical is transformed into the trityl cation in this system. This finding is in fair agreement with the chemical evidence. In a cyclohexane solution, the absorption with λ_{max}= 360 and 368 mμ did not appear in the case of either V or VI.

These observations indicate that the absorption with λ_{max}=360 and 368 mμ is attributable to a C–T complex of SO_2 with V (*cf.* A in Scheme 3).

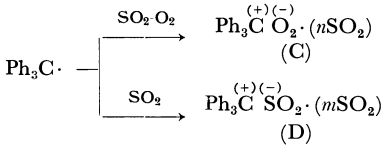


Scheme 3

Therefore, the transformation of V into C may be assumed to proceed *via* an A complex. The oxygen counter anion is stabilized by a solvated SO_2 such as $\overset{(-)}{O}_2\cdot(nSO_2)$.

The NMR spectrum shows that the cation formed from V in this system is not the 1-diphenylmethylene-2,5-cyclohexadienyl cation, but the trityl cation having only aromatic protons (2.6—3.1 τ).

Although the electron affinity of SO_2 (0.2—0.3 eV)[5] is larger than that of O_2 (0.15 eV),[5] the promotion*3 of the transformation of the trityl radical into the trityl cation in SO_2-O_2 rather than SO_2 may be expected to proceed as follows:



Scheme 4

The interaction energy between an anion and solvated SO_2 molecules with a dipole moment may

9) W. Theilacker and M. L. W. Ewald, *Ann.*, **594**, 214 (1955).

*2 The dissolved oxygen in liquid SO_2 was eliminated by the method described in the Experimental section. However, this absorption may arise from a very small amount of oxygen, or else from the trityl cation already generated in liquid SO_2.

10) A. G. Evans, J. A. G. Jones and G. O. Osborne, *J. Chem. Soc.*, **1954**, 383.

11) T. L. Chu and S. I. Weissman, *J. Chem. Phys.*, **22**, 21 (1954).

*3 Because of the following reasons, it seems feasible that a trityl cation such as D is formed even in the liquid SO_2 system, as is shown in Scheme 4. The UV spectrum of V even in liquid SO_2 shows peaks corresponding to those of the trityl cation, as Fig. 1 shows. Further, the reaction of V with phenol in the presence of SO_2 and Ar gas, as in Exp. 5, gives II (11%) and thus corresponds to the reaction of the trityl cation with phenol.

be represented by the following formula:

$$\overset{(-)}{O_2}\cdot \underset{r_i}{\longleftrightarrow} SO_2 \quad E_1 = \sum_{i=1}^{n}\{N(-e)\mu_{SO_2}\cos\theta_i/r_i^2\}$$

$$\overset{(-)}{SO_2}\cdot \underset{r_j}{\longleftrightarrow} SO_2 \quad E_2 = \sum_{j=1}^{m}\{N(-e)\mu_{SO_2}\cos\theta_j/r_j^2\}$$

$-e$: electric charge.
μ_{SO_2}: dipole moment of SO_2 (1.61 debye).
r: distance between dipole and ionic center.
θ: angle between the direction of r and that of μ_{SO_2}.
N: Avogadro number.

Since $\overset{(-)}{SO_2}\cdot$ is bulkier than $\overset{(-)}{O_2}\cdot$, the value of r_i is smaller than r_j. Therefore, the absolute value of the interaction energy between $\overset{(-)}{O_2}\cdot$ and SO_2, E_1, becomes greater than that between $\overset{(-)}{SO_2}\cdot$ and SO_2, E_2, so that the difference between the above interaction energies appears to compensate sufficiently for the electron affinity difference between SO_2 and O_2. Also, the Coulombic enregy stabilization by $\overset{(+)}{Ph_3C}$ and $\overset{(-)}{O_2}\cdot$ is greater than that by $\overset{(+)}{Ph_3C}$ and $\overset{(-)}{SO_2}\cdot$. These stabilization energies of the trityl-cation formation due to the oxygen counter anion, $\overset{(-)}{O_2}\cdot(nSO_2)$, may act as the driving force to transform the trityl radical into the trityl cation in the SO_2-O_2 system.

Experimental

Apparatus. The IR spectra were run on an EPI-S2-type Hitachi IR spectrometer. The NMR spectra were obtained with a Japan Electron Optics Lab. spectrometer (JNM3H-60). The UV spectra were taken on an EPS-3 Hitachi recording spectrometer.

Materials. The liquid SO_2 was dehydrated with P_2O_5 and distilled. The benzene was purified by an ordinary method. The phenol was obtained commercially. The phenylazotriphenylmethane (I) (mp 111°C dec.) was synthesized by the method of Cohen and Wang.[12] The 1-diphenylmethylene-4-trityl-2,5-cyclohexadiene (V) was synthesized by the method of Gomberg and Cone.[13]

Experiment 1. Compound I (4.7 mmol) and phenol (23.5 mmol) were dissolved in 95 m*l* benzene; the solution was then heated at 60°C for 2 hr with stirring while 70 g of gaseous SO_2 and O_2 were being passed through. The benzene was distilled under reduced pressure. The residue was chromatographed over silica gel, using benzene as the eluent; we then isolated and identified the *p*-hydroxytetraphenylmethane compound (58%), showed no depression of mp in a mixed-melting-point determination and which had an IR spectrum identical with that of an authentic sample.[4]

Experiment 2. Compound I (8.6 mmol) and phenol (43 mmol) were dissolved in 60 m*l* benzene; the solution was then heated at 60°C for 2 hr while 30 g of gaseous SO_2 were being passed through. The benzene was distilled under reduced pressure. The residue was crystallized from MeOH - ether, and trityl phenyl sulfone (55%) was isolated and identified. This compound showed no depression of mp in a mixed-melting-point determination with an authentic sample,[1] and the IR spectra were identical.

Experiment 3. Compound V (4.7 mmol) and phenol (47 mmol) were dissolved in 65 m*l* benzene; the solution was then heated at 60°C for 2 hr with stirring while 32 g of gaseous SO_2 and O_2 were being passed through. *p*-Hydroxytetraphenylmethane (52%) was confirmed as has been described above.

Experiment 4. In this experiment, SO_2 was eliminated from the system of Exp. 3. The residue obtained after the evaporation of the benzene was chromatographed over silica gel, using a petroleum ether - benzene mixture as the eluent by changing the polarity of the eluting medium. Bistrityl peroxide (IV) was isolated and identified, along with a small amount (3%) of *p*-hydroxytetraphenylmethane.

Bistrityl Peroxide (IV). Mp 183°C (recrystallized from toluene), 41%. This compound showed no depression of mp in a mixed-melting-point depression with an authentic sample[14] and had an identical IR spectrum.

Experiment 5. This experiment was carried out much as in Exp. 3, but Ar gas was used in place of O_2. The residue after the distillation of the benzene was chromatographed over silica gel, using a petroleum ether - benzene mixture as the eluent by changing the polarity of the eluting medium. The following compounds were isolated and identified (*p*-hydroxytetraphenylmethane (11%) was also confirmed, as has been described above):

***p*-Benzhydryltetraphenylmethane (VI).**[15] Mp 225—227°C (recrystallized from benzene - acetic acid), 45%, IR: 2880 (ν_{C-H}), 840 cm^{-1} (*p*-substituted phenyl). $\lambda_{max}^{cyclohexane}$ 263 mμ (log ε 3.11), shoulder; 255 mμ (log ε 3.15), 269 mμ (log ε 2.99) and 272 mμ (log ε 2.67). NMR (in CCl_4): τ; 2.6—3.1 (aromatic, multiplet, 29H), 4.6 (methine, singlet, 1H). Mass spectrum: *m/e*; 486, 409, 243 and 167.

Found: C, 93.71; H, 6.41%. Calcd for $C_{38}H_{30}$: C, 93.79; H, 6.21%.

Triphenylmethane. Mp 92°C (recrystallized from MeOH), 6%. This compound showed no mixed-mp depression.

Experiment 6. In this experiment, Ar gas was used in place of the SO_2 and O_2 of Exp. 3. *p*-Benzhydryltetraphenylmethane (68%), *p*-hydroxytetraphenylmethane (3%), and triphenylmethane (3%) were confirmed as has been described above.

Triphenylcarbinol. Mp 164°C, 5%. The IR spectrum of this compound coincided with that of a specimen synthesized by another method; this compound was confirmed by a mixed-mp determination.

Experiment 7. Compound V (2.9 mmol) was dissolved in 15 m*l* of benzene saturated with HCl; the solution was then allowed to stand at room temperature for half an hour. The benzene was distilled by reduced

pressure, and 25 ml of ether was added to this residue. *p*-Benzhydryltetraphenylmethane (82%) was confirmed as has been described above.

Measurement of the UV and NMR Spectra. The dissolved oxygen in liquid SO_2 was eliminated by the following method. The dehydrated and distilled liquid SO_2 was frozen by liquid N_2 and evacuated at about 10^{-3} mmHg. Subsequently, this solvent was melted at room temperature by introducing Ar gas. This operation was repeated six times. This liquid SO_2 was used in the measurement of the UV and NMR spectra at room temperature.

Kinetics for Reversible Menschutkin Reactions. The Effects of Variations in Reactant Structures on the Sensitivity of the Reaction Rate to Solvent Variations

Takeki MATSUI and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received June 5, 1969)

The reaction rates and equilibrium constants for quaternization of *N,N*-dimethylaniline and its derivatives with methyl iodide have been measured in acetonitrile, acetone, tetrahydrofuran, nitrobenzene, benzene, benzyl alcohol, and methanol at various temperatures. There is an approximate tendency for the solvent dependence of the reaction rates to diminish linearly with increasing reactivity of nucleophile. This could be interpreted in terms of the theory of an absolute reaction rate and of the concept of the rise of interaction term. In this connection it was proposed that such a problem must be considered in terms of the unitary term of rates. Using the data of rates of the reaction between pyridine and methyl iodide in various solvents, the activity coefficients of dimethylaniline and its derivatives in methanol relative to that of pyridine are estimated. Some inferences have been drawn concerning the nature of S_N2 transition state from effects of solvents on both rates and equilibria.

The nucleophilic tendency for S_N2 reactions seems to be affected by the nature of electrophiles and of solvents, and also by temperature and pressure. The effects of variations in substrates on nucleophilic tendency have the subject of some authors.

However, the subject is not so simple as Swain and Scott considered.[1] From the study of Hine and Weimar on carbon basicity, correlation of nucleophilicity of bases with the hydrogen basicity is not always good.[2] Qualitatively the priciple of hard and soft acids and bases (HSAB) seems to be an explanation for this problem. Pearson *et al.*[3] explained qualitatively the fact that no good correlation exists for the difference between methyl iodide and *trans*-$[Pt(py)_2Cl_2]$ in the variations of rates of reactions with charged and uncharged bases in terms of this principle. It seems, however, unlikely that there is no systematic tendency at all. For one thing it has been reported that there is a relatively simple linear relation between the nucleophilic tendency and the polarizability of leaving group.[4]

It should be noted that most experiments on these problems were carried out using the most complicating medium, water as solvent. It is yet uncertain whether the specificity of water as solvent contributes to the nucleophilic tendency in any way.

Thus it is of importance to examine the effects of solvents on nucleophilic tendency. For the Finkelstein or S_NAr reactions, Parker and his collaborators have tried to settle these effects on nucleophilic tendency by comparing the S_N2 reactivity in each solvent-solvent pair.[5] It remains to be proved whether the compilation of both charged

and uncharged nucleophiles should be made after due consideration of the solvent used. We have studied this type of problem within the linear free energy relationship framework of unchanged nucleophiles.[6] It has been proposed that the effects of solvents on the measure of sensitivity to the variations in nucleophiles (as an example, Hammett's ρ value) and the effects of variations in nucleophiles on the measure of sensitivity to the variations in solvents (denoted by ζ) are two aspects of the phenomenon. Therefore, the subject can be discussed as the factors influencing the value of ζ. The present paper reports a study of some factors influencing the dependence of the reaction rates of the quaternization of a base $R \cdot C_6H_4N(CH_3)_2$ with methyl iodide on solvent variations. The effects of R on ζ, the comparison of pyridine with dimethylaniline as a nucleophile, and the difference of ζ of the reaction based on methyl iodide and 2,4,6-trinitro-anisole or methyl picrate are reported here.

The reaction of dimethylaniline or its derivatives with methyl iodide have been followed in various solvents.[7] This reaction is of interest with respects to the occurrence of a reverse decomposition reaction at relatively low temperature. Rossell[7a] has made use of data for the series of this reaction to throw a doubt upon earlier views expressed by Glasstone *et al.*[8] of the resemblance of the transition state to quaternary ammonium salt produced. In this respect the present paper supports his view: The transition state is not as highly ionic as the quaternary ammonium salt.

Experimental

Materials. *N,N*-Dimethylaniline and its derivatives were prepared and purified as in our earlier work.[6] The purity was checked by glc in which only a single peak was observed. Methyl iodide was purified by the method of Cowley and Partington.[9] The purification procedure was repeated once a month. Various solvents used except acetonitrile were purified as in the previous paper. Acetonitrile was purified by the method of Coetzee *et al.*[10] The purification procedure was repeated once a week. The density of these solvents which were measured at a certain temperature agreed with the earlier values[11] within $\pm 0.2\%$. Glc chart for solvents showed sufficient purity.

Apparatus and Kinetic Procedure. Pipettes were calibrated both with water and with each solvent, and burettes were calibrated with water. The experimental procedure of Rossell[7a] was used with the following modifications; (1) Aliquot portions withdrawn were analyzed for iodide by potentiometric titration with 0.005N to 0.01N silver nitrate and not with 0.02N silver nitrate as in the Volhard method. (2) Prevention of further reaction during the extraction was done by dilution with cold benzene rather than with light petroleum. (3) The reaction vessels were pyrex glass tubes which could be closed with a polyethylene plate in place of ampoules. Sealing could be omitted. Initial concentration of each reactant was 0.02—0.1M.

a) The Simple Kinetic Runs. The kinetics except for noted in the later section gave good second order rate constants in which the rate law is the simplest. When comparison was made of results obtained with independently prepared solutions, the reproducibility was within $\pm 2\%$ even in the worst case. Examples of the results are given in Fig. 1.

b) Kinetics Accompanying the Methanolysis of Methyl Iodide. Quaternization based on *N,N*-dimethylanilines in methanol gave good second order rate constants. The use of *N,N*-dimethyl-*m*-nitro aniline makes the kinetic run complicated, not because of the reverse decomposition reaction, but because of the slow rate of quaternization relative to the concurrent methanolysis of methyl iodide.[7b] However, analysis of the kinetic data through a way similar to our earlier paper[6] gave the rate constant with reasonable accuracy. The rate law used is

$$(dx/dt)_0 = k \cdot a \cdot b + k_M \cdot a, \quad (1)$$

where a and b are the initial concentrations of methyl iodide and *N,N*-dimethyl-*m*-nitroaniline, respectively, k is the second order rate constant, k_M is the first order rate constant of methanolysis of methyl iodide, and $(dx/dt)_0$ is the initial rate of the production of salt. Modification of equation (1) shows the linear relation between the term on the left hand side and b, *viz.*,

$$(dx/dt)_0/a = k \cdot b + k_M \quad (2)$$

Therefore k is given by the slope of this linear plot and

k_M by the intercept. Fig. 2 shows such plots. The results of k and k_M are given in Table 1. We believe that the accuracy of k by this method is no less than that of other methods. Both k and k_M show the Arrhenius relationship over the temperature range of experimental condition.

This type of correction was also made for the reaction of *N,N*-dimethyl-*m*-chloroaniline with methyl iodide. The reverse decomposition reaction might give a further complication, but it did not occur in methanol even at 70°C. The concentration of iodide at 20 half-lives period showed 100.3% completion for the reaction of *N,N*-dimethyl-*m*-toluidine with methyl iodide.

c) Kinetics Accompanying the Reverse Decomposition Reactions. Most of the present reactions show a rapid fall of the second order rate constants as the reaction proceeds. The higher the temperature and the more nonpolar the solvent is, the larger the decrease becomes.

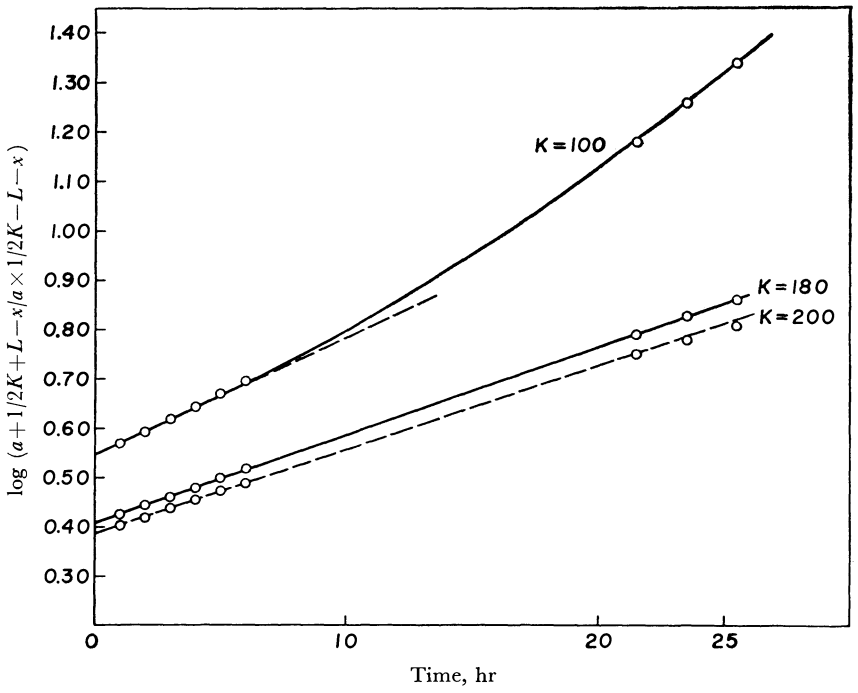

Fig. 3. Typical trial and error procedures of the treatment of kinetic data for the Menschutkin reaction containing the reverse decomposition of the salt. The reaction of dimethyl aniline with methyl iodide in nitrobenzene at 50°C.

The rate law is

$$dx/dt = k(a-x)^2 - k_d x \quad (3)$$

where k_d is the first order rate constant for the reverse reaction based on ion-pair decomposition. The hypothetical equilibrium constant is

$$K = k/k_d. \quad (4)$$

The use of Eqs. (3) and (4) gives

$$k \cdot t = 2.303/2L \log \{a+(1/2K)+L-x/a+(1/2K) -L-x\} \times \{a+(1/2K)-L/a+(1/2K)+L\}, \quad (5)$$

where L is the parameter given by

$$L = \sqrt{1+4Ka} \,/\, 2K. \quad (6)$$

The hypothesis used in the derivation might be proved to be right in terms of the linear relation between $\log\{a+(1/2K)+L-x/a+(1/2K)-L-x\}$ and time and the agreement of k obtained by the slope of this plot with k obtained from the initial slope of second order plot. The calculation for K was essentially the trial and error method, in which parameter K was adjusted so that the linear relation was obtained. The successive procedures are shown in Fig. 3. We could experimentally obtain the equilibrium point for some cases and show that the values obtained from the equilibrium point were in fair agreement with that from the hypothetical procedure. In the case of the reaction of *N,N*-dimethylaniline with methyl iodide in tetrahydrofuran (THF) at 50°C, for example, K through the former procedure is 0.432 and the latter value is 0.436. Even in acetonitrile, the most polar solvent in the present work, at 50°C, the decomposition of quaternary ammonium salt of *N,N*-dimethylaniline occurred, but in this case the degree of decomposition was *ca.* 2% after 100 hr and was too slow to obtain the value of K from the deviation of second order plot described above.

It is of interest that the rate of formation of iodide increases rapidly as soon as iodide precipitates and equilibrium is destroyed. These examples were observed in such solvents as benzene and THF. Measurement of k in the precipitation range was made on solutions ranging in concentration from *ca.* 0.08M to *ca.* 0.8M, but disagreement of each k value was over the experimental error as shown in Table 2. Thus the comparison for some nucleophiles in this solvent, was made with the same initial concentration.

solvent. The values of the equilibrium constants K were unfortunately the apparent values for the following reactions.

$$R\cdot C_6H_4\cdot N(CH_3)_2 + CH_3I \overset{K}{\rightleftharpoons} R\cdot C_6H_4\cdot N(CH_3)_3^+\cdot I^-(\text{ion-pair})$$

But the conclusion drawn from the relation based upon K may be the same.

The Unitary Term of k or K. It is necessary to compare the so-called unitary terms[12] of k or K, k_u or K_u when the effects of solvents on k or K and ζ are discussed in detail. The unitary part of k for the reactions under consideration is represented by

$$k_u = k\times 1000 d_{solv}/M_{solv} \quad (7)$$

where k is the rate constant in common use whose dimension is M^{-1} time^{-1}, and d_{solv} and M_{solv} are the density of the solvent and the molecular weight of the solvent, respectively. The relation between k_u in Eq. (7) and the representation of k through the theory of absolute reaction rate,[13] given by the equation

$$k = k_g'\times r_A\cdot r_B/r_{M^{\neq}}\times V_{solv.}/RT \quad (8)$$

is self-evident, *viz.*,

$$k_u = k_g''\times r_A\cdot r_B/r_{M^{\neq}} \quad (9)$$

In these equations r_A, r_B, and $r_{M^{\neq}}$ are the activity coefficients, based upon the solvent standard state, of reactant amine, of methyl iodide, and of the activated complex of the transition state, respectively.

12) D. W. Gurney, "Ionic Processes in Solution," Dover Publication Inc., New York (1953), Chapter 6.
13) Y. Kondo and N. Tokura, This Bulletin, **40**, 1433 (1967).

The unitary values of the activation parameters, $\Delta H_u^{\neq 0}$ and $\Delta S_u^{\neq 0}$ are given by

$$\Delta H_u^{\neq 0} = -RT - R\partial \ln k/\partial(1/T) - R\partial \ln d/\partial(1/T) \quad (10)$$

$$\Delta S_u^{\neq 0} = -R - \frac{R}{T}\partial \ln k \cdot d/\partial(1/T) + R \ln k_u - R \ln \frac{\kappa T}{h} \quad (11)$$

where κ and h are Boltzman and Planck constants respectively, k_u being independent of the composition of the solution.[12] This correction for k mainly contributes to the change of entropy.

The essential point of the correction is in the choice of the standard state. The appropriate value for k is one mole per liter of solvent and that for k_u one mole per one mole of solvent. By comparing k_u for one solvent with that for others, the effects of solvents on the reaction rates and ζ may be discussed in terms of the commonly used activity coefficients through Eq. (9). All of the data will, therefore, be treated by using k_u in place of k. The above treatment is of course applied for the equilibrium constant K. The expression of K_u is

$$K_u = K_g' \times r_A \cdot r_B / r_{A^+ \cdot B^-} \quad (12)$$

The Effects of Variations in Uncharged Nucleophiles on the Measure of k_u to Solvent Variations, ζ. The treatment is essentially the same as given previously.[6] The difference of ζ among nucleophiles arises from interaction term of the substituent variable and the solvent variable. Existence of the linear free energy relationship concerning the substituent change is necessary in order to treat the data in terms of this method. It is shown in Fig. 4. The expression of ζ for substituted dimethylanilines is defined by

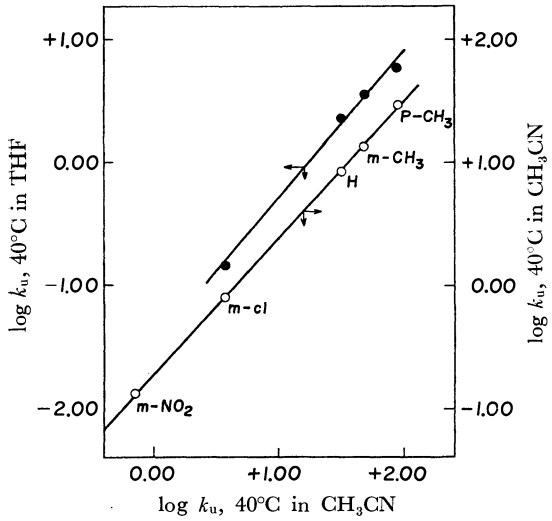

Fig. 4. The representation of the linear free energy relationships with respect to substituents.

$$\zeta = \delta_S \log k_u^X / \delta_S \log k_u^H \quad (13)$$

where δ_S means the differential with respect to the variations in solvents. The plot for this treatment is shown in Fig. 5, in which the slope gives the value of ζ. Deviation from this plot in some solvents is over the experimental error. But there is an approximate tendency for the dependence of ζ on the substituent. When the substituent is more electron donating, the value of ζ become smaller. This is illustrated in Fig. 6. The rate of reaction obtained by using a reactant with electron withdrawing substituent is more sensitive to solvent changes than others. In other words, the interaction constant between substituent variable and solvent variable has a positive value. The reason for the interaction between substituent variable and solvent variable might be interpreted in the following way. Equation (9) shows that these differences in ζ are not attributed to the effects of solvents on r_B, but to those on r_A or $r_{M^{\neq}}$, because by the first approximation the dependence of r_B on solvent change does not affect such a slope. Thus the substituent effect on the activity coefficients of either the reactant nucleophiles or of the activated complexes is somewhat modified by the nature of the solvent. The behavior is attributed to the latter for the following reasons. Firstly the modified Brϕnsted plot of $\delta_R \log k_u$ *versus* $\delta_R \log K_u$ has a relatively smaller slope than 1.00. Secondly the substituent effect in solvents with greater slopes is larger (see later section).

In terms of the solvent dependence of the Hammett's ρ value this explanation may be more clarified. That the slope of ζ *versus* σ has in general a positive value means that the value of ρ in more nonpolar solvent (in which the rate is slower) is more negative than that in polar solvent. There is a clear example of such a case; the difference of ρ in acetonitrile and that in methanol. The following equation which is derived from Eq. (9) will be applied.

$$\rho^{CH_3CN} \cdot \sigma_X = \rho^{CH_3OH} \cdot \sigma_X + \log ({}^{CH_3CN}r_{AX}^{CH_3OH} / {}^{CH_3CN}r_{AH}^{CH_3OH}) - \log ({}^{CH_3CN}r_{M^{\neq}X}^{CH_3OH} / {}^{CH_3CN}r_{M^{\neq}H}^{CH_3OH}) \quad (14)$$

In this equation ρ^{CH_3CN}, ρ^{CH_3OH}, and σ_X show Hammett's ρ in acetonitrile, in methanol, and substituent constant respectively. ${}^{CH_3CN}r_{AX}^{CH_3OH}$, ${}^{CH_3CN}r_{AH}^{CH_3OH}$, ${}^{CH_3CN}r_{M^{\neq}X}^{CH_3OH}$, and ${}^{CH_3CN}r_{M^{\neq}H}^{CH_3OH}$ denote the relative activity coefficient of the reactant, substituted amine and unsubstituted amine, and that of the activated complex with and without substituent, respectively. If the difference in quantity between ρ^{CH_3CN} and ρ^{CH_3OH} is attributed to the second term in Eq. (14), the relation of $|\rho|^{CH_3OH} < |\rho|^{CH_3CN}$ would be obtained because the solvation by methanol through hydrogen bonding will be diminished by the substitution

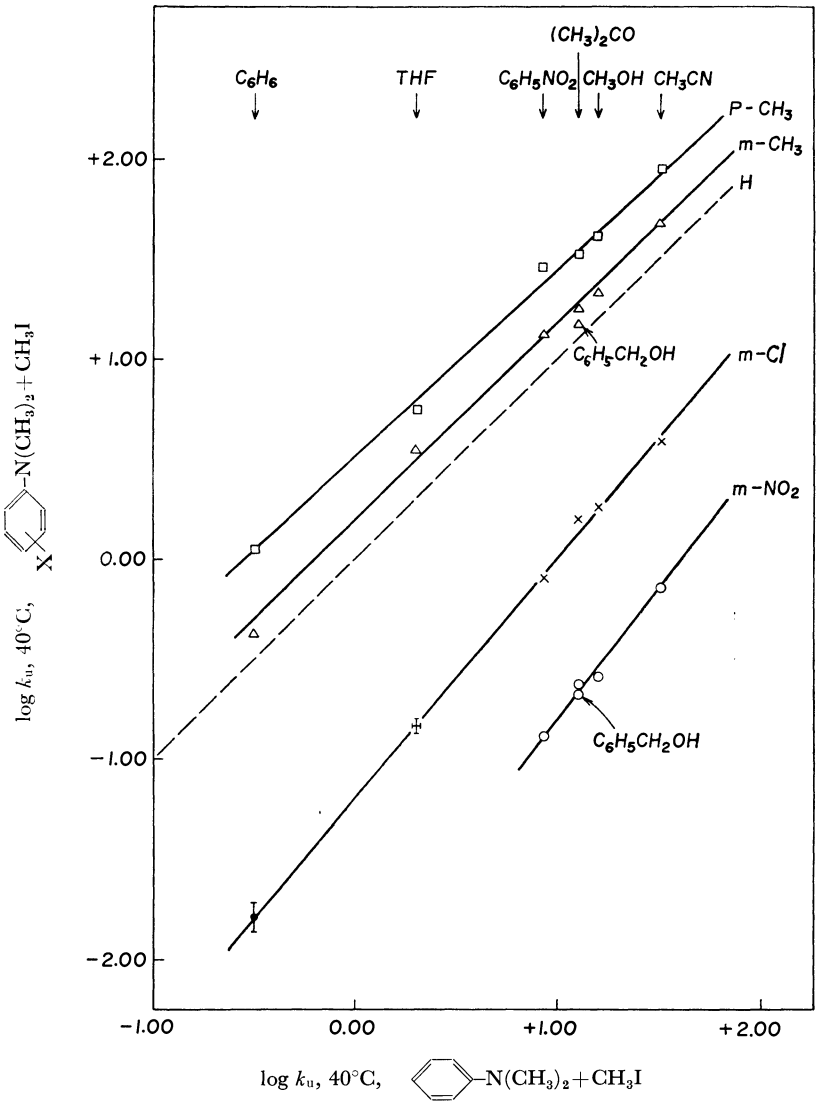

Fig. 5. The dependence of ζ on a few substituted nucleophiles at 40°C.

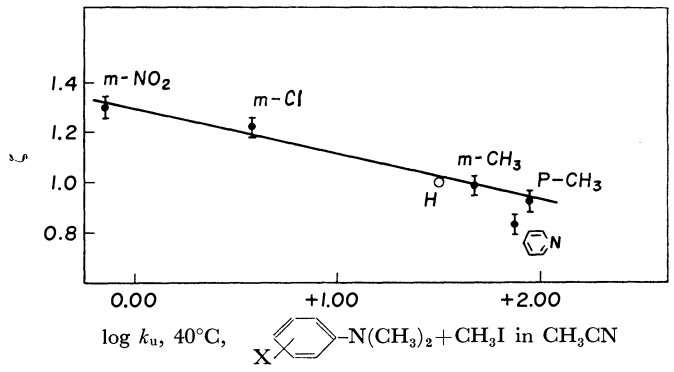

Fig. 6. The relationship between ζ and substituent variable.

of electron withdrawing group. The data show that this is not true unless the electron donating group (m-CH_3, p-CH_3) is introduced where a little downward deviation is observed (Fig. 5). The levelling off through the factor as expressed by the second factor in the right hand side of equation (14) was observed in liq. SO_2 which has strong solvation with amine bases.[14] A similar levelling off behavior is reported in ionizations of phosphines.[15]

Thus the substituent effect on ζ (Fig. 6) should result from the dependence of $\delta_R \log r_{M^*}$ on the solvent changes, and the deviation from these plots (Fig. 5) should be attributed to the dependence of $\delta_R \log r_A$ on the solvent changes. When pyridine is used as a nucleophile, the large deviation with regard to methanol (Fig. 7) clearly shows the existence of hydrogen bonding between pyridine and methanol.[16] The degree of divation expresses the difference between r_{Py} and r_{DMA} in methanol. For example, the relation of $\log r_{DMA}^{CH_3OH}/r_{Py}^{CH_3OH} = 0.70$ exists at 40°C.

It is of interest to examine the substituent effects on $\delta_S \Delta S_u^{\neq}$, the differences in $\Delta S_u^{\neq}$ among solvents. From the above explanation for ζ-δ relationship $\delta_S \Delta S_u^{\neq}$ must be larger by using the more electron withdrawing substituent. This is illustrated by the data in Table 5. Thus it also accounts for the fact that the interaction constant has positive value.

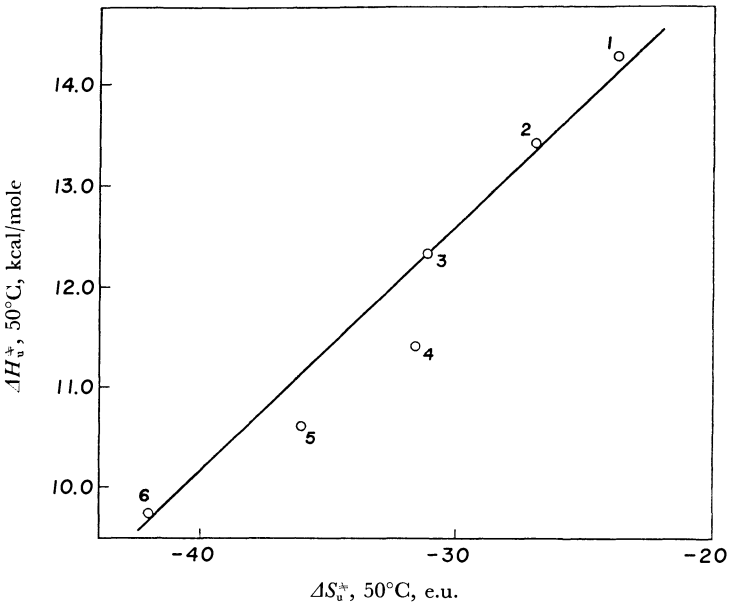

Fig. 8. The plot of $\Delta H_u^{\ddagger}$ *versus* $\Delta S_u^{\ddagger}$ for a reaction of *N,N*-dimethylaniline with methyl iodide.

There is another reason why the above tendency is denoted as the only "approximate" tendency at all. The order of the relative rates with respect to the solvent will be modified by the change of temperature. The degree of this modification is illustrated in the plot of $\Delta H_u^{\ddagger}$ *versus* $\Delta S_u^{\ddagger}$. Unless the so-called isokinetic linear relationship between these values exists, this relative order is modified. Figure 8 shows the approximate linearity between these two values.

The dependence of ζ on substituents which was explained on the basis of the above electrostriction theory will predict the variation of the pressure dependence of rates with the substitution of nucleophile. The substitution by the electron withdrawing groups will influence the pressure effect of rate by larger amount. In other words, the dependence of the volumes of activations on nucleophiles will be larger in so-called nonpolar solvents than in polar solvents. The solvent dependence of Hammett's ρ for the equilibria of a series of benzoic acids has been attributed to the activity coefficients of the carbonium ions.[6] For this type of equilibrium the pressure effect will be decreased by using the acids substituted by electron withdrawing groups. This was experimentally proved by Fischer *et al.*[17]

There is a case where the solvent effects of the nucleophilic tendency are mainly attributed to the relative activity coefficients of charged species *i*, $\delta_S \log r_i$. That is the Finkelstein reaction.[18] Thus the difference between charged and uncharged nucleophiles in the solvent dependence of the rate is clear. For the fomer the relative activity coefficients of the reactant bases are the main factor in determining the solvent dependence of ζ, but for the latter those of the activated complexes mainly affect the relative order of rates with solvent changes. Thus the compilation of both charged and uncharged reactants as nucleophiles is questionable, if the solvent used is taken into consideration.

Difference in the Factor Influencing the ζ between Methyl Iodide and Methyl Picrate. According to the compilation by Reinheimer *et al.*[19] the modification of the sensitivity of the rates to solvent changes caused by using EtI in place of EtBr for quaternization of pyridine may be made by a negligible amount at least in aromatic solvent. However, comparison of the present data with our previous data[6] shows that the ζ are markedly influenced by

the change of $CH_3Pic.$ to CH_3I. Figure 9 illustrates this situation. It is observed that the quaternization of *N,N*-dimethylaniline with methyl picrate is less sensitive to the variations in solvents than that with methyl iodide. The relation of $\zeta < 1.0$ is observed for methyl picrate. According to the interpretation of rate by the transition state theory (Eq.(9)) such a diffence should be attributed to the difference in the dependence on solvent variations between r_{CH_3I} and r_{CH_3Pic} or between $r_{M^+,I}$ and

$r_{M^{\neq},Pic}$. Although we have no data on r_{CH_3I} and r_{CH_3Pic} in various solvents, the existence of an approximately linear relationship as shown in Fig. 9 explains this behavior in terms of the difference in solvent dependence between $r_{M^{\neq},I}$ and $r_{M^{\neq},Pic}$. Our explanation is further supported by the fact that in the picrate there is large negative charge distribution and no net charge at any one atom.[20] The combination of this fact with the electrostriction theory leads to the following explanation; in the case of the transition state for the reaction with methyl picrate the negative charge distribution may be large. Thus, $r_{M^{\neq},Pic}$ may not become smaller even in polar solvents as $r_{M^{\neq},I}$ does, while in non-polar solvents the reverse relation may be true. There is less entropy loss accompanied with the electrostriction of solvent molecules along the reaction coordinate.

That the "completely" linear relation does not exist means that there is the difference in solvent effects between r_{CH_3I} and r_{CH_3Pic}. A large devia-

20) E. Grunwald and E. Price, *J. Amer. Chem. Soc.*, **86**, 4517 (1964).

tion is observed in methanol. The experimental error of reaction rate was less than 0.02 log unit. The data of r_{CH_3I} in acetonitrile and in methanol at 25°C,[3] $\log r_{CH_3I}^{CH_3CN} - \log r_{CH_3I}^{CH_3OH} \simeq 0.35$ is in accordance with this deviation 0.35 which is given as the distance, a in Fig. 9. This shows that the relation of $\log r_{CH_3Pic}^{CH_3CN} \simeq \log r_{CH_3Pic}^{CH_3OH}$ exists.

For both cases of CH_3Pic and CH_3I the relation of $|\rho|^{C_6H_5NO_2} > |\rho|^{CH_3CN}$ exists and in each solvent the differences in the substituent effects between CH_3I and CH_3Pic is apparently equal, as shown in Fig. 10. This seems to be inconsistent with the above discussion. But we can explain the relation similarly as in the previous section, if we assume that the substituent effects on the stability of each activated complex are almost independent of the leaving group.

The Nature of the S_N2 Transition State. The concept of Glasstone *et al.*[8] about the stereochemistry of the S_N2 transition complex has been criticized by Rossell[7a] and by Weale.[21] Weale *et al.* studied the volume of activation for a reversible Menschutkin reaction, $CH_3I + C_6H_5\text{–}N(CH_3)\cdot(C_2H_5) \rightleftarrows C_6H_5\text{–}N(CH_3)_2^{\delta+}\cdot C_2H_5\cdots I^{\delta-}$ in acetone and showed that in absolute value the volume of activation is less than the change of volume accompanied with an equilibrium between reactant and product as ion-pair. Rossell criticized the relevance of the view of Glasstone *et al.* which was concluded from the similarity of ΔS° and $\Delta S^\ddagger$ found in the reaction of dimethylaniline with methyl iodide in nitrobenzene. According to Rossell, "such a similarity is the exception rather than the rule."

If the solvent effects on the reaction rates are mainly attributed to the differences in the activity coefficients of the activated complexes among the variations of solvents, the dependence of k on the variations in solvents should be correlated with the dependence of K on those variations, and the slope of $\delta_S \log k_u$ *versus* $\delta_S \log K_u$ must show the degree of charge separation in the transition state. For the reaction of *m*-CH_3-DMA with CH_3I at 60°C Fig. 11 shows the approximate linear relation between $\delta_S \log k_u$ and $\delta_S \log K_u$ which has a relatively small slope. It can be considered that the nature of the transition state for the reactions is not very similar to that of the final product, quaternally ammonium salt. This result should be correlated with any relationship between $\delta_R \log k_u$ and $\delta_R \log K_u$ in each solvent. Figure 12 which shows a nearly linear relation[22] among these values reflects the fact[23] that the equilibrium between ions and ion-pairs is quite insensitive to the substituent effects. Figure 12 also shows the insensitivity of the reaction rate to substituent changes relative to that of the equilibrium constant.

Mechanism of the Ullmann Condensation. I.*1 Kinetic and Thermodynamic Studies

Tran Dinh TUONG and Mitsuhiko HIDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 3, 1969)

Kinetic studies of the Ullmann condensation of an aryl halide, sodium 1-amino-4-bromoanthraquinone-2-sulfonate and an amine, aniline, were undertaken. Cupric copper was used as the catalyst. The reaction was found to be first order in monomeric aryl halide and first order in amine, and to depend hyperbolically on the concentration of the catalyst. It was shown by ESR measurements that the copper catalyst exists largely as cupric species. The experimental results were discussed mechanistically.

A large number of patents and papers have been written on the condensation reaction of aryl halides with amines or phenoxides in the presence of a copper catalyst. This reaction is known as the Ullmann condensation reaction[1] and has been an important tool in, for example, the synthesis of dyes, drugs and compounds of biochemical interest. On the other hand, the reaction has been classified as an unknown mechanism[2,3] since the mechanism has not yet been well established in spite of the efforts of several investigators.[4-10]

Particularly it is noticeable that little information is availahle as to what the real catalytic species is. Mechanistic studies are difficult for the following reasons:

a) The reaction must often be carried out under vigorous conditions, *i.e.*, at temperatures higher than 150°C and sometimes under high pressure.

b) Since homogeneous systems are rarely obtained, kinetic studies are hampered.

Because the mechanism is not yet known in detail, the improvement of this industrially important reaction has been attempted[11-14] empirically rather than from the theoretical point of view. Thus, in order to use this reaction in synthetic chemistry more efficiently, more investigations must be undertaken in connection with the mechanism of this reaction. This necessity prompted the present study. The preliminary results will be reported in this paper.

Results and Discussion

A kinetic study was made of the condensation of sodium 1-amino-4-bromoanthraquinone-2-sulfonate (I) with aniline in an aqueous buffer solution. Cupric sulfate was selected as the catalyst because of its large solubility in water and because of the weak coordinating ability of the sulfate ion to the metal ion. The reaction is known to proceed under comparatively mild conditions.[15,16]

When aniline was used in large excess compared with I, a homogeneous system could be attained and kinetic measurements with a good reproducibility were possible.

Reaction Products. Paper chromatography revealed that the reaction products were bromamic

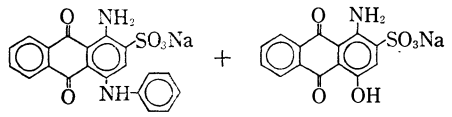
I



II III

acid (I), sodium 1-amino-4-anilinoanthraquinone-2-sulfonate (II), and sodium 1-amino-4-hydroxyanthraquinone-2-sulfonate (III).

Their amounts were determined spectrophotometrically.

Compared with the main product, II, III was found to be formed in a negligibly small quantity (less than 3% of the total concentration) and so it was neglected in the calculation of the reaction rates. This by-product was also formed in the reaction carried out in the absence of aniline, but it was not produced by treating II in an alkaline solution. These facts show without doubt that III was the condensation product of I with the alkaline aqueous solvent. Other side reactions, such as dehalogenation and biaryl formation which are known often to accompany the Ullmann condensation reaction,[17] were not observed.

Kinetics. As is shown in Fig. 1, the initial rate, v_0, was not proportional to the concentration of I.

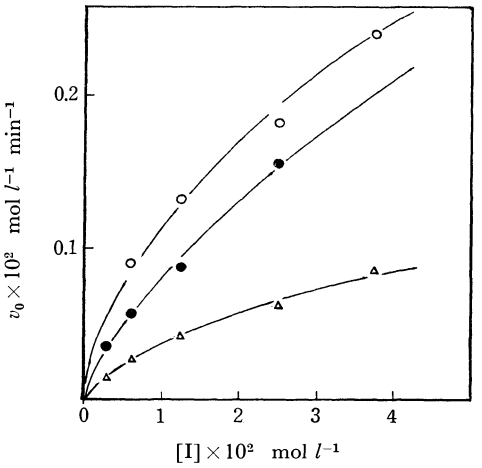


Fig. 1. Dependence of the initial rate on the concentration of I.
pH=9.94, T=343°K
$[PhNH_2]_0$=0.30 mol l^{-1}
$[Cu^{2+}]_0=2.5\times10^{-4}$ mol l^{-1} (△)
12.5×10^{-4} mol l^{-1} (●)
50.0×10^{-4} mol l^{-1} (○)

These results can be understood as follows.

The spectrum of bromamic acid (I) in an aqueous solution was observed to change bathochromically and hypochromically with an increase in the concentration. This fact suggests that I aggregates in an aqueous solution. The degree of aggregation and the aggregation constant at 70°C and at pH 9.94 were found to be 2 and about 200 respectively by the maximum slope method.[18] Thus, the monomeric and dimeric species are equilibrated in the reaction system. If the initial rate is assumed to be proportional to the concentrations of the monomer and the dimer (c_1 and c_2), the initial rate may be expressed by Eq. (1):

$$v_0 = k_1c_1 + k_2c_2 \quad (1)$$

where k_1 and k_2 are rate constants associated with the monomer and the dimer respectively.

If the analytical amount of I is denoted as c_0, we have:

$$c_0 = c_1 + 2c_2 \quad (2)$$

By combining Eq. (1) with Eq. (2), we obtain Eq. (3):

$$v_0 = \left(k_1 - \frac{k_2}{2}\right)c_1 + \frac{k_2}{2}c_0 \quad (3)$$

Therefore,

$$\frac{v_0}{c_0} = \left(k_1 - \frac{k_2}{2}\right)f_1 + \frac{k_2}{2} \quad (4)$$

where f_1 is the fraction of the monomer.

The concentration, c_1, of the monomeric species

is obtained by solving Eq. (5):

$$400c_1^2 + c_1 - c_0 = 0 \quad (5)$$

Figure 2 shows the linear plot of v_0/c_0 against f_1. The values of k_1 and k_2 can be determined from the slope ($=k_1-k_2/2$) and the intercept ($=k_2/2$) of the straight lines.

These results suggest that only the monomeric species was active and that the reaction was first order with respect to the monomer of I.

The unimolecularity of the aryl halide in the Ullmann condensation reaction has been reported by several workers.[9,10]

Figure 3, where the initial rate is plotted against the initial concentration of aniline, shows that the first order can be assigned to the amine.

The rate law is, therefore, given by:

$$\text{rate} = k_0 f_1 c_0[\text{PhNH}_2] = k_{app} c_0[\text{PhNH}_2] \quad (6)$$

where k_{app} is a function of the reaction conditions (pH, temperature and the atmosphere) and of the concentration of the copper ion.

The dependence of the apparent rate constant, k_{app}, on the concentration of the catalyst is shown by the data tabulated in Table 1. The experimental data can be satisfied by the following three relations:

a) $$k_{app} = k[\text{Cu}^{2+}]^m \quad (7)$$

where k and m are constants.

The value of m varied over the range from 0.48 to 0.70, according to the conditions of the reaction (pH and temperature). The fact that the value of m varied around 0.50 is interesting, but attempts to devise mechanisms which could fit the above relation were unsuccessful.

25	9.94	363	5.54	32.33
26	9.94	363	8.22	42.55
27	9.94	363	12.77	46.69

a) Experiments under nitrogen atmosphere, $[I]_0=1.25\times10^{-2}$ mol l^{-1}, $[PhNH_2]_0=0.30$ mol l^{-1}.

b) $$k_{app} = k\frac{[\text{Cu}^{2+}]}{[\text{Cu}^{2+}] + \alpha} \quad (8)$$

where k and α are constants, their values depending on the pH and the temperature.

The energies and entropies associated with k and α were found to be as follows:

$$\Delta E^*(k) = 12.37 \text{ kcal}\cdot\text{mol}^{-1}$$
$$\Delta S^*(k) = -19.80 \text{ eu } (T=343°\text{K})$$
$$\Delta E^*(\alpha) = 4.12 \text{ kcal}\cdot\text{mol}^{-1}$$
$$\Delta S^*(\alpha) = -60.30 \text{ eu } (T=343°\text{K})$$

This hyperbolic relation could be derived from the following mechanism (I is denoted as ArBr):

$$\text{Cu}^{2+} \overset{K_1}{\rightleftarrows} \text{Cu}^{+} \quad (9)$$

$$\text{Cu}^{+} + \text{ArBr} \overset{K_2}{\rightleftarrows} \text{Cu}^{+}\cdot\text{BrAr} \quad (10)$$

$$\text{Cu}^{2+} + \text{Cu}^{+} \overset{K_3}{\rightleftarrows} \text{Cu}^{2+}\cdot\text{Cu}^{+} \quad (11)$$

$$Cu^{+}\cdot BrAr + PhNH_2 + OH^- \xrightarrow{k} Cu^{+} + ArNHPh + Br^- + (ArOH) \quad (12)$$

If the values of both K_2 and K_3 are sufficiently small, we can derive Eq. (13) from Eqs. (9)—(12):

$$\text{rate} = (kK_1K_2/2K_3)[ArBr][PhNH_2][Cu^{2+}]/([Cu^{2+}]+K_1+1/2K_3) \quad (13)$$

Equation (13) is identical with Eq. (8) provided that:

$$k_0 = kK_1K_2/2K_3$$

and

$$\alpha = K_1 + 1/2K_3$$

In proposing this mechanism, an equilibrium between cuprous and cupric species, the activity of cuprous[19] copper and the deactivating effect of the cupric ion were postulated.

c) The dependence of the reaction rates on the catalyst concentration could also be interpreted on the assumption of the formation of clusters. Thus, the catalyst is assumed to exist in the reaction system as a monomer and as a cluster of the n-th degree, so that:

$$n\text{Cu} \underset{}{\overset{K}{\rightleftharpoons}} \text{Cu}_n \quad (14)$$

By designating the initial concentration of the catalyst as $[Cu^{2+}]_0$, we obtain Eq. (15):

$$[Cu^{2+}]_0 = [Cu] + n[Cu_n] \quad (15)$$

Further, it is assumed that the apparent rate constant, k_{app} $(=k_0f_1)$, can be written as follows:

$$k_{app} = k_1[Cu] + n\bar{k}_n[Cu_n] \quad (16)$$

where k_1 is the rate constant of the reaction of the monomeric species and where $\bar{k}_n$ $(=k_n/n)$ is the rate constant of the clusters (per molecule).

By combining Eq. (15) with Eq. (16), we get Eq. (17):

$$k_1[Cu^{2+}]_0 - k_{app} = n(k_1-\bar{k}_n)Cu_n \quad (17)$$

and:

$$k_{app} - \bar{k}_n[Cu^{2+}]_0 = (k_1-\bar{k}_n)[Cu] \quad (18)$$

By inserting Eq. (18) into Eq. (14):

$$\frac{k_1[Cu^{2+}]_0 - k_{app}}{n(k_1-\bar{k}_n)} = \frac{K}{(k_1-\bar{k}_n)^n}(k_{app}-\bar{k}_n[Cu^{2+}]_0)^n \quad (19)$$

or

$$\log (k_1[Cu^{2+}]_0-k_{app}) = n \log (k_{app}-\bar{k}_n[Cu^{2+}]_0) + \log \frac{nK}{(k_1-\bar{k}_n)^{n-1}} \quad (19')$$

where K is the equilibrium constant.

19) The addition of reducing agents, such as $NaHSO_3$, $SnCl_2$, $FeSO_4$, $TiCl_3$, *etc.*, to the reaction system, was observed to enhance markedly the reaction rate. Detailed results will be reported and discussed in a later paper of the series.

If the cluster is assumed to be inactive, we can rewrite Eq. (19′) as Eq. (20):

$$\log (k_1[Cu^{2+}]_0-k_{app}) = n \log k_{app} + \log \frac{nK}{k_1^{n-1}} \quad (20)$$

The value of k_1 is given by Eq. (21):

$$k_1 = \lim_{[Cu^{2+}]_0 \to 0} \frac{dk_{app}}{d[Cu^{2+}]_0} \quad (21)$$

The value of k_1 was determined graphically from the slope of the tangent of the plot of k_{app} *vs.* $[Cu^{2+}]_0$ at $[Cu^{2+}]_0=0$, and then $\log (k_1[Cu^{2+}]_0-k_{app})$ was plotted against $\log k_{app}$ (Fig. 4). The values of n and K were determined from the slope and the intercept; their values are summarized in Table 2. It was found that n was independent of the reaction conditions and that it has a constant value of 3.

The activation parameters associated with k_1 were determined from the Arrhenius plot:

$$\Delta E^{\ddagger}(k_1) = 9.91 \text{ kcal}\cdot\text{mol}^{-1}$$

$$\Delta S^{\ddagger}(k_2) = -18.33 \text{ eu } (T=343^{\circ}\text{K})$$

The apparent energy of activation associated with k_{app} was also determined to be 9.14 kcal mol^{-1}. As is shown in Fig. 5, the apparent energy of activation is independent of the concentration of the cupric ion. Since:

$$k_{app} = k_1f_1F_1[Cu^{2+}]_0$$

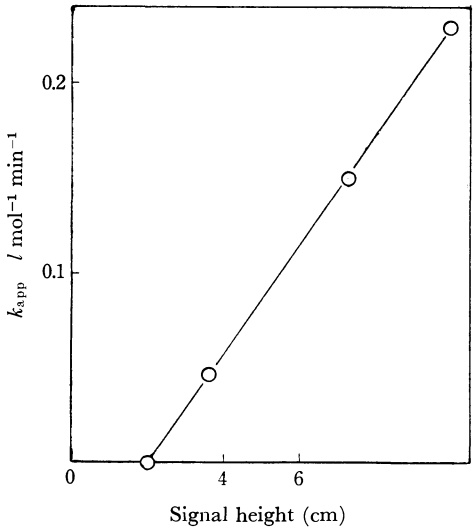

Fig. 6. Linear relationship between the apparent rate constant k_{app} and ESR absorption intensity.

where F_1 is the fraction of the monomeric catalyst, the apparent enthalpy of activation, H_{app}, is given by Eq. (22):

$$\Delta H^{\ddagger}_{app} = \Delta H^{\ddagger}_0 + \frac{1-f_1}{2-f_1}\Delta H_1 + \frac{1-F_1}{3-2F_1}\Delta H_2 \quad (22)$$

In Eq. (22), the enthalpy of activation for k_1 and the enthalpies of the aggregation of bromamic acid and the catalyst are designated as $\Delta H_0^{\ddagger}$, ΔH_1 and ΔH_2 respectively.

The second and third terms are negligibly small, compared with the first term. Therefore, the apparent energy of activation is near to $\Delta E^{\ddagger}(k_1)$ and independent of the concentration of the catalyst.

In order to obtain more information as to the nature of the catalyst species in the reaction solution, we examined the ESR spectra of the reaction system.[20] The results showed that the catalyst exists mostly in the divalent form, and a good proportionality was observed between the apparent rate constant, k_{app}, and the intensity (height) of the signal (Fig. 6). The intercept on the abcissa axis corresponds to the absorption due to the solvent water.

The kinetic data and the results of ESR measurements can be correlated if we assume that the copper clusters are inactive towards both the reaction and the electron-spin-resonance absorption. The monomeric cupric species can thus be postulated to be responsible for the promotion of the condensation reaction, but the possibility that this species exhibits the catalytic activity only after being reduced to a lower oxidation state[19] cannot be excluded.

Further studies are in progress to elucidate the nature of the "true" catalytic species and to obtain more information as to the elementary processes of the reaction.

20) Detailed results will be reported later. The authors are indebted to Dr. K. Hirasawa of The University of Tokyo for ESR measurements and helpful discussions.

Experimental

Materials. Commercial sodium 1-amino-4-bromoanthraquinone-2-sulfonate (I) was purified by repeatedly salting out with sodium acetate until the absorbance became constant. The purity was confirmed by paper chromatography (R_f=0.72), by elemental analysis (Found: N, 3.51%. Calcd: 3.47%), and by the conversion into its salts (*p*-toluidine salt : mp(corr) 241—241.2°C, Found: N, 5.82%. Calcd: 5.67%. *S*-benzylthiuronium salt: mp (corr) 202.9—203.4°C, Found: N, 7.64. Calcd: 7.66%). The visible spectrum shows a maximum at 485 mμ.[21]

Sodium 1-amino-4-anilinoanthraquinone-2-sulfonate (II) was synthesized by the reaction of I with aniline. Purification was carried out by salting out with sodium chloride. R_f=0.86. Found: N, 6.69%. Calcd 6.73%. λ_{max}=604 mμ.[21]

Sodium 1-amino-4-hydroxyanthraquinone-2-sulfonate (III) was obtained from the reaction of I and boric acid in 4% oleum, in yield of 85% (based on I). R_f=0.66. Found: N, 4.11%. Calcd: 4.54%. λ_{max}=540 mμ[21]

G.R. aniline was used after having been distilled under reduced pressure in the presence of zinc powder.

The cupric sulfate (pentahydrate) was of a reagent grade. The copper content was determined by iodometry.

The solvent was prepared by combining aqueous solutions of sodium carbonate (0.2M) and borax (0.15M) at an appropriate volumetric ratio.

21) T. Tokumitsu, M. Okamoto and T. Hayashi, *Kogyo Kagaku Zasshi*, **67**, 201 (1964).

Analytical Procedures. Paper chromatography was accomplished on Toyo Paper No. 5 at room temperature, using the *n*-BuOH - EtOH - 2% aqueous ammonia (6 : 2 : 3) solution as the solvent.[22]

The concentrations of the reaction products were determined by the usual spectrometrical method, in which the absorbances at 485, 540, and 604 mμ were used.

It was also confirmed that copper salts did not influence the spectrum of the reaction mixture.

Apparatus and Operation. Experiments were carried out in an apparatus devised to shut out the air. The nitrogen was purified of contaminating oxygen by passing it through pyrogallol.

A typical kinetic measurement was as follows:

Aniline, bromamic acid (I) and the solvent were mixed in a flask. A nitrogen stream was then introduced and allowed to bubble into the solution at room temperature for 2.5 hr. The solution was subsequently brought to the reaction temperature and the catalyst (in an aqueous solution) was added with the help of a syringe. This instant was taken to be time 0.

At 3-min intervals, 0.05-cc portions of the reaction solution were taken out with the micropipette, diluted in 50 or 25 cc of water, and subjected to spectroscopic measurements.

This research was supported financially in part by the Asahi Glass Foundation for the Contribution to Industrial Technology.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1768—1777 (1970)

The Acid-catalyzed Cleavage of 2,6-Di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexadien-1-one in the Hydroxylic Solvent. The Solvolysis of a Protonated Dienone*1

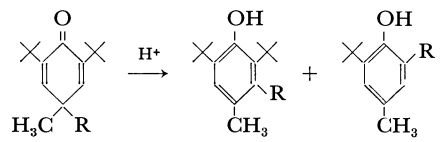
Kunio Okamoto, Issei Nitta and Haruo Shingu

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 6, 1969)

In acetic acid, aqueous methanol, and phenol solvents, 2,6-di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexadien-1-one (I) did not undergo a typical dienone-phenol rearrangement in the presence of sulfuric or perchloric acid, but yielded the solvolysis products, *viz.*, 1-phenylethyl acetate, 1-phenylethyl methyl ether, and 1-phenylethyl phenyl ether, in the respective solvents, along with 2,6-di-*t*-butyl-4-methylphenol (II). The reactions carried out with the optically-active dienone (Ia) yielded solvolysis products which were predominantly racemized, but accompanied by a net inversion of the configuration. The polarimetric rate constant of racemization, measured in acetic acid containing sulfuric acid at 25°C, is in agreement with the spectrophotometric rate constants for the decrease in the dienone Ia and for the increase in the phenol II, essentially within the limits of experimental error. These stereochemical results can be accomodated by a typical S_N1 mechanism, in which the dienone I, protonated on the carbonyl-oxygen, acts as a substrate, and the phenol II, as a leaving group.

Transformations of *p*-cyclohexadienones to phenols in the presence of acidic catalysts have been known for many years; recently Miller and Margulies[1] have observed some interesting 1,2- or 1,3-allyl migration rearrangements of 2,6-di-*t*-butyl cyclohexadienones (III), accompanied by the loss of the *t*-butyl group.

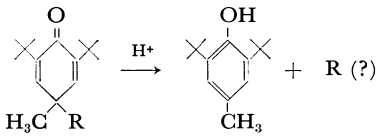


(III) R=Allyl

They have also observed the loss of a migrating group R, *e.g*, crotyl and isopropyl, under the conditions of such a dienone-phenol rearrangement:

*1 Presented at the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1969; Preprints, III, p. 1643.

1) B. Miller and H. Margulies, *Tetrahedron Lett.*, **1965**, 1727; *J. Amer. Chem. Soc.*, **87**,5106 (1965).



R=Crotyl and Isopropyl (II)

However, little study has been made of the fate of the eliminated group.

We have now prepared 2,6-di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexadien-1-one (I) in connection with our study of the solvolysis mechanism of 1-phenylethyl halide, and have confirmed, in the course of its structural assignment, that this dienone I loses its 1-phenylethyl group in acidic hydroxylic solvents and gives 2,6-di-*t*-butyl-4-methylphenol (II) in a fashion similar to the above-mentioned case for the crotyl and isopropyl dienone (III).[1]

In this paper, we will report on the results of our examinations of the fate of the 1-phenylethyl group so eliminated and of its stereochemical course. Our results show that the 1-phenylethyl group is converted into a racemized solvolysis product, with a net inversion of configuration, and that this transformation of the dienone I into the phenol II and a 1-phenylethyl derivative may be considered to be a typical S_N1 reaction of the protonated dienone I, containing the phenol II as a leaving group.

Results and Discussion

Preparation of 2,6-Di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexadien-1-one (I). This dienone I was synthesized from 1-phenylethyl halide and potassium 2,6-di-*t*-butyl-4-methylphenoxide according to the method of Kornblum and Seltzer.[2] For example, the reaction of 1-phenylethyl bromide and potassium 2,6-di-*t*-butyl-4-methylphenoxide, prepared *in situ* from potassium and the phenol II, was carried out in a *t*-butanol-tetraethylene glycol dimethyl ether solvent (1.7 : 1.0 by vol.) for 20 min at 20°C; the dienone I, bp 113—118°C/0.21—0.24 mmHg, was thus obtained in an 87% yield. The structure of I was deduced from its elemental composition and from the IR, UV, and NMR spectra (see Experimental section). This assignment was confirmed by the ozonolysis of I, which is shown in the following scheme (see also Experimental section):

racemic 1-phenylethyl bromide. The results are summarized in Table 1.

The maximum rotation for the optically active dienone, Ia, was calculated from the rotation of the dienone obtained from R-(+)-1-phenylethyl chloride and potassium 2,6-di-*t*-butyl-4-methylphenoxide. The initial concentrations of the chloride and of the phenoxide were varied over the range from 0.1 to 0.5M. Despite such a wide range of variation in the initial concentration, the calculated values for the maximum rotation of the dienone I seem to be little affected (see Table 1). This indicates that the racemization of 1-phenylethyl chloride during this S_N2 reaction, if any, is slight. Considering this, we took the highest value among those cited in Table 1, *i.e.*, +88.5°, as the maximum rotation of the optically active dienone I with the S-configuration.

Products of the Acidic Cleavage of 2,6-Di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexadien-1-one (I) in Hydroxylic Solvents. The acidic cleavage of the dienone I was carried out in wet acetic acid (containing *ca.* 1.5×10^{-3} wt% of water), aqueous methanol (14.1 vol% of water), 1,2-dichloroethane, and phenol. Sulfuric acid (*ca.* 10^{-3}M), perchloric acid (*ca.* 2M), and trifluoroacetic acid (*ca.* 10^{-2}M) were used as the acid catalyst in acetic acid, aqueous methanol, and 1,2-dichloroethane solvents respectively. In the case of the phenol solvent, no acid catalyst was added. The results are summarized in Table 2.

For each reaction, the substitution products and the phenol II were obtained in fairly good yields; in acetic acid, 1-phenylethyl acetate was obtained in a 92% yield and no elimination product was isolated from the products; in aqueous methanol, 1-phenylethyl methyl ether and 1-phenylethyl alcohol were obtained in 80 and 8% yields respectively; in phenol, 1-phenylethyl phenyl ether, *p*-1-phenylethylphenol, and *o*-1-phenylethylphenol were obtained in 12, 49, and 30% yields respectively; even in 1,2-dichloroethane containing a catalytic amount of trifluoroacetic acid, 1-phenylethyl trifluoroacetate was obtained in a 62% yield.

Rates of the Acid-catalyzed Cleavage of 2,6-Di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexadien-1-one (I). The rates of the cleavage of the dienone I were followed spectrophotometrically; the change in the optical density at 249 mμ (or 352 mμ for the reaction in aqueous methanol) was followed with the reaction mixture placed in an absorption cell. The decrease in the optical density corresponding to the dienone I obeyed good first-order kinetics. The results for wet acetic acid,[3] aqueous methanol (15.1 vol% of water), and 1,2-dichloroethane solvents are summarized in Table 6 (see Experimental section).

In Fig. 1 the logarithm of the first-order rate constant is plotted against the logarithmic concentration of perchloric acid (or trifluoroacetic acid). From the graphical presentation in Fig. 1, the ability of cleavage for these acidic media is seemingly in the sequence: perchloric acid in wet

3) The water arose from the 70% perchloric acid used as the catalyst.

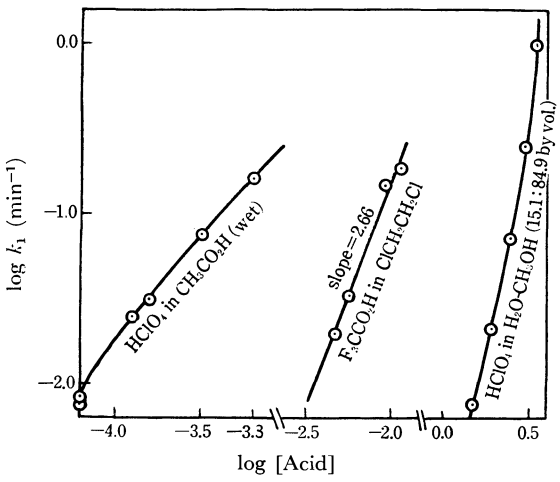

Fig. 1. Rates of acid-catalyzed cleavage of dienone I in various solvents at 25.0°C.

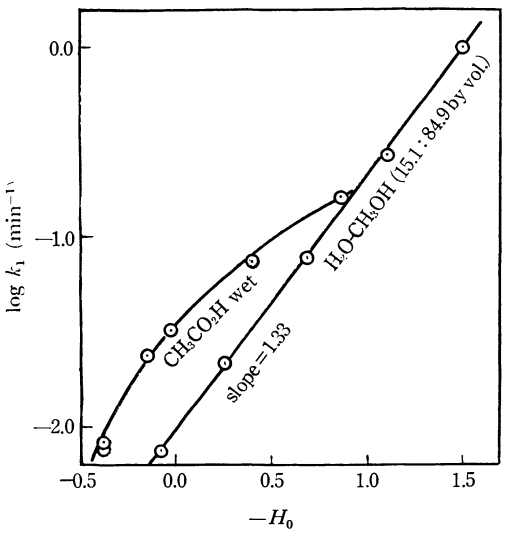

Fig. 2. Rates of cleavage of dienone I in the presence of perchloric acid at 25°C.

acetic acid (containing about 10^{-4} wt% of water)> trifluoroacetic acid in 1,2-dichloroethane>perchloric acid in aqueous methanol (15.1 vol% H_2O).

However, as is shown in Fig. 2, when the logarithm of the rate constant is plotted against the acidity function, H_0, of the acidic medium, the curve for the acetic acid solvent is not far over the line for the aqueous methanolic solvent. Consequently, the medium composed of perchloric acid and acetic acid is not so efficient as it seems in Fig. 1. In this connection, if the H_0 of these media is a measure of the ability of proton donation to the dienone I, the gap between the two in Fig. 2 may be attributed to the difference in the solvent effect on the intrinsic cleavage rate of the protonated dienone I.

The $-H_0$ value for 1,2-dichloroethane containing about 10^{-2}M trifluoroacetic acid is estimated to be −3.3——4.0 by extrapolation from the date (see Table 7) on the medium with higher concentrations of trifluoroacetic acid. These H_0 values are too small to be plotted in Fig. 2. However, it is obvious that 1,2-dichloroethane containing trifluoroacetic acid is the most effective medium among the media shown in Figs. 1 and 2 for the cleavage of the protonated dienone I. In other words, the solvent effect for the cleavage of the protonated dienone I is in the sequence: 1,2-dichloroethane>acetic acid>aqueous methanol.

In Figs. 1 and 2, the plots of $\log k$ are linear against neither log [Acid] nor $-H_0$, except in the cases of aqueous methanol in Fig. 2 and of 1,2-dichloroethane in Fig. 1. Even in these cases, the linear plots have a slope different from 1. Consequently, for these acid-catalyzed reactions the Hammett-Zucker hypothesis,[4] which discusses the details of the mechanism on the basis of the proportionality of $\log k$ to H_0 or to log [Acid], seems to be invalid. This discrepancy can probably be ascribed to the deviation of the dienone I from a group of normal Hammett bases.[5]

The Steric Course of the Acid-catalyzed Cleavage of Optically Active 2,6-Di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexadien-1-one (Ia). The optically active dienone Ia was subjected to acid-catalyzed cleavage in wet acetic acid (10^{-3}—10^{-4} wt% H_2O) containing perchloric acid or sulfuric acid, in aqueous methanol (13 vol% H_2O) containing perchloric acid and in phenol. The results are summarized in Table 3.

On the basis of the absolute configuration and of the maximum rotation for the relevant solvolysis products (see Table 3, Footnote i), it is confirmed that the cleavage of the dienone Ia gives predominantly racemized solvolysis products, with some net inversion of the configuration in wet acetic acid and also in phenol; in aqueous methanol, the cleavage affords the methyl ether with a predominant inversion of configuration. These are the stereochemical characteristics of an S_N1 type reaction.

As is shown in Table 4, one of the solvolysis products, 1-phenylethyl acetate, was found to racemize about 10% in the presence of acid under the same reaction conditions as those of the cleavage reaction. Therefore, in the calculation of the extent of racemization (or inversion) for 1-phenylethyl acetate, we made a correction for the racemization of the acetate during the course of the acidic cleavage. The rotation of 1-phenylethyl methyl ether was not affected in aqueous methanol, even at higher perchloric acid concentrations than in the

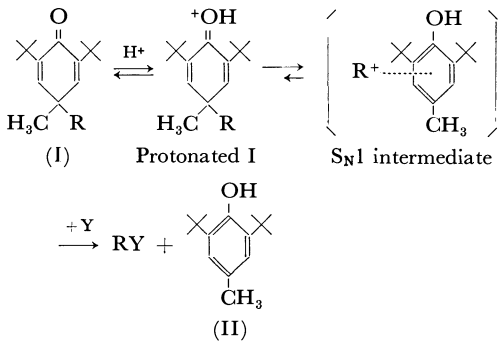
case of 1-phenylethyl acetate.

Mechanism of the Acid-catalyzed Cleavage of 2,6-Di-*t*-butyl-4-(1-phenylethyl)-4-methylcyclohexadien-1-one (I). Polarimetric rate measurements were carried out with an acetic acid solution of the dienone Ia (0.500M) at 25°C, using 3.94×10^{-3}M sulfuric acid as the acid catalyst. For purposes of comparison, the spectrophotometric rate measurements were conducted by the use of the same reaction mixture as that used for the polarimetric run; the decrease in the dienone I and the increase in the phenol II were followed at

the characteristic bands of 249 and 284 mμ respectively.

The polarimetric rate constant, k_P, the rate constant for the decrease in the dienone I, k_D, and the rate constant for the increase in the phenol II, k_{DBC}, were graphically calculated; as is illustrated in Figs. 3,4, and 5, the observed values for the three k's are all essentially the same within the limits of experimental error.

All the results, *i.e.*, steric and kinetic, are most readily accomodated by an S_N1 solvolysis mechanism of the protonated dienone I; this is illustrated by the following scheme:



The protonation of a dienone with a structure similar to that of the dienone I has been confirmed in the case of 2,6-di-*t*-butyl-4-dichloromethyl-4-methylcyclohexadien-1-one by the use of the spectrophotometric method.[6]

Since the k_P is equal to k_D or to k_{DBC}, the rate for the return of the S_N1 intermediate to the protonated dienone would be negligibly small as compared with rate for the attack of the solvent nucleophile, Y, on the S_N1 intermediate.

In view of the existence of carbonium ion-aromatic hydrocarbon charge-transfer complexes in various solvents,[7] the S_N1 intermediate would be close to a charge-transfer complex between the 1-phenylethyl cation and the phenol II.

This reaction of the protonated dienone I is considered to be an example of the S_N1 reaction of the "missing-charge" type;[8] a phenol molecule,

h) Styrene (11%)was obtained.

II, acts as a leaving group of the charged substrate, *i.e.*, the protonated dienone I. The observed solvent effect (*vide supra*) for the cleavage of the protonated dienone is consistent with that observed for such S_N1 reactions of the "missing-charge" type as the solvolyses of *t*-butyldimethylsulfonium ion[9] and of cyclohexylmercuric perchlorate.[10]

Experimental[11]

2,6-Di-*t*-butyl-4-methyl-4-(1-phenylethyl)-cyclohexadien-1-one (I). The dienones, racemic and optically active, were prepared under various conditions, according to the method of Kornblum and Seltzer.[2] The results are tabulated in Tables 1 and 5. The details of a representative run will now be described.

To a mixture of a *t*-butanol solution (22.4 m*l*) of potassium *t*-butoxide (0.87N), tetraethylene glycol dimethyl ether (15 m*l*), *t*-butanol (4 m*l*), and 2,6-di-*t*-butyl-4-methylphenol (II) (4.41 g, 0.02 mol), 1-phenylethyl bromide (3.0 m*l*, 0.022 mol) was added in one portion at 20°C. The titration analysis of an aliquot showed that the reaction was 87.5% complete within 20 min. After the mixture had stood overnight at room temperature, benzene (50 m*l*) was added; the benzene solution was then washed with water and condensed to leave an oily material (8.47 g), which was chromatographed over alumina (146 g, 200—300 mesh). The dienone I (5.25 g and 0.37 g; total yield 86.7%) was eluted successively by *n*-hexane (400 m*l*) and benzene (80 m*l*).

Found: C, 85.43; H, 10.07%; mol. wt, 322.0 (cryoscopic, benzene). Calcd for $C_{23}H_{32}O$: C, 85.13; H, 9.94%; mol. wt, 324.5.

The IR spectrum for the dienone I shows a doublet carbonyl absorption at 1640 and 1655 cm^{-1}, corresponding to a conjugated dienone; the UV maximum appears at 249 mμ (ε=10650, methanol), showing a cross structure for the conjugated dienone I. In the NMR spectrum (60 MHz) of the dienone I, five phenyl protons appear as a multiplet centered at τ 2.9; two vinyl protons, as a quartet showing an AB pattern (ν_A τ 3.55, ν_B τ 3.73, J_{AB}=3 Hz); a methine proton, as a quartet centered at τ 7.16 (J=7.5 Hz); 18 *t*-butyl protons, as two singlets (nine for each) at τ 8.78 and 8.87; three protons on a methyl group, attached to a quaternary carbon, as a singlet at τ 8.89. Three methyl protons of the 1-phenylethyl group appear in the range of τ 8.7—9.0, but they could not be well characterized because of the overlapping of the other methyl proton signals. The magnetic non-equivalence for two vinyl protons and for the protons of two *t*-butyl groups may be attributed to the asymmetric structure of the 1-phenylethyl group.

Ozonolysis of the Dienone I. A solution of the dienone I (2.32 g) in a mixture of acetic acid (150 m*l*) and ethyl acetate (90 m*l*) was treated with ozonized oxygen at 0°C. A stream of ozonized oxygen (1.6 mmol of ozone/*l*) was passed into the solution at a rate of 80 m*l*/min. The amount of unchanged ozone was determined every 20 or 30 min by collecting it in a potassium iodide trap and titrating the liberated iodine. After an uptake of 30 mmol of ozone in 7 hr, the mixture was treated with a mixture of 30% hydrogen peroxide (6 m*l*) and water (40 m*l*). After it had stood overnight and ether (500 m*l*) had subsequently been added, the resulting mixture was washed with 5% aqueous sodium chloride (6×50 m*l*), condensed to 100 m*l*, and washed with additional 5% aqueous sodium chloride (8×25 m*l*). From the alkaline extracts of the organic layer, an acidic oily material (1.869 g) was recovered by the usual working-up. The oil was distilled *in vacuo* to give a mixture of acetic acid and tri-

9) C. G. Swain, L. E. Kaiser and T. E. C. Knee, *J. Amer. Chem. Soc.*, **80**, 4092 (1958).
10) F. R. Jensen and R. J. Ouellette, *ibid.*, **83**, 4478 (1961).
11) The melting points are uncorrected. Rotations were measured with a Zeiss-Winkel "Kreis-Polarimeter 0.01°." The infrared spectra and ultraviolet spectra were obtained on Shimadzu spectrometers models IR-27 and UV-50M. The gas-liquid chromatograms were obtained with a Shimadzu model GC2B apparatus. The microanalyses were performed by the Microanalysis Center, Kyoto University.

methylacetic acid (bp *ca.* 50°C/5 mmHg, 0.810 g), leaving a residual oil (the acid equivalent: 150±10, 1.059 g). The residual oil (1.000 g) was dissolved in ether (6 m*l*), and treated with diazomethane (11.4 mmol) in ether (24 m*l*). After the usual working-up, the methylated products were distillated *in vacuo* to afford a fraction with bp of 77—91°C/0.3 mmHg. This fraction was analyzed on a 2 m×4 mm copper tubing packed with high vacuum silicone grease on Celite under the following conditions: column temperature, 175°C; hydrogen flow rate, 70 m*l*/min. The fraction contained component with the retention time of 5.1 min (26%) and dimethyl α-methyl-α-(α-phenylethyl)malonate (68%; retention time, 14.6 min). After several injections, the dimethyl ester was collected as eluted (51% of recovery; 102 mg; the IR spectrum was identical with that of the authentic sample).

Preparation of the Authentic Dimethyl α-Methyl-α-(α-phenylethyl)-malonate. To a solution of sodium (1.13 g, 49.1 mmol) in a mixture of methanol (8 m*l*) and diglyme (15 m*l*), we added dimethyl α-(α-phenylethyl)-malonate (9.03 g, 40.3 mmol), which had been prepared according to the method of Snyder and Brewster.[12] To the cooled mixture, methyl iodide (9.17 g, 64.6 mmol) was added drop by drop; after 1.5 hr, the mixture was diluted with benzene (100 m*l*), washed with 10% aqueous sodium chloride, and condensed to give a viscous oil. The vacuum distillation of the oil gave a fraction with a bp of 102—116°C/0.3 mmHg (7.1 g); this fraction was a mixture of dimethyl α-(α-phenylethyl)-malonate (27%) and dimethyl α-methyl-α-(α-phenylethyl)-malonate (73%). The composition analysis was performed by means of GLC under the above-mentioned conditions; the retention time for dimethyl α-(α-phenylethyl)-malonate was 10.9 min. The pure dimethyl α-methyl-α-(α-phenylethyl)-malonate was collected as eluted by GLC.

Prepration of 1-Phenylethyl Trifluoroacetate. A mixture of trifluoroacetic anhydride (1.00 m*l*), 1-phenylethyl alcohol (0.50 m*l*, 4.17 mmol), and a drop of pyridine was kept at 0°C overnight. After the evaporation of the low-boiling materials *in vacuo*, distillation gave 1-phenylethyl trifluoroacetate; bp 63.0—63.2°C/5 mmHg; 0.80 g, 88% yield; IR: 1700 (C=O) and 1220 (C–O–C) cm^{-1}.

Product Analysis for the Cleavage Reaction of the Racemic (I) and Optically Active (Ia) Dienones. The results are summarized in Tables 2 and 3. The details of the experimental procedure for representative runs, which were carried out in various solvents, will be described below.

The Acidic Cleavage Reaction of the Optically Active Dienone Ia in Acetic Acid (Product Analysis and Rate Measurements). To a solution of the dienone Ia (1.6226 g, 5.00 mmol, $[\alpha]_D^{19}$ +18.6°, benzene, *c* 16.4) in acetic acid (3 m*l*), a solution of sulfuric acid *ca.* 9×10^{-3}M) in acetic acid was added to make 10 m*l* of a reaction mixture (3.94×10^{-3}M sulfuric acid). After a specified length of time at 25.0°C, an aliquot (1 m*l*) was withdrawn and neutralized with a solution (0.10 m*l*) of sodium acetate (0.10N) in acetic acid. From the neutralized aliquot (1.10 m*l*), an aliquot of 0.100 m*l* was then withdrawn and diluted to 34 times its volume with methanol; the optical density at 249 mμ (the dienone Ia) and 284 mμ (the phenol II) was measured using an absorption cell 10 mm thick. The rest of the neutralized acetic acid solution was used for the rotation measurements employing a tube 1 dm long. Six aliquots (1 m*l* for each) were withdrawn from the reaction mixture in a period of 4 hr. The results of the graphical calculation of the respective rate constants are illustrated in Figs. 3, 4, and 5.

After 24 hr at 25°C, an aliquot of 1.50 m*l* was pipetted out from the reaction mixture and added to ether (30 m*l*). The resulting ethereal solution was washed with 10% aqueous sodium bicarbonate (5 m*l*) and 10% aqueous sodium chloride (2×10 m*l*) and then evaporated to give an oily material (0.265 g) which was composed of 1-phenylethyl acetate (92.2% yield, based on the dienone Ia) and the phenol II (90.9% yield, based on the dienone Ia). The analysis was performed on a 2 m×4 mm copper tubing column packed with 20% Apiezon grease L on Neosorb N under the following conditions: column temperature, 122°C for 1-phenylethyl acetate and 169°C for the phenol II; hydrogen flow rate, 80 m*l*/min; retention times: 1-phenylethyl acetate, 10.3 min (122°C); the phenol II, 14.9 min (169°C).

The rest of the reaction mixture was chromatographed over alumina. The phenol II (124.9 mg, 84.6% yield, based on the dienone Ia) and 1-phenylethyl acetate (86 mg, the IR spectrum was identical with that of the authentic sample) were eluted with *n*-hexane (150 m*l*) and with benzene (45 m*l*) respectively. The latter was distilled *in vacuo* to give a purified, optically active sample (74.3 mg); this sample was then diluted with racemic 1-phenylethyl acetate (87.3 mg) to give α_D+1.21° (1 dm, neat, at 22°C). The rotation of the original sample was calculated to be α_D+2.63° (1 dm, neat, at 22°C).

The Acidic Cleavage Reaction of the Optically Active Dienone Ia in Phenol. A mixture of the dienone Ia (3.9765 g, 12.25 mmol, $[\alpha]_D^{19}$ +18.6°, benzene, *c* 16.4) and phenol (57.0 g) was kept at 75°C for 1.5 hr. After the addition of ether (100 m*l*) the ethereal solution was washed with 10% aqueous sodium hydroxide (5×50 m*l*) and 10% aqueous sodium chloride (3×100 m*l*), and then concentrated to give an oily material (4.356 g). The oil was then subjected to chromatography on silica gel (100 g). The phenol II (2.460 g, 91.2% based on the dienone Ia) was eluted with *n*-hexane-benzene (15: 1 by vol., 50 m*l*); 1-phenylethyl phenyl ether (containing a hydroxylic compound), with *n*-hexane-benzene (15: 1 by vol., 500 m*l*); *o*-1-phenylethylphenol (743 mg, 30.0% yield), with benzene (600 m*l*), and finally *p*-1-phenylethylphenol (812 mg), with benzene-ether (4 : 1 by vol., 150 m*l*).

From the alkaline extracts additional amounts of *p*-1-phenylethylphenol (369 mg; the total yield was 48.6%) were recovered by the usual working-up and by subsequent distillation *in vacuo* (bp 120°C/4 mmHg, bath temp.).

1-Phenylethyl phenyl ether was rechromatographed over alumina with *n*-hexane as an eluent to give a pure sample (272 mg, 12.2% yield) and a hydroxylic compound (43.5 mg). The latter was not identified.

Each compound so isolated gave a sole spot in TLC on silica gel and exhibited the same IR spectrum as the corresponding authentic sample;[13] the isolated com-

a) Extrapolated or interpolated values.

pounds were redistilled *in vacuo* and then the optical rotation was measured: 1-phenylethyl phenyl ether, 235 mg, bp 100°C/0.05 mmHg (bath temp.), α_D^{20} −1.33± 0.08° (1 dm, neat); *p*-1-phenylethylphenol, 731 mg, bp 150°C/0.05 mmHg (bath temp.), $[\alpha]_D^{19}$ −0.344° (benzene, *c* 68.3); *o*-1-phenylethylphenol, bp 140°C/ 0.05 mmHg (bath temp.), α_D^{19} +0.65±0.04° (1 dm, neat).

The Acidic Cleavage Reaction of the Racemic Dienone I in 86% Aqueous Methanol. In a 10-m*l* volumetric flask we placed the dienone I (313 mg, 0.965 mmol) and a solution (7.7 m*l*) of perchloric acid in aqueous methanol ($[HClO_4]=2.80$N, $[H_2O]=18.8$ vol%); then some methanol was added to bring the volume of the reaction mixture to 10 m*l*. After standing for 6 hr at 25.0°C, the mixture was poured into 50 m*l* of benzene; the benzene solution was then washed successively with 10% aqueous sodium chloride (3× 20 m*l*), 10% aqueous sodium hydroxide (2×20 m*l*), and 10% aqueous sodium chloride (2×20 m*l*). The dried benzene layer was concentrated to about 3 m*l* and made to a 5-m*l* solution in a 5-m*l* volumetric flask by adding some benzene. The composition of the products was determined by GLC using the same column as that employed in the analysis for 1-phenylethyl acetate (at 122°C and the hydrogen flow rate 48.4 m*l*/ min): 1-phenylethyl methyl ether, 6.85 min (retention time)(80.0% yield, based on the dienone I); 1-phenylethyl alcohol, 9.1 min (7.6% yield); the phenol II, 22.8 min (at 165°C)(94.8% yield).

The Acidic Cleavage Reaction of the Racemic Dienone I in the Presence of Trifluoroacetic Acid in 1,2-Dichloroethane. The dienone I (574 mg, 1.615 mmol) and a 0.1455M solution (20 m*l*) of trifluoroacetic acid in 1,2-dichloroethane were placed in a 50-m*l* volumetric flask; some 1,2-dichloroethane was then added to bring the volume of the reaction mixture to 50 m*l*. After 22 hr of standing at 25.0°C, a portion of the reaction mixture was subjected to GLC on the Apiezon column described above under the following conditions: column temperature, 140°C; the hydrogen flow rate, 44.3 m*l*/min; retention time for 1-phenylethyl trifluoroacetate, 2.25 min (61.9% yield, based on the dienone I). An aliquot, withdrawn from the reaction mixture, was titrated with 0.1N aqueous sodium hydroxide, and the amount of trifluoroacetic acid consumed was calculated to be 60.2% of the dienone I. Another aliquot was subjected to UV spectroscopy; it was confirmed that the amount of styrene (λ_{max} 248 mμ, $\varepsilon=1.101\times10^4$) produced during the reaction was less than

1.4% of the dienone I.

The rest of the reaction mixture (46 ml) was concentrated and distilled *in vacuo* to give 1-phenylethyl trifluoroacetate (101 mg, bp 80°C/2 mmHg (bath temp.); the IR spectrum was identical with that of the authentic sample). The residual oil (485 mg) was subjected to chromatography on alumina (20 g). The phenol II (385 mg, 77.4% yield) was eluted with *n*-hexane (150 ml), and some phenolic materials (72 mg) were eluted with benzene and with ethanol. The phenolic materials were characterized by IR analysis.

Racemization of 1-Phenylethyl Acetate and of 1-Phenylethyl Methyl Ether in the Acidic Media. Optically active samples of 1-phenylethyl acetate and of 1-phenylethyl methyl ether were dissolved in the acidic solvents indicated in Table 4. After a specified length of time, the ester or the ether was recovered, purified by distillation *in vacuo*, and subjected to rotation measurements. In the case of the acetic-acid solvent containing sulfuric acid, the solution of 1-phenylethyl acetate was placed in a 1-dm tube; the change in the rotation was followed polarimetrically. The results are summarized in Table 4.

Kinetic Procedure. The rate measurement for the optically active dienone Ia was performed as has been described above. The results are illustrated in Figs. 3,4, and 5. The rate measurement for the racemic dienone I was carried out spectrophotometrically. A glass-stoppered 1-cm quartz cell was placed in a cell-compartment with circulating water thermostated at 25.0°C. Appropriate amounts of a temperature-equilibrated dienone solution was mixed with a temperature-equilibrated acid solution in the cell; the absorbance was followed at a specified wavelength. The first-order rate constants were calculated graphically. The results are summarized in Table 6.

The Measurement of the Acidity Function. The acidity function for each acidic medium measured according to the method of Braude and Stern.[14] For the mixtures of perchloric acid and aqueous methanol, of perchloric acid and acetic acid, and of trifluoroacetic acid and methanol, *o*-nitroaniline (indicator constant, −0.29[15]) was used as the Hammett base; for the mixture of trifluoroacetic acid and 1,2-dichloroethane, *p*-nitroaniline (indicator constant, +0.99[15]) was so employed. The absorbance of *o*-nitroaniline decreased in acetic acid in the course of the measurements; the value of absorbance at time zero was extrapolated from the observed data. The results are illustrated in Table 6, while the H_0 values for trifluoroacetic acid in 1,2-dichloroethane are tabulated in Table 7.

Table 7. Acidity function for trifluoroacetic acid in 1,2-dichloroethane at 25°C

CF_3CO_2H M	0.432	0.259	0.155	0.109	0.076

3,4-Benzotropolone and Related Compounds. VIII.[1] Azo, Nitro and Amino Derivatives of 6-Hydroxy-2,3-benzotropone

Masamatsu Hoshino and Seiji Ebine

Department of Chemistry, Saitama University, Urawa, Saitama

(Received September 29, 1969)

On diazo coupling and nitration, 6-hydroxy-2,3-benzotropone (I) and its 5-bromo derivative (II) gave their 7-azo (V and VI) and 7-nitro substitution products (VII and VIII), respectively. In the same reactions, 7-bromo-6-hydroxy- (III) and 5,7-dibromo-6-hydroxy-2,3-benzotropones (IV) replaced their 7-bromo substituent to give the same 7-azo and 7-nitro substitution products as above. On nitration of III and IV, 2,2-dibromo- (IX) and 2,2,7-tribromo-4,5-benzocyclohepta-4,6-diene-1,3-diones (X) were also formed. Hydrogenation of V, VI, VII and VIII gave 7-amino-6-hydroxy-2,3-benzotropone (XI), diazotization of which gave 2-diazo-4,5-benzocyclohepta-4,6-diene-1,3-dione (XII). 7-Chloro-6-hydroxy-2,3-benzotropone (XV) was brominated to 2-bromo-2-chloro-4,5-benzocyclohepta-4,6-diene-1,3-dione (XVII) at room temperature, to 5-bromo-7-chloro-2,3-benzotropone (XVI) at 100°C, and to 2-chloro-2,7-dibromo-4,5-benzocyclohepta-4,6-diene-1,3-dione (XVIII) with excess bromine at 100°C. XVII and XVIII were easily debrominated to XV and XVI, respectively, on heating with hydrochloric or hydrobromic acid. XV changed into a mixture of I and II on heating with hydrobromic acid.

Nitration, azo coupling and related reactions of 6-hydroxy-2,3-benzotropone (I)[2],*1 have been investigated as a series of benzotroponoid studies.[1-3]

I and its 5-bromo derivative (II),[2] like tropolone[4,5] and its benzologs,[6-8] underwent coupling with diazotized *p*-toluidine in a pyridine solution to give the corresponding 7-*p*-tolylazo derivatives (V and VI). 7-Bromo (III)[3] and 5,7-dibromo (IV)[3] derivatives of I also reacted with diazotized *p*-toluidine, expelling their 7-bromo substituent, to give the same products (V and VI) as above.

Nitration of I and II, like that of tropolone[5] and its benzologs,[7,9] was not successful in concentrated sulfuric acid but successful in acetic acid solution to give 6-hydroxy-7-nitro-2,3-benzotropone (VII) and its 5-bromo derivative (VIII), respectively, in good yields. On nitration of III, the 7-bromo substituent was replaced with a nitro group to give VII and the liberated bromo cation attacked an unreacted III to give 2,2-dibromo-4,5-benzocyclohepta-4,6-diene-1,3-dione (IX) (infrared absorption spectrum in KBr disk: 1690 and 1653 cm^{-1} for two carbonyls). Intermediate formation of the bromo cation, however, has no experimental evidence. A similar nitration of IV gave a tribromo diketone (X),[3] a possible product (VIII) not being isolated. X was also obtained by bromination of IV and IX.

7-Amino-6-hydroxy-2,3-benzotropone (XI) was produced by hydrogenation of azo compounds (V and VI) or nitro compounds (VII and VIII). Treatment of XI with nitrous acid at 0—5°C resulted in the formation of 2-diazo-4,5-benzocyclohepta-4,6-diene-1,3-dione (XII), which would be produced *via* an intermediate diazonium salt. The structure of XII was confirmed by intense infrared absorption at 2178 cm^{-1} characteristic to diazoketone[10] and by Wolff rearrangement reaction to 1-hydroxy-2-naphthoic acid along with a small amount of α-naphthol on heating in aqueous solution, and to

1-hydroxy-2-naphtho-*p*-toluidide on heating with *p*-toluidine in xylene solution. Acetylation of XI gave an unusual product (XIII), hydrolysis of which gave a compound (XIV). XIV is assumed to be an oxazolobenzotropone based on its infrared absorption spectrum (KBr): 1620, 1590, 1548 and 1130 cm^{-1} for C=O, C=N, C=C and C–O–C, no absorption for acetoxyl and acetamide carbonyls. The structure of XIII is also assumed as given in the chart due to infrared absorption at 1770 and 1710 cm^{-1} for two acetyl carbonyls. A similar reaction has been reported in the case of acetylation of 3-amino-4,5-benzotropolone[7] and 3-aminotropolone.[11]

By analogy to the case of III and IV, 7-chloro-6-hydroxy-2,3-benzotropone (XV) was subjected to halogenation and dehalogenation. Bromination of XV at 100°C gave 5-bromo-7-chloro-6-hydroxy-2,3-benzotropone (XVI).[3] Bromination of XV and XVI at room temperature gave the corresponding bromo chloro diones (XVII and XVIII) which, on treatment with alkali or hydrochloric acid, turned back to the original XV and XVI, respectively. Bromination of III at room temperature gave III-bromine adduct[3] instead of IX.

XV remained unchanged on heating with hydrochloric acid but changed to give both I and II on heating with hydrobromic acid. A similar treatment of XVI, XVII and XVIII with hydrobromic acid liberated one of their halogen substituents to afford II in good yield. III and XV also liberated with difficulty their halogen substituent to give I on heating with sulfuric acid. The diones (IX, XVII and XVIII) were dehalogenated under mild condition to the tropones (III, XV and XVI, respectively). Halogenation and dehalogenation of these chloro derivatives are analogous to those of the corresponding bromo derivatives.[3]

Experimental*3

Azo Coupling of 6-Hydroxy-2,3-benzotropone (I)[2] and Its Bromo Derivatives (II[2], III[3] and IV[3]). *6-Hydroxy-7-p-tolylazo-2,3-benzotropone (V).* To a solution of 300 mg of I in 5 m*l* of pyridine was added a diazotized *p*-toluidine solution prepared from 243 mg of *p*-toluidine, 132 mg of sodium nitrite and 3.14 m*l* of 2.4N hydrochloric acid. After standing overnight in an ice-chest, the precipitate formed was filtered and recrystallized from ethanol, giving 480 mg (95%) of V, reddish orange needles, mp 153—154°C, infrared

*2 Alternative structures XIII′ and XIV′ are conceivable. It is not clear which pair of structures are more correct.

*3 Thanks are due to the Department of Chemistry, Tohoku University, for the microanalyses.

spectrum above 1500 cm^{-1} (KBr, cm^{-1}): 3406, 1638, 1591, 1556, ultraviolet spectrum (MeOH), mμ (log ε): 229 (4.44), 265 (4.38), 455 (4.46).

Found: C, 74.17; H, 4.77; N, 9.43%. Calcd for $C_{18}H_{14}N_2O_2$: C, 74.47; H, 4.86; N, 9.65%.

Coupling of 200 mg of 7-bromo-6-hydroxy-2,3-benzotropone (III) with diazotized *p*-toluidine gave 30 mg (13%) of the same product (V) as above.

5-Bromo-6-hydroxy-7-p-tolylazo-2,3-benzotropone (VI). Coupling of 200 mg of 5-bromo-6-hydroxy-2,3-benzotropone (II) and 300 mg of 5,7-dibromo-6-hydroxy-2,3-benzotropone (IV) with diazotized *p*-toluidine gave 230 mg (78%) and 130 mg (39%), respectively, of the same VI, orange needles (from ethanol), mp 181—182°C, infrared spectrum above 1500 cm^{-1} (KBr, cm^{-1}): 3420, 1647, 1590, 1565, ultraviolet spectrum (MeOH), mμ (log ε): 257 (4.67), 460 (4.45).

Found: C, 58.36; H, 4.05; N, 7.34%. Calcd for $C_{18}H_{13}N_2O_2Br$: C, 58.55; H, 3.55; N, 7.59%.

4-Bromo-6-hydroxy-7-p-tolylazo-2,3-benzotropone.[2] Coupling of 4-bromo-6-hydroxy-2,3-benzotropone with diazotized *p*-toluidine gave 4-bromo-6-hydroxy-7-*p*-tolylazo-2,3-benzotropone, reddish orange needles, mp 152—153°C, in 70% yield, infrared spectrum above 1500 cm^{-1} (KBr, cm^{-1}): 3420, 1655, 1608, 1588, 1560, ultraviolet spectrum (MeOH), mμ (log ε): 230 (4.28), 265 (4.27), 450 (4.45).

Found: C, 58.50; H, 3.45; N, 7.56%. Calcd for $C_{18}H_{13}N_2O_2Br$: C, 58.55; H, 3.55; N, 7.59%.

Nitration of I, II, III and IV. *6-Hydroxy-7-nitro-2,3-benzotropone (VII).* To a stirred suspension of 400 mg of I in 10 m*l* of glacial acetic acid was dropped at 10—15°C 0.174 m*l* of concentrated nitric acid (sp. gr. 1.38), diluted with an equal volume of glacial acetic acid in the course of one and a half hours. The mixture was stirred for further 4 hr and then allowed to stand at room temperature overnight. A precipitate formed was collected and recrystallized from ethanol to give 440 mg (87%) of pale yellow, granular crystals, mp 203°C (dec), infrared spectrum above 1500 cm^{-1} (KBr, cm^{-1}): *ca.* 3388, 3026, 1640, 1600, 1560, 1515, ultraviolet spectrum (MeOH), mμ (log ε): 258 (4.63), 335 (3.89).

Found: C, 60.77; H, 3.20; N, 6.14%. Calcd for $C_{11}H_7NO_4$: C, 60.83; H, 3.25; N, 6.45%.

5-Bromo-6-hydroxy-7-nitro-2,3-benzotropone (VIII). A similar nitration of 300 mg of 5-bromo-6-hydroxy-2,3-benzotropone (II) gave 280 mg (79%) of VIII, pale yellow, granular crystals, mp 103—105°C (dec), infrared spectrum above 1500 cm^{-1} (KBr, cm^{-1}): *ca.* 3440, 3026 (shoulder), 1605, 1573, 1548, ultraviolet spectrum (MeOH), mμ (log ε): 273 (4.66).

Found: C, 44.86; H, 2.04; N, 4.31%. Calcd for $C_{11}H_6NO_4Br$: C, 44.62; H, 2.04; N, 4.73%.

2,2-Dibromo-4,5-benzocyclohepta-4,6-diene-1,3-dione (IX). III (300 mg) was nitrated in the same way as above and the crude product was fractionally recrystallized from dilute methanol to give 46 mg (18%) of VII and 127 mg (32%) of IX, intensely yellow, granular crystals, mp 110—111°C, infrared spectrum (KBr, cm^{-1}): 1690 and 1653 for two carbonyls, ultraviolet spectrum (MeOH), mμ (log ε): 243 (3.89).

Found: C, 40.10; H, 1.94%. Calcd for $C_{11}H_6O_2Br_2$: C, 40.03; H, 1.83%.

2,2,7-Tribromo-4,5-benzocyclohepta-4,6-diene-1,3-dione (X).[3] a) Nitration of 300 mg of IV in acetic acid or acetic anhydride solution gave 105 mg (28%) of X, mp 131—132°C. (Found: C, 32.91; H, 1.38%. Calcd for $C_{11}H_5O_2Br_3$: C, 32.81; H, 1.23%).

b) A solution of 30 mg of bromine in 0.2 m*l* of acetic acid was added to a solution of 50 mg of IV in 3 m*l* of acetic acid, and the resulting solution was allowed to stand at room temperature for 2 hr. The solvent was removed *in vacuo* and the residue was extracted with warm petroleum ether. After standing in an ice-chest, the precipitate formed was collected and recrystallized from ethanol to give 17 mg (27%) of X, mp 132—133°C.

The products obtained in the above two ways were identified by mixture mp determination and infrared comparison with an authentic sample.[3]

7-Amino-6-hydroxy-2,3-benzotropone (XI) and Its Derivatives. *7-Amino-6-hydroxy-2,3-benzotropone (XI).* A solution of 300 mg of V or 400 mg of VII in 50—100 m*l* of ethanol was hydrogenated with a theoretical amount of hydrogen in the presence of 100 mg of 5% palladium chloride-charcoal catalyst. After completion of the reaction, the catalyst was filtered, the solution was evaporated and the product was recrystallized from ethanol giving 160 mg (83%) or 255 mg (74%) of XI, yellow needles, mp 192—193°C (dec). A similar hydrogenation of 400 mg of VI, VIII or 4-bromo-6-hydroxy-7-*p*-tolylazo-2,3-benzotropone in ethanol in the presence of 100 mg of 5% palladium chloride-charcoal and 400 mg of fused sodium acetate gave XI in around 80% yield. Infrared spectrum above 1500 cm^{-1} (KBr, cm^{-1}): *ca.* 3386, 3046, 1638, 1573, 1538, ultraviolet spectrum (MeOH), mμ (log ε): 254 (4.51), 410 (4.05).

Found: C, 70.71; H, 5.05; N, 7.16%. Calcd for $C_{11}H_9NO_2$: C, 70.58; H, 4.85; N, 7.48%.

Hydrochloride. Colorless needles, mp 223—225°C (dec).

Found: C, 59.15; H, 4.46; N, 6.00%. Calcd for $C_{11}H_{10}O_2NCl$: C, 59.07; H, 4.51; N, 6.26%.

Sulfate. Pale yellow crystals, mp 208—210°C (dec).

Found: C, 46.23; H, 4.14; N, 4.64%. Calcd for $C_{11}H_{11}O_6NS$: C, 46.31; H, 3.89; N, 4.91%.

Picrate. Yellow needles, mp 172°C (dec).

Found: C, 55.73; H, 3.59; N, 11.16%. Calcd for $C_{28}H_{21}O_{11}N_5$: C, 55.72; H, 3.51; N, 11.61%.

Reaction of XI with Acetic Anhydride. A mixture of 400 mg of XI, 400 mg of fused sodium acetate and 12 m*l* of acetic anhydride was heated at 100°C for 30 min. After cooling the mixture was poured on ice and the precipitate which separated was collected by filtration. The precipitate (A) and the filtrate (B) were worked up as follows. Recrystallization of A from ethanol gave 304 mg (45%) of a compound (XIII), colorless prisms, mp 146°C, infrared spectrum (KBr, cm^{-1}): 1770, 1710, 1635 (shoulder), 1623, 1593, 1580, *etc.*, ultraviolet spectrum (MeOH), mμ (log ε): 236 (4.45), 325 (3.91).

Found: C, 65.14; H, 4.83; N, 4.43%. Calcd for $C_{17}H_{15}NO_5$: C, 65.17; H, 4.82; N, 4.47%.

Extraction of B with ethyl acetate, evaporation of the solvent from the organic layer and recrystallization of the residue from ethanol gave 87 mg (19%) of oxazole derivative (XIV), colorless needles, mp 192—193°C (dec), infrared spectrum (KBr, cm^{-1}): 1628 (shoulder), 1620, 1590, 1548, *etc.*, ultraviolet spectrum (MeOH), mμ (log ε): 237 (4.31), 270 (4.71).

Found: C, 73.70; H, 4.13; N, 6.14%. Calcd for

$C_{13}H_9NO_2$: C, 73.92; H, 4.30; N, 6.63%.

Heating of XIII with concentrated hydrochloric acid at 100°C for 20 min gave XIV in 83% yield.

Oxidation of XI to o-Carboxycinnamic Acid. To a solution of 200 mg of XI in 20 m*l* of 0.5N sodium hydroxide was added 5 m*l* of 35% hydrogen peroxide. After standing for 2 hr at room temperature, the solution was acidified with 6N hydrochloric acid to give 70 mg (34%) of *o*-carboxycinnamic acid, mp and mixed mp 186—188°C.

2-Diazo-4,5-benzocyclohepta-4,6-diene-1,3-dione (XII) and Its Wolff Rearrangement. *Diazoketone (XII).* To a stirred suspension of 500 mg of XI in 12.5 m*l* of 42% borofluoric acid (HBF_4) was dropped a solution of 204 mg of sodium nitrite in 1 m*l* of water and the reaction mixture was set aside for 1 hr at 0—5°C. The precipitate (A) was collected by filtration. The filtrate was set aside for several days, giving a precipitate (B) of unknown compound (mp>240°C, 149 mg). The precipitate (A) was recrystallized from methanol to afford 314 mg (59%) of XII, yellow needles, mp 118—119°C, infrared spectrum (KBr, cm^{-1}): *ca.* 2178, 1636, 1579(shoulder), 1578, 1560, *etc.*, ultraviolet spectrum (MeOH), mμ (log ε): 255 (4.61), 330 (3.90), NMR spectrum ($CDCl_3$, ppm): 8.84 (an aromatic H), 7.64 (multiplet, three aromatic H), 7.21 and 6.45 (AB pattern, 6-H and 7-H, J=13.1 Hz).

Found: C, 66.70; H, 3.30; N, 14.35%. Calcd for $C_{11}H_6N_2O_2$: C, 66.66; H, 3.05; N, 14.14%.

XII (147 mg, 69%) as well as a trace (4 mg, 2%) of 1-hydroxy-2-naphthoic acid were formed when a solution of 82 mg of sodium nitrite in 2 m*l* of water was added to a suspension of 200 mg of XI in 10 m*l* of 6N sulfuric acid, and the resulting mixture was allowed to stand at 0—5°C for 1 hr and then refluxed for 5 min.

Wolff Rearrangement of XII. a) A suspension of 100 mg of XII in 40 m*l* of water was refluxed for 4.5 hr, during which time the suspended mixture became homogeneous. After cooling, the solution was extracted with ethyl acetate and then the organic layer was shaken with aqueous sodium bicarbonate. The organic layer was evaporated and the residue was recrystallized from petroleum ether to give 12 mg (14%) of α-naphthol, mp and mixed mp 91—93°C. The aqueous sodium bicarbonate layer was acidified with dilute hydrochloric acid and then extracted with ethyl acetate. The extract was evaporated and the residue was recrystallized from benzene to give 55 mg (59%) of 1-hydroxy-2-naphthoic acid, mp and mixed mp 188.5—190.5°C, which was identified by infrared comparison with an authentic sample.

A solution of 200 mg of 1-hydroxy-2-naphthoic acid in 50 m*l* of water was refluxed for 2.5 hr to give 150 mg of α-naphthol, proving that a part of 1-hydroxy-2-naphthoic acid was decarboxylated to α-naphthol during the above Wolff rearrangement.

b) A solution of 120 mg of XII and 500 mg of *p*-toluidine in 15 m*l* of xylene was refluxed for 3 hr. The solution was washed with dilute hydrochloric acid to remove excess *p*-toluidine and the organic layer was evaporated. Recrystallization of the residue from cyclohexane gave 125 mg (74%) of 1-hydroxy-2-naphtho-*p*-toluidide, mp and mixed mp 149—151°C (Found: C, 78.17; H, 5.47; N, 5.06%. Calcd for $C_{18}H_{15}NO_2$: C, 77.96; H, 5.45; N, 5.05%).

Derivatives of 7-Bromo-6-hydroxy-2,3-benzotropone (III)[3] and 7-Chloro-6-hydroxy-2,3-benzotropone (XV)[3]. *Acetate of III.* Colorless granular crystals (from ether-petroleum ether), mp 139—140°C.

Found: C, 53.18; H, 3.30%. Calcd for $C_{13}H_9O_3Br$: C, 53.27; H, 3.09%.

Methyl Ether of III. Colorless prisms (from methanol), mp 138—139°C.

Found: C, 54.48; H, 3.58%. Calcd for $C_{12}H_9O_2Br$: C, 54.36; H, 3.42%.

Acetate of XV. Colorless plates (from methanol), mp 141—142°C.

Found: C, 62.37; H, 3.70%. Calcd for $C_{13}H_9O_3Cl$: C, 62.79; H, 3.65%.

Methyl Ether of XV. Colorless needles (from methanol), mp 137—137.5°C.

Found: C, 64.88; H, 4.15%. Calcd for $C_{12}H_9O_2Cl$: C, 65.32; H, 4.11%.

Bromination of XV.[3] *5-Bromo-7-chloro-6-hydroxy-2,3-benzotropone (XVI).* A solution of 52.5 mg of bromine in 2 m*l* of acetic acid was added to a solution of 50 mg of XV[9] in 2 m*l* of acetic acid and the resulting solution was heated at 100°C for 1 hr. On evaporation of the solvent *in vacuo*, recrystallization of the residue from ethanol gave 53.5 mg (77%) of XVI, yellow needles, mp and mixed mp 213—214°C (dec), whose infrared spectrum coincided with that of a sample prepared by a different method.[3]

2-Bromo-2-chloro-4,5-benzocyclohepta-4,6-diene-1,3-dione (XVII). Bromination of 100 mg of XV with 80 mg of bromine and 60 mg of fused sodium acetate in 10 m*l* of acetic acid at room temperature (18°C) gave 135 mg (98%) of XVII, yellow plates (from methanol), mp 121—122°C (dec), infrared spectrum (KBr, cm^{-1}): 1698 and 1663 for two carbonyls, ultraviolet spectrum (MeOH), mμ (log ε): 247 (4.10), 334 (3.65).

Found: C, 46.06; H, 2.17%. Calcd for $C_{11}H_6O_2BrCl$: C, 46.27; H, 2.12%.

2-Chloro-2,7-dibromo-4,5-benzocyclohepta-4,6-diene-1,3-dione (XVIII). a) Bromination of 100 mg of XV with 184 mg of bromine and 105 mg of fused sodium acetate in 10 m*l* of acetic acid at 60—70°C gave 119 mg (67%) of XVIII, yellow prisms (from methanol), mp 140—141°C (dec), infrared spectrum (KBr, cm^{-1}): 1706 and 1691 for two carbonyls, ultraviolet spectrum (MeOH), mμ (log ε): 270 (3.86), 277 (3.86).

Found: C, 36.39; H, 1.51%. Calcd for $C_{11}H_5O_2Br_2Cl$: C, 36.25; H, 1.38%.

b) A similar treatment of 200 mg of XVI with 150 mg of bromine and 150 mg of fused sodium acetate in 70 m*l* of acetic acid gave 230 mg (90%) of XVIII.

Dehalogenation of Halo-6-hydroxy-2,3-benzotropones (III[3], XV[3], XVI[3]) and Halo-4,5-benzocyclohepta-4,6-diene-1,3-diones (IX, XVII, XVIII). *From III and XV to I (and II).* a) A solution of 150 mg of XV in 20 m*l* of acetic acid and 20 m*l* of 47% hydrobromic acid was refluxed for 2 hr. Evaporation of the solvent and fractional recrystallization of the residue from dilute alcohol gave 44 mg (35%) of I, 208°C (dec) and 72 mg (40%) of II, mp 234°C (dec).

XV remained unchanged on heating with hydrochloric acid.

b) A solution of 100 mg of III in 15 m*l* of acetic acid and 10 m*l* of 6N sulfuric acid was refluxed for 2 hr. Concentration of the reaction mixture and dilution with 50 m*l* of water gave 76.2 mg of a precipitate of unchanged III. After filtration the filtrate was extracted

with ethyl acetate and the extract was evaporated to give 13 mg (19%) of I, mp 208°C (dec).

Heating of III with hydrobromic acid gave I (4%) and II (29%).[9]

c) A similar treatment of 100 mg of XV with 6N sulfuric acid gave 4.2 mg (5%) of I, a greater part of XV remained unreacted.

From XVI, XVII, and XVIII to II. A 50-mg sample of XVI, XVII or XVIII, dissolved in 5 m*l* of acetic acid and 5 m*l* of 47% of hydrobromic acid, was heated for 2 hr. Evaporation of the solvent and recrystallization of the residue from methanol gave II, mp 234°C (dec), in over 90% yield.

From IX, XVII and XVIII to III, XV and XVI, respectively. a) A solution of 50 mg of IX in 6 m*l* of N sodium hydroxide was set aside at room temperature for 1 hr. The solution was acidified with dilute hydrochloric acid and the precipitate which separated was recrystallized from ethanol to give 20 mg (52%) of III, mp 173.5°C (dec).

b) XVII (50 mg), 5 m*l* of 6N hydrochloric acid and 8 m*l* of acetic acid were heated under reflux for 1 hr. The solution was evaporated and the residue was recrystallized from methanol to give 24 mg (66%) of XV, mp 173°C.

c) XVIII (50 mg), 5 m*l* of 47% hydrobromic acid and 8 m*l* of acetic acid were set aside at room temperature for 2 days. Concentration of the solution gave 31 mg (79%) of XVI, mp 214°C (dec).

XVIII (50 mg), 5 m*l* of 6N hydrochloric acid and 8 m*l* of acetic acid were refluxed for 1 hr, yielding 20 mg (52%) of XVI.

XVIII (100 mg) and 20 drops of 2N potassium hydroxide in 20 m*l* of methanol were allowed to stand at room temperature for 1 hr. Removal of methanol, acidification with dilute hydrochloric acid, extraction with chloroform, and evaporation of the solvent from the extract gave 21 mg (27%) of XVI.

The above products I, II, III, XV and XVI were identified by elemental analyses, mixture mp determinations and infrared comparisons with authentic samples.[3]

(Received October 28, 1969)

1-Acetyl- and 1-isopropenyl-3-methylenecyclobutane (I and II) were prepared and then subjected to pyrolysis. The pyrolysis of I at 304—340°C gave 2-methyl-5-methylene-Δ^2-dihydropyrane, which was then converted to 4-methylenecyclohexanone at this temperature. The pyrolysis of II at 255—340°C gave 1-methyl-4-methylenecyclohexene, which was disproportionated at this temperature to *p*-xylene and 1,4-dimethylcyclohexene. In neither case was fragmentation to olefins observed. These results were interpreted by a two-step biradical mechanism.

There have been ample examples of the thermal fragmentation of a cyclobutane derivative into two molecules of olefins.[3)] For example, cyclobutane is pyrolyzed into two molecules of ethylene, and methylenecyclobutane is likewise pyrolyzed into ethylene and allene. The comparison of these two reactions reveals that the activation energy (63.3 kcal/mol)[4)] required for the pyrolysis of methylenecyclobutane is slightly higher than, or almost equal to, that (61.5—63.2 kcal/mol)[5)] required for

Ogawa, *ibid.*, **85**, 3346 (1963); C. T. Genaux, F. Kern and W. D. Walters, *ibid.*, **75**, 6196 (1953). A value of 61.2 kcal/mol is reported as the activation energy for the fragmentation of methylcyclobutane: M. N. Das and W. D. Walters, *Z. Phys. Chem.*, **15**, 22 (1958).

cyclobutane. This result may appear contrary to the expectation that the presence of an exocyclic methylene group would reduce the activation energy of pyrolytic fragmentation as a result of the extra strain (*ca.* 2.5 kcal/mol)[6] imposed by the introduction of a methylene group. It was thought of interest to learn if this seemingly anomalous value corresponds, not to the initial ring-cleavage step to give a biradical, but, rather, to the final stage of producing the fragmentation products.[4] Such distinction would be possible by a study of the pyrolysis of deliberately chosen compounds in which a second reaction path exists in preference to, or in competition with, fragmentation.

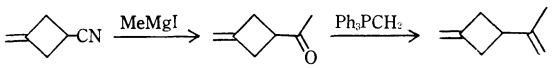
With this in mind, we studied the thermal behavior of 1-acetyl-3-methylenecyclobutane (I) and 1-isopropenyl-3-methylenecyclobutane (II). These compounds will give fragmentation and/or ring-enlargement products depending on the heights of the energy barriers existing in the two reaction paths.

During the course of this investigation, Doering and Gilbert[8] have unequivocally shown with 1,1-dideuteriomethylenecyclobutane that the fragmentation step indeed requires a higher activation energy than that of the initial ring cleavage to a biradical.

Results and Discussion

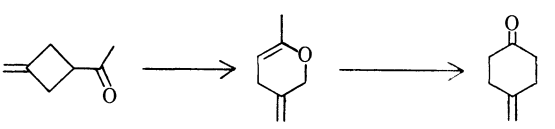
The reaction of 3-methylenecyclobutanecarbonitrile[9] and methylmagnesium iodide, followed by hydrolysis, gave 1-acetyl-3-methylenecyclobutane (I). The NMR spectrum of I, in complete agreement with the assigned structure, showed a three-proton singlet at τ 8.05 for the acetyl group, a four-proton multiplet and a one-proton multiplet at τ 7.27 and 7.25 for the two methylene and the methine groups, and a two-proton pentuplet (J=2.5 Hz) for the exocyclic methylene group. Its infrared spectrum confirmed the presence of the acetyl (1720, 1370 cm^{-1}) and the exocyclic methylene (3080, 1680, 1410, 880 cm^{-1}) groups. The mass spectrum of I showed a parent peak at *m/e* 110, in accord with the molecular formula of $C_7H_{10}O$, and major fragment peaks at *m/e* 95 $(P-Me)^+$, 67 $(P-Ac)^+$, and 43 $(Ac)^+$.

The treatment of I with methylenetriphenylphosphorane afforded 1-isopropenyl-3-methylenecyclobutane (II), the structure of which was established by the spectral data described below. The NMR spectrum of II consisted of three poorly-resolved multiplets at τ 8.32 (3H), 7.30 (5H), and 5.33 (4H), corresponding to the methyl group on the double bond, the ring protons, and the two terminal methylene groups respectively. The infrared spectrum of II had bands of the terminal methylene groups at 3100, 1680, 1650, 1420, 1380, 885, and 875 cm^{-1}.



I II

Pyrolysis of 1-Acetyl-3-methylenecyclobutane. The pyrolysis of 1-acetyl-3-methylenecyclobutane (I), as a neat liquid or as a toluene solution and in a sealed tube at 304 and 340°C, gave two products besides the starting material, which were considered as 2-methyl-5-methylene-Δ^2-dihydropyrane (III) and 4-methylenecyclohexanone (IV) on the basis of the following spectral data.



I III IV

The NMR spectrum of III consisted of a three-proton singlet (with fine splittings) at τ 8.35 corresponding to the methyl group on the double bond, a two-proton multiplet at τ 7.35 corresponding to the methylene group between the two double bonds, a two-proton singlet (with fine splittings) at τ 5.80 corresponding to the methylene group between the double bond and the oxygen atom, a one-proton triplet (J=5 Hz, with fine splittings) at τ 5.69 corresponding to the proton on the double bond, and a two-proton singlet (with fine splittings) at τ 5.10 corresponding to the terminal methylene protons. Its infrared spectrum showed bands of a terminal methylene and olefinic groups at 3100, 1680, 1430, and 900 cm^{-1} and characteristic bands of a vinyl ether at 1240 and 1050 cm^{-1}. Its mass spectrum showed a parent peak at *m/e* 110 and prominent framgent peaks at 95 $(P-Me)^+$, 67 $(P-Ac)^+$, 43 $(Ac)^+$, and 39 $(CH_2-C\equiv CH\ ?)^+$.

The NMR spectrum of the ketone IV displayed only two broad peaks, at τ 7.60 (8H) and 5.15 (2H), which are attributable to the ring protons and the exocyclic methylene groups respectively. The infrared spectrum of IV supported the presence of the exocyclic methylene (3080, 1650, 1430 and 900 cm^{-1}) and the carbonyl (1710 cm^{-1}) groups. Further support for structure IV was provided by its mass spectrum which, in addition to a parent peak at *m/e* 110, showed a fragment peak at 82 (P—

CO)$^{\cdot+}$, characteristic of a cyclic ketone, and peaks at 81 (P−CO−H)$^+$, 67 (P−Ac)$^+$, 54 ($\overline{CH_2CH_2C}$=CH_2 or $\overline{CH{=}CHC}$=O ?)$^{\cdot+}$, and 39 (CH_2–C≡CH ?)$^+$.

The results of a kinetic study of this rearrangment are shown in Fig. 1. The figure clearly shows that III is the initial product of the pyrolysis of I and that III rearranges further to IV at the reaction temperature.

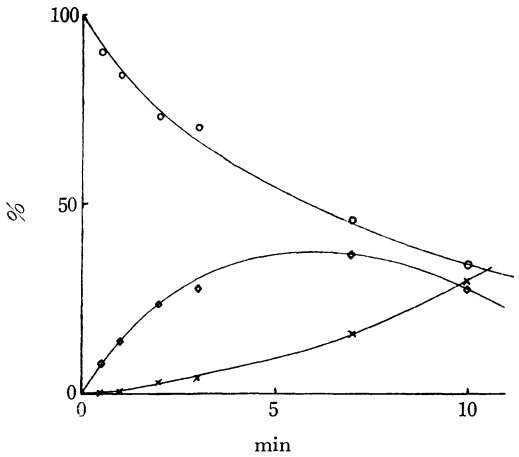

Fig. 1. Pyrolysis of 1-acetyl-3-methylenecyclobutane.
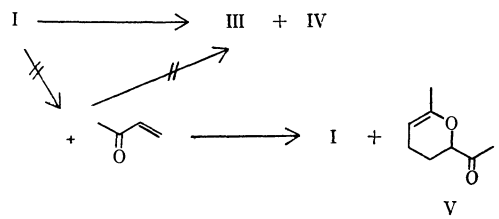
○—○ 1-Acetyl-3-methylenecyclobutane
◇—◇ 2-Methyl-5-methylene-Δ^2-dihydropyrane
×—× 4-Methylenecyclohexanone

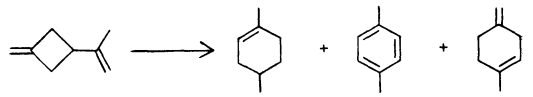
Neither allene nor methyl vinyl ketone, which is the expected fragmentation product of I, was found to be formed by the pyrolysis of I. However, it may be reasonable to assume that the observed product, III, was formed by the cycloaddition reaction of the fragmentation products. To check on this possibility, a mixture of allene and methyl vinyl ketone was heated to 220°C for two hours in an autoclave. A resinous product resulted, and from it a small amount of a distillable component could be isolated. The distillate consisted of I (1 part) and a compound (20 parts) tentatively thought to be 2-methyl-6-acetyl-Δ^2-dihydropyrane (V), a dimer of methyl vinyl ketone but neither III nor IV could be detected. This must mean that the pyrolysis of I does not proceed through the fragmentation-recombination pathway considered earlier.



V

The assignment of structure V to the addition product follows from the NMR spectrum, which showed a three-proton doublet (J=1.5 Hz) and a three-proton singlet at τ 8.25 and 7.75 for the two methyl groups, a four-proton broad multiplet centered at τ 8.10 for the ring methylene protons, a one-proton multiplet at τ 5.87 for the proton between the acetyl group and the oxygen atom, and a one-proton multiplet at τ 5.55 for the proton on the double bond. Its infrared spectrum, showing bands of an acetyl group at 1720 and 1360 cm^{-1}, and bands of a vinyl ether at 1238 and 1070 cm^{-1}, is consistent with the indicated structure.

Pyrolysis of 1-Isopropenyl-3-methylenecyclobutane. The pyrolysis of 1-isopropenyl-3-methylenecyclobutane (II) as a neat liquid or as a toluene solution, at 255—340°C and in a sealed tube, gave 1,4-dimethylcyclohexene (VI),[10] *p*-xylene (VII), and 1-methyl-4-methylenecyclohexene (VIII).



II VI VII VIII

The NMR spectrum of VIII had a three-proton singlet (with fine splittings) at τ 8.38 for the methyl group on the double bond, two overlapping two-proton multiplets at τ 7.90 and 7.78 for the two methylene groups adjacent to a double bond, a two-proton multiplet at τ 7.35 for the methylene group between the two double bonds, a slightly-broadened two-proton singlet at τ 5.38 for the terminal methylene group, and a one-proton multiplet at τ 4.75 for the hydrogen atom on the double bond. Its infrared spectrum exhibited bands of a terminal methylene group and an olefinic group at 3075, 1655, 1445, 1435, and 884 cm^{-1}. Conclusive evidence for the structure assignment could be obtained by an independent synthesis of VIII by the route to be described below.

1-Methylcyclohexene-4-carboxylic acid (IX)[11]

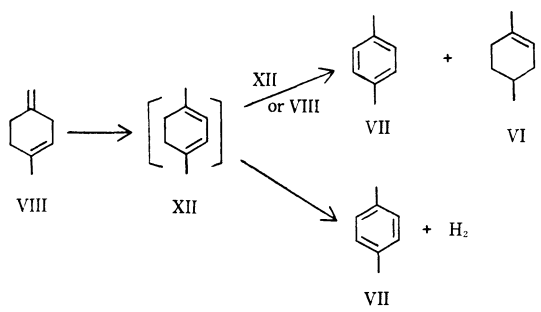
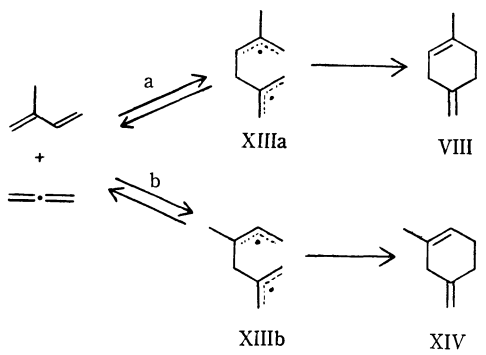
11) E. Lehmann and W. Paasche, *Ber.*, **68**, 1068 (1935).

was converted to the corresponding dimethylamide, X, through its acid chloride. The amide X was then reduced with lithium aluminum hydride to 1-methyl-(4-dimethylaminomethyl)cyclohexene (XI), which was subsequently converted to the corresponding *N*-oxide with hydrogen peroxide. The pyrolysis of the *N*-oxide afforded 1-methyl-4-methylenecyclohexene (VIII), which proved identical with the sample obtained by the pyrolysis of II.

When 1-methyl-4-methylenecyclohexene (VIII) was heated at 340°C in a sealed tube, three new products were formed in a vpc peak area ratio of 3:1:10, of which the two major products were identified as 1,4-dimethylcyclohexene (VI) (3 parts) and *p*-xylene (10 parts) respectively by comparison with authentic samples. Such a conversion of VIII may be considered to proceed through an initial isomerization to 1,4-dimethylcyclohexa-1,3-diene (XII) and its intermolecular hydrogen transfer and, in part, dehydrogenation.[12]



It was observed that no fragmentation product, allene or isoprene, was formed by the pyrolysis of II. In this case, the possibility of the fragmentation of II and recombination to VIII should also be considered. If the addition of allene and isoprene proceeds by a stepwise radical mechanism, then the reaction may be expected to proceed through pathway b to give a slightly more stabilized biradical intermediate, XIIIb, than the biradical XIIIa.



12) A similar disproportionation reaction has recently been reported with cyclohexa-1,3-diene: S. W. Benson and R. Shaw, *J. Amer. Chem. Soc.*, **89**, 5351 (1967).

The reaction of allene and isoprene at 300°C in an autoclave afforded, besides a large quantity of unreacted starting materials and polymeric substances, a small quantity of distillable products, which consisted of five components in a ratio of 7.5:4:8:1:1.5 (in the increasing order of their retention times). The vpc retention times of none of these components corresponded to *p*-xylene. The vpc retention time of the component with the shortest retention time was identical with that of VIII, and its infrared and NMR spectra were very similar to those of VIII except that the multiplet at τ 7.78 of VIII was shifted to a slightly higher magnetic field to give a poorly-resolved four-proton multiplet centered at τ 7.85. When it was subjected to the same pyrolysis conditions as those for VIII described earlier, it was converted to two products in a ratio of 1:1.3, though much more sluggishly than VIII. This isomerization could be effectively accelerated by the addition of a catalytic amount of alumina. The major product of the isomerization was identified as *m*-xylene by comparison with an authentic sample. From the above experiment, it may now be concluded that allene and isoprene react regiospecifically to give 1-methyl-5-methylenecyclohexene (XIV). This fact, as well as the absence of XIII and *m*-xylene in the pyrolysis products of II, gives conclusive evidence that no fragmentation occurred in the pyrolysis of 1-isopropenyl-3-methylenecyclobutane (II).

Interpretation of the Results. An arresting feature of the pyrolyses of I and II described above is that no fragmentation products could thus be detected. The pyrolysis of acetylcyclobutane gives ethylene and methyl vinyl ketone,[13] while the pyrolysis of isopropenylcyclobutane gives ethylene, isoprene, and 1-methylcyclohexene.[14] The activation energies of these reactions (54.5 kcal/mol and 51.0 kcal/mol respectively) clearly demonstrate the contribution of allylic resonance at the ring-cleavage step.

For steric reasons, the ring-enlargement reaction of II cannot proceed concertedly through a transition state similar to that of the Cope rearrangement,[15] to which it bears a formal analogy, nor can it be regarded as a concerted sigmatropic rearrangement.[16] The same holds true of the ring-enlargement reaction of I. Thus, it appears most reasonable to assume that the reaction proceeds by a stepwise biradical mechanism. The seem-

ingly anomalous rearrangements of I and II can, then, readily be explained on the basis of the results of the degenerate rearrangement of methylenecyclobutane, elegantly studied by Doering and Gilbert.[8]

The pyrolysis of II (or I) gives a biradical intermediate, XIIIc, in which a full delocalization of the two radical sites have been attained (Chart 1). The biradical XIIIc may regenerate II (or I) *via* a transition state, XIIId, in which one allylic delocalization is completely, and the other, partially, retained,[17] but in order for the biradical XIIIc to give fragmentation products, one of the allylic stabilizations have to be nearly completely lost at the transition state XIIIe, since the two planes occupied by the two H–C–H groups in the allyl group should be almost perpendicular to each other.

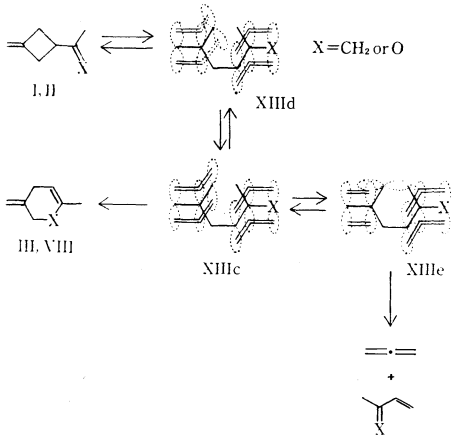

Chart 1. Pyrolytic path of 1-acetyl- and 1-isopropenyl-3-methylenecyclobutane.

Thus, the energetically most preferred path for the biradical XIIIc is ring enlargement, because, in this case, the biradical XIIIc can give a ring-enlargement product simply by rotation about a single bond, which can rotate freely with virtually no loss of stabilization energy.

In the cases of 1-acetyl- and 1-isopropenylcyclobutane, there is no such conformational preference of the biradical intermediates to warrant one of the two reaction paths (ring enlargement *vs.* fragmentation), and in the case of methylenecyclobutane, only a recombination to the starting material or fragmentation is possible.

17) It has been established that the ring-opening of (and thus recombination to) methylenecyclobutane is markedly assisted by allylic delocalization. For further discussion on the transition states and intermediates of this system, see Ref. 8.

Experimental[18]

1-Acetyl-3-methylenecyclobutane (I). A solution of 20 g (0.26 mol) of 3-methylenecyclobutanecarbonitrile[9] in 30 m*l* of ether was added, with cooling and stirring, to a solution of methymagnesium iodide, prepared from 8.7 g (0.36 g atom) of magnesium and 51.1 g (0.36 mol) of methyl iodide, in 50 m*l* of ether. The mixture was stirred for three hours at room temperature and was then hydrolyzed by the addition of dilute sulfuric acid; the organic layer was separated, and the aqueous layer was extracted repeatedly with ether. The ether extract was washed with aqueous sodium bicarbonate and then with water, and dried over sodium sulfate. Distillation gave 16.3 g (60% yield) of I boiling at 53—54°C/14 mmHg. n_D^{25} 1.4543.

Found: C, 76.45; H, 9.15%. Calcd for $C_7H_{10}O$: C, 76.32; H, 9.15%.

Semicarbazone of I: mp 146—148°C.

Found: C, 57.33; H, 7.81%. Calcd for $C_8H_{13}N_3O$: C, 57.46; H, 7.84%.

2,4-Dinitrophenylhydrazone of I: mp 142—143°C.

Found: C, 53.86; H, 5.10; N, 19.54%. Calcd for $C_{13}H_{14}N_4O_4$: C, 53.79; H, 4.86; N, 19.30%.

1-Isopropenyl-3-methylenecyclobutane (II). A solution of 8 g (0.07 mol) of 1-acetyl-3-methylenecyclobutane in 20 m*l* of ether was added, under an atmosphere of nitrogen and with cooling and stirring, to a solution of methylenetriphenylphosphorane in 300 m*l* of ether, prepared *in situ* from 35.7 g (0.1 mol) of triphenylmethylphosphonium bromide and *n*-butyllithium, and the resulting mixture was refluxed for ten hours. The precipitate was then filtered off, and the filtrate was dried over calcium chloride. The fraction distilling between 80—130°C and consisting of II and benzene was collected and subsequently purified by vpc (Carbowax 20M on Diasolid A). Bp 98—100°C, n_D^{25} 1.4531.

Found: C, 88.64; H, 10.44%. Calcd for C_8H_{12}: C, 88.82; H, 11.18%.[19]

Thermal Rearrangement of I. Samples of I (10—100 μl) were sealed in Pyrex tubes under an atmosphere of nitrogen, and were placed in an atmosphere of refluxing acetanilide (bp 304°C) or anthracene (bp 340°C) for periods of time, and then quenched by immersion in an ice bath. Vpc analysis showed the presence of three components, which were fractionated by vpc (Carbowax 20M on Diazolid A) to afford I, 2-methyl-5-methylene-Δ^2-dihydropyrane (III), and 4-methylenecyclohexanone (IV).

18) The melting points were determined on a micro hot stage, and all melting and boiling points are not corrected. The infrared spectra were recorded on a Hitachi model EPI-SII spectrophotmeter as neat liquid. The NMR spectra were determined using a Jeolco C-60 model (60MHz) spectrometer on solutions of carbon tetrachloride and the chemical shifts are represented by τ values. The vpc analyses were performed with a Shimadzu model GC-1B chromatograph. The spectral data discussed in the text are not reproduced in this section.

19) Some compounds, especially low boiling liquid, did not give satisfactory analytical values although they were proved homogeneous by vpc, and showed quite satisfactory spectra.

Samples of I containing 20% of toluene as an internal standard were heated at the refluxing temperature (340°C) of anthracene, and the concentration of the components, I, III, and IV, as evaluated by the ratio of their vpc peak areas to those of toluene, were plotted against the time. The results are shown in Fig. 1.

Reaction of Allene and Methyl Vinyl Ketone. A solution of 5 g (0.07 mol) of methyl vinyl ketone, 5 m*l* (*ca.* 0.08 mol) of allene, and 0.5 g of hydroquinone in 50 m*l* of toluene was heated at 220°C for two hours in a 100-m*l* autoclave under autogeneous pressure (20 atm). The reddish-brown product was concentrated and distilled under reduced pressure to give 0.9 g of a colorless liquid boiling at 88—90°C/50 mmHg. The residue of the distillation consisted of a large amount of a polymeric material. The distillate was separated into two components (A and B) in a ratio of 1 : 20 (Carbowax 20M on Diasolid A).

Component A had the same infrared spectrum and vpc retention time as those of an authentic sample of I.

The spectral data of component B are given in the text above.

Thermal Rearrangement of II. Samples of II were heated as has been described above at the refluxing temperature of biphenyl (bp 255°C), acetanilide or anthracene, and the product mixture was separated by vpc (Silicone DC 550 on Shimalite) giving II, *p*-xylene, 1-methyl-4-methylenecyclohexene (VIII), and a component with identical vpc retention times with those of an authentic sample of 1,4-dimethylcyclohexene (VI).[10] The infrared spectra and the vpc retention times of VIII and *p*-xylene were identical with those of authentic samples of VIII and *p*-xylene respectively.

1-Methylcyclohexene-4-carbodimethylamide (X). Into an ice-cooled, saturated solution of dimethylamine in 100 m*l* of ether, there was added with stirring, 31.7 g (0.2 mol) of 1-methylcyclohexene-4-carbonyl chloride,[11] and the resulting mixture was allowed to stand overnight at room temperature. The mixture was washed with water and then with a saturated aqueous solution of sodium chloride, and was dried over magnesium sulfate. Distillation afforded 24 g (72% yield) of X boiling at 147—153°C/23 mmHg.

Found: C, 71.70; H, 10.31; N, 8.57%. Calcd for $C_{10}H_{17}NO$: C, 71.81; H, 10.25; N, 8.38%.

1-Methyl-4-dimethylaminomethylcyclohexene (XI). Into a suspension of 5 g (0.14 mol) of lithium aluminum hydride in 100 m*l* of ether, 19 g (0.11 mol) of 1-methylcyclohexene-4-carbodimethylamide (X) was slowly added with stirring, after which the mixture was stirred for another three hours at room temperature. The excess hydride was decomposed by the addition of 5% aqueous sodium hydroxide, and the organic layer was separated, washed with aqueous sodium chloride, and dried over sodium sulfate. Distillation gave 14.2 g (80% yield) of 1-methyl-4-dimethylaminomethylcyclohexene boiling at 74—76°C/11 mmHg, n_D^{25} 1.4628.

This product was characterized by conversion to its methiodide; mp 209—210°C.

Found: C, 45.03; H, 7.58; N, 4.99%. Calcd for $C_{11}H_{22}NI$: C, 44.76; H, 7.51; N, 4.74%.

1-Methyl-4-dimethylaminomethylcyclohexene *N*-Oxide. Compound XI (10 g, 0.034 mol) was slowly added to a stirred and cooled solution of 50 m*l* of 10% aqueous hydrogen peroxide. The mixture was then stirred at room temperature for twenty hours, and the excess peroxide was decomposed by catalase. The mixture was subsequently filtered, and the water was removed under reduced pressure, and the yellow, viscous residue which remained was used for the pyrolysis reaction without further purification.

1-Methyl-4-methylenecyclohexene (VIII). The crude *N*-oxide prepared by the above-described method was decomposed at 200°C on an oil bath under reduced pressure; the distillate was collected in a trap which was cooled by a Dry Ice-acetone bath. The condensate was dissolved in 40 m*l* of ether, washed successively with dilute hydrochloric acid, water, and a saturated aqueous solution of sodium chloride, and dried over sodium sulfate. Distillation gave 2.5 g of VIII boiling at 113—114°C. The infrared spectrum and the vpc retention times of this material were identical with those of the sample of VIII isolated from the pyrolysis of II, n_D^{25} 1.4690.

Found: C, 87.97; H, 10.87%. Calcd for C_8H_{12}: C, 88.82; H, 11.18%.[19]

Thermal Rearrangement of 1-Methyl-4-methylenecyclohexene (VIII). Compound VIII (100 μl) was sealed in a Pyrex tube under an atmosphere of nitrogen and heated at 340°C for seven minutes. The product consisted of three components in a vpc peak area ratio of 3 : 1 : 10, of which the two major components (C and D) were collected by vpc (Carbowax 20M on Diasolid A).

Component C had the same infrared spectrum and vpc retention times as those of an authentic sample of 1,4-dimethylcyclohexene (VI).[10]

Component D had the same NMR and infrared spectra and vpc retention times as those of *p*-xylene.

The Reaction of Allene and Isoprene. A mixture of 5 g (0.07 mol) of isoprene, 5 m*l* (*ca.* 0.08 mol) of allene, 0.5 g of hydroquinone, and 50 m*l* of *n*-hexane was slowly heated to 300°C for seven hours in an autoclave and under autogeneous pressure (maximum, 50 atm). The product was distilled to give 1.5 g of a product boiling at 78—80°C/40 mmHg. Considerable amounts of allene and isoprene were recovered, and a transparent polymeric material was formed on the wall of the autoclave. The distillate consisted of five components in a vpc peak area ratio of 7.5 : 4 : 8 : 1 : 1.5 (Carbowax 20M on Diasolid A), none of which had the same vpc retention time as that of *p*-xylene. The first three major components (E, F, G) were collected by vpc.

Component E (1-Methyl-5-methylenecyclohexene, XIV): NMR: 8.35 (3H, s), 7.85 (4H, m), 7.38 (2H, m), 5.34 (2H, s) and 4.75 (1H, m). IR: 3075, 1660, 1445, 1440 and 885 cm^{-1}. Its vpc retention times (Carbowax 20M and Silicone DC 550) were identical with those of 1-methyl-4-methylenecyclohexene (VIII).

Component F was found to be a mixture of 1,4-dimethyl-4-vinylcyclohexene and 2,4-dimethyl-4-vinylcyclohexene by comparison of its NMR and infrared spectra with the reported values.[20]

Component G was identified as 1-methyl-5-isopropenylcyclohexene by comparison of its infrared spectrum with a previously reported chart.[21] NMR: 8.39 (3H, s), 8.29 (3H, s), 8.08 (7H, m), 5.35 (2H, s)

and 4.68 (1H, m).

Thermal Rearrangement of 1-Methyl-5-methylenecyclohexene (XIV). Compound XIV was sealed, under an atmosphere of nitrogen, in a Pyrex tube in the presence of a small amount of alumina, and then heated at 540°C for one hour. The product consisted of two components in a vpc area ratio of 1 : 1.3; the latter, major component was collected by vpc (Carbowax 20M on Diasolid A) and identified as *m*-xylene by a comparison of its NMR and infrared spectra and vpc retention times.

We are indebted to Miss Mizuko Yoshida for the measurement of NMR spectra, to the staffs of microanalysis in this laboratory for the elemental analyses, and to Takeda Chemical Industries, Ltd, for the measurement of mass spectra.

and Keikichi Uno and Yoshio Iwakura

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received November 5, 1969)

It has been found that, when the polymerization of NCA is initiated with *n*-butylamine in acetonitrile, the amino end group in the polymer produced which is insoluble in the solvent is active (Y. Iwakura, K. Uno and M. Oya, *J. Polym. Sci., Part A-1*, **8**, 2165 (1968)). The amino end group in the polymer isolated without drying could initiate the polymerization of NCA in acetonitrile. By using this characteristic of the polymer, block copolypeptides consisting of various kinds of α-amino acid and of various chain lengths were synthesized. The solubility of the block copolypeptides in a solvent was different from that of the random copolypeptides obtained by the usual copolymerization of a mixture of NCA in acetonitrile. Sometimes the infrared spectra of the block copolypeptides were different from those of the random copolypeptides.

A block copolypeptide has been synthesized by polymerizing α-amino acid *N*-carboxy anhydride, with a soluble, low-molecular weight polypeptide, *i.e.*, polysarcosine dimethylamide, poly-γ-benzyl-L-glutamate, or poly-DL-lysine, as the initiator.[1-3] Because an insoluble polypeptide in an inert solvent for NCA's, *i.e.*, polyglycine and poly-L-alanine, could not initiate the polymerization of NCA, it has generally been considered that a block copolypeptide consisting of insoluble polypeptides would be difficult to synthesize. Therefore, the kind of block copolypeptides would be limited when this method was used.

It has been considered that the polymerization of NCA's initiated with primary amine in dioxane and tetrahydrofuran proceeds by both route by nucleophilic attack and by proton abstraction from the nitrogen of the NCA's.[4] When the polymerization is initiated with the amino end group of polypeptide by proton abstraction from 3N on NCA, a block copolypeptide containing the initiator polymer would not be produced. Further, it is very difficult to synthesize block copolypeptides consisting of three kinds of α-amino acids.

When the polymerization of NCA was carried out in acetonitrile, with *n*-butylamine as an initiator, we found that the polymer formed existed in the precipitation state that the initiator was consumed completely in the earlier stage of the polymeriza-

tion, that further propagation was performed by the attack of the amino end group of the precipitated polymer on the C-5 carbonyl carbon of NCA in acetonitrile, with almost no termination, and that the degree of polymerization increased with an increase in the reaction period in the precipitation state.[1] These case, it was found that the amino end group of the polymer was active in the precipitation state in acetonitrile. Such a consideration indicated the possibility of preparing various kinds of block copolypeptides which are insoluble in an inert solvent for NCA's.

In this paper the preparation of block copolypeptides containing an insoluble polypeptide in an inert solvent for NCA's and more than two kinds of α-amino acid will be described.

Results

The polypeptide obtained by the polymerization of the first α-amino acid NCA with *n*-butylamine in acetonitrile was isolated by filtration and washed well with absolute acetonitrile in order to remove any residual NCA. The isolated polypeptide was without drying put into a second NCA solution in acetonitrile. The polymerization was initiated by the attack of the amino end group of the first polymer on the C-5 carbonyl of the second NCA; a block copolypeptide consisting of two kinds of α-amino acid was thus produced. This block copolypeptide was isolated again by filtration, washed well with absolute acetonitrile, and put into a third NCA solution in acetonitrile. Block copolypeptides consisting of three kinds of α-amino acid were thus produced. The polypeptides obtained at the first or second step became inactive upon drying. The polypeptides obtained were extracted in solvents consisting of homopolypeptides in order to remove any coexisting homopolymer. As the polymerization was carried out in a heterogeneous system, there was no need to use the first polypeptide (initiator polymer) which is soluble in the polymerization solvent, acetonitrile. Any α-amino acid NCA could be used for this synthesis.

The average sequence length of each component in the block copolypeptides could be controlled by changing the polymerization period, the temperature and the monomer concentration for each step.

By this method, various kinds of block copolypeptides were synthesized. The block copolypeptides thus obtained are shown in Tables 1 and 2. The solubility of the block copolypeptides obtained was different in several solvents compared with those of the homopolypeptides consisting of the α-amino acids in the block copolypeptides. For example, the block copolypeptide consisting of L-leucine and DL-alanine (B-1) was soluble in formic acid in spite of the insolubility of poly-L-leucine in this solvent. However, the solubility of the block copolypeptide was essentially dependent on the sequence length of each component. Copolypeptide (B-2), which was constructed of a chain of L-leucine rather longer than that of B-1, became insoluble in formic acid and was still insoluble in hot benzene. The solubility of the block copolypeptide was different from that of the corresponding random copolypeptide obtained by the polymerization of the mixture of two or three kinds of NCA's. For example, the B-2 block copolypeptide in Table 1 was insoluble in dichloroacetic acid, while the corresponding random copolypeptide, R-1, was soluble in dichloroacetic acid and highly swelled in ether. Moreover, the solubility of the B-4 and B-5 block copolypeptides is different from that of the corresponding random copolypeptides, R-2 and R-3

copolypeptides were clearly different from those of the random copolypeptide with the same components. For example, the spectra of the block copolypeptide consisting of L-alanine (68 mol%) and glycine (32 mol%) showed the spectra of both poly-L-alanine and polyglycine (an absorption at

1305 cm^{-1} which is characteristic of the α-helix of poly-L-alanine), but it was different from that of the random copolypeptide with the same component no absorption appeared at 1305 cm^{-1} (Fig. 3).

Experimental

The NCA's used in this study were prepared in a high degree of purity by methods reported previously.[5]

Synthesis of Block Copolypeptides. (L-Leu)$_m$-(DL-Ala)$_n$: First, L-leucine NCA (0.5 g) was polymerized in acetonitrile (10 m*l*), using 1.0 mol% of *n*-butylamine (to NCA) as the catalyst, for 1.7 hr at 30°C. The polymer precipitated thus was isolated by filtration and washed with absolute acetonitrile. The polymer isolated without drying was added to 10 m*l* of a DL-alanine NCA solution in acetonitrile (0.05 g/m*l*), after which the mixture was kept standing for 120 hr at 30°C. The polymer thus formed was washed with hot benzene in order to remove the coexisting homopolymer. The B-1 block copolymer (0.384 g) was thus obtained. When the polymerization was stopped at the first step, the specific viscosity ($\eta_{sp/c}$) of the poly-L-leucine obtained was 0.20 (in TFA), and its yield was 0.048 g.

The first and second steps of the polymerization described above lengthed 18 and 120 hr respectively, and the polymer isolated was washed with formic acid and hot benzene. A block copolymer (B-2) (0.376 g) was thus obtained. When the polymerization was stopped at the first step, the $\eta_{sp/c}$ value of the poly-L-leucine obtained was 0.68, and its yield was 0.20 g.

(γ-Me-L-Glu)$_m$-(DL-Ala)$_n$: First, γ-methyl-L-glutamate NCA (0.5 g) was polymerized in acetonitrile (10 m*l*), with 1.0 mol% of *n*-butylamine as catalyst, for 57 hr at 30°C. The polymer thus precipitated was isolated by filtration and washed well with absolute acetonitrile. The polymer isolated without drying was added to 20 m*l* of a DL-alanine NCA solution in acetonitrile (0.025 g/m*l*), and the mixture was left to stand for 207 hr at 30°C. The polymer thus obtained was washed with hot chloroform and formic acid to remove the homopolymers. The B-3 copolymer (0.294 g) was thus obtained. When the polymerization was stopped at the first step, the $\eta_{sp/c}$ value of the poly-γ-methyl-L-glutamate obtained was 0.46 g, and its yield was 0.205 g.

Under the polymerization conditions described above, the concentration of the γ-methyl-L-glutamate NCA was reduced to 0.45 g/10 m*l*, the other conditions were the same as those described above. The B-4 polymer (0.129 g) was thus produced. When the polymerization was stopped at the first step, $\eta_{sp/c}$ value of the poly-γ-methyl-L-glutamate obtained was 0.44, and its yield was 0.189 g.

(L-Ala)$_m$-(Gly)$_n$: L-Alanine NCA (0.65 g) was polymerized in acetonitrile (13 m*l*), with 0.5 mol% of *n*-butylamine as an initiator, for 1.7 hr at 30°C. The polymer isolated without drying was added to 10 m*l* of a glycine NCA solution (0.044 g/m*l*) after which the mixture was kept standing for 12 hr at 30°C. The B-5 polymer (0.207 g) was thus obtained. In this case, the $\eta_{sp/c}$ value of the poly-L-alanine obtained at the first step was 0.45 (in TFA).

(γ-Bz-L-Glu)$_k$-(DL-Ala)$_m$-(Gly)$_n$: γ-Benzyl-L-glutamate NCA (0.5 g) was polymerized in acetonitrile (10 m*l*), with 1.0 mol% of *n*-butylamine as an initiator, for 4 hr at 20°C. The polymer thus precipitated was isolated by filtration and washed well with absolute acetonitrile. The polymer isolated without drying was added to 10 m*l* of a DL-alanine NCA solution in acetonitrile (0.05 g/m*l*), after which the mixture was kept standing for 16 hr at 20°C. The copolymer was isolated by filtration and washed sufficiently with absolute acetonitrile, and then the copolymer was again added to 10 m*l* of a glycine NCA solution in acetonitrile (0.05 g/m*l*) and the resulting mixture was kept for 23 hr at 20°C. The polymer thus isolated was washed with hot dichloroethane and formic acid to remove the homopolymer. The B-6 block copolymer (0.15 g) was thus produced. When the polymerization was stopped at the first or second step, the specific viscosities of the polymers thus obtained were 0.107 and 0.243, and their yields were 0.045 g and 0.088 g respectively.

(γ-Bz-L-Glu)$_k$-(L-Leu)$_m$-(Gly)$_n$: The first step of the polymerization was carried out under the same conditions as were used for B-6, while the second and third steps of the polymerization were carried out by using 10 m*l* of an L-leucine NCA solution in acetonitrile (0.05 g/m*l*) for 18 hr at 20°C, and by using 10 m*l* of a glycine NCA solution (0.05 g/m*l*) for 23 hr at 20°C respectively. The B-7 copolypeptide (0.118 g) was thus obtained. The polymer obtained in the second step of the polymerization had a specific viscosity of 0.118.

(L-Ala)$_k$-(γ-Bz-L-Glu)$_m$-(L-Leu)$_n$: The first, second, and third steps of the polymerization were carried out by using 10 m*l* of an L-alanine NCA solution in acetonitrile (0.05 g/m*l*) for 3 hr at 20°C, 10 m*l* of a γ-benzyl-L-glutamate NCA solution (0.05 g/m*l*) for 10 hr at 20°C, and 10 m*l* of an L-luecine solution (0.05 g/m*l*) for 10 hr at 20°C, respectively. The copolypeptide was washed with hot dichloroethane and hot benzene. The B-8 block copolypeptide (0.185 g) was thus obtained. The specific viscosities of the polymer obtained at first and second steps were 0.69 (in TFA) and 0.83 (in TFA) respectively.

Analysis of Copolypeptides. The compositions of the copolypeptides were determined by the analysis of the nitrogen in the polymer: the results are presented in Tables 1 and 2.

Further, paper-chromatographic analysis for the hydrolyzate of these copolymers with hydrochloric acid gave two or three spots for the corresponding α-amino acids in the copolymers.

The viscosity of the polymer was measured at a concentration of 0.25 g/100 m*l* in trifluoroacetic acid (no mark or TFA) or dichloroacetic acid (DCA), using an Ostwald viscometer and at 25°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1792—1795 (1970)

Asymmetric Hydrogenation of C=N Double Bond with Modified Raney Nickel 1.*1 New Determination Method for the Reaction Mechanism Using Asymmetric Catalyst

Yoshiharu IZUMI, Hidemitsu TAKIZAWA,*2 Kunio NAKAGAWA,*3 Ryushichi IMAMURA,*4 Masami IMAIDA,*5 Toshio NINOMIYA and Shinichi YAJIMA*2

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received November 8, 1969)

The hydrogenation process of ethyl 2-acetoximinopropionate was investigated by means of a novel technique using asymmetric hydrogenation with an asymmetrically modified R–Ni catalyst. It was found that the hydrogenation of ethyl 2-acetoximinopropionate to ethyl alaninate proceeded in two steps through ethyl acetoxyalaninate, and that the asymmetric hydrogenation was performed in the step of the formation of ethyl acetoxyalaninate from ethyl 2-acetoximinopropionate. Besides, the asymmetric reductive amination of ethyl pyruvate was tested with an asymmetrically modified R–Ni catalyst.

The most impressive characteristics of the enzyme reactions are their high catalytic reactivities and their substrate- and stereo-specificities. The catalytic reactivities of the enzyme are promoted by the extreme approach of the reacting molecules to the enzyme, due to the binding of the reacting molecule with the active site of the enzyme. The substrate- and stereo-specificities are performed by the steric interaction between the protein molecule surrounding the active site and the substrate molecule. In the earlier works on catalytic asymmetric hydrogenation done by our research group, silk-palladium was used as the asymmetric catalyst; it had been prepared by the dispersion of palladium metal on silk fibroin.[1] It was expected in the investigation of the silk-palladium catalyst that the palladium and the silk fibroin molecule would act as the active site and the protein molecule surrounding the active site of the enzyme respectively. After the fundamental investigation of the silk-noble metal-type catalyst, we intended to substitute the metal catalyst surface for the active site and most of the protein molecule, which takes part in hardening the environment around the active site of the enzyme, and to give the substrate-specificity and the stereospecific environment to the catalyst by means of the adsorption of the optically active molecule on the catalyst surface.

On the basis of the fundamental considerations mentioned above, the asymmetrically-modified Raney nickel (R–Ni) catalyst was prepared by the treatment of R–Ni catalyst with an aqueous solution of the optically active α-amino or α-hydroxy acid, or other compounds. On the surface of the R–Ni catalyst, the reacting molecules, active hydrogen and the substrate, are placed in close contact, as in the enzyme reaction. As, according to the established theory, the hydrogen attacks the double bond to form a *cis*-addition product, the catalyst modified with an optically active compound would have an asymmetric hydrogenation ability if the catalyst surface could control the adsorption style of the substrate molecule. That is, the asymmetric site of the modified R–Ni catalyst would act as the protein molecule surrounding the active site of the enzyme.

The fundamental investigation of the asymmetric hydrogenation of the C=O double bond with a modified R–Ni catalyst, using methyl acetoacetate as the substrate, has been previously reported in a series of reports by our research group.[2] The experimental rules of the relation between the asymmetric hydrogenation activity of the modified R–Ni catalyst for methyl acetoacetate and the structure of the modifying reagent have been made clear.

The asymmetric hydrogenation of the C=N double bond is very useful and important in the syntheses

of the natural products, especially in the syntheses of amino acids and alkaloids. To date, however, only three reports on the asymmetric hydrogenation of the C=N double bond in the presence of an asymmetric catalyst have been published.[1,3,4] The first success was accomplished by our research group using the silk-palladium catalyst on the hydrogenation of ethyl 2-acetoximino-3-phenylpropionate, benzil dioxime, and diethyl 2-acetoiminoglutarate.[1] Subsequently, Isoda *et al.* performed the asymmetric hydrogenation of diethyl 2-oximinoglutarate and 2-acetoiminoglutaric acid with a palladium catalyst and a R–Ni catalyst which had been treated with optically-active amino acids.[3] Recently, acetophenone oxime was asymmetrically hydrogenated with a modified R–Ni catalyst by Petrov *et al.*[4] However, no systematic investigation of the asymmetric hydrogenation of the C=N double bond has been done, in spite of its scientific and economical importance.

New efforts to obtain an effective asymmetric hydrogenation catalyst, one which has an asymmetric hydrogenation activity for the C=N double bond to the optically-active amine, have been made by the present authors. The present paper will deal with our preliminary and basic research into the asymmetric hydrogenation of the C=N double bond.

Acetoximino compounds may be suitable as a substrate for the asymmetric hydrogenation of the C=N double bond. However, three hydrogenation route for acetoximino compounds to amino compounds can be expected when two moles of hydrogen are taken up in two steps during the hydrogenation. The supposed hydrogenation routes of ethyl 2-acetoximinopropionate (I) are shown schematically in Fig. 1. Ethyl alaninate (IV) can be obtained through three pathways; I-II-IV, I-III-IV, and I-II-III-IV; the A and D processes give a chance of asymmetric hydrogenation. Consequently, for the investigation of asymmetric hydrogenation, it is very important to elucidate the main route of the hydrogenation.

An asymmetrically-modified R–Ni catalyst was used in the present work in order to elucidate the reaction path of the hydrogenation of I; this is a novel technique for the investigation of the reaction mechanism. The authors proved that I-II-IV is the main route of the hydrogenation of an acetoximino compound and that the asymmetric hydrogenation occurs in the A process.

Independently of the investigation described above, the asymmetric reductive amination of ethyl pyruvate was performed.

Results and Discussion

Hydrogenation of Ethyl 2-Acetoiminopropionate (I). The hydrogenation of I was performed in alcohol and in ethyl acetate; the results are shown in Fig. 2. Depending on the solvent used for the hydrogenation, different hydrogenation products were obtained.

In methanol, ethyl alaninate (IV) was obtained by the hydrogenation with a hydrogen uptake of two moles. On the other hand, in ethyl acetate I took up only one mole hydrogen to give ethyl acetoxyalaninate (II), and at this point the hydrogen uptake was over; II was identified by elemental analysis and by gas chromatography.

The results of the gas chromatography of the hydrogenation products in methanol are shown in Fig. 3. Figure 3-a and 3-b show the analytical results for the partial hydrogenation products,

which were obtained at 28, 64, and 98% of the theoretical value of the hydrogen uptake.

From the findings that the ratio of II to IV decreases with the increase in the hydrogen uptake, it is clear that II occupies the intermediate position in the hydrogenation of I to IV in methanol.

Asymmetric Hydrogenation of I. The optically-active II and IV were, respectively, obtained by the hydrogenation of I in alcohol and in a nonpolar solvent in the presence of a R–Ni catalyst modified with optically-active histidine, as is shown in Table 1. The asymmetric direction of the product depends on the absolute configuration of the histidine used as a modifying reagent. That is, the catalyst modified with D-histidine gave (−)-II or ethyl (−)-acetylalaninate ((−)-V),*2,*3) and that modified with L-histidine gave (+)-II or (+)-V, while that, with DL-histidine gave (±)-II or (±)-V.

Hydrogenation of II. As is shown in Table 2, the optical purity of the hydrogenation product depends only on the optical purity of the substrate, II, and not on the absolute configuration of the modifying reagent; that is, II with $[\alpha]_D^{20}=-0.25$ gave V with $[\alpha]_{20}^{D}=-0.25$ upon hydrogenation in the presence of a R–Ni catalyst modified with L-histidine, D-histidine, or DL-histidine and upon N-acetylation with acetic anhydride. From these results, it is clear that the asymmetric hydrogenation does not occur in this process and that the hydrogenation of II to IV does not proceed through ethyl 2-imino-propionate (III).

As is shown in Table 2, by the hydrogenation of (−)-II with the catalyst modified with L-, D-, or DL-histidine, L-IV, which gives (−)-V, was obtained. Since this reaction proceeds with a retention of the configuration of II, (−)-II can be said to have an L-configuration.

8	DL-His	$CH_3COOC_2H_5$	Ethyl acetoxyalaninate	±0.00	63
9	L-His	$C_2H_5OC_2H_5$	Ethyl acetoxyalaninate	+0.25	46

* Ethyl alaninate, the hydrogenation product, was acetylated for the measurement of the optical rotation.
** Measured without dilution.

*2 The hydrogenation product is ethyl alaninate, and its optically rotatory power was measured after the acetylation.

*3 Ethyl (−)-acetylalaninate has an L-configuration.

Table 3. Reductive amination of ethyl pyruvate

Modifying reagent	Solvent	Product	$[\alpha]_D^{20}$ of V	Yield (%)
L-His	Ammonia-methanol	Ethyl acetyl-alaninate (V)*	+0.09	21

* Ethyl alaninate, the hydrogenation product, was acetylated for the measurement of the optical rotation.

Asymmetric Reductive Amination of Ethyl Pyruvate. The possibility of the asymmetric hydrogenation of III is confirmed by the results of the asymmetric reductive amination of ethyl pyruvate, as is shown in Table 3.

Experimental

1) Preparation of Asymmetric Catalysts. a) Preparation of the R–Ni Catalyst. Into 60 m*l* of 20% aqueous sodium hydroxide solution, 4.5 g of the R–Ni alloy (Ni : Al=40 : 60) were added in small portions without cooling. After the reaction mixture had then been maintained at 100°C for 1 hr, the aqueous solution was removed by decantation and the R–Ni catalyst was washed with deionized water.

b) Modification of the Catalyst. Onto the R–Ni catalyst obtained from 4.5 g of an alloy we poured, as soon as possible 200 m*l* of a 2% aqueous solution of histidine, which had been cooled at 0°C. The mixture was then allowed to stand, with occasional shaking, at 0°C for 1.5 hr. After the removal of the modifying solution by decantation, the catalyst was washed twice with 50-m*l* portions of water and twice with 50-m*l* portions methanol.

2) Hydrogenation of Ethyl 2-Acetoximinopropionate. *a) Hydrogenation to Ethyl Alaninate (IV) in Methanol.* Twenty grams of I in 20 m*l* of methanol were hydrogenated with the R–Ni catalyst, or with the modified R–Ni catalyst obtained from 4.5 g of an alloy, at room temperature under an initial hydrogen pressure of 90 kg/cm² and in shaking 100-m*l* autoclave. After the hydrogen uptake ceased, the reaction product, IV, was separated from the catalyst and treated with 20 m*l* of acetic anhydride at 5°C for 2 hr. The acetylated product, V, was distilled under reduced pressure, and a fraction with a bp of 100—102°C/3 mmHg was collected. The purity of the distillate was checked by means of gas chromatography and the optical rotation measured without dilution.

Found: C, 53.06; H, 8.26; N, 8.41%. Calcd for $C_7H_{13}O_3N$: C, 52.81; H, 8.23; N, 8.80%.

b) Hydrogenation to Ethyl Acetoxyalaninate (II) in Ethyl Acetate. The product obtained by the hydrogenation in ethyl acetate was distilled; a distillate boiling at 100—102°C/3 mmHg was thus collected.

Found: C, 48.30; H, 7.96; N, 7.76%. Calcd for $C_7H_{13}O_4N$: C, 47.99; H, 7.48; N, 8.00%.

3) Asymmetric Hydrogenation of II. The optically-active or racemic II prepared by the hydrogenation of I in ethyl acetate was hydrogenated in methanol with a modified R–Ni catalyst under the conditions described above. The hydrogenation product, IV, was acetylated and distilled, and its optical rotation was measured without dilution.

4) Ethyl Acetyl-L-alaninate (L-V). L-IV prepared by the esterification of L-alanine with alcohol and hydrogen chloride, and by subsequent neutralization with triethylamine, was acetylated by acetic anhydride and triethylamine in chloroform.

A fraction of bp 100—102°C/3 mmHg was collected. The optical rotatory power of the product was $[\alpha]_D^{20}$ −56° (without dilution): lit.,[5] $[\alpha]_D^{20}$ −46.4° (without dilution).

5) Reductive Amination of Ethyl Pyruvate. Twenty grams of ethyl pyruvate (0.085 mol) in 50 m*l* of a 5.4N ammonia methanol solution (0.25 mol) were hydrogenated with the modified R–Ni at 60°C under an initial hydrogen pressure of 90 kg/cm² in a shaking 100-m*l* autoclave. When the hydrogenated product was acetylated by the method described above and distilled under reduced pressure, a fraction with a bp of 100—102°/3 mmHg was collected. Yield, 2.1 g. The purity of the distillate was checked by means of gas chromatography and elemental analyses.

Found: C, 52.69; H, 8.45; N, 8.45%. Calcd for $C_7H_{13}O_3N$: C, 52.81; H, 8.23; N, 8.80%.

The authors wish to express their thanks to Misses Kiku Koike and Nobuko Ohya for their elemental analyses. This research was supported by the Kawaken Fine Chemicals Co., Ltd., Tokyo. Part of the expenses of this work has also been defrayed by a grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1796—1803 (1970)

The Migration of the Alkyl Groups of 6-Acetyl and 6-Methoxycarbonyl Derivatives of 2,3-Dimethyl-5-alkylbenzofurans*[1]

Yoshiyuki KAWASE, Setsuko TAKATA and Toshio MIWA*

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama
**Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka*

(Received November 10, 1969)

The migration of the 5-alkyl groups of 2,3-dimethyl-5-alkyl-6-benzofuranyl methyl ketones by aluminum chloride was studied further, and an analogous migration was observed in the cases of methyl 2,3-dimethyl-5-alkyl-6-benzofurancarboxylates. The 5-ethyl-, 5-*n*-propyl-, and 5-isopropyl-ketones were converted to the corresponding carboxylic acids by the bromoform reaction and then, further, to the esters. The action of aluminum chloride on the 5-*n*-propyl-ketone and the esters in carbon disulfide at room temperature afforded the corresponding 4-alkyl-compounds as a result of the migration of the 5-alkyl groups to the 4-position, analogously to the way in which the 5-ethyl- and 5-isopropyl-ketones had afforded two 4-alkyl-ketones. The structures of the compounds were confirmed by converting both the ketones and the esters to the same carboxylic acids and from the data of their IR, UV and NMR spectra and gas chromatograms. It was found that the 5-alkyl groups were less likely to migrate in the cases of the esters than the corresponding alkyl groups in the cases of the ketones, while the *n*-propyl groups of the ketone and the ester were less likely to migrate than the other alkyl groups, and that the migration seemed to be intramolecular, as the *n*-propyl group was not isomerized to an isopropyl group during the migration.

It has previously been reported that the action of aluminum chloride on *o*-alkylphenyl methyl ketones at 100—170°C,[1,2] and in some cases at room temperature[2] also, caused the migration of the *o*-alkyl groups to the *m*-position; moreover, one of the present authors and others[3,4] have recently reported that 2,3-dimethyl-5-ethyl- and 5-isopropyl-6-benzofuranyl methyl ketones (**3**a and c) afforded the corresponding 4-alkyl-ketones (**4**a and c) by the analogous migration of the 5-alkyl group to the 4-position.

Now in the present experiments, the migration of the alkyl groups of the benzofuranyl ketones (**3**), especially that of the *n*-propyl-ketone (**3**b), was studied further, and an analogous migration was observed also in the cases of the related methyl 2,3-dimethyl-5-alkyl-6-benzofurancarboxylates (**7**a, b, and c).

2,3-Dimethyl-5-*n*-propyl-6-benzofuranyl methyl ketone (**3**b) was prepared much as in the cases of the 5-ethyl-[5] and 5-isopropyl-ketones[4] (**3**a and c) by the action of acetyl chloride and aluminum chloride or stannic chloride on 2,3-dimethyl-5-*n*-propylbenzofuran (**2**b), which had, in turn, been prepared by the cyclo-dehydration of 3-(*p*-*n*-propylphenoxy)-butanone (**1**b). The ketones (**3**a, b, and c) were converted to the corresponding carboxylic acids (**5**a,b, and c) by the bromoform reaction,[6] and then to the methyl esters (**7**a,b, and c).

The ketone (**3**b) and the esters (**7**a,b, and c) were treated with aluminum chloride in carbon disulfide at room temperature to afford the corresponding 4-alkyl-ketone (**4**b) and -esters (**8**a,b, and c) as a result of the migration of the 5-alkyl groups to the 4-position, just as the 5-ethyl- and 5-isopropyl-ketones (**3**a and c) afforded the 4-alkyl-ketones[3,4] (**4**a and c) (see Table 1). The products were purified by distillation and then by crystallization from petroleum ether, except for the ketone (**4**b), which was purified by chromatography on alumina, with benzene as the solvent. The yields of the esters (**8**a,b, and c) were poorer than those of the

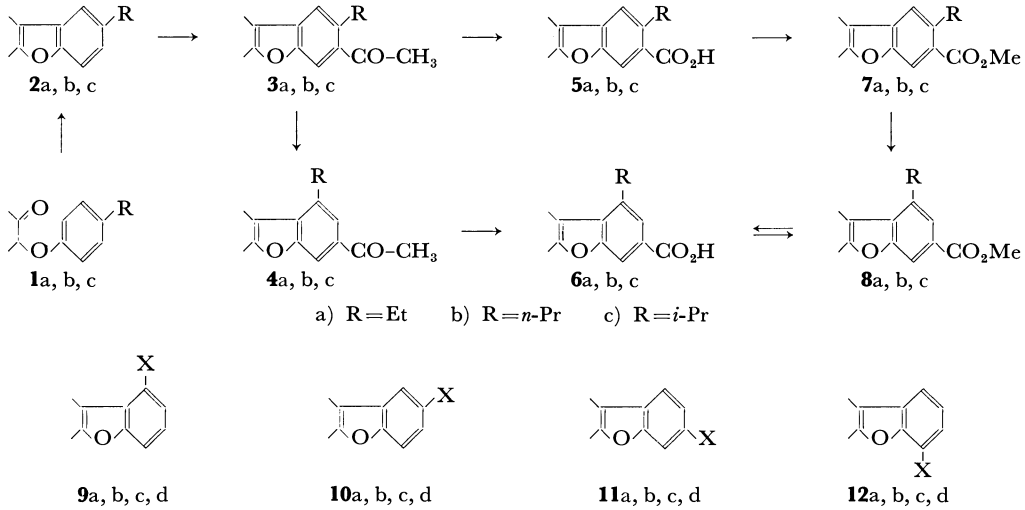

Chart 1

corresponding ketones (**4**a,b, and c), while those of the *n*-propyl-ketone (**4**b) and -ester (**8**b) were poorer than those of the other alkyl-compounds. The structures of the compounds were confirmed by converting both the ketones (**4**a,b, and c) and the esters (**8**a, b, and c) to the respective carboxylic acids (**6**a, b, and c) by bromoform reaction or hydrolysis; they were confirmed also by comparing their IR, UV, NMR, and gas chromatographical data with each other and with those of the compounds without *bz*-alkyl groups.

In the UV spectra, the absorption curves of the ketones (**3** and **4**), acids (**5** and **6**), and esters (**7** and **8**) are almost identical with each other and with those of the ketone (**11**b), acid (**11**c), and ester (**11**d) without the *bz*-alkyl group, except for a slight variation in the 210—230 mμ region according to the position of the *bz*-alkyl groups, and

except for a slight shift of peaks by 1—5 mμ or 4—9 mμ in the cases of the esters and ketones, respectively, from those in the cases of the acids. Moreover, the absorption curves of the 6-acetyl-, 6-carboxyl-, and 6-methoxycarbonyl-2,3-dimethylbenzofurans (**11**b,c, and d) are quite different from those of the isomeric 4-, 5-, and 7-substituted compounds (**9**, **10**, and **12**); the absorption curves of the 4- and 7-isomers (**9** and **12**) are very similar to each other, having three peaks at 225—235 mμ, 270—285 mμ, and 300—315 mμ, while those of the 5-isomers (**10**) have remarkably high peaks at around 240 mμ, while those of the 6-isomers (**11**) have higher and broader peaks at 285—295 mμ (see the figures and Table 4).

In the NMR spectra, it was found that the peaks corresponding to the 3-methyl protons appeared at δ=2.04—2.14 ppm in the cases of the 5-alkyl-ketones and -esters (**3** and **7**), while they appeared at a field lower by about 0.13—0.26 ppm in the cases of the 4-alkyl-compounds (**4** and **8**); these differences are comparable to the cases of 2,3-dimethylbenzofurans substituted by electron-donating methoxyl, amino, ethyl, and chloro groups.[7] The peaks corresponding to the aromatic protons appeared as two singlets in the cases of **3**a,b, and c and **7**a,b, and c, while they appeared as two doublets (J=2 Hz) in the cases of **4**a,b, and c and **8**a,b, and c, indicating that the hydrogens are in the *para* and *meta* positions to each other respectively (see Table 5).

In the gas chromatograms, the peaks corresponding to the 4-alkyl-ketones (**4**) and -esters (**8**) appeared at 200—205°C, and those of the 5-alkyl-compounds (**3** and **7**) appeared at temperatures higher by about 5°C, while those of the 6-ketone and the 6-ester (**11**b and **11**d) appeared at 195 and 198°C respectively.

On the basis of these measurements, the ratio of the 5- and 4-alkyl-compounds (**3** and **4**, or **7** and **8**) in the crude rearrangement products of 5-alkyl-ketones or -esters (**3** or **7**) was determined by estimating the area of the peaks corresponding to the 5- and 4-alkyl-compounds in the gas chromatograms and that of the peaks corresponding to the 3-methyl protons of 5- and 4-alkyl-compounds in the NMR spectra (see Table 1). It seems that the 5-alkyl groups migrate less easily in the cases of the 5-alkyl-6-esters (**7**) than do the corresponding alkyl groups in the cases of the 5-alkyl-ketones (**3**), that the *n*-propyl group migrates less easily than the other alkyl groups, and that the migration is intramolecular, for the *n*-propyl group is not isomerized to an isopropyl group during the migration.

In conclusion, it seems that the migration of the 5-alkyl groups of 5-alkyl-6-ketones and -esters (**3** and **7**) by aluminum chloride occurs through the cationic cleavage of the alkyl group caused by the electron-attracting effect of the carbonyl group and by the steric hindrance of the aluminum chloride co-ordinated to the carbonyl group, followed by the synchronous attack of the split cationic alkyl group at the adjacent 4-position.

Experimental

All the boiling points and melting points are uncorrected. The IR spectra were measured in the form of KBr disks, the UV spectra were measured in an ethanol solution, the NMR spectra were measured on a Nihon Denshi 60 MHz spectrometer in a CCl_4 solution (5—10%), with TMS as the internal standard, and the gas chromatography was carried out on a Hitachi K23 apparatus, with Silicone DC-11 on Chamelite as the stationary phase, a flow rate of 46 ml/min (0.7 kg/cm^2), and a temperature rise of 5°C/min from 180°C. The detailed data are summarized in the tables and figures.

Materials. a) Alkylbenzofurans. 2,3-Dimethylbenzofuran[8] (**2** R=H), 2,3,5-trimethylbenzofuran[5] (**2** R=Me), 2,3-dimethyl-5-ethyl-[8] and -5-isopropylbenzofurans[3,4] (**2**a and c) and 2,3-dimethyl-6- and -7-ethylbenzofurans[8] (**11**a and **12**a) were prepared following the methods in the respective references. 2,3-Dimethyl-5-*n*-propylbenzofuran (**2**b) and 2,3-dimethyl-4-ethylbenzofuran (**9**a) were prepared much as were **2**a and **11**a respectively.

a) A: 3-Chlorobutanone and K_2CO_3 in acetone, B: Cyclo-dehydration by H_2SO_4, C: Acetyl chloride and $AlCl_3$, D: Acetyl chloride and $SnCl_4$, E: Bromoform reaction, F: Esterification, G: Hydrolysis, and H: Reduction.
b) *p-n*-Propylphenol.

*3-(p-n-Propylphenoxy)butanone (**1**b).* Anhydrous potassium carbonate (98 g) was added to a solution of *p-n*-propylphenol (32 g) and 3-chlorobutanone (27.6 g) in acetone (200 m*l*), after which the mixture was refluxed for 9 hr. Most of the acetone was then distilled off, and the residue was dissolved in water and extracted with ether. The residual product obtained from the ethereal solution was distilled to give **1**b; bp 139—145°C/17 mmHg; 38.2 g (79%).

*2,3-Dimethyl-5-n-propylbenzofuran (**2**b).* Concentrated sulfuric acid (38 g) was stirred, drop by drop, into the butanone **1**b (38 g) with cooling below 30°C, and then the solution was allowed to stand at that temperature for 1 hr. The mixture was poured into ice water and extracted with ether. The ethereal solution was washed with an aqueous sodium hydroxide solution and dried, and then the ether was distilled off. The residual product from the ethereal solution was distilled to give **2**b; bp 138—140°C/18 mmHg; 25.7 g (74%).

*2,4-Dimethyl-4-ethylbenzofuran (**9**a).* A mixture of 2,3-dimethyl-4-benzofuranyl methyl ketone[6] (**9**b) (1.9 g), hydrazine hydrate (0.8 g), and diethylene glycol (30 m*l*) was heated gently for 1.5 hr in a distillation apparatus to distill off the water formed. Potassium hydroxide (2.9 g) was then gradually added to the slightly-cooled mixture in the same apparatus, and the mixture was heated gently for 1 hr to complete the development of nitrogen. The hot mixture was poured into water, acidified with dilute hydrochloric acid, and extracted with ether. After the ether was then distilled off, the residue was distilled to give **9**a; bp 127—131°C/17 mmHg; 0.9 g (51%).

b) Benzofuranyl Ketones. 2,3,5-Trimethyl-6-benzofuranyl methyl ketone[5] (**3** (R=Me)), 2,3-dimethyl-5-ethyl-[5] and -5-*i*-propyl-6-benzofuranyl methyl ketones[3,4] (**3**a and c) and 2,3-dimethyl-4-,[6] -5-,[9] -6-,[8] and -7-benzofuranyl methyl ketones[10] (**9**b, **10**b, **11**b, and **12**b) were prepared following the methods of the respective references. 2,3-Dimethyl-5-*n*-propyl-6-benzofuranyl methyl ketone (**3**b) was prepared much as were **3**a and c, as follows:

*2,3-Dimethyl-5-n-propyl-6-benzofuranyl Methyl Ketone (**3**b).*
i) By Aluminum Chloride. Powdered anhydrous aluminum chloride (15.4 g, 1.2 mol equivalents) was gradually added, with stirring and cooling, to a solution of the benzofuran **2**b (18 g) and acetyl chloride (8.3 g, 1.1 mol equivalents) in carbon disulfide (100 m*l*); the mixture was stirred at room temperature for 4 hr and then allowed to stand overnight. The mixture was poured into ice water and extracted with chloroform. The organic layer was washed with an aqueous sodium hydroxide solution and dried, and then the solvent was distilled off. The residual product was distilled, bp 187—200°C/22 mmHg, and then crystallized from petroleum ether to give **3**b; mp 45—47°C; 10.5 g (48%).

ii) By Stannic Chloride. Anhydrous stannic chloride (11.5 g, 1.5 mol equivalents) was gradually added, with stirring and cooling, to a solution of **2**b (5.5 g) and acetyl chloride (3 g, 1.3 mol equivalents) in carbon disulfide (50 m*l*); the mixture was then treated much as has been described in the case of aluminum chloride.

c) Benzofurancarboxylic Acids. 2,3,5-Trimethyl-6-benzofurancarboxylic acid[6] (**5** R=Me) and 2,3-dimethyl-4-,[6] -5-,[6] -6-,[6] and -7-benzofurancarboxylic

acids[11)] (**9c**, **10c**, **11c**, and **12c**) were prepared following the methods of the respective references.

d) Methyl Benzofurancarboxylates. Methyl 2,3,5-Trimethyl-5-benzofurancarboxylate[6)] (**7** R=Me) and methyl 2,3-dimethyl-4-,[11)] -5-,[6)] -6-,[6)] and -7-benzofurancarboxylates[11)] (**9d**, **10d**, **11d**, and **12d**) were prepared following the methods of the respective references.

Migration of the Alkyl Groups of the Ketones (3) and the Esters (7). Powdered anhydrous aluminum chloride (4.7 g, 2 mol equivalents) was gradually added, with stirring and cooling, to a solution of the ketone **3b** (4 g) in carbon disulfide (50 m*l*), after which the mixture was stirred for 4 hr at room temperature and then allowed to stand overnight. The mixture was

11) Y. Kawase, T. Okada and T. Miwa, to be published.

then poured into ice water and extracted with chloroform. The organic layer was washed with an aqueous sodium hydroxide solution and dried, and then the solvent was distilled off. The residual product was distilled to give the crude product; bp 185—195°C/19 mmHg; 2.8 g (70%). By the same procedure, the ketone **3**a and c and the esters **7**a, b, and c afforded the crude products; their compositions were determined by gas chromatography and by NMR spectroscopy. The crystallization of the crude products from petroleum ether furnished the pure crystalline products except in the case of **3**b. The crystallization in the case of **3**b furnished only the crystalline-recovery ketone (0.2 g); a part (0.5 g) of the residual oil was purified, by chromatography with alumina and benzene as a solvent, to give the recovery ketone (0.2 g) and the rearranged ketone **4**b; mp 44—45°C, 0.1 g (total 12%).

2,3-Dimethyl-5- and -4-alkyl-6-benzofurancarboxylic Acids (5a,b, and c and 6a,b, and c). *a) by the Bromoform Reaction of the Ketones (3a,b, and c and 4a, b, and c).* A solution of **3**a (8 g) in dioxane (50 m*l*) was added, with cooling and stirring, to an aqueous sodium hypobromide solution, which had been prepared by adding bromine (23 g, 3.8 mol equivalents) with cooling to a mixture of sodium hydroxide (14.5 g, 9 mol equivalents), water (45 m*l*), and ice (45 g). Stirring was continued for 30 min and then for another 1.5 hr at 45°C. The cooled mixture was diluted with water and washed with ether, and the aqueous layer was acidified after the addition of a small amount of sodium bisulfite. The crystalline precipitates thus formed were collected and recrystallized from ethanol to give 2,3-dimethyl-5-ethyl-6-benzofurancarboxylic acid (**5**a); mp 186—187.5°C; 6.3 g (78%).

2,3-Dimethyl-5-*n*-propyl- and -5-isopropyl-6-benzofurancarboxylic acids (**5**b and c) and 2,3-dimethyl-4-ethyl-, -4-*n*-propyl- and -4-isopropyl-6-benzofurancarboxylic acids (**6**a,b, and c) were also obtained by this procedure.

b) By the Hydrolysis of the Esters (8a, b, and c). An aqueous potassium hydroxide solution (1 g in 4 m*l* of water) was added to a solution of **8**a (1 g) in ethanol (5 m*l*), and then the mixture was refluxed for 3 hr. The cooled solution was diluted with water, washed with ether, and then acidified to give the crystalline product (**6**a), which was then recrystallized from ethanol; mp 198—199°C; 0.6 g (62%).

2,3-Dimethyl-4-*n*-propyl- and -4-isopropyl-6-benzofurancarboxylic acid (**6**b and c) were also obtained by this procedure.

Methyl 2,3-Dimethyl-5- and -4-alkyl-6-benzofurancarboxylates (7a,b, and c and 8a). Powdered potassium carbonate (43 g, 6 mol equivalents) was added to a solution of **5**a (11.3 g) and dimethyl sulfate (13.2 g, 2 mol equivalents) in acetone (200 m*l*), after which the mixture was refluxed for 8 hr. Most of the acetone was distilled off, and the residue was treated with water and extracted with ether. The ethereal layer was washed with a dilute aqueous sodium hyroxide solution, and then the ether was distilled off. The residual product was distilled to give methyl 2,3-dimethyl-5-ethyl-6-benzofurancarboxylate (**7**a); bp 177—180°C/20 mmHg; 9.4 g (78%).

Methyl 2,3-dimethyl-5-*n*-propyl- and -5-isopropyl-6-benzofurancarboxylates (**7**b and c) and methyl 2,3-dimethyl-4-ethyl-6-benzofurancarboxylate (**8**a) were also obtained by this procedure.

Reaction of Sulfoxides with Acylating Reagents. IV.[1] The Catalytic Effect of Both the Brönsted and Lewis Acids in the Oxygen Exchange Reaction of Diaryl Sulfoxides with Acetic Anhydride

Masahiro KISE and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshiku, Osaka

(Received November 12, 1969)

Diaryl sulfoxides undergo oxygen exchange and racemization reaction with acetic anhydide. The rate of racemization of *p*-tolyl phenyl sulfoxide was found to be twice that of oxygen exchange. The remarkably small substituents effect is also in keeping with the S_N2 type mechanism. Addition of acetic acid increases the rate of both the racemization and oxygen exchange. Racemization of sulfoxides is also known to be catalyzed markedly by a small amount of Lewis acid. When the reaction was carried out in the presence of a small amount of both acetic acid and Lewis acid, the ratio of the rate constants, k_{ex}/k_{rac} becomes unity. This may mean that the presence of both Brönsted and Lewis acids facilitates the cleavage of S–O bond by easy protonation (or hydrogen-bonding) or coordination on the sulfoxide oxygen, and the assistance of the nucleophilic attack by acetate becomes less important in the reaction. The larger substituent effect is also in keeping with the S_N1 type mechanism.

In a previous paper,[2] dealing with the reaction of diaryl sulfoxides with acetic anhydride, we suggested on the basis of our kinetic investigations (such as the value of $k_{ex}/k_{rac}=1/2$, rather small substituent effect, *etc.*,) that the reaction proceeds through an S_N2 type Walden inversion process at the rate-determining step as shown below. (Fig. 1).

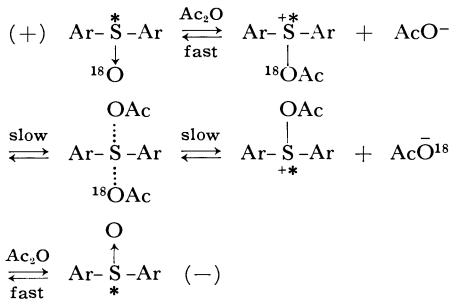

Fig. 1

The addition of acetic acid increases the rate of both the racemization[3] and oxygen exchange. Racemization of aryl benzyl sulfoxides in acetic anhydride is also known to be catalyzed markedly by a small amount of Lewis acid[4] such as mercuric chloride. In the racemization reaction of *p*-tolyl methyl sulfoxide with acetic anhydride, the large catalytic effect was reported by Jonsson[5] on the addition of metal halide such as mercuric chloride, zinc chloride or acetylating reagents. Jonsson proposed that in the racemization reaction of sulfoxide the acetylium ion formed reacts with the sulfoxide giving an acetoxysulfonium ion, and racemization was then brought about by exchange of acetate groups through a symmetrical transition state as proposed earlier.[2,3] The mechanism of the reaction is illustrated in Fig. 2.

Since intermediate III is symmetrical the recovered sulfoxide should be racemized while the ratio of the rates, k_{ex}/k_{rac}, is expected to be 1/2.

We suggested,[2] on the basis of the ratio of the rate, $k_{ex}/k_{rac}=1$, in the oxygen exchange and racemization reaction of diaryl sulfoxide with acetic anhydride containing small amounts of acetic acid that the presence of Brönsted acid and acetic acid may facilitate the cleavage of S–O bond by the easy protonation or hydrogen bonding on the sulfoxide oxygen, and that the assistance of the nucleophilic attack by acetate becomes less important.

Sulfoxides bearing at least one methyl or methylene group directly attached to the sulfur atom undergo "Pummerer Rearrangement" in the reaction with acetic anhydrides as shown below[6] (Fig. 3).

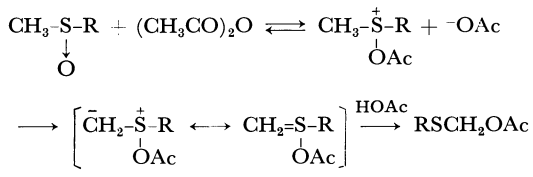

Fig. 3

We suggested on the basis of ^{18}O tracer experiments with ^{18}O-labeled acetic anhydride that the Pummerer reaction of dimethyl sulfoxide with acetic anhydride proceeds through an intermolecular nucleophilic attack of acetoxy group on the methylene carbon of the ylide-ylene intermediate. Noticeable acetoxy interchange has been found to take place during a similar Pummerer reaction of aryl methyl sulfoxide. In the reaction of *p*-tolyl methyl sulfoxide with acetic anhydride, below 65°C, under which the Pummerer reaction is minor, only the oxygen exchange proceeds slowly. But the addition of Lewis acids accelerates both the reaction of acetoxy interchange and Pummerer rearrangement.[6] We have investigated this catalyzed oxygen exchange reaction of diaryl sulfoxides by Lewis acids extensively in order to understand the nature of the reaction. With diaryl sulfoxides, our attention is focused only on the acetoxy interchange, since the other competing reactions such as Pummerer rearrangement and the heterolysis of carbon-sulfur linkage do not take place with these sulfoxides. In fact, when an optically active diaryl sulfoxide labeled with ^{18}O- atom was reacted with acetic anhydride containing Lewis acid, the sulfoxide was recovered quantitatively by quenching the reaction mixture with an excess cold water.

Results and Discussion

When the reaction were carried out at 120°C with both optically active and ^{18}O-labeled diaryl sulfoxides in a large excess of acetic anhydride, the rate of racemization of *p*-tolyl phenyl sulfoxide was twice that of oxygen exchange. This suggests that the reaction involves a Walden inversion at the rate-determining step. Sulfoxides are known to undergo concurrent oxygen exchange and racemization reactions through an acid catalyzed S_N1 type process in weak carboxylic acids such as acetic, chloroacetic, dichloroacetic and trichloroacetic acids.[7]

Table 1. Activation parameters and k_{ex}/k_{rac} values of (+) *p*-tolyl phenyl sulfoxides

d) Sulfoxide=0.05M $HgCl_2$=0.018M

Activation parameters and k_{ex}/k_{rac} values of the reaction of (+) *p*-tolyl phenyl sulfoxide with trichloroacetic acid,[7] acetic anhydride,[2] acetic anhydride containing a small amount of acetic acid and mercuric chloride are summarized in Table 1.

The small value of entropy of activation in the reaction of *p*-tolyl phenyl sulfoxide with trichloroacetic acid was assumed to be due to the solvation by the acid in the transition state.[7] However, in the reaction with acetic anhydride, the addition of acetic acid or mercuric chloride resulted in the increase of the entropy of activation and also in a probable change from the S_N2 process to the S_N1 in the transition state.

The small change of the entropy is perhaps due

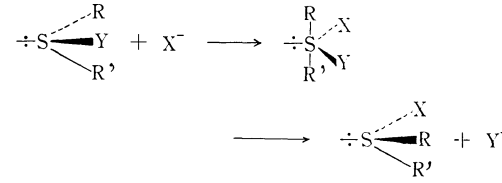
to the solvation or participation of these acids in the transition state of the reaction with a weak acid such as trichloroacetic acid. Actually the ratios of the rate, k_{ex}/k_{rac}, became unity as shown in Tables 2 and 3 in the reactions of *p*-tolyl phenyl sulfoxide with acetic anhydride containing a small amount of Brönsted acid or Lewis acid. If the reaction proceeds through the path shown in Fig. 2, the ratio of the rate, k_{ex}/k_{rac}, would become 1/2.

Thus the mechanism shown in Fig. 2 cannot account for the observation.

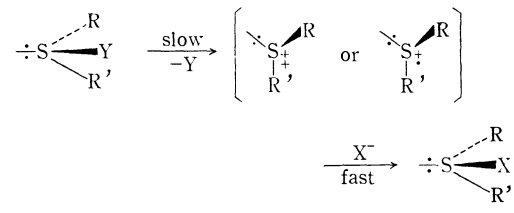
When an intermediate or an incipient activated complex at the transition state of the nucleophilic substitution reaction assumes a typical bipyramidal structure, two possible stereochemical consequences will arise depending upon the steric arrangement of both incoming and outgoing groups.[8]

When both the entering and leaving groups assume axial positions, the process is similar or identical to S_N2 reaction on carbon atom, and the net result is the inversion of configuration. A typical example of the reaction at the axial positions in trigonal bipyramidal might be the reaction of (+) *p*-tolyl phenyl sulfoxide with acetic anhydride.[2] Another example may be both the oxygen exchange and racemization reactions of (+) *p*-tolyl phenyl sulfoxide in less concentrated sulfuric acid (75.4%).[9] A similar net inversion would result also when both incoming and outgoing groups assume radial positions as shown below.



A possible example is the recent work of Day and Cram who showed that the formation of sulfilimine from the corresponding sulfoxide resulted in net inversion.[10] When the leaving and entering groups assume axial and radial arrangement with each other around the central sulfur atom of the trigonal bipyramidal structure, the displacement will lead to the retention of configuration at the sulfur atom. An example of this type was found for the first time in the oxygen exchange reaction between *p*-tolyl methyl sulfoxide and DMSO.[8]

Another reaction on the sulfur atom is similar to the S_N1 type reaction on sp^3 carbon atom, where the cleavage of S–O bond takes place in the initial slow step followed by a rapid recombination with solvent or a reagent, resulting in racemization. In this reaction, the ratio k_{ex}/k_{rac}, becomes unity.



Thus, in both the reactions in concentrated sulfuric acid (95.5%), the ratio of the rate k_{ex}/k_{rac} is unity.[11] This shift of mechanism resulting from the change of the concentration of H_2SO_4 from 95% to 75%, is caused by the change of the nature of sulfuric acid solution, namely, the protonating ability of the solution diminishes steadily as acid concentration decreases while the activity of water increases. If the S_N1-like cleavage of the S–O bond of the sulfoxides takes place through the diprotonated species $>S-OH_2$ in the rate determining step, formation of this diprotonated species will decrease with the decrease of acid concentration. Other examples of this S_N1 type reaction are concurrent oxygen exchange and racemization reaction of sulfoxides in phosphoric acid[12] and dinitrogen tetroxide.[13]

Such a change in mechanism may be assumed to

take place also in the reaction of sulfoxides with acetic anhydride containing a small amount of acid. The transition state in these reactions may be assumed to be S_N1 type as in concentrated sulfuric acid. The change of transition state of this reaction may depend on the hydrogen bonding (protonating) or co-ordination on the oxygen atom of sulfoxide by these acids. The protonation or hydrogen bonding to the carbonyl oxygen of acetic anhydride of these acids can also enhance the initial acetylating step of these reaction (Fig. 4).

0	$(1.06\pm0.07)\times10^{-4}$	$(1.34\pm0.02)\times10^{-4}$	1.19
3 days	$(2.56\pm0.35)\times10^{-4}$	$(2.91\pm0.09)\times10^{-4}$	0.90

Jonsson[5] suggested that the rate enhancement by the acids in this reaction depends only on the formation of acetylium ion in the initial step. According to this mechanism, formation of acetylium ion would bring about an increased conductivity of the acetic acid solution. However, a careful measurement of conductivity of the reaction solution revealed no increase of conductivity. Ion separation did not take place in these solutions as shown in Table 4.

This effect may be due to the gradual formation of acylinium ion species which would react with sulfoxides so rapidly that measurement of conductivity becomes impossible.

The large enhancement of the rate, however, does not seem to be due to the discrete formation of a small amount of acetylium ion, but to the hydrogen bonding or participation of these acids in the initial acetylating step and also in the suc-

ceeding fission of S–O bond. The over-all scheme of the oxygen exchange reaction of diaryl sulfoxides in acetic anhydride containing some acids may be formulated as in Fig. 4.

In order to confirm the S_N1-like character of this reaction, the oxygen exchage reaction of *p*-substituted diphenyl sulfoxides in acetic anhydride was carried out in the presence of a few acids. The results obtained with Lewis acids are shown in Table 5, while those with acetic acid are summarized in Table 6.

Kinetic data clearly reveal that the polar effect of substituents on the rate of oxygen exchange is markedly larger in this reaction than that in a typical S_N2 type reaction, such as reaction of sulfoxide with acetic anhydride[2] or with less concentrated sulfuric acid.[10] Two different mechanisms are conceivable, one in which the heterolysis of S–O bond involves the rate determining formation of the doubly charged "sulfidonium ion" intermediate (path a in Fig. 4), and the other in which the homolysis forms a radical cation intermediate (path b in Fig. 4). The relatively small polar effect ($\rho \fallingdotseq 1$) seems to favor the homolytic path for this reaction.

Experimental

Materials. *^{18}O-Labeled Diaryl Sulfoxides* were prepared by the bromine oxidation of the corresponding sulfides using ^{18}O-enriched water.[14]

An aryl sulfide (0.1 mol) was dissolved (0.2—0.5 mol) in a mixture of ^{18}O-enriched water (1.63 atom%), pyridine (0.12 mol) and small amount of acetic acid, and the solution was cooled down to 0°C, and an acetic acid solution of bromine (0.1 mol) was then added dropwise over a period of 1 hour. After one hour of stirring, the reaction mixture was poured into a large excess of ice-water, and the aqueous solution was neutralized with sodium bicarbonate. The precipitate formed was extracted with ether and the ether solution was washed with 10% sodium thiosulfate to remove both bromine and water, respectively, and dried over anhydrous sodium sulfate. After the solvent was distilled off thoroughly, the ^{18}O-labeled sulfoxide obtained was recrystallized three times from *n*-hexane-ether solution. The yields, melting points and ^{18}O-concentrations of the sulfoxides obtained are listed in Table 7.

* Prepared from 3.50 atom %-H_2O^{18}

Optically Active p-Tolyl Phenyl Sulfoxide. This sulfoxide was prepared by the method of Anderson[16] in which (−)-menthyl (−)-*p*-toluenesulfinate was allowed to react with phenylmagnesium bromide in ether (mp 91—93°C $[\alpha]_D = +27°$ in EtOH).

Acetic Acid obtained commercially was treated with chromic anhydride and after refluxing for several hours, it was distilled (bp 117.5—118°C).

Acetic Anhydride obtained commercially was treated with anhydrous sodium acetate and then distilled (bp 139.5—140°C).

Kinetic Procedure I (Oxygen Exchange Reaction). The oxygen exchange reaction was carried out in sealed tubes at a set temperature, ranging from 90 to 110°C in acetic anhydride containing a small amount of acetic acid, or from 10 to 20°C in acetic anhydride containing a small amount of mercuric chloride. In the sealed tubes were placed aliquots of the reaction mixture containing optically active *p*-tolyl phenyl sulfoxide (1.25×10^{-3} mol) in 25 m*l* acetic anhydride-acetic acid solution (Ac_2O/AcOH 9/1 (v/v)) or in the same acetic anhydride solution containg $HgCl_2$ (2.4353 g $HgCl_2$/500 m*l* Ac_2O) without other solvents. From time to time a sealed tube containing 4 m*l* of the reaction mixture was drawn out from the bath and quenched with ice water. The sulfoxide separated out was extracted with carbon tetrachloride, carbon tetrachloride was then distilled off and the resulting sulfoxide was recovered. The recovered sulfoxide was dried thoroughly and subjected to ^{18}O-analysis.[11]

Kinetic Procedure II (Racemization Reaction). The racemization reaction was carried out under the same conditions as for the oxygen exchange reaction. From time to time a sealed tube containing 4 m*l* of reaction mixture was drawn out from the paraffin bath and poured into an ice bath to stop the reaction of *p*-tolyl phenyl sulfoxide with acetic anhydride-acetic acid. In the reaction of *p*-tolylphenyl sulfoxide with acetic anhydride-mercuric chloride, the rates were measured directly by checking the polarimeter which was set at a desired temperature by connecting it with a constant temperature bath. The rate constants obtained by these methods are usually in good agreement with those obtained by isolating the product under kinetic procedure I.

Measurement of Conductivity. The electric conductivity of the solutions was measured by a universal bridge. At first the conductivity of acetic anhydride solution was measured by using a regular cell with platinum plates, and the value 40 MΩ was obtained. The conductivity of 25 m*l* acetic anhydride containing 136 mg mercuric chloride was found to be also 40 MΩ. The same value was obtained after 3 days and also after a week.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1809—1811 (1970)

Chromatographic Resolution of Several Racemates by Means of Optically Active Acidic Polymers Derived from α-Amino Acids

Tetsushi YAMASHITA and Nobuo NAKAMURA

Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received November 20, 1969)

The chromatographic resolution of several racemic amines was investigated by using three types of copolymers composed by *N*-acroylated α-amino acid and *N,N'*-dimethacroylhexamethylenediamine. The anilides of DL-phenylalanine and DL-valine, and of DL-phenylglycine and DL-1,2-diphenylethylamine, were partially resolved. The combination of substrate and sorbent giving the most efficient resolution was anilide of phenylglycine and the copolymer involving L-phenylalanine.

There have been a number of reports[1-11] concerning the use of synthetic optically active polymers as adsorbents for the chromatographic resolution of racemate.

Most such polymers have been synthesized by either one of the following two methods. The first is the method in which an optically active group is introduced into an optically inactive "reactive polymer"[7] (*e.g.*, chloromethylated polystyrene[4,5,7-9] and polymethacryl chloride[3]). The second method[1,2,6,11] includes the homogeneous copolymerization of an optically active monomer with some suitable crosslinking agent.

In a previous paper,[1] the syntheses of three types of optically active polymers by the second method and some of the results on the chromatographic resolution of racemate were reported.

This article will describe some more successful examples of resolution with DL-1,2-diphenylethylamine and with the anilides of DL-phenylalanine, DL-phenylglycine, and of DL-valine as substrates. In practice, these substrates were transformed into the corresponding acetates before the runs for resolution. The polymer sorbents used were the same as have been reported earlier[1,12] [crosslinking agent (CA): *N,N'*-dimethacroylhexamethylenediamine; copolymers A (acroyl phenylalanine-CA), B (acroyl valine-CA), and C (acroyl tryptophan-CA)].

Results and Discussion

Of course, the fraction with the highest specific rotation came out at the earliest stage of the elution

The wavelength of Hg-line is 546 mμ.

of the resolved substrate. However, 20—60 fractions had to be combined to obtain a sufficient amount of eluted substrate for the observation of specific rotation. Table 1 illustrates the observed values of specific rotation for the earliest combined fractions, along with those of the optical purity and the acid concentration of the eluent solvent.

In the case of copolymer A, the anilides of DL-phenylalanine and DL- phenylglycine were satisfactorily separated into their antipodes, whereas the resolutions of DL-1,2-diphenylethylamine and DL-valine anilide were rather poor. Only DL-phenylglycine anilide was resolved by copolymer B under similar conditions. Copolymer C, which is of interest because of its structure, with three adsorption centers per monomer unit, resolved DL-1,2-diphenylethylamine and DL-phenylalanine anilide with efficiencies next to those of copolymer A. The resolution ability was not examined extensively for this sorbent, since it was instable under acidic conditions. The results of the resolution of DL-phenylalanine anilide with copolymer A are given in detail in Table 2.

In order to investigate the dependence of the degree of optical resolution on the acid concentration of the eluent solvent, several resolutions of DL-valine anilide on copolymer A were carried out by changing the molarity of acetic acid from 0.1N to 0.001N (Table 3).

TBBLE 3. THE DEPENDENCE OF THE DEGREE OF OPTICAL RESOLUTION ON ACID CONCENTRATION OF THE ELUENT SOLVENT

Acid concentration	$[\alpha]_D(°)$	$[\alpha]_{Hg}(°)$	Optical purity (%)
0.1N	0	0	0
0.01N	−9	−13	13—15
0.001N	−15	−17	20—22

The data may be interpreted as follows. In the case of a low acid concentration, the racemate would be more strongly adsorbed on the surface of the sorbent, and hence one antipode would be more susceptible to influences from the asymmetric field of the sorbent than the other. A higher acid concentration would cause a more insufficient resolution.

It may be useful to discuss the interrelation between the substrate-sorbent and the degree of optical resolution on the basis of the results shown in Table I.

1) Roberts and Haigh[7] examined the partial resolution (22%) of DL-methionine on poly-[S-(ar-vinylbenzyl)-L-cysteine], a method which was employed on the basis of the assumption that the structual similarity between a substrate and the asymmetric site of a polymer must be a potent factor in efficient resolution.

Although a much higher resolution (52%) of DL-phenylalanine anilide on copolymer A seems to give an additional example of how their principle actually works in the adsorption process, the failure of the resolution (0%) of valine anilide on copolymer B suggests that some other factors also govern the resolution efficiency.

2*a*) Remarkable differences in optical purity are noticed between the resolved acetate of valine anilide and those of phenylalanine and phenylglycine anilides. These differences may be principally attributed to the difference in the bulkiness of the substituents on the asymmetric carbon atom of the molecule. The difference in the electronic characters of the substituents may also play a role.

2*b*) In comparing the data for the acetate of phenylglycine anilide with those for the acetate of 1,2-diphenylethylamine, it may be pointed out that the racemate involving the –CO·NH– group is much more efficiently resolved than is that having the $-CH_2-$ group in the corresponding moiety of the molecule. This is apparently due to the higher

adsorption suitability of the former group.

2*c*) The resolution ability of copolymer A with an asymmetric carbon atom carrying a benzyl group, is also higher than that of copolymer B which carries an isopropyl group, and which gave, at the highest of four examples, only a 0.7% resolution.

These results (2a—2c) are in accord with the general rules on asymmetric adsorption proposed by Krebs[13] and Dalgliesh,[14] both of whom studied sorbent polymers with some polysaccharides.

Experimental

The Syntheses of Optically Active Acidic Polymers. The optically active polymers were synthesized according to the method reported earlier.[1]

The Syntheses of the Acetates of α-Amino Acid Anilides. *N*-phthaloyl-α-amino acid anilides obtained by the ordinary method[15-17] were treated with hydrazine hydrate to give α-amino acid anilides.[15] When acetic acid was added to the ether solution of these anilides, white precipitates were formed. The recrystallization of the filtrated precipitates from ethanol or ethyl acetate gave the pure acetates of anilides. The specific rotations of these salts were determined in 0.1N-*aqueous* acetic acid.

The physical and analytical data of the several new racemates thus obtained are:

Acetate of DL-phenylalanine anilide. Mp 110—113°C. $[\alpha]_D = +93°$, $[\alpha]_{Hg} = +155°$ (*c* 1) in L-form. Found: C, 68.35; H, 6.89; N, 9.37%. Calcd for $C_{17}H_{20}N_2O_3$: C, 68.00; H, 6.66; N, 9.33%.

Acetate of DL-phenylglycine anilide. Mp 100—105°C. $[\alpha]_D = +133°$, $[\alpha]_{Hg} = +166°$ (*c* 0.56) in L-form. Found: C, 67.13; H, 6.35; N, 9.68%. Calcd for $C_{16}H_{18}N_2O_3$: C, 67.11; H, 6.34; N, 9.78%.

Acetate of DL-valine anilide. Mp 139—141°C. $[\alpha]_D = +74°$, $[\alpha]_{Hg} = +90°$ (*c* 1) in L-form. Found: C, 61.87; H, 8.06; N, 11.09%. Calcd for $C_{13}H_{20}N_2O_3$: C, 61.90; H, 7.93; N, 11.19%.

Acetate of DL-1,2-diphenylethylamine. Mp 125—130°C. $[\alpha]_D = -68°$, $[\alpha]_{Hg} = -83°$ (*c* 0.5) in L-form. Found: C, 74.91; H, 7.56; N, 5.88%. Calcd for $C_{16}H_{19}NO_2$: C, 74.68; H, 7.44; N, 5.44%.

Column Chromatography. An Example with Copolymer A. Copolymer A (80 g) suspended in a sufficient volume of *aqueous* acetic acid was poured into a column (2.5 cm in diameter; 150 cm in length; *ca.* 100 cm, the final length of the packed polymer).

Racemate (200—500 mg) dissolved in a suitable volume (*ca.* 10 m*l*) of *aqueous* acetic acid (0.1, 0.01, or 0.001N) was adsorbed on the upper zone of the sorbent and then eluted with the same solvent at room temperature. The flow rate of the solvent was *ca.* 6 m*l*/hr under atmospheric pressure. 8 m*l* portions of the eluent were collected automatically, and the concentration of the sample in each fraction was estimated by UV absorption by using a Hitachi EPS-2-spectrometer. 20—60 consecutive fractions were combined when the observed concentration was too low to determine the optical rotation. The optical rotation of the evaporated residue was determined in 0.1N *aqueous* acetic acid by a Rex-automatic polarimeter.

The chromatographic resolution of racemates on copolymers B and C were also carried out by a procedure similar to that described above.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1812—1816 (1970)

Chlorofluorination of Carbon Disulfide and Sulfur*1

Takashi ABE, Shunji NAGASE, Kazuo KODAIRA and Hajime BABA

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received November 24, 1969)

Chlorofluoromethanes and sulfur hexafluoride were obtained in good yields by the electrochemical fluorination of carbon disulfide in the presence of chlorine. The yields and compositions of the products were altered by the amount of chlorine fed in during electrolysis and also by the concentration of sulfur or carbon tetrachloride dissolved in carbon disulfide. Tetrafluoromethane, trifluoromethylsulfur pentafluoride, difluoromethylene bis-(sulfur pentafluoride), bistrifluoromethyl disulfide, and chlorodifluoromethylsulfur pentafluoride were also among the products. Further, the electrochemical fluorination of elementary sulfur was accomplished by the application of the technique of chlorofluorination, and sulfur hexafluoride was obtained in a reasonable yield. The chlorofluorinations of methyl sulfide and methyl disulfide were also attempted, but they afforded only chlorotrifluoromethane in poor yields.

Much attention has been paid to the fluorination of carbon disulfide with various fluorinating agents,[1] *e.g.*, fluorine, iodine pentafluoride, cobalt trifluoride and silver fluoride. The electrochemical fluorination of carbon disulfide has also been investigated by several workers.[2] On the other hand, the treatment of carbon disulfied with, *e.g.*, antimony pentachloride in the presence of hydrogen fluoride has been established to produce chlorofluoromethanes.[3]

In the present paper, we wish to report on the chlorofluorination of carbon disulfide and sulfur by the electrochemical process, which was found to proceed quite smoothly by a method similar to one described previously.[4]

We attempted initially to fluorinate the perchloroorganosulfur compounds, including trichloromethanesulfenyl chloride.*2 However, it was found that, upon electrochemical fluorination, these samples afforded mainly chlorofluoromethanes and sulfur hexafluoride as the cleaved products. This suggested the possible electrochemical fluorination of carbon disulfide in the presence of chlorine to obtain chlorofluoromethanes and sulfur hexafluoride. As expected, these products were obtained in good yields. In addition, their yields and compositions could be controlled satisfyingly by changing the chlorine feed rate and also by changing the composition of the substrate which was subjected to chlorofluorination.

An important feature of this halogenation is that chlorofluoromethanes and sulfur hexafluoride were simultaneously obtained in good yields from carbon disulfide. This process was applied successfully to the electrochemical fluorination of elementary sulfur. The fluorination of sulfur has previously been carried out with fluorine,[5] chlorine trifluoride,[6] and chlorine monofluoride.[7]

Results and Discussion

The electrochemical fluorination of perhalogenoorganosulfur compounds yielded, not the expected derivatives of sulfur hexafluoride, but the cleaved products, as is indicated in the following scheme:

As contrasted with the behavior of the carbon-oxygen double bond upon electrochemical fluorination, the carbon-sulfur double bond is easier to cleave. For example, phosgene afforded the trifluoromethyl hypofluorite in about a 7% yield,[8] but from thiophosgene, the corresponding product, trifluoromethylsulfur pentafluoride was obtained in only a 1% yield, and there was no trace of thiocarbonyl fluoride. It seems that the cleavage of the carbon - sulfur bond, especially in such compounds as perhalogenoorganosulfur derivatives, occurs extensively on electrochemical fluorination and that the yields of products which retain the carbon-sulfur bond are poor.

The reaction conditions for the chlorofluorination of carbon disulfide, and for that of carbon disulfide and sulfur, are presented in Tables 1 and 2 respectively.

The results obtained with carbon disulfide and those obtained with carbon disulfide and sulfur are summarized in Table 3.

While chlorine was being absorbed in carbon disulfide, the fluorination of the resulting chlorinated compounds as well as that of unchanged carbon disulfide led to the formation of chlorofluoromethanes and sulfur hexafluoride, together with trifluoromethylsulfur pentafluoride and difluoromethylene bis(sulfur pentafluoride).

Table 1. Conditions for the chlorofluorination of carbon disulfide

Anodic current density, 2.7 A/dm²; cell voltage, 6.5—7.5 V; cell temperature, 5—6°C; He, 45 ml/min; carbon disulfide containing catalytic amount of iodine (0.1% by wt), 0.2 mol

Run No.	Chlorine*a feed rate (ml/min)	Total amount of chlorine fed (mol)	Electricity passed (A·hr)
1	15	0.22	129
2	30	0.44	132
3*b	30	0.42	129
4	60	0.85	131
5*c			132

*a Gas volume is expressed in normal condition.
*b Sodium fluoride (10 g) was added.
*c Carbon tetrachloride (30.8 g) was added.

Under the reaction conditions applied, chlorofluoromethanes were obtained in the highest yield (33.9%) in Run 3, in which sulfur hexafluoride was produced in a 52.8% yield. The yield of sulfur hexafluoride is a little lower than that from the electrochemical fluorination of sulfur mono- or dichloride.[9] In Run 3, the addition of sodium fluoride can be considered to have an effect on the solubilities of the fluorinated products and to result in increased amounts of the products obtained. By increasing the molar ratios (chlorine to carbon disulfide) from approximately 1 to 2, the yield of chlorofluoromethanes is increased from 5.1 to 31.7%, but a further increase in the molar ratio has no effect on the yield.

The chlorofluorination proceeded also by the

*d The yield of sulfur hexafluoride={(the mole of sulfur hexafluoride)/(g·atom of sulfur consumed)}×100

*e The calculation of current efficiency was based on the amount of current assumed to be required to form fluorine with a discharging fluoride ion which would react with sulfur according to the following equation. $S+6F=SF_6$

non-electrochemical mechanism to a certain extent in anhydrous hydrogen fluoride. For example, without a passing current, chlorine was fed into anhydrous hydrogen fluoride containing carbon disulfide at the feed rate of 30 ml/min for 320 min (reaction conditions; CS_2 fed, 0.2 mol; total amount of Cl_2 fed, 0.43 mol; cell temp., 5—6°C); a product with the following composition (mol %) was obtained in a 40.4% yield of chlorofluoromethanes: chlorotrifluoromethane (2.0), dichlorodifluoromethane (82.0), trichlorofluoromethane (14.3), and bistrifluoromethyl disulfide (1.7).

It is interesting to note that bistrifluoromethyl disulfide was produced in these experiments. It has been reported that the fluorination of carbon disulfide with iodine pentafluoride led to the formation of bistrifluoromethyl disulfide in a good yield;[1c] however, in the present experiment, it was derived from the hydrolytic reaction of trifluoromethanesulfenyl chloride[10] in gas-washing bottles which is easy to produce, even without a passing current.

An increased amount of sulfur hexafluoride was obtained when carbon disulfide containing sulfur was subjected to chlorofluorination, and the yield of chlorofluoromethanes (in Runs 6 and 7) was reduced. Similarly, the co-fluorination of carbon disulfide and carbon tetrachloride yielded an increased amount of chlorofluoromethanes in Run 5, which might be considered to result in the chlorination of carbon disulfide by means of chlorine liberated from the carbon tetrachloride attacked by fluorine radical during electrolysis.

The electrochemical fluorination of elementary sulfur feeding chlorine yielded mainly sulfur hexafluoride, together with a trace of sulfur chloridepentafluoride. The conversion of sulfur hexafluoride, however, was low, and most of the starting material (finely powdered sulfur) was recovered in an aggregated state. The composition of the reaction product was nearly constant throughout the electrolysis. For example, the composition (mol%) of the products (direct analysis by G.C.) was as follows (in Run 9): SF_6 77.5, SO_2F_2 18.0, and $SClF_5$ 4.5. It is not clear why sulfuryl fluoride was detected in the above experiment.

The chlorofluorination of methyl sulfide and methyl disulfide was also conducted in a similar manner. The yields of chlorofluorinated compounds were, however, low, giving chlorotrifluoromethane only in yields of 0.6% and 1.1% respectively. In order to make this point clear, the fluorinations of chloromethyl sulfides were subsequently attempted. The instability of all chloromethyl sulfides, except one having a trichloromethyl group, when treated with antimony trifluoride has been reported.[14]

10) R. N. Haszeldine and J. M. Kidd, *J. Chem. Soc.*, **1955**, 2901.

In this electrochemical fluorination, similarly, α,α-dichloromethyl sulfide gave no appreciable quantities of the corresponding fluorinated products. When α,α-dichloromethyl sulfide was subjected to electrochemical fluorination (reaction conditions: sample, 0.2 mol; helium, 45 ml/min; anodic current density, 2.7 A/dm²; electricity passed, 99.2 A·hr; cell voltage, 6—7 V; cell temp., 5—6°C), the product consisted of chlorotrifluoromethane (8.6 mol %), dichlorodifluoromethane (1.3), chlorodifluoromethane (0.6), tetrafluoromethane (31.9), trifluoromethane (11.8), sulfur hexafluoride (13.6), trifluoromethylsulfur pentafluoride (26.9), bis(trifluoromethyl)sulfur tetrafluoride (4.4), pentafluoroethylsulfur pentafluoride (0.2), and hexafluoroethane (0.7). The yield of chlorofluoromethanes was 15.7%.

When α,α,α-trichloromethyl sulfide, which shows a facile halogen exchange with hydrogen fluoride, affording α,α,α-trifluoromethyl sulfide, was fluorinated under the conditions described above (electricity passed, 48.3 A·hr), the composition (mol%) of the product was as follows; chlorotrifluoromethane (1.9), dichlorodifluoromethane (2.5), tetrafluoromethane (23.6), trifluoromethane (4.6), sulfur hexafluoride (5.7), trifluoromethylsulfur pentafluoride (11.3), bis(trifluoromethyl)sulfur tetrafluoride (14.9), and α,α,α-trifluoromethyl sulfide (35.5). The yield of chlorofluoromethanes was 5.3%. Notably, bis(trifluoromethyl)sulfur tetrafluoride was obtained in better yields, 6.6% from α,α-dichloromethyl sulfide and 18.0% from α,α,α-trichloromethyl sulfide respectively, compared to the yield (3.8%) from dimethyl sulfide.

The results may suggest that, in the chlorofluorination of methyl sulfide, the fluorination takes place with a priority to chlorination, at least at the monochloro-form stage, before chlorination proceeds further.

Thus, carbon disulfide is chlorinated by chlorine in anhydrous hydrogen fluoride, affording trichloromethanesulfenyl chloride and sulfur mono- or dichloride. The former might then proceed further to carbon tetrachloride and sulfur mono- or dichloride, or to trifluoromethanesulfenyl chloride, as a result of the easy replacement of the chlorine of the trichloromethyl group in anhydrous hydrogen fluoride, then, upon the electrochemical fluorination of part of it, carbon - sulfur bond fission occurs to give tetrafluoromethane and sulfur hexafluoride.

Sulfur is considered to be converted into a divalent state (S_2Cl_2 or SCl_2) by chlorine in the cell; subsequent fluorination yields hexavalent sulfur (SF_6 and $SClF_5$).

Experimental

Materials. The carbon disulfide, sulfur (finely

powdered, guaranteed reagent), trichloromethanesulfonyl chloride, methyl sulfide, and methyl disulfide were purchased from commercial sources, while the trichloromethanesulfenyl chloride, thiophosgene,[11] thiophosgene dimer,[12] 2,2,4,4-tetrafluoro-1,3-dithietane,[13] α,α-dichloromethyl sulfide, and α,α,α-trichloromethyl sulfide[14] were synthesisted by the methods described in the literature.

All these chemicals except sulfur were purified by conventional methods; their purity was confirmed before use by gas chromatography using a Shimadzu GC - 1C model Chromatograph and by mass spectroscopy using a Hitachi Model RMU-7.

The purity of anhydrous hydrogen fluoride was better than 99%.

Apparatus. The electrochemical fluorination apparatus used was almost the same as that described in previous papers.[4,15] The cell capacity was 1 *l*. The nickel electrodes consisted of a pack of alternate anodes (8 sheets) and cathodes (7 sheets). The effective surface area of the anodes was 9.2 dm^2. For charging the liquid samples precisely, a so-called "sample injector" was devised. It was fastened on the top of the cell with a fluoroelastomer rubber stopper. It consisted of a small tube (inlet) [8 mm od. × 5 mm id. × 3 cm length; poly(tetrafluoroethylene) resin] connected with an even smaller tube (outlet) [2 mm od. × 1 mm id. × 50 cm length; poly(chlorotrifluoroethylene) resin] which was inserted into the cell so as to reach its bottom. The inlet of the tube was covered with a silicone rubber stopper. A weighed liquid sample was led into the cell through the sample injector. The sampling valve was fitted with the line next to a sodium fluoride pellet tube for the direct analysis by GC of the evolving gaseous products from the cell.

Trap-to-trap distillation was carried out by a vacuum line technique using a series of traps (100 m*l* capacity) which were a part of a low-temperature distillation unit.

IR spectrum measurements was accomplished with a Hitachi EPI-S2 recording spectrometer, using a 6-cm gas cell equipped with two NaCl windows.

Procedures. As a typical example, the procedures for the chlorofluorination of carbon disulfide containing sulfur (Run 6) will be described.

Sulfur (6.4 g) was dissolved in carbon disulfide (15.2 g) while being warmed slightly, and then 15 mg of iodine was added. This mixture was introduced into anhydrous hydrogen fluoride (1 *l*) which had been purified by electrolysis. The carbon disulfide solution and anhydrous hydrogen fluoride formed two layers. The lower layer (the carbon disulfide solution) covered the bubbler located at the bottom of the cell.

Then sodium fluoride (10 g) was added in anhydrous hydrogen fluoride, and chlorine (30 m*l*/min) diluted by helium (45 m*l*/min) was directed through the bubbler into the carbon disulfide layer; the electrolysis of the solution was then carried out with an anodic current density of 2.7 A/dm^2, at a cell voltage of 5.9—7.1 V, and with a cell temperature of 5—6°C. The electrolysis was conducted for 129 A·hr.

The gases evolved from the cell were passed through a reflux condenser kept at −30°C, and over sodium fluoride (hydrogen fluoride absorber), and then bubbled through an aqueous solution of sodium sulfite containing a small amount of potassium iodide in consecutive Ichinose gas washers in order to eliminate oxygen difluoride, chlorine, derivatives of sulfur tetrafluoride, and sulfur chloridepentafluoride, passed through a trap cooled in ice, and finally condensed in two consecutive traps immersed in liquid nitrogen.

At regular intervals, gas was sampled from the sampling valve and was analysed directly by gas chromatography (columns and conditions: Kel F 3*[5] 30% on Chromosorb PAW, 3 m, 0°C; FC 43*[5] 66% on Celite 545 SK, 6 m, 0°C: carrier gas; He).

The composition (peak area %) of the evolved gas was, for example, $CF_4+CClF_3+CHF_3$ (47), SF_6 (6), CF_3SF_5 (8), CCl_2F_2 (2), CF_3SCl (32), CS_2+CCl_3F (5) after 60 A·hr electrolysis.

The reaction products (47.7 g) condensed in the cold traps were carefully divided into five fractions by trap-to-trap distillation.

The subsequent identification and the analysis of individual species, was accomplished by gas chromatography (column: silica gel; carrier gas : He) and IR spectrum measurements, as has been described previously.[4,9]

On the Mechanism of the Vinyl Transetherification Reaction Catalyzed by Mercuric Acetate

Heimei YUKI, Koichi HATADA and Kazuhiko NAGATA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received November 26, 1969)

The vinyl interchange reaction of methyl vinyl ether and methanol, methanol-d_4, or ethanol catalyzed by mercuric acetate has been studied. Some organomercuric compounds have been isolated from the reaction mixture, and their catalytic activity for the interchange reaction has been examined. From these results, the mechanism proposed by Watanabe and Conlon (*J. Amer. Chem. Soc.*, **79**, 2828 (1957)) has been confirmed and further details of the reaction mechanism are discussed.

The vinyl transetherification catalyzed by mercuric salt is known to be of wide utility for the preparation of various vinyl ethers.

$$ROCH{=}CH_2 + R'OH \rightleftharpoons ROH + R'OCH{=}CH_2$$

In a previous work[1,2] we studied this transetherification reaction using methyl vinyl ether (MVE) as a starting vinyl ether and a mercuric acetate ($Hg(OAc)_2$) catalyst, and found that the reaction could be smoothly shifted toward the product by the selective absorption of the produced methanol on the molecular sieves. Although a probable mechanism of the reaction[3] has been proposed, sufficient evidence has not yet been obtained. In the present work we investigated the reaction of MVE and methanol, methanol-d_4, or ethanol in the presence of $Hg(OAc)_2$ to clarify the mechanism of the reaction.

Experimental

Materials. MVE was purified in a gas phase by being passed through a saturated aqueous solution of potassium hydroxide and a column packed with potassium hydroxide pellets successively; then it was collected over calcium hydride in a cold trap cooled at −78°C. It was subsequently distilled under reduced pressure and stored over lithium aluminum hydride. The MVE thus purified was redistilled under a vacuum just before use.

The methanol and ethanol were purified by refluxing them over calcium oxide and by subsequent distillation, and these were stored under a nitrogen atmosphere. The methanol-d_4 and mercuric acetate were commercially obtained and were used without further purification.

The 2-acetoxymercuri-1,1-dimethoxyethane was prepared from sodium methoxide, mercuric acetate, and methyl vinyl ether.[3] Mp 64.0—65.0°C.

Reaction of MVE and Alcohol in the Presence of $Hg(OAc)_2$. A two-necked flask, equipped with a special reflux condenser for low-boiling liquid[4] and a thermometer, was flushed with dry nitrogen and then charged with an equimolar mixture of MVE and the alcohol, and a mercuric acetate catalyst. The reaction was carried out at 30°C for 1 hr under a nitrogen atmosphere. The reaction mixture was then flash-distilled under a high vacuum, and the distillate was analyzed by gas-liquid chromatography or NMR spectroscopy. The remaining solid residue was recrystallized from ether and was identified by means of analyses.

In another experiment, the reaction mixture was treated with potassium carbonate before flash-distillation under a high vacuum.

Analytical Procedure. Gas-liquid chromatographic analysis was carried out using a Shimadzu Seisakusho gas-liquid chromatograph equipped with a column (2 m long, 4 mm I.D.) containing 30% dioctyl phthalate on Shimalite B (a kind of kieselguhr). The apparatus was operated at 80°C with a helium-carrier gas stream of 68 ml/min, while toluene was employed as the intensity standard for the determination of the product composition.

The NMR spectra were taken on a JNM-4H-100 spectrometer (JEOL) at 100 MHz in CCl_4 at 22.5°C. Tetramethylsilane was used as the internal reference.

The molecular weight was determined on a Mechrolab Vapor Pressure Osmometer (Model 310A) in carbon tetrachloride at 37.0°C.

Analysis for mercury was carried out by the decomposition of a sample with concentrated sulfuric acid and by subsequent titration with ammonium thiocyanate, according to the method of Hirai.[5]

Results

Reaction of MVE and Methanol or Methanol-d_4 in the Presence of $Hg(OAc)_2$. An equimolar reaction of MVE and methanol in the presence of $Hg(OAc)_2$ was carried out at 30°C for 1 hr under a nitrogen atmosphere. The vacuum distillation of the reaction mixture gave a recovery of 93% of the equimolar mixture of MVE and methanol, leaving a solid residue. The recrystallization of this residue from ether gave 2-acetoxymercuri-1,1-dimethoxy-ethane (I), which was identified by an NMR spectral comparison with an authentic sample. This identification was also supported by the measurements of its melting point and molecular weight, and by the results of an elementary analysis (Table 1).

When the reaction mixture was treated with potassium carbonate before vacuum distillation and the residue was extracted with diethyl ether, a viscous liquid with a high boiling temperature was obtained after the removal of ether from the extract. This compound was found by NMR spectroscopy to be bis-2,2-dimethoxyethylmercury (II) (Fig. 1). This structure was also established by the measurements of the molecular weight and by the results of an elementary analysis (Table 1).

In order to examine the catalytic activity of these two compounds for transetherification, equimolar reactions of MVE and methanol-d_4 were performed in the presence of these compounds at 30°C for 1 hr, and the reaction mixtures were analyzed by NMR spectroscopy. The NMR spectrum of the reaction mixture of MVE, methanol-d_4 and

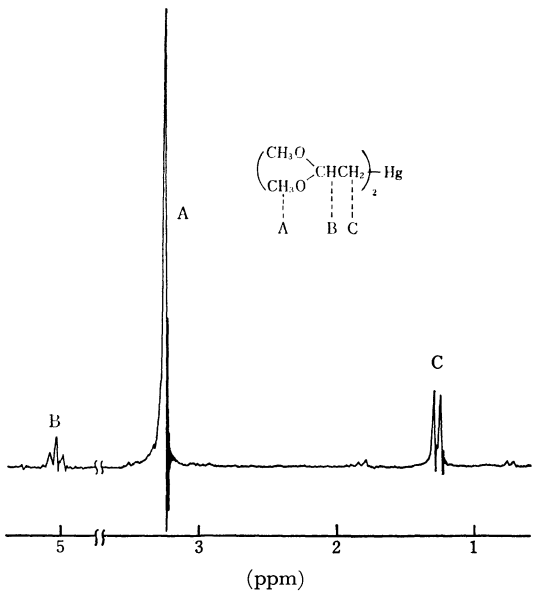

Fig. 1. NMR spectrum of bis-2,2-dimethoxyethylmercury. Intensity ratio of the signals: A : B : C=6.00 : 0.90 : 2.06.

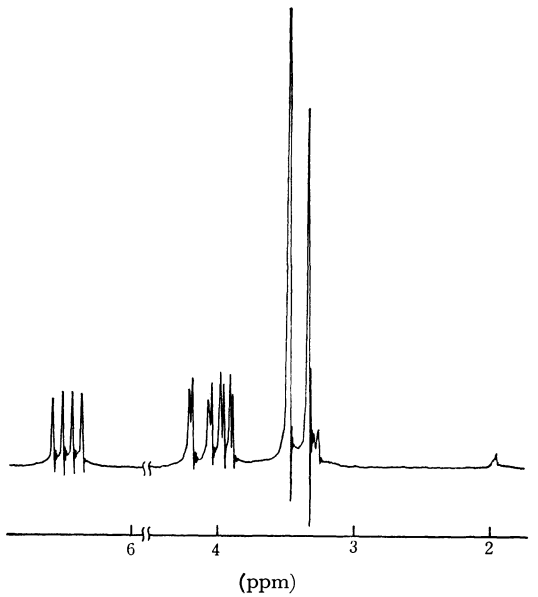

Fig. 2. NMR spectrum of the reaction mixture of MVE and methanol-d_4 in the presence of 2-acetoxymercuri-1,1-dimethoxyethane.

the compound I showed a sharp singlet

$$CH_3OCH=CH_2 + CD_3OD \rightleftharpoons CD_3OCH=CH_2 + CH_3OD$$

at 3.35 ppm due to the methyl protons of CH_3OD produced (Fig. 2). From the intensity ratio of this signal to the methoxy proton signal of MVE, the conversion of MVE to MVE-d_3 was calculated to be 44%. On the other hand, the compound II showed no catalytic activity in the interchange reaction. However, in the presence of a small amount of acetic acid, this compound catalyzed the reaction quite well and 50% of MVE-d_3 was produced.

Reaction of MVE and Ethanol in the Presence of $Hg(OAc)_2$. To prove that mercurial compounds such as I are formed in the interchange reaction of a combination of MVE and another alcohol, a mixture of 0.1 mol of MVE, 0.1 mol of ethanol, and 0.0016 mol of $Hg(OAc)_2$ was reacted at 30°C for 1 hr under a nitrogen atmosphere. From the reaction mixture the volatile component was then distilled off under a high vacuum. The residue was extracted with diethyl ether, the ether was then distilled off under a high vacuum. The NMR spectrum (Fig. 3) of the remaining liquid

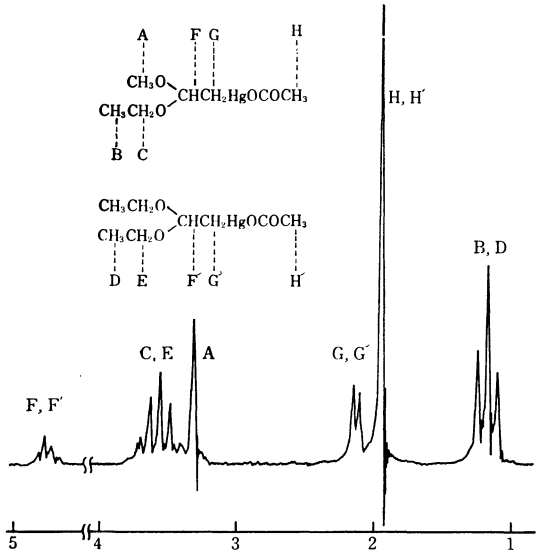

Fig. 3

with a high boiling temperature (0.6 g) shows that the product is a mixture of 2-acetoxymercuri-1-methoxy-1-ethoxyethane (III) and 2-acetoxymercuri-1,1-diethoxyethane (IV). The ratio of the compounds III and IV was roughly estimated to be 1 : 1 by the intensity measurement of the NMR signals.

When the reaction mixture was treated with potassium carbonate before vacuum distillation,

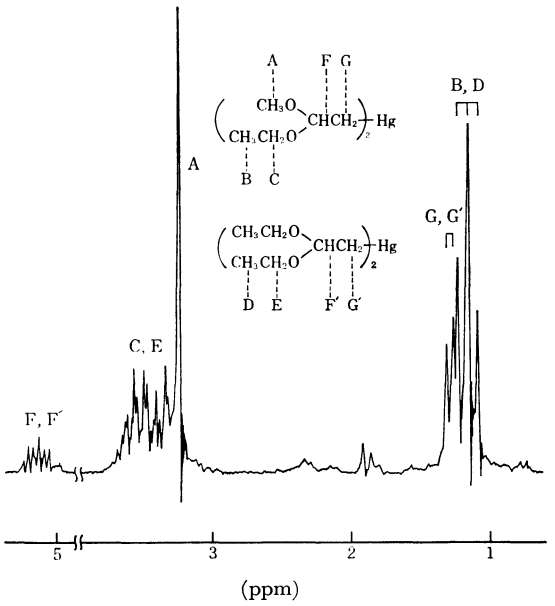

Fig. 4

0.6 g of a liquid with a high boiling temperature was also obtained. The NMR spectrum (Fig. 4) shows that the product formed is probably a mixture of bis-2-methoxy-2-ethoxyethylmercury (V), bis-2,2-diethoxyethylmercury (VI), and a small quantity of acetoxymercuric compounds.

Discussion

In 1957 Watanabe and Conlon[3] proposed a mechanism of the transetherification reaction on the basis of the fact that the 2-acetoxymercuri-1,1-diethoxyethane was decomposed readily by acetic acid to ethyl vinyl ether and ethyl alcohol. According to their proposal, the mechanism of the reaction starting with MVE can be illustrated as follows:

$$Hg(OAc)_2 \rightleftharpoons HgOAc^+ + AcO^-$$

$$HgOAc^+ + CH_3OCH=CH_2 + ROH \rightleftharpoons \underset{\text{A}}{\overset{CH_3O}{\underset{RO}{}}\!\!>\!CHCH_2HgOAc} + H^+$$

$$A + CH_3OCH=CH_2 + ROH \rightleftharpoons \underset{\text{B}}{\left(\overset{CH_3O}{\underset{RO}{}}\!\!>\!CH\text{-}CH_2\right)_2\!\!-Hg} + HOAc$$

$$\Downarrow$$

$$A + ROCH=CH_2 + CH_3OH$$

In the present work we have been able to isolate the intermediate A(R=CH_3) directly from an equilibrium mixture of MVE, methanol, and mercuric acetate; and we found this intermediate to be

catalytically active for the transetherification reaction of MVE and methanol-d_4. The intermediate B ($R=CH_3$), which was found to be catalytically inactive but become active in the presence of a small amount of acetic acid, was scarcely formed in the mixture. After the treatment of the equilibrium mixture with potassium carbonate, the intermediate A vanished and the intermediate B was formed. The formations of analogous intermediates were proved in the reaction of MVE and ethanol catalyzed by $Hg(OAc)_2$.

These results clearly confirm the mechanism proposed by Watanabe and Conlon. No direct evidence can be found for the existence of an intermediate of the type B in the reaction mixture. However, this must exist to a very small extent in equilibrium with other species. The addition of an excess of potassium carbonate to the reaction mixture causes the equilibrium to shift toward the intermediate B as a result of the salt formation with acetic acid; consequently, this inactivates the catalyst.

If a proton from the acetic acid attacks the oxygen atom of the CH_3O group in the intermediate B, the resulting oxonium ion decomposes to A and the desired vinyl ether, while the methanol is expelled. On the other hand, if the attack of a proton takes place on the oxygen atom of the RO group, the reaction proceeds to the left and the starting vinyl ether and alcohol are recovered. Therefore, it is expected that the larger the electron-repelling power of the R group, the greater the tendency for a proton attack to occur on the oxygen of the RO group and the less the tendency for the desired vinyl ether to be formed. The equilibrium constant of the transetherification reaction of MVE and alcohol (ROH) decreases in the order of; $R=C_2H_5>n\text{-}C_3H_7>i\text{-}C_3H_7>t\text{-}C_4H_9$.[2)]

$$CH_3OCH{=}CH_2 + ROH \overset{K}{\rightleftharpoons} ROCH{=}CH_2 + CH_3OH$$

This result exactly coincides with the above explanations and also supports the idea of the existence of the intermediate B.

The authors wish to express their thanks to Mr. K. Kajiyama for his help in the laboratory work and to Mrs. F. Yano for her clerical assistance in preparing the manuscript.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1820—1824 (1970)

Synthesis of Adamantane Derivatives. IX.[1] The Ritter Reaction of 1-Hydroxymethyladamantane with Acetonitrile

Tadashi SASAKI, Shoji EGUCHI, Takeshi TORU and Katsumi ITO

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received November 27, 1969)

The Ritter reactions of 1-hydroxymethyladamantane (**1**) and 3-homoadamantanol (**14**) with acetonitrile in concd. sulfuric acid were investigated. Two products, *N*-3-homoadamantyl acetamide (**2**) and *N*-1-adamantylmethyl acetamide (**3**) were isolated. Their total- and relative yields were determined in various reaction conditions by GLC analysis, indicating the facile conversion of *N*-3-homoadamantyl acetonitrilium cation (**12**) into *N*-1-adamantylmethyl acetonitrilium cation (**13**).

In contrast with numerous examples of the Ritter reactions of tertiary, secondary alcohols and their corresponding derivatives, there seem to be no reports concerning a similar reaction of aliphatic primary alcohols.[2] We wish to describe the results of the Ritter reaction of 1-hydroxymethyladamantane (**1**), regarded as one of the primary alcohols, and 3-homoadamantanol (**14**) in various conditions.

Stetter and his coworkers[3,4] have reported that both the Koch-Haaf carboxylation of **1** and the Demjanov reaction of 1-aminomethyladamantane afford the ring-expanded homoadamantyl derivatives at the sacrifice of the strain-free ring structure. On the contrary, the ring-contraction of homoadamantane to the strain-free adamantane ring system has also been described in the reaction of 3-homoadamantanol with hydrogen halide in acetic acid at 150°C to 1-hydroxymethyladamantane, though the simple bridgehead substitutions have been accomplished under the milder reaction conditions or with some other reagents, in the maintenance of the skeletal integrity of homoadamantane ring.[4] This delicate change in the reaction products might be effected by the presence of equilibrium between the primary adamantylcarbinyl cation and the tertiary homoadamantyl cation under the given reaction conditions. These problems in the solvolytic conditions have been extensively studied by Nordlander and Schleyer.[5] The Ritter reaction of **1** might provide a new synthetic method for *N*-3-homoadamantyl amide derivatives if the corresponding nitrilium cations are stable in the reaction conditions.

Results and Discussion

The Ritter reaction of **1** with acetonitrile in concd. sulfuric acid proceeded smoothly. However, the ring-expanded *N*-3-homoadamantyl acetamide **2** was produced only in low yields and the major product was *N*-1-adamantylmethyl acetamide **3**. The total yields and relative yields of the two prodcuts were dependent on reaction temperature and time (see Table 1).

$$\mathbf{1} \longrightarrow \mathbf{2} + \mathbf{3}$$

Product Analysis. The crude amide product obtained by the reaction of **1** with acetonitrile in sulfuric acid, followed by hydrolysis was purified on a silica-gel column to afford two kinds of crystalline amides, mp 138—139°C and 126—127°C to which the structures **2** and **3** were assigned respectively based on the following data. Both compounds gave satisfactory analytical results as that of $C_{13}H_{21}ON$. The IR absorption bands at 3330 (NH), 1640 (amide-I) and 1570 (amide-II) cm^{-1} for **2**, and 3300 (NH), 1640 (amide-I) and 1570 (amide-II) cm^{-1} for **3** indicate both compounds to be secondary amides. In the NMR spectrum of **2**, a signal assignable to methyl protons of acetamide moiety appeared at τ 8.05 superimposed to those of homoadamantane ring protons. However, in the NMR spectrum of **3**, a signal assignable to $N-CH_2-$ protons appeared at τ 6.97 (2H) in a doublet with $J=6.75$ Hz and also the typical signals at τ 7.95, 8.22, and 8.41 due to 1-adamantyl ring protons besides that of $-NHCOCH_3$ protons at τ 7.93. The structures of **2** and **3** were further verified by comparison with specimens prepared by the following reaction sequences, **2** *via* 3-homoadamantylamine **7**[6] and **3** *via* 1-adamantylmethylamine **9**:[4]

Equilibrium Problem. As summarized in Table 1, the total and relative yields of **2** and **3** were much influenced by the reaction time and temperature even in the presence of excess acetonitriles. From these data, it can be concluded that with the prolonged reaction time, the total yields of amides increase but the relative amounts of **2** to **3** decrease rapidly. This tendency was also observed at 50°C and the total and relative yields at both temperatures reached approximately constant values after 12 and 5 hr respectively.

Formation of **2** and **3** could be visualized as shown in Chart I: the practical isolation of **2** and **3** indicates the formation of nitrilium cations **12** and **13**. However, there are two possibilities that **12** and **13** can be produced by the addition of acetonitrile to the corresponding carbonium ions, 1-adamantylcarbinyl- and 3-homoadamantyl cations respectively, which are derivable from **1** *via* **10**, and/or **12** and **13** by addition of acetonitrile to a bridged- or nonclassical cation. This was recently demonstrated to be an intermediate in solvolytic rearrangements of 1-adamantylcarbinyl tosylate and 3-homoadamantyl bromide.[5b] Nonclassical form (**11**) is tentatively depicted in Chart 1. Our results indicate that the *N*-3-homoadamantyl acetonitrilium cation **12** is a kinetically controlled product and is converted gradually to the more stable *N*-1-admantylmethyl acetonitrilium cation **13**. The relative stability between 1-adamantylcarbinyl- and 3-homoadamantyl derivatives seems to be very much dependent on the substituents.[7] In the Ritter reaction, the ring strain of **12** could not be compensated by the stabilizing effect of the tertiary carbon.

Another aspect of this Ritter reaction is manifested by the lower yields of the amides compared to higher yields of those for the typical tertiary adamantyl bromide in similar reaction conditions.[2c] The reaction of 3-homoadamantanol **14** as the tertiary alcohol with excess acetonitrile in sulfuric acid was examined, the results of which are summarized in Table 2. Obviously, under the same conditions, **14**→**2**+**3**, higher total yields than those in the reaction of **1** were obtained, indicating the formation of the carbonium ion from **14** was more facile than from **1**.

Table 2. Reaction of **14** with acetonitrile in sulfuric acid*

* A mixture of **14** (1.2 mmol) and acetonitrile (76.5 mmol) was added to stirred sulfuric acid (1.5 m*l*).

Effects of Addition of Other Lewis Acids. The results of the Ritter reactions of **1** and **14** in the presence of aluminum trichloride and/or boron trifluoride etherate in concd. sulfuric acid are summarized in Tables 3, 4 and 5. In the reaction of **1** using sulfuric acid-aluminum trichloride system, the relative yield of **2** to **3** was much higher than those in sulfuric acid after 24 hr.

It required about 4 days to obtain an approximately constant yield. The total and relative yields of amides were almost similar to those in sulfuric acid (Table 1). These results could be explained by weaker reactivity of the catalyst-system in which an acidic calcide like aluminum sulfate might be produced.[8] Such supression of

Table 5. Reaction of **14** with acetonitrile in aluminum trichloride - sulfuric acid and boron trifluoride etherate - sulfuric acid at room temperature (*ca.* 15°C)

Catalyst system	React. time hr	Total yields of amides %	Relative yields of **2** and **3**	
			2,%	**3**,%
$AlCl_3$(0.6 g)-H_2SO_4(1.5 m*l*)	24	72	31	69
BF_3 etherate (1.5 m*l*)-H_2SO_4 (1.5 m*l*)	24	76	3	97

* A mixture of **14** (1.2 mmol) and acetonitrile (76.5 mmol) was added to the respective catalyst-system with stirring.

the rearrangement of **12** to **13** is interesting from the view point of preparation. The effects of addition of boron trifluoride etherate were different from those of the above system. The total yields were similarly as low as 24% after 24 hr at room temperature, but an extreme inclination of the products to **3** was observed. A mixture of boron trifluoride - sulfuric acid known as an effective mixed catalyst system for the Friedel-Crafts alkylation seems to have an ionized form.[8] Therefore, the observed rapid establishment of the equilibrium could be ascribed to the increased dielectric property of the reaction system. Similar effects of addition of aluminum trichloride and boron trifluoride etherate were observed in the reactions of **14** (Table 5).

The reaction of **1** with acetonitrile in sulfuric acid-acetic acid afforded 1-adamantylcarbinyl acetate (52%), **2** (9%) and **3** (trace), but no trace of 3-homoadamantyl acetate could be detected by GLC analysis.

Other fuctionalized 1-adamantylmethyl systems like tosylate and bromide were stable in acetonitrile - sulfuric acid at room temperature, indicating the lower reactivity of adamantylcarbinyl system than that of 1-adamantyl system[2c] in the Ritter reactions.

It should be mentioned that the Ritter reactions of **1** and **14** with acetonitrile afford both *N*-3-homoadamantyl acetamide (**2**) and *N*-1-adamantylmethyl acetamide (**3**) in contrast with the Koch-Haaf carboxylation of **1**, in which the exclusive formation of 3-homoadamantanecarboxylic acid is known,[3] even though both reactions are performed in sulfuric acid. Interesting effects of aluminum trichloride for the Ritter reaction were observed, in which the kinetically controlled product **2** was obtained in 21—23% yields compared to *ca.* 10% yields in the reactions without aluminum trichloride.

Experimental

Melting points were determined on a Yanagimoto micro-melting point apparatus (hot-stage type) and are uncorrected. NMR spectra were determined on a JEOLCO MINMAR spectrometer at 60 MHz using TMS as an internal standard and infrared spectra, on a JASCO Model IR-S infrared spectrophotometer. GLC analysis was carried out on a Yanagimoto Gas Chromatograph Model GCG-220 and a Hitachi Gas Chromatograph Model K-23 using 2 m column packed with Apiezon-L and/or Silicone SE-30. Percentage composition of the products was estimated by relative peak area (uncorrected). For microanalyses a Yanagimoto Automatic C.H.N. Corder Model MT-1 was used.

General Procedure for the Ritter Reactions. A mixture of 1-adamantylmethyl alcohol **1**[3] (0.2 g, 1.2 mmol) and/or 3-homoadamantanol **14**[5a] (0.2 g, 1.2 mmol) and acetonitrile (4 m*l*, 76.5 mmol) was added slowly to stirred concd. sulfuric acid (sp. gr., *ca.* 1.84, 1.5 m*l*). After stirring was continued for an appropriate time, the reaction mixture was poured onto ice-water (*ca.* 300 g) and the resulting mixture was neutralized with 10% aqueous sodium hydroxide, extracted with ether (100 m*l*×4) and the ether extracts were washed with water (100 m*l*×2) and dried (Na_2SO_4). Removal of the solvent afforded crude amides as a mixture of **2** and **3**. The crude products were analyzed by GLC. The results are summarized in Tables 1—4.

Isolation of 3-Homoadamantyl Acetamide (2) and *N*-1-Adamantylmethyl Acetamide (3). Crude amides obtained from the reactions of **1** (0.5 g, 3.0 mmol) with acetonitrile (10 m*l*, 191 mmol) in concd. sulfuric acid (3.5 g) at room temperature (*ca.* 15°C) for 40 hr, were purified on a silica-gel (Mallinckrodt, 100 mesh) column eluting with chloroform. From the first fractions, 45 mg (7.7%) of **2** was obtained as colorless crystals, mp 138—139°C (*n*-hexane - acetone).

Found: C, 75.38; H, 9.95; N, 6.65%. Calcd for $C_{12}H_{21}NO$: C, 75.31; H, 10.21; N, 6.76%.

From the second fractions, 215 mg (36.7%) of **3** was obtained as colorless crystals, mp 126—127°C (*n*-hexane - acetone).

Found: C, 75.61; H, 10.51; N, 6.78%. Calcd for $C_{12}H_{21}NO$: C, 75.31; H, 10.21; N, 6.76%.

Both **2** and **3** were identified by mixed-melting points determination and by the complete superposition of their IR spectra on those of authentic samples.

Preparation of 3-Homoadamantylamine (7). Preparation of this amine has been described in a Patent[6] *via* 3-homoadamantyl isocyanate (**6**) by using the Hofmann reaction of 3-homoadamantylcarboxamide. We prepared the amine similarly *via* **6**, though **6** was

prepared by the Curtius reaction of 3-homoadamantylcarbonyl azide **5**, since the Hofmann reaction caused considerable side reactions lowering the yield of **7** in our experiments. A solution of sodium azide (5.5 g, 0.085 mol) in 14 m*l* of water was added to a stirred ice-cooled solution of 3-homoadamantylcarbonyl chloride[9] prepared from 1.7 g (8.75 mmol) of 3-homoadamantylcarboxylic acid **4** and thionyl chloride. After stirring was continued overnight at room temperature, the mixture was diluted with water and extracted with ether (100 m*l*×3). The combined ether extracts were washed with water (30 m*l*×2) and dried (Na_2SO_4), which gave crude azide **5** (1.7 g) as an oil after removal of the solvent under reduced pressure. **5** had strong IR absorption bands at 2150 ($-N_3$) and 1705 (C=O) cm^{-1}, and it was directly decomposed by heating under reflux in 50 m*l* of dry benzene for 2 hr. Removal of the solvent afforded 1.4 g (95%) of **6** as colorless crystals, mp 150—152°C (lit,[6] 144—146°C), which had strong IR absorption at 2280 (-N=C=O) cm^{-1}.

A mixture of 1.15 g (6.0 mmol) of **6**, 10 m*l* of dioxane and 20 m*l* of 2N hydrochloric acid was heated under reflux overnight. The cooled reaction mixture was made alkaline with 10% aqueous sodium hydroxide and extracted with ether. The work-up gave colorless crystals of **7** (0.9 g, 91%), mp 193—194°C (lit,[6] 191—193°C).

Acetylation of *N*-3-Homoadamantylamine (7). A mixture of **7** (0.2 g, 1.21 mmol), dry pyridine (2 m*l*) and acetic anhydride (0.2 g, 1.96 mmol) was stirred at room temperature overnight. Addition of water resulted in the precipitation of crystals of **2**, which were filtered and recrystallized from *n*-hexane to give 0.2 g (80%) of pure **2**, mp 138—139°C.

Preparation of *N*-1-Adamantylmethyl Acetamide (3). This was prepared similarly as above by acetylation of 1-adamantylmethylamine[4] with acetic anhydride in pyridine as colorless crystals, mp 126—127°C (*n*-hexane) in 70% yield.

The Ritter Reaction of 1 with Acetonitrile in Sulfuric Acid - Acetic Acid. A mixture of **1** (0.2 g, 1.2 mmol) and acetonitrile (4 m*l*, 76.5 mmol) was added to a stirred mixture of acetic acid (1.5 m*l*) and sulfuric acid (1.5 m*l*). The mixture was stirred for 48 hr at room temperature (*ca.* 15°C) and the work-up product was analyzed on GLC. For the analysis authentic specimens of 1-adamantylcarbinyl acetate and 3-homoadamantyl acetate[5a] were used.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1824—1828 (1970)

The Rearrangement of Chromanone Oximes with Lithium Aluminum Hydride

Shoei Ito[1]

College of General Education, Tohoku University, Kawauchi, Sendai

(Received November 28, 1969)

The lithium aluminum hydride reduction of 7-methoxychromanone oxime (I) and 7-methoxy-3-methylchromamone oxime (II) gave only the rearrangement product (the 2,3,4,5-tetrahydro-1,5-benzoxazepine derivative). 7-Methoxy-2-methylchromanone oxime (III) and 7-methoxy-2-isopropylchromanone oxime (IV) gave a mixture of the rearrangement product (secondary amine) and the normal reduction product (primary amine). 7-Methoxy-2-*t*-butylchromanone oxime (V) gave only the normal reduction product. The main conclusions to be drawn from these results are as follows: (1) The chromanone oximes without a C_2 substituent give only the rearrangement product. (2) The chromanone oximes with a C_2 substituent give a mixture of the normal reduction product and the rearrangement product. (3) The more bulky substituent at C_2 gives the more normal reduction product and the smaller quantity of the rearrangement product.

The reduction of ketoximes and aldoximes with lithium aluminum hydride has been reported, in numerous instances, to give the corresponding primary amine.[2] However, in the reduction of certain arylketoximes[3] and aldoximes[4], the pri-

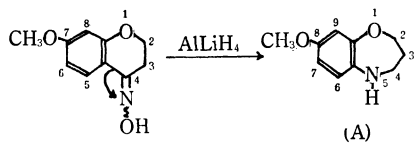
mary amine was accompanied by an isomeric secondary amine which was produced by the migration of the aryl group. It has also been reported that the addition of aluminum chloride to lithium aluminum hydride increased the yield of the secondary amine.[3]

In most of the systems investigated, the secondary amine has been a minor product of the reduction, but in special cases of highly-substituted arylketoximes where the aryl group is part of the phenoxazine ring system, the exclusive product has been the secondary amine.[5]

In the reduction of tetramethylbenzocyclobutenone oxime with lithium aluminum hydride, the sole product is the secondary amine, and the primary amine has not been detected.[6] The lithium aluminum hydride reduction of tetramethylcyclobutenone oxime gave only the rearrangement product,[7] while the same reaction of cyclopentanone oxime gave the primary amine accompanied by the secondary amine.[3] Recently it has been reported that the reduction of benzylketoximes with lithium aluminum hydride in refluxing tetrahydrofuran gave the aziridine derivatives, together with primary amine.[8]

Inoue and his co-workers reported the rearrangement in the reduction of isoflavanone oximes with lithium aluminum hydride.[9] The reduction of isoflavanone oxime, 7-methoxyisoflavanone oxime, and 7,4′-dimethoxyisoflavanone oxime with lithium aluminum hydride in refluxing ether afforded the corresponding tetrahydro-1,5-benzoxazepine derivatives. The same reaction of flavanone oximes gave no rearrangement product, but only the normal reduction product (4-aminoflavan).

From these results it was considered that the position (C_2 or C_3) and the size of a substituent in the chromanone oxime may exert a remarkable influence on the reaction between the chromanone oximes, with or without a C_2 or C_3 alkyl substituent, and lithium aluminum hydride.



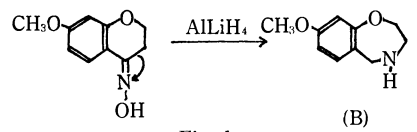


Fig. 1

The reaction of 7-methoxychromanone oxime (I) and 7-methoxy-3-methylchromanone oxime (II) with lithium aluminum hydride in refluxing ether and subsequent treatment with hydrochloric acid gave the amine hydrochlorides, X (mp 208—209°C) and XI (mp 182—183°C) respectively.

In both cases no by-product was found, and the X and XI were not identical with the 7-methoxy-4-aminochroman hydrochloride VI (mp 206—207°C) and the 7-methoxy-3-methyl-4-aminochroman hydrochloride VII (mp 205—206°C) which were obtained by the catalytic hydrogenation of I and II respectively.

The same reaction of 7-methoxy-2-methylchromanone oxime (III) gave two amine hydrochlorides, XII (mp 214—215°C) and VIII (mp 204—205°C). 7-Methoxy-2-isopropyl chromanone oxime (IV) also gave two amine hydrochlorides, XIII (mp 161—163°C) and IX (mp 196—197°C), by the same reaction. The VIII and IX were found to be identical with the 7-methoxy-2-methyl-4-aminochroman hydrochloride which were obtained by the catalytic hydrogenation of III and IV respectively.

The lithium aluminum hydride reduction of 7-methoxy-2-*t*-butylchromanone oxime (V) and subsequent treatment with hydrochloric acid gave only amine hydrochloride with a mp of 230—231°C (XIV); this was identical with the hydrochloride of the catalytic hydrogenation product of V.

The infrared spectra of X,XI, XII, and XIII all show a broad band at 3000—2400 cm^{-1} which is a characteristic absorption of secondary amine hydrochloride (ν^{+}_{NH}). On the other hand, the infrared spectra of VI, VII, VIII, IX, and XIV all show a broad band of $\nu^{+}_{NH_2}$ (primary amine salt) at 3200—2700 cm^{-1}.

The treatment of X, XI, XII, and XIII with acetic anhydride and pyridine gave acetamido derivatives, XV (mp 98—100°C), XVI (bp 160°C/2mmHg), XVII (mp 106—107°C), and XVIII (mp 95—96°C) respectively. The infrared spectra of XV, XVI, XVII, and XVIII all showed a characteristic band at 1660 cm^{-1} (ν_{CO} of CH_3CON) and no band of ν_{NH}.

The same treatment of the 4-aminochroman hydrochlorides, VI, VII, VIII, IX, and XIV, gave acetamido derivatives, XIX (mp 170—171°C), XX (mp 150—151°C), XXI (mp 184—185°C), XXII (mp 151—152°C), and XXIII (mp 177—178°C) respectively. The infrared spectra of XIX, XX, XXI, XXII, and XXIII all showed absorption bands of 3260 cm^{-1} (ν_{NH}) and 1640 cm^{-1} (ν_{CO}).

A comparison of the infrared spectra of these two series of acetamido derivatives shows that X, XI, XII, and XIII are secondary amine hydrochlorides.

The molecular weights of XV, XVI, XVII, and

Table 1. pK_a values of tetrahydrobenzoxazepines and 4-aminochromans

Compound (a)	pK_a	Compound (b)	pK_a
VI	8.62	X	5.05
VII	8.60	XI	5.05
VIII	8.65	XII	5.10
IX	8.60	XIII	5.35
XIV	8.55		

(a) Determined by UV method using Britton-Robinson's buffer solution.[12]
(b) Determined by titration using 1/100 N NaOH solution.

XVIII, as observed by mass spectrometry, were the same as those of XIX, XX, XXI, and XXII respectively.[10]

Accordingly, it may be considered that the X, XI, XII, and XIII compounds possess an A- or B-type structure which is derived by the ring enlargement of the chroman ring involving the migration of the phenyl group (A) or C_3 (B) to the nitrogen atom of the oximino group. (Fig. 1)

Since A is a monoalkylaniline derivative and B is a benzylamine derivative, there must be a remarkable difference between their pK_a values. The pK_a values of X, XI, XII, and XIII are shown in Table 1, along with those of the 4-aminochroman hydrochlorides, VI, VII, VIII, IX, and XIV.

From the data shown in Table 2 it may reasonably be concluded that the free amines of X, XI, XII, and XIII possess the A-type structure, which is a derivative of tetrahydrobenzoxazepine.

The summarized results of the lithium aluminum hydride reduction of the chromanone oximes are shown in Table 2. The reduction of flavanone oximes (2-phenylchromanone oximes) with lithium aluminum hydride gave only the corresponding 4-aminoflavans, not the rearrangement product (the secondary amine). On the other hand, the same reaction of isoflavanone oximes (3-phenylchromanone oximes) gave the rerrangement products, exclusively, not the corresponding 4-aminoisoflavan.[9]

As is shown in Table 1, 7-methoxychromanone oxime (I) and 7-methoxy-3-methylchromanone oxime (II) give the rearrangement products exclusively.

It is clear that the substituent on C_2 or C_3 exerts a remarkable influence on the yield of the rearrangement product in this reaction.

7-Methoxy-2-methylchromanone oxime (III) gives the rearrangement product in a 50% yield and the 4-amino compound in a 10% yield. 7-Methoxy-2-isopropylchromanone oxime (IV) gives the rerrangement product in a 35% yield and the 4-amino compound in a 50% yield. 7-Methoxy-2-*t*-butylchromanone oxime (V) does not give the rearrangement product, but only the corresponding 4-amino compound.

Thus, it is evident that the more bulky substituent at C_2 gives the more normal reduction product (4-aminochroman) and the smaller quantity of the rearrangement product. The chromanone oxime with a substituent at C_3 and the unsubstituted chromanone oxime give only the rearrangement product and no 4-aminochroman derivative.

The mechanism involved in the rearrangement reaction of chromanone oxime with lithium aluminum hydride will be reported by Kitahara and his co-workers in the near future.

Experimental

All the melting points are uncorrected. The infrared spectra were recorded with a Hitachi EPI-510 infrared spectrophotometer.

7-Methoxychromanone Oxime (I), 7-Methoxy-3-methylchromanone Oxime (II), 7-Methoxy-2-methylchromanone Oxime (III), 7-Methoxy-2-isopropylchromanone Oxime (IV), and 7-Methoxy-2-*t*-butylchromanone Oxime (V). *General Procedure.* The chromanone (1 g)[11] was refluxed for 10 hr with hydroxylamine hydrochloride (1 g), anhydrous ethanol (10 ml), and pyridine (10 ml). After cooling, the reaction mixture was poured into water; the precipitate was then recrystallized from dilute ethanol to give the

7-Methoxy-4-aminochroman Hydrochloride (VI), 7-Methoxy-3-methyl-4-aminochroman Hydrochloride (VII), 7-Methoxy-2-methyl-4-aminochroman Hydrochloride (VIII), 7-Methoxy-2-isopropyl-4-aminochroman Hydrochloride (IX), and 7-Methoxy-2-*t*-butyl-4-aminochroman Hydrochloride (XIV). *General Procedure.* The oxime (1 g) in acetic acid (50 m*l*) containing 0.5 m*l* of 70% perchloric acid was hydrogenated by the usual manner at ordinary pressure and temperature in the presence of 1 g of 5% palladium on carbon.[13] The catalyst was then filtered off, and the acetic acid solution was concentrated under reduced pressure. To the residue, 6N hydrochloric acid was added to give crystals, which were then recrystallized from a suitable solvent. All the experimental results are summarized in Table 4.

By the usual method, the hydrochloride was acetylated with acetic anhydride in the presence of pyridine. The analytical data of these acetamido derivatives and their melting points are reported in Table 5.

Reduction of 7-Methoxychromanone Oxime (I) with Lithium Aluminum Hydride. To a swirling suspension of 1.9 g of lithium aluminum hydride in 100 m*l* of ether, there was added, drop by drop and at room temperature, a solution of 1.9 g of I in 150 m*l* of ether. After it had been refluxed for 24 hr, the reaction mixture was decomposed with water under cooling with ice. The ether layer was washed with 1N sodium hydroxide and water, and then dried over anhydrous sodium sulfate. After the removal of the solvent, 6N hydrochloric acid was added to give 1.4 g of crude crystals (90% yield). Recrystallization from ethanol gave 0.9 g of 8-methoxy-2,3,4,5-tetrahydro-1,5-benzoxazepine hydrochloride (X); mp 208—210°C. ν_{NH}^{+} 3000—2400 cm^{-1}.

Found: C, 55.43; H, 6.28; N, 6.38%. Calcd for $C_{10}H_{14}O_2NCl$: C, 55.60; H, 6.55; N, 6.49%.

By the usual method, the hydrochloride (X) was acetylated with pyridine-acetic anhydride to give a viscous liquid; bp 160—180°C/2 mmHg. On standing at room temperature the liquid gradually deposited crystals of an amide; mp 98—100°C. ν_{COCH_3} 1660 cm^{-1}.

Found: C, 64.63; H, 6.51; N, 5.93%. Calcd for $C_{12}H_{15}O_3N$: C, 65.14; H, 6.83; N, 6.33%.

Reduction of 7-Methoxy-3-methylchromanone Oxime (II) with Lithium Aluminum Hydride. A solution of 1 g of II in 100 m*l* of ether was added, drop by drop and at room temperature, to a swirling suspension of lithium aluminum hydride in 80 m*l* of ether. After it had been allowed to reflux for 24 hr, the reaction mixture was decomposed with water under cooling with ice. The layer was washed with 1N sodium

13) Five percent palladium on carbon, obtained from the Kawakami Research Institute, was used in the experimental.

hydroxide and water, and then dried over sodium sulfate. After the removal of the ether, 6N hydrochloric acid was added to give a solid (870 mg, 85% yield). Recrystallization from chloroform-benzene gave 500 mg of 8-methoxy-3-methyl-2,3,4,5-tetrahydro-1,5-benzoxazepine hydrochloride (XI); mp 182—183°C. ν^{+}_{NH} 3000—2400 cm^{-1}.

Found: C, 57.67; H, 7.01; N, 6.10%. Calcd for $C_{11}H_{16}O_2NCl$: C, 57.45; H, 7.04; N, 6.09%.

By the usual method, the hydrochloride (XI) was acetylated with pyridine-acetic anhydride to give a liquid; bp 160—180°C/2 mmHg. ν_{COCH_3} 1660 cm^{-1}.

Found: C, 66.02; H, 6.95; N, 5.65%. Calcd for $C_{13}H_{17}O_3N$: C, 66.36; H, 7.28; N, 5.95%.

Reduction of 7-Methoxy-2-methylchromanone Oxime (III) with Lithium Aluminum Hydride. A solution of III in 130 m*l* of ether was added, drop by drop and at room temperature, to a swirling suspension of 1 g of lithium aluminum hydride in 130 m*l* of ether. After it had been refluxed for 24 hr, the reaction mixture was decomposed with water under cooling with ice. The ether layer was washed with 1N sodium hydroxide and water, and then dried over anhydrous sodium sulfate. After the removal of the solvent, 6N hydrochloric acid was added; it was then allowed to stand overnight at room temperature, and the solid which separated (530 mg, 50%) was recrystallized from ethanol to give 400 mg of 8-methoxy-2-methyl-2,3,4,5-tetrahydro-1,5-benzoxazepine hydrochloride (XII); mp 214—215°C, ν^{+}_{NH} 3000—2400 cm^{-1}.

Found: C, 57.20; H, 7.25; N, 6.05%. Calcd for $C_{11}H_{16}O_2NCl$: C, 57.45; H, 7.04; N, 6.09%.

The filtrate was allowed to stand overnight under cooling with ice; the solid which thus separated (110 mg, 10%) was identical with 7-methoxy-2-methyl-4-aminochroman hydrochloride (VIII).

By the usual method, the hydrochloride (XII) was acetylated with pyridine-acetic anhydride; this gave crystals which were then recrystallized from benzene-petroleum ether to give an amide; mp 106—107°C, ν_{COCH_3} 1660 cm^{-1}.

Found: C, 66.58; H, 7.21; N, 5.72%. Calcd for $C_{13}H_{17}O_3N$: C, 66.36; H, 7.28; N, 5.95%.

Reduction of 7-Methoxy-2-isopropylchromanone Oxime (IV) with Lithium Aluminum Hydride. To a swirling suspension of 2 g of lithium aluminum hydride in 100 m*l* of ether, there was added, drop by drop at room temperature, a solution of 2 g of IV in 150 m*l* of ether. The reaction mixture was then treated as above. After the removal of the solvent, 6N hydrochloric acid was added; the solution was subsequently allowed to stand overnight at room temperature. The solid which separated (1.03 g, 50%) was filtered and recrystallized from chloroform to give colorless crystals which were identical with 7-methoxy-2-isopropyl-4-aminochroman hydrochloride (IX). After filtrate had been allowed to stand overnight under cooling with ice, the solid which separated (720 mg, 35%) was filtered and recrystallized from ethyl acetate to give 8-methoxy-2-isopropyl-2,3,4,5-tetrahydro-1,5-benzoxazepine hydrochloride (XIII); mp 161—163°C, ν^{+}_{NH} 3000—2400 cm^{-1}.

Found: C, 61.65; H, 8.02; N, 5.05%. Calcd for $C_{14}H_{22}O_2NCl$: C, 61.86; H, 8.16; N, 5.32%.

By the usual manner, the hydrochloride (XIII) was acetylated with pyridine-acetic anhydride. Recrystallization from dilute methanol then gave an amide; mp 95—96°C, ν_{COCH_3} 1660 cm^{-1}.

Found: C, 68.12; H, 7.93; N, 5.35%. Calcd for $C_{15}H_{21}O_3N$: C, 68.41; H, 8.04; N, 5.32%.

Reduction of 7-Methoxy-2-*t*-butylchromanone Oxime (V) with Lithium Aluminum Hydride. To a swirling suspension of 1.5 g of lithium aluminum hydride in 100 m*l* of ether, there was added, drop by drop and at room temperature, a solution of 1.5 g of V in 100 m*l* of ether. The solid (1.32 g, 80%) obtained by the usual treatment was recrystallized from ethyl acetate to give colorless crystals which were identical with 7-methoxy-2-*t*-butyl-4-aminochroman hydrochloride (XIV).

Methods of the pK_a Determination of Amines. *(A) Determination by the Titration Method.* The values of pK_a in Table 1 (Compounds VI, VII, VIII, IX, and XIV) were taken as the values of the amines at the mid-points of the titration curves, plotting the volume of 1/100 N aqueous sodium hydroxide against pH.

(B) Determination by the UV Method. The ultraviolet spectra were recorded with a Hitachi EPI-032 ultraviolet spectrophotometer. The values of pK_a in Table 1 (Compounds X, XI, XII, and XIII) were taken as the pH values of the amines in the Britton-Robinson buffer solution at the mid-points of the titration curves, plotting the absorbance at λ_{max} of the free amines against pH. The concentrations and the λ_{max} values of these amines are shown in Table 6.

Table 6.

Amine	Concentration (mol/*l*)	λ_{max} (mμ)
X	2.71×10^{-4}	292.5
XI	2.43×10^{-4}	292
XII	2.71×10^{-4}	292.5
XIII	2.89×10^{-4}	293.5

The author wishes to express his gratitude to Professor Naoto Inoue and Professor Shozo Yamaguchi for their helpful discussions and encouragement throughout the course of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1829—1834 (1970)

Studies of Peptide Antibiotics. XVIII. The Synthesis of Tyrocidine E[1,2]

Nobuo MITSUYASU, Shuji MATSUURA, Michinori WAKI, Motonori OHNO,[3] Satoru MAKISUMI and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received December 1, 1969)

The synthesis of cyclic decapeptide, *cyclo*-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-phenylalanyl-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyl, which has the amino acid sequence designated as tyrocidine E by Kurahashi, and the chemical and biological properties of the synthetic product, have been described. The degree of the activity of the synthetic product toward the Gram positive microorganisms is nearly the same as that of tyrocidine A. The results indicate that the L-tyrosine residue in the molecule of tyrocidine A can be replaced by L-phenylalanine without influencing activity.

Tyrocidine E is a new basic polypeptide isolated by Kurahashi and his coworkers[4] from an incubation mixture in a cell-free enzyme system of *Bacillus brevis* ATCC 8185 when both tryptophan and tyrosine were subtracted from the standard culture mixture for the biosynthesis of tyrocidine A, B and C. They have suggested the structure of tyrocidine E to be a cyclic decapeptide shown as XVI[4] in Fig. 1 by comparison of the amino acid composition of a sample designated as tyrocidine E with that of tyrocidine A, since the amino acid sequence of tyrocidine A has been already established.[5,6] However, they did not mention the property of an antibacterial activity of tyrocidine E and data such as melting point, specific rotation and elemental analysis.

We reported previously the synthesis of tyrocidine A[6] and B,[7] and have been attempting to synthesize other tyrocidines. This paper describes the synthesis of cyclic decapeptide hydrochloride (XVI·HCl) having the amino acid sequence of tyrocidine E (Fig. 1), and the chemical and biological properties of the synthetic product.

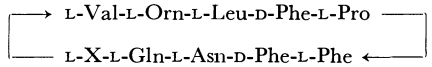

Fig. 1. Structure of tyrocidine E (XVI) and A (XVII).
X represents an amino acid residue such as Phe (XVI) and Tyr (XVII).

The synthesis of the pentapeptide derivative, Z(OMe)-Phe-D-Phe-Asn-Gln-Phe-$NHNH_2$ (VI), was achieved as follows (Fig. 2). The tripeptide derivative (III) of the C-terminal moiety was built up by stepwise elongation from the carboxyl toward the amino end to minimize racemization. The condensation of benzyloxycarbonyl-glutamine *p*-nitrophenyl ester with phenylalanine ethyl ester gave dipeptide derivative (I). This was hydrogenated in the presence of palladium black in a mixture of methanol and dimethylformamide containing an equivalent of hydrogen chloride to give dipeptide ester hydrochloride (II). The condensation of benzyloxycarbonyl-asparagine *p*-nitrophenyl ester with II gave acyl tripeptide ester (III) which was converted to tripeptide ester hydrochloride (IV) by the catalytic hydrogenation as described for II. In a previous study[6] the decarbobenzoxylation of the protected di- and tripeptide stages was performed by treatment with hydrogen bromide in acetic acid and the oily products obtained were contaminated by a small amount of impurities. However, the decarbobenzoxylation step in the

1) A part of this work was presented at the 21st Annual Meeting of Chemical Society of Japan, Osaka, April, 1968 (Preprints, Vol. 3, p. 2242), and communicated briefly; N. Mitsuyasu and N. Izumiya, *Experientia*, **26**, in press (1970).

2) The following abbreviations are used; Z-, benzyloxycarbonyl; Z(OMe)-, *p*-methoxybenzyloxycarbonyl; -ONp, *p*-nitrophenyl ester; -OEt, ethyl ester; $-NHNH_2$, hydrazide; $-N_3$, azide; TEA, triethylamine; DMF, dimethylformamide. Amino acid symbols except for D-Phe denote L-configuration.

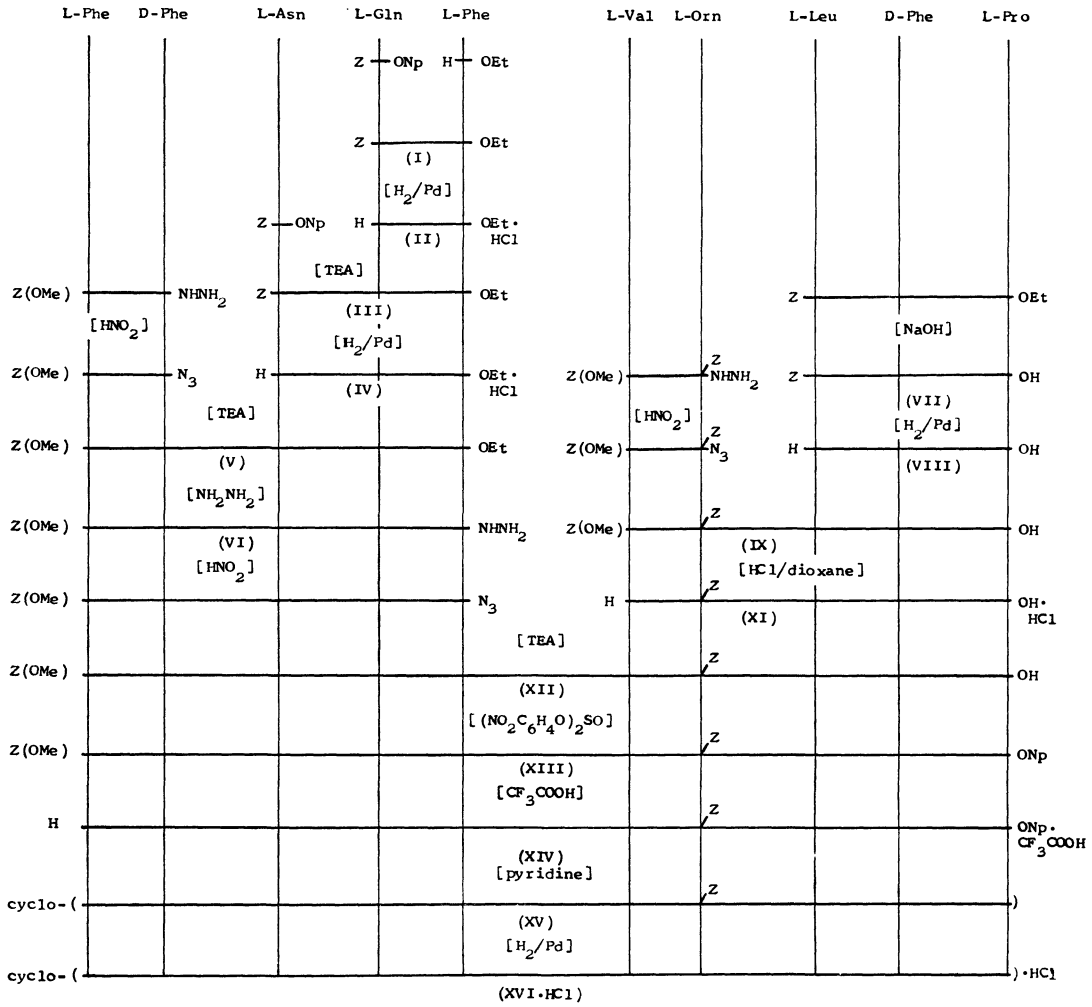

Fig. 2. Synthesis of tyrocidine E.

present study was much improved by this catalytic hydrogenation procedure which afforded pure crystalline products. The azide derived from Z(OMe)-Phe-D-Phe-$NHNH_2$[6] was allowed to react with tripeptide ester (IV) to afford acylpentapeptide ester (V) in a 73% yield. Compound V was converted to the corresponding hydrazide (VI) in a 97% yield by treatment with hydrazine.

Another pentapeptide derivative, H-Val-Orn-(δ-Z)-Leu-D-Phe-Pro-OH·HCl (XI), was prepared as follows (Fig. 2). The free tripeptide (VIII) was prepared from Z-Leu-D-Phe-Pro-OEt by saponification and successive hydrogenation in a mixture of methanol, acetic acid and water. The azide derived from Z(OMe)-Val-Orn(δ-Z)-$NHNH_2$[8] was allowed to react with VIII in the presence of an equivalent amount of triethylamine to yield crystalline protected pentapeptide (IX)[9] in a 73% yield. Treatment of IX with twenty equivalents of hydrogen chloride in dioxane afforded pure crystalline pentapeptide hydrochloride (XI)[10] in a yield of 90%.

Subsequent synthesis of the cyclic decapeptide hydrochloride (XVI·HCl) was achieved as follows (Fig. 2). Condensation of the azide derived from VI with XI in the presence of two equivalents of triethylamine gave amorphous protected decapeptide (XII) in a yield of 80%. XII was converted

8) T. Kato, M. Kondo, M. Ohno and N. Izumiya, This Bulletin, **38**, 1202 (1965).

9) Acylpentapeptide acid (IX) was prepared previously by saponification of Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OEt; M. Waki and N. Izumiya, *J. Amer. Chem. Soc.*, **89**, 1278 (1967); This Bulletin, **40**, 1687 (1967).

10) Hydrochloride (XI) of the neutral pentapeptide was prepared by the action of hydrogen chloride on BOC-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH: see Ref. 6.

to the corresponding decapeptide *p*-nitrophenyl ester (XIII) with the action of twenty equivalents of di-*p*-nitrophenyl sulfite in the presence of pyridine. Removal of the *p*-methoxybenzyloxycarbonyl group from XIII by the action of trifluoroacetic acid yielded amorphous decapeptide *p*-nitrophenyl ester trifluoroacetate (XIV). Cyclization reaction of XIV in a large amount of hot pyridine gave crude benzyloxycarbonyl-substituted cyclic decapeptide (XV), which was then purified by passing its aqueous dioxane - methanol solution through columns of cation and anion exchangers. The yield of XV from XII was 40% after recrystallization. The homogeneity of XV was established by the criteria of thin-layer chromatography and by elemental analysis. Molecular weight determination using a vapor pressure osmometer demonstrated that the molecular weight of XV corresponded to that of cyclic decapeptide. The hydrogenation of XV in the presence of an equivalent amount of hydrogen chloride in methanol afforded cyclic decapeptide hydrochloride (XVI·HCl) in an 84% yield. The homogeneity of hydrochloride (XVI·HCl) was confirmed by thin-layer and paper chromatography, paper electrophoresis, elemental analysis and amino acid analysis.

Antibacterial activity toward several microorganisms was examined[11] (Table 1). In addition to synthetic XVI, synthetic tyrocidine A[6] and natural gramicidin S[12] were examined as reference compounds. It was found that the degree of the activities of synthetic XVI toward the Gram positive microorganisms was nearly the same as that of tyrocidine A, indicating that the L-tyrosine residue in the molecule of tyrocidine A can be replaced by the L-phenylalanine without influencing activity.

Syntheses of the cyclic decapeptides corresponding to the proposed structures for tyrocidine C[13] and D[14] is in progress in this laboratory.

Experimental

Melting points were uncorrected. The optical rotations were determined with a Yanagimoto Photometric Polarimeter, OR-20 type. Paper chromatography was performed on Toyo Roshi No. 52 with the following solvent systems: R_f^{I}, *n*-butanol - acetic acid - pyridine - water, 4 : 1 : 1 : 2 v/v; R_f^{II}, *n*-butanol - acetic acid - water, 4 : 1 : 2 v/v. Thin layer chromatography was performed on Merck silica gel G with the following solvent systems: R_f^1, *n*-butanol - acetic acid - pyridine - water 4 : 1 : 1 : 2 v/v; R_f^2, chloroform-methanol, 5 : 1 v/v; R_f^3, *n*-butanol - acetic acid - water, 4 : 1 : 2 v/v; R_f^4, *s*-butanol - pyridine - water, 75 : 15 : 10 v/v; R_f^5, chloroform - benzene - methanol, 6 : 3 : 1 v/v. Spots of materials possessing a free amino group on a thin layer plate were detected by spraying ninhydrin, and those of the amino group-blocked materials, by spraying 47% hydrobromic acid and then ninhydrin. Prior to analysis, the compounds were dried over phosphorus pentoxide at 60°C and 2 mmHg to a constant weight unless otherwise described.

Z-Gln-Phe-OEt (I). To a solution of phenylalanine ethyl ester hydrochloride (1.37 g, 6 mmol) dissolved in a mixture of TEA (0.84 m*l*, 6 mmol) and DMF (10 m*l*), a solution of benzyloxycarbonyl-glutamine *p*-nitrophenyl ester (2.0 g, 5 mmol) in DMF (5 m*l*) was added. After the solution had been allowed to stand for 6 hr at room temperature, it was diluted with water (250 m*l*). The crystalline precipitate was collected by filtration and washed successively with N hydrochloric acid, a 3% sodium bicarbonate solution and water. It was recrystallized from methanol-ether. Yield, 2.12 g (93%); mp 167—169°C; R_f^1 0.86; R_f^2 0.61; $[\alpha]_D^{15}$ −4.0° (*c* 1.0, DMF).

Found: C, 63.28; H, 6.40; N, 8.83%. Calcd for $C_{24}H_{29}O_6N_3$: C, 63.28; H, 6.42; N, 9.23%.

H-Gln-Phe-OEt·HCl (II). A solution of I (1.28 g, 2.8 mmol) dissolved in a mixture of 2.53N hydrogen chloride in methanol (1.23 m*l*) and DMF (10 m*l*) was hydrogenated in the presence of palladium black. After 6 hr the filtrate from the catalyst was concentrated to a small volume *in vacuo* and then ether was added. The resulting crystals were collected by filtration. Yield, 0.99 g (99%); mp 178—182°C; R_f^1 0.79; R_f^2 0.16; $[\alpha]_D^{15}$ +17.0° (*c* 1.0, DMF).

Found: C, 52.55; H, 6.69; N, 11.58%. Calcd for $C_{16}H_{23}O_4N_3 \cdot HCl \cdot \frac{1}{2}H_2O$: C, 52.38; H, 6.87; N, 11.46%.

Z-Asn-Gln-Phe-OEt (III). To a solution of II (0.54 g, 1.5 mmol) dissolved in a mixture of TEA (0.224 m*l*, 1.6 mmol) and DMF (10 m*l*), a solution of benzyloxycarbonyl-asparagine *p*-nitrophenyl ester (0.58 g, 1.5 mmol) in DMF (5 m*l*) was added. After the solution had been stood overnight at room temperature, it was diluted with water (150 m*l*). The crystalline product deposited was collected by filtration and washed successively with N hydrochloric acid, a 3% sodium bicarbonate solution and water (0.69 g). It was recrystallized from DMF-ethanol-ethyl acetate. Yield, 0.66 g (77%); mp 225—227°C; R_f^1 0.82; R_f^2 0.28; $[\alpha]_D^{15}$ −16.0° (*c* 0.5, DMF).

Found: C, 58.76; H, 6.25; N, 12.10%. Calcd for $C_{28}H_{35}O_8N_5$: C, 59.04; H, 6.19; N, 12.30%.

H-Asn-Gln-Phe-OEt·HCl (IV). This compound was prepared by the same procedure as for II. Hydrogenolysis of III (0.62 g, 1.09 mmol) in the presence of a 1.1 equivalent of hydrogen chloride afforded IV as amorphous solid. Yield, 0.50 g (97%); mp 199—202°C; R_f^1 0.73; R_f^2 0.05; $[\alpha]_D^{15}$ −8.0° (*c* 0.3, DMF).

Found: C, 49.08; H, 6.88; N, 14.10%. Calcd for $C_{20}H_{29}O_6N_5 \cdot HCl \cdot H_2O$: C, 49.03; H, 6.58; N, 14.30%.

Z(OMe)-Phe-D-Phe-Asn-Gln-Phe-OEt (V). A solution of Z(OMe)-Phe-D-Phe-$NHNH_2$[6] (0.44 g, 0.9 mmol) dissolved in a mixture of DMF (9 m*l*) and acetic acid (6 m*l*) was cooled to −5°C. To this solution, N hydrochloric acid (2.0 m*l*) was added, followed by N sodium nitrite (1.0 m*l*). After it had been stood for 5 min at

11) We are indebted to Dr. M. Shibata of Takeda Chemical Industries for the bioassay.

12) We wish to express our thanks to Mr. I. Kitazato of Meiji Seika Co. for the generous gift of crystalline gramicidin S dihydrochloride.

13) M. A. Ruttenberg, J. P. King and L. C. Craig, *Biochemistry*, **4**, 11 (1965).

14) M. A. Ruttenberg and B. Mach, *ibid.*, **5**, 2864 (1966).

this temperature, the solution was diluted with cold water (50 ml). The azide deposited was collected by filtration, washed with a 3% sodium bicarbonate solution and water, and then dried *in vacuo* at 0°C. To a chilled (−5°C) solution of IV (0.45 g, 0.9 mmol) dissolved in a mixture of TEA (0.14 ml, 1.0 mmol) and DMF (15 ml), the azide was added. The solution was stirred for 2 days at 0°C and then diluted with water (200 ml). The precipitate formed was collected by filtration and washed successively with 0.5M citric acid, a 3% sodium bicarbonate solution and water. Yield, 0.59 g (73%); R_f^1 0.88; R_f^2 0.57; R_f^3 0.76.

For analysis 80 mg of the product was recrystallized from DMF-ethanol-ether (60 mg); mp 212—215°C; $[\alpha]_D^{15}$ −16.4° (*c* 0.5, DMF).

Found: C, 62.78; H, 6.19; N, 10.86%. Calcd for $C_{47}H_{55}O_{11}N_7$: C, 63.14; H, 6.20; N, 10.97%.

Z(OMe)-Phe-D-Phe-Asn-Gln-Phe-NHNH$_2$ (VI). A solution of V (0.49 g, 0.55 mmol) and hydrazine hydrate (0.53 ml, 11 mmol) in DMF (15 ml) was allowed to stand at room temperature. After 24 hr hydrazine hydrate (0.27 ml, 5.5 mmol) was added to allow the reaction to proceed completely and the reaction mixture was stood at room temperature for another 24 hr. The solution was then evaporated *in vacuo* to remove the excess hydrazine, after which water (200 ml) was added to the residual solution; the gelatinous product deposited was collected by filtration. Yield, 0.47 g (97%); R_f^1 0.78; R_f^2 0.10; R_f^3 0.66.

For analysis 48 mg of the product was recrystallized from DMF-ether (36 mg); mp 218—221°C; $[\alpha]_D^{15}$ −23.5° (*c* 0.5, dimethylsulfoxide).

Found: C, 60.59; H, 6.27; N, 14.12%. Calcd for $C_{45}H_{53}O_{10}N_9 \cdot \frac{1}{2}H_2O$: C, 60.80; H, 6.12; N, 14.18%.

Z-Leu-D-Phe-Pro-OH (VII). To a solution of Z-Leu-D-Phe-Pro-OEt[6] (1.07 g, 2 mmol) dissolved in a mixture of methanol (15 ml) and dioxane (10 ml), N sodium hydroxide (4 ml) was added. Saponification was carried out at 0°C for 2 hr and then at room temperature for 2 hr. The progress of the reaction was followed by thin-layer chromatography. The solution was evaporated *in vacuo*, after which the residual solution was diluted with water (20 ml) and then acidified to pH 3 with N hydrochloric acid. The resulting oil was taken up twice with each 20 ml of ethyl acetate. The combined ethyl acetate solutions were washed with water, dried over sodium sulfate, and then evaporated *in vacuo*. Yield of an oily product, 0.91 g (89%); R_f^1 0.84; R_f^2 0.72.

H-Leu-D-Phe-Pro-OH (VIII). A solution of VII (0.52 g) dissolved in a mixture of methanol (3 ml), water (1 ml) and acetic acid (6 ml) was hydrogenated in the presence of palladium black. After 3 hr the filtrate from the catalyst was concentrated *in vacuo* and then a mixture of ether and petroleum ether (1 : 1) was added. The resulting amorphous powder was collected by filtration. Yield, 0.36 g (73%); R_f^1 0.75; R_f^2 0.00; R_f^I 0.68.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH (IX). A solution of Z(OMe)-Val-Orn(δ-Z)-NHNH$_2$[8] (0.50 g, 0.95 mmol) in acetic acid (15 ml) was cooled to −5°C. To this, N hydrochloric acid (2.1 ml) was added, followed by N sodium nitrite (1.0 ml). After it had been stirred for 5 min at this temperature, the solution was diluted with cold water (150 ml). The azide precipitated was treated as for the preparation of V. The dried azide was added to a chilled solution of VIII (0.36 g, 0.95 mmol) dissolved in a mixture of TEA (0.133 ml, 0.95 mmol) and DMF (10 ml). After the solution had been stirred for 2 days at 0°C, it was concentrated to a small volume and then acidified with cold 0.5M citric acid. The resulting crystals were collected by filtration, washed with 0.5M citric acid and water. It was recrystallized from methanol-ether-petroleum ether. Yield, 0.62 g (73%); mp 138—140°C; R_f^1 0.83; R_f^2 0.54; $[\alpha]_D^{17}$ −20.1° (*c* 1.0, DMF). In order to confirm the homogeneity of the product a small portion was hydrogenated; a single ninhydrin positive spot was observed on a thin-layer chromatogram, R_f^1 0.65.

We prepared compound (IX) by saponification of the corresponding acyl-pentapeptide ethyl ester; $[\alpha]_D^{20}$ −18.2° (*c* 1.0, DMF).[9]

H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH·HCl(XI). To a solution of IX (0.53 g, 0.6 mmol) in dioxane (10 ml), 2.57N dry hydrogen chloride in dioxane (4.67 ml, 12 mmol) and anisole (0.1 ml) were added. The solution was then allowed to stand at room temperature and the reaction was followed by thin layer chromatography. After 9 hr the solution was concentrated to a small volume *in vacuo* and ether was added. The crystals precipitated were collected by filtration and washed thoroughly with ether. Yield, 0.41 g (90%); mp 139—142°C (decomp.); R_f^1 0.73; R_f^2 0.11; R_f^3 0.56; $[\alpha]_D^{15}$ −19.8° (*c* 0.5, DMF).

Found: C, 58.29; H, 7.41; N, 10.54%. Calcd for $C_{38}H_{54}O_8N_6 \cdot HCl \cdot \frac{3}{2}H_2O$: C, 58.04; H, 7.43; N, 10.69%.

We prepared compound (X) by the treatment with hydrogen chloride of the corresponding BOC-pentapeptide acid; $[\alpha]_D^{20}$ −22.5° (*c* 2.12, DMF).[10]

Z(OMe)-Phe-D-Phe-Asn-Gln-Phe-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH (XII). A solution of VI (0.42 g, 0.475 mmol) dissolved in DMF (6 ml) was treated with N hydrochloric acid (0.6 ml) and N sodium nitrite (0.52 ml). After it had been stood for 5 min, the solution was diluted with cold water (50 ml). The azide deposited was treated as described previously. The dried azide was added to a chilled solution of XI (0.38 g, 0.5 mmol) dissolved in a mixture of TEA (0.14 ml, 1.0 mmol) and DMF (8 ml). The solution was stirred for 2 days at 0°C, and then diluted with 0.25M citric acid (30 ml). The resulting product was collected by filtration and washed with water. Yield, 0.65 g (80%); R_f^1 0.82; R_f^2 0.00; R_f^3 0.90; R_f^4 0.81; R_f^5 0.77. In order to establish further the homogeneity of the product, a small portion was hydrogenated; R_f^1 0.26; R_f^5 0.07; a single ninhydrin-positive spot was observed on paper electrophoresis with pH 1.8 buffer:[6] relative mobility to gramicidin S[12] 0.89.

For analysis 100 mg of the product was recrystallized from DMF-ether (61 mg); mp 236—239°C; $[\alpha]_D^{15}$ −31.8° (*c* 0.5, dimethyl sulfoxide).

Found: C, 61.98; H, 6.73; N, 11.30%. Calcd for $C_{83}H_{103}N_{13}O_{18} \cdot 2H_2O$: C, 62.04; H, 6.71; N, 11.33%.

Z(OMe)-Phe-D-Phe-Asn-Gln-Phe-Val-Orn(δ-Z)-Leu-D-Phe-Pro-ONp(XIII). To a suspension of XII (196 mg, 0.125 mol) in anhydrous pyridine (5 ml) was added di-*p*-nitrophenyl sulfite (810 mg, 25 mmol) The mixture was stirred for 2 days at room temperature and then evaporated *in vacuo*. The oily residue was triturated with a mixture of ether and petroleum ether (1 : 1). The solid mass was collected by filtration and

washed with a mixture of ether and petroleum ether (1 : 1) until yellow color could not be discerned upon the addition of N sodium hydroxide to the filtrate. A faintly yellow product was thus obtained (179 mg); R_f^1 0.98; R_f^2 0.74. The *p*-nitrophenyl ester content of this product was estimated to be 104% by means of the method described by Schwyzer and Sieber,[15] except that a mixture of DMF and N sodium hydroxide (1 : 1) was used as the solvent and the absorption measurements were performed at the wavelength of 412 mμ. This product was used for the next reaction without further purification.

H-Phe-D-Phe-Asn-Gln-Phe-Val-Orn(δ-Z)-Leu-D-Phe-Pro-ONp·CF_3COOH (XIV). To a mixture of XIII (179 mg) and anisole (0.2 m*l*), anhydrous trifluoroacetic acid (2.3 m*l*) was added at −5°C. When swirled, the reaction mixture formed a solution after 10 min. The solution was then evaporated *in vacuo* at 0°C, and the resulting oily residue was triturated with ether. The product was collected by filtration and washed with ether: yield, 199 mg; R_f^1 0.87.

***cyclo*-(Phe-D-Phe-Asn-Gln-Phe-Val-Orn(δ-Z)-Leu-D-Phe-Pro) (XV).** A solution of XIV (199 mg) dissolved in a mixture of acetic acid (0.3 m*l*) and DMF (10 m*l*) was stirred, drop by drop, into anhydrous pyridine (60 m*l*) kept at 65—70°C over a 3.5 hr period. The solution was further stirred for 1.5 hr at this temperature, and then evaporated to dryness *in vacuo*. The resulting residue was collected by filtration with the aid of water, dried *in vacuo* (131 mg), and then dissolved in 15 m*l* of a mixture of dioxane, methanol and water (1 : 3 : 1). This solution was passed successively through columns (2×6.5 cm) of Dowex −50 (H^+ form) and Dowex-1 (OH^- form) which had been washed with a mixture of dioxane, methanol and water (1 : 3 : 1). The columns were then washed with the same solvent. The filtrate and washings were combined (total 150 m*l*) and evaporated *in vacuo*. The oily residue crystallized upon the addition of water (76 mg). It was recrystallized from dioxane-water. Yield, 68 mg (40% from XII); mp 252—255°C (decomp.); R_f^1 0.92; R_f^2 0.57; $[\alpha]_D^{23}$ −129° (*c* 0.5, methanol).

Found: C, 62.66; H, 6.80; N, 12.32%. Calcd for $C_{74}H_{93}O_{14}N_{13}\cdot 2H_2O$: C, 62.39; H, 6.86; N, 12.78%.

The molecular weight was determined on a Hitachi Osmometer, type 115, using methanol as the solvent. Found: 1435. Calcd for the benzyloxycarbonyl-substituted cyclic decapeptide dihydrate: 1425.

***cyclo*-(Phe-D-Phe-Asn-Gln-Phe-Val-Orn-Leu-D-Phe-Pro)·HCl (XVI·HCl).** A solution of XV(51 mg, 0.036 mmol) dissolved in a mixture of 0.046 N dry methanolic hydrogen chloride (0.87 m*l*, 0.041 mmol) and methanol (3.5 m*l*) was hydrogenated in the presence of palladium black. The progress of the reaction was followed by thin-layer chromatography. After 3 hr the filtrate from the catalyst was concentrated to a small volume (0.1 m*l*), and 2 m*l* of ether was added to give crystals. The crystals were collected by filtration and washed with ether. Yield, 39 mg (84%); mp 265—267°C (decomp.); $[\alpha]_D^{23}$ −126° (*c* 0.2, methanol). Homogeneity of the compound was ascertained as follows.

a) Paper chromatography: R_f^I 0.96; R_f^{II} 0.95.

b) Thin-layer chromatography: R_f^1 0.78; R_f^2 0.40.

c) Paper Electrophoresis: Paper, Toyo Roshi No. 52; solvent, formic acid-acetic acid-methanol-water (1 : 3 : 6 : 10 v/v) (pH 1.8); voltage gradient, 17 V/cm; charged period, 2.5 hr. Gramicidin S dihydrochloride[12] was used as the reference compound. Figure 3 shows

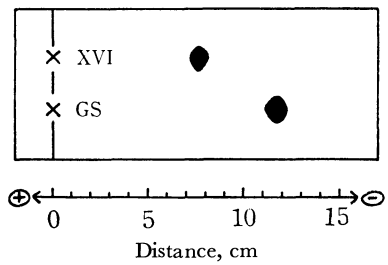

Fig. 3. Paper electrophoresis of synthetic cyclic decapeptide hydrochloride (XVI·HCl) and natural gramicidin S (GS) dihydrochloride.[12]

Microbiological Assays.[11] The microorganisms employed are listed in Table 1. The minimum amount of the compound necessary for the complete inhibition of growth was determined by a dilution method with a bouillon agar medium and with a synthetic medium. In addition to the synthetic XVI·HCl, synthetic tyrocidine A hydrochloride[6] and natural gramicidin S dihydrochloride[12] were examined as reference compounds. Table 1 shows that the degree of the activities of synthetic XVI toward the Gram positive microorganisms was nearly the same as that of tyrocidine A.

16) We are indebted to Mr. K. Noda in this laboratory for the amino acid analysis.

The authors wish to express their thanks to Professor Kiyoshi Kurahashi of Osaka University for his interest throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1834—1839 (1970)

Reaction of Glycylglycine with Formaldehyde in the Presence of Cupric Ion[1]

Kosaku NODA, Motoaki BESSHO,[2] Tetsuo KATO and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received December 8, 1969)

The reaction mixture of glycylglycine with formaldehyde in an alkaline aqueous solution containing cupric ion at 100°C gave seven ninhydrin positive components which were identified as follows; α-hydroxymethylserine, serine, glycine, 3-carboxymethyl-4-imidazolidone, α-hydroxymethylseryl-glycine, serylglycine and glycylglycine. The yield of serylglycine increased in proportion to the amount of cupric ion, whereas the yield of 3-carboxymethyl-4-imidazolidone was maximum when no cupric ion was added. A single-step synthesis in preparative scale of serylglycine or 3-carboxymethyl-4-imidazolidone under the best condition was achieved in a good yield.

Sato, Okawa and Akabori[3] reported the synthesis of a diastereomeric mixture of threonine and allothreonine by the reaction of an aqueous alkaline solution of copper glycinate with acetaldehyde. Benoiton *et al.*[4] described a general preparation of β-hydroxy-α-amino acid by the condensation of copper glycinate with various aldehydes, ketones and α-keto acids under comparable conditions. Akabori *et al.*[5] observed that the reaction of glycine with formaldehyde in the presence of cupric ion caused formation of serine and an unidentified ninhydrin reactive substance. Later Otani and Winitz characterized the unidentified substance as α-hydroxymethylserine, and they indicated that this amino acid could be derived from the interaction of serine and formaldehyde with cupric ion.[6]

Regarding the reaction of glycyl peptide with aldehyde, Akabori *et al.*[7] attempted to introduce side-chains into polyglycine, which had been dispersed on a clay, with formaldehyde or acetaldehyde in an alkaline medium; they observed that 0.4—3.1% or 1.4—1.5% of glycine residues were converted to serine or threonine residues. Furuyama *et al.*[8] treated polyglycine with acetaldehyde in

liquid ammonia in the presence of metallic sodium; 7—8% of glycine residues were shown to be converted to threonines.

This paper will describe the isolation and characterization of several components from a reaction mixture of glycylglycine with formaldehyde in the presence of cupric ion. Convenient single-step synthesis of serylglycine, which was conceived as a consequence of these studies, will also be described.

We assumed the formation of either serylglycine or glycylserine as a major product when glycylglycine is subjected to the reaction with formaldehyde in the presence of cupric ion. The methylene group in copper glycylglycinate might be more active than that in free glycylglycine and the amino group in copper salt might be protected from unfavorable side reactions. This supposition suggested the possibility for such a reaction sequence shown in Fig. 1.

$$NH_2CH_2CO\text{-}NHCH_2COOH \xrightarrow[OH^-,\ Cu^{2+}]{HCHO}$$

$$NH_2CH(CH_2OH)CO\text{-}NHCH_2COOH$$

or $$NH_2CH_2CO\text{-}NHCH(CH_2OH)COOH$$

Fig. 1. Assumed reaction sequence.

In this investigation, several dipeptides such as serylglycine, glycylserine and α-hydroxymethylserylglycine were prepared in a conventional manner as the first step of the experiment. These dipeptides were to be used as authentic samples. For example, α-hydroxymethylserylglycine was synthesized as follows.[9]

$$\text{Z-HMSer} + \text{Gly-OBzl} \xrightarrow{DCC} \text{Z-HMSer-Gly-OBzl} \xrightarrow{H_2/Pd} \text{HMSer-Gly}$$

Fig. 2. Synthesis of a dipeptide.

We observed that a reaction mixture of glycylglycine and formaldehyde with cupric ion in an alkaline medium gave seven ninhydrin positive components which were identified by the use of an amino acid analyzer (Fig. 4-B). We could easily identify six components to be α-hydroxymethylserine, serine, glycine, α-hydroxymethylserylglycine, serylglycine and glycylglycine by means of paper chromatography and an amino acid analyzer. However, one component which emerged at the fourth peak in the chromatogram by the amino acid analyzer (Fig. 4-B) could not be characterized at this stage. Therefore, the reaction mixture was prepared on a large scale, and was fractionated with a column (1.8×110 cm) of Dowex 50 (NH_4^+ form) using 0.2M ammonium acetate buffer as a solvent.[10] Thus, the unidentified component emerging at the fourth peak could be isolated as crystals, and finally its structure was characterized as 3-carboxymethyl-4-imidazolidone (Cm-Iz) shown in Fig. 3, by means of elemental analysis, molecular weight determination and IR and NMR

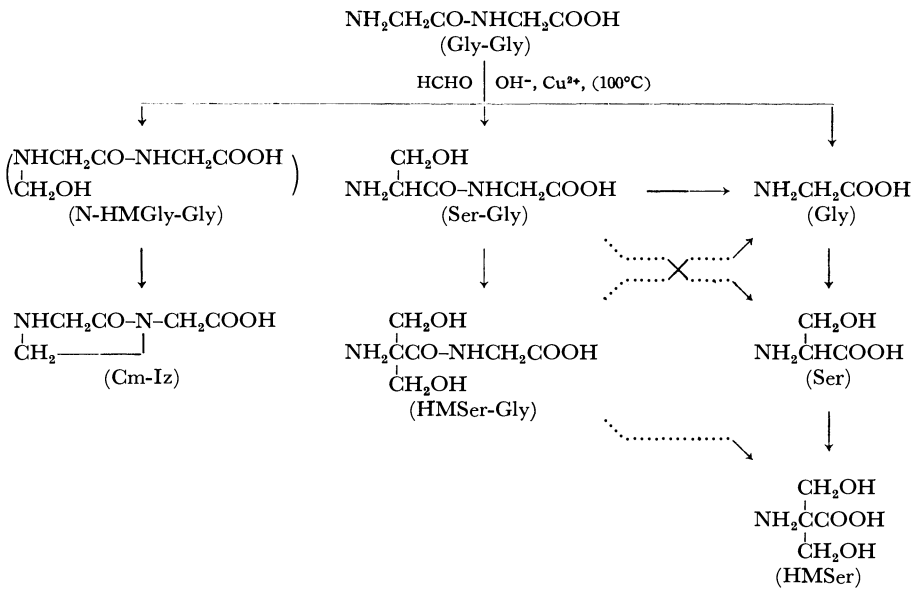

Fig. 3. Summary of the reaction of Gly-Gly and formaldehyde with cupric ion.

spectra. Later it was found that this substance, Cm-Iz, was isolated easily in a good yield from the reaction mixture of glycylglycine and formaldehyde without cupric ion (see Fig. 6).

Figure 3 indicates the reaction sequence of glycylglycine and formaldehyde with cupric ion. Kim and Martell[11] have reported the structure of copper glycylglycinate in aqueous solution in detail. They have indicated that the amino group in copper salt in sodium carbonate is protected by cupric ion. It is therefore considered that the methylene group is more active than that of free glycylglycine. We have already described the formation of serylglycine and α-hydroxymethylserylglycine. However, it should be mentioned that not even a trace of glycylserine could be found, contrary to our ex-

11) M. K. Kim and A. E. Martell, *Biochemistry*, **3**, 1169 (1964).

pectation indicated in Fig. 1. When the amount of cupric ion is decreased, the amino group in free glycylglycine is apt to react with formaldehyde to produce 3-carboxymethyl-4-imidazolidone (Cm-Iz); Cm-Iz may be produced *via* a possible intermediate, *N*-HMGly-Gly (Fig. 3). It is considered that the components of amino acid were derived by an alkaline hydrolysis at peptide bond, and some amino acid such as glycine was converted further to serine and hydroxymethylserine as Otani and Winitz reported.[6]

The effects of variations of concentration of cupric ion and reaction time were studied by using the amino acid analyzer in order to find optimal condition for the serylglycine formation. The experiments revealed that the formation of serylglycine was favored when the ratio of copper to glycylglycine increased, and no serylglycine was formed in the absence of cupric ion (Fig. 6). Within the conditions we studied, the maximum formation of serylglycine was observed when the molar ratio of copper to glycylglycine was 1 : 1 and the reaction mixture was heated at 100°C for 30 min (Fig. 7).

As an experiment on a preparative scale, we tried to prepare serylglycine under the best conditions described above. Thus, a practicable one-step synthesis of serylglycine has been achieved in a good yield of 70%. The method of synthesis of serylglycine developed in these studies has merits of simplicity, convenience and inexpensive starting materials.

Experimental

The melting points were uncorrected. Paper chromatography was run on Toyo Roshi No. 52 in 80% pyridine. The infrared spectra were measured on a Hitachi EPI-S2 spectrophotometer. The NMR spectra were recorded on a Varian Associates A-60 model, using tetramethylsilane as the internal standard and acetic acid as solvent.

Gly-Ser. This peptide was prepared by the hydrogenolysis of Z-Gly-Ser-OBzl;[12] 85%, mp 197—199°C (decomp.), R_f 0.36.

Ser-Gly. This was also prepared from Z-Ser-Gly-OBzl;[12] 82%, mp 204—206°C (decomp.); R_f 0.45.

Z-HMSer. To a solution of α-hydroxymethylserine[6] (1.62 g, 12 mmol) and sodium bicarbonate (2.52 g) in water (50 m*l*) was added benzyloxycarbonyl chloride (1.82 m*l*, 14.4 mmol) portionwise under stirring at room temperature. Stirring was continued for 4 hr and the solution was extracted with ether. After the aqueous layer was acidified with hydrochloric acid, it was extracted with ethyl acetate (4 times, each 50 m*l*). The combined extracts were dried over sodium sulfate and evaporated *in vacuo*. The residual syrup was solidified by the addition of petroleum ether. It was recrystallized from ethyl acetate-petroleum ether; yield, 1.64 g (51%); mp 109—110°C.

Found: C, 53.50; H, 5.78; N, 5.19%. Calcd for $C_{12}H_{15}O_6N$: C, 53.53; H, 5.62; N, 5.20%.

Z-HMSer-Gly-OBzl. To a solution of Z-HMSer (0.7 g, 3 mmol) and glycine benzyl ester *p*-toluenesulfonate (1.01 g, 3 mmol) in chloroform (15 m*l*) with triethylamine (0.42 m*l*) was added DCC (0.62 g, 3 mmol) at room temperature. The mixture was left to stand overnight, and evaporated *in vacuo*. To the residue was added ethyl acetate, and dicyclohexylurea was filtered off. The filtrate was washed with a 4% sodium bicarbonate solution, 2% hydrochloric acid and water, and dried over sodium sulfate. The filtered solution was evaporated and the oily residue was solidified by the addition of petroleum ether. It was recrystallized from ethyl acetate-petroleum ether; yield, 0.75 g (61%); mp 91—93°C.

Found: C, 60.48; H, 5.89; N, 6.70%. Calcd for $C_{21}H_{24}O_7N_2$: C, 60.56; H, 5.81; N, 6.73%.

HMSer-Gly. A solution of Z-HMSer-Gly-OBzl (0.42 g, 1 mmol) in a mixture of acetic acid (5 m*l*), *t*-butanol (3 m*l*) and water (1 m*l*) was treated with hydrogen in the presence of palladium black. The filtrate from the catalyst was evaporated *in vacuo* to dryness. The residual crystals were recrystallized from water-ethanol; yield, 0.154 g (80%); mp 190—192°C (decomp.); R_f 0.56.

Found: C, 37.26; H, 6.38; N, 14.70%. Calcd for $C_6H_{12}O_5N_2$: C, 37.50; H, 6.29; N, 14.58%.

3-Carboxymethyl-4-imidazolidone (Cm-Iz). A solution of Gly-Gly (1.32 g, 10 mmol), sodium carbonate (4.24 g, 40 mmol) and 37% aqueous formaldehyde (6 m*l*, 80 mmol) in water (200 m*l*) was kept at 100°C for 1 hr, and evaporated to a small volume (about 10 m*l*) *in vacuo*. It was put on a column of Dowex 50×8 (1.8×30 cm, 100—200 mesh, H^+ form). After the column was washed with water, it was treated with 2N ammonium hydroxide. The eluate was evaporated *in vacuo* and the residual crystals were recrystallized from water-ethanol; yield, 1.18 g (82%); mp 200°C (decomp.); R_f 0.42.

Calcd for $C_5H_8O_3N_2$: C, 41.66; H, 5.59; N, 19.44%. Found: C, 41.64; H, 5.67; N, 19.43%.

A definite amount of the product was hydrolyzed with 6N hydrochloric acid at 110°C for 12 hr; the hydrolysate indicated the value of $Gly_{2.03}$ by the amino acid analysis and the presence of formaldehyde qualitatively by a reagent of chromotropic acid.[13] The following observations confirm the structure of the product to be Cm-Iz. The molecular weight was determined on a Hitachi Osmometer, type 115, using methanol as a solvent. Calcd, 141.1; Found, 141.5. Infrared spectrum was shown in Fig. 5: ν_{max} 3400 (>N–H); 2750—2350 (this series is not seen in amino acid and acyldipeptide acid); 1718 (C=O in δ-lactam); 1647 (–CO–N<), 1590, 1314, 1302, 1012 (C–N–C) cm^{-1}. The NMR spectra were in accord with that assumed for Cm-Iz: δ=4.10 (singlet, methylene protons, 2H); 4.23 (singlet, methylene protons, 2H); 4.98 (singlet, methylene protons, 2H).

Chromatography of Model Mixture by Amino Acid Analyzer. We tried to obtain sufficient separation of each component of an artifical mixture by an amino acid analyzer, and found the following conditions to satisfy this purpose. A mixture of each one μmole of eight compounds listed in Table 1 was treated with a Hitachi amino acid analyzer, model KLA-3B, using

12) G. Fölsch, *Acta Chem. Scand.*, **12**, 561 (1958).

13) E. Eegriwe, *Z. Anal. Chem.*, **110**, 22 (1937).

TABLE 1. VALUES OF COMPOUNDS IN A MODEL MIXTURE

Compound	Effluent volume (ml)	Color constant[a]
HMSer	45	3.74
Ser	57	11.90
Gly	86	11.50
Cm-Iz	114	3.07
Gly-Ser	117	11.63
HMSer-Gly	119	2.71
Ser-Gly	129	11.00
Gly-Gly	135	12.15

a) Observed constants for the integration of peaks obtained from each 1 μmol of peptides and amino acids (see D. H. Spackman, W. H. Stein and S. Moore, *Anal. Chem.*, **30**, 1190 (1958)).

a 0.9×50 cm column with spherical resin under the conditions of flow rate 60 ml/hr and jacket temperature 55°C. The 0.2M sodium citrate buffer at pH 3.25 was applied until 70 ml, and then the system was changed to the pH 4.25 buffer. The effluent volumes and color yields of the compounds are summarized in Table 1, and the pattern of elution is shown in Fig. 4-A.

Isolation of Components in Reaction Mixture of Gly-Gly and Formaldehyde with Cupric Ion. *a) Preparation of Reaction Mixture.* A solution of Gly-Gly (1.32 g, 10 mmol), sodium carbonate (4.24 g, 40 mmol), cupric sulfate pentahydrate (1.25 g, 5 mmol) and 37% formaldehyde (6 ml, 80 mmol) in water (200 ml), was kept 100°C for 1 hr. The mixture was cooled with tap water and insoluble material in a small amount was filtered off. After the filtrate was acidified with acetic acid, the solution was evaporated *in vacuo*. The residue was dissolved in water, then the solution was treated with a column of Dowex 50×8 (1.8×30 cm, H^+ form). The column was washed with water and eluted with 2N ammonium hydroxide. The eluate was evaporated *in vacuo*, the residue was dissolved in water (1 ml), and the solution (about 1 ml) was used for the separation experiment as described in the following section. Approximately 1/2000 part of the solution was analyzed with the amino acid analyzer under the conditions described before, the pattern indicating the presence of seven components (Fig. 4-B).

b) Isolation and Characterization of Components. After several runs under various conditions, we found the following conditions to be satisfactory for separating the reaction mixture into each component. The solution (about 1 ml) was put on a column (1.8×110 cm) of Dowex 50×8 (200—400 mesh, NH_4^+ form), and the column was eluted with 0.2M ammonium acetate buffer of pH 4.0 with a flow rate of 30 ml/hr. An aliquot of each fraction (3 ml) was tested on a paper strip with ninhydrin, and the strip demonstrated that the reaction mixture was also separated into seven portions. The fractions containing each component were combined and evaporated to dryness *in vacuo* for removal of most of the ammonium acetate. The residue was dissolved in water and treated with a column of Dowex 50×8 (H^+ form) to remove the remaining acetate ion. After washing with water, the column was eluted with 2N ammonium hydroxide and the eluate was evaporated *in vacuo*. A residual solid was recrystallized from water-ethanol. The amount obtained is shown in Table 2 together with methods of characterization of the product isolated.

TABLE 2. ISOLATION AND CHARACTERIZATION OF COMPONENTS IN A REACTIION MIXTURE[a]

Component	Numbers of test tubes treated (tube, 3 ml)	Amount isolated and yield mg (%)	Method of characterization
HMSer	55—65	71(5)	PPC
Ser	67—80	5(0.5)	PPC
Gly	95—115	8(1)	PPC
Cm-Iz	117—145	353(25)	PPC, EA, AAA
HMSer-Gly	155—170	195(10)	PPC, EA, AAA
Ser-Gly	180—250	605(37)	PPC, EA, AAA
Gly-Gly	250—270	12(1)	PPC, AAA

a) The reaction mixture was prepared from Gly-Gly (1.32 g), formaldehyde (6 ml), sodium carbonate (4.24 g) and cupric sulfate (1.25 g) (for details, see Experimental).

b) PPC, paper chromatography compared with authentic sample. EA, elemental analysis (C, H and N). AAA, analysis by amino acid analyzer on hydrolysate derived from the component with 6N hydrochloric acid at 110°C for 12 hr.

As an example, a procedure for identification of Cm-Iz is described below. The fractions from tube number 117 to 145 were treated as described above, and the crude product obtained was recrystallized from water-ethanol; yield, 353 mg (25%); mp 200°C (decomp.); R_f 0.42; amino acid analysis, $Gly_{2.05}$.

Calcd for $C_5H_8O_3N_2$: C, 41.66; H, 5.59; N, 19.44%. Found: C, 41.59; H, 5.71; N, 19.33%.

Effect of Cupric Ion and Reaction Time on Formation of Dipeptides. *a) Effect of Cupric Ion.* Effect of variation in concentration of cupric ion was examined. A solution of Gly-Gly (132 mg, 1 mmol), sodium carbonate (424 mg, 4 mmol), 37% formaldehyde (0.6 ml, 8 mmol) and an appropriate amount of cupric sulfate (0 to 1 mmol) in water (20 ml) was heated at 100° for 1 hr, and treated as described before. The residue was dissolved in 0.2M citrate buffer (20 ml) of pH 2.2, and 0.1 ml of the solution was applied to the amino acid analyzer. The results obtained were shown in Fig. 6.

b) Effect of Reaction Time. Effect of variation in reaction time was examined. A solution of Gly-Gly (1 mmol), sodium carbonate (4 mmol), cupric sulfate (1 mmol) and 37% formaldehyde (8 mmol) in water (20 ml), was heated at 100°C. After various time intervals a portion of the solution was treated as described before. Each solution in citrate buffer at pH 2.2 was applied to the amino acid analyzer, the results being shown in Fig. 7.

Preparation of Ser-Gly from Gly-Gly. A solution of Gly-Gly (5.28 g, 0.04 mol), sodium carbonate (17 g, 0.1 mol), cupric sulfate (1.0 g, 0.04 mol) and 37% formaldehyde (24 ml) in water (800 ml) was heated at 100°C for 30 min. The reaction mixture was treated with a Dowex 50×8 column (2.5×60 cm, 100—200 mesh, H^+ form). It was washed with water and eluted

with 2N ammonium hydroxide. The eluate was evaporated *in vacuo*, and the residual crystals were recrystallized from water-ethanol; yield, 4.42 g (70%); mp 203—205° (decomp.); R_f 0.45.

Found: C, 37.15; H, 6.11; N, 17.29%. Calcd for $C_5H_{10}O_4N_2$: C, 37.03; H, 6.62; N, 17.28%.

The authors wish to thank Miss Isako Saeki, Faculty of Agriculture, Kyushu University, for her valuable technical assistance and Prof. Taku Matsuo and Mr. Yasushi Kodera, Faculty of Engineering, Kyushu University, for the NMR determination.

Reaction of 2-Aminobenzophenones with Aliphatic Acids in the Presence of Polyphosphoric Acid*1

Takumi ISHIWAKA, Mitsuo YONEMOTO, Kakuzo ISAGAWA and Yasaburo FUSHIZAKI

Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received December 15, 1969)

The reaction of 2-aminobenzophenones with aliphatic acids, such as acetic acid, propionic acid, *n*-butyric acid, and bromoacetic acid, in the presence of polyphosphoric acid afforded 6-substituted 2-anilino-4-phenylquinoline derivatives in fairly good yields. Some of these quinolines were acetylated in the usual way, and the products, 2-(*N*-acetylanilino)quinolines, were treated with sodium ethoxide to give 1-quinolyl-2(1*H*)-quinolone derivatives. 2-Amino-5-chlorobenzophenone (Ic) reacted with an equimolar amount of 2-acetamido-5-methylbenzophenone to give 2-(2-benzoyl-4-methylanilino)-6-chloro-4-phenylquinoline, which was also obtained from the reaction of 2,6-dichloro-4-phenylquinoline with Ib in the presence of copper powder. It was found that the reaction mechanism in the formation of 2-anilinoquinolines is similar in type to that in Friedländer's reaction. Furthermore, the structures of the 2-anilinoquinolines are discussed on the basis of our NMR spectral study.

In an earlier paper,[1] 2-aminobenzophenones (I) were treated with zinc chloride to afford the rearrangment products, benzanilides, together with dibenzo-[*b*,*f*]-1,5-diazocines and 9-acridones. On the other hand, it has been reported by Dippy *et al.*[2,3] that, on the treatment of *N*-monoacyl- or *N*,*N*-diacylaniline with anhydrous aluminum chloride or zinc chloride, a migration of their acyl groups occurred.

Then, 2-acetamido-5-chlorobenzophenone (IIIc), which has two acyl groups, was treated with zinc chloride at 190—200°C for 10 hr as the basis for a discussion of the rearrangement of the acyl groups. However, this reaction gave no rearrangement products. It did, though, afford intermolecular condensation product, 2-(2-benzoyl-4-chroroanilino)-6-chloro-4-phenylquinoline (IIc), in a 54% yield; it had already prepared in a 90% yield by Drukker and Judd[4] by the treatment of IIIc with polyphosphoric acid (PPA) at 130—140°C for 2 hr. The present authors found that this compound could easily be obained by slightly modifying Drukker's method.

Now, this paper will report the direct syntheses of 2-anilinoquinolines (II) from I and the syntheses of 1-quinolyl-2(1*H*)-quinolones (IX), and will des-

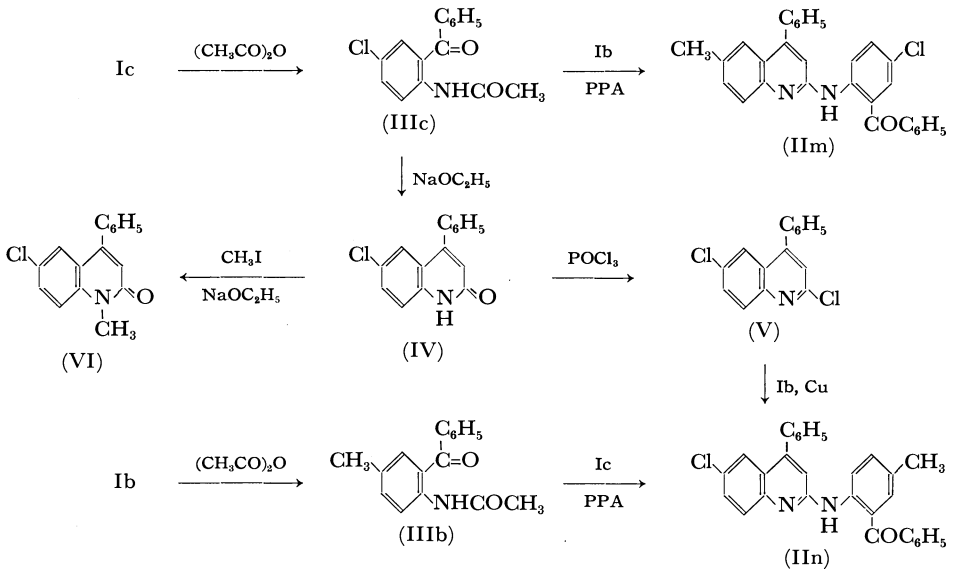
a) From the reactions of Ib with IIIc and of Ic with IIIb.
b) From the reaction of Ib with V in the presence of copper powder.
c) Measured in $CDCl_3$, using tetramethylsilane as the internal standard. b: broad, m: multiplet, s: singlet, t: triplet, q: quartet.

cribe the reaction mechanism in the formation of II.

When I was reacted with various aliphatic acids in the presence of PPA at the temperature shown in Table 1 for 10—30 min, the corresponding 2-anilinoquinolines were obtained in fairly good yields. By using this method, the reaction time could be very much shortened (Scheme 1).

The yields, physical properties, and results of the elemental analyses of II are summarized in Table 1.

In order to discuss the reaction mechanism in the formation of II, the reaction of 2-acetamido-5-chlorobenzophenone (IIIc) with Ib and that of 2-acetamido-5-methylbenzophenone (IIIb) with Ic were carried out in the presence of PPA. 2-(2-Benzoyl-4-chloroanilino)-6-methyl-4-phenylquinoline (IIm) was formed from the former reaction. On the other hand, the latter reaction afforded 2-(2-benzoyl-4-methylanilino)-6-chloro-4-phenylquinoline (IIn), which was also obtained from the reaction of 2,6-dichloro-4-phenylquinoline (V) with Ib, using copper powder as the catalyst. The formations of IIn in the former reaction and of IIm in the latter reaction were not detected (Scheme 2).



Scheme 2

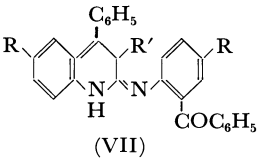
It may be suggested from these facts that this reaction involves the preliminary acylation of I by aliphatic acids to give 2-acylaminobenzophenone derivatives, which subsequently react with other 2-aminobenzophenones in a manner presumably analogous to the mechanism of the Friedländer process.

In the case of the reaction described by Drukker and Judd, Kanaoka[5] has suggested that Ic, resulting from the deacylation of IIIc, condensed with other IIIc to give IIc. Although he has not described the mechanism of this condensation in detail, it is probably analogous to that of the Friedländer process.

Drukker and Judd have reported that, in the NMR spectrum*[2] of IIc, the sharp peak at δ 6.86 ppm is due to NH (1H). On treatment with deuterium oxide, however, this peak remains and the broad peak at δ 10.90 ppm (1H) disappears. As is shown in Table 1, the other 3-nonsubstituted anilinoquinolines, such as IIa, IIb, IIm, and IIn, also reveal peaks at δ 6.88—6.96 ppm, while the 3-substituted compounds, IId—III, show no peaks in this range.

The above observations indicate that the peaks at δ 6.96 ppm and at δ 10.90 ppm in IIc are to be assigned to CH at the 3-position and to NH respectively.

On the other hand, the methine-proton signals at the 3-position of 6-chloro-4-phenyl-2(1*H*)-quinolone (IV)*[3] and its 1-methyl derivative (VI)*[2] appear at δ 6.56 ppm and at δ 6.76 ppm respectively.



(VII)

Fig. 1

The complex multiplets at δ 7.44—7.86 ppm and at δ 7.43—7.73 ppm in them correspond to aromatic proton signals. In the case of 2,6-dichloro-4-phenylquinoline (V),*[2] however, there is only the peak of the aromatic proton at δ 7.48—8.14 ppm (multiplet), not the peak of methine-proton at δ 6.5—6.9 ppm.

The differences may be successfully explained in terms of the non-aromaticity of the methine-protons in IV and VI, and the aromaticity in V.

Considering the above observations, it may be

a) Reaction conditions: temp. 75—80°C, time 60 min.
b) Reaction conditions: temp. 75—80°C, time 30 min.
c) Measured in $CDCl_3$, using tetramethylsilane as the internal standard. m:multiplet, s: singlet.
d) Methine-proton at 3-position of quinoline ring or quinolone ring.

deduced that the 2-anilinoquinolines II exist as imino-type VII, as is shown in Fig. 1.

6-Substituted 2-(4-substituted *N*-acetylanilino)-4-phenylquinolines (VIII) which had been obtained by the acetylation of the quinolines II with acetic anhydride were treated with sodium ethoxide to afford 6-substituted 1-(6-substituted 4-phenyl-2-quinolyl)-4-phenyl-2(1*H*)-quinolone derivatives (IX).

The yields, physical properties, and results of the elemental analyses of VIII and IX are listed in Table 2.

Whereas the NMR spectra of the acetyl quinolines, VIII, in deuteriochloroform reveal no peaks at δ 6.5—6.9 ppm, those of the 1-quinolyl-2(1*H*)-quinolones, IX, show the peaks at δ 6.72—6.77 ppm which are assigned to CH at the 3-position of the quinolone ring.

Experimental

All the melting points are uncorrected. The NMR spectra were determined on a Hitachi R-20 spectrometer.

Materials. The 2-aminobenzophenone (Ia) was prepared according to the method of Scheifele and DeTar;[6] mp 104—105°C (lit,[6] mp 105—106°C). The 2-amino-5-methylbenzophenone (Ib) was prepared by the method of Staskun;[7] mp 66—67°C (lit,[7] mp 66—67°C). The 2-amino-5-chlorobenzophenone (Ic) was prepared by the method of Sternbach *et al.*;[8] mp 100—101°C (lit,[7] mp 100—101°C).

The 2,6-dichloro-4-phenylquinoline (V) was prepared in the following way. 2-Acetamido-5-chlorobenzophenone (IIIc), which had been obtained by the acetylation of Ic, was treated with sodium ethoxide to give 6-chloro-4-phenyl-2(1*H*)-quinolone (IV). The treatment of IV with phosphorus oxychloride in the presence of dry pyridine at 130—140°C gave V; mp 111—112°C (lit,[9] mp 114—115°C).

The PPA was obtained from the Wako Pure Chemical Industries Co., Ltd.

The Reaction of 2-Aminobenzophenones (I) with Aliphatic Acids. Only a typical reaction will be described here. All of these reactions were carried out by a method similar to that described below.

A mixture of 2-amino-5-chlorobenzophenone (5 mmol), acetic acid (15 mmol), and PPA (20 g) was heated to 140—145°C for 15 min. After cooling, the reaction mixture was poured into ice water (*ca.* 100 m*l*), neutralized with 28% ammonia water, and extracted with methylene chloride (*ca.* 100 m*l*). The extract was then washed with water and dried over anhydrous magnesium sulfate. The solution was concentrated to 30 m*l* and chromatographed on silica gel with the same solvent. The first eluate (*ca.* 100 m*l*) was evaporated to dryness, and the resulting solid was recrystallized from a mixture of methylene chloride and methanol to afford IIc as yellow needles.

2-(2-Benzoyl-4-chloroanilino)-6-methyl-4-phenylquinoline (IIm). A mixture of Ib (4 mmol), IIIc (4 mmol), and PPA (20 g) was heated to 135—140°C for 30 min. The reaction mixture was worked up according to the procedure described for the preparation of IIc. Recrystallization from a mixture of methylene chloride and methanol afforded IIm as yellow needles.

2-(2-Benzoyl-4-methylanilino)-6-chloro-4-phenylquinoline (IIn). *i) From IIIb.* A mixture of Ic (4 mmol), IIIb (4 mmol), and PPA (20 g) was heated to 155—160°C for 1 hr. The reaction mixture was then worked up according to the procedure described for the preparation of IIc. Recrystallization from a mixture of methylene chloride and methanol afforded IIn as yellow needles.

ii) From V. A mixture of Ib (4 mmol), V (4 mmol), and copper powder (20 mg) was sealed into a glass ampoule and then heated at 175—180°C for 5 hr. After the ampoule had been cooled and opened, the reaction mixture was dissolved in methylene chloride (*ca.* 20 m*l*) and filtered to remove the catalyst. The

solution was then chromatographed on silica gel with the same solvent. The first eluate (*ca.* 100 m*l*) was evaporated to dryness, and the resulting solid was recrystallized from a mixture of methylene chloride and methanol to afford IIn as yellow needles.

The product was identified by means of mixed-melting-point measurements and by a comparison of its IR and NMR spectra with those of the sample obtained from *i*.

Acetylation of IIa, IIb, and IIc. A typical experiment will be described below.

A solution of IIc (2 mmol) in acetic anhydride (25 m*l*) was heated at 75—80°C in the presence of sodium acetate (2 g). After 1 hr, the mixture was cooled to room temperature and kept overnight. Then the solution was poured into ice water and extracted with chloroform. The extract was successively washed with water, a 5% sodium hydrogencarbonate solution, and water. The solution was dried over anhydrous magnesium sulfate and then evaporated to dryness. The residual oil was solidified by adding a small amount of methylene chloride, and the resulting solid was recrystallized from a mixture of methylene chloride and methanol to afford VIIIc as white prisms.

VIIIa and VIIIb were also obtained according to methods similar to that described above.

General Procedure for the Preparation of 1-Quinolyl-2(1*H*)-quinolone (IX). Into a solution of VIII (1.5 mmol) in absolute ethanol (120 m*l*), a sodium ethoxide solution [from sodium (0.1 g) and absolute ethanol (20 m*l*)] was stirred, drop by drop, at 75—80°C over a 15 min period. After having been stirred for an additional 15-min, the reaction mixture was poured into water. The crude product was collected by filtration and washed with warm water. Recrystallization from carbon tetrachloride afforded 6-substituted 1-(6-substituted 4-phenyl-2-quinolyl)-4-phenyl-2(1*H*)-quinolones (IX) as white prisms.

The authors wish to express their thanks to Miss N. Morimoto for her assistance in the experimental work.

Aminocyclitols. XXII. A Synthesis of Actinamine and Hyosamine[1]

Tetsuo SUAMI, Seiichiro OGAWA and Hiroshi SANO

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received December 16, 1969)

Hydrazinolysis of 2,4,5,6-tetra-*O*-acetyl-1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol, followed by catalytic hydrogenation afforded *myo*-inosadiamine-1,3 *via* an intermediary 6,7-diazabicyclo[3.2.1]-octane-2,3,4,8-tetrol. In this reaction, the use of *N,N'*-dimethylhydrazine and *N*-methylhydrazine, instead of hydrazine, gave actinamine: a component of an antibiotic spectinomycin, and *N*-methyl-*myo*-inosadiamine-1,3: an important intermediary compound for a synthesis of DL-hyosamine, respectively. Details of the convenient syntheses of actinamine and DL-hyosamine are described.

Actinamine has been found in the antibiotic spectinomycin[2,3] as its component and its structure has been established to be *N,N'*-dimethyl-*myo*-inosadiamine-1,3.[4-6] The synthesis has been done by several authors[7-10] in laborious procedures.

While hyosamine has been discovered in the antibiotic hyosamine B[11] and later in destomycin A[12] as their components. The structure has been established to be *N*-methyl-2-deoxy-streptamine[11,12] and the synthesis has been described by Nakajima and his coworkers.[13]

In the present papers, the authors wish to report

a detail of a convenient synthesis of actinamine and DL-hyosamine.

myo-Inosadiamine-1,3 has been readily prepared from 1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (I)[14] by the reaction with hydrazine,[15] and hence, actinamine and DL-*N*-methyl-*myo*-inosadiamine-1,3 could be prepared from I by the reactions with *N*,*N*′-dimethylhydrazine and *N*-methylhydrazine.

From the latter compound, DL-hyosamine could be prepared by analogous reaction procedures in which 2-deoxystreptamine had been successfully synthesized from *myo*-inosadiamine-1,3.[16,17]

When I was heated under reflux in a mixture of *N*,*N*′-di-methylhydrazine and 2-methoxyethanol for 19 hr, an oily product was obtained upon evaporation of the solvent, which was hydrogenated in the presence of the Raney nickel catalyst under 3.4 kg/cm^2 of an initial hydrogen pressure for 22 hr at 40°C. The reduction product was acylated with acetic anhydride in pyridine to give crystalline hexaacetyl-actinamine (II) in a yield of 36%, which was identified with an authentic sample[18] by a mixed melting point determination and a comparison of IR spectra.

While I was heated under reflux in a mixture of *N*-methylhydrazine and 2-methoxyethanol for 20 hr and the product was hydrogenated in the presence of Raney nickel, followed by a conventional acetylation, hexaacetyl DL-*N*-methyl-*myo*-inosadiamine-1,3 (III) was obtained in 43% yield. A selective de-*O*-acetylation of III afforded di-*N*,*N*′-acetyl-DL-*N*-methyl-*myo*-inosadiamine-1,3 (IV) in 98% yield, and a hydrolysis of III in 6N hydrochloric acid gave DL-*N*-methyl-*myo*-inosadiamine-1,3 dihydrochloride (V) in 86% yield.

The hydroxyl groups vicinal and in a *cis* position to an amino or acetamido group in aminocyclitols are preferentially displaced by halogen in a mixture of acetyl halide and acetic anhydride.[17,19] Since there is an axial hydroxyl group on C-2 in a *cis*-disposition to the vicinal amino groups in the compound V, the hydroxyl group should be displaced by halogen in a mixture of acetyl halide and acetic anhydride with an inversion of the configuration on C-2.

When V was heated in the mixture of acetyl bromide and acetic anhydride in a sealed tube at 130—135°C for 13 hr, the bromination product was obtained in 22% yield, which was identified to be pentaacetyl-DL-2-bromo-2-deoxy-*N*-methyl-*scyllo*-inosadiamine-1,3 (VI) by analogy with a bromination product of *myo*-inosadiamine-1,3 dihydrochloride in an analogous reaction condition.

Catalytic debromination of VI with Raney nickel and Amberlite IR-4B (OH^-) under a hydrogen stream of 3.4 kg/cm^2 for 20 hr afforded pentaacetyl DL-hyosamine (VII) in a yield of 87%, which was identified with an authentic sample obtained from antibiotic destomycin A[12] with an exception of an optical activity.

To elucidate the reaction mechanism of the present hydrazinolysis, an attempt to isolate an inter-

mediate in a crystalline state failed. But it seemed quite sure that these hydrazinolyses might proceed through intermediary bicyclic compounds, because II or III was obtained in a considerably good yield as a sole product, and formations of II and III were reasonably explained only by assuming an existence of bicyclic intermediates.

Experimental

The melting points reported were determined on a Mitamura Riken micro hot stage and uncorrected. The PMR spectra of the samples were measured on Varian Associate A-60D spectrometer at the frequency of 60 MHz at a concentration of 10% in deuteriochloroform, deuteriodimethylsulfoxide (d_6-DMSO) or deuterium oxide with tetramethylsilane or sodium trimethylsilylpropanesulfonate as an internal standard. The peak positions are given in τ-values.

Hexaacetyl Actinamine (II). A suspension of 2.18 g of *N,N'*-dimethylhydrazine sulfate in 50 m*l* of 2-methoxyethanol was treated with 1.31 g of sodium hydroxide in 1.5 m*l* of water. A 1.48 g portion of 1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (I) was added to the resulting solution and refluxed for 20 hr. An insoluble material was filtered off and the filtrate was evaporated *in vacuo* to give an oily residue. A solution of the residue in 35 m*l* of water was hydrogenated in the presence of Raney nickel catalyst (two spatula) in a Parr shaker type apparatus at room temperature in the initial hydrogen pressure of 3.4 kg/cm^2. After shaking for 22 hr, the reaction mixture was filtered to remove the catalyst and evaporated to dryness. The glassy residue was treated with a mixture of 15 m*l* of acetic anhydride and 15 m*l* of pyridine at room temperature overnight. Evaporation of excess reagent *in vacuo* gave an oily product, which was chromatographed on active aluminum oxide and eluted with chloroform to afford 507 mg of colorless plates (36.3%), mp 202—203°C. One recrystallization from methanol gave a pure sample of II, mp 205—206°C, which was identified with the authentic sample derived from antibiotic spectinomycin by mixed melting point determination and comparing with IR spectra.

Hexaacetyl DL-*N*-Methyl-*myo*-inosadiamine-1,3 (III). A suspension of 6.63 g of *N*-methylhydrazine sulfate in 50 m*l* of 2-methoxyethanol was treated with 3.69 g of sodium hydroxide in 5 m*l* of water and a precipitated sodium sulfate was removed by filtration. An 1.50 g portion of I was added to the filtrate and the mixture was refluxed for 20 hr under nitrogen. The reaction mixture was evaporated *in vacuo* to dryness and a solution of the residue in 20 m*l* of water was hydrogenated in the presence of Raney nickel catalyst (two spatula) in a Parr shaker type apparatus at 40—50°C in the initial hydrogen pressure of 3.4 kg/cm^2 for 22 hr. Filtering off the catalyst, the solution was evaporated *in vacuo* to dryness. Then the oily product was treated with a mixture of 15 m*l* of acetic anhydride and 15 m*l* of pyridine at room temperature overnight. The reaction mixture was evaporated *in vacuo* to remove excess reagent and the residue was chromatographed on active aluminum oxide. Elution with chloroform gave a colorless oil which crystallized upon addition of ethanol and ether. Recrystallization from ethanol gave colorless rhombic crystals weighing 582 mg (42.7%), mp 229—230°C. IR (KBr): 1750 (OAc), 1694, 1642 and 1525 cm^{-1} (amide). PMR ($CDCl_3$): τ 7.12 (NCH_3), 7.79 (3), 7.95 (6), 7.99 (6) and 8.12 (3)*1 (OAc and NAc).

Found: C, 51.39; H, 6.85; N, 6.17%. Calcd for $C_{19}H_{28}N_2O_{10}$: C, 51.34; H, 6.35; N, 6.30%.

Di-*N,N'*-acetyl-DL-*N*-methyl-*myo*-inosadiamine-1,3 (IV). A 203 mg portion of III was treated with 20 m*l* of methanol saturated with ammonia (at 5°C) overnight at room temperature. The solution was evaporated *in vacuo* to yield an oily residue which crystallized upon trituration by ethyl acetate. Crude crystals were recrystallized from 80% methanol to afford 113 mg of colorless needles (89.3%), mp 253—254°C. PMR (D_2O): τ 6.95, 7.00 (NCH_3), 7.82 (3) and 7.95 (3) (NAc).

Found: C, 48.16; H, 7.82; N, 9.77%. Calcd for $C_{11}H_{20}N_2O_6$: C, 47.82; H, 7.30; N, 10.14%.

DL-*N*-Methyl-*myo*-inosadiamine-1,3 Dihydrochloride (V). A 239 mg portion of III was refluxed with 10 m*l* of 6N hydrochloric acid for 2 hr. The reaction mixture was evaporated *in vacuo* and the crystallization was induced by addition of aqueous ethanol. Colorless needles were obtained by recrystallization from aqueous ethanol, 122 mg (85.5%), mp 300°C (dec.). PMR (D_2O): τ 7.16 (NCH_3).

Found: C, 31.64; H, 6.98; N, 10.45; Cl, 26.52%. Calcd for $C_7H_{16}N_2O_4 \cdot 2HCl$: C, 31.71; H, 6.84; N, 10.56; Cl, 26.75%.

Pentaacetyl-DL-2-bromo-2-deoxy-*N*-methyl-*scyllo*-inosadiamine-1,3 (VI). A mixture of 359 mg of powdered V (dried *in vacuo* P_2O_5 at 100°C), 0.43 m*l* of acetyl bromide and 0.94 m*l* of acetic anhydride was heated in a sealed tube at 130—135°C for 13 hr. After cooling to room temperature, the sealed tube was opened carefully, to which 25 m*l* of ethanol was added dropwise under ice cooling. The reaction mixture was allowed to stand in a refrigerator overnight, and then treated with 20 m*l* of Amberlite IRA-400 (OH^-). The solution was evaporated *in vacuo* to drynesss and the residue was acetylated with a mixture of 25 m*l* of acetic anhydride and 25 m*l* of pyridine at room temperature overnight. The mixture was evaporated *in vacuo* to remove excess reagent and the residue was dissolved in a small amount of chloroform. The solution was chromatographed on active aluminum oxide and eluted with chloroform afforded an oil which crystallized upon trituration by a mixture of ethanol and ether. Crude crystals (233 mg) showed mp 165—175°C and a small amount of III was shown to be contained by TLC (silica gel, chloroform-ethanol=8 : 2). Fractional crystallization from ethanol and ether afforded 80 mg of III and 120 mg of VI, mp 168—180°C (dec.). The yield of VI was 22.0% based on V consumed. Recrystallization from ethanol and ether gave analytical pure crystals of VI, mp 179—183°C (dec.). PMR ($CDCl_3$): τ 6.85, 7.10, 7.20 (NCH_3), 7.79, 7.88, 7.92 and 7.98 (OAc and NAc).

Found: C, 44.19; H, 5.52; N, 6.03; Br, 16.76%. Calcd for $C_{17}H_{25}N_2O_8Br$; C, 43.88; H, 5.42; N, 6.02; Br, 17.18%.

Pentaacetyl-DL-hyosamine (VII). A solution of 106 mg of VI in 8 ml of 50% aqueous ethanol was

*1 In parentheses, proton numbers are indicated.

hydrogenated in the presence of Raney nickel catalyst (one spatula) and 1.2 m*l* of Amberlite IR-4B (OH^-) in a Parr shaker type apparatus in the initial pressure of 3.4 kg/cm^2 at room temperature. After shaking for 20 hr, the catalyst and resin were filtered off and the filtrate was evaporated *in vacuo* to give a colorless oil. Trituration by chloroform and ether gave 76 mg of colorless crystals (86.6%), mp 201—202.5°C (with transition at 143—165°C). Recrystallization from chloroform and ether afforded colorless crystals, mp 202—203°C after melting and resolidified at 162—165°C. This product was identified with an authentic active material derived from antibiotic destomycin A by comparing with IR (in chloroform) and PMR (in $CDCl_3$) spectra.

Found: C, 52.50; H, 7.00; N, 7.37%. Calcd for $C_{17}H_{26}N_2O_8$: C, 52.84; H, 6.78; N, 7.25%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1846—1849 (1970)

Yields of Methylcyclohexanone Intermediates in the Hydrogenation of Isomeric Cresols over Ruthenium and Palladium Catalysts[1]

Yuzuru TAKAGI, Shigeo NISHIMURA and Kozo HIROTA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama, Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo, and Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received December 24, 1969)

Isomeric cresols have been hydrogenated over ruthenium and palladium catalysts at elevated temperature and pressure. The yields of the methylcyclohexanone intermediates formed were estimated by application of a kinetic method. Hydrogenation with ruthenium catalyst gave 77, 61 and 60% of the ketone as the intermediate for *o*-, *m*- and *p*-cresol, respectively, while with palladium catalyst all isomeric cresols yielded the ketone intermediates quantitatively. The hydrogenation pathways leading to the formation of methylcyclohexanones were discussed. The stereochemistry of hydrogenation of isomeric cresols and methylcyclohexanones were also studied, and the results were interpreted on the basis of the estimated yields of the ketone intermediates.

It is known that cyclohexanones are produced as intermediates in the catalytic hydrogenation of phenols and the ketones produced often accumulate in considerable amounts in the course of hydrogenation.[2-4] Cresols may give stereoisomeric methylcyclohexanols on hydrogenation and the stereochemistry of the hydrogenation is closely related to the production and subsequent hydrogenation of the corresponding methylcyclohexanones formed as intermediates. Although some studies on the hydrogenation of isomeric cresols have recently been reported with rhodium and ruthenium catalysts,[5] and with a rhodium-platinum catalyst,[6] a more detailed study will be required for the quantitative interpretation of the results.

In previous papers,[7,8] we estimated quantitatively the yields of the methylcyclohexanone intermediates formed in the rhodium-catalyzed hydrogenation of isomeric cresols by application of the following three methods: (a) the stereochemistry of the hydrogenation of a cresol and the corresponding methylcyclohexanone, (b) initial yield method, (c) a kinetic interpretation of the product change

during hydrogenation. Although the results obtained by the three methods did not differ much from each other and were in some cases in excellent accord, the kinetic method mentioned above seemed to be the most reliable and widely applicable to the estimation of the ketone intermediates, because of the quantitative nature of the method. In this study, therefore, the yields of the ketone intermediates formed in the ruthenium- and palladium-catalyzed hydrogenations of isomeric cresols have been determined by the kinetic method and the results compared with those obtained previously with rhodium catalyst. Stereochemistry of the hydrogenation has also been studied and interpreted on the basis of the estimated yields of the ketone intermediates.

Experimental

Materials. Cresols and methylcyclohexanones of G. R. grade of the Tokyo Kasei Kogyo Co. were used after fresh distillation through a 30 cm Vigreux column under reduced pressure. The cresols and methylcyclohexanones were sufficiently pure for the present purpose (more than 99% purity as judged from the analysis by gas chromatography of the hydrogenation products).

Catalysts. Ruthenium hydroxide used for hydrogenation was prepared by adding a slight excess of 10% sodium hydroxide solution to a 1% hot aqueous solution of ruthenium chloride.[9] The hydroxide catalyst was used without being prereduced to metals. For the palladium catalyst, 5% palladium-on-carbon of a commercial preparation (obtained from the Nippon Engelhard Co.) was used, since unsupported palladium was easily deactivated during hydrogenation under the present reaction conditions.

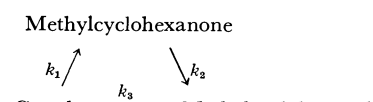
Hydrogenation. Hydrogenation was carried out without solvent at 80°C for ruthenium catalyst and at 120°C for palladium catalyst under a hydrogen pressure of 80—100 kg/cm². Cresol (0.1 mol) was hydrogenated with 20 mg of ruthenium hydroxide or with 300 mg of supported palladium in a 100 m*l* bomb equipped with an agitator driven up and down.

Analysis of Products. The reaction mixture was analyzed directly by gas chromatography (detector: hydrogen flame ionization type; column dimension: 3 m by 0.4 cm OD; stationary phase: 10 wt% diglycerol on 60 mesh firebrick; temperature: column 80—95°C, detector 80—95°C; carrier gas: nitrogen at 90—100 m*l*/min).

Results

The hydrogenation of cresol to methylcyclohexanol will proceed through two simultaneous reaction pathways: one *via* methylcyclohexanone and the other not *via* the ketone as indicated below.

As shown in a previous paper on the rhodium-catalyzed hydrogenation,[8] concentration of the ketone (C_2) varying during hydrogenation may be given by Eq. (1) in which C_1 is the concentration of cresol, k_i's are the rate constants for the respective reaction pathways in Scheme 1, and $K=k_2b_2/(k_1+k_3)b_1$ where b_1 and b_2 represent the adsorption coefficients of cresol and methylcyclohexanone, respectively. The yields of the ketone intermediates and the values of K were obtained by finding the most suitable values of $k_1/(k_1+k_3)$ and K in such a way that the following equation, when these values are substituted into it, may represent the actual variation of the concentration of the ketone with the least deviation.



Scheme 1

$$C_2 = \frac{k_1/(k_1+k_3)}{K-1}(C_1 - C_1^K) \qquad (1)$$

The yields of the methylcyclohexanone intermediates and the values of K thus obtained are summarized in Table 1, along with those for the rhodium-catalyzed hydrogenation obtained previously. The theoretical curves given by Eq. (1) showing the variation in the concentration of the ketone are compared with a set of experimental values in Figs. 1,2 and 3 for the hydrogenation of *o*-, *m*- and *p*-cresol, respectively. The data for the rhodium-catalyzed hydrogenation are reproduced in the figures for comparison. The ratios of the adsorption coefficients (b_2/b_1) can be evaluated from the values of K and the ratios of the rate constants of methylcyclohexanone and cresol $[k_2/(k_1+k_3)]$.*1

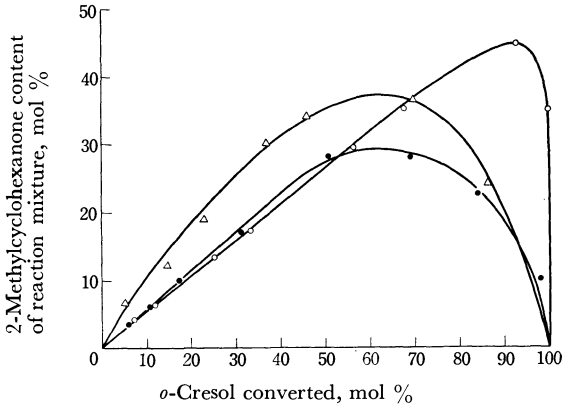

Fig. 1. 2-Methylcyclohexanone intermediate formed in hydrogenation of *o*-cresol over Ru, Rh and Pd/C catalysts as a function of the conversion of the cresol; temp., 80°C for Ru and Rh; 120°C for Rd/C; hydrogen press., 80—100 kg/cm². Experimental values in the Figure are a set of results obtained by separate experiments in each hydrogenation:
● Ru; ○ Rh; △ Pd/C. ——: Theoretical curve given by Eq. (1).

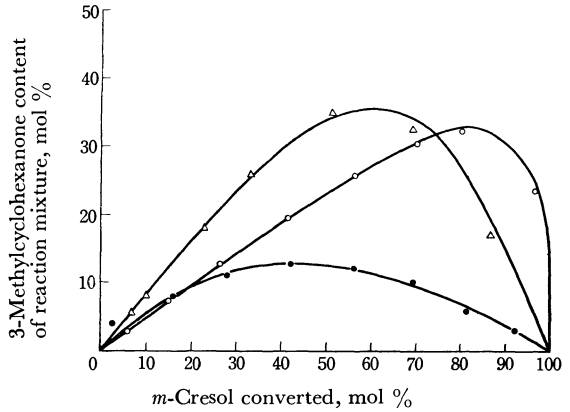

Fig. 2. 3-Methylcyclohexanone intermediate formed in hydrogenation of *m*-cresol over Ru, Rh and Pd/C catalysts as a function of the conversion of the cresol. For other indications see Fig. 1.

They are also listed in Table 1. The stereoisomeric compositions of the methylcyclohexanols produced by hydrogenation of cresols and methylcyclohexanones under comparable conditions are summarized in Table 2, along with those for the rhodium-catalyzed hydrogenation.

Discussion

It has been shown by the kinetic method that the rhodium-catalyzed hydrogenation of isomeric cresols yielded 52—55% of methylcyclohexanones as intermediates.[8] The yields obtained by the other two methods ranged between 43—66%. For the formation of the ketone intermediates in large amounts, we have suggested an explanation which is based on the assumptions that all dihydrocresols are produced from parent cresols in equal probability and that unsaturated ketones or their enols formed

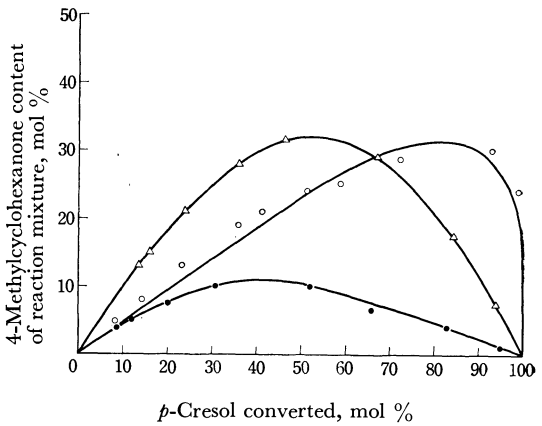

Fig. 3. 4-Methylcyclohexanone intermediate formed in hydrogenation of *p*-cresol over Ru, Rh and Pd/C catalysts as a function of the conversion of the cresol. For other indications see Fig. 1.

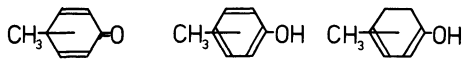
b) Reproduced from Ref. 7.

are preferentially converted to saturated ketones on further hydrogenation. According to these assumptions, all isomeric cresols should give the ketone intermediates in 67% yield. It was pointed out that the yields estimated on the rhodium-catalyzed hydrogenation were close to this value and that they were nearly the same for *o*-, *m*- and *p*-cresol. As seen from Table 1, the yields of the ketone intermediates obtained with ruthenium catalyst are even more close to the value 67%, and the assumptions mentioned above also appear to hold for the ruthenium-catalyzed hydrogenation. It is to be noted that *o*-cresol gave a considerably greater yield of the ketone (77%) than *m*- and *p*-cresol (60—61%) over ruthenium. In the palladium-catalyzed hydrogenation all isomeric cresols gave quantitative yields of the ketone intermediates.*2 Obviously the assumption that all dihydrocresols are produced in equal probability does not hold with this metal. It might be possible that over palladium cresol is hydrogenated in the keto form (I) rather than in the enol form (II) or it is hydrogenated through the selective formation of the dihydro intermediate (III). The hydrogenation of I or III is expected to give the saturated ketone



(I) (II) (III)

quantitatively.*3

From Table 1 it will also be seen that the values of K are in the order with respect to catalyst metals, rhodium<palladium<ruthenium for every isomeric cresol. With respect to the three isomers of cresol the values of K decrease in the order, para>meta>ortho for any catalyst metal. The ratio b_2/b_1 is not always in the same order as K. It is of interest that the ratio is the smallest for hydrogenation of *m*-cresol both on rhodium and ruthenium catalysts.

A rather large yield of the ketone intermediate obtained in hydrogenation of *o*-cresol with ruthenium catalyst is supported by a small difference in the stereoisomeric compositions of the methylcyclohexanols formed from *o*-cresol and from 2-methylcyclohexanone (see Table 2). The results in Table 2 also indicate that the ketone intermediates are produced quantitatively in hydrogenation with palladium catalyst, because the methylcyclohexanols of the same stereoisomeric composition were obtained in the hydrogenation of cresols and the corresponding methylcyclohexanones, and thus support the conclusion deduced by the kinetic method. The results also indicate that the adsorption-desorption equilibrium was completely established in the formation and hydrogenation of the ketone intermediate on the surface of the palladium catalyst.

*2 Nearly quantitative formation of cyclohexanone has also been reported recently on the hydrogenation of phenol with a palladium-carbon catalyst in acetic acid at 50°C under the hydrogen pressure of 1 atm [M. Matsumoto, T. Suzuki and S. Suzuki, *Kogyo Kagaku Zasshi*, **72**, 881 (1969)].

*3 The possibility that the methylcyclohexanone intermediates are formed through the production of allyl type alcohols, followed by isomerization to the ketones, is excluded, because the hydrogenolysis product (methylcyclohexane), which would result from the allyl type alcohols, was not found in the products of the palladium-catalyzed hydrogenation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1850—1854 (1970)

Studies of Peptide Antibiotics. XIX. Syntheses of 1,1′-Leucine-gramicidin S and 1-Leucine-cyclosemigramicidin S

Michio KONDO* and Nobuo IZUMIYA**

*Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga
**Laboratory of Biochemistry, Faculty of Science, Kyushu University, Fukuoka

(Received December 25, 1969)

Analogs of gramicidin S, 1,1′-L-leucine-gramicidin S (XI) and 1-L-leucine-cyclosemigramicidin S (XII), have been synthesized and tested for antibacterial properties. The cyclization reaction of a linear decapeptide active ester, in which δ-amino functions of ornithine residues were protected with benzyloxycarbonyl groups, yielded exclusively a protected cyclic decapeptide which was hydrogenated to afford the dihydrochloride of XI. A linear pentapeptide active ester afforded a mixture of protected cyclic penta and decapeptide. The pure protected cyclic pentapeptide was obtained with the use of a Sephadex LH-20 column, and the hydrogenolysis of the product afforded the hydrochloride of XII. The decapeptide analog (XI) was as active as natural gramicidin S, whereas the pentapeptide (XII) showed no activity toward any of the microorganisms tested.

We reported that 1,1′-L-alanine gramicidin S was as active as natural gramicidin S (GS) (Fig. 1) toward several microorganisms.[1] The result indicated that the side chains of valine residues, the isopropyls, in a GS molecule can be replaced by smaller aliphatic side chains, the methyls, without a decrease in the antibacterial activity. From this finding, it seemed of interest to investigate the antibacterial properties of an analog of GS with larger side chains than the isopropyls of the valines.

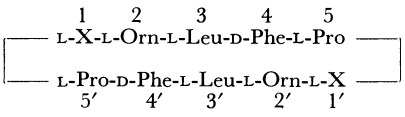


Fig. 1. Structure of GS and its analog.
X represents amino acid residue such Val (GS) or Leu (XI).

This paper will describe the synthesis and antibacterial properties of 1,1′-L-leucine-GS besides the preparation of the cyclic pentapeptide, 1-L-leucine-cyclosemiGS.

Figure 2 indicates the route for the synthesis of the desired cyclic decapeptide (XI).[2] Condensation of the azide derived from *p*-methoxybenzyloxycarbonyl pentapeptide hydrazide (V) with the corresponding neutral pentapeptide (VII) gave an acyldecapeptide acid (VIII). Acid VIII was transformed to an acyldecapeptide nitrophenyl ester, and its *p*-methoxybenzyloxycarbonyl group was removed by means of trifluoroacetic acid.

TABLE 1. RATIO OF PROTECTED CYCLIC MONOMER AND DIMER AFTER CYCLIZATION OF LINEAR PENTAPEPTIDE ACTIVE ESTERS

p-Nitrophenyl ester of[a]	Ratio of compounds in product[b]	
	Z-cyclic monomer	di-Z-cyclic dimer
H-Gly-Orn(Z)-Leu-D-Phe-Pro-OH[1]	100	0
-Ala-[1]	91	9
-Leu-	78	22
-Val-[3]	32	68
-Gly-Lys(Z)-[c]	100	0
-Val-Lys(Z)-[d]	29	71

a) The first compound is listed and only variations of the residue are shown.
b) The concentration of pentapeptide nitrophenyl esters in pyridine was 3×10^{-3} M.
c) M. Kondo and N. Izumiya, to be published.

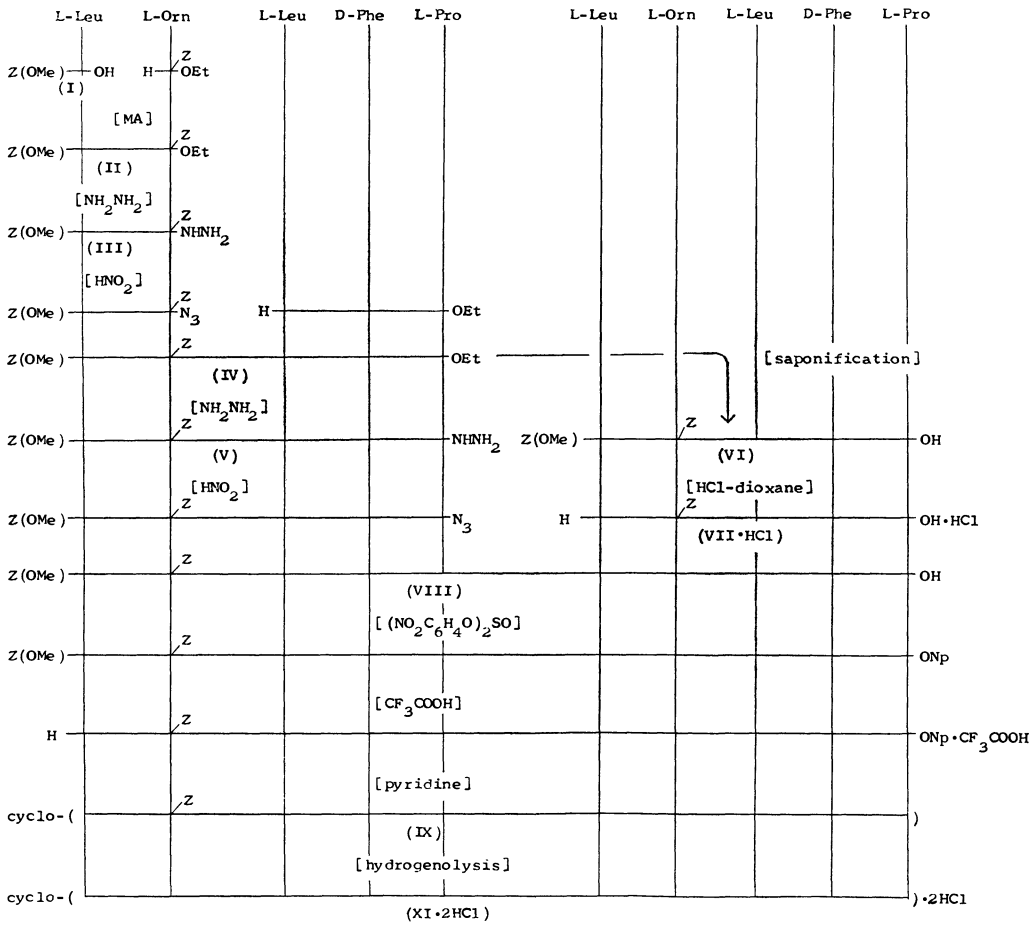

Fig. 2. Cyclization of linear decapeptide active ester.

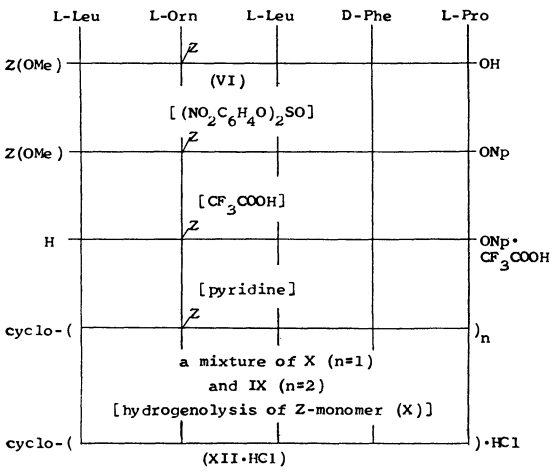

Fig. 3. Cyclization of linear pentapeptide active ester.

Decapeptide ester trifluoroacetate thus obtained was treated with pyridine for the cyclization reaction. The reaction mixture yielded a pure benzyloxycarbonyl-substituted cyclic decapeptide (IX) which was hydrogenated to afford the desired cyclic decapeptide (XI) as a crystalline dihydrochloride.

Synthesis of the protected cyclic decapeptide (IX) was attempted by possible dimerization reaction of the linear pentapeptide active ester which was derived from *p*-methoxybenzyloxycarbonyl pentapeptide acid (VI) (Fig. 3). Treatment of the active ester with pyridine afforded a mixture of the protected monomer (X) and dimer (IX); the ratio in weight of X and IX in the mixture was found to be approximately 78 : 22. Separation of the components was achieved with the use of a Sephadex LH-20 column with methanol as an eluting solvent, the protected monomer (X) being obtained as a pure crystalline material. Hydrogenolysis of X in the presence of hydrogen chloride yielded a crystalline hydrochloride of the cyclic pentapeptide (XII).

The weight ratios of the protected cyclic monomer and dimer in the crude product after the cyclization reaction of the linear pentapeptide active ester are shown in Table 1 with the previous results related to the present paper. It is recognized that the

pentapeptide sequence with the alanine or leucine residue as N-terminus is more favorable for the intramolecular cyclization reaction compared with that with the valine residue.[3] This means that the degree of the monomer formation is influenced more profoundly by the shape of the side chain of the N-terminus in the pentapeptide active ester than its size; the side chain of valine is indicated as R–CH(R)– (R, methyl), whereas that of alanine or leucine as R–CH_2– (R, H or isopropyl). In this connection, the syntheses of 1,1′-L-isoleucine-GS and several related compounds are in progress.

The antibacterial activities of the synthetic cyclic peptides toward several microorganisms are listed in Table 2. It was observed that 1-leucine-cyclo-semiGS (XII) exhibited no antibacterial activity similar to those of 1-glycine and 1-alanine-cyclosemi-GS,[1] whereas 1,1′-leucine-GS was as active as natural GS against several microorganisms. The results indicate that the side chains of the valine residues in a GS molecule can be replaced with larger aliphatic side chains, the isobutyls, without influencing antibacterial activity.

Experimental

Melting points were not corrected. Prior to analysis, the compounds were dried to a constant weight over phosphorus pentoxide at 60°C and 2 mmHg, except in the case of the cyclic peptide hydrochlorides (XI·2HCl and XII·HCl).

Z(OMe)-Leu-OH (I). The general procedure[4] to prepare Z(OMe)-amino acid was modified as follows. A mixture of L-leucine (3.93 g, 30 mmol), water (90 m*l*), dioxane (90 m*l*), sodium bicarbonate (6.05 g) and *p*-methoxybenzyloxycarbonyl azide (7.46 g, 36 mmol) was stirred at room temperature for 60 hr, the reaction being followed by TLC. The solution was evaporated *in vacuo* to a small volume, extracted with ether, acidified with 0.5M citric acid, and then extracted with ethyl acetate. The organic layer was dried over sodium sulfate and evaporated to dryness. The product was obtained as an oil; yield, 6.55 g (74%). Reported yield for the oil, 28%.[4] A part of the oily product was converted to crystalline dicyclohexylamine salt; yield 85%; mp 163°C; $[\alpha]_D^{15}$ −6.8° (*c* 2, methanol). Reported value for the salt; mp 162°C; $[\alpha]_D^{24}$ −6.67° (methanol).[4]

Z(OMe)-Leu-Orn(δ-Z)-OEt (II). To a chilled solution of I (5.02 g) and triethylamine (1.99 m*l*) in tetrahydrofuran (28 m*l*), isobutylchloroformate (1.86 m*l*) was added. After 15 min, a mixture of H-Orn(δ-Z)-OEt·TsOH,[5] triethylamine (1.99 m*l*) and chloroform (38 m*l*) was added to the chilled solution. The reaction mixture was allowed to stand overnight, evaporated *in vacuo*, and the residue was dissolved in ethyl acetate (100 m*l*). The solution was washed with 0.5M citric acid, 4% sodium bicarbonate and water, dried over sodium sulfate and then evaporated *in vacuo*. The oily residue was crystallized by the addition of a mixture of ether and petroleum ether. It was recrystallized from ethyl acetate-ether-petroleum ether; yield, 5.97 g (81%); mp 109—110°C; $[\alpha]_D^{15}$ −6.3° (*c* 2, DMF).

Found: C, 62.74; H, 7.12; N, 7.41%. Calcd for $C_{30}H_{41}O_8N_3$: C, 63.03; H, 7.23; N, 7.35%.

Z(OMe)-Leu-Orn-(δ-Z)-NHNH$_2$ (III). A solution of II (5.15 g) and hydrazine hydrate (9 m*l*) in DMF (35 m*l*) was allowed to stand for 2 days at 30°C. The solution was concentrated *in vacuo* to a small volume. The hydrazide which precipitated upon the addition of water was collected; yield, 4.70 g (94%); mp 147—148°C; $[\alpha]_D^{15}$ −7.4° (*c* 1, DMF).

Found: C, 58.41; H, 7.17; N, 12.19%. Calcd for $C_{28}H_{39}O_7N_5 \cdot H_2O$: C, 58.42; H, 7.18; N, 12.17%.

Z(OMe)-Leu-Orn(δ-Z)-Leu-D-Phe-Pro-OEt (IV). To III (4.47 g, 8 mmol) dissolved in acetic acid (35 m*l*) and N hydrochloric acid (16 m*l*) was added sodium nitrite (0.66 g) in water (5 m*l*) at −5°C. After 10 min, the solution was diluted with water (120 m*l*). The azide precipitated was extracted with ethyl acetate (150 m*l*), and the organic layer was washed with 4% sodium bicarbonate and water. After being dried over sodium sulfate for 15 min at 0°C, the filtrate was added to a solution of H-Leu-D-Phe-Pro-OEt·HCl (3.87 g, 8.8 mmol)[6] dissolved in triethylamine (1.24 m*l*) and DMF (50 m*l*). The mixture was stirred for 3 days at

Z(OMe)-Leu-Orn(δ-Z)-Leu-D-Phe-Pro-OH (VI). To a solution of IV (0.929 g, 1 mmol) in methanol (15 m*l*) and dioxane (15 m*l*), 0.46N sodium hydroxide (2.3 m*l*) was added at 0°C. The solution was allowed to stand overnight at room temperature and then concentrated *in vacuo* at 10—15°C. To the residue was added water (20 m*l*), and the mixture was extracted with ether. The aqueous layer was diluted with dioxane (10 m*l*) and acidified with N hydrochloric acid (1.07 m*l*) at 0°C. The mixture was evaporated to remove dioxane *in vacuo* at 0°C, and the crystals produced were collected by filtration. It was recrystallized from dioxane-ether-petroleum ether; yield, 0.692 g (77%); mp 109—112°C; $[\alpha]_D^{15}$ −33.6° (*c* 0.5, DMF); R_f 0.82.[7]

Found: C, 63.21; H, 7.40; N, 9.20%. Calcd for $C_{48}H_{64}O_{11}N_6 \cdot \frac{1}{2}H_2O$: C, 63.35; H, 7.20; N, 9.24%.

H-Leu-Orn(δ-Z)-Leu-D-Phe-Pro-OH·HCl (VII·HCl). To a mixture of VI (0.70 g, 0.77 mmol) and anisole (0.1 m*l*), 3.4N hydrogen chloride in dioxane (4.5 m*l*) was added at room temperature. After 2 hr, the solution was evaporated to dryness, and the residue was triturated with ether. The crystals were collected with the aid of ether; yield, 0.584 g (97%); mp 142—144°C; $[\alpha]_D^{15}$ −28.0° (*c* 1, DMF); R_f 0.79[7] and 0.81.[8]

Z(OMe)-Leu-Orn(δ-Z)-Leu-D-Phe-Pro-Leu-Orn(δ-Z)-Leu-D-Phe-Pro-OH (VIII). To V (0.601 g) dissolved in DMF (8 m*l*) and N hydrochloric acid (2 m*l*) was added sodium nitrite (0.052 g) in water at −5°C. After 15 min, cold water was added to the solution. The azide precipitated was collected by filtration and washed with 4% sodium bicarbonate and water, and then dried in a vacuum in a desiccator. The azide was added to a solution of VII (0.507 g) and triethylamine (0.18 m*l*) in DMF (12 m*l*). The mixture was stirred for 3 days at 0°C and then evaporated *in vacuo*. The precipitate formed upon the addition of water was collected, washed with 0.5M citric acid and water, and dried. The product was recrystallized from dioxane-ether-petroleum ether; yield, 0.968 g (89%); mp 119—121°C; $[\alpha]_D^{15}$ −50.0° (*c* 1, DMF); R_f 0.90;[7] R_f of hydrogenated product of VIII, 0.60.[7]

Found: C, 63.08; H, 7.56; N, 10.13%. Calcd for $C_{87}H_{118}O_{18}N_{12} \cdot 2H_2O$: C, 63.10; H, 7.43; N, 10.15%.

***cyclo*-(Leu-Orn(δ-Z)-Leu-D-Phe-Pro-)$_2$ (IX).** To a solution of VIII (0.662 g, 0.4 mmol) in pyridine (5 m*l*) was added di-*p*-nitrophenyl sulfite at room temperature. After 20 hr, the solution was evaporated and the residue was collected with the aid of a mixture of ether and petroleum ether. The yield of acyldecapeptide *p*-nitrophenyl ester was 0.655 g, and the *p*-nitrophenyl ester content was estimated to be 99% by measuring the optical density at 412 mμ.[9] This was treated with anisole (0.2 m*l*) and trifluoroacetic acid (4 m*l*) at −5°C. After 30 min, the solution was evaporated *in vacuo* at 0°C, and the residue was collected with ether. The decapeptide *p*-nitrophenyl ester trifluoroacetate so obtained was dissolved in DMF (8 m*l*) and acetic acid (0.1 m*l*). The solution was added dropwise into pyridine (150 m*l*) at 60°C for 4 hr and the stirring was continued for additional 2 hr. The solution was evaporated, and the residue was dissolved in a mixture of methanol (40 m*l*) and water (15 m*l*). After the insoluble substance in small amount was filtered off, the filtrate was passed through columns (1.8×10 cm) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were then washed with the same solvent, the combined effluents (400 m*l*) were evaporated, and the product was collected by filtration with the aid of water (yield, 0.235 g). It was recrystallized from methanol-ether-petroleum ether; yield, 0.222 g (39% from VIII); mp 138—140°C; $[\alpha]_D^{15}$ −188° (*c* 0.25, acetic acid); R_f 0.93.[7]

Found: C, 64.34; H, 8.04; N, 11.89%; mol wt, 1482.[10] Calcd for $C_{78}H_{108}O_{14}N_{12} \cdot H_2O$: C, 64.35; H, 7.62; N, 11.55%; mol wt, 1456.

***cyclo*-(Leu-Orn(δ-Z)-Leu-D-Phe-Pro-) (X).** Compound VI (0.586 g, 0.65 mmol) was treated with di-*p*-nitrophenyl sulfite (1.68 g) in pyridine (4.5 m*l*) as described for the preparation of acyldecapeptide ester, and acylpentapeptide *p*-nitrophenyl ester (0.66 g) was obtained as an amorphous powder; its *p*-nitrophenyl ester content was estimated to be 96%. The substance was treated with trifluoroacetic acid, and the pentapeptide *p*-nitrophenyl ester trifluoroacetate was added to pyridine (180 m*l*) as described above. The effluent from the ion-exchangers was evaporated to yield a powdery residue (0.186 g); the residue was designated as XIII. Two mg of XIII was hydrogenated, and the CMC column chromatography of the hydrogenated material (XIV) showed two peaks (Fig. 5-XIV). It was determined that the faster peak contained the cyclic pentapeptide (XII), the slower peak the cyclic decapeptide (XI), and the ratio of the integrated areas of the

7) The R_f of TLC with Merck Silica Gel G refers to the *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2, v/v) system. Compounds possessing a free amino group were detected by spraying with ninhydrin, and those with blocked amino groups, by spraying with 47% hydrobromic acid and then ninhydrin.

8) The R_f of the paper chromatography with Toyo Roshi No. 52 refers to the *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2, v/v) system.

The filtrate was evaporated, and the crystals were collected with the aid of ether; yield of the air dried product, 78 mg (81%); mp 242—244°C (decomp.); $[\alpha]_D^{15}$ −197° (*c* 0.3, acetic acid); R_f 0.97;[8] amino acid ratios in acid hydrolysate; Leu 2.0, Orn 1.0, Phe 0.9, Pro 1.0.

Found: C, 55.26; H, 7.96; N, 12.42%. Calcd for $C_{62}H_{96}O_{10}N_{12} \cdot 2HCl \cdot 6H_2O$: C, 55.14; H, 8.21; N, 12.45%. The air-dried product lost 6.14% of its weight after it had been dried over phosphorus pentoxide at 80°C (2 mmHg) to a constant weight. Calcd for $5H_2O$: 6.74%.

***cyclo*-(Leu-Orn-Leu-D-Phe-Pro-)·HCl (XII·HCl).** Compound X (74 mg, 0.1 mmol) was treated as described above; yield of the air-dried product, 58 mg (84%); mp 200—201°C (decomp.); $[\alpha]_D^{15}$ −143° (*c* 0.3, acetic acid); R_f 0.92;[8] amino acid ratios in acid hydrolysate; Leu 2.0, Orn 1.0, Phe 1.0, Pro 0.9.

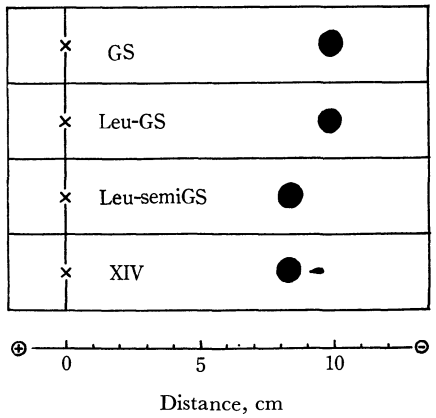

Fig. 4. Paper electrophoresis of GS, Leu-GS (XI), Leu-semiGS (XII) and the hydrogenated material (XIV) after cyclization of pentapeptide ester.

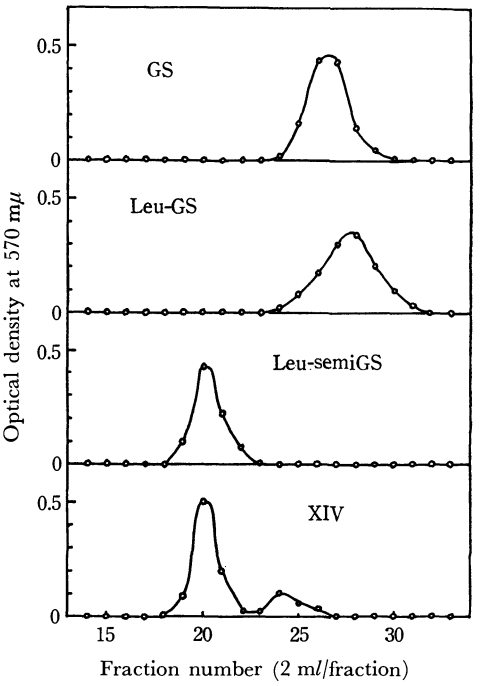

Fig. 5. CMC column chatography of the compounds.

Found: C, 55.29; H, 8.01; N, 12.50%. Calcd for $C_{31}H_{48}O_5N_6 \cdot HCl \cdot 3H_3O$: C, 55.13; H, 8.21; N, 12.45%. The air-dried product lost 5.84% of its weight after being dried. Calcd for $2H_2O$: 5.49%.

Electrophoresis and CMC Chromatography. Electrophoresis on Toyo Roshi No. 52 paper was carried out at pH 1.8 (formic acid-acetic acid-methanol-water, 1 : 3 : 6 : 10, v/v) at 500 V/30 cm for 3 hr. Figure 4 shows that XI migrates toward the cathode faster than XII and that the mobility of XI was similar to that of GS. In CMC column chromatography, a sample (0.5—1 mg) was dissolved in 0.2 m*l* of 0.2M pyridinium acetate containing 30% methanol (pH 5.0), the solution was applied to a column (0.9×50 cm) with CMC (Eastman No. 7796), and development was continued with the same solvent. Two-m*l* fractions were collected at a flow rate of 20 m*l* per 1 hr. The peptide content in the fractions was determined by the ninhydrin method, and the results are shown in Fig. 5.

Microbiological Assays.[11] The minimum amount of compounds necessary for the complete inhibition of growth was determined by a dilution method with a bouillon agar medium and with a synthetic medium. As is shown in Table 2, 1,1′-Leu-GS (XI) was found to be as active as natural GS against *B. subtilis* and *St. aureus*, whereas the cyclic pentapeptide (XII) exhibited no antibacterial activity against the microorganisms tested.

11) We are indebted to Dr. M. Shibata of Takeda Chemical Industries, Ltd. for the biological assay.

Poly-β-Amino Acids. I. The Preparation of Phenyl Substituted β-Amino Acid Polymers

Heimei YUKI, Yutaka TAKETANI, Shuzo YAMASHITA, Hiroshi OKUNO and Hiromichi TANAKA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received January 12, 1970)

α-Phenyl-, β-phenyl-, and α,β-diphenyl-β-aminopropionic acid were synthesized. Their polymers were obtained in good yields when the *p*-nitrophenyl esters of β-amino acids were polymerized at 60°C. The ethyl esters gave low-molecular-weight polymers in poor yields at 150°C *in vacuo*. By the thermal polycondensation of β-amino acids themselves at 250°C, polymers were not obtained, but the corresponding cinnamic acid derivatives were obtained by the intramolecular β-elimination reaction. Poly(α-phenyl-β-amino acid), and poly(β-phenyl-β-amino acid) were soluble in trifluoroacetic acid, and chloroform containing a small amount of dichloroacetic acid. On the other hand, poly(α,β-diphenyl-β-amino acid) was soluble only in conc. sulfuric acid, while it was insoluble in usual organic solvents. The DP of poly(β-phenyl-β-amino acid) was about 18. None of the polymers showed any melting point below 300°C.

Many reports and discussions have been published on the syntheses and the properties of poly-α-amino acids. On the other hand, only a few investigations have been reported on poly-β-amino acids, which have only one additional methylene group per residue compared with poly-α-amino acids and which may be expected to have properties as interesting as those of the α-isomers.

Poly(β-alanine) was obtained by Noguchi and Hayakawa[1] *via* the *N*-carbothiophenyl derivative of the amino acid. Breslow and his co-workers[2] prepared the polymer by the polymerization of acrylamide with base catalysts, a process which is called a proton transfer polymerization. Birkofer and Modic[3] also polymerized β-methyl-β-alanine through its *N*-carboxyanhydride. Poly(α,α-dimethyl-β-alanine) was obtained by the thermal polycondensation of β-amino pivalic acid.[4] These polymers seem not to have large molecular weights. Recently, Bestian[5] has obtained high-molecular-weight polymers by the ring-opening polymerization of some substituted β-lactams.

In order to investigate the properties of the polymer, it is necessary that the polymer have a high molecular weight and good solubilities in suitable organic solvents, the solubilities of which may be expected to be brought by a proper substituent in the monomeric unit. In this work, the syntheses of the polymers of α-, β-phenyl-, and α,β-diphenyl-β-aminopropionic acid were investigated. Thermal polycondensations were attempted on the amino acids themselves and their ethyl esters, the latter of which gave only small amounts of the polymers. The *p*-nitrophenyl esters gave the poly-β-amino acids in good yields. The ester is known as an active ester reagent in peptide syntheses. Poly(α-phenyl-β-amino acid) and poly (β-phenyl-β-amino acid) were soluble in trifluoroacetic acid, dichloroacetic acid, and chloroform containing a small amount of dichloroacetic acid. Poly(α,β-diphenyl-β-amino acid) was soluble only in conc. sulfuric acid, while it was insoluble in usual organic solvents. None of the polymers showed any melting point below 300°C.

Experimental and Results

Syntheses of β-Amino Acids. The amino acids were prepared according to the methods of Rodinow and his co-workers[6] and of Steiger.[7] All are racemic forms.

α-Phenyl-β-aminopropionic Acid (α-PA). A hot solution of hydroxylamine hydrochloride (11.0 g) in 100 m*l* of water was added, in one portion, to a solution of sodium ethoxide prepared from 3.5 g of sodium

and 105 m*l* of ethanol. The sodium chloride thus precipitated was filtered out; ethyl atropate (11.5 g) was added to the resulting solution, and the resulting mixture was boiled under reflux for 1 day. White precipitates were filtered out, washed with absolute ethanol, and recrystallized from water and ethanol.

β-Phenyl-β-aminopropionic Acid (β-PA). Benzaldehyde (36.9 g) and malonic acid (40.7 g) were added to 120 m*l* of absolute ethanol saturated with dry ammonia, after which the mixture was boiled on a steam bath for 8 hr. After cooling, white precipitates were collected by filtration and recrystallized from water and ethanol.

α,β-Diphenyl-β-aminopropionic Acid (α,β-DPA). α-Phenylcinnamic acid (78.4 g) was added to a solution of hydroxylamine prepared from its hydrochloride (49.0 g) in 35 m*l* of water and sodium ethoxide (0.7 mol) in 350 m*l* of absolute alcohol, and the mixture was boiled under reflux for 8 hr. White precipitates were collected and recrystallized from water and ethanol.

The yields and the analytical data of the amino acids are listed in Table 1.

				(74.65	6.28	5.81)

Ethyl Esters of β-Amino Acids. β-Amino acid was suspended in 300 m*l* of dry ethanol, after which dry hydrogen chloride was passed through the mixture until it became homogeneous. The solution was evaporated *in vacuo* at 60°C. Dry ethanol (100 m*l*) was added to the residue and evaporated *in vacuo*. This operation was repeated twice, and then the residue was allowed to stand in a refrigerator overnight. The crude product was recrystallized from ethanol and ether. The results are shown in Table 2.

Into the ethyl ester hydrochloride covered with ether, a 150 m*l* portion of a saturated aqueous solution of sodium carbonate was stirred. The ether layer was separated and the aqueous layer was extracted with ether. The ether solutions were combined and the solvent was distilled off. The vacuum distillation of the residue gave the ethyl esters of amino acid, except for the ester of α,β-DPA which was crystalline and was purified by recrystallization from ethanol and water to give colorless needles. The results are listed in Table 3.

***N*-Carbobenzyloxy-β-amino Acids.** β-Amino acid (30 mmol) was dissolved in 33 m*l* of a 1N aqueous sodium hydroxide solution. The solution was cooled to −3—0°C, and then 33 m*l* of 2N aqueous sodium hydroxide solution and carbobenzoxy chloride (6.1 g) was vigorously stirred into it alternately, portion by portion. After the addition, stirring was continued for 2 hr at 0°C. Then, the solution was acidified to pH 3 with 15 m*l* of 6N hydrochloric acid. The precipitates thus formed were extracted with ether. The extract was dried with anhydrous sodium sulfate, and the ether was evaporated. The residual carbobenzyloxyamino acid was recrystallized from ethanol and water. The results are shown in Table 4.

p-Nitrophenyl Esters of *N*-Carbobenzyloxyamino Acids. *N*-Carbobenzyloxy-β-amino acid (20 mmol) and *p*-nitrophenol (2.8 g) were dissolved in 90 m*l* of anhydrous ethyl acetate. Into the solution, dicyclohexylcarbodiimide (6.0 g) was stirred at room temperature. After stirring for 20 hr, the precipitated dicyclohexyl urea (4.4 g) was filtered and the filtrate concentrated at reduced pressure. The residue was recrystallized from ethyl acetate and *n*-hexane to give the *p*-nitrophenyl ester of *N*-carbobenzyloxyamino acid. The results are shown in Table 5.

p-Nitrophenyl Ester Hydrobromides of β-Amino Acids. The *p*-nitrophenyl ester of *N*-carbobenzyloxyamino acid (27 mmol) was dissolved in a saturated solution of hydrogen bromide in 33 m*l* of acetic acid at room temperature. After the solution had stood for 1 hr, 200 m*l* of ether were added; the solution was then kept overnight in a refrigerator. The precipitates thus formed were filtered and recrystallized from ethanol and ether. The results are listed in Table 6.

Thermal Polymerization of β-Amino Acids. β-Amino acid (*ca.* 1 g) was placed in a glass ampoule and the ampoule was sealed *in vacuo*. After the ampoule had been heated at 250°C for 24 hr, 10 m*l* of ethanol was added and an insoluble solid was filtered out. The filtrate was then concentrated under reduced pressure, and the residue was recrystallized from ethanol and water. Table 7 shows the results of the thermal polycondensations of the β-amino acids. From α-PA and β-PA, polymeric materials were obtained as solid materials insoluble in ethanol, but the yields were too low for the characteristics to be investigated. The amino acid, α,β-DPA, gave no products insoluble in ethanol. The ethanol-soluble materials were found to be phenyl-substituted acrylic acids, *i. e.*, cinnamic acid from β-PA, and α-phenyl cinnamic acid from α,β-DPA. The material obtained from α-PA was found from the IR spectrum to contain the polymer of atropic acid.

Thermal Polycondensation of Ethyl Esters of β-Amino Acids. The ethyl ester (1—2 g) was placed in an ampoule and sealed *in vacuo*. After it had then been heated at 150°C for 10 days, 20 m*l* of ethanol was added. An insoluble solid was separated by filtration, and the filtrate was concentrated *in vacuo*. The residue was extracted with 50 m*l* of ether, and an ether-insoluble solid was filtered out. When the ether solution was then concentrated, only a syrupy residue was obtained. The results are shown in Table 8. The thermal polycondensations of the ethyl esters gave the ethanol-insoluble polymers in appreciable yields not only *in vacuo*, but also at an ordinary nitrogen pressure. These polymers were insoluble in water, ethanol, acetone, dimethylformamide, and dimethyl sulfoxide, partially soluble in formic acid and *m*-cresol, and soluble in dichloroacetic acid. From the ethanol-soluble parts, lower-molecular-weight polymers were obtained as frac-

tions insoluble in ether. Figure 1 shows the IR spectra of the monomeric ethyl ester of β-PA and the polymer which was insoluble in ethanol. In the spectrum of the polymer, there are absorptions of polyamide (3240, 1650 and 1530 cm^{-1}), the free ester (1730 cm^{-1}), and α,β-disubstituted C=C double bond (1620 and 960 cm^{-1}). From these absorptions, the probable structure of the polymer may be presented as follows:

$$C_6H_5\text{–}CH{=}CH\text{–}CO(NH\text{–}\underset{\displaystyle C_6H_5}{\underset{|}{CH}}\text{–}CH_2\text{–}CO)_n\text{–}OC_2H_5$$

Polycondensation of *p*-Nitrophenyl Esters of β-Amino Acids. The *p*-nitrophenyl ester (PNP) hydrobromide (2 g) was suspended in 15 m*l* of a purified solvent in an ampoule, which was then flushed with dry nitrogen. In all the solvents used except dimethylformamide, the ester hydrobromides were insoluble. A slight excess of triethylamine was then added to the suspension by means of a hypodermic syringe. Triethylamine hydrobromide was thus separated, and the reaction mixture turned pale yellow. In dimethylformamide the monomer hydrobromides were dissolved completely, but massive precipitates soon appeared when triethylamine was added. The ampoule was left to stand for 72 hr at 60°C with occasional shaking. The reaction proceeded in a heterogeneous state, and the precipitates solidified after 30 minutes. The solid was crushed, filtered, and washed three times with ethanol by applying centrifugration. The resultant pale yellow powder was washed with ether and dried *in vacuo*. No insoluble material was obtained by adding ethanol.

to supernatant liquid of the reaction mixture. The results of the polymerization reaction are shown in Table 9. The polymers from α-PA-PNP and β-PA-PNP were soluble in dichloroacetic acid and trifluoroacetic acid, partially soluble in *m*-cresol, and insoluble in other usual organic solvents. They were also soluble in the mixture of dichloroacetic acid and chloroform. On the other hand, the polymer from α,β-DPA-PNP was insoluble not only in usual solvents but also in trifluoroacetic acid and dichloroacetic acid. It was soluble only in concentrated sulfuric acid, in which the solution viscosity of the polymer showed no change for a long time. All the polymers were crystalline, and none showed a melting point below 300°C. The IR spectra of β-PA-PNP·HBr and poly(β-PA) are shown in Fig. 2. The degree of polymerization was estimated from the content of the *p*-nitrophenyl group, which was analyzed as the end group by means of UV spectroscopy. The measurements were made on the polymer solution in dichloroacetic acid using the absorption band at 300 mμ and the molar extinction coefficient of the monomeric ester hydrobromide ($\varepsilon=6390$). The degree of polymerization was found to be about 18, with the polymer having a η_{sp}/c value of 0.15.

Viscosity of the Poly(β-Phenyl-β-aminopropionic Acid) *p*-Nitrophenyl Ester in a Chloroform-Dichloroacetic Acid Mixture. The polymer prepared from β-PA-PNP was dissolved in dichloroacetic acid at a given concentration. The solution was then diluted with chloroform and dichloroacetic acid in such a way that the resulting solution had a constant polymer concentration at 0.5 g/d*l* and a known composition of the solvents, the ratios of chloroform to dichloroacetic acid ranging from 0/100 to 90/10 (vol/vol). The viscosity of the solution was measured at 30°C. The results are shown in Fig. 3. No precipitation of the polymer was observed even in the mixed solvent consisting 90% of chloroform. The viscosity was almost constant over the whole range of solvent compositions measured.

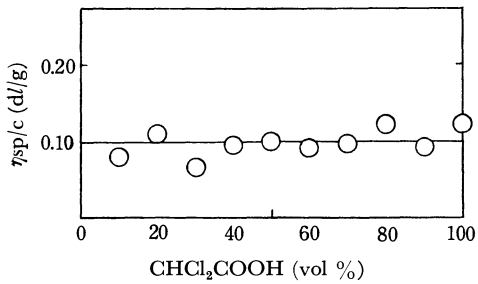

Fig. 3. Viscosity of poly(β-PA) in chloroform-dichloroacetic acid mixture at 30.0°C ($c=0.5$ g/d*l*).

Discussion

Contrary to the polycondensation of β-amino pivalic acid by Linkoln,[4] the polycondensation of the phenyl-substituted β-amino acids used here was not successful because of the removal of ammonia by β-elimination reaction. The removal of ammonia took place intramolecularly much faster than the intermolecular dehydration of β-amino acid.

$$\mathrm{NH_2\text{–}\underset{R_1}{\underset{|}{CH}}\text{–}\underset{R_2}{\underset{|}{CH}}\text{–}COOH} \longrightarrow \mathrm{\underset{R_1}{\underset{|}{CH}}{=}\underset{R_2}{\underset{|}{C}}\text{–}COOH} + \mathrm{NH_3}$$

From α-PA, atropic acid would be obtained, but the acid polymerized easily to poly (α-phenylacrylic acid) above 200°C, so it was difficult to isolate it in a monomeric form.

In the thermal reaction of the ethyl ester of β-amino acid, the polycondensation reaction can compete, although only slightly, with the intramolecular elimination of ammonia, and the polymer was obtained in a low yield. However, the elimination reaction also took place in the polymer thus produced and terminated the further growth of the polymer, forming a double bond in its molecule. By the elementary analysis, the degree of polymerization was roughly estimated to be 4—6 for the polymer derived from the β-PA ethyl ester. The large N content in the polymer obtained from the α,β-DPA ethyl ester may be due to the amide group formed by the reaction between the ester group and the ammonia produced during the polymerization.

The polycondensation of the *p*-nitrophenyl ester seemed to proceed very fast, judging from the observation of the polymer deposit in the reaction mixture. The IR spectrum of the polymer showed an absorption due to NH stretching at 3240 cm^{-1} and no absorption band in the region of the C=C double bond, suggesting that no β-elimination reaction occurred under the reaction conditions empolyed. However, the degree of polymerization of the obtained polymer did not exceed twenty and was almost constant independently of the solvent used in the reaction, as was shown by the viscosity of the polymer in solution. The low degree of polymerization may be attributed to the precipitation of the polymer during polymerization because of its insolubility in the reaction mixture.

In all the polycondensation reactions, α,β-diphenyl-β-amino acid and its esters gave the polymers in low yields and with a low degree of polymerization compared with the other two amino acids and their esters. This must be caused by the steric hindrance due to the bulky substituents occupying both the α and β positions.

Contrary to our expectation, none of the polymers exhibited any solubilities in non-polar organic solvents. The poly(β-phenyl-β-aminopropionic acid) *p*-nitrophenyl ester could be dissolved in chloroform-dichloroacetic acid mixtures, but no distinct changes corresponding to the "helix-coil" transformation such as that found in poly-α-amino acid were observed in the polymer viscosity with the variation in the solvent composition.

Reactions of Haloferrocenes. II.[1] Kinetic Studies of the Reaction of Haloferrocene with Copper(I) Chloride - Pyridine Complex

Masaru SATO, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received January 16, 1970)

The reaction of bromoferrocene with copper(I) chloride - pyridine complex was found to be second-order, that is, first-order in each of bromoferrocene and copper(I) chloride - pyridine complex. The results obtained from the competitive reactions between bromoferrocene and bromobenzene indicated that bromoferrocene was 10^3 times more reactive than bromobenzene in the halogen-exchange reaction. The effects of the pyridine bases on the halogen-exchange reaction of bromoferrocene were examined, and the trend of the results was found to be different from that of bromobenzene. The reason for this was discussed on the basis of the reaction mechanism.

In a previous paper,[1] we reported that, when haloferrocene was treated with copper(I) salt in boiling pyridine, a halogen-exchange reaction easily occurred. According to this procedure, chloro-, bromo-, and cyanoferrocene were prepared in high yields by treating iodoferrocene with copper(I) chloride, bromide, and cyanide respectively. Since the reaction of *p*-substituted halobenzene with copper(I) salt is facilitated by an electron-withdrawing group,[2,3] this reaction is generally regarded as a nucleophilic substitution.[4] In contrast with halobenzene, the reaction of haloferrocene with copper(I) salt was markedly retarded by a hetero-annularly-substituted electron-withdrawing group. This interesting observation, along with the unusually high reactivity of haloferrocene in this reaction, prompted us to a kinetic study of this reaction in the hope of getting some information concerning the reaction mechanism.

Results

As was reported in an earlier paper,[2] the heterogeneous reaction mixture of bromobenzene and copper(I) cyanide in nitrobenzene was turned into a homogeneous solution by the addition of an organic base such as pyridine at 120°C, and the halogen-exchange reaction then took place at 160—180°C. When pyridine was added to the copper(I) chloride in chlorobenzene, a homogeneous solution similarly obtained at 100°C. The subsequent addition of bromoferrocene to the homogeneous solution gave rise to a considerably rapid halogen-

exchange reaction of the bromoferrocene. During this procedure, chlorobenzene used as a solvent did not react with copper(I) bromide which arose from the reaction of bromoferrocene with copper(I) chloride. Hence, this procedure was employed for the kinetic study of the exchange reaction of haloferrocene. The effect of the base/Cu-salt ratio on the reaction rate was investigated by Ito and Watanabe.[2] It was found that, in comparison with the reaction rate when equimolar amounts of the base and the Cu-salt were used, the reaction rate stayed unchanged even if the base/Cu-salt ratio exceeded 1. However, when the base/Cu-salt ratio was less than 1, the reaction rate diminished in proportion to the base/Cu-salt ratio. Therefore, a little excess of pyridine over the copper(I) salt was used in the present experiment. When an excess of copper(I) chloride over bromoferrocene was used, a linear relationship was observed between the yield of chloroferrocene and the reaction time. When the initial concentration of bromoferrocene was kept constant and that of copper(I) chloride was varied, a linear relationship was generally found between the initial rate and the initial concentration of copper(I) chloride, although some deviations were observed. These observations clearly indicate that this reaction is second-order, that is, first-order in each of bromoferrocene and copper(I) chloride. Copper(I) salt and pyridine have been supposed to form a 1 : 1 complex in the reaction mixture.[2] Accordingly, the reaction rate may be represented as follows:

$$d[\mathrm{FcCl}]/dt = k[\mathrm{FcBr}][\mathrm{CuCl\text{-}Pyridine\ Complex}]$$

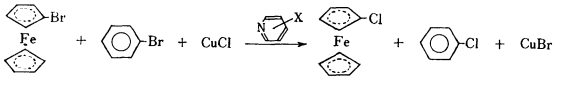
When a pyridine base was added to a heterogeneous mixture of copper(I) chloride and bromobenzene, a homogeneous solution was obtained at 102°C, and the reaction of bromobenzene with copper(I) chloride was observed to occur at this temperature. When bromoferrocene was added to this reaction system, together with bromobenzene, a competitive halogen-exchange reaction between bromoferrocene and bromobenzene was observed. The ratio of the reaction rates of the two halides was determined in such a competitive reaction using α-picoline, γ-picoline, methyl isonicotinate, or pyridine as the pyridine base. On the other hand, when the reactions of bromobenzene with copper(I) chloride in the presence of the cited pyridine bases were carried out using bromobenzene as the solvent and under conditions similar to those used in the competitive reaction, the pseudo first-order rate constants of the reaction were determined. The results of these kinetic studies are shown in Table 1, where k^2_{FcBr} and k^2_{PhBr} represent the second-order rate constants of bromoferrocene and bromobenzene respectively in the competitive reaction, and where k^1_{PhBr} stands for the pseudo first-order rate constant of the reaction of bromobenzene with copper(I) chloride in bromobenzene.

It is clear from Table 1 that bromoferrocene reacts 10^3 times or more faster than does bromobenzene in the reaction using any of these pyridine bases. This observations is qualitatively consistent with the results reported in a previous paper.[1]

In order to see the effect of the pyridine base on the halogen-exchange reaction of bromoferrocene, the k^2_{FcBr} values were calculated on the assumption that the coexistence of bromoferrocene will not affect the reaction rate of bromobenzene.*1 The ratios of the rate constants, k^2_{FcBr}, thus obtained for pyridine, α-picoline, γ-picoline, and methyl isonicotinate are 1.00, 1.47, 1.22, and 1.57 respectively.

The solvent effect on the halogen-exchange reactions was examined using three kinds of aprotic polar solvents, that is, nitrobenzene, nitromethane, and acetonitrile. These solvents gave a homogeneous solution with copper(I) chloride, even at a lower temperature (30—50°C), in the presence of an equimolar amount of pyridine. However, in the observation of the kinetics on the reaction of bromoferrocene with copper(I) chloride in these solvents,

Table 1. Rate constants of the reactions between bromoferrocene or bromobenzene and copper(I) chloride in the presence of various pyridine bases



Exp. No.	Pyridine base	$k^2_{\mathrm{FcBr}}/k^2_{\mathrm{PhBr}}$	k^1_{PhBr} (min^{-1})	k^2_{FcBr}* ($l/\mathrm{mol}\cdot\mathrm{min}$)
1	γ-Picoline	1.02×10^3	8.10×10^{-3}	8.3
2	α-Picoline	9.4×10^3	1.06×10^{-3}	10.0
3	Pyridine	1.15×10^3	5.87×10^{-3}	6.8
4	Methyl isonicotinate	3.10×10^3	3.45×10^{-3}	10.7

* Calculated from the values of $k^2_{\mathrm{FcBr}}/k^2_{\mathrm{PhBr}}$ and k^1_{PhBr}.

*1 No appreciable change in the reaction rate was observed on the addition of ferrocene instead of bromoferrocene to the reaction mixture.

TABLE 2. SOLVENT EFFECT ON THE REACTION BETWEEN BROMOFERROCENE AND COPPER(I) CHLORIDE-PYRIDINE COMPLEX AT 50.0°C

Solvent	Dielectric constants[a] (20°C)	Initial rate (mol/l·min)
Nitrobenzene	35.7	5.1×10^{-2}
Nitromethane	37.5	5.7×10^{-2}
Acetonitrile	37.5	6×10^{-4}

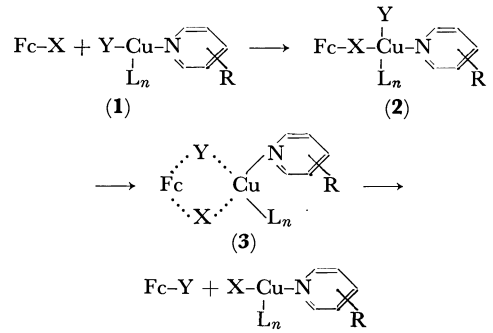
a) J. Hine, "Physical Organic Chemistry," 2nd Ed., McGraw-Hill, Inc., New York (1960), p. 39.

the plots of the rate constant gradually deviated from the second-order relation, unlike as in the reaction using bromobenzene or chlorobenzene as a solvent. Hence, the solvent effects were compared with each other by the initial reaction rates observed in these three solvents, as is shown in Table 2. These results clearly indicate that a remarkable solvent effect is present in the halogen-exchange reaction of bromoferrocene, but no significant correlation was observed between the relative rates and the dielectric constants of these solvents.

Discussion

When iodoferrocene and copper(I) iodide were refluxed in pyridine, iodoferrocene was recovered quantitatively; neither ferrocene nor biferrocenyl, both of which had been expected as the dehalogenation or coupling products, could be detected in the reaction mixture. This is consistent with the observation by Bacon and Hill,[3] who investigated the reaction of chlorobenzene with copper(I) chloride carried out by refluxing in pyridine using an isotopic chloride. The Ullmann coupling reaction of chlorobenzene was also reported not to occur at the boiling temperature of pyridine.[5] On the other hand, when iodoferrocene was treated with activated copper in boiling pyridine, both the coupling product (biferrocenyl) and the dehalogenated product (ferrocene) were isolated.[6] In view of the above facts, the most reasonable conclusion is that neither the ferrocenyl radical nor ferrocenylcopper,[7] which would give biferrocenyl and ferrocene, may be involved as the intermediate in the reaction between haloferrocene and copper(I) salts.

The reaction of bromoferrocene with copper(I) chloride-pyridine complex in chlorobenzene was confirmed to be a second-order reaction, in just the same manner as the reaction of aryl halides with copper(I) salts.[2,3] This fact strongly suggests that the reaction of haloferrocene with copper(I) chloride-pyridine complex proceeds through a process similar to that previously proposed in the benzene series.[2,3] Probably, the halogen atom in haloferrocene coordinates to the copper(I) chloride-pyridine complex (**1**) to form a metastable, reactive intermediate (**2**), which then provides a final product *via* the four-center-type transition state (**3**).



L = Pyridine base or solvent

The above reaction mechanism was strongly supported by a remarkable solvent effect found in this reaction. As is shown in Table 2, the reaction proceeds quickly in nitrobenzene and nitromethane, but slowly in acetonitrile. The observed difference seems to arise from their coordinating ability to produce a copper complex, because there is no significant correlation between the reaction rates and the dielectric constants of the solvents used. The slow reaction rate in acetonitrile may be interpreted as follows: the vacant coordination site of copper(I) chloride will be almost entirely occupied by acetonitrile because of its large affinity for copper(I) ion;[8] thus, the coordination of haloferrocene to copper(I) atom suffers a considerable hindrance, which brings about the fall in the reaction rate. An example of such a solvent effect in the reaction of a metal complex was found in the reaction between *trans*-dichlorobis(pyridine)platinum and the isotopic chloride ion in various solvents.[9] It has been shown that this halogen-exchange reaction proceeds more rapidly in nitromethane as a solvent than in acetonitrile, much as with the present result shown in Table 2.

Recently it was suggested[2] that the structure of the pyridine base coordinated in the copper(I) complex exerted a definite influence on the reaction of halobenzene with copper(I) salt. The reexamination of this reaction led to the conclusion that the more strongly the nitrogen atom of the pyridine base is coordinated to the copper atom, the more the reaction is accelerated.[10] The acceleration of the reaction of bromobenzene with copper(I) chloride by γ-picoline, and the retardation of the reaction by methyl isonicotinate, each in comparison with pyridine, were explained by means of studying the electronic effect of the substituent upon the electron density on the nitrogen atom of the base, which might affect the coordination of the base to copper(I) chloride. On the other hand, the retardation by α-picoline was attributed to the steric hindrance to the coordination of the base to copper(I) chloride. A similar trend was also observed in the substituent effect expressed by k^1_{PhBr} in Table 1.

On the contrary, no such trend of the substituent effect was observed in the reactions of bromoferrocene with copper(I) chloride-pyridinebase complexes. Those reactions were accelerated by any of the substituted pyridines examined. However, it is interesting that the trend is the opposite of that of the benzene series. As an exception, γ-picoline accelerates both the reaction of bromobenzene and that of bromoferrocene, but the acceleration in the latter is not so marked as by α-picoline or methyl isonicotinate. The equivocal behavior of the substituted pyridines might be explained by a very delicate and complicated balance among the following factors: (1) the stability of the intermediate (**2**); (2) the ease of the attack of the halogen atom in haloferrocene on the copper atom (X→Cu attack), and (3) the nucleophilicity of the halogen atom of the complex (**2**) toward the carbon atom in the ferrocene ring (Y→C attack). The results of the experiments (Table 1) suggest that the reaction of bromoferrocene with copper(I) chloride-pyridine base complex might be governed rather by the ease of the X→Cu attack in (2) than by the Y→C attack in (3), unlike the similar reaction of bromobenzene.[10]

The discussion presented above is useful in explaining most of the facts observed in the reaction of bromoferrocene with the copper(I) chloride-pyridine complex, but some difficulties still remain in explaining the fact that bromoferrocene is 10^3 times or more reactive than bromobenzene in this reaction and that heteroannular substituents on bromoferrocene exert a marked electrophilic effect upon this reaction.[1] It is necessary to consider additional factors specific to the ferrocene series in order to elucidate the mechanism of this reaction further.

10) M. Sato, I. Motoyama and K. Hata, to be published in the subsequent paper.

Experimental

All of the reactions were operated under an atmosphere of nitrogen.

Procedure for a Competitive Reaction (Table 1, Exp. 3). In a 100-m*l*, three-necked flask fitted with a sealed stirrer, a thermometer, a gas-inlet tube, and a reflux condenser, were placed 1.20 g (4.5 mmol) of bromoferrocene, 0.50 m*l* (5.0 mmol) of pyridine, 30 m*l* of bromobenzene, 0.25 m*l* (2.0 mmol) of ethylbenzene, and 0.70 g (4.5 mmol) of biphenyl. The last two substances were added as the internal standard for gas chromatography, by which process the products were analyzed. The contents were then heated to 102°C on an oil bath. When the temperature was regulated to be constant (102.7±0.1°C), 0.45 g (4.5 mmol) of copper(I) chloride was quickly added to the solution. A small quantity of the reaction mixture was taken out every two minutes and quenched with dilute hydrochloric acid. The organic layer was analyzed by gas chromatography. From the results of these measurements, the ratio of the rate constants (k^2_{FcBr}/k^2_{PhBr}) was calculated by the following equation:

$$-\frac{d(\mathrm{FcBr})}{d(\mathrm{PhCl})} = \frac{k^2_{FcBr}}{k^2_{PhBr}} \times \frac{(\mathrm{FcBr})}{a}$$

$$\text{or} \quad -\ln\frac{(\mathrm{FcBr})}{(\mathrm{FcBr})_0} = \frac{k^2_{FcBr}}{k^2_{PhBr} \times a} \times (\mathrm{PhCl})$$

where a and $(\mathrm{FcBr})_0$ are the initial concentrations of bromobenzene and bromoferrocene respectively.

Analytical Conditions for Gas Chromatography. Apparatus: OHKURA Model 1100. Column: a 2 m× 6 mm stainless-steel column packed with 5% Silicone Grease on Diachrom A (60—80 meshes). Temperature: 165°C. Carrier gas: H_2. Flow rate: 80 m*l*/min. Relative retention times: Ferrocene (0.88). Biphenyl (1.00), Chloroferrocene (1.39), Bromoferrocene (1.88), and Iodoferrocene (2.59).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1864—1869 (1970)

Tri(hetero)substituted Carbonium Ions. II. 2-Dialkylamino-1,3-dithiolanylium Ions. Reactions with Nucleophiles and Ambident Behaviors[1,2]

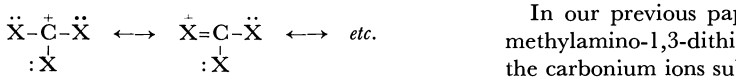
Takeshi NAKAI and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 17, 1970)

The reactions of 2-dialkylamino-1,3-dithiolanylium perchlorates with a variety of nucleophilic species including oxygen, sulfur and nitrogen nucleophiles have been investigated. Examination of the isolated products reveals that these trihetrosubstituted carbonium ions behave as ambident electrophiles toward nucleophiles with two reactive sites, *i.e.*, the electron-deficient centered carbon (a) and the ring-methylene carbon atom (b), and that the nature of nucleophiles greatly affects the reaction course in a straightforward manner. The reaction course may be classified as follows. If the nucleophile is basic, the reaction at the site (a) (mode A) is favored, but if it has large substituents, the initial proton abstraction reaction (mode C) is predominant, while if the nucleophile is polarizable, the reaction at the site (b) (mode B) is favored. The major factor deciding the reaction course is discussed in terms of the schematic energy profile of the overall reaction.

Stabilization of carbonium ions is usually done by electron-donating conjugation with a hetero atom adjacent to the electron-deficient carbon atom. Stabilization is more manifest when two or three electron-donating groups coordinate their nonbonding electron pairs with the cationic center.[3]



X = S, N, O, Cl, *etc.*

Carbonium ions stabilized through two hetero atoms are of great significance from preparative and theoretical points of view, since they are readily isolated under an ordinary condition and behave toward nucleophiles as ambident electrophiles having two reactive sites.[4] Among them dialkoxycarbonium salts are the most important as facile alkylating agents.[5] However, very little systematic investigation has been carried out as regards carbonium ions stabilized through three α-hetero atoms although reactions of trialkoxy-[6] and trialkylthiocarbonium ions[7] have been reported.

In our previous paper[2] it was shown that 2-dimethylamino-1,3-dithiolanylium ion (Ia),[8] one of the carbonium ions substituted by one nitrogen and two sulfur atoms, is isolated as perchlorate or tetraphenylborate, and that Ia reacts with hydroxide and *N,N*-dimethyldithiocarbamate ions to give, respectively, β-mercaptoethyl *N, N*-dimethylthiolcarbamate and ethylene bis(*N,N*-dimethyldithiocarbamate). These observations suggest that Ia may behave as an ambident electrophile with two reactive sites, (a) and (b), as shown below.

2) Part I: T. Nakai, Y. Ueno and M. Okawara, This Bulletin, **43**, 156 (1970).

3) To what extent one is justified in considering such a cation a carbonium ion rather than an onium ion, depends upon the extent of contribution to the resonance hybrid of the structure carrying the positive charge on carbon and on the electron-donating tendency of the hetero atom X. Other factors, *e. g.*, steric ones which enhance or diminish the internal dissipation of charge, are also important: *cf.* C. D. Nenitzescu, "Carbonium Ions," ed. by G. A. Olah and P. von R. Schleyer, Vol. 1, Interscience Publ., New York, N. Y. (1968), p. 20. In our studies these cations are regarded as triheterosubstituted carbonium ions only for a systematic nomenclature.

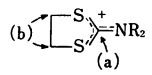
8) This carbonium ion is more exactly termed 2-dimethylamino-1,3-dithiolan-2-ylium ion. In our papers the word 1,3-dithiolanylium is used only for the sake of convenience. The carbonium ion is also termed 2-dimethylamino-1,3-dithiolenium ion: J. L. Richards, D. S. Tarbell and E. H. Hoffmeister, *Tetrahedron*, **24**, 6485 (1968).



Ia, R=CH_3 b, R=C_2H_5

In general, the relative reactivities at the two reactive sites of such ambident electrophiles should depend upon three factors: the nature of the nucleophile, the structure of the carbonium ion, and the reaction conditions. Thus a systematic investigation of the effects of these factors on the reactivities of carbonium ions stabilized through one nitrogen and two sulfur atoms was initiated.

The present paper describes the effect of the nature of nucleophile on the reactivity and reaction course of 2-dialkylamino-1,3-dithiolanylium ions. The subsequent paper[9] is concerned with structural effect on reactivities of this type of ambident electrophiles.

Results and Discussion

2-Dialkylamino-1,3-dithiolanylium ions (Ia, R=CH_3; Ib, R=C_2H_5) were isolated as perchlorate from the equimolar reaction of 1,2-dichloroethane with the corresponding sodium *N,N*-dialkyldithiocarbamate in ethanol.[2] These carbonium salts were recrystallized from aqueous solutions. In order to investigate the effect of the nature of nucleophile on reactivities of these carbonium ions, reactions of I with a variety of nucleophilic reagents including oxygen nucleophilies (hydroxide and ethoxide), sulfur nucleophiles (alkyl and aryl mercaptides, and dithiocarbamates), nitrogen nucleophiles (anilines and triethylamine) and carbon nucleophile (cyanide) were studied.

A wide spectrum of reactivity is shown by 2-dialkylamino-1,3-dithiolanylium ions (Chart 1). Reaction conditions and products obtained are summarized in Table 1. Identification of products is based upon elemental analyses, physical properties, spectral data and chemical transformations (Experimental section),

It can be said, on the whole, that these two carbonium ions behave toward nucleophiles in a similar manner, although the dimethylamino compound (Ia) seems to be more reactive than diethylamino Ib. Significant differences between the two carbonium ions were observed in reactions with aniline and with sodium cyanide. Carbonium ion Ia reacted with aniline to give 2-phenylimino-1,3-dithiolane (IVa) in a good yield, while Ib did not afford (IVa) but a small amount of *N,N'*-diphenylthiourea. With cyanide ion, Ia afforded 2-cyano-2-dimethylamino-1,3-dithiolane (IXa), while Ib did not produce diethylamino derivative (IXb) but a complex mixture.

Examination of stuructures of products reveals the following facts: (i) as expected, 2-dialkylamino-1,3-dithiolanylium ions (I) are ambident electrophiles with two reactive sites, *i.e.*, the electron-deficient centered carbon atom (a) and the ring-methylene neutral carbon atoms (b); (ii) in contrast to behaviors of ambident nucleophiles toward electrophilic reagents,[10] reactions between these ambident electrophiles and the nucleophilic reagents proceed in a more straightforward manner; (iii) the nature of nucleophile (Nu^-) greatly affects the reaction course, which may be classified into three modes (Chart 2).

Mode A involves initial attack of the nucleophile at the site (a) with the retention of the ring structure to yield adduct X, which, in turn, undergoes various subsequent reactions. Nucleophiles which react *via* mode A are oxygen nucleophiles, aryl amines and cyanide ion. The proton transfer from

Ib	$N(C_2H_5)_3$(2.0)	DMSO/Diox.	70	3	VIIIb, R=C_2H_5	63
Ia	NaCN(3.0)	DMF	60	4	IXa, R=CH_3	64
Ib	NaCN (3.0)	DMF	60	4	e)	

a) Numbers refer to compounds in Chart 1.
b) Based upon Ia or Ib. No attempt was made to maximize conditions.
c) In contrast to Ia, Ib did not produce IVa at all.
d) Both UV and IR spectra suggested that this fraction was contaiminated with *S*-vinyl dithiocarbamate (VIIIb).
e) In contrast to Ia, Ib did not afford IXb (R=C_2H_5), but a complex mixture.

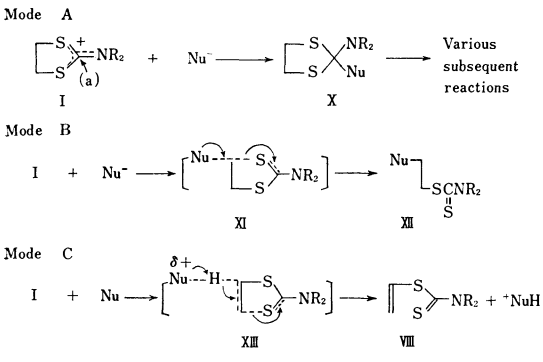

Chart 2. Reaction modes.

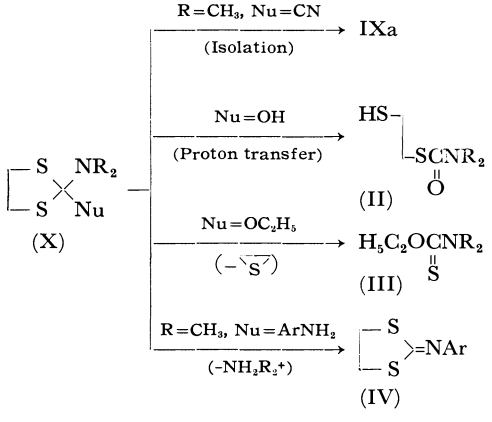

Chart 3. Subsequent reaction of X.

X (Nu=OH) results in the formation of VI, while loss of episulfide from X (Nu=OEt) can account for the formation of thioncarbamate (III).[11] Formation of IV from Ia and aniline can be interpreted by deamination of adduct X (Nu=$ArNH_2$) (Chart 3).

Mode B involves initial attack of the nucleophile at the site (b) to give β-substituted ethyl dithiocarbamate (XI). Nucleophiles which react *via* mode B are all sulfur nucleophiles examined. Attack of the nucleophiles to (b) might proceed through the S_N2-type mechanism, *i.e.*, *via* transition state XI,

11) For elimination of episulfide from sulfur-containing heterocyclics, see R. Feinaer, *Angew. Chem. Intern., Ed.*, **5**, 894 (1966). We have also observed that ethylene oxide cyclo-adds to the thiocarbonyl group to give the corresponding carbonyl compound involving loss of episulfide from the cyclo-adduct: Y. Ueno, T. Nakai and M. Okawara, This Bulletin, **43**, 168 (1970).

which has been kinetically verified with the reaction of Ia with sodium *N,N*-dimethyldithiocarbamate.[2] This fact is also supported by the observation that the yield of XII under similar conditions (see Table 1) increases with an increase in nucleophilicity of the attacking reagent, being in the order: $C_2H_5S^- < p\text{-}CH_3C_6H_4S^- < R'_2NCSS^-$[12] for both carbonium ions.

Finally, there are two possible mechanisms for the formation of *S*-vinyl dithiocarbamates (VIII) from I and triethylamine. The first mechanism involves the Hofmann elimination of tetraalkylammonium salt XII ($Nu = NEt_3$) formed *via* mode B. The other consists of mode C which involves initial abstraction of the proton of the ring-methylene followed by the ring scission through the well-known concerted mechanism accepted for the general E2 reaction. It seems reasonable to assume that mode C is operative since triethylamine is basic and so combines more preferentially with the proton that the neutral carbon atom bearing the proton.

It may be roughly summarized that if the nucelophile is basic, *e.g.*, OH^- or RO^-, mode A is favored, but if it has large substituents, *e.g.*, NEt_3, the initial proton abstraction (mode C) is predominant. On the other hand, if the nucleophile is polarizable, *e.g.*, RS^- or R_2NCSS^-, mode B is favored. According to the concept of soft and hard acids and bases,[13] it can also be said that hard bases react *via* mode A while soft bases react *via* mode B, and that, with respect to the carbonium ion, the reactive site (a) is hard and (b) is soft.

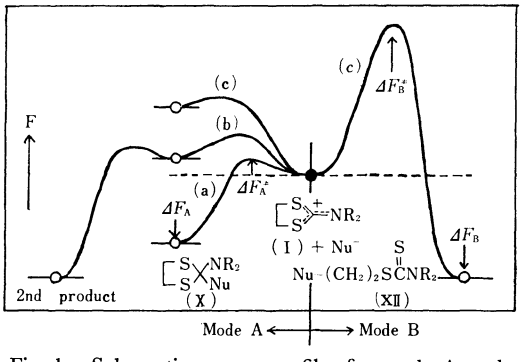

Fig. 1. Schematic energy profiles for mode A and B: curve (a), $Nu^- = e.g.$, ^-CN; (b), $Nu^- = e.g.$, ^-OH; (c), $Nu^- = e.g.$, $^-SCSNR_2$. Strictly speaking, the energy content of the initial system, I^+ and Nu^-, depends upon the nature of Nu^-.

We might conclude that the nature of the nucleophile largely changes the reaction course, though the factors deciding the reaction course remain unknown. To clarify this point, the schematic energy profile of the overall reaction was considered tentatively (Fig. 1).[14]

Since the primary process of mode A corresponds to a simple association between the cation and the anion, the free activation energy ($\Delta F_A^{\neq}$) is always less than that for mode B ($\Delta F_B^{\neq}$). It may be assumed that the position of the equilibrium between cation I and adduct X in mode A should depend upon the difference in ΔF_A between I and X, *i.e.*, upon their relative position in the energy diagram, except for steric factors. On the other hand, since the transformation of I into XII in mode B results in release of the mesomeric energy of XII as well as the energy of charge neutralization, product XII must be a thermodynamically stable product, *i.e.*, $\Delta F_B > \Delta F_A$. Both ΔF_B and $\Delta F_B^{\neq}$ may be assumed to be very large since mode B is irreversible. In short, it can approximately be said that the primary reaction of mode A is kinetically controlled, while mode B is thermodynamically controlled. These discussions substantially lead to the hypothesis that the major factor deciding the reaction course is the relative position of the kinetically controlled product (X) in the energy diagram, *i.e.*, the magnitude of ΔF_A (Fig. 1). Since the small free activation energy ($\Delta F_A^{\neq}$) changes only slightly with the nature of nucleophile, kinetic adduct (X) can be isolated only when a strong nucleophile such as CN^- was used (Table 1). In the case where the primary adduct is not so stable, if the adduct may be readily converted into the more stable second product by various irreversible reactions (Chart 3), the reaction will be also directed to mode A, while if adduct (X) cannot undergo such second irreversible reactions, the reaction will be directed to mode B, as has been observed in the reactions with sulfur nucleophiles. Naturally $\Delta F_B^{\neq}$ depends upon the nucleophilicity of the attacking reagent; this accounts for the difference in yield of product XII with a series of sulfur nucleophiles.

This may qualitatively explain behaviors of all nucleophiles except triethylamine toward the ambident electrophiles (Table 1). The fact that triethylamine reacts with I *via* mode C, not *via* mode A, might be expained by the steric factor, *i.e.*, both by an increase of $\Delta F_A^{\neq}$ and a decrease of ΔF_A. In all cases, from these qualitative results it is difficult to determine whether the major factor deciding the reaction course is the stability of kinetic adduct (X) or the steric factor. Further quantitative data based upon kinetic studies are required to ascertain this point.

12) Dithiocarbamate anions are ranked with the strongest nucleophiles in aqueous solutions: R. E. Davis, "Survey of Progess in Chemistry," ed. by A. Scott, Vol. 2, Academic Press Inc., New York, N. Y. (1964), p. 189; R. E. Davis, H. Nakshbendi and A. Ohno, *J. Org. Chem.*, **31**, 2702 (1966).

13) R. G. Pearson, *J. Amer. Chem. Soc.*, **85**, 3533 (1963).

14) For analogous considerations, see Ref. 4; S. Winstein and E. M. Kosower, *J. Amer. Chem. Soc.*, **81**, 4399 (1959); J. Miller, *ibid.*, **85**, 1628 (1963).

Experimental

General. Melting and boiling points are uncorrected. The infrared spectra were recorded with a Hitachi EPI-S2 spectrometer. Ultraviolet spectra were recorded with a Hitachi EPS-2 spectrometer. Nuclear magnetic resonance spectra were determined with either a Varian Associates A-60 or a Japan Electron Optics C-60 spectrometers. Chemical shifts are given in a parts per million (ppm) from tetramethylsilane as an internal standard. All nucleophilic reagents employed were either commercially available materials or prepared by a standard method.

2-Dimethylamino-1,3-dithiolanylium Perchlorate (Ia). To a solution of 39.0 g (0.40 mol) of 1,2-dichloroethane in 80 m*l* of ethanol, was added a solution of sodium *N,N*-dimethyldithiocarbamate (72.0 g, 0.40 mol) in 120 m*l* of ethanol. The mixture was stirred at 55°C for 3 hr. Sodium chloride formed was filtered off and the filtrate was concentrated under reduced pressure. The mixture was poured into 300 m*l* of cold water to give 4.2 g of white precipitates, ethylene bis(*N,N*-dimethyldithiocarbamate): mp 187—189°C. To the resulting aqueous solution was added sodium perchlorate (45 g) to give 62.0 g (62%) of white precipitates (Ia): mp 179—180°C (acetone) (lit,[2] 179—180°C); UV: λ_{max} (H_2O) 249 mμ ($\varepsilon=1.31\times10^4$).

2-Diethylamino-1,3-dithiolanylium Perchlorate (Ib). In a similar fashion the reaction of sodium *N,N*-diethyldithiocarbamate with 1,2-dichloroethane gave perchlorate Ib in 44% yield; mp 89—90°C (water); UV: λ_{max} (H_2O) 255 mμ.

Found: C, 30.62; H, 5.15; N, 5.01%. Calcd for $C_7H_{14}ClNO_4S_2$: C, 30.38; H, 5.12; N, 5.08%.

Hydrolyses of Salt I. Salt Ia (6.2 g, 0.025 mol) was added to a solution of 1.0 g (0.01 mol) of triethylamine and 1.0 g (0.05 mol) of water in 15 m*l* of dimethylformamide (DMF). The reaction mixture was stirred at 100°C for 3 hr, then poured into cold water. The mixture was extracted several times with ether. The ether layer was dried over sodium sulfate and the solvent evaporated *in vacuo*. Distillation of the residue gave 1.2 g of β-mercaptoethyl *N,N*-dimethylthiolcarbamate (IIa): bp 85—87°C/2 mmHg; n_D(25°C) 1.6038; IR (neat): 1650 (C=O) and 1490 cm^{-1} (N–CO). The physical properties and spectral data of this distillate were in agreement with those of the authentic sample.[2]

Hydrolysis of salt Ib carried out as in the case of Ia yielded 2.0 g of thiolcarbamate IIb: bp 116—118°C/2 mmHg; n_D(20°C) 1.5800; IR (neat): 1650 and 1495 cm^{-1}.

Both these products discolored an aqueous solution of iodine and gave mercury mercaptide on treatment with mercuric chloride indicating the presence of a mercapto group.

Reactions of Salt I with Sodium Ethoxide. Salt Ia (12.5 g, 0.05 mol) was added to a suspension of 10.2 g (0.15 mol) of sodium ethoxide in 70 m*l* of dioxane. The mixture was stirred at 100°C for 2 hr in a nitrogen atmosphere, then poured into water. The ether layer was dried over sodium sulfate and the solvent was evaporated. Distillation of the residue gave 3.5 g (52%) of ethyl *N,N*-dimethylthioncarbamate (IIIa): bp 81—82°C/10 mmHg; n_D(25°C) 1.5082; UV (EtOH): 250 and 285 mμ (shoulder) (lit, bp 82.6°C/10 mmHg;[15] n_D(20°C) 1.5075;[16] UV: 250 and 285 mμ (shoulder)[17]).

The reaction of Ib with sodium ethoxide carried out as in the case of Ia gave ethyl *N,N*-diethylthioncarbamate (IIIb) in 82% yield; bp 99—101°C/13 mmHg; n_D(23°C) 1.4968 (lit, bp 114°C/20 mmHg;[18] n_D(15°C) 1.5021[19]); UV (EtOH): 250.5 and 290 mμ (shoulder). The infrared spectrum of IIIb was in agreement with that of the authentic sample.[20]

Reactions of Salt I with Anilines. Salt Ia (6.2 g, 0.025 mol) was added to a solution of 5.0 g (0.05 mol) in aniline in 40 m*l* of dimethylsuldefoxide (DMSO). The reaction mixture was stirred at 80°C for 3.5 hr, then poured into water. The ether layer was dried over sodium sulfate and the solvent and unreacted aniline were removed *in vacuo*. Recrystallization of the residue from ethanol gave 3.6 g (73%) of 2-phenylimino-1,3-dithiolane (IVa): mp 47—48°C; IR (KBr): 1570 cm^{-1} (C=N); NMR (CCl_4): δ 3.32 (s, CH_2S) and 6.55—7.10 ppm (m, aromatic protons).

Found: C, 55.48; H, 4.89; N, 7.00%. Calcd for $C_9H_9NS_2$: C, 55.38; H, 4.65; N, 7.18%.

Imino-dithiolane IVa reacted with hydroxylamine in ethanol giving 2-hydroxyimino-1,3-dithiolane: mp 122—124°C (lit,[21] 124—127°C); IR (KBr): 3100 (OH) and 1590 cm^{-1} (C=N).

The reaction of Ia with *p*-toluidine was carried out as in the case of aniline. Salt Ia (6.2 g, 0.025 mol) and *p*-toluidine (5.0 g, 0.05 mol) gave 4.8 g (77%) of a yellowish oil (IVb); IR (neat): 1580 cm^{-1} (C=N). The oil was treated with a 6N alcoholic solution of hydrogen chloride to give white precipitates of the hydrochloride: mp 209—211°C (lit,[22] 190—192°C).

Found: C, 48.52; H, 4.99; N, 5.62%. Calcd for $C_{11}H_{11}ClNS_2$: C, 48.89; H, 4.92; N, 5.73%.

By the same procedure the reaction of Ib (7.0 g, 0.025 mol) with aniline (5.0 g, 0.05 mol) gave 0.5 g of *N,N'*-diphenylthiourea as only ether-soluble product.

Reactions of Salt I with Sodium Ethylmercaptide. Salt Ia (12.5 g, 0.05 mol) was added to a solution of 4.2 g (0.05 mol) of sodium ethylmercaptide in 40 m*l* of DMF. The reaction mixture was stirred at 70°C for 5 hr, then poured into cold water. The carbon tetrachloride layer was dried over sodium sulfate and the solvent evaporated *in vacuo*. Distillation of the residue gave 3.6 g (36%) of a pale oil, β-(ethylthio)ethyl *N,N*-dimethyldithiocarbamate (Va): bp 67—68°C/0.14 mmHg; n_D(22°C) 1.5819; IR (neat): 1500 cm^{-1} (N–CS);[23] UV (EtOH): 250 and 278 mμ.[24]

Found: C, 39.82; H, 7.53; N, 6.99%. Calcd for $C_7H_{15}NS_3$: C, 40.19; H, 7.53; N, 6.99%.

By the same procedure the reaction of salt Ib (14.0 g, 0.05 mol) with sodium ethylmercaptide (4.2 g, 0.05 mol) gave 4.5 g of a pale-yellowish oil: bp 84—86°C/0.4 mmHg; UV (EtOH): λ_{max} 250 and 280 mμ.[24] The IR spectrum of the distillate showed an absorption band at 1600 cm^{-1} (C=C) as well as bands presumably due to β-(ethylthio)ethyl *N,N*-diethyldithiocarbamate (Vb). In comparison with the IR spectrum of *S*-vinyl *N,N*-diethyldithiocarbamate (VIIIb), the spectrum indicates that the distillate was contaimnated with a small amount of VIIIb.

Reactions of Salt I with Sodium *p*-Tolylmercaptide. Salt Ia (6.3 g, 0.025 mol) was added to a solution of 4.0 g (0.027 mol) of sodium *p*-tolylmercaptide in 40 m*l* of DMF. The reaction mixture was stirred at 70°C for 5 hr, then poured into cold water. The carbon tetrachloride layer was dried over sodium sulfate and the solvent evaporated. Recrystallization of the residue from ethanol gave 5.7 g (77%) of β-(*p*-tolylthio)ethyl *N,N*-dimethyldithiocarbamate (VIa): mp 48—49°C; IR (KBr): 1495 cm^{-1} (N–CS);[23] UV (EtOH): λ_{max} 257 and 278 (shoulder);[24] NMR (CCl_4): δ 2.30 (s, $C\underline{H}_3C_6H_4$), 3.42 (s, CH_3–N), 3.10—3.80 (m, S–$C\underline{H}_2$–$C\underline{H}_2$–S–CS) and 6.80—7.40 ppm (m, aromatic protons).

Found: C, 52.86; H, 6.25; N, 4.95%. Calcd for $C_{12}H_{17}NS_3$: C, 53.13; H, 6.32; N, 5.16%.

In a similar fashion the reaction of salt Ib (10.4 g, 0.042 mol) with sodium *p*-tolylmercaptide (5.5 g, 0.037 mol) was carried out. Distillation of the oily residue gave 6.5 g (59%) of β-(*p*-tolyl)ethyl *N,N*-diethyldithiocarbamate (VIb): bp 165—170°C/0.6 mmHg; n_D(20°C) 1.6426; UV (EtOH): λ_{max} 257 and 278 mμ (shoulder).[24]

Found: N, 4.82%. Calcd for $C_{14}H_{21}NS_3$: N, 4.68%.

Reactions of Salt I with Sodium Dithiocarbamates. Salt Ia (2.5 g, 0.01 mol) was added to a solution of 1.8 g (0.01 mol) of sodium *N,N*-dimethyldithiocarbamate in 25 m*l* of DMF. The mixture was stirred at 60°C for 4 hr, then poured into cold water giving 2.4 g (96%) of white precipitates, ethylene bis(*N,N*-dimethyldithiocarbamate) (VIIa): mp 188—189°C (DMF) (lit,[25] 188—190°C).

By the same procedure salt Ib (2.8 g, 0.01 mol) and the same dithiocarbamate salt (1.8 g, 0.01 mol) gave 2.5 g (92%) of ethylene bis(*N,N*-dimethyl-*N',N'*-diethyldithiocarbamate) (VIIb): mp 102—103°C (ethanol); UV (EtOH): 253 and 279 mμ.[24]

Found: C, 40.42; H, 6.92; N, 9.11%. Calcd for $C_{10}H_{20}N_2S_4$: C, 40.54; H, 6.80; N, 9.46%.

Similarly the reaction of salt Ia with sodium *N,N*-diethyldithiocarbamate yielded VIIb in 90% yield. On the other hand, the reaction of salt Ib with the same dithiocarbamate salt gave ethylene bis(*N,N*-diethyldithiocarbamate) (VIIc): mp 93—94°C (ethanol) (lit,[26] 94—95°C); UV (EtOH): λ_{max} 254 and 280 mμ.[24]

Reactions of Salt I with Triethylamine. Salt Ia (12.5 g, 0.05 mol) was added to a solution of 6.0 g (0.06 mol) of triethylamine in a mixture of DMSO (30 m*l*) and dioxane (20 m*l*). The reaction mixture was stirred at 60°C for 5 hr, then poured into water. The ether layer was dried and the solvent evaporated. Distillation of the residue gave 2.0 g (65%) of a pale-yellowish oil, *S*-vinyl *N,N*-dimethyldithiocarbamate (VIIIa): bp 87—90°C/2 mmHg; n_D(25°C) 1.5907 (lit,[27] bp 82—83°C/1 mmHg; n_D(20°C) 1.6025); IR (neat): 1590 cm^{-1} (C=C); UV (EtOH): 253 and 280 mμ (shoulder).

By the same procedure the reaction of salt Ib with triethylamine gave *S*-vinyl *N,N*-diethyldithiocarbamate (VIIIb) in 63% yield: bp 80—84°C/0.1 mmHg (lit,[28] 92—94°C/2 mmHg); n_D(25°C) 1.5942; IR (neat): 1600 cm^{-1} (C=C); UV (EtOH): 258 and 280 mμ (shoulder).

Found: C, 48.23; H, 7.86; N, 7.96%. Calcd for $C_7H_{13}NS_2$: C, 47.99; H, 7.48; N, 8.00%.

The IR spectra of these products were identical with those of the authentic samples.[27]

Reactions of Salt I with Sodium Cyanide. Salt Ia (12.5 g, 0.05 mol) was added to a solution of 7.5 g (0.15 mol) of sodium cyanide in 50 m*l* of DMF. The reaction mixture was stirred at 60°C for 4 hr, then poured into water. The ether layer was dried and the solvent evaporated. Distillation of the residue gave 5.2 g (64%) of a yellowish oil, 2-cyano-2-dimethylamino-1,3-dithiolane (IXa): bp 114—116°C/3 mmHg; n_D(27°C) 1.5633; IR (neat): 2250 cm^{-1} (C=N); NMR (CCl_4): δ 2.47 (s, CH_3–N) and 3.37 ppm (s, CH_2–S).

Found: N, 15.69%. Calcd for $C_6H_{10}N_2S_2$: N, 16.09%.

By the same procedure the reaction of salt Ib (14.0 g, 0.05 mol) and sodium cyanide (7.5 g, 0.15 mol) gave 4.8 g of a yellowish oil: bp 83—85°C/0.2 mmHg. This distillate was proved to be not 2-cyano-2-diethylamino-1,3-dithiolane, but a complex mixture by the IR spectrum (neat) exhibiting several absorption bands due to the –S–CS–N< structure as well as C=C and C=N groups.

24) The characteristic bands due to the –S–CS–N< structure. The higher wavelength band is associated with transition to the imminium state (*N*-conjugation) while the lower wavelength feature arises from transition to the sulfonium state (*S*-conjugation): M. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1870—1873 (1970)

Synthetic Studies on Bacitracin. VII.[1] Isomerization of Amino Acid Components of Thiazoline Peptides*1

Yoshihiro HIROTSU, Tetsuo SHIBA and Takeo KANEKO

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received February 2, 1970)

Ethyl 2-(1-benzyloxycarbonylaminoethyl)-R-Δ^2-thiazoline-4-carboxylate (III), ethyl 2-(1-benzyloxycarbonylamino-2-methyl-*n*-butyl)-R-Δ^2-thiazoline-4-carboxylate (VI) and their acid amide derivatives (V, VII and VIII) were prepared by either the iminoether coupling method or the dehydration method. As a general character of thiazoline peptide, it was found that the amino acid residue connected to thiazoline ring at *N*-terminal side is completely racemized at the stage of thiazoline ring formation, and further epimerized, in the case of isoleucine, by treatment with the basic reagent.

In earlier works on an amino acid composition of bacitracin A, the ambiguity of isoleucine content made the final conclusion of the molecular formula difficult.[2-6] Amino acid analysis of the hydrolyzate of somewhat impure bacitracin A showed often less than one mole of D-alloisoleucine which compensates the loss of L-isoleucine from three mole value in pure peptide.[2,5,6] The inactivation of the antibiotic activity of bacitracin A is closely related to isomerization of *N*-terminal isoleucine residue of the peptide.[7,8] Konigsberg *et al.* separated the high and low potency forms of bacitracin A by carbomethoxy cellulose chromatography after exposure in acidic medium, and showed that the high potency forms has L-isoleucine as *N*-terminal residue which is changed to D-alloisoleucine in the low potency one.[8]

In the present investigation, optical properties of the amino acid components of thiazoline ring of the various model peptides were studied in order to clarify the basic character of the isomerization of *N*-terminal amino acid of bacitracin A and to gain fundamental knowledge of its total synthesis.

General procedure used for the syntheses of thiazoline peptides were described previously.[9-10] Measurement of optical purity of the amino acid was performed by gaschromatography after conversion into trifluoroacetyl amino acid menthyl ester[11] for alanine and by amino acid analysis for isoleucine.

Acid hydrolysis of ethyl 2-(1-benzyloxycarbonylaminoethyl)-R-Δ^2-thiazoline-4-carboxylate (III) which was obtained by imino ether coupling method[9] from L-2-benzyloxycarbonylamino-propioimino ethyl ether (IV) and ethyl L-cysteinate hydrochloride gave completely racemized DL-alanine and L-cystine, while optically pure L-alanine was recovered from an acid hydrolyzate of IV. This fact indicates that racemization occurred during ring closure of thiazoline ring through the imino ether procedure. In order to know whether racemization depends on the method of ring closure or is an essential nature characteristic to thiazoline ring, the same thiazoline peptide III was prepared by dehydration method[10] as follows.

Benzyloxycarbonyl-L-alanyl-L-cysteine ethyl ester (II) was synthesized by coupling of benzyloxycarbonyl-L-alanine with diethyl L-cystinate dihydro chloride[12] using *N,N'*-dicyclohexylcarbodiimide followed by reduction of the product, *N,N'*-bisbenzyloxycarbonyl-L-alanyl-L-cystine diethyl ester (I), with zinc dust and hydrochloric acid. Cyclization of II to the thiazoline derivative was carried out with hydrogen chloride in chloroform. Neutralization

Cystine and alanine used are of L-configurations.

of the product with aqueous potassium carbonate afforded compound III. Thiazoline peptide III thus obtained was hydrolyzed with hydrochloric acid to give DL-alanine as well as L-cystine. Acid amide derivative V derived from compound III by treatment with ammonia in ethyl alcohol gave DL-alanine and DL-cystine on acid hydrolysis.[9]

From the results, it is concluded that *N*-terminal amino acid of the thiazoline peptide III is completely racemized during the stage of ring closure regardless of the method employed for the ring formation. Cysteine residue does not change in optical property at the ring closure but is also racemized under basic condition.

A similar result was observed in hydrolyzate of the other thiazoline peptide in which isoleucine is linked at the *N*-terminal side. 2-(1-Benzyloxycarbonylamino-2-methyl-*n*-butyl)-R-Δ^2-thiazoline-4-carboxamide (VIII) was synthesized by coupling of L-2-benzyloxycarbonylamino-3-methylvaleroimino

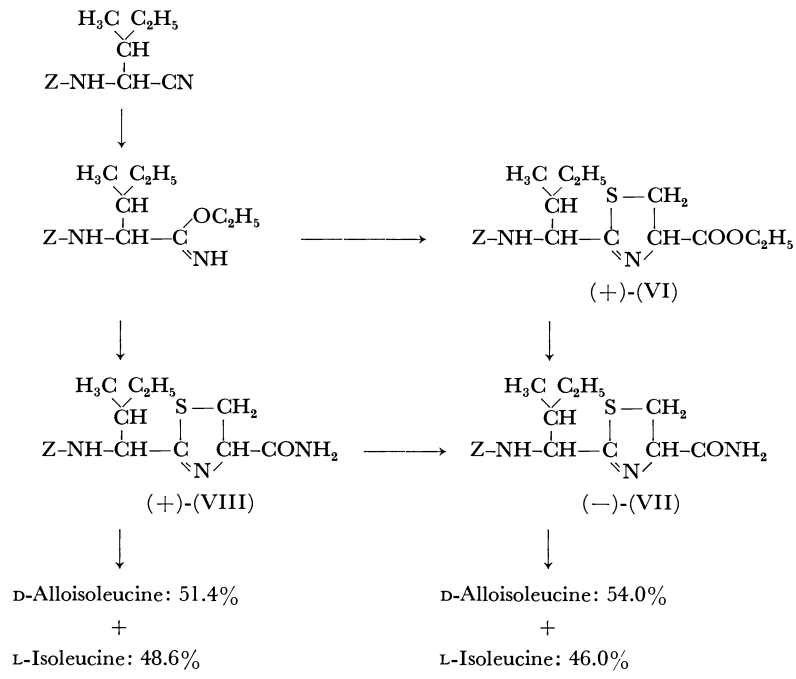

Fig. 2

Cystine and isoleucine used are of L-configurations.

ethyl ether[9] and L-cysteinamide hydrobromide[1] as shown in Fig. 2. On amino acid analysis, hydrolysis of this thiazoline compound with hydrochloric acid gave a mixture of exactly the same amounts of L-isoleucine and D-alloisoleucine. This indicates that the racemization of the amino acid residue at *N*-terminal side of thiazoline ring is not limited to alanine derivative but is probably a general character based on thiazoline ring structure.

However, after a basic treatment of the thiazoline peptide, for instance, conversion of ethyl 2-(1-benzyloxycarbonylamino-2-methyl-*n*-butyl)-R-Δ^3-thiazoline-4-carboxylate (VI)[9] into carboxamide derivative (VII) with ammonia in ethyl alcohol or keeping of VIII in ethyl alcohol saturated with ammonia at room temperature for 3 days, a ratio of L-isoleucine and D-alloisoleucine in acid hydrolyzate changed to 46 : 54. Deviation from the ratio 50 : 50 seems to be significant in consideration of the accuracy of the analytical method. This means that the isoleucine residue connected to thiazoline ring at *N*-terminal side is racemized instantly on ring closure and further epimerized under basic condition. Epimerization of α-asymmetric carbon of isoleucine might progress under the steric influence of β-asymmetric carbon atom of isoleucine.

Konigsberg *et al.* demonstrated that the high potency form of bacitracin A isomerized to a low potency form on standing in 3% acetic acid, and the amount of the two forms becomes nearly equal after two days. Interconversion of the two isomers occurs even at pH 5.45. This isomerization can be well understood as the general character of thiazoline peptide. However, it is supposed that in comparison with rapid racemization of the model thiazoline peptide, the rate of isomerization of natural bacitracin A slows down because of a peculiar structural factor like the cyclol structure in the intact molecule of bacitracin A.

For the total synthesis of bacitracin A, it is expected that the racemization of the *N*-terminal isoleucine residue can not be avoided whatever method is applied for closure of the thiazoline ring, and the product must be purified by the fractional method based on the principle of separation of diasteromers to secure pure bacitracin A.

Experimental

All melting points are uncorrected. Ultraviolet spectra were obtained in 95% ethanol and 12N hydrochloric acid - 95% ethanol (1 : 1) with a Hitachi EPS-3 spectrophotometer. For gas chromatography a Shimazu GC-4APF was used. Amino acid analysis was carried out by a Hitachi Amino Acid Analyzer LKA-3.

N,N'-Bisbenzyloxycarbonyl-L-alanyl-L-cystine Diethyl Ester (I). To a suspension of 11.0 g (0.03 mol) of diethyl L-cystinate dihydrochloride[12] in 100 m*l* of chloroform was added 6.0 g (0.06 mole) of triethylamine. After the mixture was stirred for 1 hr, 100 m*l* of ether was added. The precipitate formed was filtered off, and the filtrate was concentrated *in vacuo*. To a solution of the residue thus obtained in 150 m*l* of dioxane, 13.4 g (0.060 mol) of benzyloxycarbonyl-L-alanine and 13.6 g (0.066 mol) of *N,N'*-dicyclohexylcarbodiimide were added. After the reaction mixture had been stirred for several hours, 1 m*l* of acetic acid was added. *N,N'*-Dicyclohexylurea formed was filtered off, and the filtrate was diluted with water. The precipitate formed was filtered off and washed with water. Recrystallization from ethanol gave 18.6 g (82%) of I; mp 165—167°C, $[\alpha]_D^{15}$ −74.0° (*c* 2.00, dimethylformamide).

Found: C, 54.48; H, 6.02; N, 7.88; S, 9.05%. Calcd for $C_{32}H_{42}O_{10}N_4S_2$: C, 54.38; H, 5.99; N, 7.93; S, 9.07%.

Benzyloxycarbonyl-L-alanyl-L-cysteine Ethyl Ester (II). To a suspension of 17.7 g (0.025 mol) of I in 200 m*l* of dioxane and 16.5 m*l* of concentrated hydrochloric acid was added 7.5 g of zinc dust in many portions over a period of 15 min with vigorous stirring at 30—40°C. The mixture was stirred for additional 30 min, and then filtered. The filtrate was concentrated *in vacuo*. An oily product separated out on addition of water was extracted with ethyl acetate. The extract was washed with water, dried with magnesium sulfate and then evaporated *in vacuo*. Recrystallization of the residual solid from ethyl acetate-petroleum ether gave 11.5 g (65%) of II; mp 106—109°C, $[\alpha]_D^{15}$ −14.1° (*c* 2.18, dimethylformamide).

Found: C, 54.17; H, 6.26; N, 7.91; S, 8.86%. Calcd for $C_{10}H_{22}O_5N_2S$: C, 54.22; H, 6.26; N, 7.91; S, 9.05%.

Ethyl 2-(1-Benzyloxycarbonylaminoethyl)-R-Δ^2-thiazoline-4-carboxylate (III). A solution of 10.6 g (0.03 mol) of II in 500 m*l* of chloroform was saturated with dry hydrogen chloride gas on cooling in an ice bath. The mixture was allowed to stand at room temperature overnight and then concentrated *in vacuo*. To the residue was added 300 m*l* of ether, and the mixture was treated with a concentrated aqueous potassium carbonate. The ether layer was washed with water, dried with sodium sulfate and then concentrated *in vacuo* to give a crude oil of 7.5 g: this was dissolved in a small amount of ether and subjected to silica gel column chromatography (Mallincrodt Chemical Worker, 100 mesh, 100 g). Elution with petroleum ether - anhydrous ether gave 5.8 g (57%) of III, $[\alpha]_{25}^{D}$ +59.4° (*c* 3.26, ethanol).

Found: C, 57.06; H, 5.97; N, 8.29; S, 9.40%. Calcd for $C_{16}H_{20}O_4N_2S$: C, 57.12; H, 5.99; N, 8.33; S, 9.53%.

2-(1-Benzyloxycarbonylamino-2-methyl-*n*-butyl)-Δ^2-thiazoline-4-carboxamide (VII). A solution of 1.9 g (0.005 mole) of ethyl 2-(1-benzyloxycarbonylamino-2-methyl-*n*-butyl)-R-Δ^2-thiazoline-4-carboxylate (VI)[9] in 20 m*l* of anhydrous ethanol was saturated with ammonia at 0°C, and the mixture was kept at room temperature for 3 days. The solution was concentrated *in vacuo* below 40°C. The residue thus obtained was recrystallized from ethanol-water to give 1.4 g (82%) of VII, mp 131—133°C, $[\alpha]_D^{25}$ −5.8° (*c* 1.25, dimethylformamide), λ_{max}^{EtOH} 235 mμ (ε 2300), 252 mμ (ε 2800), $\lambda_{max}^{EtOH\text{-}HCl}$ 269 mμ (ε 4800).

Found: C, 58.36; H, 6.63; N, 12.00; S, 8.94%. Calcd for $C_{17}H_{23}O_3N_3S$: C, 58.43; H, 6.63; N, 12.03; S, 9.18%.

2-(1-Benzyloxycarbonylamino-2-methyl-*n*-butyl)-R-Δ^2-thiazoline-4-carboxamide (VIII). To a solution of 5.7 g (0.026 mol) of L-cysteinamide hydrobromide[1]

in tetrahydrofuran and 10 m*l* of anhydrous methanol was added 7.5 g (0.026 mole) of L-2-benzyloxy-carbonylamino-3-methylvaleroimino ethyl ether.[9] After the reaction mixture had been kept at room temperature for 3 hr, ammonium bromide was deposited. The reaction mixture was concentrated *in vacuo*, and the residue obtained was dissolved in ethyl acetate. The ethyl acetate solution was washed with water, dried with sodium sulfate, and then evaporated *in vacuo*. The residue obtained was recrystallized from ethyl acetate - petroleum ether gave 2.8 g (35%) of VIII; mp; 138—140°C, $[\alpha]_D^{24}$ +26.7° (*c* 2.20, dimethylformamide).

Found: C, 58.40; H, 6.69; N, 11.82; S, 8.89%.

Isolation of L-Alanine from Hydrolyzate of IV. Hydrolysis of 5.0 g (0.02 mole) of IV was carried out by refluxing in 100 m*l* of 6N hydrochloric acid for 3 hr. After cooling, the reaction mixture was extracted with ether. An aqueous layer was evaporated *in vacuo*. The residue obtained was dissolved in 30 m*l* of water, subjected to Dowex-50 column (W×8, H^+ form, 200—400 mesh, 30 m*l*) and eluted with 50 m*l* of N ammonium hydroxide. The eluate was evaporated *in vacuo* and the residue obtained was then crystallized from water - ethyl alcohol; wt. 1.45 g (81%), $[\alpha]_D^{25}$ +14.3° (*c* 2.58, N HCl).

Found: C, 40.42; H, 7.97; N, 15.61%. Calcd for $C_3H_7O_2N_2$: C, 40.44; H, 7.92; N, 15.72%.

Gaschromatography of Menthyl Trifluoroacetylalaninate obtained from Hydrolyzates of III and V. Hydrolysis of 0.3 g each of III, which was synthesized by either the imino ether or the dehydration method, and of V, was carried out by refluxing in 20 m*l* of 6N hydrochloric acid with 0.3 g of anisole for 3 hr. After cooling, the reaction mixture was extracted with ether. An aqueous layer was evaporated *in vacuo*. The residue was dissolved in 10 m*l* of water and evaporation was repeated. The residue thus obtained was dissolved in 5 m*l* of water and subjected to Dowex-50 column (W×8, H^+ form, 200—400 mesh, 10 m*l*). Eluate with 20 m*l* of N ammonium hydroxide was evaporated *in vacuo* to yield alanine. Three mg each of the samples of alanine were mixed with 0.7 g of menthol. Hydrogen chloride gas was passed through the melted mixture at 110°C for one and a half hour.[11] Excess of menthol was removed by sublimation at 100°C under reduced pressure of 3 mmHg. To the residue thus obtained, a few m*l* of trifluoroacetic anhydride was added. After the mixture had been allowed to stand at room temperature overnight, excess of trifluoroacetic anhydride was removed by evaporation *in vacuo*. The residue was dissolved in 1 m*l* of acetone and subjected to gaschromatography. Gas chromatography was carried out on a column of 3m-length packed with 1.5% NPGS on 60—80 mesh Chromosorb W at column temperature of 150°C under excess pressure of 1.8 atm, and at detector temperature of 180°C and injection temperature of 250°C. All the three samples of menthyl trifluoroacetylalaninate were shown to be of complete DL-form.

Isolation of L-Cystine from Acid Hydrolyzate of III. Hydrolisys of 1.7 g each (0.05 mol) of III, which was synthesized by either the imino ether or dehydration method, was carried out by refluxing in 50 m*l* of 6N hydrochloric acid with 0.5 g of anisole for 3 hr. The reaction mixture was cooled and extracted with ether. The aqueous layer was concentrated *in vacuo* to dryness. A solution of the residue in 30 m*l* of water was adjusted to pH about 8.5 with 28% aqueous ammonia. Air was bubbled through the solution until the nitroprusside reaction became negative by a spot test. The reaction mixture was allowed to stand at 0°C for 2 days. The precipitate thus formed was filtered off and then dissolved in 15 m*l* of N hydrochloric acid. The solution was adjusted to pH 5.5—6.0 with an aqueous sodium acetate solution. After standing at 0°C for 2 days, the precipitate formed was filtered off and dried at 80°C *in vacuo* for 4 hr to give 0.33 g (55%) and 0.37 g (62%) of L-cystine respectively; $[\alpha]_D^{20}$ −218° (*c* 1.00, N HCl).

Found: N, 11.51 and 11.62; S, 26.09 and 26.38%. Calcd for $C_6H_{12}O_4N_2S_2$: N, 11.66; S, 26.69%.

Amino Acid Analysis of L-Isoleucine and D-Alloisoleucine in Acid Hydrolyzate of VII and VIII. *a)* A suspension of 0.05 g of VIII in 10 m*l* of 6N hydrochloric acid was refluxed for 2 hr. The hydrolyzate was extracted with ether. An aqueous layer was used for amino acid analysis. The ratio of D-alloisoleucine and L-isoleucine was found to be 51.4 : 48.6.

b) In a similar way, 0.1 g each of VII and VIII, which was treated with ammonia in ethanol at room temperature for 3 days, was hydrolyzed by refluxing in 10 m*l* of 6N hydrochloric acid for 3 hr, and the hydrolyzate was applied to amino acid analysis. Ratios of D-alloisoleucine and L-isoleucine for both compounds were found to be 54.7 : 45.3 and 54.0 : 46.0% respectively.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1874—1875 (1970)

Notiz zur Umsetzung des Ketenimins

Kunihiro ICHIMURA*1 und Masaki OHTA

Laboratorium für Organische Chemie, Tokyo Institut für Technologie, Tokyo, Meguro-ku, Ookayama

(Eingegangen am 20. September, 1969)

Bekanntlich ist, daß das Ketenimin sich als so starkes Elektrophil wie andere Heteroallene verhält, und vor kurzem haben wir die Addition der aktiven Methylenverbindungen an Ketenimin beschrieben.[1] In dieser Arbeit wollen wir einige Beispiele der nucleophilen Addition an Ketenimine angeben.

Wenn man Schwefelwasserstoff in die benzolische Lösung des *N*-(*p*-Tolyl)diphenylketenimin in Gegenwart des Triäthylamins einleitet, so wird *N*-(*p*-Tolyl)diphenylthioacetamid erhalten. In Abwesenheit der Base war die Reaktion beträchtlich langsam.

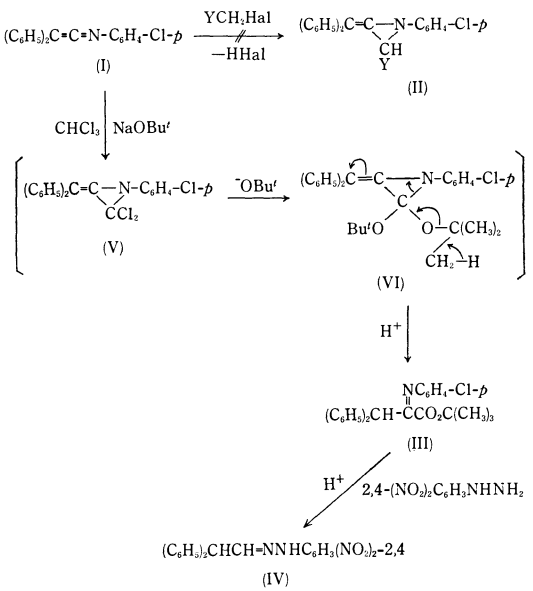
Im Zusammenhang der Entschwefelung des Thioharnstoffs zu Carbodiimid[2] haben wir dann das Zurückgewinnen des Ketenimins durch die Einwirkung des Quecksilberoxyds auf das Thioamid versucht, und jedoch nur ein strukturunbekanntes entschwefeltes Produkt erhalten.

Dieartige Bildung der kummulierten Doppelbindungen wurde ja bei der Umsetzung des *N*-Methyldiphenylthioacetamids mit Quecksilberoxyd beobachtet, während Effenberger nur das entsprechende Säureamid bei der Einwirkung des Quecksilberoxyds auf *N*-Phenyl-bis(äthoxycarbonyl)thioacetamid isoliert hatte.[3]

Nach den Ergebnissen der Anlagerung der aktiven Methylenverbindungen an Ketenimin könnte man die Entstehung des Diphenylmethylenaziridins durch die Addition-Elimination-Reaktion erwarten, wenn man das Ketenimin mit der aktiven α-Halomethylenverbindung in Gegenwart der Base reagieren läßt. Bei Benutzung des Phenacylbromids, Chloressigsäureesters sowie Benzylpyridiniumsalzes konnte man aber keine einheitliche Substanz isolieren.

Bei der Umsetzung des (*p*-Chlorphenyl)diphenylketenimin mit Chloroform in Gegenwart von Natrium-*t*-butoxyd wurde α-(*p*-Chlorphenylimino)-β,β-diphenylpropionsäure-*t*-butylester in geringer Ausbeute erhalten, dessen Struktur auf der Elementaranalyse und dem infraroten Spektrum beruht. Das *t*-Butylester III liefert durch säure Hydrolyse-*p*-Chloranilin, und die Umwandlung des Esters in 2,4-Dinitrophenylhydrazon des Diphenylacetaldehyds (IV) stützt weiter dessen Struktur. Das *t*-Butylester bildet sich vermutlich über Diphenylmethylendichloraziridin V, das nach der Bildung vom Laktamacetal VI durch Abspaltung des C–N-Bindung des Dreirings in das isolierte Produckt umgewandelt würde.

Dieartige Umsetzung in Gegenwart des Natriummethylats liefert nicht das entsprechende Methylester, sondern *N*-(*p*-Chlorphenyl)diphenylacetimidat-methylester.



Beschreibung der Versuche

***N*-(*p*-Tolyl)diphenylthioacetamid.** Man leitet 20 min Schwefelwasserstoff in die benzolische Lösung

ein, die 0.50 g *N*-(*p*-Tolyl)diphenylketenimin und 2 m*l* Triäthylamin enthält. Nach Eindampfen des Lösungsmittels erhält man 0.45 g Kristalle, die aus Methanol umkristallisiert werden. *N*-(*p*-Tolyl)diphenylthioacetamid als gelbe Prismen schmilzt zuerst bei 135—140°C und nach der anschließenden Erstarrung schließlich bei 190—191°C. Gef: C, 79.46; H, 6.67; N, 4.74%. Ber für $C_{21}H_{19}NS$: C, 79.47; H, 6.03; N, 4.41%.

Das Thioamid liefert die strukturunbekannten entschwefelten farblosen Nadeln vom Schmp 184—185°C bei Einwirkung des Quecksilberoxyds in Benzol. Gef: C, 60.84; H, 4.76; N, 3.64%.

Einwirkung des Quecksilberoxyds auf *N*-Methyldiphenylthioacetamid. Man kocht die benzolische Lösung von 0.50 g *N*-Methyldiphenylthioacetamid und 1.00 g Quecksilberoxyd, macht sie vom Niederschlag frei und erhält den glassartigen Rückstand, der ja bei 2100 cm^{-1} die starke charakteristische Bande des Ketenimins zeigt.

Umsetzung des *N*-(*p*-Chlorphenyl)diphenylketenimins mit Chloroform. In das Gemisch von 1.52 g *N*-(*p*-Chlorphenyl)diphenylketenimin (I) und aus 0.28 g Natrium erhaltenem verpulvertem Natrium-*t*-butoxyd in 20 m*l* Benzol und 20 m*l* *n*-Hexan setzt man 1.44 g Chloroform in 10 m*l* *n*-Hexan unter gutem Rühren und Eis-Kochsalzkühlung bei −17——15°C langsam zu, rührt weiter bei Raumtemperatur und läßt das Gemisch über Nacht stehen. Nach Behandlung mit der aktiven Kohle und Filtrieren dampft man die Filtrat unter vermindertem Druck ein und erhält 0.50 g kristallinen Rückstand, der aus *n*-Hexan umgelöst wird. Farblose Nadeln vom Schmp 111—113°C. Gef: C, 73.42; H, 6.04; N, 3.19.% Ber für $C_{25}H_{24}NO_4Cl$: C, 73.97; H, 5.96; N, 3.45%. IR (KBr): 1710 (s), 1615 (m), 1390 (schw), 1370 (schw), 1155 (s), 1090 (m) cm^{-1}.

Man kocht 0.28 g oben erhaltene Kristalle in 2N-Salzsäure-Methanol während 50 min, neutralisiert mit Natriumhydroxyd und extrahiert mit Äther. 0.02 g Kristalle vom Schmp 69—71.5°C werden erhalten und durch Mischprobe mit *p*-Chloranilin identifiziert.

Wenn man die Kristalle vom Schmp. 111—113°C mit 2,4-Dinitrophenylhydrazin in Äthanol in Gegenwart der katalytischen Mengen Schwefelsäure behandelt, so bildet sich das Hydrazon des Diphenylacetaldehyds (IV) vom Schmp 151°C (Ber. Schmp 150—151°C).[4] Gef: C, 63.82; H, 4.42; N, 15.38%. Ber für $C_{20}H_{16}N_4O_4$: C, 63.82; H, 4.29; N, 14.89%. IR (KBr): 3270 (m), 1620 (s), 1520 (s), 1340 (s) cm^{-1}.

Versuche zur Umsetzung des *N*-(*p*-Chlorphenyl)-diphenylketenimins mit Chloroform in Gegenwart von Natriummethylat. In der analogen Weise versetzt man das *N*-(*p*-Chlorphenyl)diphenylketenimin mit Chloroform in Gegenwart des trocknen Natriummethylats in Benzol-*n*-Hexan bei −11—18°C. Nach gleicher Aufarbeitung sind die farblosen Kristalle vom Schmp 111—112.5°C erhältlich, die sich mittels IR-Spektrums mit *N*-(*p*-Chlorphenyl)diphenylacetimidatmethylester identifizieren, das bei Einwirkung des Natriummethylats auf das Ketenimin in Methanol hergestellt wird. Gef: C, 74.53; H, 6.16; N, 4.19%. Ber für $C_{21}H_{18}NOCl$: C, 75.10; H, 5.40; N, 4.17%.

The Photoreaction of 1,2-Dibenzoylethylene in Acidic Methanol

Noboru SUGIYAMA and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received October 20, 1969)

We have previously reported that the photoreaction of β-aroylacrylic acids in methanol produced the methanol adducts, β-aroyl-α-methoxypropionic acids.[1] β-Aroylacrylic acids have the structure of an α,β-unsaturated γ-ketoacid. As an analogy, 1,2-dibenzoylethylene (I), an α,β-unsaturated γ-diketones, is expected to give the methanol adduct upon irradiation. On the other hand, Griffin[2] and Zimmerman[3] reported that the irradiation of I in methanol gave only the rearrangement product, methyl 4-phenyl-4-phenoxy-3-butenoate (II), unlike as in the methanol addition reaction. Thus, it is interesting to re-examine the irradiation of I in methanol.

Results and Discussion

We found that the irradiation of I in methanol gave II as the main product, as well as a methanol adduct, 1,2-dibenzoyl-1-methoxyethane (III), as the minor product. The structure of III was determined by the spectral data and by identification with an authentic sample.[4] The yields

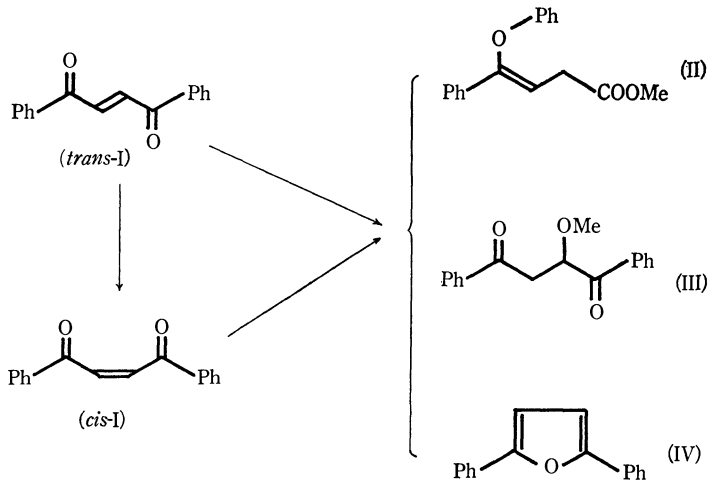

Fig. 1

Table 1. The photoproducts from *trans*-1,2-dibenzoylethylene in acidic methanol

Concn. of HCl mol/*l*	Product Total %	Products		
		II%	III%	IV%
0	68.6	95	5	0
9.9×10^{-6}	79.5	90	10	0
9.5×10^{-5}	70.0	95	5	0
9.9×10^{-5}	77.6	94	4	2
1.9×10^{-4}	57.6	78	19	4
4.7×10^{-4}	45.6	29	47	24
9.5×10^{-4}	52.1	15	56	28
9.9×10^{-4}	49.0	5	40	55

of II and III were estimated by means of the intensity of the NMR signals, which appeared as triplets at δ 6.01 and 5.43 ppm, and which were assigned to the olefinic proton of II and the methine proton of III respectively. The mechanism of the formation of III seems to be similar to that of the photoaddition of β-benzoylacrylic acids.

Considering that the addition of methanol to β-benzoylacrylic acids was initiated by protonation on carbonyl oxygen,[5] the yield of III from I was expected to increase in acidic methanol. Thus, the photoreaction of I was examined in methanol containing various amounts of hydrochloric acid. As is shown in Table 1, when the concentration of hydrochloric acid was 9.9×10^{-5} mol/*l* or less, the

effect of the acid was not observed in the photoreaction of I. At more than 1.9×10^{-4} mol/*l*, the yield of II decreased and that of III increased.

Moreover, in methanol containing more than 1.9×10^{-4} mol/*l* of hydrochloric acid, 2,5-diphenylfuran (IV) was obtained as one of the photoproducts. The structure of IV was determined by the spectral data and by identification with an authentic sample.[6] The yield of IV was estimated by means of the singlet signal of the NMR spectrum at δ 6.68 ppm assigned to two methine protons on the furan ring. In the presence of 4.7×10^{-4} mol/*l* of hydrochloric acid in methanol, the reaction mixture was shown to contain 29% of II, 47% of III, and 24% of IV. Then, the influence of the light source on the photoreaction of I was examined (Table 2). In the absence of acid, the main product is II, even when the light is filtered through an aqueous solution of nickel sulfate and a cobalt sulfate mixture or ammoniac copper sulfate. However, in the presence of 4.7×10^{-4} mol/*l* of acid, the yield of III increased when the light came through a filter of nickel sulfate and a cobalt sulfate solution. In acidic methanol, *cis*-1,2-dibenzoylethylene also gave II and III photoproducts.

Table 3. The photoproducts from *trans*-1,2-dibenzoylethylene in acidic alcohols
(5×10^{-4} mol/*l* HCl)

Alcohol	Total product %	Rearrangement product %	Alcohol adduct %	Diphenyl furan %
MeOH	70.4	29	52	19
EtOH	67.4	80	20	0
n-PrOH	53.9	75	25	0
iso-PrOH	30.8	100	0	0
t-BuOH	36.8	100	0	0

Furthermore, the photoreaction of I in alcohols other than methanol was examined in the presence of 5×10^{-4} mol/*l* of hydrochloric acid; the results are listed in Table 3. In ethanol or *n*-propanol, both the alcohol adduct and the rearrangement product were obtained, but in the sterically-hindered alcohols, such as isopropanol or *t*-butanol, only the rearrangement product was obtained. In case of alcohols other than methanol, IV was not obtained.

By the facts that the addition occurs by the irradiation in acidic methanol or ethanol, and that the *cis* isomer gives the addition product in acidic methanol, it can be deduced that the mechanism of this reaction is similar to that of the photoaddition of methanol to β-benzoylacrylic acids.[1,5]

6) S. Skraup and S. Guggenheimer, *Ber.*, **58**, 2488 (1925).

Experimental

Materials. *trans*-1,2-Dibenzoylethylene was prepared from fumaroyl chloride by a Friedel-Crafts reaction and was recrystallized from ethanol; mp 110.5°C (lit,[7] 109—110°C). λ^{EtOH} (ε): 268 (18400) and 360 nm (sh, 257). δ^{CDCl_3}: 7.97 (s, 2H), 7.9—8.15 (m, 6H) and 7.4—7.7 ppm (m, 4H). *cis*-1,2-Dibenzoylethylene was prepared by the irradiation of I in ethanol;[8] mp 135.5°C. λ^{EtOH} (ε): 260 (17800) and 340 nm (sh, 210). δ^{CDCl_3}: 7.16 (s, 2H), 7.4—7.7 (m, 6H) and 7.8—8.1 ppm (m, 4H).

Instrumentation. The infrared and ultraviolet spectra were measured with a Hitachi EPI-2-type infrared spectrometer and a Hitachi EPS-3T-type spectrometer respectively. The NMR spectra were recorded with a Hitachi H-60 high-resolution NMR spectrometer, with TMS as the internal standard. An Ushio 450 W high-pressure mercury lamp was used as the irradiation source.

Filter. The light from the high-pressure mercury lamp was filtered by three types of filters:

1) Pyrex filter; transparent at wavelengths longer than 310 nm.

2) Aqueous solution (3 *l*) of nickel sulfate (1350 g) and cobalt sulfate (320 g) and a Pyrex filter; thickness 1 cm; transparent from 290 to 370 nm; 290 nm, 5% T; 310 nm, 50% T; 330 nm, 70% T; 350 nm, 25% T; with a maximum at 320 nm, 85% T.

3) Aqueous solution (2 *l*) of copper sulfate (100 g) and aqueous ammonia (400 m*l*); thickness 1 cm; transparent from 320 to 480 nm; 330 nm, 15% T; 350 nm, 47% T; 370 nm, 68% T; 390 nm, 80% T; 410 nm, 82% T; 430 nm, 69% T; 450 nm, 40% T; 470 nm, 8% T; with a maximum at 404 nm, 82.5% T.

Irradiation of I. A solution of 100 mg of I in 5 m*l* of the methanol was irradiated at room temperature. After the solvent had been removed, the residue was analyzed by means of the intensity of the NMR signals at δ 5.43 (t, methine proton of III), 6.01 (t, olefinic proton of II), and 6.68 ppm (s, methine protons of IV). The residue was chromatographed on a silica-gel (Merck 7734) column with a benzene-ethyl acetate mixture, we thus obtained II, III, and IV in a pure state.

Methyl 4-Phenyl-4-phenoxy-3-butenoate (II). ν^{film}: 1735, 1600, 1485, 1220, 750 and 690 cm^{-1}. δ^{CDCl_3}: 3.26 (d, 2H), 3.60 (s, 3H), 6.01 (t, 1H) and 6.7—7.6 ppm (m, 10H).

1,2-Dibenzoyl-1-methoxyethane (III). ν^{film}: 1680, 1595, 1450, 1110, 1090, 755 and 685 cm^{-1}. δ^{CDCl_3}: 3.37 (s, 3H), 3.41 (d, 2H), 5.43 (t, 1H), 7.2—7.6 (m, 6H) and 7.8—8.2 ppm (m, 4H).

2,5-Diphenylfuran (IV). mp 85°C. ν^{KBr}: 1600, 1020, 920, 910, 795, 760 and 690 cm^{-1}. δ^{CDCl_3}: 6.68 (s, 2H) and 7.1—7.9 ppm (m, 10H).

The Photoreaction of 3-Hexene-2,5-dione in Methanol

Noboru SUGIYAMA and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received October 25, 1969)

We have investigated the photoreactions of α,β-unsaturated γ-dicarbonyl compounds, such as 1,2-dibenzoylethylene,[1] β-aroylacrylic acids,[2,3] β-acylacrylic acids,[4] and their esters. The photoproducts of these systems in methanol are the *cis* isomers, 4-hydroxy- and 4-methoxy angelica lactones, and methanol adducts. As a part of these investigations, we have now examined the photoreaction of 3-hexene-2,5-dione, one of the α,β-unsaturated γ-diketones, in methanol.

Results and Discussion

By the irradiation of a filtered light through a Pyrex filter in methanol for 6 hr, *trans*-3-hexene-2,5-dione (I), which shows absorption maxima at 228 (ε 14000) and 331 mμ (ε 69), gave the *cis* isomer (II). The structure of II was deduced by means of the spectral data and by identification with an authentic sample.[5] Upon continuous irradiation for 22 hr, I gave two products, III and IV, which were separated by vapor-phase chromatography. In the NMR spectra, III showed singlet signals at δ 5.78, 3.20, and 1.40 ppm, while IV showed them at δ 5.77, 3.10, and 1.48 ppm. From these results and from other spectral and elemental analysis data, the structures of III and IV were deduced to be *cis*- and *trans*-2,5-dimethoxy-2,5-dimethyl-2,5-dihydrofuran respectively. Although the stereo isomers were not separated, the preparation of 2,5-dimethoxy-2,5-dimethyl-2,5-dihydrofuran from 2,5-dimethylfuran has been reported by Levisalles.[5] Thus, we also prepared III and IV by the method of Levisalles, and identified them with the photoproducts.

For the purpose of clarifying the reaction mechanism from I to II, III, and IV, kinetic studies were carried out. The concentrations of I, II, III, and IV in the reaction mixture were measured by means of the NMR spectra and by vapor-phase chromatography. The changes in the concentration with the time are shown in Fig. 1. The curve for II showed a maximum at 5 hr, and those for III and IV, a gradual increase. Also, it was confirmed

that II does not react with methanol at room temperature without irradiation.

Thus, a probable reaction mechanism for the formation of III and IV from I may be proposed (Fig. 2). That is, I is isomerized to II, the excited species of which is attacked by methanol to produce the hemiacetal intermediate. This intermediate is immediately cyclized to III and IV in parallel.

From these results, it seems that the photoreaction from I to III and IV is similar to the formation of 4-methoxy angelica lactone.

Experimental

Material. *trans*-3-Hexene-2,5-dione was prepared from 2,5-hexanedione by oxidation with selenium dioxide, and then recrystallized from *n*-hexane; mp 73°C (lit,[6] 78°C). λ^{EtOH} (ε): 228 (14000) and 331 mμ (69). δ^{CDCl_3}: 6.78 (s, 2H) and 2.38 ppm (s, 6H).

Instrumentation. The infrared and ultraviolet spectra were measured with a Hitachi EPI-2-type infrared spectrometer and a Hitachi EPS-3T-type spectrometer respectively. The NMR spectra were recorded with a Hitachi A-60 high-resolution NMR spectrometer, with TMS as the internal standard. A Hitachi KGL-2A-type gas-chromatograph analyzer was used with 10% PEG-adipate at 104°C. The light from a Ushio 450-W high-pressure mercury lamp was irradiated on the sample through the Pyrex filter.

***cis*-3-Hexene-2,5-dione (II).** A solution of 100 mg of I in 5 m*l* of methanol was irradiated at room temperature. After 2 hr, the solvent was removed; we then measured the spectra and chromatographed them on a silica-gel thin layer. λ^{EtOH} (ε): 224 mμ (8600). ν^{KBr}: 1675, 1610, 1415, 1390, 1355, 1255, 1215, 1170 and 985 cm^{-1}. δ^{CDCl_3}: 6.30 (s, 2H) and 2.29 ppm (s, 6H).

The photoproduct was identified with the *cis*-3-hexene-2,5-dione prepared from 2,5-dimethoxy-2,5-dimethyl-2,5-dihydrofuran.[5]

***trans*- and *cis*-2,5-Dimethoxy-2,5-dimethyl-2,5-dihydrofuran (III and IV).** A methanol solution of I was irradiated for 22 hr, and then the solvent was removed. The residual oil was passed through preparative vaporphase chromatography. The first fraction, with Rt 9.5 min, was collected as III. λ^{EtOH} (ε): 251 mμ (342). ν^{film}: 1450, 1370, 1350, 1285, 1170, 1125, 1090, 1050, 945, 890 and 770 cm^{-1}. δ^{CDCl_3}: 5.78 (s, 2H), 3.20 (s, 6H) and 1.40 ppm (s, 6H).

Found: C, 60.59; H, 9.17%. Calcd for $C_8H_{14}O_3$: C, 60.74; H, 8.92%. The second fraction, with Rt 12.0 min, was collected as IV. λ^{EtOH} (ε): 224 (sh, 179) and 253 mμ (sh, 104). ν^{film}: 1450, 1370, 1350, 1170, 1095, 1050, 945, 890 and 770 cm^{-1}. δ^{CDCl_3}: 5.76 (s, 2H), 3.10 (s, 6H) and 1.48 ppm (s, 6H).

Found: C, 60.36; H, 8.89%. Calcd for $C_8H_{14}O_3$: C, 60.74; H, 8.92%. Both III and IV were identical with the mixture of *trans*- and *cis*-2,5-dimethoxy-2,5-dimethyl-2,5-dihydrofuran previously prepared from 2,5-dimethylfuran[5] by vapor-phase chromatography.

Kinetic Studies. A solution of 1 g of I in 50 m*l* of methanol was divided into 10 aliquots, which were irradiated at 30°C for 1, 2, 4, 5, 6, 8, 12, 16, 20, and 22 hr, respectively. Each portion was then concentrated, and the concentrations of I, II, III and IV were measured by means of intensity of the NMR signals at δ 6.78 (s, olefinic protons of I) and 6.30 ppm (s, olefinic protons of II), and by means of those of a vapor-phase chromatogram at Rt 9.5 min (III) and 12.0 min (IV).

Photochemical Reactions of Bridged Polycyclic Ketones

Noboru SUGIYAMA, Takehiko NISHIO, Kazutoshi YAMADA and Hiromu AOYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received October 31, 1969)

By photochemical reactions, the non-conjugated cyclic ketones which have hydrogens close to the carbonyl group undergo internal hydrogen transfer, thus giving cyclic tertiary alcohols.*1,1)

In this paper, we wish to report the results of our photochemical reactions of bridged polycyclic ketones (**1**, **2** and **3**),[2,3] where the hydrogen extremely close to the carbonyl oxygen was not

*1 In these reactions, the hydrogen to be abstracted is usually γ-hydrogen. However, if by virtue of structure other hydrogens are closer to the excited carbonyl group, they will be transferred to the carbonyl group.[1f)]

abstracted.

When **1** in ethanol was irradiated in the n–π^* region of the carbonyl group, an unsaturated aldehyde (**4**) (α-cleavage product) was obtained. The structure of **4** was established by elemental analysis and by a study of its physical data. The NMR spectrum showed a triplet (1H) at δ 9.82 (the aldehyde proton) and a complex multiplet (2H) at δ 5.40 (the olefinic protons).

The irradiation of **2** under the same conditions also gave an α-cleavage product (**5**). On the other hand, **3** did not show any changes upon irradiation, but was recovered almost quantitatively.

In any one of these three cases, no internal hydrogen transfer product could be detected. This may result from the stereoelectronic requirements for the hydrogen-abstraction step.*[2]

Unperturbed Dimensions of Poly-*p*-chlorostyrene

Kimiyoshi MATSUMURA, Masamichi FUKAYA and Keisuke MIZUNO

Department of Chemistry, Aichi Kyoiku University, Nagoya

(Received November 4, 1969)

The unperturbed dimensions of various polymers have been studied by light-scattering measurements of polymers in a theta solvent, or from results of viscosity measurements in a good solvent by the use of the Kurata-Stockmayer[1] or the Stockmayer-Fixman[2] relation.

In this paper, the temperature dependence of the unperturbed dimensions of poly-*p*-chlorostyrene was obtained by the viscosity measurements of poly-*p*-chlorostyrene in critical consolute solvents, which were mixtures of benzene (solvent) - cyclohexane (nonsolvent) at various ratios of mixing.

Experimental

Polymer. Poly-*p*-chlorostyrene was prepared by heating *p*-chlorostyrene in a sealed tube at 95°C without any initiator. A benzene solution of the polymer was fractionated at 30°C by successive precipitation with methanol. The obtained fractions were redissolved in benzene, reprecipitated with methanol, and dried under reduced pressure. Five fractions were used for the measurements.

The molecular weights of these fractions were determined by viscosity measurements of the toluene solutions at 30°C with an intrinsic viscosity - molecular weight relationship of $[\eta]=1.28\times10^{-4}\cdot M^{0.64}$.[3] The molecular weights were 100.9×10^4 (fraction 1-1), 76.8×10^4 (1-3), 49.9×10^4 (2-2), 41.2×10^4 (3), and 26.7×10^4 (4) respectively.

Solvent. The benzene and the toluene was washed successively with sulfuric acid, water, a solution of sodium hydroxide, and water, and refluxed with metallic sodium and distilled. Cyclohexane was washed with a mixture of sulfuric acid and nitric acid, and then treated in the same way as benzene.

The critical consolute solvent mixtures were prepared by mixing benzene and cyclohexane by volumes at 25°C.

Measurements. For the determination of the theta temperature, the method of Mandelkern and Flory[4] was used.

For the measurements of the viscosity of the solutions, the viscometer described in a preceding paper[5] was used.

Results and Discussion

The Determination of the Theta Temperature. The ratios of benzene *vs.* cyclohexane used for the measurements were (A) 1.8/1, (B) 1.4/1, and (C) 1.1/1 at 25°C. By the method of Mandelkern and Flory, the theta temperatures for poly-*p*-chlorostyrene in the above critical consolute solvent mixtures, (A), (B), and (C), were determined to be 28 ± 2°C, 43 ± 2°C, and 60 ± 3°C respectively. An example of the measurements of the precipitation temperature and the determination of the theta temperature for poly-*p*-chlorostyrene in one critical consolute solvent mixture, (A), is shown in Fig. 1.

Viscosity. The results of the viscosity measurements of poly-*p*-chlorostyrene in the critical consolute solvents and in toluene are shown in Table 1. As is shown in Fig. 2, from the data of the toluene solutions the following relations were obtained: $[\eta]=1.72\times10^{-4}\cdot M^{0.62}$ (dl/g) (28°C), $[\eta]=1.35\times10^{-4}\cdot M^{0.64}$ (43°C), and $[\eta]=1.07\times10^{-4}\cdot M^{0.66}$ (60°C).

Discussion. The relations between $[\eta]/M^{1/2}$ and $M^{1/2}$ at each temperature, as obtained by the

Stockmayer-Fixman equation,[2] are shown in Fig. 3. The determined K_θ values are shown in Table 2. Here $K_\theta=[\eta]_\theta/M^{1/2}$ and $[\eta]_\theta$ is the intrinsic viscosity in the theta state. The K_θ values of the toluene solutions are in fairly good agreement with those of the critical consolute solutions at each temperature. The temperature dependence of the K_θ values of poly-*p*-chlorostyrene in the critical consolute solvents gives a linear relation, in which the K_θ values is smaller the higher the temperature, similar as with the temperature dependence of K_θ for polystyrene and for poly-*p*-chlorostyrene.[6]

The K_θ values obtained from the viscosity measurements for the critical consolute solutions are slightly larger than those values by many authors.[3,6-8] From the results for polystyrene in the theta solvents, cyclohexane and diethylmalonate, at about 35°C, it can be seen that the K_θ values of a polymer in different solvents show a fairly large disagreement at the same temperature.[9] Therefore, it can be considered that the difference between the K_θ values of poly-*p*-chlorostyrene in the theta solvents in this paper and those in the previous paper[6] is a result of the solvent effect.

On the basis of the K_θ values, the values of $\{\langle L^2\rangle_0/M\}^{1/2}=(K_\theta/\Phi_0)^{1/3}$ ($\Phi_0=2.87\times10^{21}$) and $\sigma=\{\langle L^2\rangle_0/\langle L^2\rangle_{of}\}^{1/2}$, were found; here $\langle L^2\rangle_0$ is the unperturbed dimension, and $\langle L^2\rangle_{of}$ is the mean-square end-to-end distance of the polymer chain for the free rotation model. The results are shown in Table 2. The obtained σ values are slightly larger than those obtained by other authors. However, as the difference is very small, it is considered our results confirm the conclusion by many authors,[8,10] that the effect of the chlorine atom on the unperturbed dimension of poly-*p*-chlorostyrene is not very large.

Modified Benzyloxycarbonyl Groups for Protection of ε-Amino Group of Lysine

Kosaku NODA, Shigeyuki TERADA and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received November 18, 1969)

The benzyloxycarbonyl[1] group has been found suitable for protection of the ε-amino group of lysine in peptide synthesis by either the solution or solid phase method. Since the use of ε-Z group is compatible with that of BOC group in the solid phase method, there have been many reports regarding the use of α-BOC-ε-Z-L-lysine.[2] However, there have been suggestions that ε-Z group was partially cleaved by either N hydrogen chloride-acetic acid or 4N hydrogen chloride-dioxane used for the removal of the α-BOC group during the synthesis of oligopeptide by the solid phase method.[3] Deprotection of ε-Z group was avoided by the use of the α-N protecting group which is much more readily removed than BOC group; such sensitive α-groups so far reported are 2-(*p*-biphenyl)isopropoxycarbonyl[4] and 2-benzoyl-1-methylvinyl.[5]

Another approach to avoid partial deprotection from ε-amino group is the use of a protecting group more stable than Z. The present paper will describe the syntheses of some ε-Z-L-lysine derivatives in which phenyl is substituted with negative group and their stabilities toward treatment with hydrogen chloride as compared with ε-Z-lysine. Behavior of these protecting groups toward liquid hydrogen fluoride will also be described.

It has been observed that several ε-Z groups sub-

1) The following abbreviations are used; Z, benzyloxycarbonyl; Z(*p*-Cl), Z(*m*-Cl), Z(*p*-CN), Z(*p*-NO_2), *e. g. p*-chlorobenzyloxycarbonyl for Z(*p*-Cl); BOC, *t*-butyloxycarbonyl.

stituted with *p*-chloro,[6] *p*-cyano,[6] and *p*-nitro,[7] are more stable toward hydrogen bromide than ε-Z group. We observed a similar tendecny regarding the stabilities toward 4N hydrochloric acid-dioxane (Table 3). The results indicate that the modified ε-Z groups can be satisfactorily used in the solid phase method if the groups are readily removed by hydrogen fluoride from a finished peptide polymer. The behavior of these groups toward hydrogen fluoride was therefore investigated. Sakakibara and Shimonishi have reported that ε-Z group is easily removed with hydrogen fluoride.[8] Sakakibara observed recently that ε-Z(*p*-Cl) group was also removed by the treatment of hydrogen fluoride.[9] We found that ε-Z groups having *p*-cyano and *p*-nitro group were highly resistant against deprotection, whereas ε-Z with *p*-chloro and *m*-chloro were removed completely within 2 to 3 hr. The ε-Z(*m*-Cl) group seemed to be slightly more resistant than ε-Z(*p*-Cl) (Table 4). Syntheses of several oligopeptides containing lysine residue by the solid phase method using α-BOC-ε-Z(*p*- or *m*-Cl)-L-lysine as a starting material are in progress in this laboratory.

Experimental

Modified Benzyloxycarbonyl Chlorides. Z(*p*-Cl)-chloride[10] and Z(*p*-NO_2)-chloride[7] were prepared as described in literature. Other chlorides were prepared as follows.

To a chilled solution of *p*-cyanobenzyl alcohol (2.66 g, 0.02 mol) or *m*-chlorobenzyl alcohol (2.85 g, 0.02 mol) in dry ether (10 m*l*) was added a solution of phosgene (10 g, 0.1 mol) in dry dioxane (10 m*l*) at −10°C. The reaction mixture was left to stand for 2 hr at −10°C and overnight at 0°C, and then evaporated *in vacuo*. The oily product, 3.92 g for Z(*p*-CN)-chloride or 4.01 g for Z(*m*-Cl)-chloride, thus obtained was used without further purification in the following reaction.

ε-*N*-Modified Benzyloxycarbonyl-L-lysines. As an example, preparation of Z(*p*-CN)-Lys is described. Others were prepared by a procedure essentially the same. To a hot solution of L-lysine hydrochloride (0.91 g, 0.005 mol) in water (15 m*l*) was added cupric carbonate (1.25 g) portionwise. The mixture was refluxed for 20 min, and the insoluble material was filtered off. To the filtrate was added sodium bicarbonate (1.2 g) at 0°C. To the solution was added Z(*p*-CN)-chloride (1.6 g, about 0.008 mol) in 3 portions over a period of 30 min under vigorous stirring. Stirring was continued for 5 hr. The alkoxycarbonylated copper complex which deposited was collected, washed successively with water, acetone and ether. After the complex was dissolved in dilute hydrochloric acid, the solution was treated with hydrogen sulfide and cupric sulfide was filtered off. The pH of the filtrate was adjusted to 6 with 6N ammonium hy-

Z(*m*-Cl)-Lys	○ (about 3 hr)	○ (about 1.5 hr)
Z(*p*-CN)-Lys	± (after 12 hr)	○ (about 4 hr)
Z(*p*-NO_2)-Lys	± (after 12 hr)	○ (about 8 hr)

a) ○, Complete deprotection; ±, deprotected about 1%.

droxide. The precipitate was collected after being left for several hours at 0°C, and washed with water and ethanol. It was recrystallized from dilute hydrochloric acid - dilute ammonium hydroxide; yield, 1.35 g (89%). Analytical data on this compound are listed in Table 1, together with those on the other derivatives.

R_f values on TLC of each ε-protected-lysine thus prepared and lysine hydrochloride are shown in Table 2.

Procedure for Treatment of ε-*N*-Protected-lysine with 4N HCl-dioxane. Fifty μmol (about 15 mg) of each of the ε-protected-lysines were dissolved in 4N HCl-dioxane (1 m*l*) at 25°C. At various time intervals, an aliquot (about 1 μ*l*) of the reaction solution was chromatographed on a plate of Silica gel G using two different solvent systems. On the same plate, aliquots (each 1 μ*l*) of lysine hydrochloride solution at various concentrations were applied as controls; thus, the amount of lysine produced from ε-protected lysine after a definite time could be estimated semiquantitatively. The results are summarized in Table 3.

Reaction of ε-*N*-Protected-lysine with Hydrogen Fluoride and 36% Hydrogen Bromide-Acetic Acid. To fifty μmol each of the ε-protected-lysines was added anhydrous HF (about 3 m*l*) at 0°C or 36% HBr - acetic acid (about 4 m*l*) at 25°C. After a certain time, the solution was evaporated *in vacuo* at 0°C (in the case of HF) or at room temperature (36% HBr), and the residue was dissolved in 10% acetic acid (1 m*l*). An aliquot (1 μ*l*) was subjected to TLC as described before, and the amount of free lysine produced by the deprotection or ε-protected-lysine remaining was estimated semiquantitatively. The results are summarized in Table 4, giving optimum reaction time for complete deprotection on each protecting group.

The Pyrolysis and Photolysis of Triphenylphosphine-carbethoxymethylene in Solution[1]

Yoshihiro NAGAO, Kensuke SHIMA and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received November 25, 1969)

Although there have been intensive investigations of the reaction of phosphine-ylids,[2] the pyrolysis of ylid in solution has received little attention, except for an unstable ylid, triphenylphosphine-*n*-butoxymethylene, which was studied by Wittig *et al.*[3]

We have studied the pyrolysis of a typical stable ylid, triphenylphosphine-carbethoxymethylene (I), in cyclohexene, and compared the results with those of the photolysis of I, which was reported previously.[4] In this paper, we wish to report the novel observation that, in pyrolysis, only P=C bond fission occurs, while P-phenyl bond fission occurs preferentially in photolysis.

Results and Discussion

The results of the photolysis and pyrolysis of I in cyclohexene are summarized in Table 1.

As may be seen from Table 1, I exhibited considerable thermal stability.

Ph_3PO (V)	10.4	23.5	61	45

Before comparing the results of the photolysis with those of pyrolysis, it is necessary to check if the pyrolysis of I was induced by the attack of the radicals produced in this system. Therefore, a typical radical initiator, di-*t*-butyl peroxide, was added to the solution in order to verify this probability. The results are shown in Table 2.

In this case the recovered solid was found to be a mixture of unreacted I and triphenylphosphine oxide (V) from a study of its IR spectra ($\nu_{C=O}$ 1615 cm^{-1}, ν_{C-O} 1115 and 1100 cm^{-1}, $\nu_{P=O}$ 1175 cm^{-1}). The ratio of I to V was calculated by means of the intensity ratio of the signals for phenyl protons (τ=2.5) and methyl or methylene protons (τ_{CH_3}=8.92, τ_{CH_2}=6.12). Although V was produced and the yield of ethyl cyclohexaneacetate (III) increased in this reaction, it was obvious that the pyrolysis itself was not accelerated by the addition of the peroxide. V is thought to have been produced by the reaction of the *t*-butoxy radical with triphenylphosphine or with I.

Azobisisobutylonitrile was also used as an addend since it had no oxygen atom which was liable to interact with the phosphorus atom. The temperature of the bath was about 130°C, and a mixed solvent (cyclohexene 2 : benzene 1) was used to dissolve I at room temperature. In this case the decomposition caused by the attack of the radical on I was negligible.

Pyrolysis was carried out in a 100-m*l* autoclave in order to examine the effect of oxygen (Table 2b). The reaction was very fast; the conversion had reached 94% after 8 hr. In this experiment V and III were both obtained in quite good yields. It is reasonable that the yield of V increased in the presence of oxygen, but we cannot explain why the III increased also. Further studies will be necessary to explain the results of the pyrolysis of I in the presence of air.

Now let us compare the results of the pyrolysis

and photolysis of I in cyclohexene. In the case of photolysis, triphenylphosphine was not obtained at all, while diphenylphosphinic acid was obtained on the oxidation of the photolysate with hydrogen peroxide. Benzene was also formed almost quantitatively. The quantum yield of the benzene formation was 0.02. This value was equal to that for the photolysis of triphenylphosphine under the same conditions. Furthermore, the yield of benzene increased linearly with the irradiation time until the conversion reached 20%.[4] From these results, we could reject the possibility that triphenylphosphine was produced by P=C bond fission, followed by photolysis. It is most probable that P-phenyl bond breaks first in photolysis (Eq. (2a)). However, we cannot reject the probability that the electronically-excited triphenylphosphine produced in photolysis decomposes immediately (Eq. (2b)). On the other hand, in the pyrolysis no benzene and phenylcyclohexane were detected at all, while triphenylphosphine was obtained. Consequently, it is obvious that only P=C bond fission occurs, while P-phenyl bond fission does not occur at all, in the pyrolysis (Eq. (1)).

The yield of triphenylphosphine was very low, probably because of its high reactivity to the radicals.

No effect of oxygen was observed in photolysis, whereas in pyrolysis there was a remarkable effect and the decomposition was accelerated enormously.

The rate constants of this pyrolysis were obtained by titrating the unreacted ylid with HCl after the pyrolysis over the temperature range of 160—200°C.[5] The Arrhenius plot of the pyrolysis of I was linear (Fig. 1), and the activation energy of this reaction was calculated to be 28 kcal/mol.

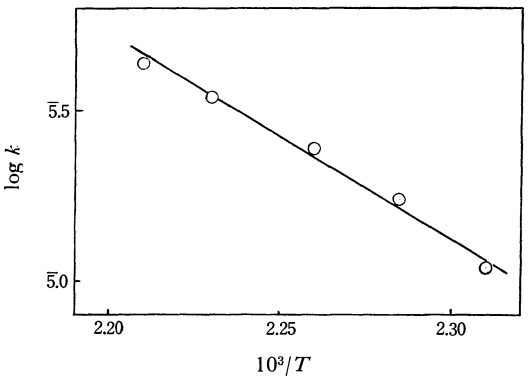

Fig. 1. Arrhenius plot of the pyrolysis.

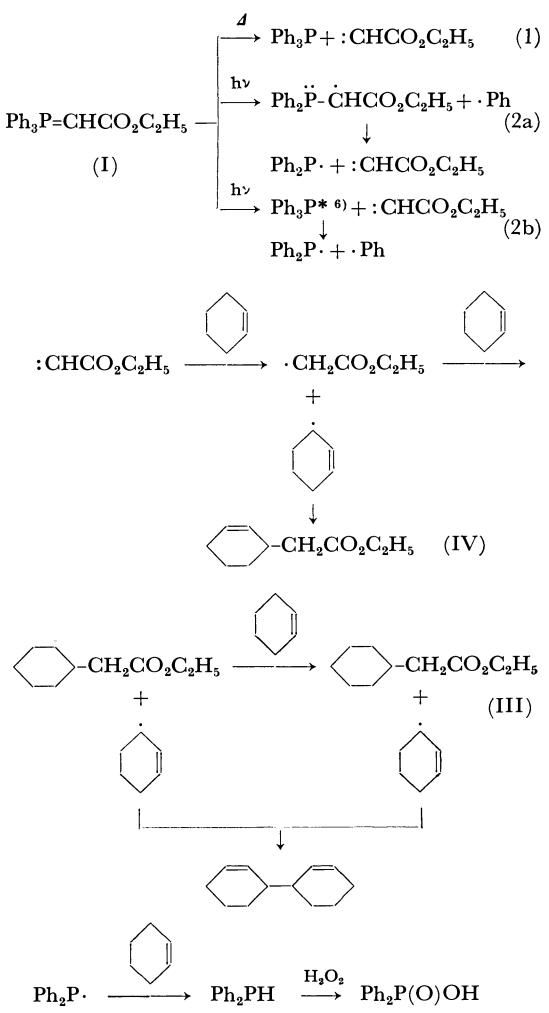
The probable pyrolysis and photolysis mechanisms are as follows:



Experimental

Pyrolysis in the Pyrex Tube. A solution of I (500 mg, 1.44 mmol) in cyclohexene (15 m*l*) was degassed in a 20-m*l* Pyrex tube (10 mm I.D.) by the usual freeze-and-thaw method. This solution was then heated for 40 hr in an oil bath (at about 180°C). After cooling, the low-boiling material was distilled under reduced pressure. Benzene was not detected in this distillate. By the addition of *n*-hexane to the residue, the unreacted I was removed. The recovered I was 331 mg. 3,3′-Bicyclohexenyl (II), ethyl cyclohexaneacetate (III), and ethyl 2-cyclohexeneacetate (IV) were obtained from the *n*-hexane layer. A quantitative determination of these products were made by glc (Dinonyl phthalate), as has been described in a previous paper.[4] The triphenylphosphine was determined by glc (Thermol-3), using ethyl stealate as the internal standard.

The Isolation of $Ph_2P(O)OH$. The phosphorus-containing compound produced in the photolysis of I was isolated in the following manner.

5) The Ph_3P produced in the pyrolysis was assumed to have scarcely any effect upon the titration because of its small quantity.

6) The asterisked Ph_3P has an excess energy; hence, it decomposes as soon as it is produced.

The photolysed material was oxidized with hydrogen peroxide at pH 12—13, and then extracted with ether. A white precipitate was formed on the acidification of aqueous layer with HCl. This was extracted with ether and then recrystallized from EtOH. The IR spectrum of this material was identical with that of an authentic sample; mp 186—189°C (lit,[7] 191°C).

The Determination of the Activation Energy. After the pyrolysis at 160—200°C, the unreacted I was titrated with HCl, and the rate constants of the decomposition of I were calculated.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1888—1889 (1970)

The Oxidation of Thiols to Disulfides with Manganic Tris (acetylacetonate)

Tadao NAKAYA, Hideo ARABORI and Minoru IMOTO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received December 5, 1969)

Various methods are available for oxidizing thiols to disulfides.[1] However, only a few procedures are available for the oxidation of thiols to disulfides, in the absence of oxygen, by means of metal salts, such as lead tetraacetate,[2] ferric octanonate,[3] cupric octanonate,[3] and transition metal oxides.[4] It has recently been reported that manganic tris (acetylacetonate) (MTA) in carbon disulfide or acetonitrile acts as a coupling agent for phenols.[5]

The present note will describe a successful extension of this method to oxidizing thiols, including alkyl, benzyl, and aryl, to the corresponding disulfides. Thus, 1-pentanethiol, α-toluenethiol, benzenethiol, and 2-napthalenethiol, were readily converted into *n*-pentyl disulfide,[6] benzyl disulfide,[2b] phenyl disulfide,[2b] and 2-naphthyl disulfide,[7] respectively. All the reactions were carried out in carbon disulfide under nitrogen at room temperature. The reaction conditions employed and the results obtained are summarized in Table 1. All the yields recorded in Table 1 are based on the amount of disulfide isolated. The advantages of this convenient method are that all the reactions proceed rapidly at room temperature and that all give virtually quantitative yields of the disulfides and no other highly-oxidized products. One mole of MTA was found to oxidize about one mole of thiol. During the reaction, there was formed a precipitate which had a manganous bis (acetylacetonate) as its main component.[5] Accordingly, the following equation for the reaction is appropriate:

TABLE 1. OXIDATION OF THIOLS TO DISULFIDES WITH MTA

Reactant	Thiol/MTA[a]	Time (min)	Product	Mp or bp, °C(mmHg)		Yield[b] (%)
				Found	Reported	
1-Pentanethiol	1.05	90	*n*-Pentyl disulfide	110—113(4)	90—92(1)[6]	85

b) Molar ratio.

$$2RSH + 2Mn(Acac)_3 \longrightarrow RSSR + 2Mn(Acac)_2 + 2AcacH$$

As can be seen from Table 1, about one mole of MTA was consumed per mole of benzenethiol, when a one-molar excess of MTA was present. These results suggest that MTA in carbon disulfide acts as a specific oxidant for the oxidation of thiols.

For the oxidation of thiols to disulfides by ferric octanonate, Wallace[3)] proposed the following mechanism (the radical nature of the reactions was established by trapping the thiyl radical with 1-dodecene):

$$RSH + Fe(Oct)_3 \longrightarrow RS\cdot + Fe(Oct)_2 + OctH$$
$$RS\cdot \longrightarrow \tfrac{1}{2}RSSR$$

In order to obtain information regarding the nature of the oxidation of thiols to disulfides by MTA, the addition reactions of 1-dodecanethiol to 1-dodecene catalyzed by MTA were attempted in xylene according to the procedure of Wallace.[3)] The results are shown in Table 2. In contrast to the results obtained by Wallace, however, no dodecyl sulfide was detected; dodecyl disulfide was the only product. The fact that no dodecyl sulfide was formed may be explained by the following reaction scheme, involving thioxynium ion as an intermediate:[8)]

$$RSH + Mn(Acac)_3 \longrightarrow RS\cdot + Mn(Acac)_2 + AcacH$$
$$RS\cdot + Mn(Acac)_3 \xrightarrow{\text{fast}} RS^+ + Mn(Acac)_2 + Acac^-$$
$$RS^+ + RSH \longrightarrow RSSR + H^+$$

In the above reaction scheme it is assumed that MTA rapidly oxidizes the thiyl radical to the corresponding thioxynium ion because the oxidizing agent[5)] is more powerful than ferric octanonate.

Experimental

Materials. The 1-pentanethiol, α-toluenethiol, benzenethiol, 2-naphthalenethiol, 1-dodecanethiol, 1-dodecene, and cetane were commercial materials and were purified by crystallization or distillation. The MTA was prepared according to the method of Charles.[9)]

General Procedure for the Oxidation of Thiols to Disulfides. The following is the general procedure by which the disulfides listed in Table 1 were prepared. Into a solution of 15.8 mmol of the required thiol in 20 m*l* of carbon disulfide, we stirred, drop by drop and under nitrogen, a solution of 15 mmol of MTA in 250 m*l* of carbon disulfide. After a while, a pale yellow crystalline solid began to separate from the solution. After the reaction mixture had been vigorously stirred at room temperature for 1 hr, the solvent was evaporated to dryness under reduced pressure. The residue was extracted twice with 100 m*l* of petroleum ether (bp 30—60°C). The insoluble material was then filtered off and washed with 30 m*l* of petroleum ether. The combined filtrate was cautiously evaporated under reduced pressure to give the crude disulfide. With the exception of *n*-pentyl disulfide, which was distilled under reduced pressure, the products were recrystallized from petroleum ether.

The elemental analyses of the products were satisfactory, and the IR and NMR spectra were consistent with the proposed structures.

The Attempted Addition Reactions of 1-Dodecanethiol to 1-Dodecene Catalyzed by MTA. The procedures were identical with those reported by Wallace.[3)] For the analyses of the reactions, a Yanagimoto Model GCG-550-FP-type gas chromatograph was used.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1890—1892 (1970)

Synthesis of 2-Substituted Ethyl Hydrodisulfides

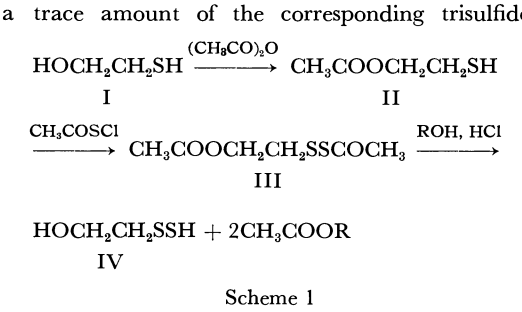
Jitsuo TSURUGI, Yasuo ABE and Shunichi KAWAMURA

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka

(Received December 8, 1969)

Alkyl hydrodisulfides synthesized so far are methyl,[1] ethyl,[1] benzyl,[1,2] benzhydryl[2] and trityl[3] hydrodisulfides, the latter three of which have been reported sufficiently stable for a few weeks. Compounds containing hydrodisulfide group (-SSH) have been postulated by biochemists as intermediates of various enzymatic reactions.[4-6] However, alanyl hydrodisulfide $HOCOCH(NH_2)CH_2SSH$, which has been called thiocysteine and proposed as an intermediate of enzymatic cleavage of cystine by Cavallini,[4] has never been isolated. Only circumstantial evidence is available to support the intermediate formation of thiocysteine[4-6] and similar polysulfidic species containing labile sulfur.[7,8] This note describes the synthesis or attempted synthesis of mono-2-substituted ethyl hydrodisulfides.

2-Hydroxyethyl hydrodisulfide (IV) was prepared as indicated in Scheme 1 by the Böhme method.[1] In Scheme 1, prior conversion of 2-mercaptoethanol (I) to 2-acetoxyethanethiol (II) was necessary, because direct reaction of I with acetyl sulfenyl chloride yielded an oily mixture, suggesting that hydroxyl group of I was also attacked by acetyl sulfenyl chloride. Compound II was then allowed to react with acetyl sulfenyl chloride to yield 2-acetoxyethyl acetyl disulfide (III). Alcoholysis of III with anhydrous methanolic or ethanolic hydrogen chloride produced IV almost quantitatively as viscous oil along with methyl or ethyl acetate. Alcoholysis of both R'SS-$COCH_3$ and CH_3CO-OR'' bonds of III apparently took place simultaneously. Compound IV seems unstable even at room temperature. Slight and continuous evolution of hydrogen sulfide was observed during alcoholysis, isolation and storing.



Scheme 1

Although analysis was carried out immediately after isolation, analytical values did not completely agree with calculated ones. However, NMR spectra showed the corresponding protons (-SSH, -OH and ethylenic ones) and no other signals. These results suggest that IV was contaminated with a trace amount of the corresponding trisulfide.

Contrary to our expectation that the introduction of hydroxyl group would make the hydrodisulfide water-soluble, IV was found to be insoluble in water and to decompose slowly on contact with water as evidenced by the evolution of hydrogen sulfide. More stable aralkyl hydrodisulfides also were reported to decompose on contact with water.[9]

Preparation of 2-carboxyethyl hydrodisulfide (VIII) was attempted next, as indicated in Scheme 2. Unlike Scheme 1, sulfenyl chloride reacted with 2-mercaptopropionic acid (V) exclusively on the sulfur side. Esterification took place during the alcoholysis of 2-carboxyethyl acetyl disulfide (VI). Thus 2-carboalkoxyethyl hydrodisulfides (VIIa, VIIb) were separated as oily substances in good yields. Neither hydrolysis of VII to the corresponding acid (VIII) with hydrochloric acid

nor transesterification of VII to VIII with formic acid was successful, because the susceptibility of hydrodisulfide group to hydrolysis led to unidentified products. Instability, slight disagreement of analytical data, and NMR spectral evidence, all of which are similar to those of IV, indicate that VIIa may be also contaminated with a trace amount of the corresponding trisulfide. Compound VIIb, on the contrary, shows good coincidence of analytical data. The behavior of VII toward water was similar to that of IV.

Spectroscopic data of hydrodisulfides IV and VII are shown in Table 1 along with those of the starting thiols I and V. Proton of hydrodisulfide group of IV and VII is exchangeable with that of water, because their peaks in NMR were diminished without change in the remaining parts of the spectra by shaking with deuterated water. Although the hydrodisulfides are unstable in the presence of water as mentioned above, the decomposition of IV and VII did not disturb the NMR spectral determination. The singlet peak of each hydrodisulfide group is found in a much lower field than the triplet center of the corresponding thiol, presumably because of the anisotropic effect of additional sulfur atom. IR spectra also show that SH stretching frequency of each hydrodisulfide group is slightly lower than that of the corresponding thiol. This fact suggests that the lowering of force constant between S and H is caused by the effect of neighboring S–S bond.

Table 1. Spectroscopic data

Compound	NMR (δ, ppm)	IR (cm^{-1})
$HOCH_2CH_2$**SH**(IV)	3.09 (s)	2,500 (m)
$HOCH_2CH_2$**SH**(I)	1.45 (t)	2,560 (w)
$CH_3OCOCH_2CH_2$**SSH**(VIIa)	3.00 (s)	2,510 (m)
$C_2H_5OCOCH_2CH_2$**SSH**(VIIb)	3.06 (s)	2,510 (m)
$HOCOCH_2CH_2$**SH**(V)	1.59 (*t*)	2,600 (w)

Synthesis of 2-aminoethyl acetyl disulfide and 2-acetamidoethyl acetyl disulfide (IX) by the Böhme method was not successful. Synthesis of IX was realized, however, by the Field[10] method as shown below. By ethanolysis of IX an oily substance and ethyl acetate were obtained. The oily substance continued to evolve hydrogen sulfide during and after the evaporation of the solvent, and after one night decomposed to unidentified yellow solids, which were insoluble in most organic solvents. Although direct evidence for the formation of 2-acetamidoethyl hydrodisulfide could not be obtained, indications are the formation of ethyl acetate on ethanolysis, and a positive result in the lead acetate test characteristic for hydrodisulfides.[11] We previously reported that amines can decompose aralkyl hydrodisulfide (benzyl, benzhydryl and trityl hydrodisulfides) at room temperature.[12] The instability of this oily substance may be ascribed to the introduction of an amino group into hydrodisulfide molecule. Judging from the instability of this compound and the failure of synthesis of 2-aminoethyl hydrodisulfide, it may be concluded that the isolation of alanyl hydrodisulfide, which is considered to be an intermediate of cystine decomposition, would be difficult, even if it is formed during the enzymatic reaction.

$$CH_3CONHCH_2CH_2SSO_2CH_2CH_2NHCOCH_3 + CH_3COSH \longrightarrow \underset{\text{IX}}{CH_3CONHCH_2CH_2SSCOCH_3} + CH_3CONHCH_2CH_2SO_2H$$

Experimental

Commercial 2-mercaptoethanol and 2-mercaptopropionic acid was distilled under reduced pressure before use. Other reagents and solvents were commercial products. NMR spectra were taken on a JNM 3H-60 spectrometer with tetramethylsilane as an internal standard and IR spectra were obtained on a JASCO IR-S spectrometer.

2-Acetoxyethyl Acetyl Disulfide (III). 2-Acetoxyethanethiol (II) was prepared from 2-mercaptoethanol by the method of Miles and Owen,[13] bp 57°C/16 mmHg (lit, 62—64°C/16 mmHg). To a solution of II (15.0 g, 0.125 mol) in anhydrous ether, freshly distilled acetyl sulfenyl chloride[14] (15.2 g, 0.137 mol) in absolute ether was added with stirring at 0—5°C under a nitrogen atmosphere. Gaseous hydrogen chloride was evolved gradually. After being kept standing overnight the reaction mixture was separated off, and volatiles were removed *in vacuo*. Highly viscous oil of III was obtained in near 100% yield and proved to be pure enough for the following synthesis. Distillation did not change the properties of the product. The IR spectrum (neat) showed a strong C=O band at 1740 cm^{-1}. The NMR spectrum (10% in CCl_4) was consistent with the structure of III having two kinds of acetyl group, $OCOCH_3$, δ 2.03 and $SCOCH_3$, δ 2.43. Both IR and NMR spectra indicated no peak corresponding to sulfhydryl group.

Found: C, 36.96; H, 5.50; S, 33.35%. Calcd for $C_6H_{10}O_3S_2$: C, 37.09; H, 5.19; S, 33.01%.

2-Hydroxyethyl Hydrodisulfide (IV). To a solution of III (1 g, 5.15 mmol) in absolute methanol was added a few m*l* (0.7—2) of 5N methanolic hydrogen chloride, and the solution was kept standing for *ca.* 3 hr at room temperature. Complete removal of volatiles

(hydrogen chloride, methanol and methyl acetate) by a rotary evaporator in a vacuum gave viscous oil of IV quantitatively. The IR spectrum (neat) exhibited a medium band at 2500 cm^{-1} characteristic for sulfhydryl groups of hydrodisulfides (*cf.* Table 1). NMR spectrum (10% in $CDCl_3$) showed a characteristic signal for singlet proton of –SSH at δ 3.09 which was exchangeable with deuteron in D_2O, as well as hydroxylic δ 3.4—4.2 (*cf.* OH of I, δ 4.12—4.60) and ethylenic protons. Qualitative test by lead acetate gave a black precipitate which resulted from the hydrodisulfide group.[11]

Found: C, 22.43; H, 5.56; S, 56.62%. Calcd for $C_2H_6OS_2$: C, 21.80; H, 5.49; S, 58.19%.

2-Carboxyethyl Acetyl Disulfide (VI). In the same way as for the preparation of III, VI was obtained quantitatively as white crystals from freshly distilled 2-mercaptopropionic acid (11.3 g, 0.106 mol) and acetyl sulfenyl chloride (26.9 g, 0.267 mol). The crystals were recrystallized from carbon tetrachloride, mp 69—70°C. The IR spectrum (KBr) showed a broad band at 1690 cm^{-1} ($SCOCH_3$). The NMR spectrum (10% in $CDCl_3$) indicated signals at δ 2.49 ($SCOCH_3$), and δ 11.70 (COOH).

Found: C, 33.20; H, 4.71; S, 35.72%. Calcd for $C_5H_8O_3S_2$: C, 33.32; H, 4.47; S, 35.58%.

2-Carboalkoxyethyl Hydrodisulfide (VII). VI (1 g, 5.55 mmol) was suspended in anhydrous methanol or ethanol (4 m*l*) with magnetic stirring. To this was added 5N methanolic or ethanolic hydrogen chloride (3 m*l*). Disulfide VI was gradually dissolved in alcohol as alcoholysis proceeded. After 3 hr, volatiles were removed by using a rotary evaporator (*in vacuo*) at room temperature. 2-Carbomethoxyethyl (VIIa) or 2-carboethoxyethyl hydrodisulfide (VIIb) was obtained as an oily substance. IR spectra (neat) of both VIIa and VIIb showed bands at 2510 cm^{-1} corresponding to hydrodisulfide group (*cf.* Table 1). NMR signals (10% in $CDCl_3$) of SSH proton were at δ 3.00 (VIIa) and δ 3.06 (VIIb) (*cf.* Table 1), and other reasonable signals were found. Addition of lead acetate solution to VII gave a black precipitate.[11]

Found: C, 31.75; H, 5.30; S, 39.49%. Calcd for $C_4H_8O_2S_2$ (VIIa): C, 31.56; H, 5.30; S, 42.13%.

Found: C, 36.26; H, 6.02; S, 38.35%. Calcd for $C_5H_{10}O_2S_2$ (VIIb): C, 36.12; H, 6.06; S, 38.57%.

Reaction of 2-Acetamidoethyl Acetyl Disulfide in Alcoholic Hydrogen Chloride. 2-Acetamidoethyl acetyl disulfide[10] was allowed to react with alcoholic hydrogen chloride under the conditions similar to those in the case of VII. After volatiles were completely evaporated, an oil remained. After a few minutes, the oily substance decomposed with evolution of hydrogen sulfide and solidified. The solid was washed with acetone and dried *in vacuo*, mp 143—146°C (unidentified). IR spectrum (KBr) showed that $SCOCH_3$ group (1734 cm^{-1}) was removed by the above treatment. In NMR (DMSO-d_6), neither the signal corresponding to $SCOCH_3$ nor SSH was found. The oily material, immediately after its formation, produced black precipitates by treatment with lead acetate solution.[11]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1892—1894 (1970)

Hydration of Potassium Hyaluronate

Yasuko SUZUKI and Hisashi UEDAIRA

Research Institute for Polymers and Textiles, 4 Sawatari, Kanagawa-ku, Yokohama

(Received December 17, 1969)

Hyaluronic acid is one of the mucopolysaccarides, whose structure consists of a repeating disaccaride unit, D-glucronic acid and 2-acetamide-2-deoxy-D-glucose. It occurs in various animal tissues and fluids such as (bovine) vitreous humour, (human) umbilical cord and synovial fluid. One important function is to bind water in interstitial spaces of tissue and have a definite resistance to compression.[1,2] Jacobson and Laurent[3] and Laurent[4] carried out studies of streaming dielectric property and X-ray diffraction on aqueous hyaluronic acid solution, but no positive information on the interaction between hyaluronic acid and water molecules was obtained.

We present here the ultrasonic velocity data and partial specific volume for the aqueous potassium hyaluronate solutions. The adiabatic compressibility of the solution is calculated and the hydration number of hyaluronate ion is estimated.

Experimental

Potassium hyaluronate used was obtained from bovine vitreous humour (Tokyo Kasei G. R.). It was stirred in water under a stream of nitrogen at 60°C for 2 hr, filtered by Milipore filter (pore size $1.2\pm0.3\ \mu$), lyophilized and then dissolved in deionized water.

Ultrasonic velocity of solution was measured by an ultrasonic interferometer, at 5 MHz in frequency. Density was determined by picnometer (10 cc) at (25±

0.01) and (30±0.01)°C. Adiabatic compressibility was calculated from the data of ultrasonic velocity and density of the solutions. Concentrations of the solutions were determined by gravimetric method and by measurement of the refractive increment using a Zeiss interferometer. The molecular weight of potassium hyaluronate was determined by a Shimazu light scattering instrument at 23°C, where the same sample solution as above was subjected to ultracentrifuging at 2.4×10^4 g and 10°C for one hour and filtered with a Corning ultrafine glass filter for optical clearance.

Results and Discussion

The weight average molecular weight of potassium hyaluronate, M_w, is obtained as 2.71×10^5 from the Zimm plot of light scattering data. The partial specific volume of potassium hyaluronate at infinite dilution, $\bar{v}_{20}$, was obtained from solution density. The values of $\bar{v}_{20}$ at 25 and 30°C are given in the table.

Table 1. The amount of hydration of potassium hyaluronate

t (°C)	M$\times10^{-5}$	$\bar{v}_{20}$ (cc)	$\bar{\kappa}_{20}\times10^{12}$ (cm²/dyn)	n_{h_1} (mol/base mol)	n_{h_2} (mol/base mol)
25	2.71	0.51	−35.0	9.22 (6.7)*	18.4 (15.9)*
30		0.55	−66.5	19.4 (16.2)*	30.8 (27.6)*

* hydration number of hyaluronate ion.

The relation between adiabatic compressibility κ, ultrasonic velocity c and density of solution ρ is given by

$$\kappa = 1/\rho c^2 \tag{1}$$

The amount of hydration is obtained from the equations

$$\omega = (n_h v_1) = \frac{\bar{\kappa}_{20} - \kappa_2}{\kappa_h - \kappa_1}\bar{v}_{20} \tag{2}$$

$$\bar{\kappa}_{20} = -\frac{1}{\bar{v}_{20}}\left(\frac{\partial \bar{v}_2}{\partial \rho}\right)_0 = -\frac{1}{\bar{v}_{20}}\left(-\bar{v}_{20} - \frac{1}{\kappa_1}\frac{\mathrm{d}\kappa}{\mathrm{d}x}\right) \tag{3}$$

where ω and n_h are the volume and number of water molecule bounded to one gram of solute, respectively.[5] v_1 and v_2 are the specific volumes of solvent and solute, respectively, and $\bar{v}_{20}$ the partial specific volume of solute at infinite dilution. κ_1, κ_2 and κ_h are the adiabatic compressibilities of solvent, solute and hydrated water respectively and $\bar{\kappa}_{20}$ the partial specific compressibility of solute at infinite dilution. The relations between the compressibilities and the concentrations of solutions at 25 and 30°C are given in Fig. 1.

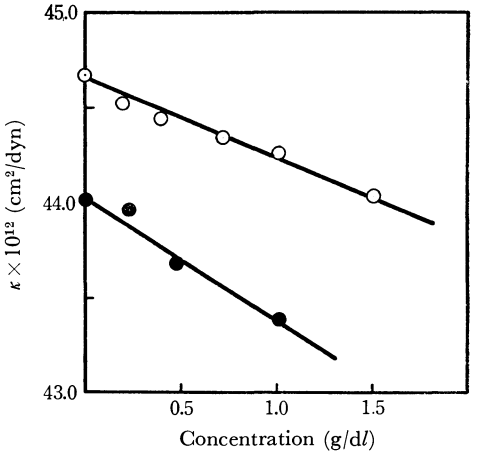

Fig. 1. The relations between adiabatic compressibilities of potassium hyaluraonate and its concentrations at 25 (open circle) and 30°C (closed circle).

In the calculation of the hydration number from Eq. (3), the following two limiting values of hydration number are obtained.

(1) When it is assumed that the solute and the water molecules very near the solute have zero compressibility (*viz.* $\kappa_h=0$ and $\kappa_2=0$), the lower limiting value of hydration number (n_{h_1}) is obtained. The values of n_{h_1} at 25 and 30°C are given in the forth column of the table.

(2) When it is assumed that the solute and bound water molecules participate in compression, the upper limiting value of hydration number (n_{h_2}) is obtained. The value of compressibility of potassium hyaluronate is not available, and so we assume its value to be the same as that of dextrin, 12×10^{-12} cm²/dyn.[6] Following Shiio, Ogawa and Yoshihashi,[6] we assume that the compressibility of hydrated water is the same as that of ice I, 1.2×10^{-11} cm²/dyn.[7] The values of n_{h_2} at 25 and 30°C are given in the fifth column of the table.

The hydration numbers of potassium ion determined from ultrasonic velocity are 2.5 and 3.2 mol/mol ion at 25 and 30°C, respectively.[8,9] It follows that the values of n_{h_1} of hyaluronate ion at 25 and 30°C are 6.7 and 16.2 mol/base mol (or 0.32 and 0.77 cc/g), respectively, and the values of n_{h_2} at 25 and 30°C are 15.9 and 27.6 mol/base mol (or 0.70 and 1.21 cc/g), respectively.

The values of n_{h_2} for glucose, sucrose, maltose and raffinose at 25°C are 0.35, 0.20, 0.22 and 0.22 cc/

g,[10] respectively. Thus, the hyaluronate ion is hydrated more strongly than sugars.

The amount of hydration of hyaluronate ion increases with increasing temperature, as in the case of polyvinyl alcohol.[11] One of the authors (H.U.) together with Uedaira[12] showed that sugars oriented the water molecules around them, and that the degree of hydration of sugars was increased by the addition of structure breaking solute. According to Samoilov's theory on salting-out,[13] the break of water structure increases the degree of hydration of the structure making solute. With increasing temperature, the water structure is destroyed by heat motion of molecule. Thus, the water molecules around hyaluronate ion are oriented more easily, and the amount of hydration increases. It is suggested that the hyaluronate ion strongly affects the hydration of ions in organism (for example, Ca^{2+}, Na^{+}, K^{+} ions).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1894—1896 (1970)

Radiation-induced Reaction of Isobutene in the Gas Phase. Effects of Pressure, Temperature and Additives on Polymerization

Yasuyuki NORO, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received December 20, 1969)

In previous papers,[1,2] we have shown that cationic mechanism dominates in the radiation-induced polymerization of isobutene in the gas phase. The propagating rate constant and the mean lifetime of the propagating ion have also been estimated by a quantitative study of the effect of ammonia on the polymerization.[2]

We have investigated the effects of pressure, temperature and some additives to get a deeper understanding of its reaction mechanism.

Experimental

The purification of isobutene was described previously.[1] Research grade oxygen (99.9%) and nitrogen dioxide (99.0%) were dried prior to use. Sulfur hexafluoride was purified by distillation under vaccum. Methyl bromide was purified by passing through a silica gel column and by distillation under vacuum.

γ-Irradiation of samples and the analysis of products were described previously[1]. The temperature of samples was controlled using a thermostat.

1) H. Okamoto, K. Fueki and Z. Kuri, *J. Phys. Chem.*, **71**, 3222 (1967)

2) Y Noro, K. Fueki and Z. Kuri, This Bulletin, **41**, 1737 (1968).

Results and Discussion

Effect of Pressure. Figure 1 shows the effect of pressure on the polymerization rate of isobutene. We see that the polymerization rate is proportional to the square of pressure below ~800 Torr, and tends to become proportional to the pressure above ~800 Torr.

These results may be qualitatively explained in terms of the competition between fragmentation and deactivation of the excited isobutene ion, provided that a significant fraction of fragment ions do not initiate polymerization. A conventional kinetic treatment leads to the following expression for the polymerization rate:

$$R = \frac{k_p}{k_t}\left[\Phi + \Phi' \frac{k_1(\mathrm{M})}{k_2 + k_1(\mathrm{M})}\right](\mathrm{M})I_{\mathrm{abs}}, \qquad (1)$$

where Φ and Φ' are the quantities proportional to the initial yields of the ground and excited isobutene ions, k_1 and k_2 are the rate constants for deactivation and fragmentation of the excited ion, k_p and k_t are the rate constants for the propagation and termination reactions, I_{abs} is the dose rate absorbed by isobutene, and (M) is the concentration of isobutene.

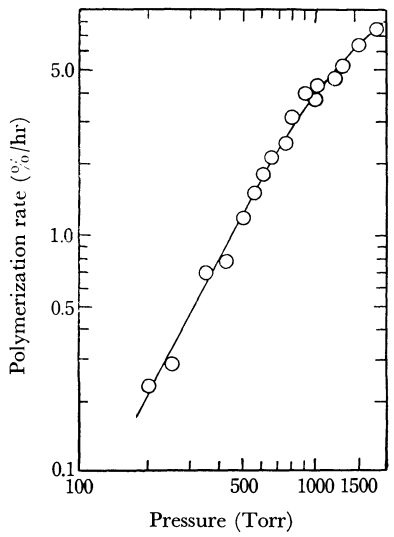

Fig. 1. Dependence of the polymerization rate on the initial pressure of isobutene.
Dose rate, 0.15 Mrad/hr; dose, 0.1—3 Mard; temperature, 20°C

If we assume that $\Phi \ll \Phi' k_1(M)/(k_2+k_1(M))$,*1 Eq. (1) is reduced to

$$R \simeq \frac{k_p}{k_t} \Phi' \frac{k_1(M)^2}{k_2 + k_1(M)} I_{abs}. \quad (2)$$

Equation (2) implies that R is proportional to $(M)^2$ at low pressures when $k_2 \gg k_1(M)$ and it is proportional to (M) at high pressures when $k_2 \ll k_1(M)$.

The molecular weight of the polymer produced, when irradiated to 0.3 Mrad at an initial pressure of isobutene of 1000 Torr, was determined to be 11000, and 5700 when irradiated to 1.2 Mrad at 500 Torr.

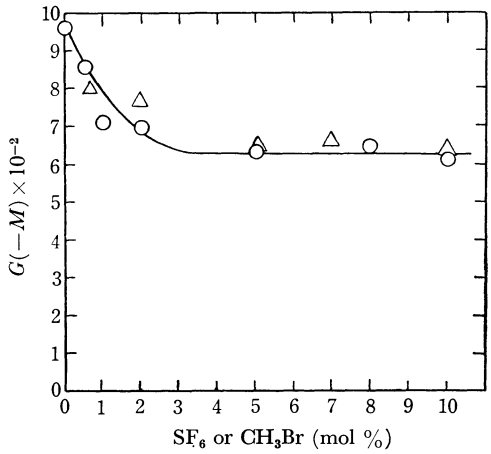

Fig. 2. Effect of sulfur hexafluoride and methyl bromide on the polymerization yield.
SF_6, ○; CH_3Br, △. Initial pressure of isobutene, 500 Torr; dose rate, 0.15 Mrad/hr; dose, 1—2 Mard; temperature, 20°C.

Effect of Temperature. The polymerization rate of isobutene irradiated to 0.3 Mrad at 0°C and at 500 Torr was 1.8 times greater than that at 20°C and at the same pressure and dose. The polymerization did not occur to an appreciable extent when irradiated to 0.3 Mrad at 50°C. At higher temperatures than 50°C, the polymerization was not observed at a dose of 1 Mrad, although a small amount of nonviscous liquid products were obtained when irradiated to 100 Mrad at 100°C. These results indicate the existence of a ceiling temperature between 50°C and 100°C.

Effect of Additives. *a) Sulfur Hexafluoride and Methyl Bromide.* Figure 2 shows the effect of SF_6 or CH_3Br on the G-value for isobutene consumption at an initial pressure of isobutene of 500 Torr at 20°C. The G-value decreases with increasing concentration of SF_6 or CH_3Br, approaching a plateau value which is about 65% of the G-value obtained for pure isobutene, at ~3 mol% of these additives.

Both SF_6 and CH_3Br are known as electron scavengers, *viz.*, they capture electrons to form negative ions:

$$SF_6 + e^- \longrightarrow SF_6^-,$$
$$CH_3Br + e^- \longrightarrow CH_3 + Br^-.$$

The retarding effect of these additives on the polymerization may be interpreted in terms of the acceleration of charge neutralization forming the negative ions. In the absence of these scavengers, the propagating ions would disappear by diffusion to the wall of the reaction vessel[2] and possibly by reacting with a trace of impurities.

If the polymerization terminates by the neutralization between the propagating cation and the negative ion in the presence of SF_6 or CH_3Br, it can be expected that the termination will be of the

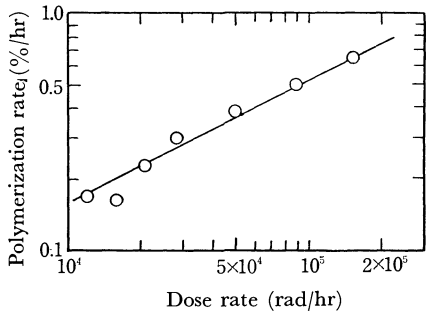

Fig. 3. Dependence of the polymerization rate on the dose rate.
Initial pressure of isobutene, 500 Torr; pressure of SF_6, 50 Torr; dose, 0.1—1 Mrad; temperature, 20°C.

*1 Abundance of the parent ion of isobutene is relatively small in its mass spectrum (E. Collinson, F. S. Dainton and H. A. Gillis, *J. Phys. Chem.*, **63**, 909 (1959)).

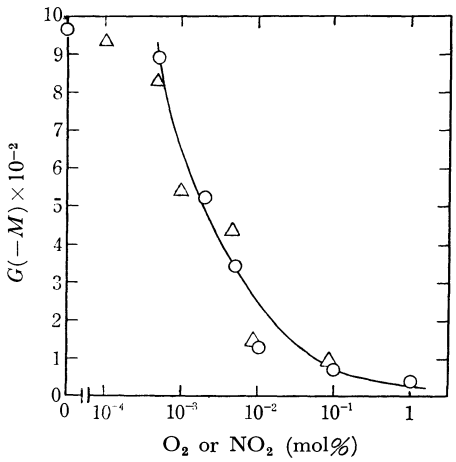

Fig. 4. Effect of oxygen and nitrogen dioxide on the polymerization yield.
O_2, ○; NO_2, △. Initial pressure of isobutene, 500 Torr; dose rate, 0.15 Mard/hr; dose, 1—5 Mrad; temperature, 20°C.

second-order with respect to the concentration of the ions. As shown in Fig. 3, it is found that the polymerization rate is proportional to the square root of dose rate, indicating a second-order termination reaction. This is in contrast with a first-order dependence of the polymerization rate on the dose rate for the case of pure isobutene in the gas phase.[1)]

b) Oxygen and Nitrogen Dioxide. Figure 4 shows the effect of O_2 or NO_2 on the G-value for isobutene consumption at an initial pressure of isobutene of 500 Torr at 20°C. Polymerization is retarded remarkably by the presence of O_2 or NO_2, and almost completely at a concentration of ~1 mol% of these additives. Such an effect of O_2 or NO_2 on the polymerization is quite different from that of SF_6 or CH_3Br, and it cannot be explained simply by electron capture by O_2 or NO_2. A similar result was obtained for N_2O.[1)] This might explain the retarding effect of oxygen-containing compounds such as O_2, NO_2 and N_2O on the polymerization of isobutene in the gas phase where these compounds*[2] capture electrons to form O^- (at least, as a fraction of negative ions), which will subsequently react with isobutene to produce water,[3)] a cation scavenger.

Conclusion

(1) The pressure effect on the polymerization of isobutene in the gas phase has been investigated over a wider range of pressure than in the previous studies. It has been interpreted in terms of the competition between fragmentation and deactivation of the excited isobutene ion.

(2) It has been found that there exists a ceiling temperature between 50°C and 100°C.

(3) The present study of the effect of electron scavengers such as SF_6 and CH_3Br has further confirmed the role of ionic processes in this polymerization. Termination of polymerization by ion neutralization has been verified by investigating the dose-rate dependence of the polymerization in the presence of electron scavengers.

(4) It has been found that the oxygen-containing compounds such as O_2, NO_2 and N_2O retard remarkably the polymerization, perhaps by producing water.

*[2] Since the ionization potentials of O_2, NO_2 and N_2O are higher than that of isobutene, the positive charge transfer from isobutene to these compounds is unlikely to occur.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1897—1899 (1970)

Hydrogenolysis of a Quinonoid Oxygen of Alkoxynaphthoquinones

Teruo HAYASHI and Hiroshi KAKISAWA

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received December 30, 1969)

During the course of our experiments on the structural determination of hydroxytanshinone[1] (I), catalytic hydrogenation of I was carried out in an acidic condition to afford two substances. One was a known orange pigment cryptotanshinone[2] (II), which was formed by hydrogenolytic removal of benzylic hydroxy group followed by autoxidation of the corresponding hydroquinone. The other was a colorless compound which was also slowly autoxidized to cryptotanshinone (II), but the structure remained undecided.

In order to determine the structure of this unusual reaction product, the hydrogenation product was isolated as a stable acetate. After prolonged hydrogenation of hydroxytanshinone (I) in the presence of palladium charcoal and acid, the reaction product was immediately acetylated to afford a monoacetate (IV). Acetate (IV) was also obtained from tanshinone-II[3] (VI) under the same conditions of reaction and time. Although quinones are usually reduced to the corresponding hydroquinones by catalytic hydrogenations and smoothly re-oxidized in the air into the original quinones, physical and chemical properties of acetate (IV) showed that, besides benzylic hydroxy group of hydroxytanshinone (I), one of the quinonoid oxygen atoms was also removed during the course of hydrogenation reaction. The position of the removed oxygen atom was first deduced from the NMR spectrum. The NMR spectrum of monoacetate (IV) is quite similar to that of cryptotanshinone (II), and shows the presence of *gem*-dimethyl group (δ 1.32, s), a methyl group (δ 1.30, d, J=6 Hz) attached to a methine group (δ 3.75, m), a methylene (δ 4.25, 4.82, dq, J=10, 9 and 6 Hz) bonded to an oxygen atom and two aromatic protons (C_9-H and C_{10}-H; δ 7.35, d, J=9 Hz and δ 7.70, brd, J=9 Hz, respectively). However, there are differences between the two spectra; whereas aromatic protons (C_9-H and C_{10}-H) of cryptotanshinone appear at δ 7.50 and δ 7.68 as sharp AB-quartet, one component (δ 7.70) of the corresponding AB-quartet of acetate (IV) is broadened by a long-range coupling[4] with epi-proton C_4-H (δ 7.12, br s). This type of long-range coupling was also found in the spectrum of a synthetic compound[5] (VII), in which the signal of C_{10}-H (δ 7.95, brd, J=9 Hz) is broadened by a long-range coupling with C_4-H (δ 6.80, brd, J=2 Hz). Benzylic protons of acetate (IV) appear at a higher field (δ 2.98, br t) than that (δ 3.24, br t) of diacetyldihydrotanshinone-II[3] (VIII), in which benzylic

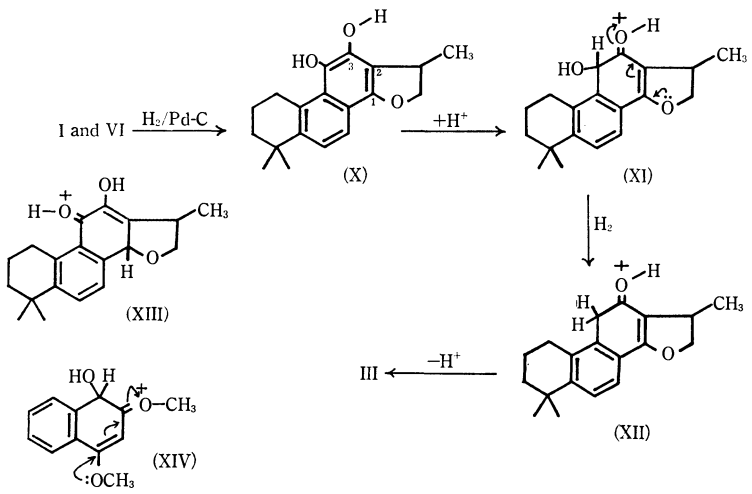

Fig. 2

protons (C_5-2H) are shifted to a low field by the deshielding effect of C_4-acetoxyl group. From these NMR properties, the position of the removed oxygen atom was assigned to C_4, and the structure of the monoacetate was deduced to be IV. For confirmation of the structure, reduction product (III) was converted into a known compound (IX). Hydrogenation product (III) was first methylated by dimethyl sulfate to afford a monomethyl ether (V). Ether (V) was dehydrogenated by refluxing with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone[6] to afford a furanonaphthyl ether (IX), which was identical with the synthetic compound (IX) prepared in the total synthesis of tanshinones.[5] Thus the structure of the air sensitive compound obtained by catalytic hydrogenation in acidic condition could be assigned to III.

Catalytic hydrogenation of tanshinone-II proceeded very rapidly to afford a colorless solution of the corresponding hydroquinone within a few minutes, when the reaction was allowed to stop just to obtain a mixture of tanshinone-II (VI) and cryptotanshinone (II). On the other hand, when the hydrogenation mixture was stirred in hydrogen atomosphere for a longer time (fifteen hours or more), the sole reaction product was monohydroxy compound (III). These observations show that a hydroquinone (X) produced from tanshinone-II is an intermediate of the hydrogenolysis reaction. Protonation to a carbon atom of hydroquinone (X) forms benzyl alcohol (XI), which would readily lose a hydroxy group in hydrogenolytic condition to give (XII). Protonated ketone (XII) loses a proton to afford the monohydroxy compound (III).

The *meta*-oriented two oxygen functions (C_1–O and C_3–O) in the hydroquinone (X) have a particularly important effect on the formation of carbon-protonated species (XI), because unsubstituted 1,2-naphthoquinone showed no hydrogenolytic removal of quinonoid oxygen atom even under much severer conditions, and the product expected from another protonated intermediate (XIII) was not detected from the reaction mixture. The same effect of two oxygen atoms situated in *meta* orientation was recently found[7] in alkoxy exchange reaction of naphthyl alkyl ethers. Thus, while 1-hydroxy-2,4-dimethoxynaphthalene exchanges methoxy groups to give 1-hydroxy-2,4-diethoxynaphthalene in acidic ethanol through carbon-protonated species (XIV), 1,4-dimethoxy-naphthalene does not exchange in the same condition.

Experimental[8]

Hydrogenolysis of Tanshinone-II (VI). To a solution of 240 mg of tanshinone-II in ethanol (60 m*l*) were added 250 mg of palladium charcoal (5%) and 0.1 m*l* of concentrated hydrochloric acid. The mixture was stirred overnight at room temperature in hydrogen atmosphere. The solution was filtered and the filtrate was neutralized with saturated sodium bicarbonate solution and extracted with ether. Evaporation of the solvent afforded a white viscous oil which slowly changed into orange compound, cryptotanshinone, in the air.

Monoacetate(IV). The above reaction product (*ca.*

8) Melting points were measured by a mp apparatus, type MP-1, of Yamamoto Scientific Co. Ltd., and are uncorrected. The IR spectra were measured with a Hitachi EPI-S2. The UV spectra were measured with a Hitachi EPS-3T recording spectrometer in ethanol. The NMR spectra were measured with a Hitachi R-20 at 60 MHz in $CDCl_3$ solution using TMS as an internal reference.

100 mg) was dissolved in 1 m*l* of pyridine, acetic anhydride (2 m*l*) was slowly added, and the reaction mixture was stood overnight at room temperature. The solution was treated as usual, and the acetate was purified by repeated chromatography. λ_{max}^{EtOH} 232 (sh), 244, 293, 303, 317 and 331 mμ. $\nu_{max}^{CHCl_3}$ 1760, 1640, 1600, 1580, 1100 and 1040 cm^{-1}. *m/e* 324.175 (M^+): calcd for $C_{21}H_{24}O_3$, *m/e* 324.172.

The acetate obtained from hydroxytanshinone under the same reaction conditions is identical with this acetate.

Monomethyl Ether (V). About 100 mg of the reaction product of the hydrogenation was dissolved in 5 m*l* of acetone. To this were added 0.2 m*l* of freshly distilled dimethyl sulfate and 1 g (excess amount) of finely pulverized potassium carbonate. After refluxing the mixture under nitrogen for three hours, the same amounts of potassium carbonate and dimethyl sulfate were added, and refluxed for another three hours. The reaction mixture was filtered off while hot, and the filtrate was evaporated to dryness *in vacuo* until crystals appeared. The crude crystals were purified by column chromatography(SiO_2) and the monomethyl ether was eluted with benzene-hexane (1 : 2), and then recrystallized from ethanol to give white crystals (70 mg): mp 125—125.5°C; Found: C, 80.59; H, 8.07%. Calcd $C_{20}H_{24}O_2$: C, 81.04; H, 8.16%. λ_{max}^{EtOH} 224, 242 (sh), 248, 280, 283, 303, 317 and 332 mμ. ν_{max}^{KBr} 3090, 1635, 1603, 1520 and 1115 cm^{-1}. δ^{CHCl_3} ppm, 1.34 (s, 6H), 1.35 (d, 3H, J=6 Hz), 1.8 (m, 4H), 3.00 (brt, 2H, J=6 Hz), 3.7 (m, 1H), 3.92 (s, 3H), 4.30 (q, 1H, J=9 and 6 Hz), 4.80 (t, 1H, J=9 Hz), 6.75 (s, 1H), 7.30 (d, 1H, J=8 Hz) and 7.70 (d, 1H, J=8 Hz).

Oxidation of Monomethyl Ether (V) with 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). To a solution of 39 mg of V in benzene (4.5 m*l*) was added 33 mg of DDQ. After the solution was refluxed under nitrogen for 75 min, separated hydroquinone was filtered off. Evaporation of the filtrate afforded white crystals (37 mg); mp 124—124.5°C (EtOH). The spectrum of UV and IR, and melting point were all identical with those of synthetic compound (IX), and the latter was not depressed in mixed melting. λ_{max}^{EtOH} 240, 248, 255.5, 275 (sh), 286 (sh), 325 and 338 mμ. ν_{max}^{KBr} 3080, 1635, 1225 and 1115 cm^{-1}. δ^{CHCl_3} ppm, 1.40 (s, 6H), 1.8 (m, 4H), 2.40 (d, 3H, J=1 Hz), 3.08 (brt, 2H, J=6 Hz) 3.98 (s, 3H), 6.80 (s, 1H), 7.35 (q, 1H, J=1 Hz), 7.45 (d, 1H, J=9 Hz) and 8.00 (d, 1H, J=9 Hz).

The authors wish to express their thanks to Dr. Nobuhide Wasada of Government Chemical Industrial Research Institute for his measurement of the mass spectrum.

Poisoning of Zeolite Catalyst with Ammonia

Hiroshige MATUMOTO, Michiaki TOKUNO, Hideo FUTAMI and Yoshiro MORITA

Department of Applied Chemistry, School of Science and Engineering, Waseda University, Nishiokubo, Shinjuku, Tokyo

(Received January 12, 1970)

In the acid-catalyzed reactions of hydrocarbons such as isomerization,[1] alkylation[2,3] and cracking,[4] the catalytic activity of zeolite increased with the amount of adsorbed water, which was controlled by thermal treatment of zeolite prior to being brought to catalysis. The activation energies of these reactions were, however, almost independent of the water content in zeolite.[1,2] The result suggests that the catalytically active surface of zeolite is regarded as homogeneous, while the existence of several different OH groups in the lattice was confirmed by IR measurements.[5] This work was carried out to confirm the homogeneity of the active surface of zeolite catalyst by means of partial poisoning with ammonia.

The reaction apparatus and its procedure were similar to those given in previous work.[6] Cumene cracking was chosen for the activity test of zeolite. The reaction was carried out at 350°C under a constant pressure of ammonia in order to measure the activity of zeolite at an equilibrium state of ammonia adsorption. The partial pressure of cumene was maintained constant (36 mmHg). Dried hydrogen was used as a carrier gas. Pretreatment of zeolite was done in a stream of hydrogen for two hours at a desired temperature and the resulting weight change was measured with a thermobalance. CaY Zeolite used in this work was prepared by the ion exchange of Linde Molecular Sieves (SK-40). The ion exchange level,

a) Initial rate determined by first order kinetics.

defined as the percentage of the original sodium ion replaced, was determined to be 70.

The cracking activity of CaY zeolite pretreated at various temperatures is shown in Table 1 in comparison with the amount of adsorbed water. Water content and catalytic activity of CaY decreased with the rise of pretreatment temperature. The active protonic sites of zeolite may be produced by the adsorption of water.[7] A low activity of CaY pretreated at 350°C was due presumably to poisoning by the adsorption of excessive water on the active surface.

The catalytic activity of CaY zeolite considerably decreased by the addition of ammonia to the reaction system. The relation between the cumene conversion and the on-stream period is shown in Fig. 1.

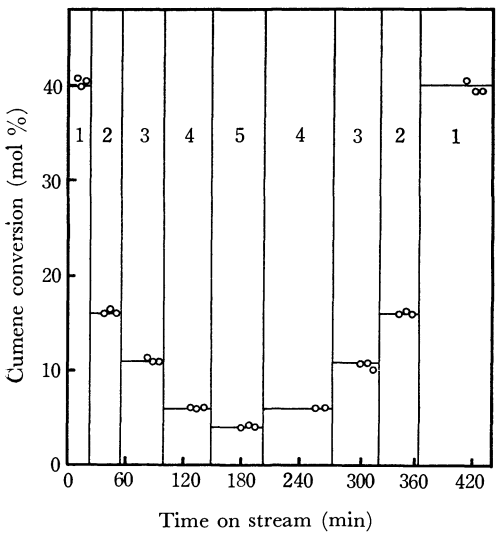

Fig. 1. Reversible poisoning of CaY with ammonia.

Pressure of ammonia; 1 0 mmHg
2 11.5
3 16.4
4 31.9
5 42.3

CaY pretreated at 450°C was brought to 350°C in a stream of hydrogen and then a continuous flow of cumene was started. During this period 40% of the conversion was observed. On the introduction of 8.23 mmHg of ammonia to the system, the conversion decreased sharply and reached the stationary value of 16% within 10 min. Cumene conversion decreased with the increase of ammonia pressure in the system. When the pressure of ammonia decreased, the conversion again increased. In this series of runs, the same conversion was obtained under the same partial pressure of ammonia. Thus, the poisoning of CaY with ammonia was completely reversible and the establishment of equilibrium was expected between the ammonia in the gas phase and that adsorbed on the active surace of zeolite.

If we postulate that the decrease in the activity of zeolite depends in first order on the amount of adsorbed ammonia, the initial rate of the reaction, r, will be expressed by the equation

$$r = r_0(1-\theta),$$

where r_0 stands for the initial rate in the absence of ammonia and θ for the fraction of the active surface occupied by ammonia. The poisoning effect of ammonia may be expressed as a function of ammonia pressure in the system (P_{NH_3}), postulating the establishment of the Langmuir assumption for the effective adsorption of ammonia on the active

surface of zeolite. Thus, the ratio of these initial rates, r_0/r, was evaluated by the simple relation under a constant pressure of the reactant

$$r_0/r = 1 + K \cdot P_{NH_3},$$

where K represents the constant of ammonia adsorption effective for the catalysis.

In accordance with this equation, plots of the ratio of initial rates against the pressure of ammonia should be linear. Such plots for CaY zeolite pretreated at various temperatures have been obtained in Fig. 2, where the initial rate of cumene cracking was determined by first order kinetics.[6] The data evidently satisfy the above equation. As evident from Fig. 2, the adsorption constant K was approximately independent of the pretreatment temperature (or the water content) of the zeolite, on which the catalytic activity strongly depends. This probably indicates that the catalytically active surface of CaY is nearly homogeneous.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1901—1902 (1970)

The Dissociation of 7-Triphenylmethyl-1,3,5-cycloheptatriene in *m*-Xylene*[1]

Kunio Okamoto, Kôichi Komatsu, Tomomi Kinoshita and Haruo Shingu

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received January 20, 1970)

The enthalpy of the dissociation of bitropyl (bis-2,4,6-cycloheptatrien-1-yl) into the tropyl (cycloheptatrienyl) radicals has recently been evaluated to be 35 ± 1 kcal/mol using ESR spectroscopy,[1] whereas that of "hexaphenylethane," whose structure has been proved to be 1-diphenylmethylene-4-triphenylmethyl-2,5-cyclohexadiene (I),[2] into the trityl (triphenylmethyl) radicals is known to be only about 11.5 kcal/mol.[3] When these two values are available, it should be of considerable interest to know the value of the dissociation energy of 7-trityltropilidene (7-triphenylmethyl-1,3,5-cycloheptatriene), a coupling product of the trityl and the tropyl radicals.

Incidentally, we have synthesized this compound[4] by the coupling of the two unlike radicals in connection with our studies of the one-electron reduction of the tropylium ion;[5] we undertook the measurement of the degree of the dissociation by means of ESR spectroscopy in order to evaluate the enthalpy of the dissociation of this compound.

A degassed solution (0.1 M) of 7-trityltropilidene in *m*-xylene gave the ESR signals of the trityl radical at 60—100°C; the signal gradually increased in intensity and became constant after 1—5 hr at 85—90°C or after 10—20 hr at 65°C. The concentrations of the trityl radical were estimated to be 3×10^{-6}—6×10^{-5} M at 60—95°C by a comparison of the integral spectrum constructed from the first derivative spectrum, recorded under overmodulated conditions (modulation width, 5.0 G), with that of a standard diphenylpicrylhydrazyl solution. The signal intensity of the trityl radical in a sample preheated at 100°C decreased when the sample was kept at lower temperatures, thus reaching the same value as that of another sample not preheated. After each measurement, no discoloration of the solution was observed, and the TLC analysis of an aliquot gave a sole spot with the same R_f value as that of the authentic 7-trityltropilidene.[6]

3) a) K. Ziegler and L. Ewald, *Ann.*, **473**, 163 (1929); b) E. Müller and I. Müller-Rodloff, *ibid.*, **521**, 89 (1936); c) F.S. D'yachkovskii, N.N. Bubnov and A.E. Shilov, *Doklady. Akad. Nauk S.S.S.R.*, **122**, 629 (1958).

4) 7-Trityltropilidene was first synthesized from triphenylmethylsodium and tropylium fluoroborate by M. R. Rifi and H. J. Dauben, Jr. (M. R. Rifi, Ph. D. Thesis, p. 105, the University of Washington, 1963); we are indebted to Professor K. M. Harmon of the University of Washigton for informing us of the details of Dr. Rifi's thesis.

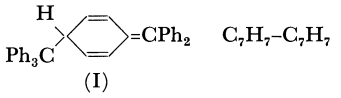
5) K. Okamoto, K. Komatsu and H. Shingu, This Bulletin, **42**, 3249 (1969).

6) It has been found that 7-trityltropilidene gave a small amount of an oily product when heated in refluxing benzene for 4.5 days (F. R. Hunter, Ph. D. Thesis, p. 155, the University of Washington, 1966); we are grateful to Professor K. M. Harmon for informing us of the details of Dr. Hunter's thesis.

The ESR signal for the tropyl radical was not observed under the conditions here employed. This is most probably the result of the lowering of the concentration of the tropyl radical due to its dimerization to bitropyl. Since the trityl radical is also in equilibrium with the cyclohexadiene I ("hexaphenylethane"), we may assume the following equilibration scheme:

$$Ph_3C\text{-}C_7H_7 \overset{K_1}{\rightleftharpoons} Ph_3C\cdot + C_7H_7\cdot$$

K_2 ⇕ ⇕ K_3



(I) $C_7H_7\text{-}C_7H_7$

If the above scheme holds under the conditions employed, the equilibrium consant, K_1, for 7-trityltropilidene can be calculated from Eq. (1):

$$K_1 = (b/a)\{-1+\sqrt{1+(16b^2/K_2K_3)+(8b/K_3)}\}(K_3/4) \quad (1)$$

where a and b are, respectively, the concentrations of 7-trityltropilidene and the trityl radical.[7] The results are summarized in Table 1, along with the thermodynamic parameters.

Thus, in the temperature range from 60 to 95°C, the values of the equilibrium constant are in the sequence: the cyclohexadiene I > $Ph_3C\text{-}C_7H_7$ > $C_7H_7\text{-}C_7H_7$, whereas the values of ΔH and of ΔS are in the sequence: $Ph_3C\text{-}C_7H_7$ > $C_7H_7\text{-}C_7H_7$ > the cyclohexadiene I. It seems to be difficult to explain the abnormally high values of ΔH and of ΔS for 7-trityltropilidene on the basis of the steric and the electronic factors which were considered in the cases of genuine hexaphenylethane[8] and bitropyl.[1] These quenstions remain to be elucidated in the future.[9]

a) The initial concentration of 7-trityltropilidene was 0.1M.
b) I = 1-diphenylmethylene-4-triphenylmethyl-2,5-cyclohexadiene.
c) Calculated from Eq. (1) (see text).
d) The values for K's were extrapolated from data at the other temperatures: see Refs. 1 and 7.

Experimental

7-Trityltropilidene. This was synthesized by the coupling of the trityl radical with the tropyl radical in benzene-acetonitrile. To a stirred benzene solution (18 m*l*) of the cyclohexadiene I (1.13 mmol) containing zinc dust (2.94 g), an acetonitrile solution (18 m*l*) of tropylium fluoroborate (4.50 mmol) was added, drop by drop, under a nitrogen atmosphere over a 15-min period at room temperature. The reaction mixture was then filtered; the filtrate was washed with water, dried, and concentrated to give an oily solid (0.849 g), which was then chromatographed over slica gel (70 g). Bitropyl (0.185 g, 45.3%) and 7-trityltropilidene (0.459 g, 61.0% yield based on the cyclohexadiene I; 30.5% yield based on the tropylium ion) were eluted with 95 : 5 and 90 : 10 *n*-hexane - benzene respectively. 7-Trityltropilidene melts at 167—170°C (dec.) (lit, mp 156°C[4]). Found: C, 93.52; H, 6.62. Calcd for $C_{26}H_{22}$: C, 93.37; H, 6.63%. NMR spectrum: τ 2.80 (15H, singlet, aromatic), 3.25 (2H, triplet, 3- and 4-C), 3.81 (2H, multiplet, 2- and 5-C), 4.72 (2H, doublet of doublet, 1- and 6-C) and 7.06 (1H, triplet, 7-C); UV: $\lambda_{max}^{CH_3OH}$ 260 mμ (log ε=3.66) and two shoulders at 265.5 and 272 mμ (lit,[4] $\lambda_{max}^{95\%\ EtOH}$ 259 mμ ($\varepsilon=4.7\times10^3$) and 272 m$\mu$ (shoulder, $\varepsilon=3.20\times10^3$)).

ESR Measurements. The ESR spectra were taken on a Japan Electron Optics X-band spectrometer, model JES-3BS-X, equipped with a 100 kc/s field modulation unit. The evacuated sample tube to be heated was placed in a JEO Associates JES-UCT-2X quartz Dewar sleeve set in a TE_{011} JEO cavity.

7) The values of K_2 and ΔH for the dissociation of the cyclohexadiene I were taken to be, respectively, 2×10^{-4} (25°C) and 11 kcal/mol in benzene.[3b] The values of K_3 and ΔH for the dissociation of bitropyl were evaluated by means of ESR spectroscopy following the method of Vincow and his collaborators;[1] K_3 for a 2.9M solution of bitropyl in *m*-xylene, 1.2×10^{-13} (126°C); ΔH (the average value for three runs), 34.5 kcal/mol (124.5—152.0°C) (lit, ΔH for a neat sample, 35±1 kcal/mol[1]).

8) a) G. W. Wheland, "Resonance in Organic Chemistry," John Wiley & Sons, New York (1955), Section 7·6; b) S. W. Benson, *J. Chem. Educ.*, **42**, 502 (1965).

9) The sequence of ΔH $Ph_3C\text{-}C_7H_7$ > $C_7H_7\text{-}C_7H_7$ may suggest that the ΔH for the genuine $Ph_3C\text{-}CPh_3$, which has not yet been prepared,[2a] might be greater than that of $Ph_3C\text{-}C_7H_7$.

SHORT COMMUNICATIONS

The Structure of the *trans*-Dichlorobistrimethylenediaminecobalt(III) Ion, *trans*-$[CoCl_2tn_2]^+$ *1

Keiji MATSUMOTO, Shun'ichiro OOI and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received March 4, 1970)

Ethylenediamine, $H_2N-CH_2-CH_2-NH_2$ (=en), can form a stable five-membered chelate ring in combination with many transition metals; the geometry of the ring has been well established. On the other hand, trimethylenediamine, $H_2N-CH_2-CH_2-CH_2-NH_2$ (=tn), possesses one more CH_2-group than does ethylenediamine and forms a six-membered ring in chelation with several metals. The metal chelates of the trimethylenediamine are, however, less stable and less easily prepared than the corresponding ethylenediamine chelates.[1] The instability of the tn-compounds may be due to the distortion which is presumably existent in the six-membered chelate ring. In order to elucidate the conformation of the tn-chelate ring, we have attempted a crystal structure analysis of *trans*-$[Co\ Cl_2\ tn_2]Cl \cdot HCl \cdot 2H_2O$.

The crystal is green and monoclinic, with cell dimensions of $a=10.68$, $b=8.55$, $c=9.46$ Å, and $\beta=112.2°$. The space group is $P2_1/c$, and the unit cell contains two formula units ($\rho_{obsd}=1.59$ and $\rho_{calcd}=1.60\ g\cdot cm^{-3}$). The *h0l* and *hk0* intensity data were recorded on Weissenberg photographs (Ni$K\alpha$ radiation, $\lambda=1.6591$ Å). The intensities were measured visually, and no absorption corrections were applied. The positions of the heavy atoms could be obtained from Patterson projections, *P(UW)* and *P(UV)*, and those of the light atoms, from Fourier maps. The *R*-value was reduced to 0.14 by means of the usual refinements. Refinement on the basis of the three-dimensional data is now going on.

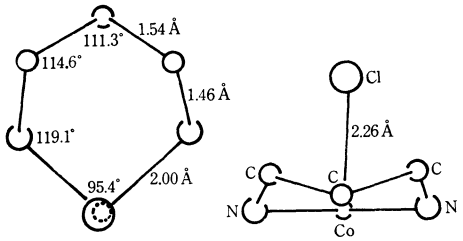

Fig. 1. The elevation and projection of *trans*-$[Co\ Cl_2\ tn_2]^+$. Asymmetric half of the cation is drawn.

The crystal structure is similar to that of *trans*-$[Co\ Cl_2\ en_2]Cl \cdot HCl \cdot 2H_2O$;[2] the crystal consists of *trans*-$[Co\ Cl_2\ tn_2]^+$, Cl^- and $[H_2O\cdots H\cdots OH_2]^+$. In Fig. 1 the structure of the complex ion is illustrated. Since the cobalt is located on a special position, the symmetry of the complex ion is $\bar{1}$.

The chelate ring takes a chair form.[3] The ring has an approximate mirror plane which is normal to the ring plane and which passes through the cobalt atom and the middle carbon atom. The bond lengths of Co–N, N–C, and C–C are in good agreement with those in *trans*-$[Co\ X_2\ en_2]^+$.[4,5] In Table 1 the average values of the two bond angles which are related by the pseudo mirror plane are compared with the corresponding values in the en-complexes. The deviation of the N–Co–N angle from 90° in the tn-complex is almost equal to that in the en-complexes. However, the values of the Co–N–C and N–C–C angles in the former are appreciably larger than 109.5°, while they are quite close to the tetrahedral angle in the latter. The lower stability in the tn-complexes may be attributable, at least in part, to these bond-angle strains. Recently a tn-ring which takes a twisted form and the N-Co-N angle of which is less than 90° was found in [Cu(*o*-haph:tn:*o*-haph)].[6]

Polymerization of *N*-Vinylcarbazole by Chlorides and Oxychlorides of Some Group V Elements. I. Polymerization by $POCl_3$, $AsCl_3$ and $SbCl_3$

Mukul Biswas and Devapriya Chakravarty

Department of Chemistry, Indian Institute of Technology, Kharagpur, India

(Received July 30, 1969)

In the course of our studies[1-3] on initiator systems for *N*-Vinylcarbazole (NVC) polymerization we have observed that $POCl_3$, $AsCl_3$ and $SbCl_3$ can effectively initiate the solution polymerization of NVC. This communication reports our preliminary observations on these systems.

Polymerization was carried out under nitrogen at 30°C with purified and dry reagents. Conversion at intervals of 2, 4, 6 and 8 up to 30 min was followed gravimetrically after purifying the polymer.[3] Molecular weights ($\bar{M}_n$) were determined cryoscopically in benzene. Polymer melting points were >350°C.

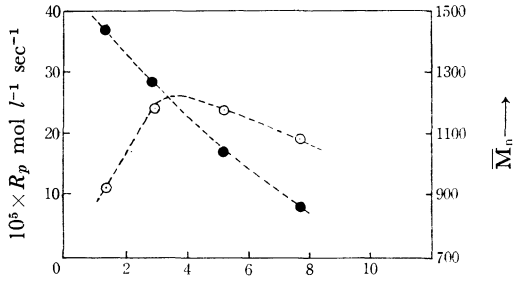

Fig. 1. Dependence of R_p on [NVC] (⊙) and of $\bar{M}_n$ on [NVC] (●); $[AsCl_3] = 16.2 \times 10^{-4}$ M.

For NVC-$AsCl_3$-benzene system, R_p was first order in $AsCl_3$ concentration. The variation of R_p and $\bar{M}_n$ with NVC concentration is shown in Fig. 1. With NVC-chloranil-nitrobenzene system, Pac and Plesch[4] found a maximum by plotting specific rate constant against NVC concentration. Dependence of the maximum on $AsCl_3$ concentration is being investigated. We feel that increased termination and transfer may be important, but any definite comment on this trend would not be justified at this stage.

The reactions were usually exothermic. R_p of NVC-$AsCl_3$ system was dependent on solvent dielectric constant (Fig. 2) and so was $\bar{M}_n$ (1269 in benzene and 3982 in nitrobenzene, for example). Additives such as water, dimethylaniline, aniline and triethylamine related the rate. These features suggest a cationic mechanism.

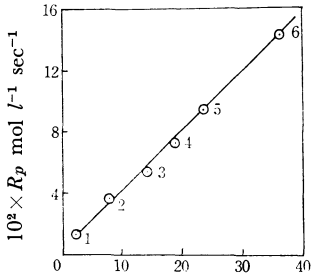

Fig. 2. Dependence of R_p on solvent dielectric constant. $[NVC] = 0.29$ M; $[AsCl_3] = 16.2 \times 10^{-4}$ M; (1) B (100%); (2) 75% B+25% NB; (3) 50% B+50% NB; (4) 37.5% B+62.5% NB; (5) 25% B+75% NB; (6) NB (100%). (B=Benzene; NB=Nitrobenzene). Values of solvent dielectric constant taken from Ref. 5.

Some experiments were performed with $POCl_3$ and $SbCl_3$. Thus $POCl_3$ (0.063—0.19 M) and NVC (0.77 M) produced (30°C; benzene; 1320 min) 94% deep yellow orange poly NVC, $\bar{M}_n$: 2704, mp >350C°. $SbCl_3$ (0.068 M) and NVC (0.29 M) produced (30°C; benzene; 765 min) 74% white poly NVC, $\bar{M}_n$: 2254, mp >350°C.

In a few cases a colour change was noted during reaction. With NVC-$Fe(NO_3)_3$, $9H_2O$ system Okamura *et al.*[6] reported a similar colour change. In our case this colour change was not a necessary condition for polymerization. In fact, colour could be produced by mixing poly NVC with $AsCl_3$ in benzene. This latter observation may be related to the possibility of charge transfer interaction between poly NVC and $AsCl_3$. Interaction between poly NVC and acceptors such as $SbCl_5$ is known.[7] Spectrophotometric investigations are in progress.

Details of all these observations will appear in due course.

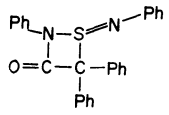
The Molecular Structure of the Reaction Product from Sulfurdiimide and Diphenylketene

Noritake YASUOKA, Nobutami KASAI, Toru MINAMI, Yoshiki OHSHIRO, Toshio AGAWA and Masao KAKUDO

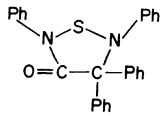
Department of Applied Chemistry, Osaka University, Yamadakami, Suita, Osaka

(Received March 7, 1970)

In a series of studies of the reaction of hetero-cumulenes with ketene, the reaction of sulfurdiimide with diphenylketene has been reported on by some of the present authors.[1] The structure of the reaction product was assumed to be 1-phenylimino-2,4,4-triphenyl-1,2-thiazetidine-3-one (I) on the basis of the IR, the mass spectra, and some chemical properties.



(I)



(II)

An X-ray structure investigation has, however, shown that the structure is an unexpected structure, 2,3,3,5-tetraphenyl-1,2,5-thiadiazolidine-4-one (II), instead of (I). After we completed our X-ray structure determination, Hoerhold and Eibisch have proposed a structure on the basis of some organo-chemical methods.[2] Their result agrees with ours.

The three-dimensional X-ray diffraction data were collected on a Rigaku on-line controlled single-crystal diffractometer with zirconium-filtered Mo$K\alpha$ radiation. Crystal data: $C_{26}H_{20}ON_2S$, mp=167°C, F. W.=408.5, monoclinic, $P2_1/n$, a=10.975 (5), b=15.315(6), c=12.616(6) Å, β=98.28(2)°, V=2098 Å^3, Z=4, D_c=1.29 g·cm^{-3}.

The structure was established by the heavy-atom method. The refinement was carried out by the block-diagonal least-squares procedure (R=0.089 for 1483 non-zero reflections).

The molecular is shown in the Fig. 1.

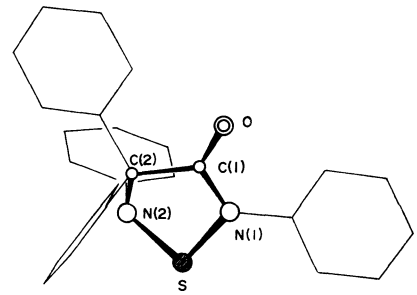


Fig. 1. The molecular structure.

Two S–N bond distances, S-N(1) and S–N(2), (Table 1) are comparable to, or somewhat shorter than, the sum of the covalent radii (1.74 Å) and are assumed to be normal single bonds. From this fact and from the N(1)–S–N(2) bond angle, the S atom seems to be bonded to nitrogen atoms using two mutually orthogonal 3p orbitals. This compound is probably the first one in which such a bonding scheme has been observed.

It is interesting to note that the C(1)–N(1) bond is significantly shorter than the C(2)–N(2) bond. The C–N bond distance in the =N–C=O group is usually shorter than the normal single bond distance: for example, the value of 1.326 Å has been reported in acetanilide.[3] The N(1) atom lies almost on the plane defined by C(1), S, and C(31). In contrast to this, the N(2) lies 0.4 Å above the plane defined by C(2), S, and C(41). These differences in the bonding states of N(1) and N(2) are interesting in connection with the reactivity of this compound.

TABLE 1.* SELECTED BOND LENGTHS AND ANGLES

S–N(1)	1.726 (0.011) Å	N(1)–S–N(2)	92.4 (0.5)°

Thermal *trans-cis* Isomerization of $[CrBrH_2O(NH_3)_4]Br_2$

Yoriko KAJI, Akira UEHARA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received March 10, 1970)

There are only a few examples of thermal *trans-cis* isomerization of transition metal complexes in solid phase.[1] In general, the isomerization of the complexes which contain crystalline or coordinated water occurs simultaneously with dehydration or after.[2] Isomerization prior to dehydration is still unknown. One of such rare examples was investigated in the present work.

When the complex, *trans*-$[CrBrH_2O(NH_3)_4]Br_2$,[3] was heated, it turned to reddish-violet from violettish-brown, and the coordinated water was then liberated. This suggests a change from *trans* to *cis* form. The derivatogram of the *trans* complex is given in Fig. 1. It shows an endothermic peak without any mass loss in the DTA curve at 145°C.

In order to confirm the *cis-trans* isomerization, absorption spectra of the compounds obtained after heating the complex with a thermobalance at both 143 and 153°C were measured by diffusion reflectance method in solid state. They are given in Fig. 2, together with those obtained at room temperature for the starting *trans* complex and for the *cis* isomer prepared by the standard method.[3]

The *d–d* band in the long wavelength region of the starting complex is split into two peaks, indicating the validity of the *trans* form. On heating, the splitting of these peaks became gradually weaker, approaching one peak corresponding to that of the *cis* form. The results suggest that *trans-cis* isomerization occurs in thermal reaction.

The enthalpy change, ΔH, for the reaction was calculated to be 1.9 kcal·mol^{-1} by analysis of DTA, and the activation energy, $E^{\neq}$, was evaluated by the same analysis to be 87 kcal·mol^{-1}. The values are very interesting for discussing the mechanism of isomerization reaction in the solid phase.

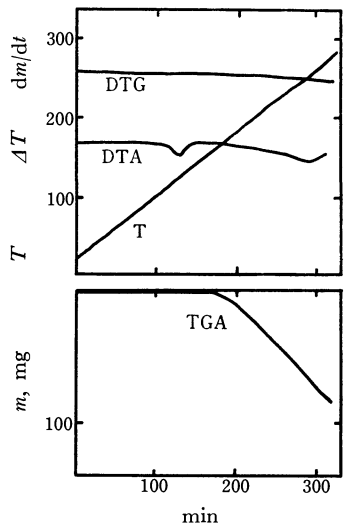

Fig. 1. Derivatogram for *trans*-$[CrBrH_2O(NH_3)_4]Br_2$.

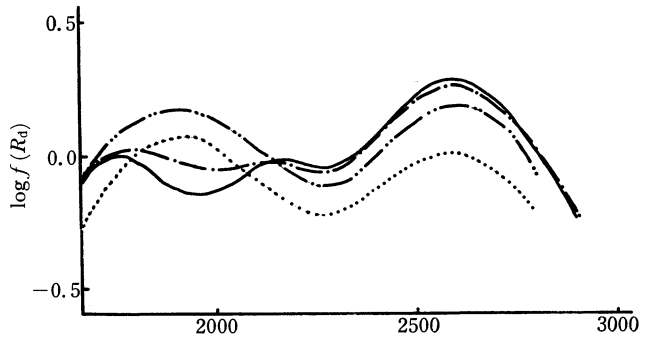

Fig. 2. Absorption spectra for *trans*-$[CrBrH_2O(NH_3)_4]Br_2$ (————), *cis*-$[CrBrH_2O(NH_3)_4]Br_2$ (·····), and the compounds obtained after heating at 143 (—·—·—) and 153°C (—··—··—).

Effect of Crystal Size on the Radiolysis of Solid Succinic Acid

Tetsuo MIYAZAKI, Shigehiro OKADA, Terunobu WAKAYAMA, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received March 14, 1970)

Recently we studied the radiolysis of hydrocarbons in the solid state and proposed that the formation of the exciton may play an important role in the radiolysis.[1,2] In the present work we have studied the radiolysis of crystalline succinic acid ($HOOCCH_2CH_2COOH$) at 77°K. The γ-irradiation of the acid was performed at 77°K in the form of a single crystal of 0.5—1.0 cm long or the powdered form. After irradiation, the sample was melted at 185°C, and then the gaseous products were analyzed as follows: the gaseous products (a mixture of CO and H_2) not condensable at the temperature of liquid nitrogen were analyzed by a gas burette connected to a Toepler pump and a cupric oxide furnace kept at 240°C, while another gaseuous product (CO_2) not condensable at the temperature of dry ice was measured by means of the gas burette alone.

The yield of $CO+H_2$ is plotted against the total dose in Fig. 1. The $G(CO+H_2)$ from the powder and the single crystal are about 0.5 and 0.1 respectively at a dose of 4.6×10^6 rad. There is no difference in the yield of CO_2 between the powder and the single crystal; in both cases it is about 1.9 G-unit. It should be noted that the $G(CO+H_2)$ from the powder is much higher than that from the single crystal. In order to examine whether the difference in $G(CO+H_2)$ can be attributed to the analytical procedure, the CO and H_2 were measured after the γ-irradiated sample had been dissolved in ethanol at room temperature without melting the sample at 185°C. The clear difference in $G(CO+H_2)$ between the powder and the single crystal was also observed in this case. In the radiolysis of succinic acid in the powdered form, the $G(CO)$ and $G(H_2)$ were about 0.4 and 0.1 respectively. Most of the CO and H_2 could be measured without melting the irradiated sample, while most of the CO_2 was not measurable until the sample had melted. The results indicate that CO and H_2 may be produced at the surface of the crystal and that $G(CO+H_2)$ may depend upon the surface area or the size of the crystal. It is conceivable that the mobile active entity formed by the γ-irradiation of the crystal migrates to its surface and produces CO and H_2.

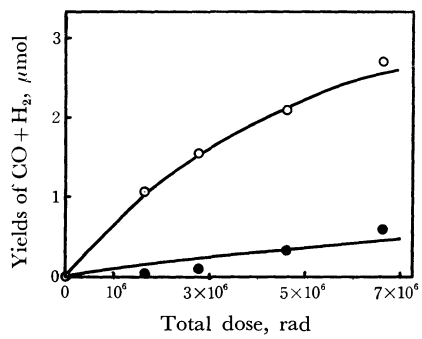

Fig. 1. Yields of $CO+H_2$ in the radiolysis of solid succinic at 77°K against the total dose.
dose rate: 3.0×10^5 rad/hr. Yields are expressed as 10^{-6} mol of products from 1 g of γ-irradiated succinic acid.
○: Yields from succinic acid in the powdered form.
●: Yields from succinic acid in the single crystal.

Since the effect of crystal size on the radiolysis has not been reported previously, it is not possible at present to discuss fully whether the mobile entity is a hole, an electron, or an exciton. It is expected, from an ESR study[3] of γ-irradiated succinic acid, that holes and electrons may be trapped in the crystal by the hydride-ion-transfer reaction and the electron-capture reaction:

$$HOOCCH_2CH_2COOH \rightsquigarrow HOOCCH_2CH_2COOH^+ + e^- \quad (1)$$

$$HOOCCH_2CH_2COOH^+ + HOOCCH_2CH_2COOH \longrightarrow HOOCCH_2CH_2COO\cdot + HOOCH_2CH_2COOH_2^+ \quad (2)$$

$$HOOCCH_2CH_2COO\cdot \longrightarrow HOOCCH_2CH_2\cdot + CO_2 \quad (3)$$

$$e^- + HOOCCH_2CH_2COOH \longrightarrow HOOCCH_2CH_2COOH^- \quad (4)$$

$$HOOCCH_2CH_2COOH^- \longrightarrow HOOCCH_2CH_3 + CO_2^- \quad (5)$$

Further studies of the effect of crystal size on the radiolysis are now in progress.

Pure Quadrupole Resonance of Halogens in Sodium Tetrahaloaurate(III) Dihydrates and Sodium Tetrachloroiodate(III) Dihydrate[1)]

Akinobu SASANE, Takayo MATUO, Daiyu NAKAMURA and Masaji KUBO

Department of Chemistry, Nagoya University, Chikusa, Nagoya

(Received March 16, 1970)

The pure quadrupole resonance of chlorine in sodium tetrachloroaurate(III) dihydrate was observed between 77 and 400°K using a sample synthesized and identified by means of chemical analysis and X-ray powder technique. We could observe four resonance lines attributable to ^{35}Cl each showing no discontinuity in its temperature dependence. This indicates that four kinds of nonequivalent chlorine atoms exist in a crystal and that no phase transition takes place in this temperature range.

The lowest-frequency line of the quartet shows a positive temperature coefficient ($\Delta\nu/\Delta T=0.4$ and 2.5 kHz/deg at 77 and 400°K, respectively), whereas other lines have normal negative temperature coefficients in the whole range of temperature studied. Moreover, its line width is very broad and its frequency is much lower than that of other lines (25.356, 27.998, 28.867, and 29.466 MHz at 77°K).

Vaciago *et al.*[2)] have carried out X-ray analysis on this compound and found that it forms orthorhombic crystals with four formula units in a unit cell and that four chlorine atoms are crystallographically nonequivalent in a distorted square coordination in agreement with our observation of the quartet lines. In this complex ion, one chlorine atom (Cl_1) is separated from the nearest sodium ion by 4.37 Å, whereas three others are closer to sodium ions, the average distance being equal to 3.05 Å. The chlorine atom Cl_1 has four oxygen atoms at the shortest and the second shortest distances (3.36 and 3.42 Å), while other O–Cl distances are longer than 3.45 Å. The four oxygen atoms form a very flat, slightly distorted square pyramid along with the Cl_1 atom at the apex, the Au–Cl_1 axis pointing to the center of the square. Each oxygen atom has two chlorine atoms in its vicinity, *i. e.*, Cl_1 and Cl_1' belonging to different complex anions. The $\angle Cl_1$–O–Cl_1' angle (118°) is nearly equal to the valency angle of oxygen in a water molecule. Although hydrogen atoms are not located by the X-ray analysis, it is plausible that weak O–H···Cl_1 hydrogen bonds are formed in the crystal.

The positive temperature coefficient of the lowest-frequency line of the quartet can be interpreted in terms of hydrogen bond formation. To the first approximation, the quadrupole resonance frequency of a halogen is proportional to the number of unbalanced p electrons, $U_p=(N_x+N_y)/2-N_z$, where N_x, N_y, and N_z denote the number of electrons in the p_x, p_y, and p_z orbitals of the halogen atom, respectively. The origin of the coordinate system is taken at the halogen nucleus, the z axis being directed along the metal-ligand bond. When hydrogen bonds are formed, four O–H groups approximately lying on the x and y axes attract electrons from the p_x and p_z orbitals of the chlorine atom, leading to a decrease in the number of unbalanced p electrons. Accordingly, the lowest-frequency line is assigned unequivocally to Cl_1 atoms. As hydrogen bonds are weakened by thermal motion, N_x and N_y increase with increasing temperature and the resonance line shifts to a higher frequency. Because hydrogen atoms are present in the vicinity of Cl_1 atoms, the resonance line is broadened by nuclear spin-spin interaction as was observed experimentally.

We studied also the temperature dependence of the pure quadrupole resonance of ^{79}Br in sodium tetrabromoaurate(III) dihydrate ($\nu=201.70$, 217.66, 224.48, and 229.43 MHz at 77°K; $\Delta\nu/\Delta T=7$ and 18 kHz/deg at 77 and 270°K, respectively, for the lowest-frequency line) and ^{35}Cl in sodium tetrachloroiodate dihydrate[3)] ($\Delta\nu/\Delta T=0.5$ and 3.3 kHz/deg at 77 and 300°K, respectively) and found that the resonance pattern of these complexes bears a strong resemblance to that of sodium tetrachloroaurate(III) dihydrate. The crystal structures of these complexes were confirmed to be isomorphous with that of sodium tetrachloroaurate(III) dihydrate, the structural data being $a=13.29$, $b=7.28$, and $c=9.43$ Å for the former and 13.61, 7.14, and 9.24 Å for the latter.

Formation of Inclusion Compounds of β-Cyclodextrin with Hydroperoxides

Yoshihisa MATSUI, Haruki NARUSE, Kazuo MOCHIDA and Yoshio DATE

Department of Agricultural Chemistry, Shimane University, Nishikawazu-cho, Matsue

(Received March 16, 1970)

The degradation of starch by the action of *Bacillus macerans* amylase yields cyclic dextrins composed of six, seven, eight, or more α-D-glucopyranose units linked 1→4 as in amylose. They have void spaces in the molecules and enclose a number of organic compounds in it to form crystalline adducts.[1] We wish to report that various hydroperoxides are also enclosed by β-cyclodextrin (I), a cyclic dextrin with seven glucosyl residues, to form crystalline adducts.

When I (1.00 g) and *t*-butyl hydroperoxide (II) (0.50 g) were dissolved in 50 m*l* of warm water and the solution was cooled in ice water, a white precipitate was formed. On the other hand, no appreciable change occurred when D-glucose, instead of I, was dissolved in the aqueous solution of II. In the former case, the precipitate was separated from the solution by filtration, washed with cold water, dried under vacuum (2 mmHg) at room temperature, and weighed as 0.91 g. mp 215°C (decomp.). The resulting solid (III) contained 0.80 mmol/g of hydroperoxide residue, which was determined by the iodometric method.[2] The content of I in III was determined to be 0.74 mmol/g by the measurement of the optical rotation on the assumption that the specific rotation of I, determined to be +168° in water at room temperature (lit,[3] +162.5°), dose not change by the interaction with II. These results suggest that I and II form an inclusion complex with the mole-ratio of about 1 : 1.

It is interesting that II, which is fairly volatile (bp 4.5—5.0°C/2 mmHg[4]), did not evaporate even at room temperature under 2 mmHg as a result of the formation of the adduct, although at 56°C under 2 mmHg the hydroperoxide content of III decreased to 0.24 mmol/g. This indicates that II is fairly strongly bonded to I. It is considered[5] that the main forces binding the constituents of cyclodextrin complexes are hydrogen bonding, van der Waals forces, and hydrophobic interactions. In the present case, it seems that hydrogen bonding plays a major role, for hydroperoxides are known to have the strong ability of hydrogen bond. This is supported by the fact that no crystalline adduct was formed between I and *t*-butyl alcohol which has less strong ability of hydrogen bonding than II.

Hydroperoxides other than II, such as *n*-butyl, isoamyl, *t*-amyl, *s*-octyl, and cumene hydroperoxides, also formed the crystalline adducts with I. Primary and secondary hydroperoxides, as well as tertiary hydroperoxides, form the inclusion compounds of I with the mole-ratio of about 1 : 1. All the inclusion compounds studied can be dried without loss of hydroperoxides at room temperature under 2 mmHg. In the case of isoamyl, *t*-amyl, and cumene hydroperoxides vacuum drying even at 56°C caused no loss of hydroperoxides. Thus, I serves not only as a precipitant for hydroperoxides but also as a reagent making volatile hydroperoxides non-volatile by means of inclusion.

Stabilization of Hydroperoxides by Means of the Formation of Inclusion Compounds with β-Cyclodextrin

Yoshihisa MATSUI, Haruki NARUSE, Kazuo MOCHIDA and Yoshio DATE

Department of Agricultural Chemistry, Shimane University, Nishikawazu-cho, Matsue

(Received March 16, 1970)

Cyclodextrins are known to stabilize a number of labile materials by means of inclusion.[1-3] We wish to report that hydroperoxides are also stabilized by the formation of inclusion compounds with β-cyclodextrin (I).

It is known[4] that *t*-butyl hydroperoxide (II) decomposes moderately at 95—100°C and explosively at 109°C. However, the crystalline adduct[5] (III) of I with II showed no change under these conditions. When the rate of the pyrolysis of II in III was measured at 160°C by means of the iodometric method, a moderate decrease of the hydroperoxide content was observed (Fig. 1). The crystalline adduct (IV) of I with *t*-amyl hydroperoxide decomposed more slowly than III at 160°C. Similarly, it was found that hydroperoxides such as *n*-butyl, isoamyl, *s*-octyl, and cumene hydroperoxides are stabilized by the formation of inclusion compound with I.

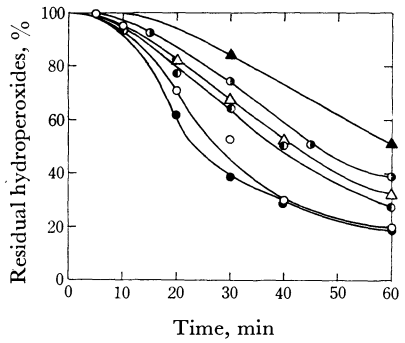

Fig. 1. Effect of I on the rate of the pyrolysis of hydroperoxides at 160°C.
△ III, ▲ IV, ○ II (0.11M) in H_2O,
◐ II (0.11M) + I (0.01M) in H_2O,
◑ II (0.11M) + I (0.02M) in H_2O,
● II (0.11M) + D-glucose (0.07M) in H_2O

The depression of pyrolysis of hydroperoxides by the interaction with I was also observed in an aqueous solution. As shown in Fig. 1, the rate of the pyrolysis of II (0.11M) in an aqueous solution was markedly decreased by the addition of 0.01M of I. The higher the concentration of I, the slower is the rate. However, the addition of D-glucose (0.07M) had no effect on the pyrolysis rate. These results clearly indicate that I stabilizes II by means of inclusion.

The stabilizing effect may be due to the formation of the strong hydrogen bonding between I and II.[5] The fact that the pyrolysis of II in an aqueous solution was depressed by the addition of I indicates that the hydrogen bond between I and II is stronger than that between I and water. It is also possible that the prevention of a chain mechanism in pyrolysis of hydroperoxides by means of inclusion may cause the stabilizing effect.[3]

Sulfurization of 1,3-Diphenylpropanetrione

Kōzō Inouye, Shigeru Sato and Masaki Ohta

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 19, 1970)

During the course of synthesis of mesoionic 1,2-dithiole compounds, we attempted the sulfurization of 1,3-diphenylpropanetrione(I), expecting the formation of 1,3-dithion-2-one(II) which might be stabilized by the S–S bond formation to give mesoionic compound(V).

Treatment of a solution of I in chloroform-ethanol mixture (1 : 7) with hydrogen sulfide and hydrogen chloride afforded yellow crystalline salt (A) of mp 197—204°C (dec.) in 40% yield. The chloride is unstable and can not be purified by recrystallization. When the chloride was treated with a base such as triethylamine, pyridine, or sodium bicarbonate, chlorine-free brown crystals (B) ($C_{15}H_{10}OS_2$, mp 236—241°C, dec.) were obtained. IR (KBr): 1495 cm^{-1} (highly polarized carbonyl), 1490, 1480, 1435 cm^{-1} (aromatic 1,2-dithiolium ring).[1] UV: λ_{max}^{DMF} (log ε): 317 (3.78), 366 (3.62), 562 mμ (4.20). Mass spectrum : M^+, *m/e* 270. Compound B gave perchlorate (mp 232—233°C), picrate (mp 192—195°C) and acetylated perchlorate (mp 171—174°C) by acetyl perchlorate. Compound B was also obtained in poor yield when I was refluxed in toluene with phosphorus pentasulfide.

Recently, Schönberg[2] reported that the reaction of 1,1,3,3-tetrabromo-1,3-diphenylpropan-2-one with potassium xanthate yielded 1,3-diphenylpropane-1,3-dithion-2-one (II). The physical and chemical properties of compound B are almost the same as those of II. However, considering the reaction sequence of the formation of B from I, and its spectroscopic and chemical properties, B should be more appropriately expressed by mesoionic structure (or anhydro-3,5-diphenyl-4-hydroxy-1,2-dithiolium hydroxide (IV or V) rather than 1,3-dithion-2-one structure (II) as proposed by Schönberg.[2]

On the basis of the above observation, it may safely be concluded that the product A is 3,5-diphenyl-4-hydroxy-1,2-dithiolium chloride (III) and the deprotonated product B is mesoionic 1,2-dithiole compound (V).

Ethoxalylnitrene

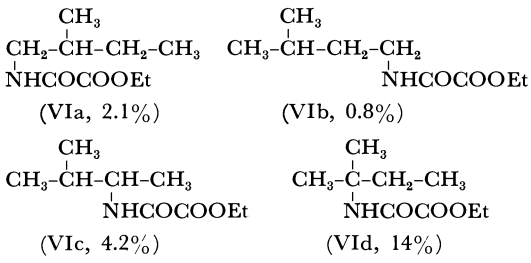
Tadao SHINGAKI,* Masao INAGAKI,* Matsuji TAKEBAYASHI,* Rolf LEBKÜCHER** and Walter LWOWSKI**

* *Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka*

** *Research Center, New Mexico State University, Las Cruces, New Mexico 88001, U.S.A.*

(Received March 19, 1970)

Thermolysis of ethoxalyl azide (I) in ethanol gave quantitatively ethoxycarbonylurethane (III) *via* isocyanate (II),[1] the Curtius rearrangement product, whereas photolysis of I, with the light of a low-pressure mercury arc at −78°C, in a solution of dichloromethane with alcohols yielded *N*-alkoxyethoxalamides (IV) and ethoxalamide (V) in addition to the corresponding urethanes (III). Similarly, the photolysis of I with saturated hydrocarbons gave *N*-alkyl- or *N*-cycloalkyl ethoxalamides (VI), V and II under the same experimental condition (Table 1). The formation of IV, V and VI suggests that the reaction involves a carbonyl nitrene, ethoxalylnitrene (VII), as an intermediate in a similar manner to the cases of ethyl azidoformate[2] and pivaloyl azide.[3]



In the reaction with 2-methylbutane, the product (VI) was observed to be a mixture of four kinds of isomers (VIa—VId).

The relative reactivity of ethoxalylnitrene toward primary (1°), secondary (2°) and tertiary (3°) C–H bonds in 2-methylbutane is shown to be 1 : 6.6 (±10%) : 44 (±13%). The results indicate that the reactivity of ethoxalylnitrene is more selective than that of ethoxycarbonylnitrene[2] owing to the resonance stabilization (Table 2).

Table 2. Relative reactivities of carbonylnitrenes toward the C–H bonds in 2-methlbutane

Nitrene	1° :	2° :	3°
N·CO·COOEt	1 :	6.6(±10%) :	44(±13%)
N·COOEt	1 :	9(±10%) :	34(± 5%)
N·CO·C(CH$_3$)$_3$	1 :	8.6(±10%) :	160(±25%)

The mechanism of the insertion of ethoxalylnitrene into C–H bonds will be discussed elsewhere.

Table 1. Photolysis of ethoxalyl azide in dichloromethane

Substrate	Product (mol%)

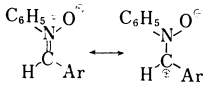
"Reverse-oriented" Cycloaddition of Nitrone to Enamine

Yujiro NOMURA, Fumio FURUSAKI and Yoshito TAKEUCHI

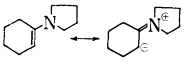
Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo

(Received April 4, 1970)

In the preliminary communication[1] we showed that the reaction between benzylidenaniline *N*-oxide (diphenylnitrone) (Ia, Ar=C_6H_5) and 1-pyrrolidino-1-cyclohexene (II) gave the expected 5-pyrrolidino-isoxazolidine III.



I



II

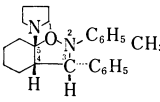
In the 1,3-dipolar cycloaddition between a nitrone and a monosubstituted olefin, the oxygen atom of the former generally attacks the substituted carbon atom of the olefin to give a "normal" cycloadduct, 5-substituted isoxazolidine. Thus, from 1-hexene,[2] styrene,[2] acrylonitrile,[3] or ethyl acrylate,[3] the expected normal cycloadducts are formed. If the other end of the olefinic double bond is overcrowded to a similar extent, the electronic effect will then become important; from ethyl crotonate or α,β-dimethylcrotonate, the "reverse-oriented" cycloadduct 4-ethoxycarbonylisoxazolidines are formed.[3] In such cases the reaction is under "electronic" control.

In the case of the reaction between a nitrone and an enamine, the normal cycloadduct formation is expected not only from the steric, but also from the electronic basis.

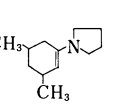
Here we report an unexpected "reverse-oriented" cycloaddition of nitrones to an enamine where no steric effect comparable to that in crotonates is involved. A dimethylformamide solution of Ib (Ar=*m*-$NO_2C_6H_4$) and 1-pyrrolidino-*cis*-3,5-dimethylcyclohexene (IV) was stirred at room temperature for 48 hr. After the removal of the solvent *in vacuo*, the residue was crystallized from ethanol to yield yellow crystals of 4-pyrrolidinoisoxazolidine Vb, mp 65—67°C, in 66% yield.

Found: C, 71.35; H, 7.60; N, 10.18%; mol wt (mass), 421. Calcd for $C_{25}H_{31}N_3O_3$: C, 71.23; H, 7.41; N, 9.97%; mol wt, 421.

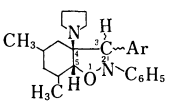
The proton NMR spectrum (in $CDCl_3$) of Vb shows a sharp singlet at τ 5.60 (3-H) and a doublet at τ 6.33 (the angular 5-H, deshielded by the neighboring oxygen atom), in contrast with that of the normal cycloadduct III[1] where benzylic-H (3-H) appears at τ 5.40 as a doublet (coupled with the angular 4-H, J=*ca.* 10 Hz) and 4-H as a broad doublet centered at τ 7.35.



III



IV

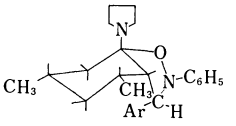


V

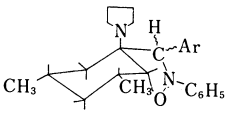
In a similar manner, from Ic(Ar=*p*-ClC_6H_4) and IV, 3-*p*-chlorophenyl-4-pyrrolidinoisoxazolidine Vc was obtained as colorless plates (from ethanol), mp 112—112.5°C, in 27% yield.

Found: C, 72.85; H, 7.50; N, 6.72%; mol wt (mass), 410. Calcd for $C_{25}H_{31}ClN_2O$: C, 73.01; H, 7.60; N, 6.82%; mol wt, 410.

It is well established that the electrophilic reagent attacking the β-carbon atom of cyclohexanone enamines can approach only from the direction to form the axial bond because of the large allyl strain (Johnson strain) in the enamine (or in its immonium structure).[4] Assuming that the reaction between a nitrone and an enamine is one-step concerted type,[5] and that no ring inversion is involved during the cycloaddition as we confirmed,[6] the structure of the hypothetical normal cycloadduct between I and IV would be VI. Apparently there is in VI a severe non-bonded interaction between C-aryl and one of the methyl groups. Since this interaction should be even greater in the transition state, VI is kinetically as well as thermodynamically less favorable than the reverse-oriented VII (=V) which is free from this type of interaction.



VI



VII

This unexpected formation of reverse-oriented cycloadduct gives, in turn, a support for the stereochemistry of nitrone-enamine reaction.[6]

Observation of Dynamic Nuclear Polarization in the Reaction of *N,N*-Dimethylaniline Oxide with Acetic Anhydride

Hiizu IWAMURA, Michiko IWAMURA,*1 Toshiaki NISHIDA*2 and Iwao MIURA*2

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received March 25, 1970)

The mechanism of the reaction of *N,N*-dimethylaniline oxide (I) with acetic anhydride has been a subject of controversy.[1] Although the free radical pair mechanism seems to have been concluded by an ellegant ^{18}O-labelling experiment,[2] recent findings that 3,3-sigmatropic shift predominates in scrambling the oxygen atoms of acetyl peroxide,[3] and that even 1,3-sigmatropic rearrangement is operative in heteroatomic systems[4] prompted the present authors to reconsider these mechanistic possibilities[5] for the reaction of I to give *o*-acetoxy-*N,N*-dimethylaniline (II). A method of detecting the chemically induced dynamic nuclear polarization (CIDNP)[6] in the NMR spectrum of the reaction mixture has been employed as an operational test.

In a typical run, 32 mg of I was dissolved in a solution of 58 mg of acetic anhydride in 0.5 m*l* of benzene. The NMR trace obtained on a Varian HA 100 D spectrometer at 60 sec after mixing is reproduced in Fig. 1. In the course of the reaction which could be followed by decrease of the *N*-methyl signal at 341 Hz of I and was completed in 30 min at room temperature, a strong emission of radiation was observed at 258 Hz which decayed as shown in Fig. 2. Peaks at 196, 251 and 280 Hz increased exponentially with the progress of the reaction. It was found by comparison with the spectra in benzene of the authentic samples that the origin of the emitting line was the *N*-methyl protons of *N,N*-dimethylaniline (III) formed in 5% yield. Similarly the absorption peaks were unambiguously assigned to the methyl protons of II and *N*-methylacetanilide. Under no circumstances was observed any sign of either emission or enhanced absorption for these signals of the main reaction products. Thus the evidence is not in favor of the intermediacy of the free radical pair for the formation of II.[2] It might be argued that in the intimate radical pair in the solvent cage the singlet spin correlation between the two fragments will be kept throughout the rearrangement and there will be no chance of dynamic nuclear polarization. Mechanistically, however, the situation is indistinguishable from, and had better be described as, 1,3- and 3,3-sigmatropic rearrangements.

On the other hand, it was confirmed by the observation of CIDNP that III is indeed formed by a free radical reaction[7] and is independent of the rearrangement to give II.

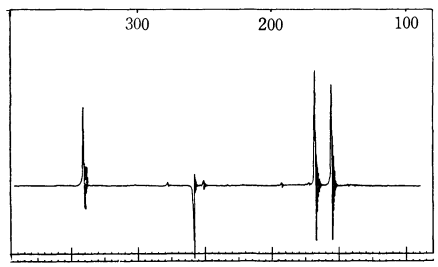

Fig. 1. The NMR spectrum of a mixture of I and acetic anhydride in benzene.

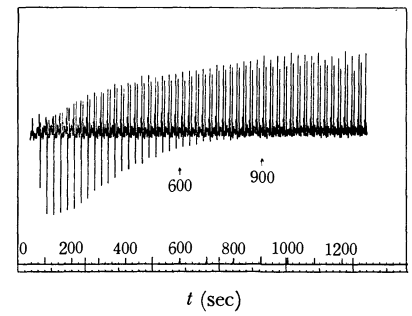

Fig. 2. Plot of signal intensities *vs.* time. The upper envelopes represent the formation of II and *N*-methylacetanilide, while the lower one demonstrates the CIDNP in III.

The Absolute Configuration of the Tris-*l*-propylenediaminecopper(II) Ion, $(-)_{589}$-$[Cu(l\text{-}pn)_3]^{2+}$

Tosaku OKAMOTO, Keiji MATSUMOTO and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received April, 1, 1970)

Few investigations have been made of the absolute configurations of metal complexes other than those of cobalt(III). Fortunately, we have succeeded in preparing a copper(II) complex, $(-)_{589}$-$[Cu(l\text{-}pn)_3]Br_2\cdot 2H_2O$,*1 and in determining its crystal structure. We wish here to report on its conformational features and on the absolute configuration of the complex cation.

Crystal data: monoclinic, space group $P2_1$; $a=10.71$, $b=8.93$, $c=10.88$ Å, $\beta=107.2°$; $Z=2$, $D_c=1.56$, $D_m=1.56$ g·cm^{-3}, $\mu=66.9$ cm^{-1} (for Cu$K\alpha$). The intensity data were recorded on multiple-film, equi-inclination Weissenberg photographs taken about the *a*- and *b*-axes; they were visually estimated. Absorption corrections were applied. The determination of the crystal structure was carried out by means of the three-dimensional Fourier techniques. The least-squares refinement led to the *R* value of 0.102 for 1437 reflections. In deciding the absolute configuration of the $(-)_{589}$-$[Cu(l\text{-}pn)_3]^{2+}$ ion, that of *l*-propylenediamine was cautiously referred to.

Figure 1 shows a perspective of the complex ion, viewed along the *b*-axis, the ion has an approximately three-fold axis. The *l*-propylenediamine molecules are linked to the Cu(II) atom in the "*lel*" form, every C–CH_3 bond lying in an approximately equatorial plane of the five-membered ring, as is the case with $(-)_{589}$-$[Co(l\text{-}pn)_3]^{3+}$ [1] and

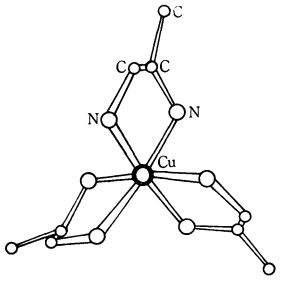

Fig. 1. A perspective of the complex ion viewed along the *b* axis.

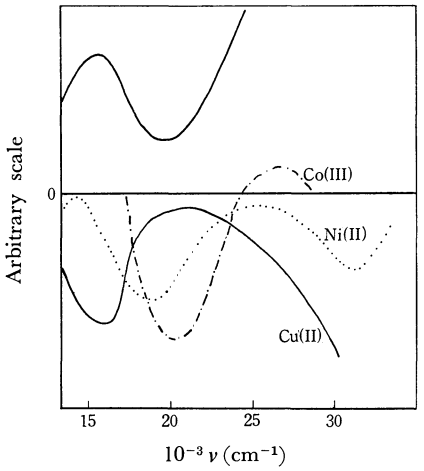

Fig. 2. The CD Spectra of tris-*l*-propylenediamine complexes and the absorption spectrum—of $(-)_{589}$-$[Cu(l\text{-}pn)_3]^{2+}$

trans-$[CoCl_2(l\text{-}pn)_2]^+$ [2]; the absolute configuration of $(-)_{589}$-$[Cu(l\text{-}pn)_3]^{2+}$ can be denoted as $\Delta(\lambda\lambda\lambda)$. The average value of the longer two of the Co–N bond lengths is 2.31 Å, and that of the other four, 2.09 Å. All the bond distances and angles within the N–C–C–N skeleton of the *l*-propylenediamine are quite normal.

Figure 2 depicts the CD curves of the tris-*l*-propylenediamine complexes of Co(III), Cu(II),*2 and Ni(II)*3 as well as the absorption spectrum of the Cu(II) complex.*2 In the first absorption-band region, a large negative CD peak can be seen for each of these three complexes; two of these have been confirmed to have the same absolute configuration. So far as this fact is concerned, it may be presumed that complexes of the same absolute configuration possess CD peaks of the same sign in the first band region, regardless of the kind of central metal atom.

*1 *l*-pn=*l*-propylenediamine.

2) Y. Saito and H. Iwasaki, *ibid.*, **35**, 1131 (1962).

*2 The CD curve and the absorption spectrum of $(-)_{589}$-$[Cu(l\text{-}pn)_3]^{2+}$ in the bromide crystals were obtained by the present authors, but qualitatively.

*3 The CD curve of $(-)_{589}$-$[Ni(l\text{-}pn)_3]^{2+}$ was measured in a solution of its perchlorate. Crystal structure analysis of the complex is now in progress.

The Glassy Crystalline State —A Non-Equilibrium State of Plastic Crystals

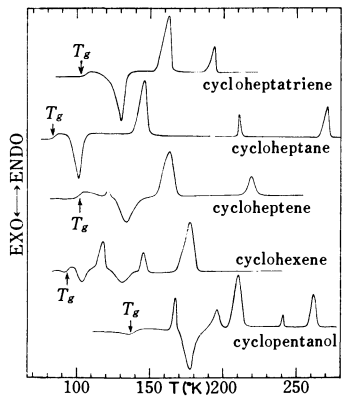
Keiichiro ADACHI, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received April 6, 1970)

In a previous paper,[1] we reported that the supercooled crystal-I (plastic crystal) of cyclohexanol showed in its heat capacity curve an anomalous jump resembling that associated with ordinary glass transition. From heat capacity data we establsihed the existence of the residual entropy for this supercooled plastic crystalline phase and also found the relaxation effect at this anomalous region. Based upon these findings we have proposed a new term "**Glassy Crystal**" for this supercooled non-equilibrium state. In the present paper we should like to report several new examples of the glassy crystal found by using differential thermal analysis method. They are 2,3-dimethylbutane, cycloheptanol, cycloheptatriene, cycloheptane, cycloheptene, cyclohexene and cyclopentanol. Among them, 2,3-dimethylbutane and cycloheptanol have been investigated in detail by measuring their heat capacities, the results of which will be reported elsewhere.

Cycloheptatriene was synthesized by photochemical reaction of benzene with diazomethane. Its purification was carried out by fractional and vacuum distillation. Cycloheptane was prepared by the catalytic hydrogenation of cycloheptatriene with use of Raney nickel. Cycloheptene was synthesized by dehydration of cycloheptanol. Cyclopentanol was obtained from the Tokyo Kasei Co. LTD. Cyclohexene was obtained from the Nakarai Chemicals LTD. Both cyclopentanol and cyclohexene were purified by means of vacuum distillation. The apparatus employed was reported previously.[2] The specimens were transferred by vacuum distillation in the sample containers. The results are shown in the figure. Measurements were performed with heating rate about 1°K min^{-1} after the plastic phases of the specimens had been supercooled down to 77°K with cooling rate of about 3°K sec^{-1}. In the cases of cycloheptatriene and cycloheptane, direct irreversible transition was observed from the supercooled plastic crystalline phase to the most stable crystalline phase just above the glass transition temperature. Cyclopentanol and cyclohexene, however, transform irreversibly and indirectly to the most stable low temperature phase by passing through the intermediate metastable crystalline states. This phenomenon may be explained by the so-called Ostwalrd's step rule. The measurements of the heat capacities of cyclohexanol, 2,3-dimethylbutane and cycloheptanol also show a similar behavior.



D.T.A. curves of quenched plastic crystals

TABLE

Sample	T_g (°K)	T_t (°K)	T_g/T_t
Cycloheptatriene	106	153	0.69
Cycloheptane	84	135	0.61
Cycloheptene	100	153	0.65
Cyclohexene	92	140	0.65
Cycloheptanol	135	258	0.52
Cyclohexanol	150	265	0.57
Cyclopentanol	138	201	0.69
2,3-Dimethylbutane	76	136	0.55
cis-1,2-Dimethyl-cyclohexane[3]	94	173	0.54

All the glass transition points of glassy crystals known hitherto are listed in the accompanying table where the values of the ratio of T_g to T_t (transition point from the low-temperature phase to the plastic crystalline phase) are also given. It is found that the ratio has the value 0.5—0.7 and this fact corresponds to the empirical rule known for the ordinary glass where the ratio of T_g to T_m (melting point) amounts to 0.5—0.7.

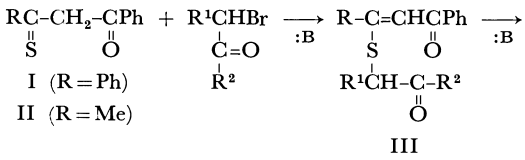
A New Synthesis of Thiophenes

Masaaki TAKAKU, Yosio HAYASI and Hitosi NOZAKI*1

Department of Industrial Chemistry, Kyoto University, Kyoto

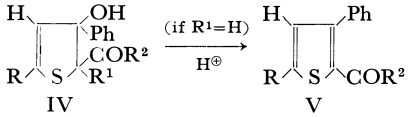
(Received April 13, 1970)

A new route to thiophenes from 2-thiocarbonylenamines and α-bromocarbonyl compounds was reported recently.[1] In an exploration of the reactions of readily available monothio-β-diketones,[2] we eventually found an analogous way to thiophenes as outlined below. This seems to be easier and more versatile than the published methods. Physical data of products obtained (III—V) are listed in Table 1.



I (R=Ph)
II (R=Me)

III



IV V

a: R=Ph, R^1=H, R^2=Ph
b: R=Ph, R^1=H, R^2=OEt
c: R=Ph, R^1=Ph, R^2=OEt
d: R=Me, R^1=H, R^2=Ph

A mixture of α-(thiobenzoyl)acetophenone (I, 5.0 mmol) and phenacyl bromide (5.0 mmol) dissolved in benzene (30 m*l*) was treated with triethylamine (15.0 mmol) at room temperature for 1 hr. Addition of water followed by extraction with benzene gave IVa in a quantitative yield. A solution of IVa (1.40 mmol) and concentrated hydrochloric acid (0.5 m*l*) in methanol (50 m*l*) was heated to reflux for 30 min and extracted with benzene to afford Va quantitatively. An S-alkylated compound IIIb (70%) was isolated in the reaction of I with ethyl bromoacetate under the same condition. In contrast, however, the use of sodium hydride (10.0 mmol) suspended in benzene (50 m*l*) in place of triethylamine yielded a cyclization product IVb (50%), whose treatment with hydrochloric acid gave Vb quantitatively.

S-alkylated products IIIc and IIId were isolated also in triethylamine-treatment of a mixture of I and ethyl α-bromophenylacetate and that of α-(thioacetyl)acetophenone (II) and phenacyl bromide in 55% and 54% yield, respectively. These are easily cyclized by more basic reagents. Treatment of IIIc (1.25 mmol) with sodium ethoxide (4.4 mmol) in ethanol (50 m*l*) at room temperature for 3 hr gave a dihydrothiophene IVc (42%), whereas that of IIId (5.0 mmol) with sodium hydroxide (10.0 mmol) in water (2.0 m*l*) and ethanol (50 m*l*) mixture yielded a thiophene Vd (60%).

The IR spectra of IIIb, IIIc and IIId showed characteristic two bands at *ca.* 1640 and 1530 cm^{-1}, which would reasonably be ascribed to the mesomeric group  . The R^1–CH–CO–R^2 group exhibited normal absorption.

TABLE 1. MPS AND SPECTRAL PROPERTIES OF NEW COMPOUNDS[a]

Compd	Mp °C	IR[b] cm^{-1}	NMR δ ppm from TMS in $CDCl_3$

Thermal Decomposition of Dibenziodolium Halides. Evidence for a Homolytic Pathway[1]

Takeo SATO, Shigeru SHIMADA, Kuniaki SHIMIZU and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received April 16, 1970)

The thermal decomposition of dibenziodolium iodides, such as **1**/I;*1 is an efficient way of preparing 2,2′-diiodobiphenyls.[2,3] Recently, Heaney and Lees[4] reported that the thermal decomposition of dibenziodolium chloride (**1**/Cl) gave 2-chloro-2′-iodobiphenyl as the sole product. We obtained, however, conflicting results which led us to examine a series of dibenziodolium halides (**1**) in details. We here present our findings which are in accord with a radical mechanism.

Contrary to the former report by Heaney and Lees[4] the decomposition of **1**/Cl[5] at 295°C was found to produce a mixture of five halogenobiphenyls as analysed by gas chromatography using XE-60 silicone gum rubber on Chromosorb W column. They were 2-chloro-, 2,2′-dichloro-, 2-iodo-, 2-chloro-2′-iodo-, and 2,2′-diiodobiphenyls (in the order of the retention time), among which three dihalogenobiphenyls constituted major portions (Table 1). The decomposition of bromide **1**/Br occurring at 290°C again afforded five halogenobiphenyls as shown in Table 1.

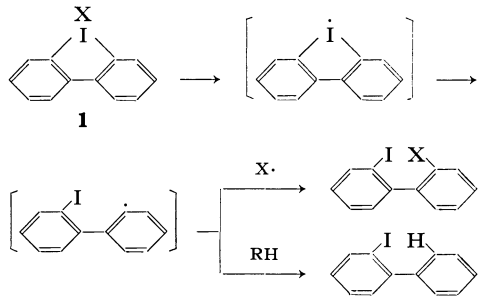
Iodide **1**/I decomposed at a lower temperature of 210°C producing 98% of 2,2′-diiodobiphenyl and 2% of 2-iodobiphenyl, the ratio of which varied markedly when the reaction was performed in solvents. For example, 2-iodo- and 2,2′-diiodobiphenyls were formed in a ratio of 1 : 2 when **1**/I was heated in triethylene glycol at 240—245°C. A small amount of biphenyl was also produced. The decomposition of **1**/Cl and **1**/Br in the same solvent gave 2-iodobiphenyl even in higher yields, 77 and 60% respectively.

TABLE 1. DIHALOGENOBIPHENYLS FROM DIBENZIODOLIUM HALIDES (**1**)[a]

X	Temp. °C	Product ratio, % 2,2′-Di-X	2-X-2′-I	2,2′-Di-I	Total biphenyl yield, %
Cl	295	4	74	22	55[b]
Br	290	10	76	14	72[c]
I	210		98		84[d]

a) Reactions were carried out for 30 min in nitrogen. b, c, d) In addition, small amounts of 2-chloro-,[b] -bromo-,[c] and -iodobiphenyls[b,c,d] were detected.

Need for high temperatures and the formation of disproportionation and hydrogen transfer products suggest that these decomposition reactions are best interpreted as a radical mechanism. Increasing temperatures for decomposition as going from **1**/I to **1**/Cl seem to reflect increasing bond energies of halogen-iodine bondings. The main route of the reaction leading to 2-halogeno-2′-iodobiphenyl as well as 2-iodobiphenyl is explained in the following way.



To account for the formation of dichloro-, dibromo-, and diiodobiphenyls one must postulate the cleavage of both of the carbon-iodine bonds as a minor process.[6,7] Such a cleavage was further indicated by the reaction of **1**/I in dimethyl acetylenedicarboxylate, which afforded the expected adduct, dimethyl 9,10-phenanthrenedicarboxylate, mp 127—128°C,[8] as one of the products.

Selective *cis* Hydrogenation of *o*-Xylene and 1,2-Dimethylcyclohexene over Osmium and Iridium Catalysts

Shigeo NISHIMURA, Fuminobu MOCHIZUKI and Shigenori KOBAYAKAWA

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei-shi, Tokyo

(Received April 18, 1970)

Detailed studies by Siegel and his coworkers[1] on the stereochemistry of hydrogenation of isomeric xylenes and their tetrahydro derivatives indicated that a considerable amount of *trans* isomer was contained in the products from hydrogenation of isomeric xylenes with Adams platinum catalyst and also that desorption of the tetrahydro derivatives from the catalyst surface would be responsible for the formation of the *trans* isomer. Actually, the presence of such desorbed intermediates in the hydrogenation products has later been observed by Hartog and Zwietering[2] with nickel, rhodium and ruthenium catalysts and also by Siegel *et al.*[3] with platinum and rhodium catalysts.

The *trans* isomer was also formed in a considerable amount (18.2% at 25°C under 1 atm in acetic acid) in the platinum-catalyzed hydrogenation of 1,2-dimethylcyclohexene[4] which is expected to yield only *cis*-1,2-dimethylcyclohexane by simple *cis* addition of hydrogen.

In the study of the stereochemistry of hydrogenation of *o*-xylene and its tetrahydro derivatives with other platinum metals, it has been found that hydrogenation of *o*-xylene and 1,2-dimethylcyclohexene with osmium and iridium catalysts yield *cis*-1,2-dimethylcyclohexane with high stereospecificity. Thus, formation of the *trans* isomer was only 3.2 and 1.4% when *o*-xylene was hydrogenated over osmium and iridium catalysts in isopropyl alcohol at 25°C under one atmosphere of hydrogen.[5] The *trans* isomer was formed even in a smaller amount in the hydrogenation of 1,2-dimethylcyclohexene (1.9 and 1.3% in isopropyl alcohol and 1.4 and 1.1% in *t*-butyl alcohol, respectively with osmium and iridium metals). It is to be noted that formation of the *trans* isomer (15.0 and 17.6%) in hydrogenation of 2,3-dimethylcyclohexene with osmium and iridium catalysts as much as with the other platinum metals. Hydrogenation of *m*- and *p*-xylene with osmium and iridium catalysts also gave the *trans* isomer in a much smaller amount than with other platinum metals (9.6 and 10.3% for *m*-xylene; 18.3 and 11.1% for *p*-xylene), although the hydrogenation was less stereospecific than in the case of *o*-xylene.

The selective-formation of *cis*-1,2-dimethylcyclohexane from *o*-xylene may be explained either by selective formation of 1,2-dimethylcyclohexene as the intermediate or by only slight desorption of the intermediate 2,3-dimethylcyclohexene from the catalyst surface. The maximum amounts of 1,2- and 2,3-dimethylcyclohexene in the reaction mixture during the course of the hydrogenation over iridium were only 0.3 and 0.02%, respectively.[6] Only a slight extent of the desorption of 2,3-dimethylcyclohexene formed on the catalyst surface will explain the selective formation of *cis* isomer. The results seem to indicate that the *cis* addition of hydrogen to unsaturated hydrocarbons during a single period of residence on the catalyst surface may largely occur over osmium and iridium catalysts.[7]

The catalyst metals used in this study were prepared by the reduction of corresponding metal hydroxides (Ru, Rh, Ir) or metal oxides (Os) in water followed by a thorough washing with distilled water.

6) The maximum amounts of 1,2- and 2,3-dimethylcyclohexene in hydrogenation of *o*-xylene were 3.9 and 1.0% over ruthenium catalyst and 0.84 and 0.18% over rhodium catalyst. *Cf.* Refs. 2 and 3.

7) It was reported that only 2% of *trans*-decalin was formed in deuteration of $\Delta^{9,10}$-octalin with an iridium-carbon catalyst at 25°C under 360 to 400 psig deuterium, while hydrogenation of tetralin with the same catalyst gave 7.5% of *trans*-decalin at 25°C under 1000 psig hydrogen [A. W. Weitkamp, *Advan. Catal.*, **18**, 1 (1968)].

The Reaction of 8-Cyanoheptafulvene with Benzyne

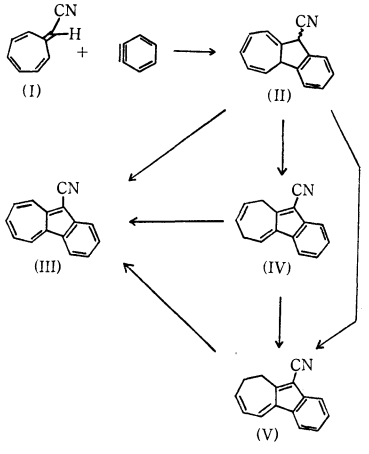
Masaji ODA and Yoshio KITAHARA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received April 25, 1970)

Heptafulvene and 8-monosubstituted heptafulvenes[1-3] undergo 8+2 cycloadditions when dimethyl acetylenedicarboxylate is used as a dienophile leading to azulene derivatives. We wish now to report a similar cycloaddition of 8-cyanoheptafulvene (I) using benzyne.

The refluxing of (I) and benzenediazonium-2-carboxylate[4] (1.2 equiv.) in methylene chloride for 70 min yielded a 1 : 1 addition product (II) in a 36% yield (based on 22% recovered I) on separation by silica-gel chromatography. Although the stereochemistry at C-3 is not yet certain, the sturcture was proved to be a 1,8-cycloaddition product, 1,2-benzo-3-cyano-3,9-dihydroazulene, from the following spectral and chemical evidence; *m/e* 205(M^+); ν_{max} (film) 3050 (w), 3020 (w), 2250 (w), 1610 (w), 750 (s) and 715 (s) cm^{-1}; λ_{max} (cyclohexane)251 (sh, log ε 3.75), 258 (3.80) and 265 nm (sh, 3.76); τ (CCl_4, TMS) 2.50—2.90 (m, 4H, aromatic), 3.38 (m, 3H, H-4~6), 3.85 (m, 1H, H-7), 4.87 (dd, J=9.5 and 4.0 Hz, 1H, H-8), 4.98 (br. s., 1H, H-3) and 6.41 (br., 1H, H-9). On dehydrogenation with *o*-chloranil (refluxing benzene, 15 min), II gave



1,2-benzo-3-cyanoazulene[5] (III), (mp 153—154°C) in a 63% yield.

Compound II is liable to be isomerized to more conjugated systems by the presence of an active hydrogen at C-3. Therefore, on delayed elution from a silica-gel column, II suffered double-bond migration to give mainly 1,2-benzo-3-cyano-4,7-dihydroazulene (IV) as yellow prisms; mp 88—89°C; ν_{max} (KBr), 3040 (w), 2225 (m), 1629 (m) 1603 (w), 1557 (w), 762 (s) 733 (m) and 710 (m) cm^{-1}; λ_{max} (EtOH) 267 (log ε 4.30), 328 (3.71) and 372 nm (sh 3.45); τ (CCl_4, TMS) 2.50—3.00 (m, 5H, aromatic and H-8), 4.06 (m, 2H, H-5 and H-6), 6.51 (d-like, 4.0 Hz, 2H, H-4a and 4b) and 6.85 (t-like, 2H, H-7a and 7b). The IR and NMR spectra indicate the presence of a conjugated cyano group, an isolated double bond (from the chemical shifts and the pattern of the signals), and two kinds of doubly-allylic methylene groups. As is to be expected from the structure of IV, on treatment with triethylamine it suffered further migration of the double bond to give, quantitatively, the most conjugated isomer, 1,2-benzo-3-cyano-4,5-dihydroazulene (V), as orange needles; mp 69—70°C; ν_{max} (KBr) 3050 (w), 3010 (w), 2220 (m), 1632 (w), 1603 (w), 1577 (m), 1551 (m), 768 (s), 759 (s), 729 (s) and 710 (s) cm^{-1}; λ_{max} (EtOH) 216 (log ε 4.42), 259 (4.00), 2.66 (3.97), 295 (3.70) and 377 nm (3.95); τ (CCl_4, TMS) 2.50—3.10 (m, 5H, aromatic and H-8), 3.75 (m, 2H, H-6 and H-7), 7.10 (m, 2H, H-4a and 4b) and 7.58 (m, 2H, H-5a and 5b). In the NMR spectrum, two methylene groups, at C-4 and C-5, are assigned as above by the double resonance technique, the former being affected paramagnetically by the cyano group. Compound (V) was also rightly obtained from II with triethylamine. The dehydrogenation of IV and V also gave III; this fact further supports the above assignments.

Thus, in contrast to the results with tropone,[6] compound (I) afforded exclusively an 8+2 cycloadduct (II), and no trace of a 4+2 cycloadduct.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1921—1926 (1970)

Calculation of the Chemical Shifts by the Semi-empirical SCF MO Method for All Valence-elctron Systems

Hajime KATÔ,*1 Hiroshi KATO*2 and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 26, 1969)

The proton chemical shifts in the nuclear magnetic resonance spectra of CH_4, C_2H_6, C_2H_4, H_2CO, pyridine, and protonated pyridine were evaluated on the basis of Pople's theory (*J. Chem. Phys.*, **37**, 53 (1962)) in which the shielding tensor is expressed in terms of the magnetic susceptibility of each atom in the molecule. The wave functions were obtained using a semi-empirical SCF MO method for valence-electron systems (*Bull. Chem. Soc. Jap.*, **40**, 536, 1017 (1967)). The ^{13}C- and ^{14}N- chemical shifts in the above compounds were calculated on the basis of the "Coupled Hartree-Fock perturbation theory."

The general expression of the nuclear magnetic shielding constant for an isolated molecule was first derived by Ramsey,[1] but Ramsey's formula is not suitable for the fractional calculation of the shielding constants of large molecules. A variety of methods for the calculation of chemical shifts in molecules have been developed, such as breaking up the total shielding constants into the local contributions in some manner.[2-5] On the other hand, an attempt has been made to relate the shielding constants to other molecular properties, such as the dipole moment,[6] the electronegativities of the substituent group,[7] and the magnetic anisotropy of the bond.[8,9]

For proton shifts, an empirical correlation between the shift and the π-electron density on the atom to which it is bonded has been advocated.[10] On the other hand, more theoretical calculations have been carried out by many authors.[11] Of these, Pople[12] has proposed a formulation for the shielding constant in which a dipole approximation is used and the shielding constant is expressed in terms of the atomic contributions to the magnetic susceptibility. Although Musher[13] has given a critical discussion of a dipole approximation, it seemed that it would be of interest to calculate the shielding constant by Pople's formula. The critical discussion is based on the calculation of the Lamb term for an electron in an s or a p state using Slater atomic wave functions. In Pople's formula, the molecular orbitals are written as linear combinations of gauge-invariant atomic orbitals. It is uncertain whether or not the critical discussion is useful for the calculation based on Pople's formula. The calculation requires the knowledge of the ground-state wave function and those of the excited states. In many cases of the practical calculations, because of the lack of the knowledge of excited-state wave functions, an approximation was made.

We used the wave function obtained by a semi-empirical SCF LCAO MO method for all valence-electron system.[14] We calculated the proton chemical shifts for CH_4, C_2H_6 C_2H_4, and H_2CO without using the "mean excitation energy approximation" (ΔE approximation) used in Pople's theory. For pyridine and protonated pyridine, the calculation needs so many excitation energies that we used the ΔE approximation; some discussions of the approximation will be made.

For the investigation of ^{13}C and ^{14}N chemical shifts in the above compounds for which it is easy

to carry out more rigorous calculation, the "Coupled Hartree-Fock perturbation thery"[15] without the ΔE approximation is applied.

Calculation

Using a dipole approximation, the mean value of the shielding tensor on the A atom has previously been given.[12]

$$\sigma^{A} = \frac{e^2}{3mc^2}\sum_{\mu}^{A} P_{\mu\mu}\langle r^{-1}\rangle_{\mu\mu} - \frac{2}{N}\langle r^{-3}\rangle_{A}\chi_{P}^{A} - \frac{1}{3N}\sum_{\alpha\beta}\sum_{B(\neq A)}\chi_{\alpha\beta}^{B}R_{B}^{-5}(R_{B}^{2}\delta_{\alpha\beta} - 3R_{B\alpha}R_{B\beta}) \quad (1)$$

$$P_{\mu\nu} = 2\sum_{i}^{occ} C_{i\mu}C_{i\nu} \quad (2)$$

$$\chi_{P}^{A} = \{(\chi_{P}^{A})_{xx} + (\chi_{P}^{A})_{yy} + (\chi_{P}^{A})_{zz}\}/3 \quad (3)$$

The first term in Eq. (1) gives the Lamb term,[16] and $\langle r^{-3}\rangle_{A}$ in the second term is the mean value of r^{-3} for the atomic orbital which contributes to paramagnetic terms on the A atom, but this term becomes zero in the calculation of the proton chemical shifts so long as the valence AO approximation is adopted. The third term, which gives the effect of currents on neighboring atoms, is divided into two terms (these two terms we shall henceforth call "the neighboring paramagnetic term" and "the neighboring diamagnetic term"). $\boldsymbol{R}_{B}$ is the radium vector to the B nucleus from the A nucleus, at which the shielding is calculated. The $R_{B\alpha}$ notation, is the $\alpha(x,y,z)$ component of the $\boldsymbol{R}_{B}$ vector, and $(\chi_{P}^{A})_{XX}$ is the diagonal x component of the paramagnetic susceptibility tensor of the A atom. In the above formula,

$$\chi_{\alpha\beta}^{B} = (\chi_{d}^{B})_{\alpha\beta} - (\chi_{P}^{B})_{\alpha\beta} \quad (4)$$

$$(\chi_{d}^{B})_{\alpha\beta} = -\frac{Ne^2}{4mc^2}\sum_{\mu}^{B} P_{\mu\mu}\langle r^2\delta_{\alpha\beta} - r_{\alpha}r_{\beta}\rangle_{\mu\mu} \quad (5)$$

$$(\chi_{P}^{B})_{\alpha\beta} = \frac{Ne^2\hbar^2}{m^2c^2}\sum_{i}^{occ}\sum_{j}^{unocc}\sum_{\mu<\nu}^{B}\sum_{A}\sum_{\lambda<\sigma}^{A} \times \frac{(C_{i\mu}C_{j\nu} - C_{i\nu}C_{j\mu})(C_{i\lambda}C_{j\sigma} - C_{i\sigma}C_{j\lambda})(l_{\alpha})_{\mu\nu}(l_{\beta})_{\lambda\sigma}}{E_{i\to j}} \quad (6)$$

where $E_{i\to j}$ is the excitation energy of the electronic transition from the ith molecular orbital to the jth molecular orbital. The other notations are the same as in Ref. 12.

Using Eqs. (1)—(6), we calculated the proton chemical shifts of CH_4, C_2H_6, C_2H_4 and H_2CO (Table 1). The coordinate axes, the x, y, and z axes, were taken on the mirror-reflection plane of these molecules. Therefore, the susceptibility tensor has nonzero values only for the diagonal elements for the sake of simplicity in calculation. (For this proof, see the appendix.) However, in the cases of pyridine and protonated pyridine (Fig. 1), according to the reason stated in the appendix, the coordinate axes chosen as has been described above do not coincide with the principal axes of the magnetic susceptibility tensor on 2C, 3C, 5C, and 6C atoms. Using the ΔE approximation, the elements of the paramagnetic susceptibility tensor in Eq. (6) are written as follows:

$$(\chi_{P}^{B})_{xx} = \frac{Ne^2\hbar^2}{m^2c^2\Delta E}\sum_{A}\sum_{i}^{occ}\sum_{j}^{unocc}(C_{iyB}C_{jzB} - C_{izB}C_{jyB}) \times (C_{iyA}C_{jzA} - C_{izA}C_{jyA}) \quad (7)$$

$$(\chi_{\mathrm{P}}^{\mathrm{B}})_{yz} = -\frac{Ne^2\hbar^2}{m^2c^2\Delta E}\sum_{\mathrm{A}}\sum_{i}^{\mathrm{occ}}\sum_{j}^{\mathrm{unocc}}(C_{iz\mathrm{B}}C_{jx\mathrm{B}} - C_{ix\mathrm{B}}C_{jz\mathrm{B}})\times (C_{iy\mathrm{A}}C_{jz\mathrm{A}} - C_{iz\mathrm{A}}C_{jy\mathrm{A}}) \quad (8)$$

etc.

If the off-diagonal elements, $(\chi_{\mathrm{P}}^{\mathrm{B}})_{\alpha\beta}$'s are all zero, *i.e.*, if the coordinate axes are taken to be the principal axes and the summation over the A atom in the diagonal element of $(\chi_{\mathrm{P}}^{\mathrm{B}})_{\alpha\beta}$ is limited only over the B atom, the neighbouring paramagnetic constant part of Eq. (1) becomes equal to the term due to the local paramagnetic currents[5] in the shielding constant derived by the induced-current-density theory.[4]

On the basis of the relations of Eqs. (5)—(8), we have calculated the diamagnetic and paramagnetic susceptibility tensors, $\chi_{\mathrm{d}}^{\mathrm{B}}$ and $\chi_{\mathrm{P}}^{\mathrm{B}}$, on the B atom in pyridine and protonated pyridine (Tables 2, and 3, and Table 4 respectively). Using these results and Eq. (1), the proton-shielding constants of pyridine and protonated pyridine

have been calculated to be as is shown in Table 5. In the ΔE approximation, ΔE was taken to be 10.0 eV.

The ^{13}C- and N^{14}-chemical shifts are calculated by the formula based on the "Coupled Hartree-Fock perturbation theory." The expressions for the diagonal component (μ is x, y, or z) of the paramagnetic and diamagnetic shielding tensors, $\sigma^{p}_{\mu\mu}$ and $\sigma^{d}_{\mu\mu}$, are given as follows:[15)]

$$\sigma^{p}_{\mu\mu} = -\alpha^2 \sum_{i}^{occ} \sum_{k}^{unocc} \times \frac{\langle\varphi_k|l_\mu|\varphi_j\rangle\langle\varphi_j|\frac{l_\mu}{r^3}|\varphi_k\rangle + \langle\varphi_j|l_\mu|\varphi_k\rangle\langle\varphi_k|\frac{l_\mu}{r^3}|\varphi_j\rangle}{\varepsilon_k - \varepsilon_j - J_{kj} + K_{kj}} \tag{9}$$

$$\sigma^{d}_{\mu\mu} = \alpha^2 \sum_{j}^{occ} \langle\varphi_j|\frac{r^2-\mu^2}{r^3}|\varphi_j\rangle \tag{10}$$

where α is the fine-structure constant and where φ_j is the jth MO. The other notations are the same as those in Ref. (23). In these ^{13}C- and ^{14}N-chemical shift calculations, only one-center terms in the matrix elements, such as $\langle\varphi_k|l_\mu|\varphi_j\rangle$, $\langle\varphi_j|l_\mu/r^3|\varphi_k\rangle$, and $\langle\varphi_j|1/r|\varphi_j\rangle$, in Eq. (9) and Eq. (10) are taken into account.

Results and Discussion

Table 1 gives the calculated and experimental proton chemical shifts, referred to CH_4 and their components, such as the Lamb term, the neighbouring diamag. term, and the paramag. term, for CH_4, C_2H_4, and H_2CO. It can be pointed out that the chemical shift of C_2H_2 comes mainly, and equally, from the Lamb term and the neighbouring paramagnetic term, while that of C_2H_4 is governed by the neighbouring paramagnetic term. In these molecules, the contribution from the field effect[6,17)] is nearly equal to zero. However, this effect arising from the electric dipole of the C–O group plays an important role, as may be seen in Table 1. For these compounds, the calculated results are in good agreement with the experimental values.

In order to investigate the practical difference between the two theories proposed by Pople in Ref. 12 and Ref. 5, further calculations were carried out for pyridine and protonated pyridine.

The calculated components of the diamagnetic susceptibility tensor, χ^{B}_{d}, and the paramagnetic susceptibility tensor, χ^{B}_{p}, on the carbon and nitrogen atoms in pyridine and protonated pyridine are shown in Tables 2, 3, and 4; $(\chi^{N}_{p})_{zz}$ shows a remarkable change from pyridine to protonated pyridine, in contrast to the conclusion of the localized-model calculations by Gil and Murrell.[18)] In the present calculation of the shielding constants, we have considered the contribution of the off-diagonal elements of the paramagnetic susceptibility tensor and found that these elements can not be ignored. This is because the exclusion of these elements leads to the dependence of the shielding constant on the choice of the coordinate.[19)] The coordinate system for pyridine and protonated pyridine in Fig. 1 does not accord with the principal axes of the magnetic susceptibility tensor on 2C, 3C, 5C, and 6V atoms. In this choice of the coordinate, the off-diagonal elements of the paramagnetic susceptibility tensor are only about 20% of the diagonal elements, but the contribution to the shielding constant through the third term in Eq. (1) is very important. For example, the contribution of the $(\chi^{C}_{p})_{yz}=0.866\gamma$ and $(\chi^{C}_{p})_{xy}=$

18) Y. M. S. Gil and J. N. Murrell, *Trans. Faraday Soc.*, **60**, 248 (1964).

19) H. Kato, H. Kato and T. Yonezawa, *Spect. Lett.*, **2(9)**, 267 (1969).

0.873γ (γ is a constant, see Table 4) in pyridine to the shielding constant through the neighboring paramagnetic term is -0.422 ppm, 2.985 ppm, and -0.191 ppm for αH, βH, and γH respectively. If we consider the change of the proton chemical shifts due to the field effect from the electric-charge distribution, the change of shifts due to this effect was calculated to be -0.259 ppm, -0.131 ppm, and -0.074 ppm for αH, βH, and γH, of pyridine and -0.034 ppm -0.017 ppm, -0.010 ppm, and -0.147 ppm for αH, βH, γH, and N–H of protonated pyridine respectively. In contradiction to the expreiment, the calculated shifts of γH (Table 5) in both pyridine and protonated pyridine show large shifts relative to βH. This discrepancy might be due to the difficulty involved in the MO treatment of lone-pair electrons or a non-negligible error in the dipole approximation. The relative shifts from pyridine to protonated pyridine (Table 5) are in fairly good accordance with the experimental results. In our calculation of the molecular orbitals, we have considered the interaction between the ($1s$) atomic orbital in the hydrogen atom and the (2ρ) atomic orbitals in the carbon or hygrogen atoms. Accordingly, the electric-field correction proposed by Musher,[20] which comes from the change in the local part of the Lamb contribution due to the change in the electron density, ρ^{H}, on the proton, is automatically included. Therefore, the electric-field effect due to the distortion of an spherically symmetric s state[6,17] is calculated by:

$$\sigma_{\parallel} = \frac{e^2}{3mc^2a}\left[1-\frac{439}{40}\frac{a^4E^2}{e^2}\right]$$
$$\sigma_{\perp} = \frac{e^2}{3mc^2a}\left[1-\frac{193}{15}\frac{a^4E^2}{e^2}\right] \quad (11)$$

The calculated carbon-13 chemical shifts in CH_4, C_2H_6, C_2H_4, and H_2CO which are obtained by the "Coupled Hartree Fock Method" are shown

in Table 6. The calculated values of the ^{13}C-chemical shifts, ($\delta^{13}C$), are also in fairly good agreement with the experimental values, except in the case of H_2CO. If we consider the change in the Slater exponent caused by the atomic charges in the evaluation of $\langle r^{-3}\rangle$,[21] the calculated $\delta^{13}C$ in CH_4, C_2H_6, C_2H_4, and H_2CO become −101.3 ppm, −108.2 ppm, −208.5 ppm, and −202.3 ppm respectively. The ^{13}C- and ^{14}N-chemical shifts in pyridine and protonated pyridine are shown in Table 7. The values are mainly determined by the paramagnetic term. In the $\delta^{13}C$ in pyridine, the calculated value of the paramagnetic term from the lowest (n–π^*) state is −132.8 ppm, while in protonated pyridine the corresponding contribution is −71.5 ppm. This difference corresponds to about 50% of the total difference. Table 8 shows how each excited state contributes to the paramagnetic terms in C_2H_4, as an example. The lowest excited state (5σ, $7\pi^*$) shows the largest contribution at δC^{13}. Moreover, the (6σ, $9\pi^*$) state, which needs a much larger excitation energy, shows a contribution almost comparable to that of the (5σ, $7\pi^*$) state; there are also several states which show the contribution of the same order as the (5σ, $7\pi^*$) states. In the other compounds, the same situations are found. Accordingly, it cannot be said generally that a particular state governs the chemical shift. In the present paper, we have considered only one-center terms, but it will be necessary, as a further improvement, to include two-center terms at least, as well as to refine the MO calculation. The MO calculation was carried out on a HITAC 5020E computer at the computation center of the University of Tokyo.

Appendix

The susceptibility tensor, χ_M, on the M atom is a second-rank tensor:

$$\chi_M = \begin{pmatrix} \chi_{xx} & \chi_{yx} & \chi_{zx} \\ \chi_{xy} & \chi_{yy} & \chi_{zy} \\ \chi_{xz} & \chi_{yz} & \chi_{zz} \end{pmatrix}$$

If the M atom in a molecule lies on a mirror-reflection plane on the xy-plane, χ_M must satisfy the following relation:

$$\chi_M = s_h^z \chi_M {}^t s_h^z$$

where $s_h^z = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}$ *i. e.*, the matrix representation corresponding to the mirror-reflection operator. Accordingly, χ_M is as follows:

$$\chi_M = \begin{pmatrix} \chi_{xx} & \chi_{yx} & 0 \\ \chi_{xy} & \chi_{yy} & 0 \\ 0 & 0 & \chi_{zz} \end{pmatrix}$$

Further, if the M atom also lies on an other mirror reflection plane, the xz or yz plane, the susceptibility tensor should have nonzero values only for the diagonal elements.
