(Received October 11, 1969)

The ozone formation reactions in the silent electric discharge starting from oxygen under atmospheric pressure and varied electric conditions were investigated. The results were found to be in line with the theory based on the postulates of reactional and electrical pattern, proposed earlier by authors. The reaction regime in discharge columns where the main reactions proceed is unusual. The duration of high frequency discharge which initiates the primary reactions is extremely short compared to the apparent duration of discharge of basic primary current. Thus, in the discharge columns a non-steady reaction regime is established. A rate theory is developed for the processes in silent discharge based on a non-steady state assumption, which is acceptable in view of the experimental results. The proposed pattern of processes is useful for obtaining more detailed mechanism of the reaction involved.

Ozone formation in silent electric discharge has been a richly productive research project[1,2] for many years both from pure chemical and technical, as well as electrical viewpoints. Nevertheless, several points in the reaction mechanism, above all the dependence of the reactions on electrical processes, still remain unclarified.

The authors have tried to explain the experimental results without using a steady state assumption. It does not seem appropriate to apply this assumption to the silent discharge reaction regime of the present type, which is remarkably different from ordinary gas phase reactions.

The earlier proposed postulate is briefly summarized below.

1. The primary reaction is initiated by electrons in a high frequency electric field established by discharge due to the applied base potential of a low frequency current of 50 Hz of city source[1].

2. The rate of initiation reaction is proportional to the electric quantity, or the number of electrons, passing through the discharge space during a certain period, such as half cycle of low frequency current.

3. The discharge essentially takes place through numerous tiny columns strewn across the entire discharge space which are perpendicular to both electrode surfaces. In other words, the discharge space between the electrodes is divided into two regions,; one, the discharge columns through which displacement currents flow, and the other, the discharge free zone which is essentially free from electrons during and also after discharge.[1]

4. The number of discharge columns which are visibly observable, for instance, on photographic plates eventually serving as alternates of electrodes, is proportional to the total displacement current passing through the discharge columns under similar conditions.[1]

5. The sites of initiation reaction are then the space within the discharge columns, and further reactions will proceed either in discharge columns exclusively, or both in discharge columns and in discharge free zone according to the nature of individual chemical reactions and to the surrounding and ambient conditions.

Experimental

1. The device for the electric discharge and the flow system for the reactions were essentially similar to those described.[1] The block diagram and specifications are given in Fig. 1.

The discharge vessel or the ozonizer used was of a plate type (Fig. 2). The area of electrode, viz., the area of the copper foil pasted outside both electrodes which face each other parallel and congruently, was 37.5 cm^2, and the space gap between the electrodes was 1.25 mm for almost all runs. The pressure was maintained at 1 atm. in the ozonizer.

The reactions were highly sensitive to the chemistry and geometry of the reaction system as well as to electricity, which sometimes showed poor reproducibility of the measurements. Thus, the physical conditions, such as electrode material, thickness, nature of elec-

trode surface, and the geometry of the experimental details or individual measurement gadgets, were kept as consistent as possible in order to eliminate cumber.

2. An optical method was employed for analysis of the produced ozone. The ozone concentration in down stream gas mixture was automatically recorded, while the absorption of 2540 Å line of ozone was continuously measured by a spectrophotometer, Hitachi EPU 2A Type, combined with a micro recorder, Hitachi QPD 33 Type. Validity of the recording scale was calibrated using the values of chemical analysis, which was found to be within 0.1% error.

3. The high frequency displacement current was sometimes unsteady and inreproducible. The electrical items involved in the measuring system were controlled with contingent precautions for each series of runs.

The high tension voltage (V) applied to the discharge system was measured by a static voltmeter (Fig. 1). The indicated values on the voltmeter gave the values of electric potential with which the condenser system (Cs and OZ in Fig. 1) should be charged. The actual field strength along the discharge path during the high frequency discharge is not yet clearly known, but some useful informations are available. The relations among various electrical quantities, such as the values of applied potential on individual condenser and the quantity of electricity were extensively discussed by Miura and Kawai.[3] This was of help in the estimation of various electric quantities from directly measured values, in spite of little knowledge of the field strength in the discharge columns.

The quantity of electricity (Q) transferred through the electrodes during a half cycle of primary base current governs the processes of chemical reactions, above all the initiation reactions originated in discharge columns.

The length of each hair[1] *i.e.* the pulse current on an oscillogram monitor of a half cycle of 50 Hz base current (Fig. 8) represents the high frequency current passing through discharge columns. From the summation of the lengths of these individual hairs the value of Q could be estimated.[1,3]

A synchroscope Iwasaki SS-5004 was used for the monitoring of discharge patterns. The indicated scale values on the gadget were taken to be valid.

Specifications of the electrical equipments were checked to ensure elimination of any possible irreproducibilities. Air or oxygen was used in the streaming gas mixture, though in the present investigation air was almost entirely used, because the theoretical treatment did not differ much for the two gas mixtures.

Results

1. Relation between the Applied Voltage and the Quantity of Electricity. The quantity of electricity carried through parallel plate electrodes is a linear function of the applied voltage on the electrodes. The slope of a straight line

related to both quantities is governed virtually by the value of the electric constants of the discharge circuit. Such relations were obtained for a wide range of flow velocity variations. The results are shown in Fig. 3.

2. Ozone Formation and Electrical Quantities. The results obtained are summarized in Table 1. In Fig. 4 the concentrations of ozone [O_3] (10^{-3} g l^{-1}) in the exit gas mixture from the discharge vessel are shown against the quantity of electricity Q (10^{-7} coulombs during a half cycle of base current) for various flow velocities F(cm³ sec^{-1}). The slopes of straight lines in sequence, each of which refers to a certain flow velocity, increase almost in proportion to the decrease of the flow velocity. The relation shows that the final ozone concentration after passing through the successive discharge columns is virtually inversely proportional to the flow velocity. The quantity $F\times$[O_3], which is in turn the ozone yield Y (10^{-6} g sec^{-1}) *vs.* Q should be expressed then as a single straight line irrespective of the flow velocities, which vary to as much as ten times (Fig. 5).

In Fig. 6 similar lines for O_3 *vs.* V are shown.

The features of the lines are similar to those on Fig. 4, which is conceivable from Fig. 3.

3. Flow Velocities and Ozone Yields. The ozone concentration $[O_3]$ is inversely proportional to F as shown in Fig. 7. The diagrams are examples picked up from Table 1. The relations hold within the range given in Table 1.

Discussion

1. Electrical Pattern in Discharge Columns. In the course of ozone formation, the initiating primary step is involved in collisions between oxygen molecules and electrons. The paths of electrons are confined in discharge columns strewn across the discharge space between the two electrodes. Such columns which connect both electrodes electrically could be considered as channels solely through which electrons travel.

Neither the shape of cross sections of the channels which may be circular, nor their area which may be consistent along the channel from one electrode to the other, is known definitely, though it is almost certain that the channels are perpendicular to both electrode surfaces.

On the other hand, it is known that from the image of discharge columns on a photographic plate which served as a substitute of an electrode, the size of images of each column were found to be fairly equal.[1] The linear dimension at the bottom of columns was less than 1 mm. As the size of the columns is essentially governed by the number of electrons travelling through them, the number of electrons will be fairly consistent in each column. The current density in individual discharge columns is very likely to be constant.

The current flowing through columns is a high frequency one, or a displacement current whose frequency is dependent on the time constants of discharge circuit. Both from the oscillogram and the numerical value of actual electrical items in the measurement system, the oscillation frequency of high frequency current could be estimated to be about 10^6—10^7 Hz. Because of the high resistance of electrode material, the oscillation is highly dampened and only the first one oscillation of the high frequency current was confirmed by oscillogram patterns.[1]

When the applied high potential is gradually raised to a certain definite value, for instance V_1, a discharge or emission of electrons will take place in certain spots on one of the electrodes, which is eventually negative. A glass electrode does not usually have a perfectly flat surface, and there are numerous very small protrusions and indentations all over it. The smaller the radius of curvature r_1 of a very small protrusion, the easier the advent of a discharge from the protrusion, because the

$Q=3.0\times10^{-7}$ coulombs.

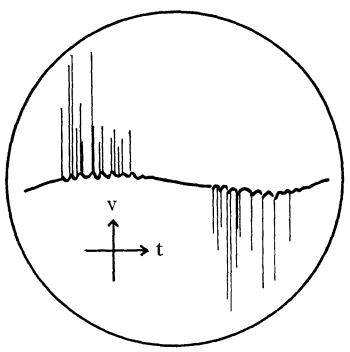

Fig. 8. Synchroscope monitoring of the pulse current (hairs) on primary current wave form.

smaller the r_1 the larger the field strength.

In Fig. 8 which shows the pulse current, the applied voltage (base line) increases from left to right, though the rise is not very distinct because of the deliberate suppression of ordinate scale. Each hair corresponds to pulse current corresponding to a certain value of applied voltage V_1. The pulse current is the sum of each individual pulse current originating from the protrusions whose radii of curvature are r_1. The pulses from left to right correspond to the protrusions for increasing r_1, corresponding to the increase of voltage which enables a discharge from the protrusions. In the other half cycle of base current analogous processes in opposite direction will take place. The high frequency discharge is actually realized only once from the same spot during course of the half cycle of basic current.

2. Reaction Mechanism in Discharge Regime. The proposed reaction sequence of ozone formation in silent discharge is as follows

$$O_2 + e \xrightarrow{k_0} O + O + e \qquad (0)$$

$$O + O_2 + M \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} O_3 + M \qquad \begin{matrix}(1)\\(-1)\end{matrix}$$

$$O_3 + e \xrightarrow{k_2} O_2 + O + e \qquad (2)$$

$$O_3 + O \xrightarrow{k_3} O_2 + O_2^* \qquad (3)$$

$$O + O + M \rightarrow O_2 + M \qquad (4)$$

$$O_2 + O_2^* \rightarrow O + O + O_2 \qquad (5)$$

where e is electron, and M could be either oxygen or nitrogen. For the sake of simplicity M is treated here exclusively to be oxygen because the effectiveness of both molecules in the reactions does not essentially show much difference.[4] Some of the values of k were estimated.

$$k_1 = 6.0\times10^7 \exp\ (+0.6/\boldsymbol{R}T)\ \ l^2\,\mathrm{mol}^{-2}\,\mathrm{sec}^{-1}$$ [4,5]

$$k_{-1} = (4.61\pm0.25)\times10^{12} \exp\ (-24.4/\boldsymbol{R}T)\ \ l\,\mathrm{mol}^{-1}\,\mathrm{sec}^{-1}$$ [5,6]

$$k_3 = (3.0\pm0.3)\times10^{10} \exp\ \{(-6.0\pm0.7)/\boldsymbol{R}T\}\ \ l\,\mathrm{mol}^{-1}\,\mathrm{sec}^{-1}$$ [6]

Reactions (3) and (4) are negligible because of the low concentration of O atoms and O_3 molecules, and reaction (5) was discarded[7] because of its eligibility only at high temperatures. Finally reaction (−1) could be put aside[4] at room temperature, which is essentially the temperature of the discharge vessel. Because of very short and intermittent advent of discharges, essentially any considerable temperature enhancement in the discharge vessel could hardly be perceptible. Thus the reactions (0), (1) and (2) are of practical interest in this reaction regime. The reaction (0) or the initiation reaction will proceed solely in discharge columns. The duration of high frequency current through columns is 10^{-6}—10^{-7} seconds. The electron drift velocity depends on E/p value in the discharge vessel, where E is the value of potential gradient (volt cm^{-1}) between the electrodes and p is the ambient pressure (mmHg), from which E/p is far less than unity.[8] In consideration of this value, the electron drift velocity could be estimated to be about 10^6—10^7 cm sec^{-1}. If the linear flow velocity of gas mixture is taken to be 10 cm sec^{-1}, and diameter of the discharge column to be 0.5 mm in average, then the resident time of gas mixture whithin a discharge column is about 5×10^{-3} sec. Now the number of columns through which streaming gas mixture passes is inversely proportional to its flow velocity. The number of electrons which shower on the gas mixture is proportional to the number of columns. Thus we conclude that the number of oxygen atoms produced by reaction (0), which in turn produced ozone molecules, should be roughly inversely proportional to the flow velocity. As the experimental results show, the ozone concentration of a certain gas mixture is really inversely proportional to the flow velocity (Fig. 7) under similar conditions.

A more detailed insight of the reaction mechanism will be discussed in the following section.

3. The Reaction Pattern based on a Non-steady State Assumption. In silent discharge both from spacial and time-resolved viewpoints three types of reaction regime could be designated: **A_1**) reactions going on in any discharge column within the time of high frequency discharge, during which the electrons reside in the column and their resident time is about 10^{-6}—10^{-7} sec; **A_2**) reactions going on in any discharge column within the interval between any two successive high frequency discharges which is 10^{-2} sec or a half cycle of base current, where any electrical phenomena are precluded; and **B**), reactions going on in the space outside discharge columns during the resident time of reaction gas mixture in the discharge vessel.

These three types of reaction regime will be discussed individually.

A_1: this is a reaction regime where electrons participate. The density of electrons will be larger on account of the smallness of the volume

of columns compared to the whole discharge space, and it will tend to be smaller as the electron velocity becomes faster (up to 10^7 cm sec^{-1}).[9] The actual value of the electron concentration in the discharge columns in the present investigation is roughly estimated to be about 10^{-10}—10^{-11} mol l^{-1} during the course of high frequency discharge.

The site of reaction (0) is exclusively in the discharge columns, the produced O atoms may react according to reactions (1) and (3), but some part may flow out of the columns along with the gas stream. The electrons will play roles in reactions (0) as well as in (2). Ozone will be produced through reaction (1) and destroyed by reactions (2) and (3), and finally washed out from the columns as O atoms.

Based on a non-steady state assumption, reactions (0), (1), (2), (3) and washing out effect will be expressed in the following way, reaction (-1), (4), (5), *etc.* being discarded.

$$\frac{dx}{dt} = Ay - Bx - Fx \qquad (A_1\text{-}1)$$

$$\frac{dy}{dt} = -Ay + Bx - Fy + C, \qquad (A_1\text{-}2)$$

where $x=[O_3]$ mol l^{-1}, $y=[O]$ mol l^{-1} and $A=k_1[O_2]^2$. In this case $A=1.1\times10^4$ sec^{-1} at 300°K and at 760 mmHg.[5] Also $B=k_2[e]$, in which case [e], the electron density, is about 10^{-11} mol l^{-1}, and k_2 mol^{-1} l sec^{-1} is unknown, although from various viewpoints B is most likely less than A. In addition $C=2k_0[O_2][e]$, where k_0 is presumably 10^6—10^8 mol^{-1} l sec^{-1}, [10] although the exact value is not estimated. Finally, F is flow velocity (sec^{-1}) which is taken to be 10^{-2} sec^{-1}. F in Table 1 and Figs. 3—7 is expressed in volume velocity, whereas in this section F times concentration represents the quantity carried by flow. Although the Eq. (A_1-2) is often assumed to be zero, in the present postulate it should most likely remain finite in $\mathbf{A}_1$ regime. The above two equations could then be reduced to

$$\frac{d^2x}{dt^2} + Q\frac{dx}{dt} + Px - AC = 0, \qquad (A_1\text{-}3)$$

where $P=(A+B)F+F^2=(A+B)F$ and $Q=A+B+2F=A+B$. Eq. (A_1-3) is so simple that its general solution is obtained directly under consideration of boundary conditions. Thus we get the final result

$$Px_0 = AC[1 - \exp(-Qt_0)] \qquad (A_1\text{-}4)$$

where t_0 is the duration of high frequency oscillations, x_0 is the ozone concentration at t_0 or at the stage of reaction at the moment when the high frequency discharge is extinguished. In the course of solving the equations, a physically more suitable complementary root of the characteristic equation is selected. All the right hand side terms of (A_1-4) are independent of flow velocity, but P is proportional to it. Thus x_0 is inversely proportional to the flow velocity.

$\mathbf{A}_2$: In discharge columns after the high frequency discharge terminated, O atoms will still react according to reaction (1) and continue to flow away in the outer zone. Similarly O_3 molecules will be produced by reaction (1) and flow out in the same manner as O atoms. Electrons play no roles here.

Then the tentative equations will be

$$\frac{dx}{dt} = Ay - Px \qquad (A_2\text{-}1)$$

$$\frac{dy}{dt} = -Ay - Fy \qquad (A_2\text{-}2)$$

which can be solved easily. The solution is

$$x_1 = [x_0+y_0\{1-\exp(-At_1)\}]\exp(-Ft_1) \fallingdotseq (1-Ft_1)(x_0+y_0). \qquad (A_2\text{-}3)$$

Because of $1 \gg Ft_1$, it will further be changed into

$$x_1 \fallingdotseq x_0 + y_0, \qquad (A_2\text{-}4)$$

where t_1 is the duration which is a half period of basic current or 10^{-2} sec., and x_1 is the ozone concentration at the beginning of another overtaking high frequency discharge.

The value of y_0 or [O] at the termination of $\mathbf{A}_1$ regime can be calculated from (A_1-1) and (A_1-4), which gives

$$y_0 = (C/P)[(A+F)\exp(-Qt_0) + (B+F)] \fallingdotseq (C/P)[A\exp(-Qt_0)+B]. \qquad (A_2\text{-}5)$$

In a similar way as discussed in the foregoing section, the terms in the bracket on the right hand side of (A_2-5) are free from F, while P is proportional to F, y_0 is then inversely proportional to F. Thus the $[O_3]$ value at the termination of $\mathbf{A}_2$ is, as in $\mathbf{A}_1$, proportional to $1/F$. Furthermore, the fact that the value of x_1 in (A_2-4) is almost equivalent to (x_0+y_0) shows that, almost all O atoms react into O_3 molecules, except those washed out of the columns, which are very small, before the termination of $\mathbf{A}_2$ regime. Thus it may be concluded that the ozone formation in the zone outside of columns is very small.

B: Outside the discharge columns, O atoms and O_3 molecules are flowing, while they may react, to a very small extent, according to reaction (1). These particles may incessantly flow into and then emerge out of discharge columns, but processes in and out will obviously cancel each other, and the effect of flow could be neglected.

The required equations are then

$$\frac{dx}{dt} = Ay \qquad (B\text{-}1)$$

$$\frac{dy}{dt} = -Ay \qquad (B\text{-}2)$$

9) C. E. Normand, *Phys. Rev.*, **35**, 1217 (1936).
10) To be published.

and the solution, under the consideration of the boundary conditions is

$$x = x_a + y_a[1-\exp(-At)] \fallingdotseq x_a \quad \text{(B-3)}$$

where x is the value of $[O_3]$ at any time, so long as the gas mixture resides in the discharge zone, particularly outside discharge columns, and x_a and y_a are the $[O_3]$ and [O] at the time when the gas mixture is streaming out of a discharge column. The value of y_a is very small (*cf.* $\mathbf{A}_2$). Then x_a is equivalent to x_1 in (A_2-3) and again proportional to $1/F$. It is also conceivable from (B—3) that the extent of ozone formation in space outside discharge columns is very small, as suggested before.

Putting these three reaction regimes together, in $\mathbf{A}_1$ regime where the main part of the reaction proceeds, the ozone concentration is proportional to $1/F$; in $\mathbf{A}_2$ and **B**, where the reactional part of the substrate decreases the produced ozone concentration is again proportional to $1/F$. The experimental results show that the ozone concentration is proportional to $1/F$ for a considerable wide range of flow velocities. This agrees with the proposed theory.

In static system the ozone yield is very low. In very rapid flow where the flow velocity, or the resident time of streaming gas mixture in a column is comparable to the high frequency discharge duration, the reaction pattern should be different from those described above. The values of k_0 and k_3 of reactions (0) and (3) were left unsettled.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1933—1939 (1970)

The Molecular Structure of Tin Tetrachloride as Determined by Gas-electron Diffraction

Hideji FUJII and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 24, 1969)

The molecular structure of tin tetrachloride was determined by the sector-microphotometer method of gas-electron diffraction. By taking into account the phase-shift for the Sn-Cl pair, the following results were obtained: the tetrahedral structure with r_g(Sn–Cl)$=2.280_8\pm0.003_7$ Å, l(Sn–Cl)$=0.049_9\pm0.003_3$ Å, and l(Cl···Cl)$=0.108_6\pm0.005_0$ Å. These values, especially that of the mean amplitude, l(Sn–Cl), are different from those previously reported by other workers. This is because the effect of the phase shift was neglected in the previous investigations.

Schomaker and Glauber first pointed out the fault of the first Born approximation for the interpretation of the electron-diffraction patterns of molecules containing both heavy and light atoms;[1] subsequently, Hoerni and Ibers calculated the complex atomic-scattering factors for electrons by the partial-waves method in order to explain the observed intensities of UF_6 at 40 and 11 keV.[2,3] Since then, the angle-dependent phase factor in the scattering of electrons has been the subject of several theoretical and experimental investigations.[3] Especially, the studies carried out by Seip[4] and also Kimura *et al.*[3a] have provided extensive experimental data for solving this phase problem. The molecules treated in these experimental studies contain both very heavy and light atoms, and their diffraction patterns show distinct cut-off points in intensities at moderate scattering angles. However, the influence of the phase factor on structure analysis is not limited to such molecules. If this effect is not taken into consideration, inaccurate structure parameters might be yielded, even for molecules whose diffraction patterns have no cut-off point. The tin tetrachloride molecule is considered to be one such molecule.

There have been a few structure determinations of tin tetrachloride by electron diffraction;[5-7] the values reported by Livingston and

7) R. L. Livingston and C. N. R. Rao, *J. Chem. Phys.*, **30**, 339 (1959).

Rao,[7] $r(\mathrm{Sn-Cl})=2.31\pm0.01_5$ Å, $r(\mathrm{Cl\cdots Cl})=3.77\pm0.03_0$ Å, $l(\mathrm{Sn-Cl})=0.08$ Å and $l(\mathrm{Cl\cdots Cl})=0.10$ Å, have often been quoted as the interatomic distances and mean amplitudes of the molecule. These values, however, have not been accurate enough to withstand recent critcal discussion of the molecular structure, for they were determined by the visual-sector method, without taking into account the phase shift for the Sn–Cl atom pair. Since, in structure analysis, the mean amplitude of the Sn–Cl stretching vibration is correlated very closely with the effect of the phase shift, the experimental mean amplitudes reported by Livingston and Rao may be larger than the true values.

It is well-known that the mean amplitudes can be calculated from the molecular geometry and the internal force field which satisfies the normal frequencies, while, conversely, unknown force constants of the internal force fields can be determined by using the observed mean amplitudes as additional information. Morino *et al.* determined, in this way, the force constants for the tetrachloride molecules, CCl_4,[8] $SiCl_4$[9] and $GeCl_4$.[8] The force constants of an internal force field can also be determined by the use of the relative intensities of the Raman lines in addition to the fundamental frequencies.[10] Chantry and Woodward applied this method to tetrahalide molecules, MX_4 (M=C, Si, Ge, and Sn; X=Br and Cl).[11] However, this method gives four sets of force constants accounting for the vibration of species, F_2, and specifies no unique set of force constants. Therefore, they selected one set from among the four by consulting the experimental mean amplitudes of vibration. Because of the inevitable ambiguities of the results for $SnCl_4$, Chantry and Woodward's choice of the force constants for $SnCl_4$ is not decisive.

Recently, Bürger and Ruoff[12] and also Kebabçioglu *et al.*[13] independently determined the force constants for the tetrachloride molecules of the group-IV_b elements by the use of the Coriolis coupling constants, which were estimated from a separation between the P and R branches of the F_2 band. The results for $SiCl_4$ and $GeCl_4$ were in reasonable agreement with each other, and also with those determined from the mean amplitudes and the relative intensities of the Raman lines. However, it seems that the values previously reported for $SnCl_4$ are inconsistent with one another. In these circumstances it is very desirable to determine the precise interatomic distances and mean amplitudes of tin tetrachloride by the sector-microphotometer method of electron diffraction. Especially, the values of the mean amplitudes are expected to be revised significantly by taking into account the phase shift for the Sn–Cl pair.

Experimental

The sample of tin tetrachloride was loaded in a sample holder by manipulating it in a dry box filled with nitrogen. The vapor pressure of the sample was about 20 Torr at 20°C.

Photographs were taken at 18°C with an r^3-sector at camera lengths of 24.430 cm and 10.930 cm; the exposure times were about 40 sec, with a beam current of about 0.15 μA. The fluctuations of the accelerating voltage (about 47.5 kV) were maintained within 0.1 per cent throughout a sequence of exposures. Carbon disulfide was employed as a reference material in determining the wavelength.[14]

The intensities of the diffraction patterns of $SnCl_4$ decreased rapidly with an increase in scattering angles, so that intensity measurements were practically impossible in a range beyond about $q=100$. This is certainly due to the effect of the phase shift in addition to the damping effect caused by molecular vibrations. This suggests that information can be obtained by using photographs taken at a long camera distance. Therefore, three plates from the long camera distance were selected for analysis; hereafter, they will be referred to as plates 1, 2, and 3 for the sake of convenience. The wavelength for each plate was determined by the use of two plates of carbon disulfide taken in the same sequence of exposures.

With a double-beam microphotometer, Model NLM-III, of the Nalumi Co., Ltd., the optical densities of the diffraction patterns were measured by the following two methods:

(1) This microphotometer was equipped with a cam converting transmission into optical density and a pen-recorder. Optical densities were read at intervals of $\Delta q=1$ on the left and right sides of the diffraction center. In this method the optical densities were determined by averaging the corresponding observed values on the two sides (the pen-recording method).

(2) By connecting an integrating digital voltmeter to the microphotometer, the values of the output voltages from the photomultiplier of the microphotometer were perforated in digits directly onto an input tape for an electronic computer. From these values, taken every one-third of a milimeter on a plate, the optical density at every integral number of q was obtained by interpolation by a second-degree polynomial which passes through the three observed points closest to each q. In this case, the diffraction center was determines so as to minimize the value of $\sum_i [D_{li}-D_{ri}]^2$, where

the D_{li} denotes the optical density at $q=i$ on the left side of the diffraction center, and the D_{ri}, the corresponding value on the right side. Thus, by this method two sets of the observed optical densities, D_l and D_r, were obtained for each plate (the digital method). The whole process was performed by the use of an electronic computer.

The optical densities measured by the two methods differ from each other by only one per cent at most. Since the observed optical densities for all plates were below 0.7, it was assumed that the optical densities are proportional to the scattering intensities, I_T^{obs}.[15] The observed intensities ranging from $q=10$ to 70 were adopted for analysis.

Analysis and Results

The observed molecular scattering intensity, $qM(q)^{obs}$, was obtained from the I_T^{obs} and the smooth background, I_B^{obs}, according to the equation:

$$qM(q)^{obs} = q(I_T^{obs}-I_B^{obs})/I_B^{obs}. \tag{1}$$

The corresponding theoretical expression is:

$$qM(q)^{theor} = k\sum_{i,j}' A_{ij}\mu_{ij}\cos(\Delta\eta_{ij})\exp[-a_{ij}q^2] \times \sin\left[\frac{\pi}{10}q\left\{r_{aij}-\left(\frac{\pi}{10}q\right)^2\kappa\right\}\right], \tag{2}$$

$$a_{ij} = \frac{1}{2}(\pi/10)^2 l_{ij}^2, \tag{3}$$

$$A_{ij} = \frac{Z_iZ_j}{\sum_k Z_k(Z_k+1)}\cdot\frac{20}{\pi r_{aij}} \tag{4}$$

$$\mu_{ij} = \frac{\sum_k Z_k(Z_k+1)}{Z_iZ_j}\cdot\frac{|F_i||F_j|}{\sum_k\{|F_k|^2+S_k\}}, \tag{5}$$

$$|F_k| = h^2s^2|f_k|/8\pi^2me^2, \quad s=\left(\frac{\pi}{10}\right)q. \tag{6}$$

Here, all the notations follow usual usage. Starting from a trial experimental background described below, the final I_B^{obs} and $qM(q)^{obs}$ were determined according to Karle's non-negativity criterion[16] by repeating a few times the calculation of the radial distribution curve and its inverse Fourier transformation for the $r=0.00$–1.60 Å range. The trial experimental background was determined in the following way: By replacing the $q(Mq)^{obs}$ in Eq. (1) by the theoretical molecular intensity, $q(Mq)^{theor}$, the observed background can be expressed as:

$$I_B^{obs} = I_T^{obs}\frac{q}{q+kqM(q)^{theor}}.$$

From this equation a preliminary background can be calculated by using $qM(q)^{theor}$ for a reasonable molecular model and an appropriate k value.

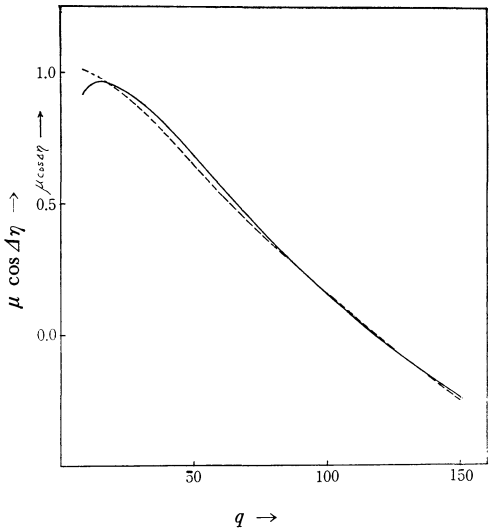

Fig. 1. $\mu_{SnCl}\cos(\Delta\eta_{SnCl})$ (the solid line) and $\chi_{SnCl}(q)$ (the broken line).

By fitting the background to a polynomial in terms of q, $\sum_{n=0}^{5} a_nq^n$, a smooth trial background, I_B^{obs}, was obtained.

Since the $\mu_{SnCl}\cos(\Delta\eta_{SnCl})$ values are far from unity, as may be seen in Fig. 1, the corrections for the non-nuclear scattering in the calculation of the radial distribution cannot be made satisfactorily by the conventional form, $1-\mu_{SnCl}\cos(\Delta\eta_{SnCl})$. Generally, the $\mu_{ij}\cos(\Delta\eta_{ij})$ values for an i and j atom pair can be approximated by the following function, $\chi_{ij}(q)$:[17]

$$\chi_{ij}(q) = \alpha_{ij} + \beta_{ij}\cos\left(\frac{\pi}{10}\Delta r_{ij}\cdot q\right) + \gamma_{ij}\exp[-\delta_{ij}q^2], \tag{7}$$

where the α_{ij}, β_{ij}, γ_{ij} and δ_{ij} are positive constant coefficients. The correction term, then, becomes:

$$\Delta qM(q) = \sum_{i,j}' A_{ij}\sin\left(\frac{\pi}{10}qr_{ij}\right)\exp[-a_{ij}q^2] \times\{\chi_{ij}(q)-\mu_{ij}\cos(\Delta\eta_{ij})\}, \tag{8}$$

and the corresponding radial distribution curve, $f(r)$, is given by:

$$f(r) = \sum_{i,j}' \frac{A_{ij}}{4}\sqrt{\frac{\pi}{a_{ij}+b}}\exp\left[-\frac{\pi^2}{400}\frac{(r-r_{ij})^2}{a_{ij}+b}\right]\alpha_{ij} + \sum_{i,j}' \frac{A_{ij}}{4}\sqrt{\frac{\pi}{a_{ij}+b}} \times\left\{\exp\left[-\frac{\pi^2}{400}\frac{(r-r_{ij}+\Delta r_{ij})^2}{a_{ij}+b}\right] + \exp\left[-\frac{\pi^2}{400}\frac{(r-r_{ij}-\Delta r_{ij})^2}{a_{ij}+b}\right]\right\}\frac{\beta_{ij}}{2} + \sum_{i,j}' \frac{A_{ij}}{4}\sqrt{\frac{\pi}{a_{ij}+b+\delta_{ij}}} \times\exp\left[-\frac{\pi^2}{400}\frac{(r-r_{ij})^2}{a_{ij}+b+\delta_{ij}}\right]\gamma_{ij}. \tag{9}$$

Here, the b is an artificial damping factor, and the Δr_{ij} corresponds to an apparent splitting of the i and j interatomic distance due to the phase difference. The Δr_{ij} value was estimated from the $(\pi/10)\Delta r_{ij}\cdot q_c=\pi/2$ relation, with a theoretical first cut-off point, q_c. The anharmonicity parameter, κ, in Eq. (2) can be ignored in the calculation of the radial distribution. It readily be seen from Eq. (9) that the non-negativity criterion holds for this radial distribution curve.

In the case of $SnCl_4$ we employed the functions of $\chi_{ij}(q)$ with the following coefficients:

$\alpha_{Sn-Cl}=0$ $\alpha_{Cl-Cl}=1.20$

$\beta_{Sn-Cl}=0.625$ $\beta_{Cl-Cl}=0$

$\gamma_{Sn-Cl}=0.4$ $\gamma_{Cl-Cl}=0.3$

$\delta_{Sn-Cl}=0.00039$ $\delta_{Cl-Cl}=0.00014$

$\frac{\pi}{10}\Delta r_{Sn-Cl}=0.01333$

The broken line in Fig. 1 indicates the $\chi_{SnCl}(q)$. The final molecular intensity, $qM(q)^{obs}$, and the corresponding radial distribution, $f(r)$, are shown in Figs. 2 and 3 respectively.

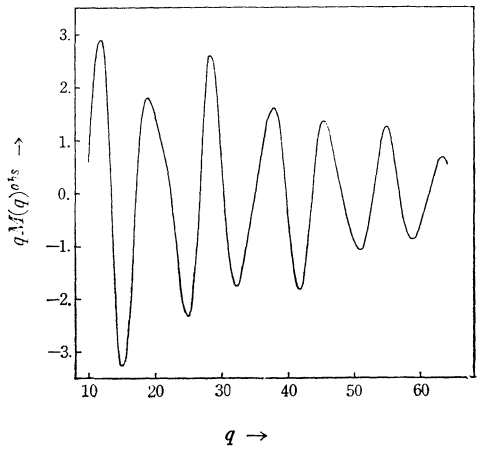

Fig. 2. The molecular intensity curve, $qM(q)^{obs}$.

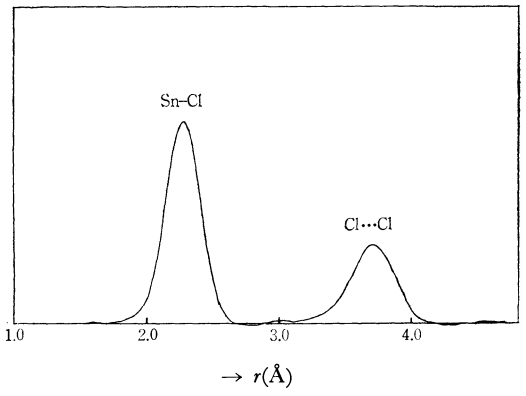

Fig. 3. The radial distribution curve, $f(r)$.

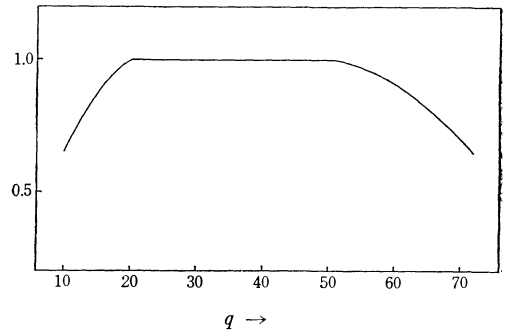

Fig. 4. The weight function employed for the least-squares fitting.

The molecular parameters were determined by the least-squares method applied to the $qM(q)^{obs}$, with the weight function shown in Fig. 4. A regular tetrahedral symmetry was assumed.

The atomic scattering factors, $|F|$, and the phase shift, $\Delta\eta$, used in the $qM(q)^{theor}$ are those calculated by Kimura *et al*,[18] the inelastic scattering factors, S, for Cl and Sn are those calculated by Tavard *et al*[19] and by Bewilogua[20] respectively.

The anharmonicity parameters, κ, fixed in the least-squares treatment were estimated to be 16×10^{-7} Å^3 for Sn–Cl and 100×10^{-7} Å^3 for Cl···Cl by following the method applied to $SiCl_4$ by Morino and Murata.[9] Errors based on the uncertainties in κ were included in the total errors, which will be described in the next section.

The measurements of the optical densities were carried out by the digital and the pen-recording methods. Table 1 shows the values of r_a observed by the digital method. The results obtained from the D_l and the D_r agree with each other within their standard deviations. The final values of r_a for each plate were determined by multiplying the averages of the two values by the scale factor. The final results obtained by the two methods for plate 1 are compared in Table 2. The two results agree with each other, but the standard deviations are about a half as much in the digital method as in the pen-recording method. This is because the smoother intensity curve was obtained by the former method than by the latter. Therefore, the results by the digital method were adopted as the final values for plates 1 and 2. Plate 3 was measured only by the pen-recording method.

* Distances and mean-amplitudes in Å unit. The errors are the standard deviations obtained from the least-squares treatment. The r_a values in the third column are those in Table 1 multiplied by the scale factor.

The results of the least-squares refinements for the three plates are summarized in Table 3. The σ_1 and σ_2 values, which represent the standard deviations for the average values, were estimated according to these formulas: $\sigma_1^2=\langle\sigma\rangle^2/3$ and $\sigma_2^2=\sum V_i^2/6$. Here, $\langle\sigma\rangle$ is the average of the standard deviations for the three plates, while V_i is the residual of the value for the ith plate subtracted from the average value.[9] All the σ_1 values are larger than the corresponding values. The final random errors were, then, given by $2.5\sigma_1$, corresponding to the 99 per cent confidence intervals. Two plates of carbon disulfide were measured in order to determine the scale factor for each plate and were analyzed in the same way as were the sample plates. Therefore, various systematic errors involved in the experiment and analysis may be regarded as included in the error of the scale factor.[14] The practical procedure is to determine the scale factor for each plate by comparing the results of analysis at a presumed wavelength with the true structure of carbon disulfide. Analysis was made by assuming the two independent interatomic distances, r(C–S) and r(S···S). Then, the scale factor obtained from one plate of carbon disulfide may be given by a weighted mean of the scale factors determined from the two individual distances, while its standard deviation is given by $\sigma=[1/\sigma_{cs}^2+1/\sigma_{ss}^2]^{-1/2}$.*1 The final scale factor and its standard deviation were determined using the results for the two plates of carbon disulfide. The limit of error of the scale factor was taken as 2.5 times the standard deviation thus obtained, corresponding to 0.12 per cent in interatomic distance.

*1 The off-diagonal element of the error matrix, $B^{-1}{}_{cs,ss}$, is one to two hundredth as small as the diagonal elements, $B^{-1}{}_{cs,cs}$ and $B^{-1}{}_{ss,ss}$. Therefore, even if the least-squares treatment is performed under the condition that the distances, r(C–S) and r(S···S), are not independent of each other, the results do not change.

The errors associated with the ambiguity of κ were estimated from the results of the least-square fittings carried out by assuming various κ values. They were ± 0.0020 Å for r_g(Sn–Cl) and ± 0.0040 Å for r_g(Cl···Cl).

The total errors for the interatomic distances were estimated by regarding these errors independent of one another. Systematic errors for the mean amplitudes were ignored, for their magnitudes may be considered to be much smaller than the random errors. The final parameters are given in Table 4.

Table 4. Molecular parameters of tin tetrachloride at 18°C

r_g(Sn–Cl)	$2.280_8 \pm 0.003_7$ Å
r_α(Sn–Cl)	$2.274_9 \pm 0.003_7$ Å

l(Cl···Cl)	$0.108_6 \pm 0.005_0$ Å
δ_g	$0.007_6 \pm 0.006_0$

Discussion of the Results

The r_g(Sn–Cl) value, 2.281 ± 0.004 Å, determined by the present study is about 0.03 Å shorter than those reported by the previous studies[5–7] and 0.11 Å less than the sum of the covalent radii, 2.39 Å. From the results of the electron-diffraction studies of $SiCl_4$[9] and $GeCl_4$[8] the corresponding values of bond shortening are estimated to be 0.14 Å for the Si–Cl bond in $SiCl_4$ and 0.10 Å for the Ge–Cl bond in $GeCl_4$. It may be noted here that the amount of bond shortening for the Sn–Cl bond is smaller than that for the Si–Cl bond, but virtually equal to that for the Ge–Cl bond. These bond shortenings were explained by the partial ionic and the partial double-bond character of these bonds reported to Pauling.[21] From the fact that the same electronegativity value, 1.8 in Pauling's scale, is given to Si, Ge, and Sn atoms, it is reasonable to expect the same partial ionic character; consequently, the bond shortening is the same for all of the Si–Cl, Ge–Cl, and Sn–Cl bonds. Thus, the amounts of bond shortening, 0.14 Å for the Si–Cl, 0.10 Å for the Ge–Cl, and 0.11 Å for the Sn–Cl, become a measure of the extent of their double-bond character. By using the results previously reported by Pauling and Brockway[6], *i.e.*, 2.30 Å for the Sn–Cl bond length and the bond shortening of 0.07 Å, Gordy has mentioned that the quantities of double-bond character decrease in the order of the Si–Cl, Ge–Cl, and Sn–Cl bonds and that a tendency to form multiple bonds decreases with an increase in the size of the atoms.[22] It was found in the present study, however, that the amount of bond shortening for the Sn–Cl bond was similar to that for the Ge–Cl bond. It seems that, for these two bonds, the effect of the increase in atomic size from Ge to Sn is compensated for by that of the decrease in promotion energy from p to d orbitals, and that, as a result, the Ge–Cl and Sn–Cl bonds have almost the same double-bond character.

The r_g values can be converted to r_α by using the relation: $r_\alpha = r_g - [\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle]/2r_g - \delta r$, where $\langle \Delta x^2 \rangle$ and $\langle \Delta y^2 \rangle$ are the perpendicular mean amplitudes, and δr, the centrifugal stretching. Using the force constants determined from the fundamental frequencies and the Coriolis coupling constants,[13] the values of the perpendicular mean amplitudes were estimated to be 0.0054 Å for the Sn–Cl and 0.0033 Å for the Cl···Cl.*2 The stretchings, δr, were estimated by Iwasaki and Hedberg's method[23] to be 0.0005 Å for the Sn–Cl and 0.0008 Å for the Cl···Cl. The r_α values thus obtained are also listed in Table 4. The ratio of r_α(Cl···Cl) to r_α(Sn–Cl) is 1.6320 ± 0.0026, a value which is in perfect agreement with the corresponding ratio, 1.6330, for a regular tetrahedral structure.

The mean amplitude for the Sn–Cl atom pair is $0.049_9 \pm 0.003_3$ Å, which is much smaller than the value of 0.08 Å reported by Livingston and Rao.[7] Such a large discrepancy between the two results cannot have been produced simply by employing different methods of measurement, *i.e.*, the microphotometer method and the visual method. The ignorance of the phase shift in the previous study certainly led to an inaccurate mean amplitude for the Sn–Cl pair. The mean amplitudes for $SnCl_4$ were calculated by Long and Seibold[24] and also by Müller and Cyvin.[25] The former authors used the Urey-Bradley force field with the assumption that $H'=0$ and gave the values of 0.046 Å for the Sn–Cl and 0.119 Å for the Cl···Cl at 298°K, while the latter used symmetry force constants which had been calculated by the method of the "Verfahren der nächsten Lösung"[26] and gave the values of 0.046 and 0.120 Å for the respective

bonds at the same temperature. These calculated values are fairly close to the experimental values. The slight differences must be connected with the force constants used in the mean-amplitude calculations, and originally with the assumptions on which the force constants were given. The mean amplitudes determined in the present study will be helpful in assigning a reasonable set of force constants for tin tetrachloride. The determination and discussion of the force constants for tin tetrachloride will be described in a separate paper.

A Deuteron and Proton Magnetic Resonance Study of Ammonium Oxalate Monohydrate

Takehiko CHIBA

Department of Chemistry, Nihon University, Sakurajosui, Setagaya-ku, Tokyo

(Received October 25, 1969)

The quadrupole spectra of deuteron magnetic resonance were observed on single crystals of $(ND_4)_2C_2O_4D_2O$. The quadrupole coupling tensors for stationary deuterons were determined at -110°C. eqQ/h and η are 163.7—172.8 kHz and 0.005—0.015 for the ammonium deuterons and 213.3 kHz and 0.090 for the water deuteron. The eqQ values and principal axis directions of EFG tensors are consistent with the structure deduced from the diffraction studies with the exception that the z principal axes of D in the ammonium ion deviate appreciably from the NH directions derived from neutron diffraction. From the change in the line-width with the temperature, the rate of the C_3 reorientation of ammonium ions and that of the 180° flip of water molecules were estimated at various temperatures. The ammonium-ion reorientation is found to be quite isotropic. The temperature dependence of the proton T_1 and $T_{1\rho}$ and the deuteron T_1 were measured on $(NH_4)_2C_2O_4H_2O$ and $(ND_4)_2C_2O_4D_2O$ powers. The T_1 values were then compared with the calculated values, assuming ammonium reorientation. The sharp drop of the proton $T_{1\rho}$ with the temperature above 50°C can be interpreted as being due to the 180° flip motion of water molecules through a relaxation mechanism of "slow motion." The rates of motion derived from the relaxation-time measurements are consistent with those estimated from the line-width change.

Deuteron magnetic resonance (DMR) has been successfully applied to problems of the structure and the motions of molecules in the crystals in which hydrogen atoms participate. DMR studies have often been made of O–H–bond systems, but studies of systems in which H is bonded to atoms other than O have been rather rare. The electric field gradient (EFG) at a deuteron is always nearly in the direction of the D–X bond. The DMR of an ND_4^+ ion gives, at a high temperature, a single line or a doublet of small separation due to the effect of the averaging of the EFG at each D by rapid reorientation. The doublet line may originate from the deviation from the regular tetrahedron of the ND_4^+ ion as well as from the effect due to external charge distribution. However, it is not clear what the relative importance of each contribution is. The motion of the NH_4^+ ion in ammonium salts has been studied by various techniques: IR, heat capacity, neutron diffraction, neutron inelastic scattering, proton magnetic resonance, *etc.* The mode of the NH_4^+ reorientational motion in the crystal has not been well known in most of the cases with the exception of some of the ammonium halides with a high crystal symmetry. Although reorientation about a single C_2 axis of NH_4^+ ions has been assumed in a particular case to explain the change in the second moment of the proton magnetic resonance (PMR),[1] the evidence is not fully decisive.

1) D. Pendred and R. E. Richards, *Trans. Faraday Soc.*, **51**, 468 (1955); J. B. Leane and R. E. Richards, *Spectrochim. Acta*, **10**, 154 (1957).

In DMR on single crystals, as compared to PMR, the line-width transition due to motion is often much more specific to the mode of the motion in the crystal, and if the line-width change is carefully followed it can provide more detailed information than does PMR. DMR study with single crystals, including the measurement for the stationary ND_4^+ ion, has thus far been made on ND_4Cl,[2,3] ND_4Br,[2] and $(ND_4)_2SO_4$.[4] In the cubic phase of ammonium halides, the D's are all equivalent, the bond directions are strictly fixed by the high symmetry of the crystal, and there is no preferred axes of rotational motion. Ammonium sulfate has a phase transition which complicates the DMR spectra so much that the accurate determination of quadrupole coupling for each deuteron is almost impossible. Ammonium oxalate monohydrate $(NH_4)_2C_2O_4H_2O$ provides a favorable system for a detailed study of the ND_4^+ ion—its structure and motion—because it has no phase transition in the temperature range of our interest, because each N–H bond is linked by a hydrogen bond of moderate strength, because the barrier to reorientation appears to be sufficiently high so that, for the observation of the spectra of the stationary ND_4^+ ion, one need not go down to very low temperatures, because its crystal structure is well established and is relatively simple, and because single crystals can be easily grown from the aqueous solution.

The four N–H···O hydrogen bond distances in this crystal are slightly different from each other; therefore, one might be able to detect an anisotropy in the reorientational motion. From the results of neutron diffraction study[5] the NH_4^+ ion in ammonium oxalate monohydrate can be said to assume fairly distorted tetrahedron; therefore, if one gets a quadrupole coupling tensor for each D of the four N–D bonds, one might be able to get information about the relation between the distortion of the ammonium ion and the quadrupole coupling averaged by rapid motion. These are the motivations of the present investigation.

In addition to steady-state DMR measurements of single crystals, the proton spin-lattice relaxation time in the laboratory frame, T_1, and that in the rotating frame, $T_{1\rho}$, were measured by pulse techniques on powdered samples at various temperatures. The temperature dependence of the T_1 of the deuteron in the deuterated crystal powder was also measured.

Experimental

The $(ND_4)_2C_2O_4D_2O$ was obtained by repeated exchange with D_2O of $(NH_4)_2C_2O_4$. The single crystals were grown from a saturated, heavy-water solution of deuterated ammonium oxalate by slow cooling. The single crystals used for the study were about $5\times5\times10$ mm^3. For proton resonance, a recrystallized powder sample of a reagent-grade product was used. The measurements of the steady-state DMR were made by sweeping frequency. The field was fixed at a value corresponding to the deuteron Larmor frequency of 10 MHz. The accuracy of the mounting of the crystal on the probe head was achieved by using a reflecting goniometer. In order to reduce complication in the rotation pattern as much as possible, the measurements were made with a static field (H_0) in the *ab*, *bc*, or *ac* plane. The T_1 for the proton and that for the deuteron were measured by the pulse technique at 10 MHz. The T_1 for the proton was measured at 30 MHz. The apparatus for the measurement of the steady-state type and those of the pulse type have been described previously.[6–8]

Results

According to X-ray and neutron structure analyses[9,5] the crystal is orthorhombic, belonging

Fig. 2. Rotation patterns of deuteron magnetic resonance lines of $(ND_4)_2C_2O_4D_2O$ single crystal when the magnetic field is rotated about the crystalline axes *a*, *b* and *c*.

Solid lines represent calculated rotation patterns from the quadrupole coupling tensors given in Table 1.

to the $P2_12_12$ space group. A unit cell contains two formula units (Fig. 1). The ammonium ions are all crystallographically equivalent, and so are all the water molecules. Four hydrogen atoms of the ammonium ions are nonequivalent. The water oxygen atom is placed on the two-fold axis and therefore the water hydrogen atoms are equivalent. There are, thus, a total of 5 nonequivalent deuterons in the crystal of $(ND_4)_2C_2O_4D_2O$. Because a quadrupole interaction splits a deuteron resonance line into two components, from the symmetry of the crystal the maximum number of resonance-line-pairs is expected to be 10 when the static field is applied in the *ab*, *bc*, or *ac* plane, and 20 when H_0 is applied in an arbitrary direction. Spectra in accordance with the expectation are observed below -106°C. Above about -30°C a single line or a pair of lines with a small separation depending on the direction of H_0 characteristic of rapidly-reorienting ammonium ions were observed, together with the lines from the water deuterons. The water lines did not change their shape and position appreciably up to 50°C, where they started to broaden. The angular dependence of the quadrupole splitting for the stationary deuterons was measured at -110°C with H_0 in the *bc* plane (*a*-axis rotation), in the *ac* plane (*b*-axis rotation), and in the *ab* plane (*c*-axis rotation). Since the rotation patterns are symmetric about the crystalline axis direction, it is necessary only to measure the spectra for the angles between the two axes (for instance, between *b* and *c* axes in the *a*-axis rotation pattern). The rotation patterns are shown in Fig. 2.

In the first-order perturbation the frequency difference between the quadrupole-split doublet, $2\Delta\nu=\nu_+(m=1\leftrightarrow0)-\nu_-(m=0\leftrightarrow-1)$, is given by:[10]

$$2\Delta\nu = (3eQ/4\hbar)\{-q_{ZZ}+(q_{XX}-q_{YY})\cos 2\theta + 2q_{XY}\sin 2\theta\}, \quad (1)$$

where q_{ij} is the ij element of the EFG tensor in the XYZ coordinate system and where θ is the angle of rotation of H_0 about the Z-axis in the XY plane, measured from the X-axis. The estimated angular dependence of the quadrupole splitting or the "rotation pattern" was drawn with the following assumptions for the EFG. For ammonium deuterons, the EFG is axially symmetric about the direction of the N–H bond, as determined by the neutron diffraction. For water deuterons, the z principal component of EFG, q_{zz}, is along the OH bond, as determined by the neutron diffraction; the y component, q_{yy}, is perpendicular to the H_2O plane, and the asymmetry parameter $\eta=0.1$ ($|q_{zz}|\geq|q_{yy}|\geq|q_{xx}|$). Each curve of the rotation pattern is assigned to a particular deuteron with the help of this estimated pattern. The lines of the water deuterons are generally sharp and strong and can easily be discriminated from those of the ammonium deuterons, which are relatively weak, broad, and structureless. The rotation patterns of five nonequivalent deuterons are designated as D_α, D_β, D_γ, D_δ (ammonium), and D_w (water). For ammonium deuterons, due to the complexity of the rotation patterns, the assignment of each line is not as simple as for water deuterons. However, the following fact was useful for this purpose. It is seen that each rotation pattern always has one extremum about 60 kHz from the center. We expect this to occur when H_0 is perpendicular to the z axis, and $\Delta\nu$ in this case must be negative (assuming $q_{zz}>0$). Thus, in the *c* rotation pattern, the $\Delta\nu$'s of D_α and D_δ at the *b* axis are positive and those of D_β and D_γ are negative, and the sum of the four $\Delta\nu$'s is nearly zero. The sign of $\Delta\nu$ for the *a* or *b* rotation could, then, be determined referred to the above sign by comparing the $\Delta\nu$ values in the crystalline axis directions. D_α, D_β, D_γ, and D_δ are assigned to H_4, H_1, H_3, and H_2 respectively.*1 In order to determine the eqQ tensor from the rotation patterns about the *a*, *b*, and *c* axes by the method described previously,[6] we must combine the rotation patterns of the right phase, for there are two alternative rotation patterns 90° out-of-phase to each other. The four orientations for the NH_4^+ ion and the H_2O molecule will be denoted by A, B, C, and D, for which the equivalent interatomic vectors have the (xyz), $(x\bar{y}\bar{x})$, $(\bar{x}y\bar{z})$, and $(\bar{x}\bar{y}z)$ components respectively. In the *a* axis rotation, the pattern of A overlaps that of B, and the pattern of C, that of D. In the *b* rotation, the patterns of A and C, and of B and D, overlap. In the *c* rotation, the patterns of A and D, and of B and C, overlap. The rotation patterns of $\Delta\nu$ corresponding to the site-A deuterons were chosen and were combined to determine the quadrupole coupling tensor.*2 The values of eqQ, η and the direction cosines of the principal axes are given in Table 1.

The rotation patterns for the reorienting NH_4^+ deuteron were measured at room temperature. The separations are so small that it is not possible to determine the eqQ tensor. From the observed maximum separation frequency, the value of quadrupole coupling is estimated to be about 1.5 kHz.

To estimate the rate of the reorientation of the ND_4^+ ion and to get information about the mode of

the motion, the line broadening of the spectra in the limits of rapid motion and of slow motion were observed. As will be mentioned in the next section, we assume only C_3 reorientations for the motion of the NH_4^+ ion in this crystal. In the case of isotropic reorientation, the average rate, Ω, of C_3 reorientation about one of the four axes is related to the average lifetime, τ, for a hydrogen atom to be in one of the four equilibrium positions by:

$$3\Omega = 1/\tau\,. \tag{2}$$

From the theory of the motional broadening of the spectral line,[11] we have, for the rapid limit spectra:

$$\Delta\nu_M = \frac{\pi}{8\Omega}\sum(\Delta\nu_i)^2\,, \tag{3}$$

and, for the slow limit spectra:

$$\Delta\nu_M = \frac{3}{2\pi}\,\Omega, \tag{4}$$

where $\Delta\nu_M$ is the line width due to the motion and where $\Delta\nu_i$ is the separation from the average frequency (here, the Larmor frequency) of the line of the stationary i-th deuteron. The broadening process is observed with H_0 in the a- and b-axisdirections. (The rapid-limit spectra, except when H_0 is in the crystalline axis directions, consist of two-line components with different degrees of broadening.) The values of $\Delta\nu_M$ at the two limiting cases were estimated by an approximate procedure from the observed line width, which includes the dipolar width.[7] These values were then used to derive the reorientation rate, Ω, of the ND_4^+ ion. The results are shown in Fig. 3. From the slope of this plot, the activation energy of reorientation, ΔE, is estimated to be 8.8 kcal/mol. The effect of the possible anisotropy of the motion will be discussed in the next section.

The lines of water deuterons start to broaden at about 50°C. The line-broadening process of water deuterons was observed, and the rate of reorientation was estimated in the same way as was done in the case of other hydrates. The reorientation rates thus derived are shown in Fig. 3.

The results of pulse measurements are shown in Fig. 4. It can be seen in this figure that the temperature dependence of the T_1 of both the proton and the deuteron is adequately explained by the reorientational motion, whose correlation frequency is expressed by the Arrhenius equation. The relevant motion is that of the NH_4^+ ion. The T_1 values will be analyzed in the next section. As is to be exprected from the theory, the log $T_{1\rho}$ *vs.* $1/T$ plot is roughly a straight line, coinciding with the log T_1 curve at the high-temperature side of the minimum and then extending further to low temperatures. The $T_{1\rho}$ could not be measured down to its minimum because of the instrumental difficulty. Above 50°C $T_{1\rho}$ starts to drop again.

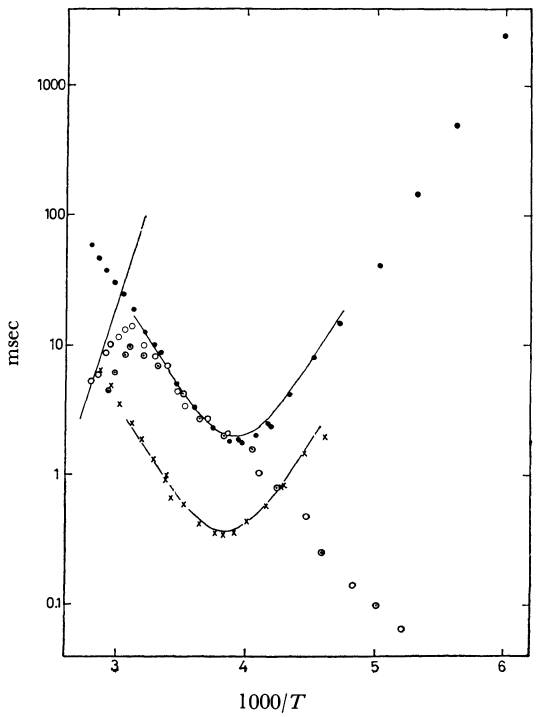

Fig. 4. Temperature dependence of the relaxation times of ammonium oxalate monohydrate powder samples.
● Proton T_1 ○ Proton $T_{1\rho}(H_1=6G)$
⊙ Proton $T_{1\rho}(H_1=4G)$ × Deuteron T_1
The straight line at the left represents $T_{1\rho}$ due to 180° flip of H_2O. Curves through T_1 minima are from Eqs. (5), (7) and (8).

This is considered to be due to the effect of the reorientation of the water molecule and will be discussed in the next section.

Discussion

In 1965, almost concurrently two independent works on the structure analysis of ammonium oxalate monohydrate were published; one was a refinement of the X-ray analysis at 30°K by Robertson,[9] and the other was a neutron diffraction study by Padmanabhan *et al.*[5] In view of the practical limits of precision of the two techniques, we will quote, in comparing the structure and EFG tensors, the heavy-atom coordinates from the X-ray study and the NH and OH bond directions from the neutron study.

Quadrupole Coupling Values. As has been discussed previously, the correlation between the O–D···O hydrogen bond length and the eqQ/h of D is fairly well represented by an empirical curve[12] or by empirical formulas.[6] The value of eqQ/h 213.3±0.4 kHz for the water deuteron is a reasonable value for a "fairly strong" hydrogen

bond with an O-O length of 2.743 Å, and it falls on the empirical curve. This value is close to that of 209.7±2.5 kHz for D in $K_2C_2O_4D_2O$,[13] which has nearly the same hydrogen bond length, 2.744± 0.017 Å.[14] In Table 2 the eqQ values of ammonium deuterons are listed, along with the corresponding N—O hydrogen bond distances and N–H bond distances. The values of eqQ/h decrease as the N—O distance decreases and as the N–H distance increases. The correlation between eqQ and the N–D···O hydrogen bond length, similar to that in the O–D···O hydrogen bond system, is quite apparent. Table 3 lists some of the deuteron quadrupole coupling constants in the N–D bonds. It seems that it would be very interesting to know whether a curve similar to the one for the O–O system can be drawn of eqQ *vs.* the N–O distance, with eqQ/h=282 kHz as the limit of the weakest hydrogen bond. However, a few more experimental data must be added before this can be done.

Structure of Water Molecules. The direction of the z principal axis of the water deuteron is in good agreement with the O–H bond direction obtained from the neutron diffraction, the deviation being only 3.0°. The angle between the z axes of the two water deuterons in the water molecule is 109.4°. It should be noted that the plane containing two z principal axes makes an angle of 14.6° with the crystalline a axis; this angle is in excellent agreement with 15.2°, the angle between the O_1–O_w–O_1' plane and the a axis, in contrast to a fairly large twisting of the water molecule in the hydrogen bond system (4.6° between O_1–O_1' and H_w–H_w' directions) reported in the neutron diffraction study. The principal y axis of EFG of the water deuteron is nearly perpendicular (within 2.3°) to the plane formed by the two z axes, which is in accord with the empirical relation about the y axis.[12,15]

Structure of Ammonium Ions. The directions of the z principal axes of the EFG tensors in the ND_4^+ ions are approximately in the N–H directions, as determined by the neutron diffraction, but the deviation angles, 5.2°, 2.3°, 4.6°, and 7.3° for NH_1, NH_2, NH_3, and NH_4 respectively, are somewhat larger than those usually found. The mean standard deviations in bond angles from the neutron diffraction study are estimated to be 1.9°, and the standard deviation of the z direction in this study is well below 1°. Therefore, these deviation angles exceed the limits of experimental error. The angles between the z principal axes in the ND_4^+ ion are quite close to the tetrahedral angle, as is shown in Table 4. A comparison of these with the HNH angles from the neutron diffraction study indicates a rather large distortion of the NH_4^+ tetrahedron. The small deviation angles from perfect parallelism of the z axis of the deuteron EFG with the bond direction determined from the diffraction study may be attributed to the effect of charges from the atoms which are not directly bonded to the hydrogen atom in question. In the present case of the ND_4^+ ion, however, it seems rather unrealistic that a nearly tetrahedral arrangement of the EFG tensors is due to the effect of nearby atoms on an otherwise considerably dis-

TABLE. 4. DEVIATION FROM 109.5° OF HNH ANGLES DETERMINED BY DMR, AND BY NEUTRON DIFFRACTION STUDY (in the parentheses)

	H_1	H_2	H_3
H_2	−0.1 (−0.6)		
H_3	+0.3 (+7.6)	+0.3 (−4.4)	
H_4	+0.8 (−5.2)	−0.5 (+1.9)	−1.0 (+0.1)

torted arrangement of the z principal axes along the N-D bonds. The parallelism between the N–O directions and the z axis is to be compared with that between the N-O and N–H directions. The average angle of deviation of the N–H···O hydrogen bond from perfect linearity, assuming that the N–H bond is in the direction of the z axis, is 7.5°, while that determined by the neutron diffraction is 6.0°. Therefore, in this respect at least, the N–D bonds directed in the z axes can be almost as reasonable as the directions given by the neutron diffraction.

Let us now consider a few possible causes of these rather large discrepancies between the bond directions derived from the two methods:

a) The isotope effect as the cause of discrepancies—that is, the NH_4^+ ions in this compound are distorted, while the ND_4^+ ions are not. The changes in the bond angles seem to be too large to be ascribed to an isotope effect, however, and it is difficult to find any particular reason for such a large effect to be operative in this case.

b) The z principal direction not in the true bond direction—(1) crystalline field effect. External charges in the crystal to the EFG, the type of effect considered previously,[16,17] would cause a deviation of the z axis from the bond direction. However, it seems too artificial to say that such an effect results in the regular tetrahedral arrangement of the z directions. (2) Bent orbital effect. Assume that the bond orbitals of N are tetrahedrally directed, but the the H–N–H angle, for instance, is larger than the tetrahedral angle because of a force in intermolecular nature. In such a bent orbital or incomplete orbital-following case, the center of the overlap charge of the bond orbitals of N and H are located slightly inside the HNH triangle. A negative contribution to the EFG from this charge will have the effect of tipping the z principal axis of the total EFG at H (which is positive) in such a way that the angles between the two z directions of EFG will be closer to the tetrahedral angle than the actual HNH angle. When the HNH angle is smaller than the tetrahedral angle, the situation is reversed and again the HNH angle becomes closer to the tetrahedral angle. At least qualitatively, this seems to be a plausible explanation; it could also favorably account for the smaller net distortion of eqQ from a regularly tetrahedral arrangement in ammonium sulfate than that expected from structure analysis.[4] We have, however, no estimate of the magnitude of this effect at present. Moreover, in the case of ammonium dihydrogen phosphate (ADP), distortion from the tetrahedral symmetry determined by neutron diffraction is consistent with that estimated from the quadrupole interaction[17] despite the fact that, from the symmetry at the site of ND_4^+, a pronounced effect of deviation from the orbital following is to be expected.*3 Another experimental evidence against the above view is to be found in the deuteron-quadrupole coupling in some C–ND_3 systems where there is a rapid reorientation of the ND_3 group about the C–N bond. In triglycine sulfate, eqQ values ranging from 37.3 to 54.8 kHz have been reported from various ND_3 sites of para- and ferro-electric phases.[18,19] For CH_3ND_3Cl we obtained an eqQ value of 45 kHz from the room-temperature powder spectrum. In these cases the quadrupole coupling is given approximately by $eq_0Q(1-3\cos\theta)2$, where θ is the angle between the z axis of EFG of D at rest and the C–N bond and where q_0 is the magnitude of this EFG. Though q_0 should vary from one compound to another, the wide distribution of the observed eqQ values can be attributed to a wide distribution in θ. A definite conclusion as to the validity of the above effect must, however, be deferred until a quantitative calculation is made for this effect and until the measurements of the DMR as well as of the neutron diffraction are made on various ammonium salt crystals. Such studies seem to be of great importance because, in view of the usefulness of DMR as a means of determining the bond direction of H–(X), the limitations of this technique should be well established.

The averaging of the four quadrupole coupling tensors of the ND_4^+ ion gives $eqQ/h=-1.67$ kHz and $\eta=0.92$, values consistent with the small quadrupole coupling value of ~1.5 kHz observed at room temperature. Since the principal z directions of EFG did not agree with the bond directions by neutron diffraction, no general conclusion can be drawn concerning the relation between the averaged quadrupole coupling in the rapidly reorienting ND_4^+ ion and the distortion of the ion. However, judging from the close correlation of eqQ values with the N···O distances,

17) T. Chiba, This Bulletin, **38**, 490 (1965).

*3 In the tetragonal phase of ADP, NH_4^+ forms a slightly "flat" tetrahedron (site symmetry: D_{2d}) In this structure it is not possible to form 4 equivalent orthogonal orbitals of N directed in the N–H directions from s and p orbital hybridization.

it appears that the average eqQ is determined mainly by the local structure of the ion and that the crystalline field effect is relatively unimportant.

Motion of Ammonium Ions. For an NH_4^+ tetrahedron, reorientational motions can either by about its C_2 axes or about its C_3 axes. In ammonium halides where the crystal structure is such that a rotation about the C_2 axis is subject to a four-fold potential, 90° reorientations about the C_2 axes are considered to be the substantial ones. When the NH_4^+ ion is held by four hydrogen-bond-acceptor oxygen atoms in a nearly tetrahedral arrangement, the potential barrier to the C_3 reorientation is considered to be less than that to the C_2 reorientation, for the former requires 3 hydrogen bonds to be broken in the course of the rotation, while the latter requires 4 bonds to be broken. Therefore, we assume only C_3 reorientations in the present case.

Suppose the rate of reorientation about the N–H_1 axis, Ω_1, is different from that about the other 3 axes (N–H_2, N–H_3, and N–H_4), Ω_2. Then the probability for a given hydrogen atom in site 1 to be transferred to other sites is $3\Omega_2$, while the corresponding probability for Sites 2, 3 and 4 is $2\Omega_2+\Omega_1$. The width due to motion at the slow exchange limit (measured in angular frequency units) of a line corresponding to a particular site is just the probability of a jump from that site to others. For instance, if $\Omega_1=2\Omega_2$ the width due to the motion of the Site-1 line relative to that of the Site-2 line at the slow exchange limit will be 0.75, and if $\Omega_1=1/2\Omega_2$ it will be 1.20. The spectra near the limit of the slow exchange rate when H_0 is in the b axis direction are shown in Fig. 5. At −110°C where deuterons are practically stationary, the lines corresponding to the four sites (D_1, D_2, D_3, and D_4) are separately observed with approximately the same intensity.

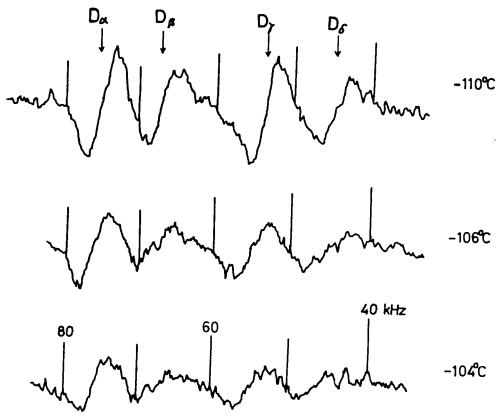

Fig. 5. Ammonium deuteron lines at the slow exchange limit recorded with H_0 in the b axis direction.

The broadened spectra at −106°C and at −104°C show no appreciable difference in the extent of broadening among the four lines. In view of the high sensitivity of the signal height as recorded as a derivative curve to the line-broadening effect, it can safely be said that the ratio of the motional line-width between any two of the four lines is well within the 0.75—1.20 range. Therefore, the reorientation of the NH_4^+ ion is considered to be quite isotropic.*4 If it is further assumed that Ω_1 and Ω_2 are governed by Arrhenius equations with the same pre-exponential factor, $\Omega_1=\Omega_0\exp(-\Delta E_1/RT)$ and $\Omega_2=\Omega_0\exp(-\Delta E_2/RT)$, $\Omega_1/\Omega_2=2$ or 0.5 gives, at −105°C, $\Delta\varepsilon=\Delta E_1-\Delta E_2=\pm 233$ cal/mol. From the rough estimate given above, it appears that the difference in the activation energy is quite small. This conclusion is unaltered when more than two different Ω values are involved. If one considers the hydrogen-bond energy to be a main factor in determining ΔE, one may conclude that the difference in hydrogen-bond energy in the four bonds is rather small, although a fairly large difference in hydrogen-bond lengths has been reported from the X-ray study. This is in contrast to the case of the H_2O flip motion, where a marked dependence of ΔE on the hydrogen-bond distance is seen.[6]

The average proton relaxation time for reorienting NH_4^+ ions (the intraionic effect only) in a powdered sample is given by O'Reilly and Tsang[4] as:

$$\frac{1}{T_1}=(1.91\times10^{10})\left(\frac{\tau_c}{1+\omega^2\tau_c^2}+\frac{4\tau_c}{1+4\omega^2\tau_c^2}\right) \quad (5)$$

where τ_c is related to the τ in Eq. (2) as:

$$\tau_c=3\tau/4\,. \quad (6)$$

with $\omega=2\pi\times10^7$ sec^{-1}, Eq. (5) gives a T_1 minimum of 2.27 msec at $\omega\tau=0.62$, or $\tau=1.31\times10^{-8}$ sec^{-1}. Since the cross-relaxation time between protons in the NH_4^+ ion and the H_2O molecule in the crystal must be much shorter than this T_1 value, the 10 protons in $(NH_4)_2C_2O_4H_2O$ are to be relaxed by this mechanism instead of the 8 protons in $2(NH_4)$. Therefore, the actual T_1 minimum will be $(10/8)\times$ 2.27 msec=2.84 msec. The observed T_1 minimum is 2.6 msec at $T=254$°K. Since the interionic contribution to relaxation is not included in Eq. (5), the agreement is quite satisfactory.

In the deuteron resonance, T_1 is determined almost entirely by the quadrupole interaction. The pulse experiment is made on the deuteron line of the reorienting ND_4^+ ion, which has a nearly zero spliting. Therefore, water deuterons which

*4 After this work had been completed we learned that, in a suitable temperature range, the $NaND_4SO_4$-$2D_2O$ crystal exhibits the DMR spectra of the ND_4^+ ion under rapid reorientation about a single C_3 axis (D. J. Genin and D. E. O'Reilly, *J. Chem. Phys.*, **50**, 2842 (1969)).

have a large splitting are not involved in the observed T_1 practically. The theoretical expression for the quadrupole relaxation in the present case is given in the Appendix. When numerical values $(eqQ/h)=168$ kHz and $\omega=6.28\times10^7$ sec^{-1} are substituted in Eq. (A9), the T_1 for a powdered sample will be given by:

$$\frac{1}{T_1}=(8.36\times10^{10})\left(\frac{\tau}{1+\omega^2\tau^2}+\frac{4\tau}{1+4\omega^2\tau^2}\right). \quad (7)$$

The T_1 minimum is attained when $\omega\tau=0.62$ or $\tau=0.98\times10^{-8}$ sec. The calculated T_1 minimum= 0.53 msec is in good agreement with the experimental value, 0.52 msec, observed at 262°K.

The values of the reorientation rate $\Omega(=1/3\tau)$ at the temperature of the T_1 minima derived above for the proton and the deuteron are found to be in satisfactory agreement with the results from the line-width transition, as may be seen in Fig. 3. The values of the activation energy, ΔE, derived from the high- and low-temperature-side slopes of the T_1 minima of log T_1 *vs.* $1/T$ curves are:

	From the high-temp. slope	From the low-temp. slope
Proton	7.07 kcal/mol	7.46 kcal/mol
Deuteron	7.27 kcal/mol	

Averaged: 7.27 kcal/mol.

With this average value of ΔE, the best fits of τ at the T_1 minimum for both the proton and the deuteron are obtained by:*5

$$\tau=10^{-14.1}\exp(7.27/RT). \quad (8)$$

log T_1 *vs.* $1/T$ curve near the T_1 minimum, calculated from Eqs. (5) and (8) for the proton and from Eqs. (7) and (8) for the deuteron, are drawn in Fig. 4. The agreement with the observed data is satisfactory.

The ΔE value of 7.27 kcal/mol obtained from the proton and deuteron relaxation times is probably more reliable than that obtained from the line-width transition. This value is higher than those for most of the ammonium salts, indicating fairly strong hydrogen bonds holding the ammonium ion.

In Fig. 3 a serious disagreement is found between the Ω derived from the line broadening at the slow exchange limit and that derived from Eq. (8) (shown by the solid line). This might seem to indicate a variation in activation energy at low temperatures. However, in the temperature dependence of T_1 in Fig. 4 no such effect is indicated. The reason for this disagreement is not clear.

Motion of Water Molecules. As has been stated before, the broadening of the water-deuteron line at about 50°C is considered to be due to the 180° flip motion about the bisector axis of the water molecule. The line broadening takes place at a considerably higher temperature than in most of the hydrates studied thus far. The water of hydration is lost before the temperature reaches the point where the motion is rapid enough to allow observation of the averaged spectrum. We estimate the value of activation energy from the reorientation rate derived from the line broadening at the slow exchange limit, assuming a pre-exponential factor of the reorientation rate to be 10^{14} sec^{-1}, a value often found for water of hydration.[6] The value of $\Delta E=15.5$ kcal/mol thus derived is the highest value obtained thus far for the 180° flip motion of water molecules. It is interesting that, in a crystal with a similar composition, $K_2C_2O_4H_2O$, a high activation energy of 14 kcal/mol has been reported.[20] In this latter compound, DMR line broadening begins just above room temperature.[13] The high activation energies in these crystals are parallel with the short hydrogen-bond distances and the small deuteron-quadrupole coupling values.

A short drop of the $T_{1\rho}$ of the proton at the high temperature in Fig. 4 can also be understood as associated with the 180° flip motion of water molecules. Since the *rf* field strength, H_1, used in the measurement of $T_{1\rho}$ is comparable to the local field, and since $T_{1\rho}$ decreases with an increase in the temperature, that is, with an increase in the assumed reorientation rate of the H_2O motion, the $T_{1\rho}$ in this range must be determined by the mechanism of "slow motion." Such cases have been dealt with by Slichter and Ailion.[21] $T_{1\rho}$ is given by the formula:

$$\frac{1}{T_{1\rho}}=\frac{2}{\tau}(1-p)\frac{H_L'^2}{H_L'^2+H_1^2}, \quad (9)$$

where $1/\tau$ is the rate of the motion and H_L' is the local field in the rotating frame and is related to the second moment, $\langle\Delta H^2\rangle$, by $H_L'^2=(1/3)\langle\Delta H^2\rangle$. The $1-p$ factor gives a measure of the effectiveness of the motion to the relaxation, and when the nuclei exchange positions between two sites, r and q, it is given by:

$$1-p=\sum_i(A_{ir}-A_{iq})^2/\{\sum_i(A_{ir}^2+A_{iq}^2)+\sum'A^2\} \quad (10)$$

where $A_{ab}=(3\cos^2\theta_{ab}-1)/r_{ab}^3$. r_{ab} is the length of the internuclear vector, $\boldsymbol{r}_{ab}$, joining a spin at Site a to that at Site b, and θ_{ab} is the angle between H_0 and $\boldsymbol{r}_{ab}$. The suffix i refers to all the stationary spins which interact with the spins, r and q, in

*5 The pre-exponential factor is dependent on the mass difference of H and D by a factor $1/\sqrt{2}$ (see Ref. 4, Appendix). In the present case, however, since unknown isotope effects of various origin may also be involved, the small correction of $1/\sqrt{2}$ is ignored.

20) J. W. McGrath and A. A. Paine, *J. Chem. Phys.*, **41**, 3551 (1964).

21) C. P. Slichter and D. Ailion, *Phys. Rev.*, **135**, A1099 (1964).

motion. The last term in the denominator represents a sum over all the spin-pairs which are motion-independent (including A_{rq}^2). To apply Eq. (9) to the present measurements, which are made on powdered samples, $1-p$ must be averaged over the direction of H_0. The denominator of Eq. (10) is just the lattice part of the second moment. The evaluation of the angular average of Eq. (10), $(1-p)_{AV}$, can be done by numerical integration, but would be quite laborious to perform. For the present discussion it may be sufficient to estimate $(1-p)_{AV}$. For this purpose it may be permitted to approximate it by taking the angular averages of the numerator and denominator separately. A second moment of about 7.5 G^2 is obtained from the powder spectrum of proton resonance at room temperature. Thus, the denominator averaged over the H_0 direction will be:

$$\langle\text{denom.}\rangle_{AV} = \langle\Delta H^2\rangle/(4/5)\cdot(3/4)^2\hbar^2 I(I+1) = 0.021\ \text{Å}^{-6}.$$

For the evaluation of the numerator, a sum is taken over all the inter-proton pairs between a given H_2O molecule and the nearest 8 NH_4^+ ions. A can be expressed in terms of the inter-proton vectors and the H_0 directions in the coordinate system of the crystalline axes. The angular average is readily made, and

$$\langle\text{num.}\rangle_{AV} \simeq 0.0022\ \text{Å}^{-6}.$$

We get $(1-p)_{AV}\sim\langle\text{num.}\rangle_{AV}/\langle\text{denom.}\rangle_{AV}=0.1$.

At $H_1=6$ G, from Eq. (9) the $T_{1\rho}$ due to the H_2O motion is given by:

$$\frac{1}{(T_{1\rho})_{H_2O}} = \frac{2}{\tau}\times 0.1\times\frac{(7.5/3)}{(7.5/3)+6^2} = \frac{1}{\tau}\times\frac{1}{77} \quad (11)$$

Near the $T_{1\rho}$ maximum, $1/T_{1\rho}$ consists of contributions from the H_2O motion and the NH_4^+ motion; that is, $(T_{1\rho})_{obs}^{-1} = (T_{1\rho})_{H_2O}^{-1} + (T_{1\rho})_{NH_4}^{-1}$. Since, in this case $\omega\tau\ll 1$ for the NH_4^+ motion, $(T_{1\rho})_{NH_4}\approx(T_1)_{NH_4}$ (see Eqs. (10) and (16) of Ref. 4). $(T_{1\rho})_{H_2O}$ is obtained from $(T_{1\rho})_{obs}$ by assuming $(T_{1\rho})_{NH_4}$ to be equal to the observed proton T_1. The values of $1/\tau(=\Omega)$ calculated from Eq. (11) at temperatures above 48°C are plotted in Fig. 3. The agreement of this result with that from the line-width change is satisfactory, considering the approximations in the analysis.*6 From the slope of $\log(T_{1\rho})_{H_2O}$ *vs.* $1/T$ curve in Fig. 4, an activation energy for the H_2O motion of about 14 kcal/mol is obtained; in view of the limited temperature range observed, this value is in good agreement with the 15.5 kcal/mol estimated in the previous section. Thus, the sharp drop of $T_{1\rho}$ at the high temperatures can be reasonably accounted for by the motion of the H_2O molecule in consistency with the line-width change of the D_2O spectra at these temperatures. It should be noted, however, that similar sharp drops of $T_{1\rho}$ are often observed in some ammonium salts at high temperatures; these drops may be considered to be due to the diffusional motion of the NH_4^+ ion or its fragments. We cannot exclude the possibility that, in the case of ammonium oxalate monohydrate, such effect is involved.

*6 Actually, in the present case H_1 (=6 G) is considerably larger than H_L'. Therefore, the application of the low-field relaxation formula of Eq. (9) may not be appropriate. However, since the difference between the high-field relaxation formula and the low-field one is small (Ref. 21, pp. 1103A—1104A), this does not have serious effect on the conclusion.

The author would like to thank Mr. Masaki Funakoshi for his great assistance in the preparation of the crystal and in the NMR measurements. Most of the measurements and the computor processing of the data were made at the Institute for Solid State Physics, the University of Tokyo. The author wishes also to thank the Institute for the use of its facilities.

Appendix

The expression for the T_1 of the deuteron is obtained from the standard treatment of the spin-lattice relaxation by a random modulation of a quadrupole interaction due to ND_4^+ reorientations. Assume an isotropic C_3 reorientation of a regularly-tetrahedral ND_4^+ ion. Let τ_c be the correlation time for this motion. The mean residence time of a spin in one site, τ, is then given by:

$$1/\tau = 3/4\tau_c \quad (A1)$$

The probability that a spin at Site 1 at $t=0$ remains in that site at $t=t$ is given by $\{1+3\exp(-t/\tau)\}/4$, and the probability that it is transferred to one of the other sites, by $\{1-\exp(-t/\tau)\}/4$. Therefore, the autocorrelation function of a given component of the EFG tensor, F, for a spin at Site 1 at $t=0$ will be:

$$F(0)F^*(t) = 1/4\{|F_1|^2(1+3x) + (F_1F_2^*+F_1F_3^*+F_1F_4^*)(1-x)\}, \quad (A2)$$

where $F_i(t)$ denotes that EFG component for a given spin at Site i at time t and $x\equiv\exp(-t/\tau)$. Since, at $t=0$, the probability of a spin in a particular site is 1/4, it follows that:

$$\langle F(0)F^*(t)\rangle_{AV} = \frac{1}{16}\{(1+3x)\textstyle\sum_i|F_i|^2+2(1-x)\sum_{i>j}|F_iF_j|\}. \quad (A3)$$

The power spectrum of F at an angular frequency, ω, $I(\omega)$, is given by:

$$I(\omega) = \int_{-\infty}^{\infty}\langle F(0)F^*(t)\rangle e^{i\omega t}dt = \left\{\frac{3}{16}\textstyle\sum_i|F_i|^2+\frac{1}{8}\sum_{i>j}|F_iF_j|\right\}j(\omega) = \left\{\sum_{i>j}\frac{1}{16}|F_i-F_j|^2\right\}j(\omega), \quad (A4)$$

with:

$$j(\omega) = 2\tau/(1+\omega^2\tau^2). \quad (A5)$$

For deuterons ($I=1$), T_1 is given by:

$$1/T_1 = P_1 + 2P_2 , \tag{A6}$$

where:

$$P_1 = (e^2Q^2/8\hbar^2)I^{(1)}(\omega) \text{ and } P_2 = (eQ^2/8\hbar^2)I^{(2)}(2\omega) . \tag{A7}$$

In $I^{(1)}(\omega)$ and $I^{(2)}(2\omega)$, the components of the EFG tensor relevant to $\Delta m=\pm 1$ and ± 2 transitions respectively are to be used for F's of Eq. (A4). Thus, for $I^{(1)}(\omega)$, $|F_i-F_j|^2$ in Eq. (A4) will be $\{(\varphi_{xz})_i-(\varphi_{xz})_j\}^2 + \{(\varphi_{yz})_i-(\varphi_{yz})_j\}^2$, and for $I^{(2)}(2\omega)$, it will be $[\{(\varphi_{xx})_i - (\varphi_{xx})_j\} - \{(\varphi_{yy})_i - (\varphi_{yy})_j\}]^2 + 4\{(\varphi_{xy})_i - (\varphi_{xy})_j\}^2$, where $(\varphi_{ab})_i$ denotes the ab element of the EFG tensor at Site i. We take, for convenience, a coordinate system of an ND_4^+ ion such that the x, y, and z axes coincide with their C_2 axes. φ's are expressed in terms of the EFG component along the D-N bond direction, q, and the direction cosines (l, m, n) of H_0 in the assumed coordinate system.

The expression of T_1 for an arbitrary direction of H_0 are computed following the procedure of O'Reilly and Tsang.[4] The symmetry consideration leads to the expression for P in Eq. (A7) of the form:

$$P = C_1 + C_2(l^4+m^4+n^4) .$$

where C_1 and C_2 are the factors to be determined. To do this it is only necessary to calculate P for two independent cases of H_0 direction, where such calculations are most conveniently made, and to solve the simultaneous equations thus obtained for C_1 and C_2. The expression for T_1 thus obtained is:

$$\frac{1}{T_1} = \frac{(eqQ)^2}{8\hbar^2}\left[(l^4+m^4+n^4)\frac{\tau}{1+\omega^2\tau^2} + \{3-(l^4+m^4+n^4)\}\frac{\tau}{1+4\omega^2\tau^2}\right] \tag{A8}$$

with a powdered sample, T_1 varies from one microcrystallite to another as $(l^4+m^4+n^4)$ takes values between 1 and 1/3, but since the orientation dependence of T_1 seen from Eq. (A8) is mild, the average T_1 measured for powdered sample may be compared with the theoretical expression, Eq. (A8), averaged over H_0 directions, as is done in the discussion of the proton T_1. Thus $\langle l^4+m^4+n^4\rangle_{AV}=3/5$ gives:

$$\frac{1}{(T_1)_{\text{powder}}} = \frac{3\pi^2}{10}\left(\frac{eqQ}{h}\right)^2\left(\frac{\tau}{1+\omega^2\tau^2}+\frac{4\tau}{1+4\omega^2\tau^2}\right) \tag{A9}$$

which is just the expression for quadrupole relaxation by the isotropic random rotation of the molecule.[22]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1950—1955 (1970)

Photochemical Reactions of Uranyl Ions with Organic Compounds. I. The Mechanism of the Uranyl Ion-Photosensitized Oxidation of Lactic Acid

Shukichi SAKURABA and Ryoka MATSUSHIMA

Faculty of Engineering, Shizuoka University, Hamamatsu

(Received November, 12, 1969)

The photochemical reaction of lactic acid with uranyl ions in an aqueous solution was studied with radiations of 4050 and 4360 Å. The quantum yields and molar ratios of the reaction products were measured under various conditions. Two competing photo-reactions appeared to take place; through them lactic acid was oxidized to form pyruvic acid at a lower pH and to form acetaldehyde, with an evolution of carbon dioxide, at a higher pH. The results obtained can be well explained by assuming that the excitation of the uranyl lactate complex is involved in the formation of acetaldehyde and that a collision between lactic acid and the excited uranyl ion, without any complex formation, is involved in the formation of pyruvic acid.

Both the intermolecular (collisional) mechanism[1,2] of the energy transfer from the excited uranyl ions to organic substrates and the intramolecular mechanism,[3-6] in which the formation of complexes between uranyl ions and substrates prior to the photolysis is involved, have been proposed for the photo-reactions of organic acids, alcohols, and aldehydes by uranyl ions in an aqueous solution. Evidence for both the mechanisms

has been found in the photolysis of uranyl oxalate.[7,8] However, the collisional mechanism has been assumed to be less important in the photooxidations of alcohols,[9] aldehydes,[10] α-hydroxy acids,[11] and other organic acids[6] with uranyl ions.

We observed that lactic acid in an aqueous solution containing uranyl ions decomposed upon irradiation with visible light to produce acetaldehyde, carbon dioxide, pyruvic acid,*1 and uranium(IV), and that the molar ratios of the reaction products depended on the acidity of the solution, *i.e.*,

$$UO_2^{2+} + CH_3CH(OH)CO_2H + h\nu$$

$$\xrightarrow{pH \ll 1} CH_3C(=O)CO_2H + \text{U(IV) species}$$

$$\xrightarrow{pH \sim 2} CH_3C(=O)CO_2H + CH_3C(=O)H + CO_2 + \text{U(IV) species}$$

$$\xrightarrow{pH > 3.5} CH_3C(=O)H + CO_2 + \text{U(IV) species}$$

The present investigation was undertaken in order to elucidate the mechanisms by means of kinetic treatments.

Experimental

Doubly-distilled water and guaranteed reagents (Koso Chemical) were used. The solutions were de-aerated by the passage through of oxygen-free nitrogen for 40 to 60 min per 25 ml and then placed into 1-cm spectrophotometer quartz cells with pipets kept air-tight with liquid parafine; they were further de-aerated for several minutes, and then exposed to light (4050 or 4360 Å) using either an interference filter or a suitable combination of glass filters. The intensities of light absorbed by the reactants, needed for the estimation of the quantum yield, were measured by using a ferricoxalate actinometer.[13] In order to minimize the inner filter effect of the uranium(IV) formed and in order to avoid further oxidations of organic products, the measurements were carried out within 5% of the reaction extent. The light source was a 100-W high-pressure mercury lamp (Riko Co., Ltd.) or a 500-W xenon lamp (Ushio Co., Ltd.). The acidities of the solutions were adjusted with 1 N NaOH and 1 N $HClO_4$ by using a pH meter (Toa-Dempa Co., Ltd.). The pH values of the solutions were constant during the irradiation. No direct photodecomposition of lactic acid occurred in the absence of uranyl ions, and no thermal decomposition was detected in the dark in 8 hours at 70—80°C in the presence of uranyl nitrate.

The concentrations of the uranium(IV) formed were measured colorimetrically with arsenazo-III.[14] The acetaldehyde and pyruvic acid formed were identified as 2,4-dinitrophenyl hydrazones by comparing their infrared spectra, melting points, and R_f values (TLC) with those of authentic samples. To aliquots of the irradiated solutions, excess acidic solutions of 2,4-dinitrophenyl hydrazine were added; orange precipitates were then isolated and washed with water. To the precipitates, an aqueous solution of 0.5 N Na_2CO_3 and an equal volume of chloroform were added and shaken well; then the aqueous layer (containing 2,4-DNP of pyruvic acid) and the chloroform layer (containing 2,4-DNP of acetaldehyde) were separated. The absorbances of the aqueous solutions and of the chloroform solutions were measured at 380 nm and 360 nm respectively. The reproducibility of this method was checked. Carbon dioxide was identified with barium hydroxide. Spectrophotometric measurements were carried out by means of a recording spectrophotometer (Hitachi 124-Type). Fluorescence was measured by using a Hitachi fluorescence photometer.

Results

The Equilibria of the Uranyl Lactate System

Mononuclear complexes having combining ratios (lactate/uranyl) of one, two, and three to one have been reported in the uranyl lactate system in the pH range from 2 to 3.5,[15–17] while Rajan and

Martell[18,19] suggested the existence of polynuclear complexes as well. At the pH range of less than unity, no complexes between the uranyl and the lactate ions were found by spectrophotometric studies to exist. Examples at pH=1 and at pH=3.5 are shown in Fig. 1.

The Effect of Acidity on the Quantum Yield. The quantum yields of uranium(IV) formation at various pH's are shown in Table 1. It may be seen that the quantum yield decreases with the increase in pH, though the apparent rate of photolysis may be increased due to the remarkable increase in the absorption coefficient with the pH (Fig. 2). The acidity-dependency of the quantum yield is contrary to the view[3-6,11] that the reacting species are complexes between the uranyl ions and the substrates.

The Effect of Acidity on the Molar Ratios of the Products. The molar ratios of the total organic products to the uranium(IV) are about unity, as is shown in Table 2, but the pH-dependency of the molar ratio of pyruvic to the uranium (IV) is in contrast with that of acetaldehyde (Fig. 3). The increase in acetaldehyde formation with the increase of pH is interpreted as indicating that the photoreactive species are the complexes between the uranyl and the lactate ions; this is in accord with the earlier view. However, the pH-dependency of pyruvic acid formation cannot be explained by the same theory. Further, it is noticed that the pyruvic acid formation is interfered with by the addition of a small amount of iodine, the iodide ion, the chloride ion, or oxygen (in this order), while the acetaldehyde formation is not affected. The influence of the iodide ion is shown in Fig. 4. Thus, a mechanism involving encounter collisions between the excited uranyl ion and lactic acid is proposed for the formation of pyruvic acid.

The Effect of the Initial Concentration of Lactic Acid on the Quantum Yield. The dependency of the quantum yield on the initial concentration of lactic acid at pH=1 (not complexed) and that at pH=3.5 (complexed) are shown in Table 3 and Fig. 5 and in Fig. 6, respectively. At pH=1, a straight line of reciprocal quantum yields *versus* reciprocal initial concentrations of lactic acid was obtained, while such was not the case at pH=3.5 (Fig. 5). At pH=3.5 the quantum yield reaches a limiting value (Fig. 6).

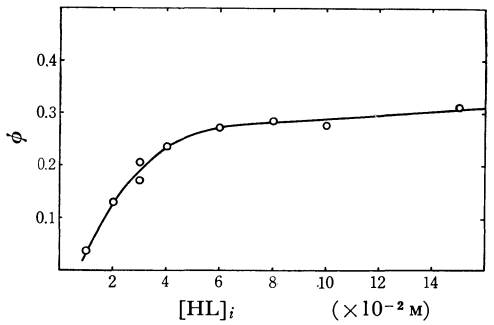

Fig. 6. Plot of the quantum yield of uranium(IV) *vs.* initial concentration of lactic acid at pH=3.5.
Initial concentration of uranyl nitrate was 0.02 M.

Discussion

The acidity-dependency of the formation of acetaldehyde is in contrast to that of pyruvic acid, as is shown in Fig. 3. Figure 1 shows that complex formation between the uranyl and lactate ions takes place in the system at pH=3.5 prior to the photolysis, while such is not the case at pH=1. Therefore, it seems reasonable to assume that the opposite dependency of the product-ratios on the acidity is attributable to the difference in the initial species of the system to be photolyzed. Further, the formation of pyruvic acid is inhibited by the trapping agents, while acetaldehyde formation is not affected (Fig. 4). This difference in the inhibitory effect suggests that the primary intermediates at pH=1 are $CH_3\dot{C}(OH)CO_2H$ and UO_2^+, while intramolecular photoredox reactions of the uranyl-substrate complexes are involved at pH=3.5. The following mechanism is, therefore, proposed for the photolysis at pH=1:

$$UO_2^{2+} + h\nu \xrightarrow{I_a} (UO_2^{2+})^*$$

$$(UO_2^{2+})^* \xrightarrow{k_1} UO_2^{2+}$$

$$(UO_2^{2+})^* + CH_3CH(OH)CO_2H \xrightarrow{k_2} CH_3\dot{C}(OH)CO_2H + UO_2^+ + H^+$$

$$CH_3\dot{C}(OH)CO_2H + UO_2^{2+} \xrightarrow{k_3} CH_3C\overset{O}{\diagdown}CO_2H + UO_2^+ + H^+$$

$$2UO_2^{+} + H^{+} \xrightarrow{k_4} UO_2^{2+} + \text{U(IV) species}^{20)}$$

I_a is the rate of light absorption in einsteins$\cdot l^{-1}\,sec^{-1}$. A similar scheme was proposed for the photolysis of uranyl oxalate by Carter and Weiss[7] and later by Volman and Seed.[8] The radical $CH_3\dot{C}(OH)CO_2H$ would be rapidly oxidized by $UO_2^{2+}(k_3)$ before the disproportionation reaction:

$$2CH_3\dot{C}(OH)CO_2H \longrightarrow CH_3C(=O)CO_2H + CH_3CH(OH)CO_2H$$

since the concentration of $CH_3\dot{C}(OH)CO_2H$ would be small compared to that of UO_2^{2+}. Assuming the steady state with respect to $(UO_2^{2+})^*$, UO_2^{+}, and $CH_3\dot{C}(OH)CO_2H$, the quantum yield of the uranium(IV) formation is given by:

$$\phi = \frac{1}{I_a}\cdot\frac{d[U(IV)]}{dt} = \frac{k_2[HL]}{k_1 + k_2[HL]},$$ HL: Lactic acid

or, $$\frac{1}{\phi} = 1 + \frac{k_1}{k_2}\cdot\frac{1}{[HL]}$$

That is, the reciprocal quantum yields *vs.* the reciprocal concentrations of lactic acid should form a straight line. This is consistent with the experimental facts (Fig. 5). In addition, the plot of the relative reciprocal intensity of uranyl fluorescence *vs.* the concentration of lactic acid obeys the Stern-Volmer equation, as in the case of isopropyl alcohol, but such is not the case at pH=3.5 (Fig. 7). It has been reported that the efficiency of intramolecular energy transfer between lanthanide ions and organic ligands is much higher than that of collisional (intermolecular) transfer between lanthanide ions and non-chelating molecules.[21-23] Figure 7 shows that the quenching constant (or the slope) of lactic acid at pH=1 nearly equals that of non-chelating isopropyl alcohol, indicating an intermolecular energy transfer from excited uranyl ions to lactic acid molecules in stronger acidic media.

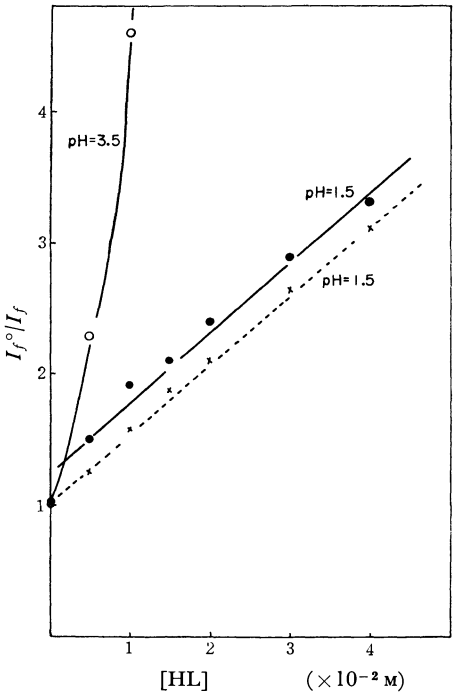

Fig. 7. Plot of I_f°/I_f *vs.* concentration of lactic acid. I_f° and I_f are the relative intensities of uranyl fluorescence at 509 nm in the absence and in the presence of lactic acid, respectively. Excitation was at 436 nm. $[UO_2(NO_3)_2]=0.02$ M. Isopropyl alcohol was included for comparison (dotted line).

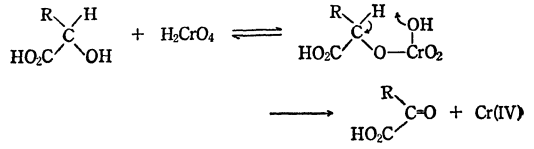
The alternative explanation for the formation of pyruvic acid is a mechanism involving ester-like intermediates, as has been proposed for the thermal oxidation of α-hydroxy acid by chromic acid[24-26]:



This, however, is not the case with the formation of pyruvic acid in the photolysis of lactic acid by uranyl ions, since pyruvic acid was also obtained upon the irradiation of lactic acid with cupric ions in an aqueous acidic solution, where no such ester-like intermediates are conceivable.

In the case of the photolysis at pH=3.5, the quantum yield reaches a limiting value (Fig. 6). Heckler and his co-workers[6] found a phenomenon similar to that shown in Fig. 6 for the uranyl ion-photosensitized decomposition of such organic acid as malonic, succinic and glutaric acids in solution; they concluded that the photosensitive species are complexes formed between uranyl ions and organic acid ions.

Thus, the photosensitive species for the formation of acetaldehyde are the $UO_2^{+}L$ and UO_2L_2 complexes, both formed prior to the photolysis;

$$UO_2^{2+} + HL \overset{K_1}{\rightleftharpoons} UO_2^{+}L + H^{+}$$

$$UO_2^{+}L + HL \overset{K_2}{\rightleftharpoons} UO_2L_2 + H^{+}$$

where HL and L represent $CH_3CH(OH)CO_2H$ and $CH_3CH(OH)CO_2^-$ respectively and where K_1 and K_2 are the equilibrium constants. The following mechanism may be proposed for the formation of acetaldhyde though more experimental data are needed to describe it in detail:

$$UO_2^+L + h\nu \longrightarrow (UO_2^+L)^*$$

$$(UO_2^+L)^* \longrightarrow UO_2^+L$$

$$(UO_2^+L)^* \rightleftharpoons CH_3\underset{\cdot}{C}H\begin{matrix}\diagup O \diagdown \\ \cdot\ \ \ \cdot \\ CO_2\end{matrix}UO_2^+ \longrightarrow$$

$$CH_3C\begin{matrix}\diagup O \\ \diagdown H\end{matrix} + H^+ + CO_2 + U(IV)$$

Similarly,

$$UO_2L_2 + h\nu \longrightarrow (UO_2L_2)^*$$

$$(UO_2L_2)^* \longrightarrow UO_2L_2$$

$$(UO_2L_2)^* \rightleftharpoons CH_3\underset{\cdot}{C}H\begin{matrix}\diagup O \diagdown \\ \cdot\ \ \ \cdot \\ CO_2\end{matrix}UO_2L \longrightarrow$$

$$CH_3C\begin{matrix}\diagup O \\ \diagdown H\end{matrix} + H^+ + CO_2 + U(IV) + L^-$$

Though the details of the mechanism at high pH are not clear, it may safely be concluded that the variation in the products and mechanisms with pH is to be attributed to the subject whether the formation or dissociation of the uranyl-lactate complex is predominant.

The authors wish to express their thanks to Mr. M. Koshio for a grant given to our research from the "Koshio-Hōonkai".

Relations between Intramolecular Energy Transfer Efficiencies and Triplet State Energies in Rare Earth β-diketone Chelates

Susumu SATO and Masanobu WADA

Department of Electronic Engineering, Faculty of Engineering, Tohoku University, Sendai

(Received November, 17, 1969)

The fluorescence yield of europium chelates in several solutions varies, through its maximum value, with the increase in the energy difference between the triplet state of a ligand and the emitting level of an europium ion. The time-resolved spectroscopic measurements show that the excitation energy is transferred from the triplet state to the lower and nearest resonance level of the europium ion. The intramolecular energy transfer mechanisms for europium chelates and terbium chelates are proposed, taking the resonance exchange interaction and the thermal deactivation processes from the emitting levels of rare earth ions into consideration. Steady-state rate equations are made, and the equation of the fluorescence yield is obtained. Thus, the relations between the fluorescence yield and the triplet state energy are estimated and the fluorescence properties of rare earth β-diketone chelates may be qualitatively described.

A number of europium and terbium β-diketone chelates give a narrow-band emission from the rare earth ion under near UV excitation, and some of these chelates exhibit laser action when dissolved in organic solvents.[1-3] The absorbed pump energy is transferred to a triplet state (by the intersystem crossing), and is then intramolecularly transferred to the rare earth ion.[4] Since this intramolecular energy transfer from the triplet state to the resonance level of the rare earth ion is of a spin-forbidden type, the energy is transferred by the resonant exchange interaction[5] and the role of the triplet state is very important. There have been some reports discussing the role of the triplet state, and it has been concluded that the excitation energy could not be transferred from the ligand to the rare earth ion if the triplet state of the ligand was below the resonance level of the rare earth ion.[4] However, few experimental

studies have been done on the dependence of the energy transfer efficiency upon the triplet state energy. The fluorescence yield of rare earth β-diketone chelates varies widely depending on the temperatures, the solvents, the ligands, the central ions and bases, and, further, whether they are of a tris or a tetrakis form. Therefore, the dependence of the fluorescence yield upon the triplet state energy must be measured by changing only the energy level of the triplet state, maintaining the other conditions as constant as possible.

The europium β-diketone chelate derived from BTFA (benzoyltrifluoroacetone), which contains a benzene ring and a trifluoromethyl group, shows a high fluorescence yield of an europium-ion emission at room temperature. Many other β-diketone compounds similar to BTFA have been prepared in which the benzene ring was replaced by other aromatics, such as naphthalene, phenanthrene, and anthracene. The optical and fluorescent properties of europium chelates derived from substituted β-diketone compounds were measured.[6] The triplet state energy of these substituted β-diketone compounds is expected to be changed. In this paper, using europium and terbium chelates prepared from these substituted β-diketone compounds, the effects of the triplet state energy upon the energy transfer mechanism will be investigated and discussed.

Sample Preparation

The compounds discussed in the present article are listed, along with their abbreviation codes, in Table 1. In these β-diketone compounds, BTFA and TTA were obtained from Dotite reagents. All the other compounds were synthesized from the proper monoketone and ethyltrifluoroacetate by a manner reported previously.[6]

The europium, terbium, and gadolinium β-diketone chelates were synthesized by ordinary piperidine methods. The analytical data of the rare-earth-metal contents for these chelates are shown in Table 2. It can be seen that all of the

europium chelates and most of the terbium chelates are of the tetrakis form, (HQ)R.E.(β-diketone)$_4$ (Q=pyrrolidine, R.E.=Eu or Tb), but the gadolinium chelates are of the tetrakis form or the tris form, R.E.(β-diketone)$_3$ (R.E.=Gd), or a mixture of these two forms.

Results and Discussion

Triplet State Energy of β-Diketones. The phosphorescence spectra of gadolinium chelates were measured at 77°K in an EPA solution (5 parts diethylether, 5 parts isopentane, and 2 parts ethanol by volume). The exciting light source was a combination of a high-pressure Hg lamp and a UV-DIB bandpass filter (300—400 mμ transmission range). The phosphorescence band emission of gadolinium chelates was strong, and two or three clearly-defined bands were observed for most of the chelates investigated. The shortest-wavelength phosphorescence band was assumed to be the 0–0 transition[7], and the triplet state energy was determined. The results are summarized in Table 3. However, the phosphorescence of Gd(CTFA)$_3$ was so weak that it was very difficult to determine the triplet state energy exactly. The resonance levels of europium and terbium ions and the triplet state of each β-diketone compound listed in Table 3 are shown in Fig. 1.

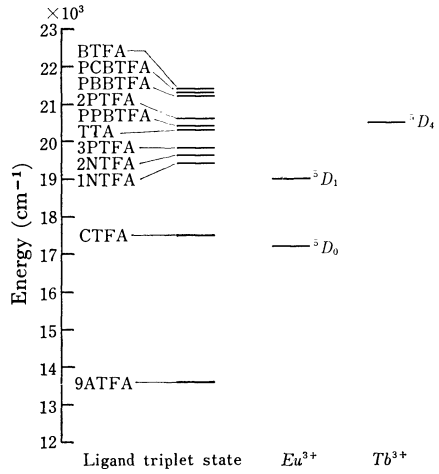

Fig. 1. Triplet states of β-diketonates and related levels of europium and terbium ions.

Europium chelates prepared from the β-diketone compounds, the triplets state of which is above the $^5D_0$ level of the Eu^{3+} ion, emit the intense fluorescence of the Eu^{3+} ion at room temperature, but $Eu(CTFA)_4^-$ fluoresces only at relatively low temperatures. $Eu(9ATFA)_4^-$ does not fluoresce even at the temperature of liquid nitrogen. On the other hand, terbium β-diketone chelates derived from the β-diketone with a triplet state higher than that of TTA emit the fluorescence of the Tb^{3+} ion at low temperatures, but no other terbium

chelates fluoresce.

Relation between the Fluorescence Yield and the Triplet State Energy. Measurements of the fluorescence quantum yields were made at room temperature by a method similar to one reported previously.[6] The relations between the fluorescence quantum yields at room temperature and the energy difference between the ligand triplet state and $^5D_1$ level of the Eu^{3+} ion are plotted for several solutions in Fig. 2. It can be seen that the fluorescence yield varies through its maximum value as the energy difference becomes larger. In terbium chelates, the fluorescence was nearly quenched at room temperature; therefore, a relation such as that shown in Fig. 2 could not be obtained. These results will be discussed in detail later.

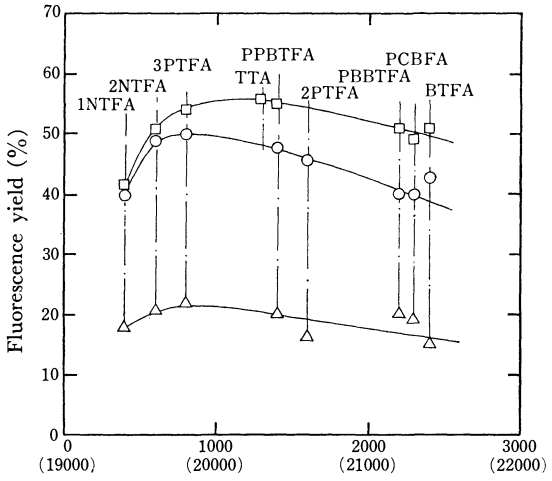

Fig. 2. Relations between fluorescence yields of europium β-diketone chelates and the energy difference between the ligand triplet state and the $^5D_1$ level of the Eu^{3+} ion.

Temperature Dependences of Fluorescence Lifetimes. The fluorescence lifetimes of the europium and terbium chelates were obtained by a stroboscopic method[6]; their values were of the order of 10^{-3}—10^{-4} sec. The normalized temperature dependences of the fluorescence lifetimes of europium and terbium β-diketone chelates are shown in Fig. 3. It can be seen that the quenching temperature moves toward the higher-temperature region as the energy difference between the triplet state of the ligand and the emitting level of the rare earth ion becomes larger. The temperature dependence of the fluorescence intensities showed thermal quenching properties quite similar to those of the temperature dependence of the fluorescence lifetimes.

Time-resolved Spectroscopy. Time-resolved spectroscopy was carried out by a stroboscopic technique similar to that described by Bhaumik *et al.*[8] The resolution time of our apparatus was about 0.3 μsec. Figures 4 (a) and (b) show the time-resolved spectra of $Eu(BTFA)_4^-$ in an acetonitrile solution at room temperature and of $Eu(CTFA)_4^-$ in an EPA solution at 77°K. For most europium chelates with the same properties as that of $Eu(BTFA)_4^-$, the emission due to the $^5D_0 \rightarrow {}^7F$ transition begins to build up as the emission due to the $^5D_1 \rightarrow {}^7F$ transition begins to decrease. On the other hand, the emission from the $^5D_1$ level of

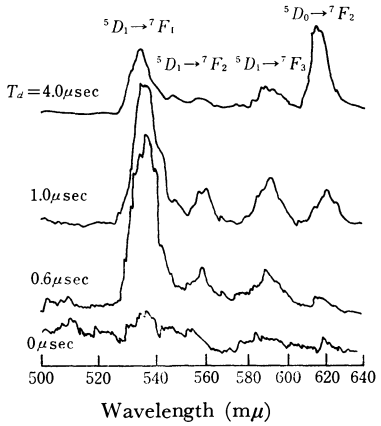

Fig. 4(a). Time-resolved spectra for (HQ)Eu(BTFA)$_4$ Q=pyrrolidine in acetonitrile solution at room temperature.
The delay time after the flash of exciting light is given by T_d.

8) M. L. Bhaumik, G. L. Clark, J. Snell, and L. Ferder, *Rev. Sci. Instr.*, **36**, 37 (1965).

*1 The same phenomenon was observed in $Eu(1NTFA)_4^-$ at room temperature; this will be discussed elsewhere.

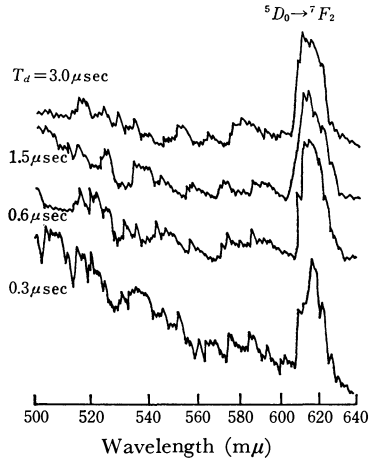

Fig. 4(b). Time-resolved spectra for (HQ)Eu-(CTFA)$_4$ (Q=pyrrolidine) in EPA solution at 77°K.
The delay time after the flash of exciting light is given by T_d.

$Eu(CTFA)_4^-$ can not be detected, and the rise time of the emission originating from the $^5D_0$ level is very short and is beyond the resolution time of the apparatus.*1 As can be seen in Fig. 1, the triplet state of CTFA exists between the $^5D_1$ level and the $^5D_0$ level of the Eu^{3+} ion, but the triplet states of all the other β-diketone compounds except 9ATFA are above the $^5D_1$ level. Therefore, in the europium chelates other than $Eu(CTFA)_4^-$, it may be concluded that the excitation energy is transferred from the ligand's triplet state to the $^5D_0$ level *via* the $^5D_1$ level of the europium ion. In $Eu(CTFA)_4^-$, it may be transferred directly from the triplet state to the $^5D_0$ level.

Intramolecular Energy Transfer Mechanism. The energy-level scheme to be used in describing the intramolecular energy transfer mechanism for europium chelates, is similar to that given by Samelson *et al.*[9]; it is shown in Fig. 5, where the wavy lines represent the energy transfer or the loss due to the radiative or nonradiative transition to the ground state, while the straight lines represent the absorption or the radiative transition due to $^5D_0 \rightarrow {}^7F_2$ or thermal-deactivation processes. In this figure, the singlet state is denoted by S, the triplet state of a ligand is denoted by T, and the $^5D_1$, $^5D_0$, $^7F_2$, and $^7F_0$ levels of the Eu^{3+} ion are shown as 4, 3, 2, and 1 respectively. The transitions associated with the other levels have not been considered. The steady-state rate equations are:

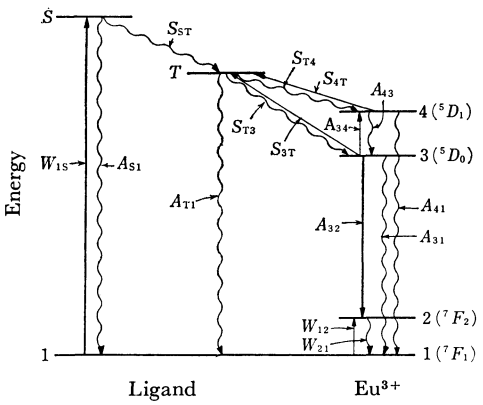

Fig. 5. Energy transfer diagram for europium chelates.

$$dN_S/dt = W_{1S}N_1-(A_{S1}+S_{ST})N_S = 0 \quad (1)$$

$$dN_T/dt = S_{ST}N_S-(A_{T1}+S_{T4}+S_{T3})N_T+S_{4T}N_4 + S_{3T}N_3 = 0 \quad (2)$$

$$dN_4/dt = S_{T4}N_T-(A_{43}+A_{41}+S_{4T})N_4+A_{34}N_3 = 0 \quad (3)$$

$$dN_3/dt = S_{T3}N_T+A_{43}N_4 -(A_{32}+A_{31}+A_{34}+A_{3T})N_3 = 0 \quad (4)$$

$$dN_2/dt = A_{32}N_3+W_{12}N_1-W_{21}N_2 = 0 \quad (5)$$

$$N_0 = N_1+N_2+N_3+N_4+N_T+N_S \quad (6)$$

where W_{1S} is the transition probability for the absorption; where A_{S1}, A_{T1}, A_{41}, and A_{31} are loss probabilities due to the transitions from the excited states to the ground state; where S_{ST}, S_{T4}, and S_{T3} are the transition probabilities for radiationless processes; where A_{32} is the radiative transition probability for the europium fluorescence, and A_{43}, the transition probability for the decay from the $^5D_1$ level to the $^5D_0$ level; where W_{12} and W_{21} are the transition probabilities for the thermal and relaxation processes between the ground state and the terminal states, and where S_{T3}, S_{T4}, and A_{34} are the probabilities for the thermal-deactivation processes and are the inverse processes of S_{T3}, S_{T4}, and A_{43} respectively. The population of the jth state is denoted by N_j, and the total concentration of molecules, by N_0. Degenerations should be considered for each level; the thermal deactivation probabilities are, then, given by:

$$S_{4T} = S_{T4}\exp(-E_{T3}/\boldsymbol{k}T) \quad (7)$$

$$S_{3T} = 3S_{T3}\exp(-E_{T3}/\boldsymbol{k}T) \quad (8)$$

$$A_{34} = 3A_{43}\exp(-E_{43}/\boldsymbol{k}T) \quad (9)$$

where E_{T4}, E_{T3}, and E_{43} are the energy differences between the corresponding respective two levels. The fluorescence yield for the $^5D_0 \rightarrow {}^7F_2$ transition is defined as follows:

$$\eta_{Eu} = A_{32}N_3/W_{1S}N_1 \quad (10)$$

Under the steady-state condition, the fluorescence yield, η_{Eu}, is obtained from Eqs. (1) to (10) as follows:

$$\eta_{Eu} = [1+(S_{T3}/S_{T4})(1+A_{41}/A_{43})+(S_{T3}/A_{43}) \times \exp(-E_{T4}/\boldsymbol{k}T)]/(1+A_{S1}/S_{ST})[(1+S_{T3}/S_{T4}$$

9) H. Samelson, A. Lempicki and C. Brecher, *J. Chem. Phys.*, **40**, 2553 (1964).

$$+ A_{T1}/S_{T4})(1+A_{41}/A_{43})(1+A_{31}/A_{32})$$
$$+ (1+A_{31}/A_{32})\{(A_{T1}+S_{T3})/A_{43}\}\exp(-E_{T4}/\boldsymbol{k}T)$$
$$+ (3S_{T3}/A_{32})\{(A_{41}/A_{43}+A_{T1}/S_{T4}+A_{T1}A_{41}/S_{T4}A_{43})$$
$$+ 3A_{T1}/A_{32}\}\exp(-E_{T3}/\boldsymbol{k}T)$$
$$+ (1+S_{T3}/S_{T4}+A_{T1}/S_{T4})(3A_{41}/A_{32})$$
$$\times \exp(-E_{43}/\boldsymbol{k}T)+(3A_{T1}S_{T3}/A_{32}A_{43})$$
$$\times \exp\{-(E_{T3}+E_{T4})/\boldsymbol{k}T\}] \quad (11)$$

Assuming that $A_{S1}/S_{ST} \ll 1$, $A_{41}/A_{43} \ll 1$, and $S_{T3}/S_{T4} \ll 1$ for the sake of simplicity, we have:

$$\eta_{Eu} = 1/[1+A_{T1}/S_{T4}+(A_{T1}/A_{43})\exp(-E_{T4}/\boldsymbol{k}T)$$
$$+ (3A_{T1}/A_{32})\exp(-E_{T3}/\boldsymbol{k}T)] \quad (12)$$

Equation (12) shows that when the temperature is low or the energy difference is large (provided that A_{T1} is constant), the exponential terms may be negligible and the fluorescence yield depends only upon S_{T4}. On the other hand, when the temperature is high or the energy difference is small, the exponential terms become large and the term of S_{T4} may be negligible.

In the case of terbium chelates, the situation is somewhat simpler; the energy transfer diagram is shown in Fig. 6.

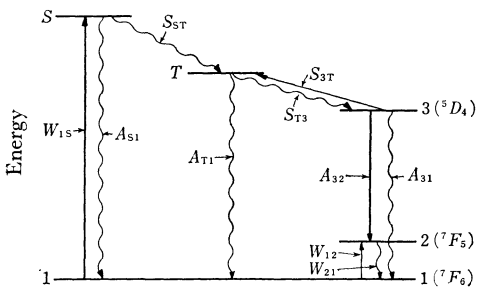

Fig. 6. Energy transfer diagram for terbium chelates.

The fluorescence yield, given by a similar way, is:

$$\eta_{Tb} = 1/[(1+A_{S1}/S_{ST})\{(1+A_{T1}/S_{T3})(1+A_{31}/A_{32})$$
$$+(A_{T1}/3A_{32})\exp(-E_{T3}/\boldsymbol{k}T)\}] \quad (13)$$

Therefore, the fluorescence yield also depends upon S_{T3} when the temperature is low or the energy difference is large, and *vice versa*.

In Eqs. (11), (12), and (13), which represent the fluorescence yields of europium and terbium chelates, the transition probability for the nonradiative energy transfer, S_{T3} or S_{T4}, is important. This transition probability was taken into consideration by Ermolaev *et al.*[5] and by Matsuda *et al.*,[10] along with the exchange-interaction theory described by Dexter.[11] The transition probability for the exchange interaction, P_{sa}, is given as follows:

$$P_{sa} = (2\pi Z^2/\hbar)\int F_s(E)\varepsilon_a(E)\mathrm{d}E \quad (14)$$

where F_s is the emission spectrum of the sensitizer (donor) and corresponds to the phosphorescence spectrum of a ligand in this case, where ε_a is the absorption spectrum of the activator (acceptor) and corresponds to the absorption spectrum for the $^7F \rightarrow {}^5D$ transition in the Eu^{3+} ion or the Tb^{3+} ion, where E is an energy (and now we use the unit of a wave number), and where Z^2 is the term of the overlap of electron clouds and cannot be determined by optical experiments. In the following discussions, the coefficient $(2\pi Z^2/\hbar)$ in Eq. (14) will be assumed to be equal and constant in all the chelates investigated.*2 Therefore, the transition probability may be proportional to the overlap between the phosphorescence spectrum and the absorption spectrum. The results obtained for the europium chelates are plotted in Fig. 7, and those for the terbium chelates are shown in

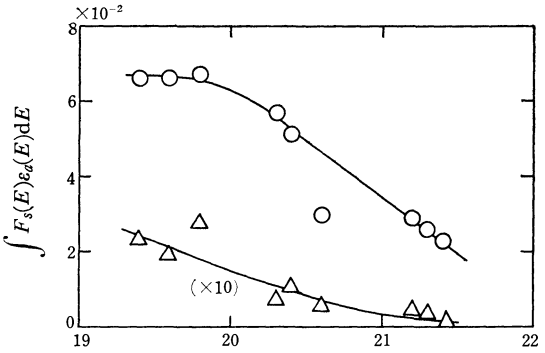

Fig. 7. Overlap for europium chelates.

11) D. L. Dexter, *J. Chem. Phys.*, **21**, 836 (1953).

*2 This term may probably depend upon the mutual distance between the central ion and an oxygen atom of the ligand[10] but this distance is assumed to be not greatly changed among each β-diketone chelate in this case.

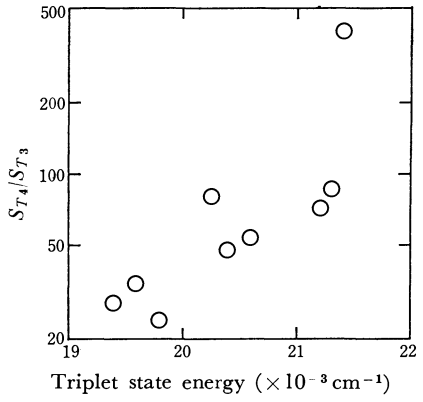

Fig. 9. The ratio of a transition probability for the $^5D_1$ level and the $^5D_0$ level of the europium ion.

Fig. 8, where the horizontal axis is the triplet state energy and where the circles show the values calculated for each β-diketone chelate. It can be seen in Fig. 7 that the overlap decreases as the triplet state energy increases. The ratio of the overlap for the $^5D_0$ and $^5D_1$ levels, that is, the ratio of the transition probability (S_{T4}/S_{T3}), is estimated from Fig. 7 and is shown in Fig. 9. As the triplet state energy increases, this ratio tends to increase exponentially, so that the excitation energy is transferred mainly from the triplet state to the $^5D_1$ level. The transition probability from the triplet state to the $^5D_0$ level is very small, but not zero. Therefore, the energy transfer to the $^5D_0$ level becomes important for the europium chelates which have the triplet state between the $^5D_1$ level and the $^5D_0$ level.

Since the energy of the $^5D_4$ level of the Tb^{3+} ion is about 20500 cm^{-1}, the value of the overlap is at its maximum for the β-diketone chelates with a triplet state energy of near 20500 cm^{-1}. This value of the overlap decreases rapidly or gradually according as the triplet state is lower or higher than the $^5D_4$ level.

The dependence of the energy transfer probabilities, S_{T4} and S_{T3}, on the energy difference must be taken into consideration, because these probabilities can reasonably be considered to depend upon the triplet state energy, as may be seen in Figs. 7 and 8. The energy transfer probability for the transition from the triplet state to the resonance level of the Eu^{3+} ion was obtained as 10^7—10^8 sec^{-1} from the quenching effects of anthracene on the fluorescence of europium chelates.[12] If the coefficient, $2\pi Z^2/\hbar$, in Eq. (14) is assumed to be 10^9, the energy transfer probability, S_{T4} (or S_{T3} from Fig. 8), can be obtained as 10^7—10^8 sec^{-1} using the values of the overlap shown in Fig. 7 or Fig. 8. This value of 10^7—10^8 sec^{-1} is coincident with the result obtained in Ref. 12 and seems reasonable. Therefore, the value of $2\pi Z^2/\hbar$ is taken as 10^9 and the energy transfer probability is obtained for each triplet state energy from the results shown in Figs. 7 and 8. Using these results, the fluorescence yield, η_{Eu}, for europium chelates is estimated from Eq. (11) and is plotted in Fig. 10,

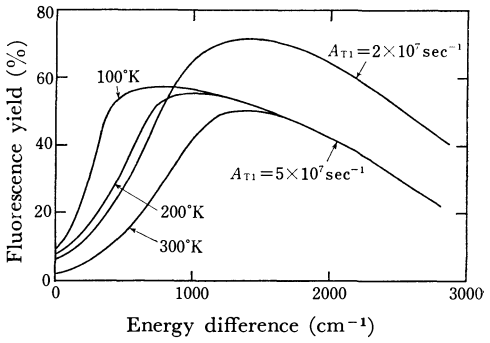

Fig. 10. Fluorescence yields *vs.* energy difference ($T-{}^5D_1$) for europium chelates.

where $A_{S1}=A_{41}=A_{31}=0$, $A_{43}=10^6$ sec^{-1}, $A_{32}=10^3$ sec^{-1}, $A_{T1}=2\times10^7$ sec^{-1} (for 300°K), and 5×10^7 sec^{-1} (for 100°K, 200°K, and 300°K) are assumed. η_{Tb} is estimated from Eq. (13) and is plotted in Fig. 11, where $A_{S1}=A_{31}=0$, $A_{32}=10^3$ sec^{-1}, $A_{T1}=2\times10^7$ sec^{-1} (for 300°K), and 5×10^7 sec^{-1} (for 100°K, 200°K, and 300°K) are assumed. In both cases, the fluorescence yield decreases because of the thermal deactivation process where the energy difference is small. Where the energy difference is large, the fluorescence yield also decreases because of the decrease in the energy transfer probability due to the diminution in the overlap between the phosphorescence spectra of the ligands and the absorption spectra of the rare earth ions. Consequently, the fluorescence yield shows a maximum for the proper energy difference between the triplet state and the resonant level of the rare earth ion; the experimental results shown in Fig. 2 are, therefore, confirmed. The temperature depen-

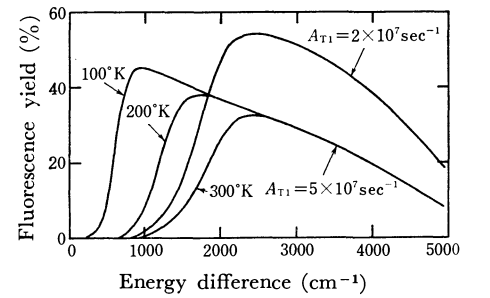

Fig. 11. Fluorescence yields *vs.* energy difference ($T-{}^5D_4$) for terbium chelates.

12) V. L. Ermolaev, E. A. Saenko, G. A. Domrachev, Yu. K. Khudenskii, and V. G. Aleshin, *Opt. Spectry.*, **22**. 466 (1967).

dences of fluorescence yields are also shown in Fig. 10 and Fig. 11, which show that the chelate compounds with small energy differences (*e.g.*, $Eu(CTFA)_4^-$, $Tb(BTFA)_4^-$, $Tb(TTA)_4^-$, and $Tb(PPBTFA)_4^-$) do not fluoresce at room temperature, but they begin to fluoresce if temperature is lowered. Since the thermal quenching for the fluorescent level decreases as the energy difference is large, the temperature dependence of fluorescence lifetimes in Fig. 3 is explained. Thus, several properties of the energy transfer mechanism for rare earth chelate compounds can be explained, but the explanation of the phenomena is qualitatively limited because so many undetermined factors in the system remain.

The authors are grateful to Dr. T. Seki and Dr. H. Watanabe for their valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1962—1966 (1970)

Crystal Structure of Bis(nitrosocyclohexane)*1

Masamitsu TANIMURA,*2 Kiyotomi KOBORI,*3 Michio KASHIWAGI and Yukio KINOSHITA*3

Basic Research Laboratory, Toray Industries Inc., Tebiro, Kamakura

(Received December 1, 1969)

The crystal structure of bis(nitrosocyclohexane), $(C_6H_{11}NO)_2$, has been determined by means of three-dimensional X-ray analysis by the photographic method. The crystal belongs to the triclinic space group $P\bar{1}$, with cell parameters, $a=10.133$ A, $b=6.758$ A, $c=5.583$ A, $\alpha=121°42'$, $\beta=96°50'$, $\gamma=78°06'$. The unit cell contains one molecule. The nitrogen and oxygen atoms and the carbon atoms bound to nitroso-groups, CNO–O'N'C', are almost coplanar, and the oxygen atoms take a trans configuration around the N–N' bond. The cyclohexane ring takes a chair form and the nitrogen atom is bound to an equatorial bond. The CNO–O'N'C' plane is twisted from the cyclohexane ring by 73°.

Bis(nitrosocyclohexane), which is easily converted into cyclohexanone oxime by light, is a very important material from an industrial point of view. However, its structure has not been determined. The present investigation was carried out in order to determine a detailed structure by means of X-ray diffration.

Experimental

Single crystals of bis(nitrosocyclohexane), $(C_6H_{11}NO)_2$, were obtained by slow evaporation from methanol solution as triclinic plates tabular on (100). The cell dimensions were determined from the oscillation and Weissenberg photographs taken around the three axes using Cu$K\alpha$ radiation. The space group was determined from the measurement of piezo-electricity and from the Wilson ratio test. The results are listed in Table 1.

Intensity data were recorded on the equi-inclination Weissenberg photographs taken around b-axis up to the fifth layer and around c-axis up to the fourth layer, using the multiple film technique. The relative intensities, estimated visually with a set of standard scales, were corrected for the Lorentz-polarization factors. No absorption corrections were made. A total of 1096 independent reflections were observed.

TABLE 1. CRYSTAL DATA

Triclinic	
$a=10.133$ A	$\gamma=78°06'$
$b=6.758$	$Z=1$
$c=5.583$	$p\bar{1}$
$\alpha=121°42'$	$\mu=0.0794\,cm^{-1}$ (Cu$K\alpha$)
$\beta=96°50'$	

Structure Determination

The space group was assumed to be $P\bar{1}$. Choice of the space group was corroborated by structure determination.

An approximate structure was readily deduced from the three dimensional Patterson syntheses. The structure thus obtained was refined by Fourier

syntheses projected along the *b*- and *c*-axes, and later by a three dimensional isotropic least-squares method with ERBR1 program.[1] After a few cycles of this refinement, the structure was further refined by a block-diagonal anisotropic least-squares method with HBLS program.[2] Finally the difference Fourier syntheses were carried out in order to find the positions of the hydrogen atoms.

The final discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$ became 0.105 for all the observed reflections. Atomic scattering factors were taken from the International Tables for X-ray Crystallography. Final atomic parameters and their standard deviations are listed in Tables 2a and 2b. The observed and calculated structure factors are listed in Table 3.

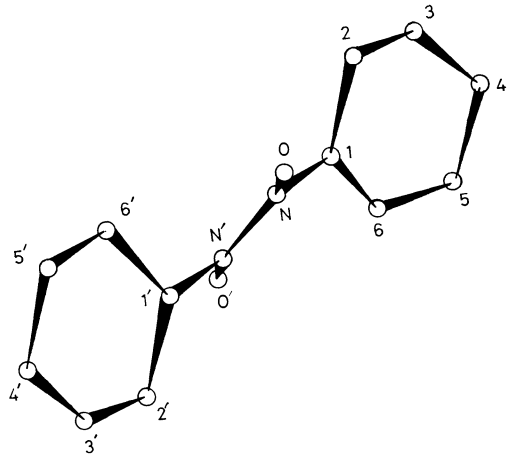

Fig. 1. Schematic diagram projected along c-axis.

Results and Discussion

The interatomic distances and bond angles are listed in Table 4. A schematic diagram of the molecule along the *c*-axis is shown in Fig. 1.

The atoms C(1), O, N, C′(1), O′ and N′ are almost coplanar, and oxygen atoms are placed *trans* with regard to the N–N′ bond. The cyclohexane ring takes a chair form, and the C(1)–N bond is equatorial.

The least-squares plane through C(1), O, N, N′, O′ and C′(1) is given by the equation.

$$0.9532X - 1.3248Y + 0.1805Z = 0 \quad (1)$$

Deviations of the atoms from this plane are apparently not significant as shown in Table 5.

The planes through C(1), C(3), C(5) and through C(2), C(4) and C(6) are given by the fol-

1) J. H. Van den Hende, "Crystallographic Structure Factor and Least-Squares Refinement Program" (1961).

2) T. Ashida, "Block-Diagonal Matrix Least-Squares Refinement Program" (1964).

lowing equations.

$$0.3534X - 0.3270Y + 0.7918Z = -0.0837 \quad (2)$$

$$0.4569X - 0.2034Y + 0.7720Z = 0.7862 \quad (3)$$

Planes (2) and (3) are almost parallel, and these planes make an average angle of 73° against plane (1).

The distances of N–N bond (1.32Å) and N–O bond (1.27 Å) suggest their double-bond characters. The N–C(1) bond (1.49 Å) has a single-bond character.

The C–C bond distances and C–C–C angles of the cyclohexane ring are normal. The bond distances and bond angles including the hydrogen atoms do not considerably deviate from the normal values as shown in Table 4. The values of other bond distances and bond angles including hydrogen are of the same order as those listed in Table 4.

All the intermolecular atomic distances observed are within the limits of experimental error, equal to or greater than the sum of the van der Waals radii of the corresponding atoms.

TABLE 3. OBSERVED AND CALCULATED STRUCTURE FACTORS

The running indices are *hl*, the value for *k* immediately precedes the group. The central column is $|F_o|$, the right hand column F_c.

Kurita *et al.*[3] determined the configuration of the C(1)–H(1a), C(1)–C(2) and C(1)–C(6) bonds around the N–C(1) bond from ESR analysis of the irradiated single crystal. The results show that the plane through C(1), N, and O makes an angle of 40° against the plane through C(2), C(1) and N. The result agrees within 5° with the value calculated from the structure of the molecule.

The authors are grateful to Dr. Y. Kurita for kindly supplying the specimen and for valuable discussions.

(Received December, 8, 1969)

The stereochemically-complete molecular structure of demycarosyl leucomycin A_3, $C_{30}H_{49}NO_{11}$, has been determined by means of an X-ray crystal analysis of its hydrobromide. The crystals of the hydrobromide are orthorhombic with four chemical units in a unit cell with the dimensions of $a=19.52\pm0.03$, $b=20.63\pm0.03$, and $c=9.28\pm0.03$ Å. The space group is $P2_12_12_1$. As a result of the present study, it has been found that the crystals contain about 0.6 mole of ethanol per mole of the hydrobromide as alcohol of crystallization. The intensity data were obtained from equi-inclination integrating Weissenberg photographs taken with Cu$K\alpha$ radiation around the b and c axes. The structure was elucidated by means of the minimum function, least-squares, and Fourier methods. The atomic coordinates obtained were refined by the block-diagonal least-squares method, anisotropic thermal motion being assumed for only the bromine atom. The final R factor is 14.6%. The molecular structure thus obtained corresponds exactly to that proposed in 1967 by Hata *et al.* on the chemical evidence, considering the allylic rearrangement in the hydrolysis of leucomycin A_3 with dilute hydrochloric acid. The conjugated diene system in the macro ring has the *trans-trans* configuration. The sugar component, mycaminose, forms a β-glycosidic linkage with the lactone ring.

Leucomycin A_3 is a basic macrolide antibiotic obtained from the broth-filtrate of *Streptomyces Kitasatoensis* Hata.[1] A partial structure was reported by Watanabe *et al.* for the compound,[2] which contains, as sugar components, the mycaminose and 4-*O*-isovaleryl mycarose found in many other antibiotics.[3] Later, the total structure

shown below was proposed by Hata *et al.* on the basis of a comparison with those of magnamycin B and spiramycin A.[4] For the purpose of confirming the proposed structure, an X-ray study of leucomycin A_3 hydrobromide has recently been undertaken by some of the present authors. However, it has been found that the bromine atom is placed at an unfavorable position in the crystal with the space group $P2_12_12_1$; thus, the analysis has been led to difficulty. Therefore, an X-ray structure determination has been tried for the hydrobromide of demycarosyl leucomycin A_3 instead of leucomycin A_3 itself. The crystal analysis of the derivative has proved successful, and the present paper will describe in detail the complete molecular structure, including the absolute configuration.

Experimental

Demycarosyl leucomycin A_3 (I) was derived from leucomycin A_3 by hydrolysis with 0.3 N hydrochloric acid and then further converted into its hydrobromide by the neutralization of an ethanol solution of I with a water-ethanol solution of hydrobromic acid. Single crystals of the hydrobromide were obtained in colorless prisms by adding ether to a methanol-ethanol solution and by then letting it stand overnight in an icebox. The crystal data determined from the present experiment are summarized in Table 1. The cell dimensions were determined from Weissenberg photographs calibrated with the standard silicon powder lines. The crystal density was measured by flotation in a mixture of carbon tetrachloride and cyclohexane.

Table 1. Crystal data

Formula	$C_{30}H_{49}NO_{11}\cdot HBr\cdot xC_2H_5OH$
Orthorhombic	
	$a=19.52\pm0.03$ Å
	$b=20.63\pm0.03$
	$c=9.28\pm0.03$
Space group	$P2_12_12_1$
U	3737 ± 23 Å
Z	4
D_m	1.258 g/cm³ (at 26°C)
D_x	1.209 g/cm³ (for $x=0.0$)
	1.258 (for $x=0.6$)
	1.291 (for $x=1.0$)

The intensities of reflections were visually measured from equi-inclination integrating Weissenberg photographs around the b and c axes taken with Ni-filtered Cu $K\alpha$ radiation. These intensities were corrected for the Lorentz-polarization factor, but not for the absorption effect, though the crystals used were not sufficiently small. The relative values of the observed structure factors of the 2450 reflections thus obtained were put on an absolute scale by Wilson's method, the estimated overall temperature factor, B, being 7.27 Å².

Structure Determination

As the first step in the structure analysis, a three-dimensional Patterson function, $P(u, v, w)$, was calculated at intervals of 1/120 for u and v and at intervals of 1/60 for w. Since all the three peaks corresponding to the Br–Br vectors were sufficiently separated from the other high peaks, though they were not always the highest in the Harker sections, it was easily found that the bromine atom might be situated at the position, (0.144, 0.098, 0.171). Five cycles of the least-squares treatment were then carried out. As a result of this treatment, it was found that the bromine position was adequate, since the temperature factor converged into a reasonable value of 6.28 Å²; the coordinates also converged into (0.144, 0.097, 0.177). At this stage, the discrepancy factor, R, was 0.48 for all the observed reflections. In order to seek for positions of light atoms, the minimum-function method was applied by using the three independent Br–Br vectors. Out of many maxima in the minimum function diagram, forty-nine were selected as the positions of light atoms on the basis of their heights; they were tested for adequacy by means of the least-squares method, with the coordinates fixed and using the atomic scattering factor of carbon for all.[5] After five cycles it was found that, out of the forty-nine positions, only eighteen were adequate. Then, the first Fourier synthesis was carried out with phases based on these eighteen positions in addition to the bromine. By applying again the above-mentioned method, it was found that thirty-one maxima in the Fourier map were adequate, five other peaks being excluded as false.

4) S. Omura, H. Ogura and T. Hata, *Tetrahedron Lett.*, **1967**, 1267.

5) M. Nishikawa, K. Kamiya, M. Tomita, Y. Okamoto, T. Kikuchi, K. Osaki, Y. Tomiie, I. Nitta and K. Goto, *J. Chem. Soc.*, *B*, **1968**, 652.

Out of these thirty-one rechosen positions, five were taken as those of oxygen atoms on the basis of their very small temperature factors. The second Fourier map thus calculated contained forty-one significant peaks, out of which seven were regarded as oxygen, one as nitrogen, and the remaining thirty-three as carbon, on the basis of both their heights and the chemical information. After three cycles of the usual least-squares refinement using the block-diagonal matrix approximation, it was further found that one of the carbon positions was inadequate and that three others were probably oxygen positions because their temperature factors were definitely small as compared with those of the carbon atoms previously established. The discrepancy factor, R, was 0.28 at this stage.

In order to look for the two atoms of I which had not yet been found, a difference synthesis was carried out. The map obtained had five peaks, with heights ranging from 1.3 to 1.7 e/Å^3. Of these peaks, two could be taken as an oxygen and a carbon atom of I on the basis of the chemical information. On the other hand, the remaining three seemed to correspond to a nonlinear triatomic molecule independent of I, judging from the calculated distances. The presence of the molecule was also supported by the consideration of the molecular packing. Thus, this was considered to be an ethanol molecule which is contained as alcohol of crystallization. However, after three cycles of the least-squares refinement, it turned out that the temperature factors of the three atoms in the alcohol molecule became abnormally large, though the R factor dropped from 0.27 to 0.24. Accordingly, excluding the parameters of the alcohol molecule for a while, six cycles of the least-squares method were repeated, assuming the anisotropic thermal motion for the bromine atom, the R factor calculated being 0.19. In the third Fourier map, computed with the parameters from the refinement, three peaks, with heights of from 1.0 to 1.7 e/Å^3, appeared again at almost the same positions as the peaks in the difference map already mentioned. Thus, it became certain that these peaks were not mere ghost peaks. The least-squares refinement including the ethanol parameters decreased the R factor to 0.177, but again made greater the thermal parameters of the alcohol molecule (20.8 Å^2 for O_E, 16.5 Å^2 for $C_E(1)$ and 20.1 Å^2 for $C_E(2)$). While so far it had been assumed that the mol ratio of ethanol to I was 1 : 1, this assumption no longer seemed to be reasonable. Accordingly, we attempted to estimate the mol ratio from a careful measurement of the crystal density and the unit-cell volume; the estimated value was about 0.6. Using, for the ethanol molecule, 0.6 times the usual values of the atomic scattering factors, three cycles of the refinement were carried out. The R factor thus reached a value of 0.152. Though four more cycles of the finement were performed in consideration of the anomalous dispersion correction of bromine for Cu $K\alpha$ radiation, the R factor did not drop ap-

preciably, the final value being 0.146. The final atomic parameters thus obtained are listed in Table 2, while the final electron-density distribution computed from these parameters is shown in Fig. 1. Tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan.*2

The Absolute Configuration of I

When a non-centric crystal contains atoms which give rise to an observable anomalous scattering of X-rays, Friedel's law $|F(hkl)|^2=|F(\bar{h}\bar{k}\bar{l})|^2$ no longer holds.[6] Since, for the $P2_12_12_1$ space group, $|F(hkl)|^2=|F(\bar{h}\bar{k}l)|^2=|F(h\bar{k}\bar{l})|^2=|F(\bar{h}k\bar{l})|^2$ and $|F(\bar{h}\bar{k}\bar{l})|^2=|F(hk\bar{l})|^2=|F(\bar{h}kl)|^2=|F(h\bar{k}l)|^2$, pairs of (hkl) and $(\bar{h}\bar{k}\bar{l})$ reflections need not be selected for a study of the absolute configuration. In the

present study, the intensities of pairs of (hkl) and $(h\bar{k}l)$ reflections were compared with each other on the above-mentioned Weissenberg photographs around the c axis. On the other hand, the structure factors of these reflections were calculated using the atomic parameters shown in Table 2 and the imaginary part of the dispersion correction, $\Delta f''=+1.5$, for the bromine atom. The results are given in Table 3. A comparison between the observed and calculated intensities indicates that the absolute configuration of I corresponds exactly to the structure given in Table 2. The complete molecular structure thus determined is shown in Figs. 2 and 3.

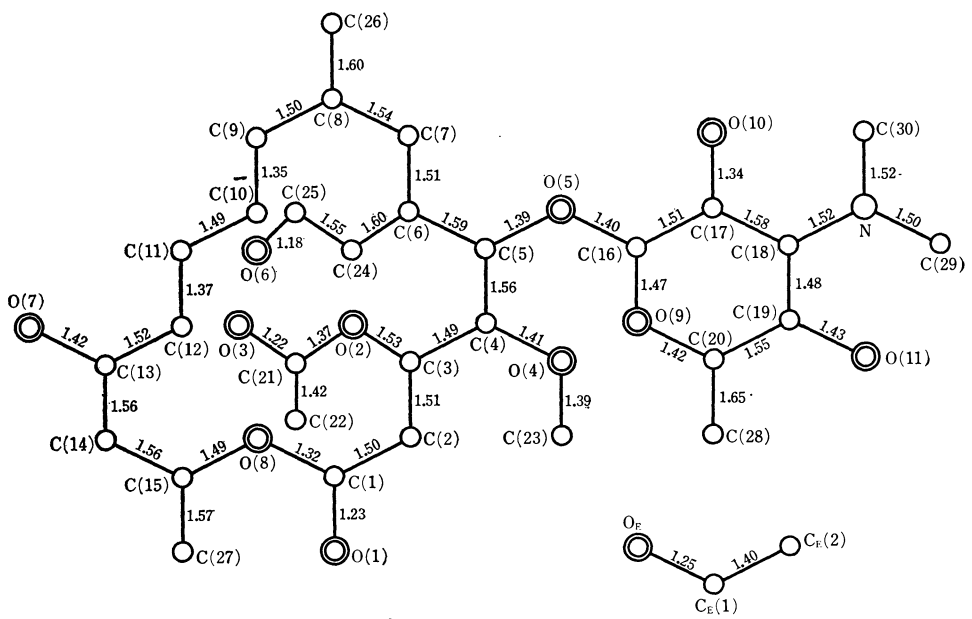

Fig. 4. The bond lengths (Å) in the demycarosyl leucomycin A_3 molecule.

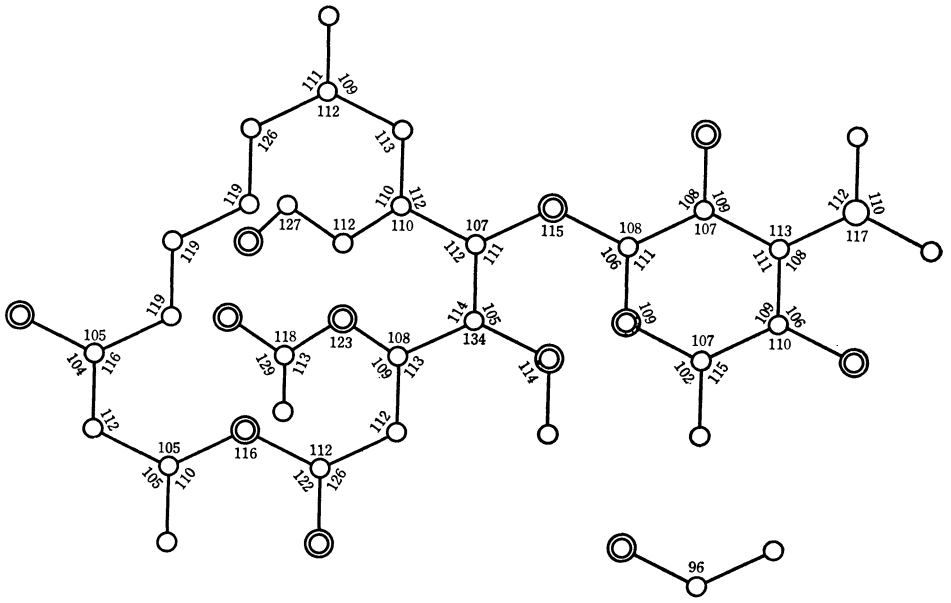

Fig. 5. The bond angles (°) in the demycarosyl leucomycin A_3 molecule.

Results and Discussion

The bond lengths and angles calculated from the final coordinates are shown in Figs. 4 and 5 respectively. The mean estimated standard deviations in the atomic distances of I are 0.025 Å for C–O, 0.028 Å for C–N, and 0.030 Å for C–C, while those of the ethanol molecule are 0.066 Å for C–O and 0.079 Å for C–C. From these lengths and angles, it is now found that demycarosyl leucomycin A_3 has the structural formula shown in Fig. 6. This is different in part from the corresponding part of the structure proposed by Hata *et al.*; that is, in the present case, the two conjugated double bonds in the macro ring are C(9)–C(10) and C(11)–C(12) and a hydroxyl oxygen, O(7), is attached to C(13), while in the latter, the diene system is C(10)=C(11)–C(12)=C(13) and O(7) is at C(9). Since, in the latter structure, the O(7)–H hydroxyl group is situated at the allylic position with respect to the C(10)=C(11) double bond, it can easily be eliminated as a hydroxide ion. If the elimination of the hydroxyl group occurs, the conjugated diene system changes easily from C(10)=C(11)–C(12)=C(13) to C(9)=C(10)–C(11)=C(12) by the successive migration of the two π-bonds, and lastly a hydroxide ion, OH^-, is connected to C(13). The new system thus formed corresponds exactly to the structure established by the present study. In fact, an organic chemical investigation has recently established that such structural changes occur in the process of the hydrolysis of leucomycin A_3 with dilute hydrochloric acid.[7] Table 4 gives the bond distances of I grouped in accordance with the chemical bond nature. In every group, the individual values deviate to some extent from the ordinary value, but the average of these is in good agreement with it.

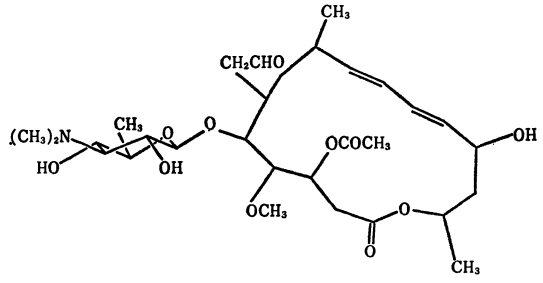

Fig. 6. The structural formula of demycarosyl leucomycin A_3 corresponding to the absolute configuration in Fig. 2.

The aglycone of demycarosyl leucomycin A_3 is composed of a sixteen-membered lactone ring with a conjugated diene system and its seven substituents, *i.e.*, a methoxyl, an acetyl, a formylmethyl, two methyl and two hydroxyl groups. The mean plane of the macro ring is represented by the equation; $0.1031x+0.3567y+0.9285z=5.850$ and is inclined by about 22° from the crystallographic c plane. The deviations of some atoms from the plane are given in Table 5. As may be seen from this table, the sixteen ring atoms deviate alternately in opposite directions except for two pairs, C(5)–C(6) and C(7)–C(8). It is of great interest to compare the conformation of the present sixteen-membered ring with that of

the twelve-membered ring in cyclododecane[8] and that of the thirty-four-membered ring in cyclotetratriacontane.[9] When viewed along the normal of the ring plane, the cyclododecane ring looks nearly like a square with a side of three C–C bonds, while the cyclotetratriacontane ring appears to be almost a rectangle, with one side of three bonds and the other of fourteen bonds. It is worth noticing that, in either of these cases, one side of the square or rectangle is made of three bonds. Such a partial molecular form may be the most compact and most stable one that molecules with a large ring can take. The four corners of the square or rectangle are made in such a way that two adjacent bonds take the *gauche* conformation. As may be seen from Fig. 2 and Table 6, in the present ring also, one half (from C(4) to C(13)) has a conformation very similar to that found in cyclododecane or cyclotetratriacontane, in spite of its containing

* This is the azimuthal angle which, in the part -X-A-B-Y- of the ring, X-A and B-Y make around A-B. The positive sign denotes that the angle is measured in the right-handed way, while the negative sign denotes the measurement in the other way.

** T, G and $\bar{G}$ mean the *trans*, right-handed *gauche* and left-handed *gauche* conformations respectively.

*** This is the deviation from the perfect *trans* or *gauche* conformation.

a conjugated diene system. The diene part is incorporated into the longer side of the rectangle form because if its property of keeping six of the ring carbon atoms zig-zag in a plane. On the other hand, the conformation of the remaining half is considerably different from that of the regular part. The main difference is that the conformations of four bonds, C(1)–C(2), C(14)–C(15), C(15)–O(8), and O(8)–C(1), are, respectively, *gauche*, *gauche*, *trans*, and *trans*, while in the regular ring conformation, such as in cyclododecane or cyclotetratriacontane, they should be, respectively, *trans*, *trans*, *gauche*, and *gauche*. Such a deviating behavior of the conformations seems to be attributable mainly to the existence of the lactone group. That the C(2), C(1), O(8), C(15), and O(1) atoms lie on a plane with the C(1)–O(8) *trans* bond is due to the interaction of the π-orbitals of the C(1) and O(8) of the lactone group. The *gauche* nature of the C(1)–C(2) bond would be more favorable than the possible *trans* conformation, which makes the C(2)–C(3) bond *cis* oriented with the C(1)–O(1) bond.

The orientation of the acetyl group attached to the C(3) from the macro-ring plane is on the same side as O(1). Accordingly, some atoms of the group are near to the oxygen atom; the distances are 2.93 Å for O(2)···O(1), 3.01 Å for C(21)···O(1), and 3.27 Å for O(3)···O(1). The C(3) atom lies nearly on the mean plane of the acetyl group; its deviation from the plane is only 0.15 Å. As in the case of the lactone group, this shows that the energy of the conjugation between the C(21)–O(3) double bond and the O(2) oxygen atom is superior to the energy loss due to the close contact of 2.77 Å between C(3) and O(3). The mean plane of the acetyl makes an angle of about 82° with the macro-ring plane, and one of about 85° with the plane through C(2), C(3), and C(4). The O(2) oxygen atom has a *gauche* relation with both C(5) and O(4), and also with C(1).

The methoxyl group, O(4)–C(23), is placed on the opposite side of the ring plane from the acetyl. The plane through C(4)–O(4)–C(23) is almost perpendicular to the ring plane, the dihedral angle being about 85°. The O(4) oxygen atom has a *gauche* relation with C(2), O(2), and O(5), and a *trans* relation with C(6).

Though the formylmethyl group, O(6)–C(25)–C(24), lies on the same side of the ring as the acetyl, these two groups are not extremely close to each other; for example, the distances of O(6) from C(21), C(22), O(2), and O(3) are, respectively, 3.28, 3.36, 3.53, and 3.70 Å. Nevertheless, it must be taken into account that the two groups exert on each other some considerable attractive forces, such as electrostatic; we may thus understand the fact that the aldehydic carbonyl oxygen, O(6), is almost in a *cis* conformation with C(6) around C(24)–C(25) - in other words, the azimuthal angle for O(6) and C(6) is only 13° and, consequently, the distance between O(6) and C(6) is no more than 2.95 Å. The methylene carbon, C(24), takes a *gauche* conformation with both C(8) and O(5) around C(6)–C(7) and C(5)–C(6) respectively.

The diene system has a nearly planar *trans-trans* conformation. The mean plane of the diene part, C(9)–C(10)–C(11)–C(12), makes an angle of about 77° with the macro-ring plane. As may be seen from Table 6, one of the two double bonds, C(9)=C(10), is somewhat twisted, while the other, C(11)=C(12), is not. This twisting may be due to the incorporation into the regular part of the large ring. Since C(7)–C(8) and C(9)–C(10) make an azimuthal angle of about 90° around C(8)–C(9), though, roughly speaking, they are *gauche*, C(26) is very close to C(10), the distance being only 2.99 Å.

From Fig. 2, it can also be seen that the sugar component, mycaminose, is connected to the C(5) of the macro ring through a β-glycosidic linkage. The six-membered ring takes a regular chair form similar to that of cyclohexane, and its mean plane makes an angle of about 86° with the macro-ring plane. The five groups in the ring occupy the five possible equatorial positions, one by one. The

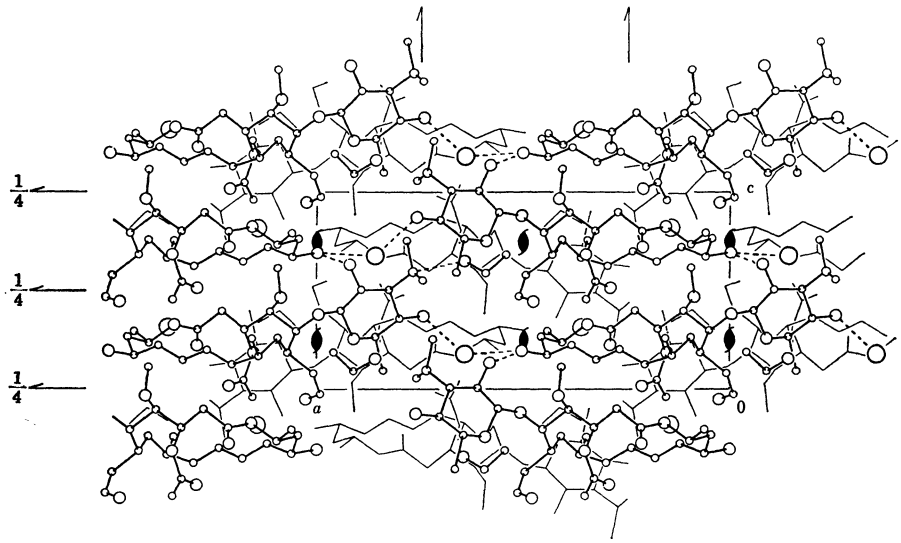

Fig. 7. The molecular arrangement viewed down along the *b* axis.

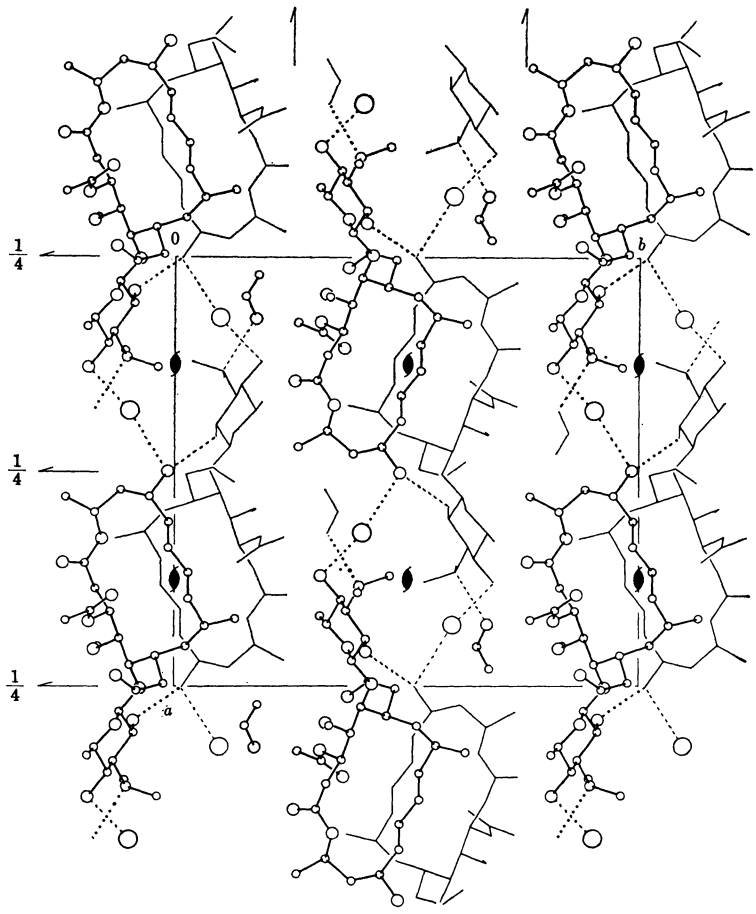

Fig. 8. The molecular arrangement viewed down along the *c* axis.

dimethylamino group takes such a conformation around N–C(18) that C(30) has a *gauche* relation with either C(17) or C(19), and C(29) also has one with C(17). As a result, the C(29) and O(10) atoms approach each other somewhat closely, the distance being 2.95 Å. As for the C(16)–O(5) bond, C(17) and O(9) are, respectively, *trans* and *gauche* with C(5).

The molecular arrangements viewed along the *b* and *c* axes are shown in Figs. 7 and 8 respectively. The macro rings of the molecules are arranged near to one another around the screw axis along the *c* axis at $x=1/4$ and $y=1/2$. The principal interatomic distances in this kind of intermolecular contact are listed in Table 7. All of these correspond to the usual van der Waals contacts except for the distance, 2.70 Å, of the O(10)-H···O(7)′ hydrogen bond. Through this hydrogen bonding, the molecules are one-dimensionally connected together around the screw axis. The molecular chains thus formed are further held together by two hydrogen bonds of the bromide ion, O(11)–H···Br^- (3.24 Å) and O(7)–H···Br^- (3.25 Å), finally making a hydrogen-bonded molecular layer parallel to the (010) plane.

Table 7. Intermolecular distances within the hydrogen-bonded molecular layer

O(3)···C(10)	3.69 Å	O(7)···C(24)	3.66 Å
O(3)···C(26)	3.56	O(7)···C(25)	3.25
O(5)···O(7)	3.48	O(8)···C(8)	3.75
O(6)···O(7)	3.76	C(2)···C(9)	3.86
O(7)···O(10)	2.70	C(4)···C(11)	3.87
O(7)···C(17)	3.50	C(12)···C(23)	3.86

Besides these strong contacts, the bromide ion is in contact with C(14), C(19), and C(30) at distances of 3.76, 3.61, and 3.71 Å respectively. The ethanol molecules are connected to the glycoside molecules only by the hydrogen bond of the N^+–H···O_E type, with a distance of 2.88 Å. The intermolecular distances from the ethanol are given in Table 8. As may be seen from this table, the hydrogen atom of the ethanol hydroxyl group does not take part in the formation of the hydrogen bonding at all. This may be one of the reasons why the ethanol molecule is easy to get out of the crystal. Between the glycoside molecules about the screw axis at $x=3/4$ and $y=1/2$, there is no intermolecular contact with a distance smaller than 4.0 Å.

Table 8. Distances from the ethanol molecule

O_E···O(1)	3.49 Å	O_E···C(30)	3.57 Å
O_E···O(2)	3.25	C_E(1)···O(2)	3.68
O_E···O(4)	3.53	C_E(1)···O(4)	3.46
O_E···O(11)	3.26	C_E(2)···O(4)	3.63
O_E···N	2.88	C_E(2)···O(11)	3.64
O_E···C(2)	3.65	C_E(2)···N	3.58
O_E···C(29)	3.20	C_E(2)···C(30)	3.83

Table 9. Intermolecular distances between the hydrogen-bonded molecular layers

O(1)···N	3.62 Å	O(11)···C(2)	3.63 Å
O(1)···C(18)	3.66	O(10)···C(27)	3.73
O(1)···C(29)	3.17	C(23)···C(27)	3.70

The relatively small interatomic distances between the molecular layers parallel to the (010) plane are listed in Table 9. These distances correspond to the ordinary van der Waals interaction, and all but one are found between the aglycone part of one molecule and the sugar part of another molecule related with the first one by the screw axis along the *a* axis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1976—1980 (1970)

Crystal Structure of Fukinolidol Di-Bromoacetate

Chuji KATAYAMA,*1 Akio FURUSAKI, Isamu NITTA, Mitsuo HAYASHI*2 and Keizo NAYA

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received December 16, 1969)

Fukinolidol di-bromoacetate, $C_{19}H_{24}O_6Br_2$, is a derivative of the new sesquiterpenoids isolated from the flower stalks of wild butterburs. The crystal of this derivative is monoclinic, with two molecules in a unit cell with dimensions of $a=17.13$, $b=8.21$, $c=7.59$ Å, and $\beta=98.8°$, and with the space group $P2_1$. The structure was elucidated by the heavy-atom method, and the absolute configuration was determined by the application of the anomalous dispersion effect of bromine. The atomic parameters were refined by the least-squares method, using a block-diagonal approximation. The structure thus obtained is the same as that shown by the organic chemical investigation which was carried out parallel with the present X-ray analysis. The molecule has a novel bicyclononane structure with a *cis*-fused system of a five-membered and a six-membered ring; it also has a spiro γ-lactone ring connected to the former ring. The lactone ring is almost planar, and the other five-membered ring takes a typical envelope conformation, while the six-membered ring is of the chair form.

Three new sesquiterpenoids, named fukinolide, fukinanolide, and S-fukinolide, were isolated from the flower stalks of wild butterburs, *Petasites japonicus* Maxim (Japanese name, "Fuki").[1] By alkaline hydrolysis, these substances were then converted to fukinolidol, $C_{15}H_{22}O_4$, mp 177—178°C. In order to elucidate the molecular structure of this compound, including the absolute configuration, an X-ray analysis of its di-bromoacetate derivative was carried out in company with the organic chemical investigation.

Experimental

Fukinolidol di-bromoacetate, $C_{19}H_{24}O_6Br_2$, mp 156—158°C was prepared by the bromoacetylation of fukinolidol with monobromoacetyl bromide under reflux in benzene. This substance is easily soluble in ethyl acetate, but is nearly insoluble in ethanol and in petroleum benzine. Single crystals of a prism shape were obtained from an ethyl acetate - petroleum benzine solution by slow evaporation at room temperature, while those of a crescent shape were obtained from an ethyl acetate - ethanol solution in the same way. A preliminary experiment showed that these two types of crystals gave the same X-ray diffraction pattern. The former crystal elongates along the direction of the b axis, and the latter, along the c axis, as is shown in Fig. 1; all these crystals are monoclinic with the following cell dimensions; $a=17.13\pm0.02$, $b=8.21\pm0.01$, $c=7.59\pm0.01$Å, and $\beta=98.8\pm0.5°$. The space group was uniquely determined to be $P2_1$ from the systematic absence of the reflections. The density observed by the floatation method is 1.61g·cm^{-3}, while that calculated assuming two molecules in the unit cell is 1.607 g·cm^{-3}.

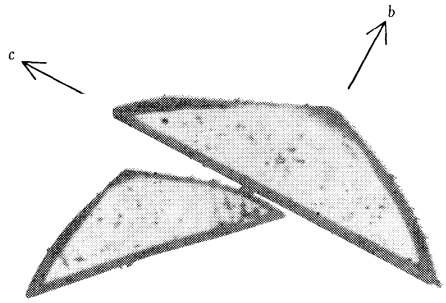

Fig. 1. The crescent shape crystals obtained from an ethyl acetate - ethanol solution.

For the purpose of collecting the intensity data, integrating Weissenberg photographs around the b and c axes were taken with nickel-filtered Cu$K\alpha$ radiation for k values from 0 to 6 and for l values from 0 to 5. The intensities were measured by visual comparison with a standard intensity scale; these values ranged between 1 and 6×10^3. The correction for Lorentz and polarization factor was made in the usual way. The relative values of the observed structure factors of 1678 reflections thus obtained were converted into an absolute scale by Wilson's method.

Structure Determination

The positions of the two bromine atoms were derived from a three-dimensional Patterson function. For the elucidation of the positions of the light atoms, a Fourier synthesis by means of Sim's modified heavy-atom method[2] was carried out. The resulting map revealed that the main frame of the present molecule involves a bicyclic system of a five-membered and a six-membered ring. Besides these twenty-one light atoms, the positions of the remaining four were obtained from the second Fourier map; the R-factor was 0.32. At this stage, as a structure test, the least-squares method was performed assuming the atomic scattering factor of the carbon atom to holds for all the light atoms. After three cycles, the R-factor dropped to 0.25. Since the temperature factors of five atoms converged into values which were smaller than those of the others, these were identified as oxygen atoms. The four atoms which had been formerly regarded as an acetoxy group attached to the six-membered ring turned out to be false peaks, because their temperature factors inclined to diverge. In this way, the positions of five oxygen atoms and sixteen carbon atoms were confirmed, and the reliable positions of the acetoxy group were elucidated from another Fourier synthesis. The structure thus obtained was refined by a block-diagonal least-squares method. After three cycles of refinement using isotropic temperature factors for all the atoms, the R-factor decreased to 0.15. Three more cycles of the final refinement were carried out with anisotropic temperature factors for bromine atoms and isotropic for light atoms. Thus, the final R-factor reached a value of 0.13. The tables of the observed and calculated structure factors are kept by the Chemical Society of Japan.*3

Absolute Configuration

By applying the effect of the anomalous dispersion of bromine, the absolute configuration of the present molecule was determined. The Bijvoet inequalities for twenty pairs of $I(hkl)$ and $I(h\bar{k}\bar{l})$ were observed visually from the Weissenberg photographs around the c axis indexed on the right-handed system. On the other hand, these twenty pairs of structure factors were calculated by including the imaginary part of the anomalous dispersion correction of the scattering factor of bromine for Cu$K\alpha$ radiation ($\Delta f''=1.4$). These observed and calculated inequalities are listed in Table 1. It may be seen that the atomic coordinates correspond to the expression by the left-

handed system. At the same time, it was established that the positive direction of the *b* axis corresponds to the direction from chord to arc of the crescent-shape crystal, as is shown in Fig. 1. The final atomic parameters, transformed into the right-handed system, are listed in Table 2. Figure 2 shows a composite diagram of the (010) sections, taken as through the atomic centers of the molecule, of the final three-dimensional electron distribution.

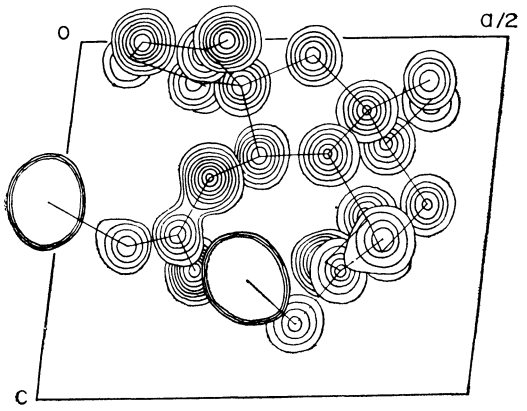

Fig. 2. The final electron distribution. Contours at 1 e.Å^{-3} beginning at 2 e.Å^{-3}.

Result and Discussion

The bond lengths and angles calculated with the final coordinates are listed in Table 3. The average estimated standard deviations of the coordinates are 0.004, 0.018, and 0.028 Å for bromine, oxygen, and carbon atoms respectively.

The molecular framework is shown in Fig. 3; the absolute configuration is taken into consideration. This is the same structure as that concluded by the organic chemical investigation. The molecule has a novel bicyclononane structure, with a

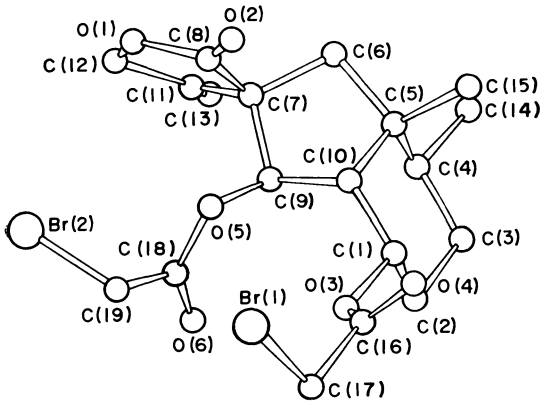

Fig. 3. The molecular framework, taking the absolute configuration into consideration.

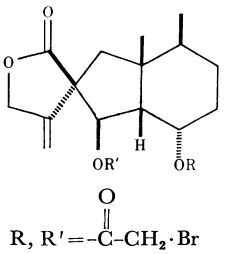

cis-fused system of a five-membered and a six-membered ring; it also has a five-membered γ-lactone ring spiro-fused with the former ring. The lactone ring is almost planar, while the other five-membered ring takes a typical envelope conformation; the C(10) atom is remarkably displaced from the mean plane through the C(5), C(6), C(7), and C(9) atoms. The six-membered ring is a chair form, and the configurations of the C(14) and C(15) atoms are β and O(3) and C(9) atoms α. The O(5), C(8), and C(15) atoms are located on the same side of the five-membered ring. Both acetoxyl groups are almost planar, including C(1) or C(9), but the bromine atoms are considerably out of these planes. The C(16)–O(4) and C(18)–O(6) bonds are orientated nearly in the same direction as the C(1)–H and C(9)–H bonds respectively.

The molecular arrangements projected along the *b* and *c* axes are shown in Figs. 4 and 5 respectively. The intermolecular distances of less than 4.0 Å are all listed in Table 4. The molecules related by a 2_1-screw axis at $x=0$ and $z=1/2$ are linked together along the *b* axis by Br–Br contacts of 3.59 Å. This contact seems to be quite strong, since twice the ordinary Van der Waals radii of bromines are 3.90 Å. Such a short contact

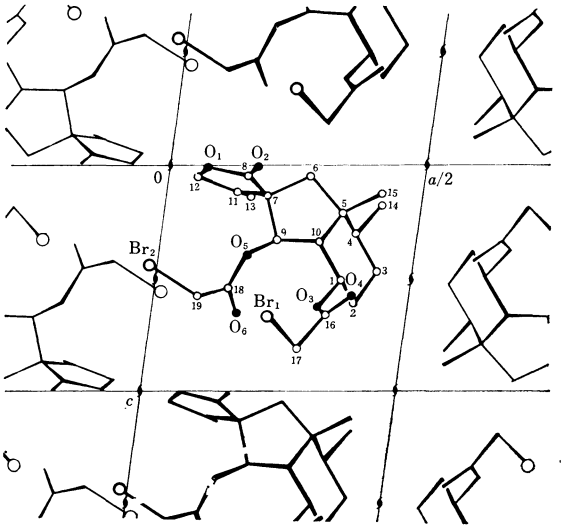

Fig. 4. The molecular arrangements along the *b* axis.

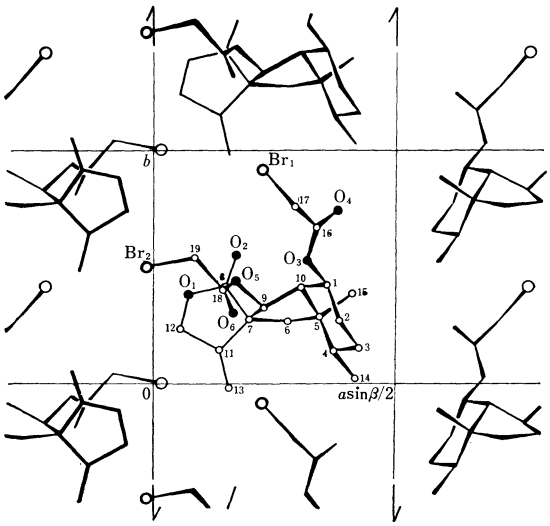

Fig. 5. The molecular arrangements along the *c* axis.

has also been found in the crystal of methyl bromide (3.57 Å).[3] The contacts along the *c* axis are concentrated between the C(8)–O(2) bond of the lactone group and the C(18)–O(6) bond of the acetyl group, related by the translation *c*. This contact seems to be caused by the dipole-dipole interaction between these polar bonds. As a whole, the contacts along the *a* axis are weak compared with those along the *b* and *c* axies.

In the early stages of the present analysis, it was not easy to elucidate the position of the acetyl group attached to the six-membered ring because of the large temperature factor of the group, especially that of the O(4) atom. In the final stages also, the temperature factor of the O(4) atom is about twice as large as those of the other oxygen atoms, and the O(3)–C(16) bond is considerably shorter than the normal bond length even if its estimated standard deviation is taken into consideration. In seeking to explain these facts, it may be considered that this acetyl group has some degree of freedom for the movement, since the group seems to be relatively free from the other part of the molecule and also from the other molecules, considering the interatomic contacts described above.

Metastable Solid Solution with Nepheline-type Structure in the $CaO-Al_2O_3-SiO_2$ System

Takashi YOSHIOKA

Research Laboratory, Nihon Cement Co., Ltd., Kiyosumi, Koto-ku, Tokyo

(Received December 15, 1969)

The metastable nepheline-type solid solution in the $CaO-Al_2O_3-SiO_2$ system shows the best crystal development upon devitrification on the $CaAl_2O_4-CaAl_2Si_2O_8$ join. The crystallization occurs through the devitrification of glass at relatively low subsolidus temperatures, around 1000°C in the air. The X-ray powder diffraction patterns of the solid solution can be indexed on the basis of a hexagonal unit cell of the nepheline structure without exception. The cell parameter a of the solid solution is similar to that of nepheline, while its parameter c is smaller than that of nepheline and corresponds to that of high-temperature tridymite. When the cell parameters of the solid solution on the join are plotted against the composition, there is a break in the slope at $Ca_6Al_{12}Si_4O_{32}$, though the cell volume varies continuously. The nepheline-type solid solution on the join may be expressed as $Ca_{8-(1/2)x}\square_{(1/2)x}Al_{16-x}Si_xO_{32}$, where $\square$ means the interstitial vacant site. The relationship between the cell parameter and the composition suggests that there should be two kinds of Ca-sites in the structure of the present solid solution, and that these kinds correspond to the alkali sites of two different sizes in the nepheline structure.

Certain aluminosilicate crystals composed of a three-dimensional network of AlO_4 and SiO_4 tetrahedra are known to have crystallographic structures similar to those of some silica modifications. They have been termed "the stuffed derivatives of the silica structures".[1] A wide range of solid solutions are often formed between the stuffed derivatives and pure silica.[2-6]

Sugiura and Yoshioka[7] reported a new metastable solid solution in the $CaO-Al_2O_3-SiO_2$ system, a solid solution which was formed as a single phase over a relatively wide range of composition within a triangle having $CaAl_2O_4$, $CaAl_4O_7$, and $CaAl_2Si_2O_8$(anorthite) as the vertices; crystals of the solid solution were developed best on the $CaAl_2O_4-CaAl_2Si_2O_8$ join. Since then, it has been made clear by the present author[8] that the solid solution is structurally related to nepheline or one of the stuffed derivatives of high-temperature tridymite. The nepheline-type solid solution may be regarded as a solid solution formed between $CaAl_2O_4$,[9] one of the stuffed derivatives of the tridymite structure, and pure silica.

The present paper will deal mainly with the members formed on the $CaAl_2O_4-CaAl_2Si_2O_8$ join.

Experimental

Preparation of Glass. Homogeneous glass of the $CaO-Al_2O_3-SiO_2$ system was prepared by melting mixtures of chemicals in a platinum crucible at from 1600°C to 1700°C in an electric furnace. Pure quartz powder and guaranteed reagents of $CaCO_3$ and Al_2O_3 obtained from the Kanto Kagaku Co., Ltd., were used as the raw materials. The homogeneity of the glass was tested by the uniformity of its refractive index.

Divitrification of Glass. Crushed glass (2—8 mmϕ) was heated and devitrified under various conditions in an electric furnace equipped with SiC heating elements. The products were identified by a polarizing microscope and by the X-ray powder diffraction.

X-Ray Powder Diffraction. The cell parameter a was determined on the basis of the 52.0 reflection, using Si as the standard, and the parameter c, from the 00.4 reflection, using quartz as the standard. Diffraction

conditions of the Geigerflex (Rigaku Denki Co., Ltd.) were as follows: Ni filtered Cu$K\alpha$ radiation, 40 KV-20 mA or 35KV–15 mA; slits, 1°–1°–0.1 mm; scanning speed, 0.25°(2θ)/min; chart speed, 10 mm/min; time constant, 4 sec; full scale, 200 counts/sec.

Measurement of Refractive Index. The refractive index of the phases encountered in the study was measured by the oil-immersion method with the sodium light at 20°C. The measurements were made within an accuracy of ±0.002.

Results

Mode of Formation. The subsolidus crystallization products of the glasses on the $CaAl_2O_4$–$CaAl_2Si_2O_8$ join in the CaO–Al_2O_3–SiO_2 system are given in Table 1; they are also shown in Fig. 1. As may be seen in Table 1 the single phase of the nepheline-type solid solution was obtained in the compositions between No. 4 and No. 7.

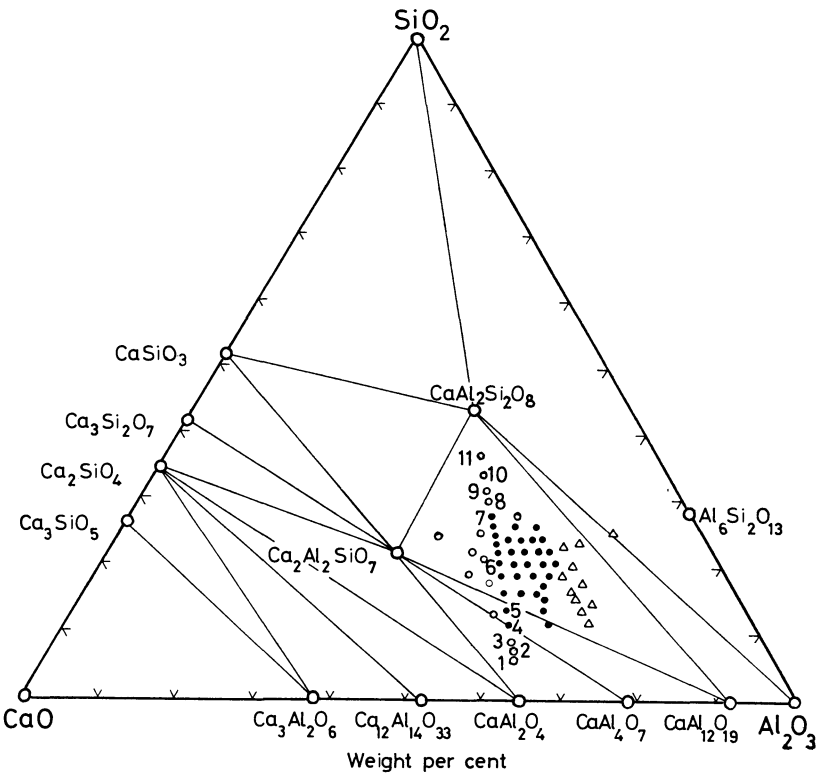

Fig. 1. Mode of formation of the nepheline-type solid solution in the CaO-Al_2O_3-SiO system.
● All nepheline-type solid solution.
○ Nepheline-type solid solution is accompanied by other crystalline phases.
△ Complete glass is not obtained, but nepheline-type solid solution is crystallized from the glassy part.
Numbers correspond to those in Table 1.

The nepheline-type solid solution appears as the first crystalline phase during the devitrification of glasses of these compositions at low subsolidus temperatures (around 1000°C).

The nepheline-type solid solution crystallized at a certain temperature decomposes when it is treated at higher subsolidus temperatures, or it decomposes when treated at the same temperature after a longer time of heating; in either case, this leads to a different assembly of crystalline products, as is shown in Table 1. This tendency was promoted when the solid solution was pulverized and reheated. In addition, the solid solution was shown by differential thermal analysis,[7] to undergo an exothermic reaction and to decompose into just the same assembly of the crystalline products described above. These results clearly suggest that the nepheline-type solid solution is of a metastable nature. The nepheline-type solid solution persists at higher temperatures or persists for much longer periods of heating at a given temperature when the solid solution increases in its SiO_2 content along the $CaAl_2O_4$–$CaAl_2Si_2O_8$ join (Table 1). A similar quality of persistence is shown by the metastable quartz-type solid solution on the SiO_2–$MgAl_2O_4$ join.[4]

X-Ray Observations. The X-ray powder patterns of the nepheline-type solid solution in the CaO–Al_2O_3–SiO_2 system are similar to those of nepheline, and all the reflections can be indexed on the basis of a hexagonal unit cell which is similar to that of nepheline. The cell parameters of the solid solution on the $CaAl_2O_4$–$CaAl_2Si_2O_8$ join are shown in Table 3. However, there are some differences between synthetic nepheline[10] and the present solid solution; they are compared in Table 2 for the sake of convenience. The cell volume of the nepheline-type solid solution on the $CaAl_2O_4$–$CaAl_2Si_2O_8$ join decreases continuously with an increase in the SiO_2 content over all the compositions. The variations in the two cell-parameters, a and c, are not thoroughly continuous against the composition; rather, they show a break in the cell parameters at the composition of No. 6 (Fig. 2).

Optical Properties. The nepheline-type solid solution on the $CaAl_2O_4$–$CaAl_2Si_2O_8$ join showed the best crystal development, while all those which were crystallized not on the join but in the lime-poor side of the CaO–Al_2O_3–SiO_2 system showed poor crystal development (Fig. 3), though they were formed as a single phase. The solid solution showed a granular or lathlike shape with an irregular outline, and those which were crystallized from the high SiO_2 compositions often showed a hexagonal skeletal development. Neither a characteristic twin nor a cleavage was ob-

served.

The nepheline-type solid solution generally shows a weak birefringence. The No. 4 member shows a particularly weak birefringence, but it becomes stronger as the solid solution increases in its SiO_2 content along the join, as is illustrated in Fig. 4. The members with more SiO_2 in the composition than the No. 4 are uniaxially positive. The member crystallized from the glass, No. 3, has an appreciably stronger birefringence than does No. 4, and it is confirmed to be negative. It will be noticed, therefore, that the solid solution changes its optic sign at a certain composition between No. 3 and No. 4. as in the melilite solid solution of the gehlenite-åkermanite series. The refractive index of the phases on the join is illustrated in Fig. 4. The solid solution has a lower refractive index than that of the glass with the same composition. A similar phenomenon appears in Mg-indialite.[11]

Discussion

The cell parameter a of the nepheline-type solid solution is similar to that of nepheline, and it is twice as large as that of the ideal high-temperature tridymite. On the other hand, the parameter c is not consistent with that of nepheline but corresponds to that of the high-temperature tridymite (Table 4). The cell parameter c of the solid solution may be four times the height of a tetrahedron standing on its base, as in the ideal high-temperature tridymite.[12] The reason why, in the solid solution, the repeat distance along the a-axis is twice as large as that in tridymite is uncertain.

The nepheline-type solid solution on the $CaAl_2O_4$–$CaAl_2Si_2O_8$ join may be expressed as $Ca_{8-(1/2)x}\square_{(1/2)x}Al_{16-x}Si_xO_{32}$, where $\square$ means the interstitial vacant site, based on 32 oxygen atoms of the nepheline-unit cell. It is well known that the nepheline solid solution of $Na_{8-y}K_yAl_8Si_8O_{32}$ shows a break in the cell parameter when plotted against the composition at $y=2$ in the chemical formula.[10,13] The composition at which the break appears in the cell parameters of the present solid solution may be compared with that of the ideal nepheline as follows: the ideal composition of nepheline is known to be $Na_6K_2Al_8Si_8O_{32}$, while the present nepheline-type solid solution is represented by the formula $Ca_6\square_2Al_{12}Si_4O_{32}$, in which x is equal to 4. If there are two kinds of interstitial sites in the structure of the present solid solution, as in the nepheline structure,[14,15] six Ca^{2+} ions of the member must be situated in one kind of site, one which corresponds to the smaller Na-sites in the nepheline structure. The variation in the cell parameters in the compositions with x values smaller than 4 may be attributed to the Al–Si substitution and to the omission of Ca^{2+} ions in the larger sites, which correspond to K-sites in the nepheline structure. In the compositions with x values larger than 4, the number of the Ca^{2+} ion should be less than 6 and hence the omission of the Ca^{2+} ion will take place at the other kind of site, namely, at the smaller Na-sites in the typical nepheline structure.

The author wishes to express his thanks to Dr. K. Sugiura of the Nihon Cement Co., Ltd., for his general guidance of the study. The author is also much indebted to Professor T. Katsura, Professor H. Yamada and Professor S. Iwai of the Tokyo Institute of Technology for their critical reading of the manuscript and for their kind advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1988—1991 (1970)

Effect of Some Metal Oxides on the Specific Resistivities of Magnesium Oxide

Akira UEHARA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Japan

(Received December 30, 1969)

The specific resistivities of magnesium oxide prepared by igniting magnesium hydroxide at about 1700°C were investigated in the temperature range 200—1200°C. The magnesium oxide was found to have a *p*-type character by the thermoelectric power method. Ignition at 1000°C in an oxygen stream brought about a small increase in specific resistivities, whereas ignition in a vacuum of 10^{-3} mmHg caused no appreciable change. The sample including univalent-metal oxides such as Na_2O or Li_2O showed a distinct decrease in specific resistivities and was converted from a *p*-type to an *n*-type semiconductor. Addition of tervalent-metal oxides such as γ-alumina or B_2O_3 to the magnesium oxide, however, raised the resistivities but gave no change in type.

Magnesium oxide is widely used as an excellent insulator since a long time ago.[1] Goodwin and Mailey found that the electrical conductivity increases rapidly with temperature.[2] A recent study showed that the activation energy for electrical conductivity through single crystals of magnesium oxide is 2.8±0.1 eV in 400—1800°C.[3]

Although the electrical resistivity of magnesium oxide was thought to decrease in the presence of a small amount of impurities,[4] it was found lately that some impurities raise the resistivity. It has already been reported that the addition of 0.25 mol % of TiO_2 sharply increases the electrical resistivity of magnesium oxide, while the addition of TiO_2 more than 2.5 mol % does not give any effective change in the temperature range 1200—1800°C.[5]

In this study we will discuss the electrical resistivity of magnesium oxide from the viewpoint of semiconductor. Change of the specific resistivity of magnesium oxide with temperature was measured, and classification of magnesium oxide into either *n*- or *p*-type semiconductor was decided by means of the thermoelectric power method.

On the basis of these results, considerations on the change of specific resistivities were made, and the effect of metallic oxides contained as impurities on the electrical resistivity was investigated in the temperature range 200—1200°C.

Experimental

Magnesium Oxide. Magnesium oxide was prepared by igniting magnesium hydroxide at 1700°C and by crushing it to 100—200 meshes.

Analytical results: MgO, 99.81; SiO_2, 0.06; Al_2O_3, 0.03; Fe_2O_3, 0.04; CaO, 0.06%.

Preparation of Specimen for Specific Resistivity Measurements. The resistivity measurement for the samples was carried out with the specimen as shown in Fig. 1-a. The sample powder was packed between the inner and the outer electodes. As described in Fig. 1-b, MgO powder was packed under the desired pressure by means of an oil-press. In the preliminary experiments, it was found that the effect of the packing density on the specific resistivities was not recognized within the range 2.0—3.0 g/cm³. When the density exceeded the upper limit (3.0 g/cm³), the outer electrode was broken. 2.3 g/cm³ was chosen as the optimum packing density for all the measurements. A Pt-PtRh thermocouple was spot-welded on the surface of outer electrode for temperature measurements, and leading wires for the resistivity measurements were also spot-welded as shown in Fig. 1-a.

Measurement of Specific Resistivity. Resistivity was measured by the potential drop method with a Yokogawa Teraohmmeter RM-21C. The heating rate was 5°C/min. The values of specific resistivity (R) were calculated from the equation

$$R_s = \frac{2\pi hR}{2.303 \log \frac{r_2}{r_1}} \ (\Omega\text{-cm})$$

where h is the height of MgO layer packed in specimen, R, observed resistivity, r_1, diameter of inner electrode, and r_2 is diameter of outer electrode.

Determination of *n*- or *p*-Type. The thermoelectric power method was used to decide the type of magnesium oxide (*n* or *p*) as semiconductor. Decision was made from the direction of the thermoelectric power detected by a Yokogawa Galvanometer D-2L.

(a) Section of specimen

(b) Procedure for packing of MgO powder

Fig. 1. Specimen for the resistivity measurement.

Addition of Oxide Impurities. B_2O_3 and γ-Al_2O_3 of special grade reagents were used as tervalent-metal oxides, and Na_2CO_3 and Li_2CO_3, as univalent-metal oxides. All the compounds were added to magnesium oxide in an amount corresponding to the desired fraction, and were fully triturated in an agate mortar. The resulting mixture was ignited at 1000°C for 10 hr, and then pulverized to 100—200 meshes.

Results and Discussion

Specific Resistivity of MgO. Figure 2 shows the curves of R_s (specific resistivity) *vs.* $1/T$ (reciprocal of absolute temperature) for magnesium oxide and for the same oxide ignited in an oxygen stream for 3 hours. The resistivity of MgO itself was $\sim 10^7$ Ω-cm at 1000°K.

The specific resistivity can also be given by the equation

$$R_s = Ae^{E/kT}$$

where E is activation energy, k, Boltzmann's constant (8.63×10^{-5} eV deg^{-1}), T, absolute temperature, and A is frequency factor.

Thus, the activation energy could be estimated from the slope of R_s-$1/T$ curve as 2.68 eV. This value is close to but somewhat smaller than that of 2.8±0.1 eV estimated by Lewis and Weight with a single crystal.[3] From the study on the light absorption of magnesium oxide the intrinsic activation energy for resistivity might be 7.3 eV.[6,7] From these values the specific resistivity seems to be affected by the presence of impurities or lattice defects.

It is well known that the over-all conductivities are the sum of conductivities in donor and acceptor; *viz.*, $\sigma=\sigma_n+\sigma_p=e(N\mu_n+N\mu_p)$, where σ_n is conductivity in donor, σ_p conductivity in acceptor, e, electronic charge, N, donor concentration, P, acceptor concentration, μ_n, donor mobility, and μ_p is acceptor mobility.

The MgO prepared at high temperature was expected to be deficient in oxygen atom and to be of n-type. However, it was found to be of p-type by thermoelectric power (Sample I in Table 1). That the MgO is of p-type suggests that $N=0$ or $P>N$. Thus it can be assumed that the content of oxygen atoms in the MgO is, stoichiometrically, slightly greater than that of magnesium atoms. The magnesium oxide was ignited in a vacuum of 10^{-3} mmHg for 3 hr, but no change was found in type and resistivity. The sample ignited in an oxygen stream for 3 hr was expected to show the decrease of resistivity. However, increase was observed as shown in Fig. 2. The reason for these discrepancies is not clear, but they might be due to the change of conductivity caused by the presence of other impurities.

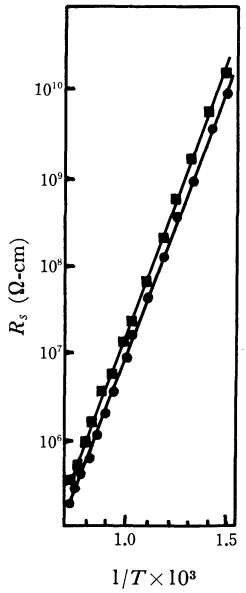

Fig. 2. R_s-$1/T$ curves for MgO (●—●) and MgO ignited in an O_2 stream (■—■).

7) H. Weber, *Z. Phys.*, **130**, 392 (1951).

The color of the sample ignited in an oxygen stream changed to very faint brown, while the sample ignited in a vacuum, to very faint bluish green. Though these phenomena may be ascribed to the color center related to the lattice defects, the substitution of a part of atoms and/or to the interstition of other atoms in crystal structures,[8,9] further investigations were not carried out in the present study.

Change in Resistivity and Transformation of Types due to Mixing Impurities. It may be expected that the addition of univalent- or tervalent-metal oxides would change the resistivity of magnesium oxide and, in some cases, transform the type into a semiconductor. Figure 3 shows the R_s-1/T curves of the samples containing univalent-metal oxides, and Table 1 shows the types of various samples. We see that the resistivity is diminished to large extent, when Na_2O or Li_2O is added to magnesium oxide, and the type is converted from *p* to *n* (samples IV, V, VII and

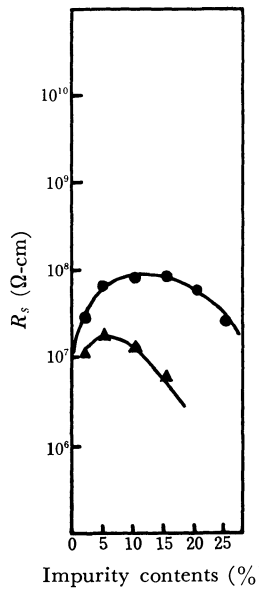

Fig. 4. R_s *vs.* impurity contents (%) curves for γ-Al_2O_3 (●—●) and B_2O_3 (▲—▲) at 1000°K.

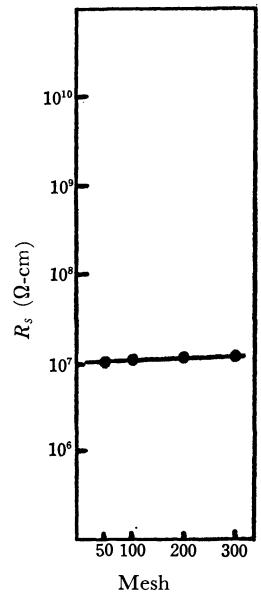

Fig. 5. R_s *vs.* grain size (mesh) curve at 1000°K.

VIII in Table 1). When γ-Al_2O_3 is added to the above samples, the resistivity is again increased (Fig. 3) and the type turned from *n* to *p* (sample VI in Table 1).

On the contrary, the addition of γ-Al_2O_3 or B_2O_3 increases the resistivity but no change is found in the type (Table 1, samples IX through XV). Figure 4 shows the curves of resistivity *vs.* the content of γ-Al_2O_3 or B_2O_3 at 1000°K. The maximum appeared at 10 % of γ-Al_2O_3 and 5 % of B_2O_3, respectively. All the samples were *p* type as shown in Table 1. Various modifications of Al_2O_3 were reported.[10-12] However, the alumina acted effectively as descrived above is γ-Al_2O_3, but not α-Al_2O_3.

11) K. Funaki and Y. Shimizu, *Kogyo Kagaku Zasshi*, **56**, 53 (1953).
12) T. Sato, *ibid.*, **55**, 66 (1952).

On the activation energy for resistivity of these samples, only a small difference is found, *i.e.*, the sample containing 1 % of Li_2O showed 2.60 eV, whereas the sample containing 10 % of γ-Al_2O_3 2.72 eV.

From the principle of valency-control, it is expected that MgO containing the univalent-metal oxide should show a *p*-type character, whereas MgO with the tervalent-metal oxide, an *n*-type. The results obtained in the present work, however, can be recognized to be inconsistent with what we expected. However, the reason of this inconsistency is unknown for the present.

Grain Size and Resistivity. To observe the effect of grain size on resistivity, magnesium oxide was separated into portions 50, 100, 200 and 300 meshes with a standard sieve. Figure 5 gives the curve of the resistivity *vs.* mesh at 1000°K. The smaller the grain size, slightly larger becomes the resistivity. The resistivity hardly changes with grain size.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1991—1998 (1970)

Radiotracer Studies on Adsorption of Surface Active Substance at Aqueous Surface. I. Accurate Measurement of Adsorption of Tritiated Sodium Dodecylsulfate

Kazuo TAJIMA, Mitsuo MURAMATSU and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received January 16, 1970)

We carried out direct measurement of adsorbed amount at the air-solution interface to confirm the validity of the Gibbs adsorption equation by using radiochemically and surface chemically pure tritiated sodium dodecylsulfate (TSDS) and a sheet scintillation counter, which was developed for the purpose of counting β-rays of tritium in air. The adsorbed amount increased with increasing SDS concentration and showed the saturation values of 3.19×10^{-10} mol/cm^2 in the concentration region from 3.2×10^{-3} to 14.4×10^{-3} mol/1000 g solution at 25°C. For the salt-free solution of ionic surfactant the Gibbs adsorption equation is confirmed to be valid for $n=2$ when activity in place of concentration is used. The equation of state for the ionic adsorbed film is further proposed. The cohesive pressure due to the attraction between hydrocarbon chains was given as a function of inverse molecular area.

The direct measurement of adsorbed amount, Γ, at the air-solution interface of ionic surfactant has been carried out by many workers to check the validity of the Gibbs adsorption equation.[1-4] Although a factor of $n=2$ in the Gibbs equation,[5] $\mathrm{d}\gamma=-\boldsymbol{R}Tn\Gamma\mathrm{d}\ln a$, is predicted theoretically, the experimental verification of the equation has

not been conclusive; several workers[2,3,6] indicate $n=1$ for ionic surfactant in a salt-free solution.

It is well known that the radiotracer method[7] is particularly suited for the measurement of Γ in many respects compared with the others such as "moving bubble" method[8] or microtome method.[9] However, the adsorption experiments using surfactants labelled with ^{14}C or ^{35}S involve considerable uncertainty in the measurement of Γ of ^{35}S-labelled sodium dodecylsulfate,[4] for instance, because these isotopes are not soft enough. On the other hand, owing to the extremely soft β-rays, ^{3}H renders the measurement of Γ highly accurate.[10] However, in such reports[7,11,12] which are still limited in number, the measurement of surface radioactivity is made with a 2π windowless gas-flow counter using humidified propane gas, which inevitably produces undesirable adsorption at "hydrocarbon gas-solution" interface instead of air-solution interface.

In the present paper, a radiochemically and chemically pure sample of tritiated sodium dodecylsulfate (TSDS) was synthesized and accurate determination of Γ at "air-solution" interface was made by employing a sheet scintillation counter.

Experimental

Materials. Sodium dodecyl-2,3-^{3}H,^{3}H sulfate (TSDS) was prepared by the previous method[13] with slight modifications. *n*-dodecene-2,3-ol-1 was synthesized from decanal and diethyl malonate[14] and the product was tritiated to give *n*-dodecan-2,2-^{3}H,^{3}H-ol-1 (TDOH). The unsaturated alcohol was purified by preparative gas chromatography (Yanagimoto GCG-3DH) and subsequently tritiated with tritium gas (Radiochemical Centre, Amercham, England, ca. 0.8 cc at S.T.P. 98% ^{3}H). The tritiated alcohol thus obtained was subjected to simultaneous gaschromatography (Yanagimoto GCG-5DH) for the substance and radioactivity. The results proved to be chemically and radio chemically pure for the sample obtained. It was then sulfated by the usual method[15] to give TSDS, which contained a trace amount of unreacted TDOH. The product was purified seven times by isotopic mixing with non-radioactive dodecanol in ethanol solution, followed by extraction with ether to remove dodecanol and to lower the specific activity of TDOH.[13] The specific activity of TSDS obtained was 9.16 Ci/mol. The surface-chemical purity of TSDS was confirmed by the disappearence of minimum near the critical micelle concentration (CMC) in surface tension versus concentration curve.

Thus, special care should be taken for the purity of the substance used. In fact, we had found[16] that many radioactive impurities are produced in the originally pure tirtiated stearic acid of specific activity of about 10 Ci/mol, when it is kept standing for 6.5 years in solid state. In the present experiments, therefore, the purification by Soxhlet extraction was continued until just before the adsorption experiments.

Water was distilled three times after being refluxed overnight by adding sulfuric acid and potassium permanganate. Ammonium sulfate used for the substrate solution was twice recrystallized from water and an oily substance was removed by ethereal extraction.

Apparatus. The tritium radioactivity was measured by the sheet scintillation counter,[17] modified so as to count the radioactivity at air-solution interface as shown in Fig. 1. The effective area of scintillator sheet (a) was 37.50 cm^2, and the periphery of the sheet was masked to avoid the effects of corners and edges of trough and scintillator sheet upon the scintillae. The scintillator probe was placed on the horizontally supported plate (b), which was moved vertically by the gear (c) at the rate of 2 mm per revolution. The counting was made at the applied voltage of 1250 V and with a discrimination with from 5 V to infinity.

All experiments were carried out in nitrogen gas atmosphere contained in a dark glove box. The gas controlled to 25°C by passing through a copper tube

(i) and completely humidified by passing through two bubblers (j) and a long tube (g) filled with pieces of wet paper was introduced in and allowed to leak slowly out of the cell to avoid the effects of carbon dioxide and evaporation on adsorption. Humidity of the gas was measured by the weight increase of $CaCl_2$ due to passage of the gas. It was found to be $98\pm3\%$ at 25.0 ± 0.2°C.

Procedure. An aqueous solution of TSDS was introduced into a Teflon trough (n in Fig. 1), and the surface of solution was carefully swept twice by a Teflon barrier. The end of the second sweeping was taken as time zero in the surface aging of adsorption. The scintillator probe was then lowered to a fixed position about 0.8 mm above the water surface, which was assured by the electric contact of Pt-electrode (f) fixed at the scintillator probe with aqueous solution connected to another electrode. The warm gear (m) and needle point electrode in Fig. 1 enabled the distance between the probe and the aqueous surface to be adjusted to within an accuracy of 0.02 mm. The standard deviation of counting rate due to this error was less than 1%. Counting was started to measure the time dependence of radioactivity over the surface of solution.

Results

Figure 2 shows the time dependence of radioactivity at the surfaces of SDS solution varying in its concentrations. The time required for attaining the saturation value of counting rate decreased with increasing bulk concentration of solution, and the time dependence practically disappeared above CMC.

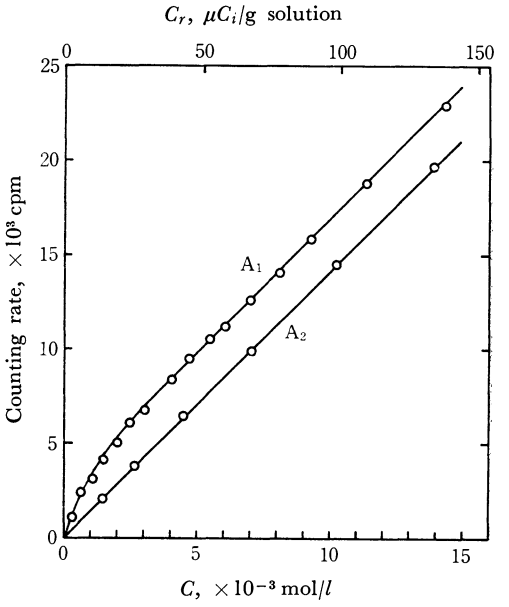

Fig. 3. A_1 plot for SDS and A_2 plot for DOH.

The counting rate of horizontal part in each curve of Fig. 2 was taken as the equilibrium value, A_1, which is plotted against SDS concentration in Fig. 3. The radioactivity due to the bulk of the solution, A_2, was determined from the radioactivity over the surfaces of the solutions of TDOH in non-radioactive DOH under the same geometrical conditions as that of A_1 determination. The A_2 values thus obtained were corrected for the difference in absorption and scattering of β-particles between water and DOH and plotted against radioactive concentration, C_r, in Fig. 3 in the same manner as in the previous report.[11] The calcu-

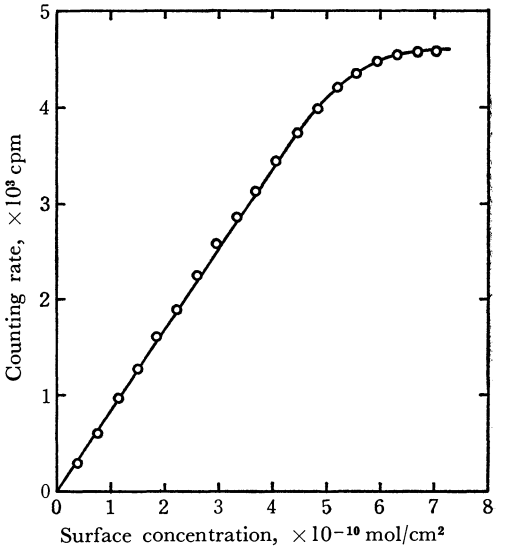

Fig. 4. Radioactivity *vs.* surface concentration for TSDS.

lation of Γ was made by

$$\Gamma = \frac{A_1 - A_2}{\kappa} \quad (1)$$

where a constant κ must be known. It was determined by counting the surface radioactivity for known amounts of TSDS film spread over the aqueous ammonium sulfate solution of 80% saturation in the Teflon trough.[18] Figure 4 shows the relationship between the surface radioactivity and the amounts of TSDS.

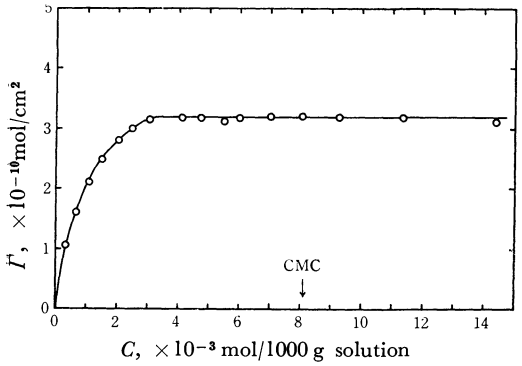

Fig. 5. Adsorption isotherm of SDS at air-solution interface (25°C).

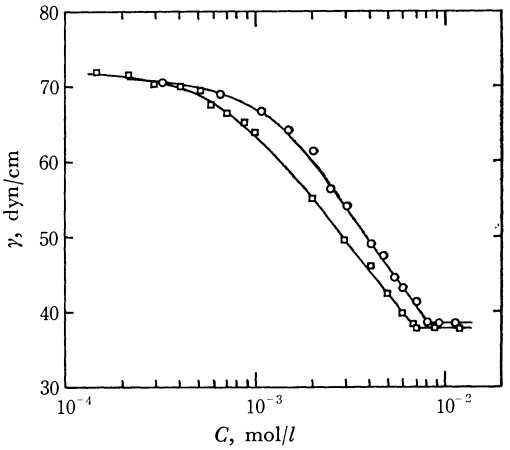

Fig. 6. Surface tension *vs.* concentration curves of SDS solution.

—○—: drop volume method
—□—: Wilhelmy plate method

The adsorption isotherm obtained is shown in Fig. 5. It can be seen that Γ markedly increases with increasing concentration of SDS and arrives at the saturated adsorption of 3.19×10^{-10} mol/cm^2 at bulk concentration of about 3.2×10^{-3} mol/1000 g solution beyond which Γ does not change

with the concentration even beyond CMC (8.1×10^{-3} mol/1000 g solution). The area per molecule at the saturated adsorption is found to be 52.0 Å^2. The surface tension of the solution was measured by the drop volume method, the correction of Harkins and Brown being applied. The results (circles) shown in Fig. 6 show that the surfactant employed was surface-chemically pure. The Wilhelmy plate method was also adopted for the surface tension measurement for comparison.

Discussion

Evaluation of Γ. In Table 1 are shown the values obtained together with those obtained by other methods. The values are seen to fluctuate widely. Evidently the β-rays of ^{35}S are too hard for an accurate measurement of the SDS adsorption to be made, while ^3H much reduces the experimental error. However, the measurements of ^3H radioactivity with a 2π windowless gas-flow counter involve many difficulties which should be overcome. First, there is the possibility that the counting gas (humidified hydrocarbon) is adsorbed at the surface and solubilized in the bulk of surfactant solution.[19] Also, it is probable that the adsorption of the surfactant is affected by the high voltage applied and by the gas phase being hydrocarbon instead of air. These effects are unfavorable for the use of a 2π windowless gas-flow counter and the use of an end-window type is recomended.

It is seen in Table 1 that the results obtained happen to be close to some of the adsorption data obtained by the foam method. However, the latter method is not favorable because of the difference in adsorption on plane and non-plane surfaces, and also the difference in adsorption on solution surface and on two sided film where the van der Waals and coulombic interactions between the two parallel films are effective.[28] Difficulties also arise from uncertainty in the estimation of surface area, non-equilibrium state of adsorption due to the short period of passage of bubbles, and the gradual changes of bulk concentration and pH of solution during the passage of a large number of bubbles.[29] Thus, it is not surprising to find discrepancies in Γ values between the foam and the radiotracer methods, the latter being free of the difficulties mentioned above.

Surface Tension *vs.* Concentration Curve. Figure 6 shows the values of equilibrium surface tension, γ, measured by the Wilhelmy plate method[30] (squares) and by the drop volume method (circles) as a function of SDS concentration. A systematic difference seems to exist between surface tension data obtained by these methods. A similar tendency has been reported by Boucher *et al.*[31] for sodium hexyl α-sulfopelargonate. They inferred that the surface tension data obtained by these methods appear to be reliable in so far as they do not affect molecular cross-sectional areas of surfactants obtained by applying these data to the Gibbs equation. However, the results of the present measurement exhibited limiting slopes of curves being different from each other as shown in Fig. 6. This would be reasonable, when we consider marked aging phenomena observed in surface tension of detergent solution.

Gibbs Adsorption Equation. In the present system the Gibbs adsorption equation[5] is expressed by

$$-\mathrm{d}\gamma = \boldsymbol{R}T\Gamma_{Na^+}\mathrm{dln}a_{Na^+} + \boldsymbol{R}T\Gamma_{D^-}\mathrm{dln}a_{D^-} + \boldsymbol{R}T\Gamma_{H^+}\mathrm{dln}a_{H^+} + \boldsymbol{R}T\Gamma_{OH^-}\mathrm{dln}a_{OH^-} \quad (2)$$

where γ, Γ and a express the surface tension of solution, the amount of adsorption and activity, both for the solutes. The subscripts Na^+, D^-, H^+, and OH^- denote sodium, dodecylsulfate, hydrogen and hydroxyl ions, respectively. Since the SDS solution was almost neutral and pH was kept practically constant to 6.0 ± 0.2 throughout the measurements for all solution, we put for approximation $\mathrm{d}\,a_{H^+}=\mathrm{d}\,a_{OH^-}=0$. Assuming no surface hydrolysis,[32] $\Gamma_{H^+}=\Gamma_{OH^-}=0$, and electrical neutrality both in bulk and surface layer, namely $C_{Na^+}=C_{D^-}=C$, and $\Gamma_{Na^+}=\Gamma_{D^-}=\Gamma$,[33] we get from Eq. (2)

$$-\frac{\mathrm{d}\gamma}{\boldsymbol{R}T\,\mathrm{d\ln}C} = 2\Gamma\left(1+\frac{\mathrm{d\ln}f_\pm}{\mathrm{d\ln}C}\right) \quad (3)$$

where $f_\pm=(f_{Na^+}\times f_{D^-})^{1/2}$ is the mean activity coefficient of SDS. It has been reported[34] that activity coefficient of SDS solution varies according to the method of measurement such as the glass or membrane electrode methods. However, $f_\pm$ is better approximated by the Debye-Hückel second approximation. Thus, for uni-univalent

electrolytes, we have

$$-\ln f_{\pm} = \frac{1.18\sqrt{C}}{1+\frac{r_{\pm}}{3.08}\sqrt{C}} \tag{4}$$

where $r_{\pm}$ is the average radius of hydrated anion and cation in the solution (Å unit). According to Kielland's report[35] and in agreement with Haydon's opinion[36] that $r_{\pm}$ for alkylsulfate and quaternary ammonium ions should be slightly higher than 5 Å, we put $r_{\pm}=7$ Å in Eq. (4) for SDS ion of all concentration. Differentiating Eq. (4) we have

$$\Delta = -\frac{\mathrm{d}\ln f_{\pm}}{\mathrm{d}\ln C} = \frac{0.59\sqrt{C}}{\left(1+\frac{r_{\pm}}{3.08}\sqrt{C}\right)^2} \tag{5}$$

The values of Γ were calculated from Eq. (3) by the evaluation of $\mathrm{d}\gamma/\mathrm{d}\ln C$ from γ *vs.* C measurement and Δ from Eq. (5). The result is shown in Fig. 7 as solid and broken lines for the Wilhelmy plate and the drop volume methods, respectively. The amount of adsorption directly measured by the radiotracer method was also plotted as shown by circles in Fig. 7. The observed values are in good agreement with those calculated by Eq. (3) applying the surface tension data of the Wilhelmy plate method, compared with those of drop volume method throughout the whole range of bulk concentration. The deviation of drop volume data is marked especially at low concentration. This may be understood since the drop volume method is insufficient for giving an equilibrium surface tension at low concentration where the rate of attainment of equilibrium is slow. On the other hand, a slight discrepancy at lower concentration in the case of the Wilhelmy plate method probably comes either from the uncertainty of surface tension data or from the invalidity of Eq. (3), which has been derived by neglecting the H^+ ion terms.

— : calculated values (Wilhelmy plate method)

It should be emphasized that for the salt-free solution of not so dilute ionic surfactant the Gibbs adsorption isotherm is proved to be valid for $n=2$ in the Gibbs adsorption equation, provided that activity is used in place of concentration.

Equation of State. Many investigators have reported[36,37] various types of equation of state for the monomolecular film at an air-solution interface. Davies proposed a surface equation of state,[38]

$$(\pi-\pi_s-\pi_r)(A-A_0) = \boldsymbol{k}T \tag{6}$$

for charged monolayer at air-water interface, where π is the total surface pressure, A and A_0 the area and co-area per molecule in adsorbed film, $\boldsymbol{k}$ the Boltzmann constant, T the absolute temperature, π_s the cohesive surface pressure due to the van der Waals forces of attraction between the hydrocarbon parts of the adsorbed surface-active ions as given by

$$\left.\begin{aligned} \pi_s &= -\frac{400\,m}{A^{3/2}} \\ \text{for } A>71 \text{ Å}^2\text{/molecule, and} & \\ \pi_s &= -0.67\,m \end{aligned}\right\} \tag{7}$$

for $A<71$ Å^2/molecule, with m for the effective number of CH_2 groups present in the long-chain ion. Further, π_r in Eq. (6) represents the repulsive surface pressure due to the polar head groups of adsorbed ions. Davies gave

$$\pi_r = 6.03C_i^{\frac{1}{2}} - \frac{2\boldsymbol{k}T}{A} \tag{8}$$

where C_i denotes total (uni-univalent) electrolyte concentration.

Figure 8 shows the observed equation of state for the adsorbed film of SDS, using the data of surface tension measured by the Wilhelmy plate method and the amount of adsorption by radiotracer method. In Fig. 9 plots of $1/(\pi-\pi_s-\pi_r)$ against A are shown as circles, assuming that π_s and π_r are expressed by Eqs. (7) and (8), respectively. If we draw a line with the slope of $\boldsymbol{k}T$ and through the point $A_0=33$ Å^2 given by Davies for adsorbed films of SDS, it largely deviates from the observed values (circles). This clearly shows the inapplicability of the empirical equation (7), which has been presumed from the behavior of π *vs.* A relation for the monolayer of octadecyltrimethylam-

— : calculated from Davies equation

monium ions, but has not yet been confirmed actually, at least for monolayers of shorter carbon chain length. Thus, Eq. (7) turned out to be inapplicable to soluble adsorbed films, and the present authors propose the empirical equation

$$\pi_s = -\frac{K}{A} \tag{9}$$

where K is a proportionality constant, determined from the π *vs.* A curve. Substitution of Eqs. (8) and (9) into Eq. (6) yields an equation of rectangular hyperbola when $A(\pi-\pi_r)$ is plotted against A. Thus, graphical plots give

$$K = 2.43\,kT$$

$$A_0 = 38.4\ \text{Å}^2/\text{molecule}$$

and the final equation becomes

$$\left(\pi+6.03\,C_i^{\frac{1}{2}}+\frac{0.43\,kT}{A}\right)(A-A_0) = kT \tag{10}$$

Figure 10 shows the curves based on Davies' equation and Eq. (10) together with the experimental data (circles). Eq. (10) is shown to fit the actual behavior of adsorbed film better than Davies' equation. The observed π *vs.* A curve shows a more condensed film than that predicted by Davies' equation. The large deviation of Davies' equation, especially in the region of large molecular area, may be ascribed to the insufficient contribution of π given by Eq. (7) to total surface pressure. It should be emphasized that Eq. (10) holds regardless of the value of A being smaller or larger than 71 Å²/molecule, which is not the case in Eq. (7). It is shown that Eq. (10) with $K=2kT$ and $A_0=27.0$ Å²/molec. also fits the π *vs.* A curve for the monolayer of octadecyltrimethylammonium ion, while Davies' equation fairly deviates from the curve.

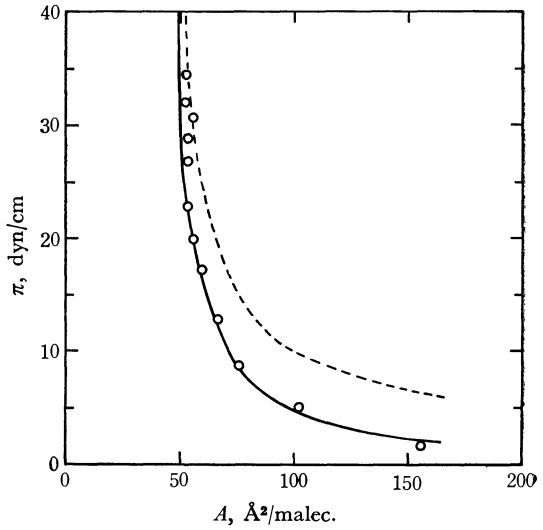

Fig. 10. π *vs.* A plot for SDS.
○ : observed values
— : Eq. (10)
··· : Davies equation

Recently, Chattoraj *et al.*[39] proposed the following equation for π_s on the basis of the two-dimentional van der Waals attraction,

$$\pi_s = \frac{\alpha_s}{A^2} \tag{11}$$

where α_s is the van der Waals constant for a surface phase. To explain the deviation of Eq. (11)

39) C. K. Chattoraj and A. K. Chatterjee, *J. Colloid Interfac. Sci.*, **21**, 159 (1966).

from their experimental data, they assumed the existence of surface micelles for the region of $A<$ 130 Å^2/molecule. In the present studies, however, Eq. (11) has been confirmed not to hold in the region of $A<150$ Å^2/molecule, suggesting the inapplicability of their equation and the uncertainty of the existence of surface micelles in adsorbed layer.

As for the value of A_0 for the charged adsorbed films, there is always disagreement among various authors. Phillips and Rideal[40] give $A_0=20$ Å^2 for the dodecylsulfate ion, and Davies[38] considers 33 Å^2 reasonable, though Cook and Tablot[41] suggest A_0 being as large as 50 Å^2. The present experiments give $A_0=38.4$ Å^2. This value is reasonable when we take account of the fact that the cross-sectional area for a hydrated sulfate ion is 28 Å^2 per molecule.[42] The difference may be ascribed to the presence of the hydrocarbon chain attached to the ion. It should be emphasized that the value A_0 obtained in the present study is based upon the equation of state which is in agreement with the direct measurement of π *vs.* A relation, while the values of other workers are based upon the equations which are not in agreement with the experimental results, at least for SDS.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1998—2002 (1970)

The Magnetic Susceptibilities and ESR of Wurster's Ions in Crystals

Jiro TANAKA, Motomichi INOUE, Masagi MIZUNO and Kazumi HORAI

Department of Chemistry and Department of Physics, Faculty of Science, Nagoya University, Chigusa-ku, Nagoya

(Received January 20, 1970)

The magnetic susceptibilities and the electron spin resonances of Wurster's blue bromide, blue iodide, and red bromide have been measured over a wide temperature range. The results show that the paramagnetism of Wurster's blue bromide above 210°K and of iodide can be explained by the linear Ising model, consistent with the crystal structure. Wurster's blue bromide showed a deviation from the linear Ising model below 210°K; the dimer model is most appropriate for the explanation of the experimental data.

The intensities of the single ESR line are consistent with the results of the static susceptivility measurements. The hyperfine structures are not observed, perhaps because of the rapid movement of the triplet exciton. The magnetic results are explained in terms of the J-values, the origin of which are discussed on the basis of the interaction between the charge-transfer states and the singlet state. The values are resonably correlated with the interaction parameter, β, as estimated from the crystal structure and the electronic spectral measurements.

The magnetic susceptibilites of Wurster's radical salts are of particular interest, as they show the effects of intermolecular spin coupling between the radicals. The electronic interaction between the radicals may be observed in several physicochemical properties; the electronic spectra have been shown to be greatly influenced by the charge-transfer effect.[1)] The singlet-triplet energy gap of the radical crystal may be produced by two mechanisms; one is a convalent-like exchange interaction between the radicals, and the other is the stabilization of the singlet ground state by the charge-transfer state. The charge-transfer interaction is more important than the exchange effect, because the electron overlap is very small between the radicals, and because the exchange interaction is second-order compared to the electron overlap.

In the present paper the result of magnetic susceptibility measurements of several Wurster's salts will be presented, together with the results of ESR measurements over a wide temperature range. The magnetic data will be discussed in terms of the exchange parameter, J. The localized spin models are most adequate for the consideration of the electronic behavior of the organic radical crystals. The observed J-values will be correlated with the calculated stabilization energies of the

*1 Present address: The Government Chemical Industrial Research Institute, Tokyo.

ground state by means of the charge-transfer effects.

Experimental

The materials used in this investigation were prepared by the method of Michaelis and Granick.[2] The magnetic susceptibilities of Würster's blue iodide and bromide and Würster's red bromide have been measured by the Gouy method at temperatures between 80—300°K.

The results are shown in Fig. 1. Since the radicals are not very stable, some fluctuations are observed in the magnetic data. The accuracy of the absolute values was estimated to be about ±5%. Corrections were made for diamagnetic contributions (in 10^{-6} emu/mol) from neutral tetramethyl-*p*-phenylenediamine (−118), the bromide ion (−36), and the iodide ion (−52).[3] The value for the neutral amine was based on the observed susceptibility of *p*-phenylenediamine.[4] The susceptibility of Würster's blue iodide increases with decrease in the temperature; the maximum is reached at 140°K. The susceptibility of Würster's blue bromide gradually decreases with a lowering of the temperature and it reaches its minimum at 120°K. The susceptibility of Würster's red bromide shows only the diamagnetism at 300°K.

The ESR spectra have been observed by means of a conventional spectrometer at 9310 MHz. The intensity of the absorption lines was measured in comparison with the intensity of a small crystal of $CuSO_4 \cdot 5H_2O$ mounted in the same resonant cavity.

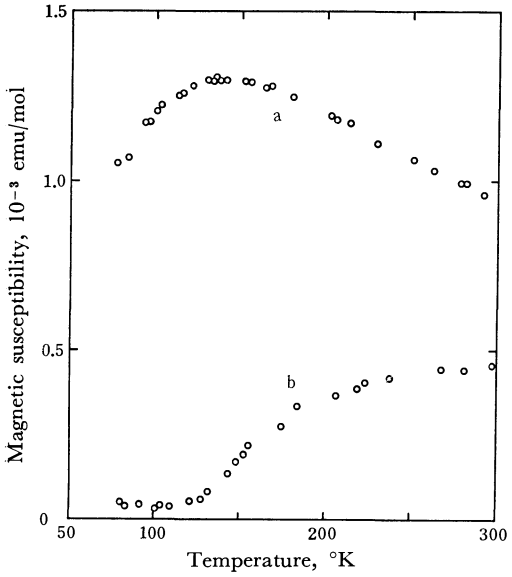

Fig. 1. Magnetic susceptibilities of Würster's Blue iodide (a) and bromide (b) at 70—300°K.

Discussion

The crystalline structure of Würster's blue iodide have been found to be a regular one-dimensional chain;[5] the structure of Würster's blue bromide has also been found to be a regular chain at room temperature.[6] The magnetic susceptibility of a regular antiferromagnetic chain will be given by the linear Ising model as

$$\chi = \frac{N_0 g^2 \mu_B^2 \exp(J/kT)}{4kT} \qquad (1)$$

where $g=2.00$ is the g-factor, μ_B is the Bohr magneton, k is the Boltzmann constant, N_0 is the Avogadro number, and J is the exchange parameter between the radical pairs.

The plot of log $(4k\chi T/N_0\mu_B^2)$ against the inverse temperature is shown in Fig. 2. The experimental values of Würster's blue iodide coincide with the line calculated by the linear Ising model, although a slight deviation from the line is found at lower temperatures. The deviation from the calculated line is monotonous; therefore, it may be ascribed to the gradual increase in the J-value, which is accompanied by a decrease in the interplanar spacing as a result of a shrinkage of the lattice dimensions. The J-values are estimated from Eq. (1) to be -59 cm^{-1} at 300°K and -83 cm^{-1} at 80°K; the average value is -71 cm^{-1} for the 80—300°K range. Since the crystal structure of Würster's blue iodide is a regular chain, the use of the linear Ising model will be most

6) Unpublished results of this laboratory.

suitable. In addition, it is most probable that the equal spacing between the radicals is maintained down to low temperatures, for no sharp change in the susceptibility with the temperature is observed. The increase in the J-values at low temperatures is also reasonable, since the interaction will be enlarged by close contact between radicals.

The results on Würster's blue bromide are in contrast to those on the iodide; a sudden change in the slope is observed at 210°K. The abnormal decrease in the susceptibility below this temperatures implies that a phase transition may take place at this temperature. Several discussions have been presented with regard to the stability of the linear interacting system;[7-9] a phase transition has actually been reported on the crystal of Würster's blue perchlorate.[9-11] Although no X-ray results have yet been found for Würster's blue bromide, a similar transition is plausible at lower temperatures. Therefore, the linear Ising model will be used above 210°K and the dimer model will be employed below this temperature. From Eq. (1) the J-value is estimated to be $-210\ \mathrm{cm}^{-1}$ in the 210—310°K range. According to the dimer model, the susceptibility is given by:

$$\chi = \frac{N_0 g^2 \mu_B{}^2}{3kT[(1 + (1/3)\exp(2|J|/kT))]} \qquad (2)$$

By the use of Eq. (2), the J-value for 120—210°K is determined to be $-350\ \mathrm{cm}^{-1}$. This value is justified in view of the value above a phase transition, since the charge-transfer interaction will be much increased by the dimer formation at low temperatures.

ESR Spectra. The intensities of the ESR spectra were measured with Würster's blue bromide and iodide for the temperature range of 80—300°K. The results are nearly in agreement with the static measurements, as is shown in Fig. 3, where the results for Würster's blue bromide is presented. The ESR spectra of these radical salts do not show any hyperfine structures; a single line is observed in both salts. The lack of the hyperfine structures may suggest that the movement of the triplet exciton is so rapid that the triplet dipolar structure is washed out.[12,13]

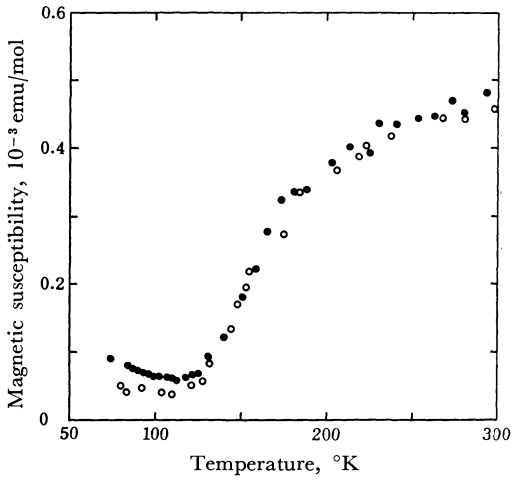

Fig. 3. The Comparison of Susceptibility Measurements by Static (○) and the ESR (●) methods.

The g-factors are those of the free spin values; the values are $g=2.0028\pm0.0005$. The measurement of the single crystal of the iodide shows no anisotropy on the g-values and the line-width. The line widths are 11 Oer (31 Mc) for iodide and 4 Oer (14 Mc) for bromide. The line-width is not changed markedly with the temperature for Würster's blue iodide. The width of Würster's blue bromide is decreased in the 120—170°K range, where the dimer is presumably formed, and it increases below 120°K because some impurities may contribute dominantly in this temperature range.

Singlet-Triplet Energy Gap. The observed J-values can theoretically be correlated with the intermolecular electronic interactions between the radicals; the values can be calculated if the molecular wave functions and the energies of the intermolecular interactions are known precisely. In a previous paper[1] we have presented the calculations for the triplet state of the dimer system.

The wave functions for the singlet ground state and the triplet state are given by;

$$\Psi_S = \frac{1}{\sqrt{2(1+S^2{}_{mm})}}[\phi_a{}^m(1)\phi_b{}^m(2) + \phi_a{}^m(2)\phi_b{}^m(1)] \times [\alpha(1)\beta(2) - \alpha(2)\beta(1)]$$

$$\Psi_T = \frac{1}{\sqrt{2(1-S^2{}_{mm})}}[\phi_a{}^m(1)\phi_b{}^m(2) - \phi_a{}^m(2)\phi_b{}^m(1)] \times \begin{cases}\alpha(1)\alpha(2)\\ \alpha(1)\beta(2) + \alpha(2)\beta(1)\\ \beta(1)\beta(2)\end{cases} \qquad (3)$$

where $\phi_a{}^m$ and $\phi_b{}^m$ denote the highest molecular orbitals which are half-occupied, where α and β are spin functions, and where S_{mm} is the overlap integral between the $\phi_a{}^m$ and $\phi_b{}^m$ orbitals.

The Hamiltonian and notations for the molec-

ular integrals are the same as in the previous paper.[1] The diagonal energy for the triplet state and the separation of the singlet and the triplet state are:

$$\left.\begin{aligned} E_T &= 2\varepsilon_a - 2\langle\psi_a{}^m|1/R_b|\psi_a{}^m\rangle \\ &\quad + (\psi_a{}^m\psi_a{}^m|\psi_b{}^m\psi_b{}^m)(1+S^2{}_{mm}) \\ &\quad + \sum\frac{\delta_i\delta_j}{R_{a_i,b_j}} + 2S_{mm}\langle\psi_a{}^m|1/R_b|\psi_b{}^m\rangle \\ &\quad - 2S^2{}_{mm}\langle\psi_a{}^m|1/R_b|\psi_a{}^m\rangle \\ &\quad - (\psi_a{}^m\psi_b{}^m|\psi_a{}^m\psi_b{}^m) \\ \Delta(T-S) &= 4S_{mm}\langle\psi_a{}^m|1/R_b|\psi_b{}^m\rangle \\ &\quad - 4S^2{}_{mm}\langle\psi_a{}^m|1/R_b|\psi_a{}^m\rangle \\ &\quad + 2S^2{}_{mm}(\psi_a{}^m\psi_a{}^m|\psi_b{}^m\psi_b{}^m) \\ &\quad - 2(\psi_a{}^m\psi_b{}^m|\psi_a{}^m\psi_b{}^m) \end{aligned}\right\} \quad (4)$$

The evaluation of those integrals would require extensive calculations; however, the order of magnitudes can be estimated by an empirical relation between the overlap integrals and the assumed β values, the charge-transfer matrix elements of the previous paper. The spectral data showed that the β value between the charge-transfer and the singlet-ground configuration of Würster's blue crystals are in the vicinity of 0.1—0.2 eV, and the formula for the matrix elements showed that β should be proportional to the overlap integrals times the integrals of the $\langle\psi_a{}^m|1/R_b|\psi_a{}^m\rangle$ type. Each term in $\Delta(T-S)$ of Eq. (4) is related to the square of the overlap integrals times $\langle\psi_a{}^m|1/R_b|\psi_a{}^m\rangle$. Therefore, if we use a rough relation that:

$$\beta \simeq kS^2{}_{mm} \quad (5)$$

then Δ may be approximated by:

$$\Delta \simeq kS^2{}_{mm} \quad (6)$$

If we put $k=40$ eV (which is estimated from spectral results) then Δ can be evaluated as being smaller than a few cm^{-1} by using the overlap integrals tabulated in Table 1. This obviously shows that the exchange interaction of this type is not the true origin of the separation of the triplet and singlet energy levels.

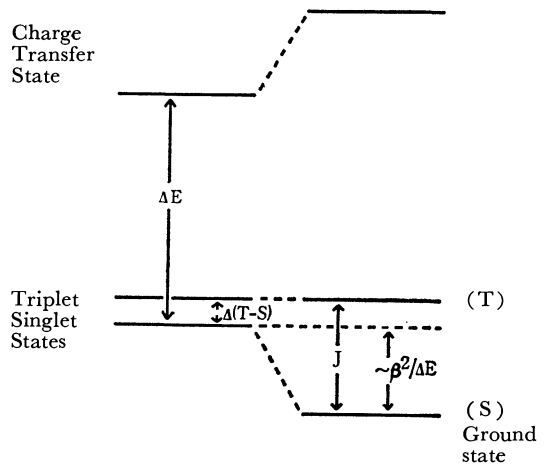

Fig. 4. Energy Levels of Singlet, Triplet and Charge Transfer States.

On the other hand, the singlet-ground state is stabilized by the charge-transfer effect, which is far more significant in the present system.[1] This resonance effect is important only for the singlet-ground state (Fig. 4); the triplet state is not stabilized at all because of the lack of the intermolecular charge-transfer effect.

The stabilization energies have been evaluated by solving Eq. (10) of the previous paper[1]; they are reproduced in Table 1. The β parameters in Table 1 were estimated by considering the spectral data, such as the energy and the intensity of the charge-transfer band.

Würster's red bromide shows only diamagnetism; this is consistent with the large stabilization energy calculated. By this mechanism it can be seen that Würster's red bromide is a diamagnetic crystal at room temperature. With other crystals,

Table 1.

		S_{mm}*	$-\beta$ (eV)	Stabilization Energy		Observed J-value
Würster's red bromide	(II)†	0.025	0.9	−0.415 (eV)	−3352 (cm^{-1})	—
	(III)		0.6	−0.187	−1500	
Würster's blue bromide	(IV)	0.0034	0.25	−0.038	−300	−210 (cm^{-1})**
	(V)		0.23	−0.0298	−238	
Würster's blue iodide	(III)	0.0025	0.11	−0.0075	−60	−70
Würster's blue perchlorate	(IX)	0.0012	0.08	−0.004	−32	−16***

* S_{mm} is the overlap integrals between the half-filled molecular orbitals.
** The value is for the 210—300°K range.
*** The value is estimated from the data of Okumura.[10]
† The numbers in parenthesis are referred to the Table 1 of Ref. 1.

the calculated energies are reasonably correlated with the observed J-values. These results show convincingly that the singlet-triplet energy gap is produced by the charge-transfer mechanism.

The magnetic interaction in such radical crystals is thus shown to be dominated by the charge-transfer mechanism. The stabilization of the ground state is approximately given by $-\beta^2/\Delta E$, where ΔE is the energy difference between the charge-transfer and the ground state and where β is the interaction energy. Since ΔE is almost constant at about 1.6—1.8 eV for all Würster's salts, the β value is very important in both spectral and magnetic studies. The motion of the triplet exciton in the crystal is governed by the transfer-matrix element between radicals and pairs; it is also connected with β-values and, hence, with the overlap integrals.

A more detailed approach to the evaluation of these intermolecular interactions would be desirable in future studies.

The Photosensitized Decomposition of Methyl Acetate at 77°K. A Kinetic Analysis of the Biphotonic Process

Shigeru MIZUTANI, Yukihiko NAKAJIMA, Kazuo SHIMOKOSHI and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 26, 1970)

The photosensitized decomposition of methyl acetate at 77°K has been investigated using an ESR technique. Naphthalene, α-naphthol, phenanthrene, anthracene, and benzophenone were used as sensitizers. When wavelengths longer than 2700Å were used, the formation of methyl radicals was observed except in the cases of anthracene and benzophenone. For the systems containing naphthalene, phenanthrene, and α-naphthol, the rate of the formation of methyl radicals was studied in detail and was found to obey the following relation:

$$R=\alpha I^{3/2}C^{1/2}$$

Here, α is a proportional constant, I is the light intensity, and C is the solute concentration, which ranged from 5×10^{-5} to 2×10^{-3} mol l^{-1}. Possible reaction mechanisms to explain the above relation were discussed; they include the biphotonic excitation of sensitizers, the triplet-triplet annihilation for the decay of the solute triplet, and the photolysis of the radicals produced in the photosensitization.

The lowest triplet states of some aromatic compounds have very long lifetimes at 77°K.[1,2] The subsequent absorption of another photon by the triplet molecule, therefore, often occurs, even with a conventional ultraviolet light source, and produces a higher triplet state. When the ionization potential of the solute molecule is close to the energy of the higher triplet state, the charge separation takes place. Such is the case when tetramethyl-*p*-phenylenediamine (TMPD) is photolyzed in a rigid matrix.[3,4] The formation of benzyl radicals in the 2537 Å photolysis of toluene at 77°K has also been attributed to the biphotonic process.[2] The rate of the formation of this radical is reported to be proportional to $I^{3/2}$. Here, I denotes the light intensity. When an aromatic compound is dispersed in a rigid matrix solvent, the decomposition of the solvent by the biphotonic process is frequently observed.[5] Recently, one of the present authors investigated the photosensitized decomposition of methanol at 77°K using several aromatic compounds as sensitizers and concluded that the formation of CH_2OH radicals is due to the biphotonic process described above.[6]

In this paper, methyl acetate has been used as

the matrix solvent, because the methyl radicals produced in the photosensitization show a clear and comparatively stable ESR spectrum. Therefore, we expected that a detailed kinetic analysis of the biphotonic process would be feasible.

Experimental

The methyl acetate (Tokyo Kasei Co.) was distilled at 57.5°C before use. The α-naphthol, phenanthrene, and benzophenone were used as supplied by the Wako Pure Chemical Co. The naphthalene and anthracene purified by the zone-melting method were kindly supplied by Professor Hayakawa of this Institute.

About 0.4 m*l* of a methyl acetate solution containing a known amount of a sensitizer was sealed in a Spectrosil quartz tube (2.5 mm in diameter) and they immersed in liquid nitrogen in an unsilvered quartz Dewar flask. The solution in the flask was irradiated with a high-pressure mercury arc (Toshiba SHL 100 UV-2) through a combination of two quartz lenzes, a glass filter, and a calibrated wire net to control the light intensity. The glass filters used were Toshiba UV-27, Corning CS-054, and Toshiba UV-33 filters; they were used to cut off the wavelengths shorter than 2700, 3000, and 3300 Å respectively.

After the irradiation, the radicals produced were examined by means of a JEP-1 X-band ESR spectrometer with a field modulation of 100 kc/sec. The concentrations of the radicals were measured by comparing the signal heights from the solutions and a Mn marker (Mn^{2+} in MgO).

In order to ascertain the kind of products formed in photolysis, prolonged irradiation was made on a rigid solution. After warming the irradiated sample up to room temperature, the gas non-condensable at −120°C was analyzed by gaschromatography.

Results

The ESR spectrum obtained with an irradiated methyl acetate solution of naphthalene is shown in Fig. 1, along with the assignment of the peaks. With other sensitizer solutions almost the same spectra were obtained, although the relative peak heights due to the different radicals were a little changed.

Table 1 summarizes the general features of the experimental results. Pure methyl acetate gave an ESR signal only when irradiated for a long period with light and through no filter. In the presence of naphthalene, it was necessary to use wavelengths shorter than 3000 Å to obtain the ESR spectrum. The strong absorption band of naphthalene has its onset at 3000 Å. When anthracene and benzophenone were used as sensitizers, no ESR signals were obtained. When a mixture of benzophenone and naphthalene was used, an ESR spectrum similar to that in Fig. 1 was obtained even by the irradiation of the light at wavelengths longer than 3300 Å. The luminescence observed from this solution was the same as that from a naphthalene solution. These results suggest an energy transfer from triplet benzophenone to naphthalene in the rigid matrix of methyl acetate. A similar observation has already been made in the matrix of methanol.[6]

Decay of Methyl Radicals in the Rigid Matrix. During the measurement of the ESR

spectrum of the rigid matrix, the peak height due to methyl radicals gradually decreased. The rate of the decrease was dependent upon the initial peak height. The results obtained with a naphthalene solution are shown in Fig. 2. When the reciprocal of the peak height is plotted as a function of the time of measurement, a linear relationship is always obtained. This suggests that the initial decay of methyl radicals is of a second order. For the sake of simplicity, the peak heights shown in the following data are those obtained by extrapolating the linear relation to zero time, that is, the time when the irradiation was terminated.

Dependence on the Light Intensity. Using two calibrated wire nets, three light intensities were examined, one of them without a net. Figure 3 shows the irradiation-time dependence obtained with a naphthalene solution. Initially, the peak height increased linearly with the irradiation time, but on further irradiation the peak height reached a maximum and then gradually decreased. This decrease is probably due to the screening of light by decomposition products. In Fig. 4, the initial slopes obtained with three sensitizer solutions are plotted as a function of the light intensity. In every case, the rate of increase in peak height, *i.e.*, the rate of the formation of methyl radicals, was found to be proportional to $I^{1.5\pm0.1}$. Here,

B(△), α-naphthol
C(□), phenanthrene

I denotes the light intensity.

Dependence on the Concentrations of Solutes. Two series of experiments were made for each sensitizer solution. The results are shown in Fig. 5. Where the logarithm of the rate of the formation of methyl radicals is plotted as a function of the logarithm of the concentration. An approximately linear relationship was obtained over a wide range of concentrations from 5×10^{-5} to 2×10^{-3} moll^{-1} for each solution. All the slopes were nearly equal to 0.5. At concentrations higher than 10^{-2} moll^{-1}, the slope decreased with an increase in the concentration.

Reaction Products. To identify gaseous products in photolysis, a long irradiation was made on a rigid methyl-acetate solution. The products non-condensable at −120°C were analyzed by gaschromatography. The product consisted of methane and a small amount of ethane, although no quantitative measurement could be made because of their small amounts. To check whether these gases are produced during the photolysis or when the sample is warmed up for analysis, a sample kept for a long period at 77°K after irradiation, during which period most of the methyl radicals decayed, was analyzed; the amounts of methane and ethane obtained were, however, almost the same as those obtained immediately after irradiation.

Discussion

The following mechanism is usually assumed for the interpretation of the kinetics of biphotonic

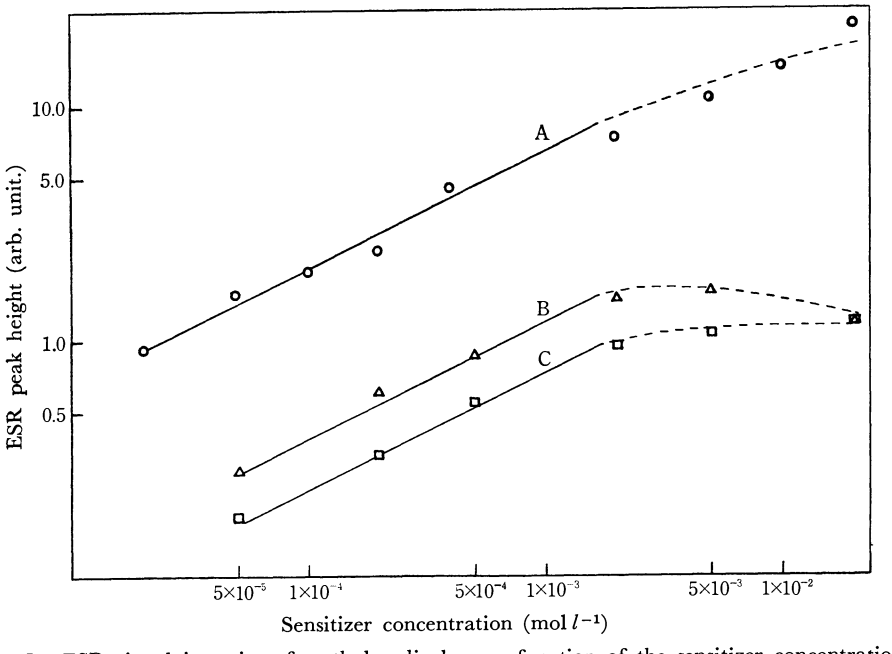

Fig. 5. ESR signal intensity of methyl radicals as a function of the sensitizer concentration.
A(○), naphthalene B(△), α-naphthol C(□), phenanthrene

processes:[2]

$S + h\nu \rightarrow S^*$ rate$=I\varepsilon_S C_S l$

$S^* \rightarrow S(+h\nu)$, $S^* \rightarrow T$ } quantum yield of $T=\phi_T$

$T \rightarrow S(+h\nu)$ rate$=(1/\tau)C_T$

$T + h\nu \rightarrow T^*$ rate$=I\varepsilon_T C_T l$

$T^* \rightarrow T$, $T^* + M \rightarrow S +$ radical } quantum yield of radical $=\phi_P$

Here, S and T represent the lowest singlet and triplet states; S^* and T^* represent the higher excited states; τ is the lifetime of the triplet state with respect to decay, $T \rightarrow S$, by phosphorescence or a radiationless process; ε_S and ε_T are the extinction coefficients; C_S and C_T are the concentrations of the ground-state and triplet molecules, and $C_S + C_T = C$ is the initial concentration. I is the light flux in the sample, and M represents the matrix solvent molecule, while l is the path of the impinging light in the matrix.

Using this mechanism, however, the experimentally-obtained relation:

$$R = \alpha I^{3/2} C^{1/2} \qquad \text{(I)}$$

cannot be easily derived. We have tried various assumptions regarding ε_S, ε_T, ϕ_T, ϕ_P and τ, but were not successful in deriving the relation (I) in the frame of the mechanism proposed above. The most stubborn difficulty was the concentration dependence.

As far as we have found in the literature, the solute concentration dependence in biphotonic processes have not been measured extensively. Brocklehurst *et al.* reported, in a study of the biphotonic photolysis of 3-methyl pentane sensitized by benzene, that the rate of the formation of radicals was not proportional to the solute concentration, but, rather increased with an increase in the concentration more slowly than the first order.[2] They tentatively attributed this to the participation of impurities.

If the triplet-triplet annihilation:

$$2T \rightarrow S^* + S \qquad \text{rate}=k_a C_T^2$$

is the most important among the decay processes of T (although this is not likely to occur in a very dilute solution such as 5×10^{-5} moll^{-1}),[7,8] the relation (I) can easily be derived as follows:

$$R = \varepsilon_T l \phi_P [\varepsilon_S l \phi_T / k_a (2-\phi_T)]^{1/2} I^{3/2} C^{1/2} \qquad \text{(II)}$$

This mechanism is very tempting, but, obviously, it needs more consideration and more extensive experiments on it before it can be adopted.

Another possible mechanism we have considered includes the participation of the produced radicals in the following manner:

$T^* + M \rightarrow S + CH_3O + CH_3CO$ (1)

$CH_3O + CH_3CO \rightarrow M$ (2)

$CH_3CO + h\nu \rightarrow CH_3^* + CO$ (3)

$CH_3^* + M \rightarrow CH_4 + CH_2COOCH_3$ or CH_3COOCH_2 (4)

$CH_3^* \rightarrow CH_3$ (5)

CH_2COOCH_3 or CH_3COOCH_2 $+ h\nu \rightarrow CH_3^* + 2CHO$ (6)

In this mechanism, a solvent molecule excited by the interaction with T^* is assumed to decompose into CH_3O and CH_3CO radicals. Moreover, the subsequent absorption of a photon by a CH_3CO radical is assumed to occur and to lead to the formation of CH_3^* and CO. Here, CH_3^* denotes an activated methyl radical; it is considered to be a precursor of methane. The absorption of a hydrogen atom by a thermal methyl radical is not probable in the matrix at the temperature of liquid nitrogen, but, as is shown in the Results section, much more methane than ethane was produced during the photolysis.

To explain the light-intensity dependence of the methyl radical formation, we did not adopt the following reactions in the above mechanism:

$T^* + M \rightarrow CH_3 + CH_3COO + S$ (7)

$CH_3COO + h\nu \rightarrow CH_3 + CO_2$ (8)

This discrimination seems to correspond to the following observations. First, as is shown in Fig. 1, the ESR spectrum we obtained has a rather large singlet at the center; this we assigned to CH_3O radicals. The formation of this radical can easily be explained by the above mechanism, but not by the mechanism consisting of the formation of methyl radicals by the reactions (7) and (8). Second, although we could not detect the formations of CO and CO_2 in photolysis because of their small amounts, the radiolysis of methyl acetate at 77°K is known to produce a large amount of CO compared with CO_2, as has been stated in a previous paper.[9] This fact seems to support the occurrence of the reaction (3) rather than the reaction (8).

Judging from the peak height of the ESR spectra of methyl radicals and the amounts of CH_4 and C_2H_6 observed, the quantum yields of these products are estimated to be very small. In other words, the reaction (2) is probably very fast in the matrix. If so, the steady-state treatment gives the following equation:

$$R = \varepsilon l I [\varepsilon_S \varepsilon_T l^2 \phi_T \phi_P \tau I^2 C / k_2 [1 + (\varepsilon_T \phi_P + \varepsilon_S \phi_T) l \tau I]]^{1/2} \qquad \text{(III)}$$

Here, ε is the extinction coefficient of the CH_3CO radical, while k_2 is the rate constant of the re-

action (2). Then, by assuming a tentative relation, $1 \ll (\varepsilon_T \phi_P + \varepsilon_S \phi_T) l\tau I$, we can derive an equation which has the experimentally-observed dependences of the light intensity and the solute concentration.

At higher concentrations of solutes, the rate of the formation of methyl radicals showed a tendency toward saturation. This cannot be explained by the relation (III), which has been derived on the basis of inadequate relations: the rate of light absorption by $C_S = I\varepsilon_S C_S l$ at high concentrations. If a more proper relation is used, the tendency toward saturation can easily be explained. This point has already been discussed by other investigators.[2)]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2007—2011 (1970)

Effects of Iodine Addition on the Electrical and Optical Properties of the Semiquinoid Phenothiazine Bromide

Yoshio MATSUNAGA and Kosuke SHONO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received January 29, 1970)

The electrical resistivity and the electronic and vibrational spectra of the semiquinoid phenothiazine bromide have been found to be drastically modified by the addition of iodine. The resistivity minimum lies around the mole ratios of 0.25 to 0.30, while the value in this composition range is from 4 to 5 ohm cm. The combined spectroscopic data indicate three different stages in the intermolecular interactions in this system; the first around a mole ratio of 0.25, the second near 0.5, and the third above 1.00. The higher the iodine content, the less conductive the adducts appear to be. Iodine addition was attempted also to the *p*-phenylenediamine bromide; however, no pronounced effect on the physical properties could be found in this system.

Earlier one of the present authors reported that the vibrational spectrum of the phenothiazine-iodine complex, which exhibits a resistivity of 20 ohm cm at room temperature, is quite different from that of the parent organic compounds, but identical with that of semiquinoid phenothiazine bromide.[1] On the basis of these observations, it was concluded that every phenothiazine molecule in the solid iodine complex bears an approximately unit-positive charge. The hypothesis that the highly-conducting iodine complexes of phenothiazine and its derivatives have essentially dative ground states seemed to receive strong support from the additional observations that the iodine adducts of semiquinoid phenothiazine chloride and bromide have resistivities of the order of 10 ohm cm. Thus far, though, no attempt has been made to determine the exact composition of such mixed halogen complexes. Now we wish to report the results of our measurements of the electrical and optical properties of the semiquinoid phenothiazine bromide-iodine system.

Experimental

Materials. Semiquinoid phenothiazine bromide was prepared by the oxidation of the parent organic compound with bromine, as has been described by Kehrmann and Diserens.[2] For example, 0.4 g of bromine, dissolved in 30 m*l* of ethyl ether, was slowly added to 1.0 g of the thiazine in 30 m*l* of the same solvent cooled with an ice-salt mixture. The greenish-black precipitate was filtered and washed with the solvent. As the bromide is not stable above 50°C, the sample was dried at room temperature over silica gel and under a vacuum.

The addition of iodine to the bromide was carried out by the careful grinding of the weighed components in the presence of a small amount of benzene. The solvent was evaporated at room temperature; then the mixture was heated to 80°C for a short time to complete the reaction and also to remove all traces of the solvent. Samples with the following mole ratios were prepared: 0.10, 0.20, 0.25, 0.30, 0.40, 0.50, 0.75. 1.00, 1.25, and 1.50.

The phenothiazine-iodine complex was precipitated by mixing 1.5 g of the thiazine in 25 m*l* of hot benzene with 3 g of iodine in 75 m*l* of the same solvent. The mole ratio of the complex is known to be 2 : 3.[1]

The *p*-phenylenediamine bromide was prepared by the oxidation of the diamine with bromine.[3] The addition of iodine to the bromide was made by the same method as has been described above.

Measurements. The electrical resistivities of the phenothiazine bromide-iodine system and the phenothiazine-iodine complex were examined on pressed pellets by a potential-probe method. The temperature de-

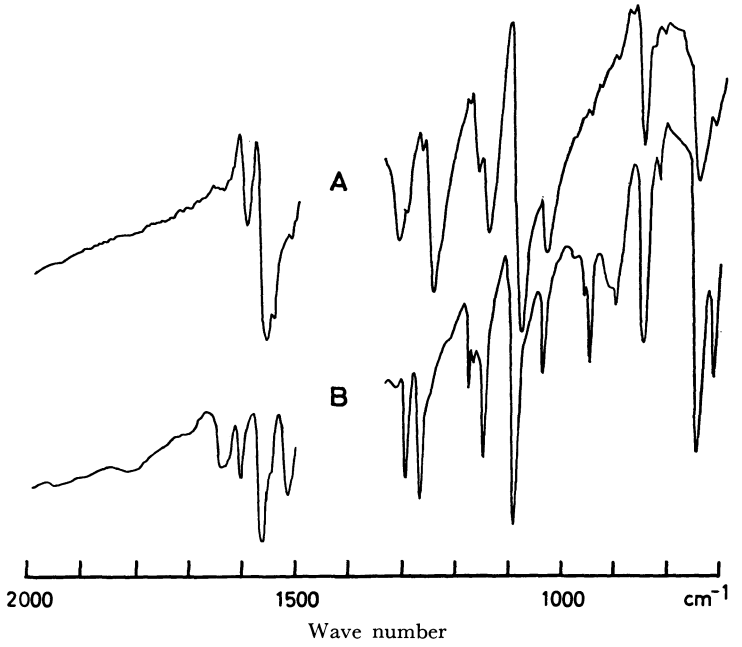

Fig. 1. Two extremes in the vibrational spectrum of semiquinoid phenothiazine bromide. The spectrum is often a superposition of these two.

pendence was measured in the range from 20 to 70°C unless otherwise stated. The resistivities observed in the *p*-phenylenediamine bromide-iodine system are in the order of 10^6 ohm cm or higher; therefore, only the values at room temperature were examined by a two-probe method employing a cell similar to that reported by LaFlamme[4] and a TOA Electronics DC microvolt ammeter, Model PM-18C.

The diffuse reflection spectra were measured with a Beckman DK-2A spectroreflectometer in the range from 4 to 30 kK. The pulverized sample was diluted with potassium bromide in concentrations of the order of 0.1 weight percent. The spectra were recorded as the difference in reflectance between the mixture and pure potassium bromide and were plotted using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance.

The vibrational spectra in the rock salt region were measured as Nujol mineral oil mulls by means of a Jasco IR-G infrared spectrophotometer. Because of the presence of an electronic absorption in this region, the reference light had to be highly attenuated in many cases in order to obtain a reasonable transmittance.

Results

Phenothiazine Bromide. We found that the vibrational spectra exhibited by the samples are often superpositions of two patterns in various ratios. The two extremes are presented in Fig. 1 as the spectra A and B. The transformation of the spectrum B to A by storage was observed on one occasion only. Although there is essentially no difference in the electronic spectrum in the region from 10 to 30 kK between the samples showing the vibrational spectra A and B, a considerable change may be noted in the region below 10 kK. As is shown in Fig. 2, the sample showing the vibrational spectrum A exhibits an electronic absorption extending into the rock salt region, but the one showing the vibrational spectrum B does not.

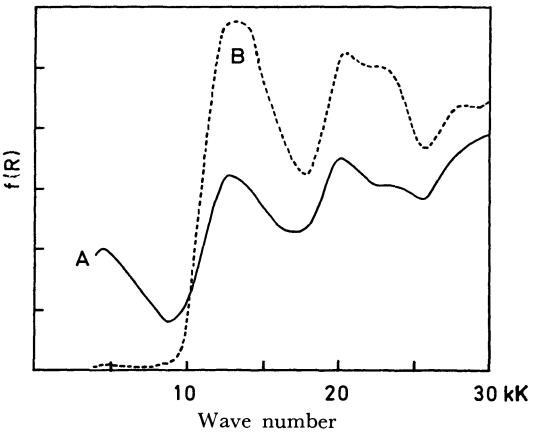

Fig. 2. Two extremes in the electronic spectrum of semiquinoid phenothiazine bromide.

The bromide samples had resistivities in the order of 10^4—10^5 ohm cm, *e.g.*, a resistivity of 1.5×10^5 ohm cm at 20°C, and an activation energy of 0.30 eV defined by $\rho=\rho_0\exp(E/kT)$ in the temperature range from 4 to 35°C was obtained by one of the

preparations. Above 50°C, a rapid irreversible decrease in the resistivity was observed. The vibrational spectrum of such a heat-treated sample was found to be different from either the spectrum A or B.

Phenothiazine Bromide-iodine System. The electrical resistivity value at 20°C is plotted against the mole ratio (iodine/bromide) in Fig. 3. A deep minimum is located around mole ratios from 0.25 to 0.30, the value in this composition range being from 4 to 5 ohm cm. When the mole ratio is below these values, the vibrational spectrum of the iodine adduct consists of very broad lines as is represented by the spectrum a in Fig. 4, measured at a mole ratio of 0.25. Nevertheless, it may be noted that the whole pattern is rather close to the spectrum A of the bromide. The electronic spectrum bears also some resemblance to that of the bromide, especially the one showing the vibrational spectrum A. However, the low-energy absorption is shifted further into the rock salt region and its maximum is located below 4 kK. In addition, an extra absorption appears at about 9 kK as a shoulder. The absorption in the region above 20 kK becomes high and almost flat, as is shown in Fig. 5. The activation energies for semiconduction in the four samples in this composition range were found to be 0.10 ± 0.01 eV.

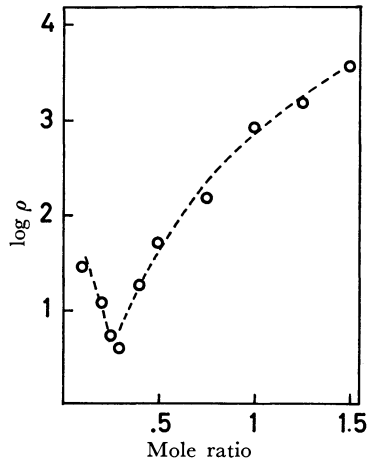

Fig. 3. Electrical resistivity plotted against the mole ratio (iodine/bromide) in the phenothiazine bromide-iodine system.

As the iodine content rises above 0.30, the resistivity increases monotonously. At a mole ratio of 0.40, a new electronic absorption is observed at 5.5 kK in addition to the one found in the low-energy region of the spectrum a in Fig. 5. By the further addition of iodine, the absorption having a maximum in the region below 4 kK is completely replaced by the one at 5.5 kK. The spectrum b in Fig. 5, recorded at a mole ratio of 0.50, represents such a stage. At this composition the resistivity at room temperature is about 50 ohm cm and the activation energy is 0.20 eV. It must be pointed out that the absorption lines in the vibrational spectrum b in Fig. 4 are a little bit sharper

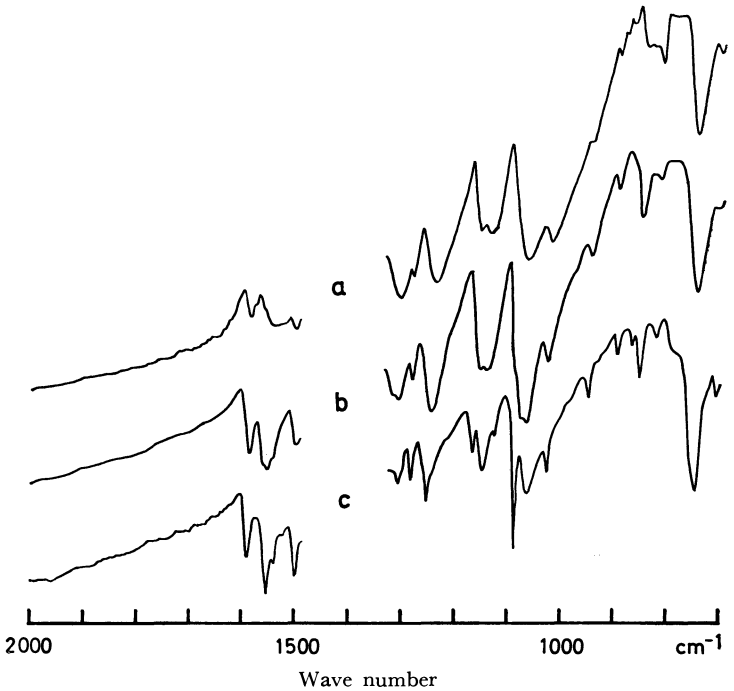

Fig. 4. Vibrational spectra in the phenothiazine bromide-iodine system; a) mole ratio 0.25, b) 0.50, c) 1.00.

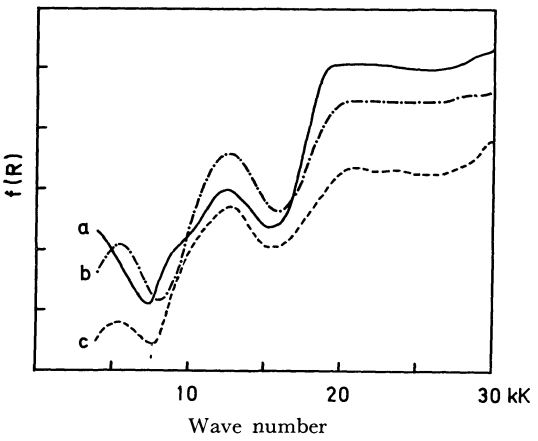

Fig. 5. Electronic spectra in the phenothiazine bromide-iodine system;
a) mole ratio 0.25, b) 0.50, c) 1.00.

than those in the spectrum a.

Then, at a mole ratio of 1.00 the intensity of the electronic absorption at 5.5 kK is markedly diminished. Moreover, the vibrational spectrum is characterized by a superposition of a pattern consisting of lines as sharp as those in the spectrum B of the bromide. The resistivity is about 8.4×10^2 ohm cm at this composition. If more iodine is added, the electronic absorption in the low-energy region disappears completely and the intensities of the sharp vibrational absorption lines belonging to the newly-appeared pattern are much enhanced. At the maximum iodine content of 1.50 the electrical resistivity is almost one thousand times as high as the minimum value.

The iodine adducts exhibiting low electrical resistivities are more stable than the semiquinoid bromide. Neither a change in the vibrational spectrum nor the vaporization of the iodine is observed by heating to 80°C. However, the coloration of polyethylene stoppers by iodine after a short storage of the samples in vials can be noticed even at room temperature if the mole ratios are higher than 0.75.

Phenothiazine-iodine Complex. An electrical resistivity of 13 ohm cm and an activation energy of 0.19 eV were obtained in the present work. These values are in good agreement with those found earlier by one of the present authors,[1] however, our resistivity is approximately two orders of magnitude lower than that reported by Gutmann and Keyzer.[5] In Fig. 6 the vibrational spectrum is compared with the spectrum of the parent organic compound. They are much better resolved than those cited in an earlier paper and are still in accordance with our previous argument.

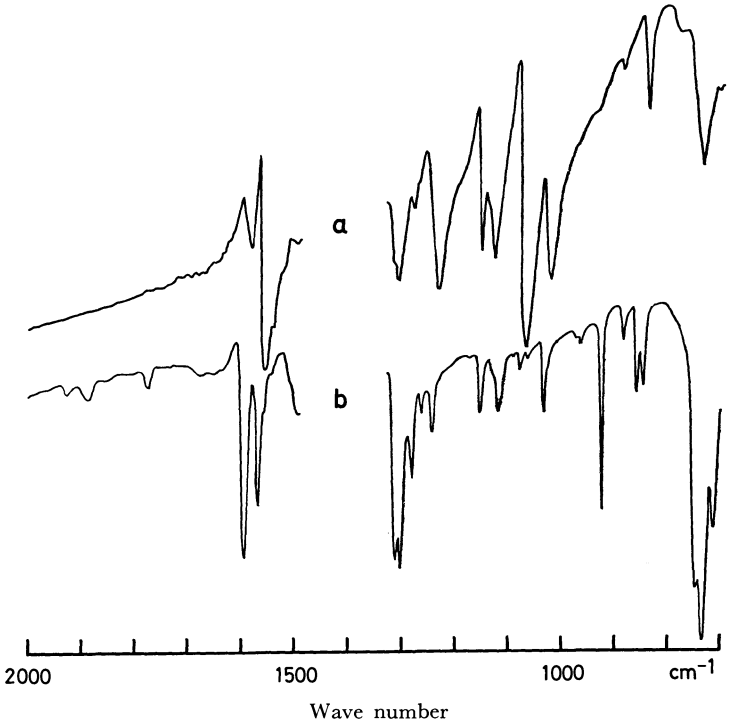

Fig. 6. Vibrational spectra of the phenothiazine-iodine complex (a) and phenothiazine itself (b).

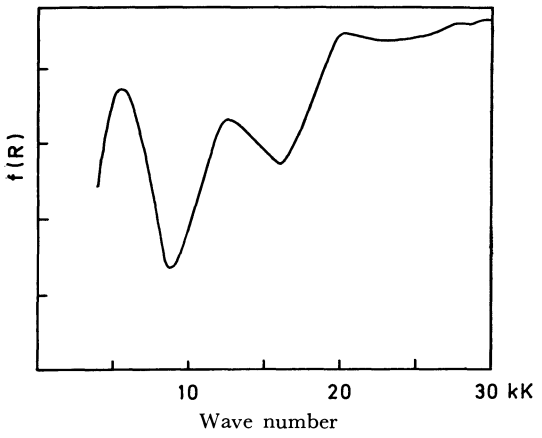

Fig. 7. Electronic spectrum of the phenothiazine-iodine complex.

It is easy to see that the spectrum of the iodine complex is quite similar to the spectrum A of the bromide, but very different from the spectrum of phenothiazine itself. The electronic spectrum was also examined. As is shown in Fig. 7, the maximum of low-energy absorption is located at 5.5 kK.

***p*-Phenylenediamine Bromide-iodine System.** The bromide has a resistivity of 5×10^7 ohm cm at room temperature. The compound becomes ten times more conductive by the addition of 0.25 to 0.75 mol of iodine. The further addition results in an increase in the resistivity again to the order of 10^7 ohm cm. Thus, this system was found to be less conductive than the iodine complex, for which Nishizaki and Kusakawa reported the minimum resistivity of 1.7×10^5 ohm cm at a mole ratio of 0.82.[6] No significant change could be observed in the electronic and vibrational spectra.

Discussion

The molecule of phenothiazine is known to have a folded configuration.[7] The large difference in the vibrational spectrum between phenothiazine and its semiquinoid bromide should be attributed to the change in the electronic and geometrical structures caused by the loss of one electron. Although the cation radical has often been assumed to be planar,[8] Pullman favored a bent form to the planar one because of its better agreement with the ESR data.[9] The barrier to the flattening the molecule is probably of about the same energy as that of a rather strong intermolecular interaction;[10] it is likely that the balance of these two forces is achieved at two different configurations, depending upon the mode of intermolecular interaction. By analogy with the electronic spectra of Würster cations,[11,12] we may assume that the cation radicals in the bromide sample showing the electronic spectrum A in Fig. 2 are in an interaction more extended than those in the sample showing the spectrum B.

In the phenothiazine bromide-iodine system the three different stages in the intermolecular interactions can be pointed out on the basis of the electrical and optical data. The first stage is represented by the adduct at mole ratios from 0.25 to 0.30. As the composition corresponds approximately to $(\text{phenothiazine})_2Br_2I$, and as the mixed halide ion, Br_2I^-, is a known species, we may suggest the formation of a complex cation radical salt, $(\text{phenothiazine})^+(\text{phenothiazine})^0Br_2I^-$, which is a cationic analogue of the TCNQ complex anion radical salts, well known for their low electrical resistivities.[13] The composition range from 0.50 to 0.75 may be considered to be the second stage, which is characterized by an electronic absorption having a maximum at 5.5 kK. This location is the same as that of the low-energy absorption appearing in the iodine complex; however, these adducts are less conductive than the complex. The shift of the low-energy absorption by the transition from the first to the second stage is parallel with an increase in the activation energy for semiconduction. It should be noted that the vibrational spectra of the iodine adducts in these two stages and also that of the iodine complex resemble the spectrum A of the semiquinoid bromide. In these adducts and the complex the intermolecular interaction is supposed to be more-than-by-pairs; otherwise, we would not observe such low electrical resistivities. These observations are in good accordance with the assumption made at the end of the last paragraph. The third stage appears in the composition range above 1.00. Not only the vibrational but also the electronic spectra are similar to the spectra B of the bromide. The high resistivities observed in this stage are consistent with such optical behavior.

The absence of a low-resistivity phase in the *p*-phenylenediamine bromide-iodine system indicates that the formation of a mixed halide complex such as the one found in the present work may be rather specific.

Variational Calculation of Atoms and Molecules by a Modified Hassé Method Using Hulthén Functions. I. Hydrogen and Helium Atoms

Tokio YAMABE, Shingo ISHIMARU and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received February 12, 1970)

A modification of the Hassé method is presented in an attempt to describe perturbed systems. This method resolves divergence difficulties which are often encountered when the simple Kirkwood-Hassé method or Unsöld approximation is used for the coulombic perturbation problems. The procedure is illustrated for the perturbed hydrogen atom; energy values which are close to the exact ones are thus obtained. The method is also applied to the case of the ground-state helium atom; a closed-form expression of the energy is thus derived. The optimized value is −2.8983 a. u. Some other discussions are given in connection with the perturbation theory.

In the perturbation problems of atoms and molecules, the Unsöld approximation[1] is often employed to calculate the second-order perturbation energy; it is known to be equivalent to the so-called average-energy method,[2] where the operator $(H_0 - E_0)$ in the first-order perturbation equation is replaced by an average energy, ε. The approximate first-order wave function, ϕ_1, then becomes:

$$\phi_1 = -\varepsilon^{-1}(H_1 - E_1)\phi_0, \tag{1a}$$

where ϕ_0 is the unperturbed eigenfunction and where H_1 and E_1 are the perturbation and the first-order perturbation energy respectively. This wave function is also employed for the first-order wave function in the variation-perturbation method (VP method). In this case, ε^{-1} is regarded as a scale parameter; Eq. (1a) is, then, usually rewritten in the following form:

$$\phi_1 = A(H_1 - E_1)\phi_0, \tag{1b}$$

where A is a constant. In the variation method, the simple Kirkwood-Hassé form[3] is often used for the perturbative part, χ, of a trial function, $\phi = \phi_0 + \chi$:

$$\chi = AH_1\phi_0, \tag{1c}$$

which is not generally orthogonal to ϕ_0. The orthogonalized form corresponds to Eq. (1b).

It has been pointed out by several authors[2,4], however, that these approximations often lead to physically unacceptable wave-functions and, accordingly, unreasonable results for the perturbation energies. For example, consider an atomic hydrogen perturbed by the removal of a small amount (ΔZ) of the nuclear charge. In this case, $H_1 = \Delta Z/r$, where r is the distance from the nucleus to the electron. In accordance with the approximation (Eq. (1a)), ϕ_1 is singular at $r=0$; hence, the second- or the third-order perturbation energy will be infinite. Such a result can be essentially attributed to the divergency of the integrals, $\langle\phi_0|r^{-3}|\phi_0\rangle$ and $\langle\phi_0|r^{-4}|\phi_0\rangle$, involved in the energy calculations. Many other examples were given by Kirtman and Benston.[2] They applied the average-energy method to some of these examples and showed that such difficulties could be successfully avoided by making the average-energy infinite only in the neighborhood of singularity and finite elsewhere (the eae method). This method is, however, difficult to use for multidimensional problems, in particular, molecular problems.

The purpose of the present paper is to show that difficulties of divergence can be removed, easily and elegantly, not by the variation of the average energy, but by a slight modification of H_1 in Eq. (1c). In this work, we will use the variation method for energy calculations; this approximation may correspond to an extension of the simple Kirkwood-Hassé form. It will be demonstrated in the first section of this paper that the energy obtained is, besides being an upper bound, in agreement with the results of the extension of the perturbation theory to the third order. The present method is illustrated by this example and then applied to the calculation of the ground-state energy of the helium atom.

The Variation Method

Assume that a system with a Hamiltonian operator, H_0, is given, and that the function, ϕ_0, describing its state and its energy, E_0, in the state are known; then:

$$H_0\phi_0 = E_0\phi_0. \tag{2}$$

When a perturbation is applied to H_0, changing it to H_0+H_1, the energy, E, of this perturbed system, H, is optimized by the variational principle:

$$\langle H\rangle = N^2\int \phi^* H\phi \mathrm{d}\tau \geqq E, \tag{3}$$

where ϕ is an arbitrary trial function and where;

$$N = \left[\int \phi^*\phi \mathrm{d}\tau\right]^{-1/2}.$$

In Hassé's method, one may take the following type of function:

$$\phi = \phi_0(1 + v), \tag{4}$$

where v is a function to be specified later. As a consequence, Eq. (3) can be rewritten[5] in atomic units:

$$\langle H\rangle = E_0 + N^2\left\{((1 + v)^2H_1)_{00} + \frac{1}{2}\sum_i((\partial v/\partial x_i)^2)_{00}\right\}, \tag{5}$$

where $(F)_{00}$ signifies $\langle\phi_0|F|\phi_0\rangle$; that is, the matrix elements calculated with the ϕ_0 function, and where the summation extends over all the Cartesian coordinates of the problem.

Now we need a concrete form of v to calculate the energy of the perturbed system. The simplest and useful form of v is the one proportional to H_1, namely, the simple Kirkwood-Hassé form, Eq. (1c):

$$v = AH_1. \tag{6}$$

As has been pointed out in the introduction,[2,4] however, when one uses this approximation one encounters serious defects in many cases, particularly in the important case of the coulombic-type perturbation problem which we will discuss in this paper. In other words, these defects can be ascribed to the fact that the integrals in Eq. (5) diverge because of the singularities at $r=0$ (except, of course, if ϕ_0 vanishes at the nuclei). To remove the difficulties, we replaced the coulomb potential in v by the following function, $\tilde{H}_1$:

$$v = A\tilde{H}_1 = A\{\Delta Z\sum_a\sum_i(1 - e^{-\kappa_i R_{ai}})R_{ai}^{-1} + \frac{1}{2}\sum_i\sum_{(i\neq j)}(1 - e^{-\lambda_{ij}r_{ij}})r_{ij}^{-1}\}, \tag{7}$$

where:

ΔZ	:	the decrease in the nuclear charge,
a	:	the number of a nucleus,
i, j	:	the number of an electron,
κ_i, λ_{ij}	:	variational parameters,
R_{ai}, r_{ij}	:	the distances between a nucleus, a, and an electron, i, and between the i and j electrons respectively.

The function $\tilde{H}_1$ is the one known as the Hulthén function.[6] When κ and λ are positive, this function behaves like the original coulomb potential at larger distances, but it is finite as r approaches zero. In this case, the main factor underlying the correctness of Eq. (7) is that the v function is finite at $r=0$, which causes even $\langle\phi|r^{-4}|\phi\rangle$ to become finite. This is the essential point of the present method for solving this divergence problem.

The perturbed wave function that we have presented may not be considerably different from the one using the Unsöld approximation or, more generally, the Dirichlet form in the VP method. In order to investigate the relation between our method and the VP method, we will write Eq. (5) with the present $v=A\tilde{H}_1$. The perturbed wave function, ϕ, is, then obtained from Eq. (4) as:

$$\phi = \phi_0(1 + A\tilde{H}_1). \tag{8}$$

Hence, from Eq. (5):

$$\langle H\rangle = E_0 + E_1 + \frac{2A\{(H_1\tilde{H}_1)_{00} - E_1(\tilde{H}_1)_{00}\} + A^2\left\{\frac{1}{2}\sum_i((\partial\tilde{H}_1/\partial x_i)^2)_{00} + (\tilde{H}_1H_1\tilde{H}_1)_{00} - E_1(\tilde{H}_1^2)_{00}\right\}}{1 + 2A(\tilde{H}_1)_{00} + A^2(\tilde{H}_1^2)_{00}} \geqq E, \tag{9}$$

where $E_1=(H_1)_{00}$. On the other hand, following the VP theory,

$$\tilde{E}_2 = \langle\tilde{\phi}_1|H_0 - E_0|\tilde{\phi}_1\rangle + 2\langle\tilde{\phi}_1|H_1 - E_1|\phi_0\rangle \geqq E_2, \tag{10}$$

where E_2 is the second-order perturbation energy and where $\tilde{\phi}_1$ is an arbitrary function; the equality in Eq. (10) holds only when the variation function, $\tilde{\phi}_1$, is the true first-order wave function. Regarding $A\tilde{H}_1\phi_0$ as $\tilde{\phi}_1$, the approximate second and third-order energies are, respectively:

$$\tilde{E}_2 = 2A\{(H_1\tilde{H}_1)_{00} - E_1(\tilde{H}_1)_{00}\} + \frac{1}{2}A^2\sum_i((\partial\tilde{H}_1/\partial x_i)^2)_{00} \geqq E_2, \tag{11}$$

5) H. Margenau, *Rev. Mod. Phys.*, **11**, 1 (1939).

6) L. Hulthén, *Arkiv Fys.*, **28A**, 5 (1942).

$$\tilde{E}_3 = -2A\tilde{E}_2(\tilde{H}_1)_{00} + A^2\{\tilde{H}_1H_1\tilde{H}_1)_{00} - E_1(\tilde{H}_1^2)_{00}\}. \tag{12}$$[7]

Then, one obtains from Eq. (9):

$$\langle H\rangle = E_0 + E_1 + \tilde{E}_2 + \tilde{E}_3 + E_R \geqq E, \tag{13}$$

where:

$$E_R = -\frac{\{2A(\tilde{H}_1)_{00} + A^2(\tilde{H}_1^2)_{00}\}\tilde{E}_3 + A^2(\tilde{H}_1^2)_{00}\tilde{E}_2}{1 + 2A(\tilde{H}_1)_{00} + A^2(\tilde{H}_1^2)_{00}} = O(H_1^4). \tag{14}$$

The above results show that the present method is in agreement with the perturbation theory to the third order. More general investigations have been presented by Sinanoğlu.[8]

Finally, it is necessary to consider the effect of the orthogonalization. Corresponding to Eq. (1b) the orthogonalized form is given by:

$$\tilde{\psi} = \psi_0 + \tilde{\chi} \quad \text{and} \quad \tilde{\chi} = A(\tilde{H}_1 - (\tilde{H}_1)_{00})\psi_0,$$

which leads to a slight correction of the energy, $\Delta E_{\text{corr.}}$:

$$\Delta E_{\text{corr.}} = \bar{E} - \tilde{E} = \frac{-2A(H_1)_{00}\{\bar{E} - E_0 - E_1 - A(E_0\tilde{H}_1)_{00} + (H_1\tilde{H}_1)_{00})\} - A^2(\tilde{H}_1)_{00}^2(\bar{E} + E_0 + E_1)}{N^{-2} - 2A(\tilde{H}_1)_{00} - A^2(\tilde{H}_1)_{00}^2}, \tag{15}$$

where:

$$\bar{E} = \frac{\langle\psi|H|\psi\rangle}{\langle\psi|\psi\rangle}, \quad \tilde{E} = \frac{\langle\tilde{\psi}|H|\tilde{\psi}\rangle}{\langle\tilde{\psi}|\tilde{\psi}\rangle}.$$

The dependency of $\Delta E_{\text{corr.}}$ upon the arguments, κ, λ, A, and Z, is not simple. This will be given numerically in the case of the helium atom.

Applications to Hydrogen and Helium Atoms

In the first place, we would like to choose the case of a hydrogen atom merely for the purpose of illustrating our method. Consider the hydrogen atom perturbed by the removal of the ΔZ charge from the nucleus. Then, in atomic units,

$$H_0 = -\frac{1}{2}\Delta - r^{-1}, \quad H_1 = \Delta Z r^{-1}$$

$$\psi_0 = \pi^{-1/2}e^{-r}, \quad v = A(1 - e^{-\kappa r})r^{-1}. \tag{16a}$$

Hence,

$$\psi = \psi_0\{1 + A(1 - e^{-\kappa r})r^{-1}\} \tag{16b}$$

results from Eq. (4),
where, for convenience, ΔZ has been absorbed in A.

Now we are ready to obtain $\langle H\rangle$ by substituting Eqs. (16a) and (16b) into Eq. (5). In this calculation, however, there appear several well-known integrals which diverge, namely, in general forms.

$$\int_0^\infty \frac{e^{-sr}}{r}dr = -\lim_{\varepsilon\to 0} Ei(-s\varepsilon) \tag{17}$$

and:

$$\int_0^\infty \frac{e^{-tr}}{r^2}dr = \lim_{\varepsilon\to 0}\left[\frac{1}{\varepsilon} - t + tEi(-t\varepsilon)\right]. \tag{18}$$

Fortunately, however, these integrals cancel each other out in $(\tilde{H}_1H_1\tilde{H}_1)_{00}$ and $\sum_i((\partial\tilde{H}_1/\partial x_i)^2)_{00}$ respectively when our modification is used. Thus, one gets the perturbed energy in the following closed form:

$$\Delta E = \frac{2A\Delta Z(1 - 2\alpha)^2 + A^2\{4(1 - \Delta Z)\log(4\alpha^2/\beta) + \kappa^2\beta(1 - 2\alpha\Delta Z)\}}{1 + 2A(1 - 4\alpha^2) + 2A^2\kappa^2\alpha\beta}, \tag{19}$$

where:

$$\Delta E = \langle H\rangle - E_0 - E_1,$$
$$\alpha = (2 + \kappa)^{-1}, \quad \beta = (1 + \kappa)^{-1}.$$

8) O. Sinanoğlu, *J. Chem. Phys.*, **34**, 1237 (1961).

Determining the optimum values of κ and A variationally, one obtains the minimum energy for a given ΔZ. The results listed in Table 1 are almost equal to the correct value ($\Delta E/(\Delta Z)^2=-0.5000$).

Table 1. The energy $\Delta E/(\Delta Z)^2$ for various perturbation ΔZ

ΔZ	κ	A	$\Delta E/(\Delta Z)^2$
0.0	0.000	∞	−0.5000
0.1	−0.146	25.20	−0.4999
0.2	−0.285	11.93	−0.4999
0.3	−0.415	7.39	−0.4999
0.4	−0.537	5.12	−0.4998
0.5	−0.650	3.74	−0.4997
0.6	−0.753	2.81	−0.4993
0.7	−0.843	2.13	−0.4987
0.8	−0.918	1.63	−0.4981
0.9	−0.977	1.26	−0.4982
1.0	−1.000	1.00	−0.5000

In the calculations, the value of A giving the minimum of the energy for a given κ is, of course, determined by a simple quadrature satisfying $\partial\Delta E/\partial A=0$. Figure 1 shows the relationships between the energy and κ. For large positive values of κ, where the present treatment approaches the average-energy method, the energy converges to zero, as has often been pointed out.[2] It should be noticed here that the κ giving the lowest energy is always negative in the present case. The negative κ value is not unexpected, considering that the function of Eq. (16b) is a kind of trial function. In this connection, it seems adequate to regard the present method, not as a modification of the simple Kirkwood-Hassé or Unsöld procedure, but as a method using the wave-function in which the effect of the mixing of the Os function is taken into account.[9] This can easily be understood by rewriting Eq. (16b) so that:

$$\psi = \pi^{-1/2}e^{-r} + A\pi^{-1/2}\{e^{-r} - e^{-(1+\kappa)r}\}r^{-1}. \quad (20)$$

The inclusion of the Os function into ψ seems not to be strange, considering the discussion presented by Robinson.[10] A parallelism is found between κ and ΔZ. This result is reasonable in view of Eq. (20).

Kirtman and Benston showed that, by their eae method, the difficulty of the divergency can also be avoided. They gave the exact first-order wave function for the same problem. Their way around this difficulty is to let the average energy be infinite in the neighborhood of the singularity, while the present method is to let H_1 in χ be finite; it also gives almost the exact energy, though the wave function is of a variational type.

Secondly, let us apply the present method to the ground state of the helium atom. Let the perturbed Hamiltonian, H, be split as H_0+H_1:

$$H_0 = -\frac{1}{2}(\Delta_1 + \Delta_2) - Z(r_1^{-1} + r_2^{-1})$$
$$H_1 = -\Delta Z(r_1^{-1} + r_2^{-1}) + r_{12}^{-1},$$
$$\psi_0 = \pi^{-1}Z^3e^{-Z(r_1+r_2)}, \quad (21a)$$

where: $Z + \Delta Z = 2$.

According to the present method, the perturbed wave function, ψ, is given from Eq. (4) by:

$$\psi = \psi_0(1 + A[-\Delta Z\{(1-e^{-\kappa r_1})r_1^{-1} + (1-e^{-\kappa r_2})r_2^{-1}\} + (1-e^{-\lambda r_{12}})r_{12}^{-1}]) \quad (21b)$$

for the four parameters κ, λ, A, and Z. From Eqs. (5), (21a), and (21b), one easily obtains the energy expression in a closed form (shown in the Appendix). Our result is given in Table 2, along with those calculated by other researchers. Sur-

9) R. McWeeny and C. A. Coulson, *Proc. Phys. Soc.* (London), *A*, **62**, 509 (1949); R. McWeeny *ibid.*, *A* **62**, 519 (1949); J. T. Zung and R. G. Parr, *J. Chem. Phys.*, **41**, 2888 (1964).

10) P. D. Robinson, *ibid.*, **45**, 1858 (1966).

prisingly, in view of the result obtained, Eq. (21b) is a very good approximation of the perturbed wave function in spite of its simple form. Orthogonalization leads no better result, *i.e.*, $\Delta E_{\text{corr.}} = -0.0006$ in the present case.

Kirtman and Benston also obtained an approximate first-order wavefunction by their eae method and computed the energies to the third order numerically. They indeed avoided the difficulties of divergency, but one will scarcely be able to find a physical meaning in the form of their wave-function. Moreover, the energy obtained is not satisfactory, namely, $E_2^{\text{eae}} = -0.135$ a.u. ($\geqq E_2$) and $E_3^{\text{eae}} = 0.01194$ a.u.*1

Recently, Weare *et al.*[11] showed that, in correlated trial wave-functions of the $\psi = \phi(r_1)\phi(r_2)(1+v(r_{12}))$ form for helium-like atoms, the Os function, when used for ϕ and/or v, gave excellent results. As one of several expected Os trial wavefunctions, they proposed $\psi = 1s_\zeta(r_1)1s_\zeta(r_2)[1+A\,Os_{\gamma\delta}(r_{12})]$, which partly resembles the present function (Eq. (21b)) in its apparent form. It should be stressed, however, that our treatment has quite a different basis than theirs, which is due to the correlated Hartree-Fock orbital approximation. In fact, our method is easily connected to the perturbation method, as has already been discussed. From Eqs. (11) and (12), we can estimate the respective energy terms from E_0 to E_R for the best variational result. As is shown in Table 3, these terms descend monotonously, disclosing the relation of the present method to the perturbational treatment. Additionally, it is worth emphasizing that the present method gives a closed form for the energy expression, whereas Weare *et al.* were unable to obtain such an expression.[11] The extension to isoelectronic atoms is trivial; further applications of this method, in particular, to the important problems of the long-range force between atoms will be presented elsewhere.

TABLE 3. THE VALUES OF RESPECTIVE ENERGY TERMS

Appendix

The integrals used in calculating the energy for the helium atom from Eq. (5) are as follows;

$$(H_1)_{00} = Z\left(\frac{5}{8} - 2\Delta Z\right),$$

$$(\tilde{H}_1)_{00} = Z\left[\left(\frac{5}{8} - 2\Delta Z\right) + 8\Delta Z b^2 + \frac{1}{2}df - 4df^4(\lambda+6)\right],$$

$$(\tilde{H}_1^2)_{00} = Z^2\left[\frac{2}{3} - 8\left\{\frac{1}{16}d - \frac{1}{4}df + \frac{3}{16}f + \frac{1}{4}f^2 + \frac{1}{3}f^3\right\} + \frac{1}{2}e\left\{\frac{1}{2} + \frac{1}{2}e + \frac{1}{3}e^2\right\} - 4\Delta Z\left\{\frac{3}{4} - 4b^2(1-4c^2) + df(1-16c^2) + 16d^2f^2(1-4c-4f+4g)\right\} + 2(\Delta Z)^2\{3+2a-8b-8b^2+16b^4\}\right],$$

$$(H_1\tilde{H}_1)_{00} = Z^2\left[\frac{2}{3} - 4\left\{\frac{1}{16}d - \frac{1}{4}df + \frac{3}{16}f + \frac{1}{4}f^2 + \frac{1}{3}f^3\right\} - 4\Delta Z\left\{\frac{3}{4} - 2b^2(1-4c^2) + df(1-16f^2)\right\} + 2(\Delta Z)^2\{1+2\kappa b-4b^2\}\right],$$

Structure and Intramolecular Motions in Bicyclo[2.2.2]octane as Studied by Gas Electron Diffraction

Akimichi YOKOZEKI, Kozo KUCHITSU and Yonezo MORINO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received February 12, 1970)

A least-squares analysis of the electron-diffraction intensities for bicyclo[2.2.2]octane in gas phase measured at 28°C has given the following structural parameters: r_g(C–C) (average) = 1.542 ±0.004Å, r_g(C–H) (average) = 1.107±0.009Å, $r_g(C_1–C_2) = 1.53_8 \pm 0.01_5$Å, $r_g(C_2–C_3) = 1.55_2 \pm 0.02_9$Å, $\angle C_1–C_2–C_3 = 109.7° \pm 0.7°$, and $\angle$H–C–H = $110._1° \pm 5._6°$, where the uncertainties represent estimated limits of error. The potential function for the twisting motion around the D_{3h} symmetry axis is found to have a broad minimum; in terms of the dihedral angle of torsion about the C_2–C_3 axis, ϕ, the potential has an rms angle of 12.0°±1.5° and a "classical turning point" of 21.5°±0.5° (7.2° and 12.8°, respectively, in terms of the dihedral angle of twist, τ). Best fit to the observed intensities has been achieved when a quartic function, $V(\phi) = k_2\phi^2 + k_4\phi^4$ with $k_2 = -4.0$ kcal/mol and $k_4 = 54.2$ kcal/mol, is assumed. The potential function probably has a hump of the order of 100 cal/mol at the D_{3h} conformation. Hence, this molecule may be regarded as having a "quasi-D_{3h} structure". The above features are consistent with those for the derivatives of this molecule in crystal phase studied by Dunitz and Ermer by X-ray diffraction, and also with semiempirical estimates based on the calculations of the intramolecular strain energy.

Bicylco[2.2.2]octane (BO) has three cyclohexane rings fused together at the carbon atoms 1 and 4 (Fig. 1). In the structure with the highest symmetry, D_{3h}, the rings are locked in a boat form, one of the unstable conformations of cyclohexane.[1] As the rings are twisted about the three-fold axis, the symmetry is lowered to D_3.

There have been controversial reports in the literature as to the symmetry of this molecule. Turner *et al.*[2] concluded from the relatively large heats of hydrogenation of bicyclo[2.2.2]octane and octadiene that BO should have a D_3 symmetry. They thought that such a twisted structure should relieve some of the torsional strain in the system, since for D_{3h} the atoms are in eclipsed positions about the C_2–C_3 axes. This structure was supported by Hendrickson,[3] who calculated the strain energy and found that it favored a structure twisted slightly around the C_3 axis. On the other hand, Gleicher and Schleyer[4] preferred a D_{3h} structure based on results from a similar calculation.

The infrared and Raman spectra of BO by MacFarlane and Ross[5] were consistent with those predicted on the assumption that the molecular symmetry was D_{3h}; the twsiting, if present, was thought to be slight. The microwave studies of 1-chloro and 1-bromo derivatives by Nethercot and Javan[6] also estimated the twist angle*1 to be essentially

*1 See Analysis section for the definition of the "twist" angle and the "torsional" angle.

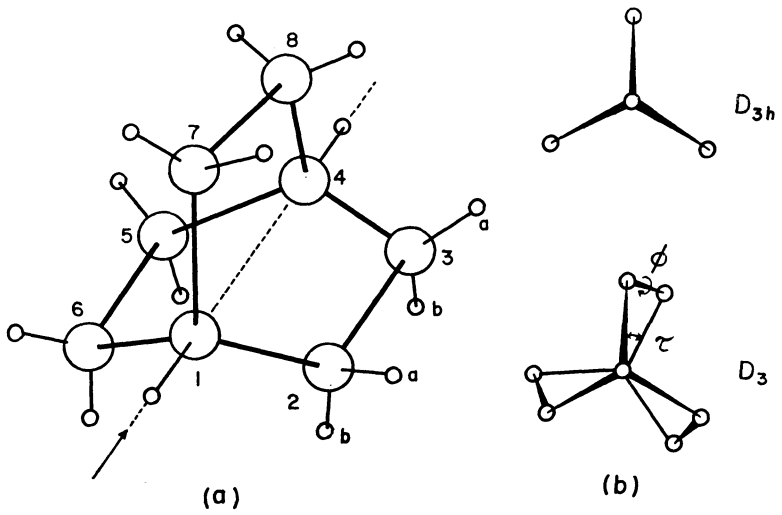

Fig. 1. a) Bicyclo[2.2.2]octane. b) Carbon skeletons as viewed from the C_1–C_4 axis.

zero (0°±4°). As for the crystal structures of BO derivatives, Cameron *et al.*[7] estimated the twist angle to be about 3°, whereas Ermer and Dunitz[8] found no significant deviation from D_{3h} symmetry in the carbon skeleton; an rms amplitude of the half-twist angle (upper limit) of 5.9°±0.2° was derived from the analysis of their anisotropic thermal ellipsoids.

From all the above studies no conclusive structure of the free BO molecule is yet known. The potential function for the twist motion may have a broad minimum near the D_{3h} conformation, where a hump may or may not exist. In this connection, a recent semiempirical calculation of Ermer and Dunitz[8,9] predicted the potential to have a small hump of only about 100 cal/mol with an rms torsional angle*1 of 13.8°. Under these circumstances, the structure of unsubstituted BO has been investigated by means of gas-phase electron diffraction with the aim of obtaining information on the twisting potential function.

Experimental

Purified sample of BO was kindly provided by Dr. Hiroshi Tanida of Shionogi Research Laboratory. Diffraction photographs were taken at 28°C on Fuji Process Hard Plates with an apparatus equipped with an r^3-sector.[10] The accelerating voltage (about 40 kV) was stabilized within 0.01% during exposure, 17—20 min for a camera length of 107.79 mm and about 7 min for 243.24 mm. The beam current was 0.31 μA, and the vacuum was kept under 5×10^{-5} Torr while the sample gas was introduced into the chamber through a nozzle of 0.2 mm diameter. The wavelength of the electron beam was calibrated to within 0.07% with reference to the r_a(C–O) bond length of carbon dioxide,[10] 1.1646 Å.

The photographs were developed at 20°C for 5 min with FD-131 developer diluted twice. Four plates for each camera length were used for density measurements. The optical densities (0.19 to 0.41) were recorded digitally at intervals of integral q values[11] (from 20 to 140 and from 8 to 65 for the short and long camera lengths, respectively); they were assumed to be proportional to the electron intensities.[12]

The intensity curve obtained above was corrected for sector imperfection and divided by a theoretical background function, which took account of elastic and inelastic atomic scattering.[13] In addition, extraneous scattering observed at large q values (15% at q=80 and 45% at 120) was subtracted so as to make the background nearly flat for all the scattering angles. This procedure seemed justified because an intensity measurement of carbon dioxide, after a similar background correction, gave experimental mean amplitudes in good agreement with their theoretical values. This procedure, however, had a significant influence on the measurement of the C_1–C_2 and C_2–C_3 bond distances, since they are so closely spaced that their mean amplitudes correlate strongly with the bond distances (see next section).*2

As illustrated in Fig. 2, the observed molecular in-

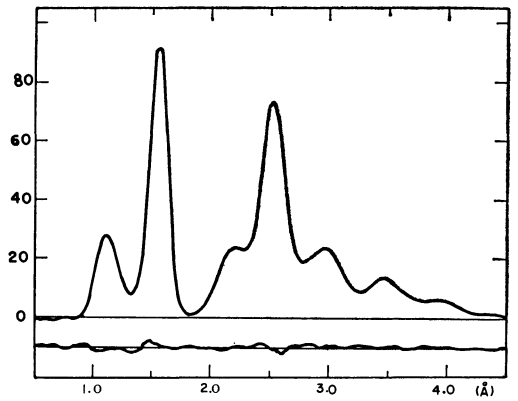

Fig. 3. Experimental radial distribution curve for bicyclo[2.2.2]octane. Lower curve: theoretical minus experimental.

tensity is in reasonable agreement with the best-fit theoretical intensity obtained from the least-squares analysis[14] described below. The corresponding radial distribution curve, calculated with an artificial damping function of the form $\exp(-0.0016s^2)$ and with a correction for nonnuclear scattering,[15] is shown in Fig. 3. Most of the computations were carried out by a HITAC-5020E computer in the Computer Centre of the University of Tokyo.

Analysis

Definition of Dihedral Angles. As shown in Fig. 1, the dihedral angle between the C_1–C_2–C_4 and C_1–C_3–C_4 planes is called the "twist angle" τ about the C_3 axis, while the dihedral angle between the C_1–C_2–C_3 and C_2–C_3–C_4 planes is called the "torsional angle" ϕ about the C_2–C_3 bond. They are related by

$$\tan(\tau/2) = r_2[(r_2-2r_1\cos\alpha)^2 + 4r_1^2\sin^2\alpha\sin^2(\phi/2)]^{-1/2}\tan(\phi/2) \quad (1)$$

where the C_1–C_2 (r_1) and C_2–C_3 (r_2) distances and the C_1–C_2–C_3 angle (α) are assumed to be constant. For small ϕ, τ is equal to 0.605ϕ. In the following analysis the ϕ angle is taken instead of τ as a parameter representing the twist motion.

Choice of Independent Parameters. The number of independent parameters sufficient to describe the D_{3h} structure is seven, while for the D_3 structure, in general four additional parameters are required. In order to facilitate the analysis, the following assumptions were made:

a) The C_1–H and C_2–H bond lengths are equal. Since a weighted average, $[r_g(C_1\text{–H})\times 2/14+r_g(C_2\text{–H})\times 12/14]$, is obtained from the analysis for r_g(C–H), it is likely that r_g(C–H) represents the C_2–H bond length.

b) The angles C_1–C_2–C_3, C_2–C_3–H and H–C_2–H do not depend on the torsional angle.

c) The plane H–C_2–H is perpendicular to the C_1–C_2–C_3 plane and bisects the C_1–C_2–C_3 angle (α), and *vice versa*.

Thus for D_3 symmetry the following six independent parameters were taken: the C_1–C_2 and C_2–C_3

distances, the angles α, the equilibrium torsional angle ϕ_e, the weighted mean C–H distance, and the H–C_2–H angle.

Calculation of Mean Amplitudes. The mean amplitudes and the vibrational corrections on internuclear distances, r_a–r_α, were calculated by the method discussed in a previous paper[16] with a set of the Urey-Bradley force constants for a D_{3h} structure. The force constants, given in Table 1, were transferred mainly from those for cyclohexane.[17] The vibrational frequencies obtained from this calculation are compared in Table 2 with the observed values of Brüesch and Günthard.[18] The agreement is fair, although their assignments are still far from complete.

Table 1. Urey-Bradley force constants for bicyclo[2.2.2]octane[a] (in md/Å)

K(C-C)	2.30	F(C-C)	0.20
K(C-H)	4.10	F(C-H)	0.41
H(C-C-C)	0.32	F(H-H)	0.18
H(C-C-H)	0.225	Y[b]	0.11
H(H-C-H)	0.40		

a) Estimated from the force constants for cyclohexane.[17]
b) Defined in Eq. (3); in md·Å units.

As for the twisting mode, the symmetry coordinate is given by the equation

$$S_4(A_1'') = \frac{1}{\sqrt{3}}(\phi_{23}+\phi_{56}+\phi_{78}) \quad (2)$$

where ϕ_{ij}, the torsional coordinate about the C_i–C_j axis defined by Miyazawa and Fukushima,[19] is practically synonymous with the ϕ coordinate defined here according to the assumption (b) made above. The force constant Y for this torsional motion is defined by*3

$$V(\text{torsion}) = \frac{1}{2}Y(\phi_{23}^2+\phi_{56}^2+\phi_{78}^2) \quad (3)$$

Since the corresponding normal mode has the lowest frequency, Y has a strong influence on some of the calculated mean amplitudes. Accordingly, the mean amplitudes were calculated by the use of several different Y values. While analogous force constants for torsion about the *gauche* conformation (Y_{gauche}) have been reported for normal hydrocarbons[20] and cycloalkanes,[17] no comparable Y_{cis} constant for the *cis* conformation (possibly negative) is known. A semiempirical estimate of the potential function in terms of intramolecular strain energy (see Discussion) shows that the Y constant for this molecule (Eq. (3)) originates essentially from the positive Y_{gauche} about the C_1–C_2, C_3–C_4, ··· axes balanced by the negative Y_{cis} about the C_2–C_3, C_5–C_6, and C_7–C_8 axes. Thus the Y constant should be appreciably smaller than the Y_{gauche} given in the literature, ~0.11 md·Å, and may even be negative. For the present purpose,

a) Calculated with the use of the force constants listed in Table 1; in cm^{-1} units.
b) Observed values[18b] in the solid or CS_2 and CCl_4 solutions.
c) The value calculated in Ref. 18a, 65 cm^{-1}, seems to be in error because of the confusion of the torsional force constant Y defined in Eq. (3) (corresponding to $3H_\tau$) with H_τ defined in Ref. 20a. See text.

16) K. Kuchitsu and S. Konaka, *J. Chem. Phys.*, **45**, 4342 (1966).
17) H. Takahashi and T. Shimanouchi, *J. Mol. Spectry.*, **13**, 43 (1964).
18) a) P. Brüesch, *Spectrochim. Acta*, **22**, 867 (1966). b) P. Brüesch and Hs. H. Günthard, *ibid.*, **22**, 877 (1966).
19) T. Miyazawa and K. Fukushima, *J. Mol. Spectry.*, **15**, 308 (1965).

*3 On the assumption (b), the force constant Y corresponds to three times the constant H_τ defined by Schachtschneider and Snyder[20] provided their definition of the torsional coordinate in regard to the *trans* conformation is translated into that in the *cis* conformation.

20) J. H. Schachtschneider and R. G. Snyder, *Spectrochim. Acta*, a) **19**, 117 (1963); b) **21**, 169 (1965).

it is sufficient to assume Y to be positive and quadratic with the above upper limit. For the Y values of 0.11, 0.08, 0.05, and 0.025 md·Å, the corresponding frequencies of the twisting motion are 134, 116, 92, and 66 cm^{-1}, respectively, whereas all the other frequencies are insensitive to Y. This indicates that this normal mode is almost completely separable from other modes. In fact, the S_4 coordinate contributes more than 95% of the potential energy distribution[21] to the lowest A_1'' mode. Calculated mean amplitudes (listed in Table 3) and vibrational corrections were used in the subsequent least-squares analyses as fixed constants so as to facilitate convergence.

Least-squares Analysis of Molecular Intensity. The experimental molecular intensity was analyzed by a standard least-squares method[14] with the sets of mean amplitudes II through V based on the above choice of the Y constant. The analysis based on Set II converged to a D_3 structure with the ϕ_e angle of 12.2°±0.7°, where the uncertainty represents standard error. For the other sets of Y, all the parameters were essentially unchanged except for ϕ_e, which decreased with the decrease in Y. For Set V, where Y=0.025, ϕ_e was essentially zero, apparently giving a D_{3h} structure. Accordingly, the shape of the potential function as derived from the above analysis depends significantly on the assumption about Y. Nevertheless, it is clear from the analysis that this molecule has a floppy structure in thermal equilibrium as regards the twisting motion. The potential function for this motion is studied in more detail in later sections.

Estimation of Uncertainties. The structural

a) Error matrix for fixed mean amplitudes. Units for the distances are Å, those for the angles are rad., and the index of resolution k is dimensionless. Elements of the matrix are given by $\sigma_{ij}=\mathrm{sgn}[(B^{-1})_{ij}][|(B^{-1})_{ij}|V^*PV/(n-m)]^{1/2}$, where the notations follow Ref. 14. The diagonal element σ_{ii} represents the random standard error for the parameter i.

parameters determined are listed in Table 4. The limits of error were estimated as 2.5 times the random standard errors derived from the least-squares analysis,[14] which are included in the error matrix[22] given in Table 5 as diagonal elements, plus systematic errors. Principal sources of systematic errors are as follows: a) uncertainty in the scale factor, b) sector imperfections, c) extraneous scattering, and d) the use of theoretical mean amplitudes in the analysis. The errors due to sources a) and b) are estimated to be 0.07% and 0.05% of the corresponding distances, respectively.[23] The uncertainties due to c) and d) for all the distance and angle parameters, except for the bonded C–C distances, are at most of the order of their random standard errors, since the systematic error in the estimation of extraneous scattering causes uncertainties in the mean amplitudes and the index of resolution,[14] and since all the parameters (except for the C_1–C_2 and C_2–C_3 distances) are practically uncorrelated with the mean amplitudes and the index of resolution, as confirmed by a test analysis with systematic variations of the mean amplitudes used in the analysis.

As for the C_1–C_2 and C_2–C_3 distances, their difference derived from the analysis is contingent on their estimated amplitudes. Therefore, a systematic error due to the uncertainties in the C–C bond-stretching force constants used for calculating the mean amplitudes were taken into account as well as the uncertainty in the estimation of extraneous scattering. The total systematic errors in the C–C amplitudes are thus estimated to be 0.002 Å for C_1–C_2 and 0.005 Å for C_2–C_3, resulting in the final estimates of the uncertainties in their distances given in Table 4. Thus the C_1–C_2 and C_2–C_3 distances are hardly distinguishable in the present analysis, although the most probable value of the latter distance appears to be appreciably longer than the former.*4,24,25 The weighted mean value of the r_g(C–C) distances, on the other hand, has been determined with much higher precision.

Large-amplitude Analysis. In order to further investigate the potential function $V(\phi)$ for the twisting motion as represented in terms of ϕ, the following "large-amplitude" analysis was undertaken. Since the S_4 coordinate is separable from other coordinates to a good approximation, the twisting motion can be described in terms of a single coordinate ϕ. The molecular intensity for such a nonrigid molecule may be given by a classical weighted average of the intensity in regard to the torsional angle,[26]

$$qM(q) = k\sum_{i\neq j} A_{ij}\mu_{ij}(q)\exp\left[-\frac{1}{2}(\pi l_{ij}q/10)^2\right] \int_{-\pi}^{\pi} w(\phi)\left\{\sin\left[\frac{\pi}{10}qr_{ij}(\phi)\right]\Big/r_{ij}(\phi)\right\}\mathrm{d}\phi \quad (4)$$

where k is the index of resolution, A_{ij} is a constant proportional to the atomic numbers of i and j, μ_{ij} is a known function[15] of q related to the elastic and inelastic scattering factors for i and j, and l_{ij} is the mean amplitude of the i-j pair due to the framework vibrations (*i.e.*, those apart from the twisting motion); the calculated mean amplitudes listed in Table 3 [Set I for $Y=\infty$], which were assumed to be independent of ϕ, were used for l_{ij}. The weight function w is given by Boltzmann statistics as

$$w(\phi) = \exp[-V(\phi)/\boldsymbol{k}T]\Big/\int_{-\pi}^{\pi}\exp[-V(\phi)/\boldsymbol{k}T]\mathrm{d}\phi \quad (5)$$

It is sometimes more convenient to work on the corresponding radial distribution function,[27]

$$f(r) = k\sum_{i\neq j}\frac{1}{2}A_{ij}(\pi H_{ij})^{1/2} \int_{-\pi}^{\pi}\left(w(\phi)\exp\{-H_{ij}[r-r_{ij}(\phi)]^2\}/r_{ij}(\phi)\right)\mathrm{d}\phi \quad (6)$$

where H_{ij} is defined in terms of the artificial damping coefficient b by

$$H_{ij} = (4b+2l_{ij}^2)^{-1} \quad (7)$$

In order to estimate the potential function from the present experimental data, the various functions for V, *viz.*,

(a) Square well: $V(\phi)=0$ for $\phi<\beta$ and ∞ for $\phi\geq\beta$
(b) Double parabola: $V(\phi)=a(|\phi|-b)^2$
(c) Quadratic: $V(\phi)=c\phi^2$
(d) Quadratic-quartic: $V(\phi)=k_2\phi^2+k_4\phi^4$

were applied to Eqs. (5) and (6).

A best-fit set of parameters for each potential function was searched for by a trial-and-error comparison of the observed and theoretical $qM(q)$ and $f(r)$ curves. The ranges of the experimental data most sensitive to $V(\phi)$ are q=45—60 Å^{-1} for the molecular intensity, and r=2.7—3.5 Å for the radial distribution curve. Typical examples are shown in Fig. 4.

For case (a), the limit angle β is found to be 22°± 4°. The coefficients a and b for case (b) are about 17 kcal/mol and 11°, respectively, corresponding to a potential cusp $V(0)$ of about 500 cal/mol, while for case (c) the constant c is 4.3 kcal/mol. For case (d) the set of parameters thus obtained was further refined by a least-squares analysis.

*4 Our recent electron-diffraction study of triethylenediamine (1,4-diazabicyclo[2.2.2]octane)[24] has shown that the r_g(C_2–C_3) distance is about 0.02 Å longer than that of the C–C distance in cyclohexane.[25]

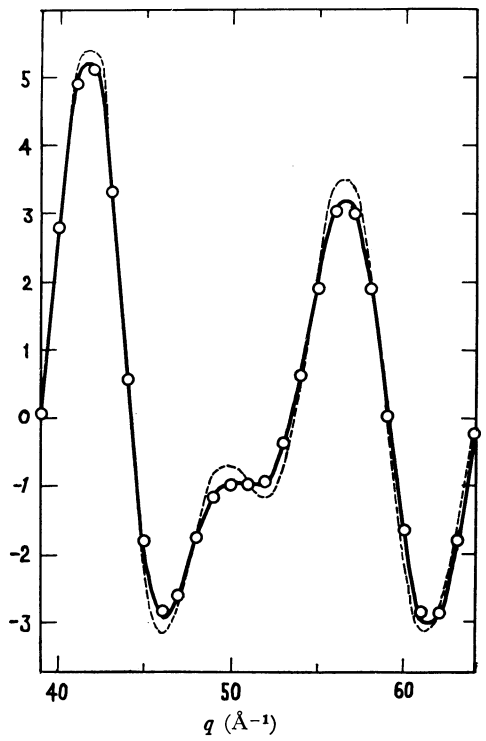

Fig. 4. (a)

The most probable set is $k_2=-4.0\pm3.3$ and $k_4=54.2\pm34.5$ (kcal/mol).

With the above adjustment of parameters, the experimental curves agree with the theoretical curves based on any one of the functions of (a) through (d) to a similar degree of consistency. As shown in Fig. 5, all the best-fit functions given above yielded a nearly equal rms angle, $\langle\phi^2\rangle^{1/2}$, of about 12° and a nearly equal "classical turning point" (the angle where the potential energy is comparable with the thermal energy at room temperature), $\phi_t\sim21°$. Since the intensity curve is sensitive to $\langle\phi^2\rangle^{1/2}$ and ϕ_t, they are the parameters readily determinable from the diffraction experiment irrespective of the type of the potential function assumed in the analysis.

On a physical basis, the function of (d) seems to be more realistic than the other functions. The most probable set of the k_2 and k_4 parameters has a potential hump of 75 ± 100 cal/mol at the D_{3h} position and a broad double minimum at about 11°; the standard error given above has been estimated by taking into account the correlation between the k_2 and k_4 parameters.[28]

Discussion

Structure. The weighted mean value of the r_g(C–C) distances, $[(2/3)r_g(C_1–C_2)+(1/3)r_g(C_2–C_3)]$

Circles, experimental values representing their estimated uncertainties; solid curve, case (d) (quartic) potential function with the parameters given in the text; broken curve, case (c) (quadratic) potential function with $c=17$ kcal/mol corresponding to the force constant for torsion, $Y=0.08$ md·Å.

28) Y. Morino and T. Nakagawa, *J. Mol. Spectry.*, **26**, 496 (1968).

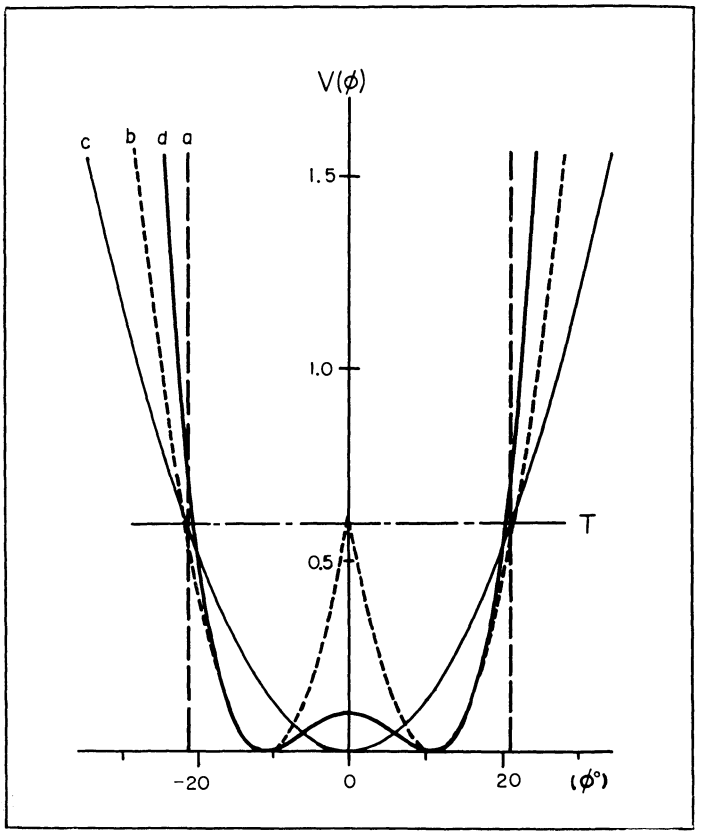

Fig. 5. Best-fit estimates of the potential functions for torsion (in kcal/mol), a—d, corresponding to the cases (a)—(d) discussed in the text. Line T denotes the thermal energy at room temperature, where the experiment was made.

$=1.542\pm0.004$ Å, is not significantly different from the r_g(C–C) distance in cyclohexane,[25] $1.540_4\pm0.001_0$ Å, indicating little overall influence of intramolecular strain on the C–C bond distances. The thermal-average C–C–C bond angle is similar to the tetrahedral angle. This structure appears to be consistent with the corresponding structures in crystalline BO derivatives determined by X-ray diffraction[8] (Table 4), although one should note that the latter parameters are based on a different definition and may also be subject to a crystal-field effect. The parameters for a free molecule estimated by a strain-minimization calculation[4] are also compatible with the present experimental values. The hydrogen parameters for the methylene group are analogous to those in cyclohexane[25] within their experimental uncertainties.

Twisting Motion. The present analysis has shown that the twisting motion has a large amplitude; the potential has a classical turning point of 21.5°±0.5° for the C–C torsional angle and an rms angle of 12.0°±1.5°, which correspond to 12.8°±0.3° and 7.2°±0.9°, respectively, in terms of the twist angle τ. The potential probably has a hump at the D_{3h} position much lower in height than the thermal energy at room temperature. Hence, the BO molecule may be said to have a "quasi-D_{3h} structure".

Semiempirical Calculation of the Potential Function It seems of interest in this connection to investigate whether the potential function derived above can be accounted for by a semiempirical model.[29] The strain energy of this molecule may be given as a function of the torsional angle by

$$E(\phi)=\frac{1}{2}H\sum_i[\alpha_i(\phi)-\alpha_0]^2+\frac{1}{2}f\sum_j(1+\cos 3\phi_j)+\sum V_{nb}(\phi) \quad (8)$$

where the bending and torsional force constants, H and f respectively, are estimated to be 98.5 kcal/mol (a bending force constant of the Urey-Bradley type for alkanes[20b,29]) and 2.93 kcal/mol (the torsional barrier for ethane[30]). The reference

for the CCC bond angle, α_0, is taken as the tetrahedral angle. In addition to the three assumptions made in the analysis section, the bond distances are assumed to be constant. The nonbonded interactions assumed for C–C, C–H, and H–H pairs (in kcal/mol) are

$$\left.\begin{aligned} V_{nb}(C\cdot\cdot C) &= 1.66\times 10^4 \exp(-3.63r) - 325/r^6 \\ V_{nb}(C\cdot\cdot H) &= 1.29\times 10^4 \exp(-4.12r) - 125/r^6 \\ V_{nb}(H\cdot\cdot H) &= 1.00\times 10^4 \exp(-4.60r) - 49.2/r^6 \end{aligned}\right\} \quad (9)$$

as taken from Hendrickson's paper.[31]

The resulting function $E(\phi)$ has a broad minimum around $\phi=10°$, as illustrated in Fig. 6, with a small hump of about 50 cal/mol at $\phi=0°$. The turning point ϕ_t is estimated to be about 23°, in good agreement with the experimental result given above. The general feature of the curve for $\phi \gtrsim 15°$ rests on the contributions from the first and third terms in Eq. 8; as the molecule is twisted from the D_{3h} conformation, the distortion of the bridgehead-carbon valence angles and the increasing interactions among the nonbonded C–C pairs contribute nearly equally to the steep rise in the potential, outweighing a slight decrease in the interactions among the nonbonded C–H and H–H pairs. For smaller torsional angles ($\phi<10°$), on the other hand, the sum of the first and third terms makes a nearly flat curve, and the potential shape is sensitive to the second term in Eq. 8. This term causes a small hump at the D_{3h} conformation, and the height and the minimum position depend on a competitive sum of six *gauche* terms (about the C_1–C_2 axis, *etc.*), which favor the D_{3h} conformation, and three *cis* terms (about the C_2–C_3 axis, *etc.*), which work in the opposite direction.

A recent calculation of this potential by Ermer and Dunitz[8,9] using a range of semiempirical functions has reached essentially the same conclusion, with a predicted minimum of about 100 cal/mol and an rms torsional angle of 13.8°.

Estimation of Energy levels. The energy levels for this twisting motion were calculated from

31) J. B. Hendrickson, *J. Amer. Chem. Soc.*, **83**, 4537 (1961).

the Hamiltonian,[32,33]

$$H = P_\phi^2/2M(\phi) + V(\phi) \quad (10)$$

where $V(\phi)$ is the quartic function estimated above, and P_ϕ is the angular momentum conjugate to ϕ. The reduced mass $M(\phi)$ was estimated with a semirigid framework,[32],*5 where, besides the assumptions (a)—(c) made in the analysis section, all the bond distances were assumed to be constant in the twisting motion. The resulting $M(\phi)$ depends only slightly on ϕ:

$$M(\phi) = 29.08 - 5.29\phi^2 + 6.54\phi^4 \text{ (amu)}$$

for ϕ (in rad.) $\lesssim 40°$. Thus the reduced mass was assumed to be constant (28.9 amu); the error due to the use of this effective mass is less than 1% of the energy levels estimated. A computer program written by Ueda and Shimanouchi[32] was used for calculating the levels listed in Table 6. Since the energy values, particularly those of lower levels, depend critically on the detailed shape of the potential, the listed values are only semiquantitative. Nevertheless, the presence of several levels under the thermal energy at room temperature is clearly demonstrated. Comparable energy values were obtained from the model potential function (8). Ermer and Dunitz[8,9] have estimated the energy differences between higher levels to be about 60 cm^{-1} by the use of their semiempirical potential functions. Though the fundamental transitions are infrared inactive, a direct measurement of the levels by some spectroscopic means, such as an analysis of combined transitions appearing in near-infrared band progressions,[34] could supply further information on this potential function.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2027—2029 (1970)

A Kinetic Investigation of Oxidation of Ethyl Methyl Ketone by Manganese(III) Sulphate

K. K. BANERJI, P. NATH and G. V. BAKORE*1

Department of Chemistry, University of Jodhpur, Jodhpur, India

(Received September 10, 1969)

The oxidation of ethyl methyl ketone with manganese(III) sulphate has been studied. The main product of oxidation is acetaldehyde. The reaction is first order with respect to each manganese(III) and the ketone. The rate of oxidation is independent of acidity and is not affected by changes in solvent composition. Addition of manganese(II) also does not affect the rate. The energy of activation, the entropy of activation and free energy of activation at 35°C have values 20.5 kcal/mol, −3.50 e.u. and 21.6 kcal/mol respectively. The rate of enolisation, measured by bromination method, is less than that of oxidation under similar conditions. A mechanism involving an attack directly on the ketone by manganese(III) sulphate-complex has been suggested.

Ketones were shown to be oxidised by manganic pyrophosphate *via* their enolic form.[1] Littler,[2] however, observed that manganese(III) sulphate oxidizes cyclohexanone at a rate faster than its enolisation and suggested that oxidation of ketones does not necessarily proceed through enolisation. Oxidation of aliphatic ketones by manganese(III) has not received adequate attention and, therefore, this investigation was taken up.

Experimental

Materials. B.D.H. ethyl methyl ketone was used after fractionation. Acetic acid (B.D.H., 99.5%) was distilled over chromic acid before use. All other chemicals used were chemically pure.

Manganese(III). Sulphate was prepared by the method described by Vogel.[3] Manganese(III) solutions were standardized iodometrically.

Kinetic Measurements. Unless otherwise stated the solvent used was 20% acetic acid - 80% water (*v*/*v*). Sufficient excess of manganese(II) was added to prevent disproportionation and subsequent hydrolysis of manganese(III).

Throughout the investigation the concentration of the ketone was kept in sufficiently large excess to ensure that the rate of reduction of manganese(III) is proportional to the oxidation of the ketone itself and not to the rate of destruction of any reactive intermediate.

Reaction mixtures were prepared by mixing all reagents except the ketone, in requisite quantities and were brought to the thermostatic temperature (±0.03°C). Reaction was started by adding the ketone rapidly.

Reactions were followed by quenching aliquots, withdrawn at fixed intervals of time, in slight excess of ferrous ammonium sulphate and estimating the residual iron(II) by titrating it against standardized cerium(IV) solution using ferroin as an indicator. From this the amounts of manganese(III) left in the reaction mixture at different time intervals were calculated.

Rates of Enolisation. Enolisation rates were measured by bromination method.

The rates of bromination was followed by adding bromine to a thermostated solution of the ketone in acetic acid containing sulphuric acid. Aliquots were withdrawn at fixed intervals of time, acidity adjusted by sodium bicarbonate and bromine left unreacted was determined iodometrically.

Results

Product Analysis. Completely reduced reaction mixtures gave a blue colour with solution of morpholine and sodium nitroprusside[4] indicating that acetaldehyde is the main product of oxidation.

Rate Laws. When ketone is in excess the rate of disappearance of manganese(III) follows first order rate laws. The rate constant is independent of the initial concentration of the oxidant (Table 1). Thus the order with respect to manganese(III) is one. The order with respect to the ketone is also one (Table 2).

Under the conditions of constant ionic strength the rate of oxidation is practically independent of hydrogen ion concentration (Table 3).

Effect of Manganese(II). Addition of manganous sulphate does not affect the rate of oxidation

of ethyl methyl ketone by manganese(III). Similar results were observed in the oxidation of cyclohexanone with manganese(III) sulphate.[5]

Similarly, change in the solvent composition caused by varying the proportion of glacial acetic acid in the solvent mixture, has no appreciable effect on the oxidation rate (Table 4).

Increase in the concentration of bisulphate ions also does not have any effect on the oxidation rate (Table 5).

Effect of Temperature. The reaction was studied at different temperatures between 30 to 45°C (Table 6). The specific rate constant, k, is defined as

$$k = \frac{k_1\ (\text{min}^{-1})}{[\text{ketone}]\times 60}$$

The plot of $\log k$ against the inverse of temperature is a straight line. The Arrhenius equation is,

therefore, valid for this reaction. The thermodynamic parameters were evaluated in the usual way (Table 7).

Rates of Bromination. The bromination of ethyl methyl ketone is of first order with respect to the ketone, first order with respect to hydrogen ion but zeroth order with respect to bromine. The rate of bromination divided by concentrations of ketone and hydrogen ions gives (k_2 l mol^{-1} sec^{-1}). Table 8 records the values of k_2 at different proportions of acetic acid-water.

The rate of bromination was studied at temperatures between 30 and 40°C and thermodynamic parameters were evaluated (Table 9).

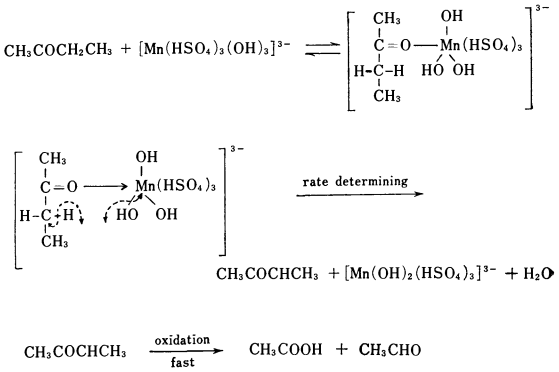
Discussion

Manganese(II) is known to affect the rate of oxidation of several compounds,[5,6] where the oxidizing species is Mn(IV) and this has been attributed to its effect on the following equilibrium:

$$Mn(IV) + Mn(II) \rightleftharpoons 2Mn(III)$$

Absence of any effect of manganese(II) on the rate of the oxidation suggests that in this case, Mn(III) is the only oxidizing species.

In sulphuric acid medium manganese(III) exists as a sulphato-complex. In stronger solutions of sulphuric acid, which are used to prepare Mn(III), sulphate ion exists as HSO_4^-. The coordination number of manganese(III) is probably six and hence the probable composition of sulphatocomplex could be $[Mn(HSO_4)_3(OH)_3]^{3-}$. Therefore, the oxidizing species is $[Mn(HSO_4)_3(OH)_3]^{3-}$.



Enolisation of ethyl methyl ketone is an acid catalysed reaction, whereas the oxidation is independent of acidity. Had the enol form been involved in the oxidation, the rate expression would have included a term containing hydrogen ion concentration. Furthermore, the increase in the proportion of acetic acid in the solvent mixture decreases the dielectric constant of the medium and favours reactions involving protonation. Acid catalysed enolisation of ketone is such a reaction. No effect of the change in the solvent composition on the rate of the oxidation again suggests that enolisation is not the rate determining factor in this reaction.

The rate of enolisation of ethyl methyl ketone in 20% acetic acid solution at 35°C is 3.92×10^{-4} l mol^{-1} sec^{-1}, while the specific rate constant, k, for the oxidation under similar condition is 41.5×10^{-4} l mol^{-1} sec^{-1}. If enolisation was to precede oxidation, the rate of oxidation in the limit could be equal to the rate of enolisation, but could never exceed the rate of enolisation. This, therefore, clearly proves that oxidation of ethyl methyl ketone by manganese(III) sulphate proceeds by a direct attack on the keto- form.

The first step in the oxidation is the rapid, reversible formation of complex between the ketone and the manganese(III) sulphate complex, followed by the rate-determining step to give a radical which is then oxidized by several fast steps to acetaldehyde and acetic acid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2030—2038 (1970)

Oxidation of Vanadium(II) by Nitrate Ion

Kazuyoshi TANAKA

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo

(Received August 15, 1969)

The oxidation rates of vanadium(II) to vanadium(III) by nitrate ion were determined from the time dependence of the polarographic diffusion currents. As supporting electrolytes sodium perchlorate and sodium sulfate were used. The oxidation rates were linearly dependent on hydrogen ion concentration in strongly acidic solutions (pH<2) and independent in weakly acidic solutions (pH>2). Polarographic half-wave potentials, reversibility and diffusion currents indicated that vanadium(II) in sulfate medium formed a sulfato-complex or an ion-paired species which was oxidized faster than V^{2+} (hydrated) in perchlorate medium. The oxidation in sulfate medium proceeded mainly by a single two-electron oxidation, and further reaction between vanadium(II) and vanadium(IV) yielded a stable dimer of vanadium(III) detected by absorption experiments. The rates measured in various halide solutions, except fluoride, gave almost the same rate constants in perchlorate medium. The gaseous products from nitrate ion were identified as NO and N_2O by infrared spectrum measurements. The overall oxidation was proposed;

$$8V(II)+2NO_3^-+10H^+ \rightarrow 8V(III)+N_2O(g)+5H_2O$$

There have been a number of studies concerning the oxidation of vanadium(II) with oxidizing agents such as chlorate,[1] perchlorate,[2] oxygen and hydrogen peroxide,[3] and with higher oxidation states of metals such as vanadium(IV),[4] thallium(III),[5] chromium(III),[6] iron(III),[7] and uranium(VI).[8] The possibility of the reaction proceeding by way of a one- or a two-electron oxidation step is of interest. The vanadium is suitable for clarifying this problem because vanadium ions in aqueous solution are in various oxidation states from vanadium(II) to vanadium(V). Although the oxidation of cerium(III),[9] molybdenum(V),[10] and uranium(III)[11] by nitrate ion has been studied, no report has appeared concerning the oxidation of vanadium (II) by nitrate ion. The rates could be followed by the time dependence of polarographic diffusion current corresponding to the disappearance of vanadium(II) ion in the solution. Vanadium(II) species were polarographically investigated in various supporting electrolytes.[12,13] Many spectrophotometric measurements have been carried out in a strongly acidic solutions ($[H^+]>0.1$ M) because of the low extinction coefficient and high acidity of vanadium(II) stock solution. However, it was polarographically possible to determine the rate in weakly acidic solution of low vanadium(II) concentration.

Newton and Baker reported that the rate of reaction between vanadium(II) and vanadium(IV) changed with sulfate ion concentration, and the reaction intermediate VOV^{4+} was formed.[14] When the oxidation by nitrate ion proceeds by a single two-electron step, it is expected that the dimer of vanadium(III) may be formed and be stable in sulfate medium. This problem in particular is discussed in this paper.

Experimental

Materials. Vanadium(IV) perchlorate solutions were prepared from vanadyl sulfate solutions by adding $Ba(ClO_4)_2$ to precipitate $BaSO_4$. Vanadium(II) stock solutions were prepared by reduction of $VO(ClO_4)_2$

solutions containing perchloric acid with zinc amalgam in a pure nitrogen stream. The vanadium(IV) concentration was spectrophotometrically determined using the absorption at 720 mμ, which is mainly due to vanadium(IV). The standard vanadium(IV) solutions were prepared by dissolving vanadium metal (>99.5 %) in a dilute nitric acid. Vanadium(II) concentration was also determined as vanadium(IV) produced by air oxidation in a concentrated perchloric acid solution.

Sodium nitrate solutions were prepared from Wako reagent grade chemicals which had been dried over concentrated sulfuric acid. As supporting electrolytes used for polarographic measurements, perchloric acid (70%), sulfuric acid and their salts, sodium fluoride, chloride, bromide, and iodide were also of reagent grade. Redistilled water was used.

Measurements. The proper amount of vanadium(II) solution was added to deaerated solution containing supporting electrolytes. After the solution was vigorously stirred with nitrogen gas, d.c. and a.c. polarographic measurements were performed at 25°C to obtain the values of half-wave potential and reversibility[15] of vanadium(II). The appropriate amount of sodium nitrate was added to the solution, and mixed by passing nitrogen gas. The time dependence of the polarographic diffusion current of vanadium(II) was recorded at a constant potential (−0.1 — 0.2V *vs.* SCE) where the diffusion current appeared. In the course of these measurements, the solution was protected from air oxidation by a stream of pure nitrogen gas. In order to follow the reactions, the sensitivity of the polarograph was set at 0.10 μA/mm, and the damping capacitance at 5 μF where the current change corresponds to the derease in vanadium(II) concentration. The ionic strength was adjusted to 0.5 by adding sodium perchlorate, except for experiments in which the rates at different ionic strengths were compared.

The visible spectra of the oxidation products were obtained as follows. After vanadium(II) solution was added to a deaerated sodium nitrate solution, the solution was mixed with nitrogen gas and then taken into a capped 1 cm cell in the spectrophotometer, and the time dependence of the absorption was measured. Gas analysis was performed in the following way. After the addition of nitrate ion to vanadium(II) solution in a vacuum vessel, the gases evolved were collected in a CaF_2 gas cell with liquid nitrogen to measure their infrared spectra in the rage 1000—4000 cm^{-1}. The experiments were performed at room temperature and all pH measurements were carried out after completion of the reactions.

Instruments. A Yanagimoto d.c. and a.c. polarograph Model PA-101 was used to obtain the polarograms and the time dependence of diffusion current of vanadium(II). An H-type cell with a saturated calomel electrode was used. The reaction vessel was large enough to hold more than 100 m*l*. The dropping time of the mercury electrode was measured by a Yanagimoto polarograph timer Model SY-2. The characteristic of dropping mercury was 0.830 mg/sec at a height of mercury reservoir of 72.2 cm. All pH measurements were made by a Towadenpa pH meter Model HM-5A. Visible absorption spectra were measured by a Hitachi Model EPV-2 and infrared spectra were recorded using JASCO Model DS-301 and DS-402G infrared spectrophotometers.

Results and Discussion

Polarographic Behavior of Vanadium(II). Linearity between vanadium(II) concentration and its diffusion current was necessary to obtain kinetic data from the time dependence of the diffusion current. Diffusion currents were measured at various concentrations of vanadium(II) in perchlorate, and sulfate media. Typical results are shown in Fig. 1. On adding vanadium(II) to the electrolyte solution, vanadium(II) was partially oxidized by air. It was found from the value of diffusion current, however, that about 90% of the vanadium ions were in the +2 oxidation state. From Fig. 1, it is polarographically possible to follow the decrease of vanadium(II) concentration by nitrate ion and calculate the rate constant of oxidation. As shown in Fig. 1, the diffusion currents in perchlorate medium are larger than those in sulfate medium. Although the diffusion currents in perchlorate medium were independent of hydrogen ion concentration, those in sulfate medium increased with hydrogen ion concentration and decreased with sulfate ion concentration. The polarographic half-wave potentials, diffusion currents and reversibility are shown in Table 1. The half-wave potentials were almost constant below pH 2 in perchlorate medium. However, they

shifted to more negative potential and the reversibility markedly decreased above pH 2. It was therefore concluded that vanadium(II) species was V^{2+} (hydrated) and the electro-oxidation product vanadium(III) was the same hydrated species in strongly acidic solution (pH<2). On the other hand, vanadium(III) in weakly acidic solution might form a hydrolyzed species which made the electrode reaction irreversible. In this case, the half-wave potential depends on hydrogen ion concentration. Lingane and Meites found that VO^+ in acetate buffer solution was reduced at more negative potential than VOH^{2+}.[16] However, it is more reasonable to conclude that a considerable amount of vanadium(III) ions in weakly acidic solution formed a dimer VOV^{4+}. Biermann and Wong reported that vanadium(II) species, above 2.5×10^{-3} M in perchloric acid, has a dimeric form, and below this concentration the polynucleation process seems incomplete.[17] From the diffusion currents obtained at various acidities, vanadium(II) species was, however, estimated to be mainly V^{2+}(hydrated) even in weakly acidic solution.

Although the diffusion currents in sulfate medium decreased both with sulfate ion concentration and with increasing pH values, they were linear with respect to vanadium(II) concentration. The half-wave potentials in sulfate medium were more negative than those in perchlorate medium at the same pH value. When sulfuric acid concentration decreased, the half-wave potential shifted to more positive potential and the reversibility became higher. In 0.25 M sodium sulfate, the half-wave potentials slightly shifted to more positive potential with the increase in vanadium(II) concentration, and became almost constant at the potential -0.53 V *vs.* SCE above 0.7×10^{-3} M vanadium(II). Thus, in the present work we could not obtained the results as published in which the half-wave potential is not affected by sulfate ion concentrations.[17] The second wave was observed at a more positive potential ($\sim+0.03$V *vs.* SCE) in weakly

acidic sulfate medium, which corresponded to the oxidation wave of vanadium(III) to vanadium-(IV). From these data, it was concluded that vanadium(II) in sulfate medium partially formed a sulfato-complex or an ion-paired species with sulfate ion and almost all vanadium(III) formed a sulfato-complex.

Zinc(II) ion was present in all of the solution used for the polarographic measurements and its concentrations were almost three times larger than those of vanadium(II). No influence of zinc ion could be observed in the polarograms of vanadium-(II).

Measurement of Rate Constant. A typical time dependence of the diffusion current obtained is shown in Fig. 2. As all reactions were carried out in excess nitrate ion, the rate constants of the oxidation reaction could be calculated from the half-life time of the reaction ($\tau_{1/2}$ shown in Fig. 2) by

$$k=0.6931/\tau_{1/2} \quad (1)$$

This relation is valid only if the rate of the oxidation is first-order with respect to vanadium(II). The logarithmic current-time plots in perchlorate, and sulfate media are shown in Fig. 3 and the rate constants calculated from Eq. (1) are listed in Table 2. From the results, the rates were indicated to be first-order with respect to vanadium(II) concentration, and the rate law is therefore given by

$$-d[V(II)]/dt = k_{obs}[V^{2+}] \quad (2)$$

where k_{obs} is equal to k in Eq. (1).

The possibility for zinc ion to act as a catalytic impurity in this oxidation process was investigated by using electrically prepared vanadium(II). The rate constant ($k_{obs}=6.96\times10^{-3}$ sec^{-1}) at pH 1.66 was almost the same as that ($k_{obs}=6.81\times10^{-3}$ sec^{-1}) obtained using vanadium(II) prepared on zinc amalgam. Oxidation of vanadium(II) by perchlorate ion could not be detected until completion of the reaction by nitrate ion (about 30 min).

Dependence of Rate on Hydrogen Ion Concentration. The rate constants for strongly acidic solutions are plotted in Fig. 4. Sodium sulfate was added to sulfate medium in order to keep the sulfate ion concentration constant at 0.01 M assuming K_a of HSO_4^- to be 4.37×10^{-2} M.[18] Perchloric acid was used to regulate the hydrogen ion concentration of the solution. As shown in Fig. 4, the rate constants in sulfate medium were larger than those in perchlorate medium, but in both cases they were linearly proportional to the hydrogen ion concentration. The rate constants measured in weakly acidic solutions are shown in Fig. 5. In sulfate medium, 0.05 M sodium sulfate was added to the solutions and the hydrogen ion concentration was adjusted with perchloric acid. The results gave the same relationship as in strongly acidic solutions, *viz.*,

sulfate ion increased the rate of the oxidation reaction. Although the rate constants in both media were almost independent of hydrogen ion concentration above pH 2, they slightly increased above pH 3.5, particularly in sulfate medium. The kinetic data obtained shows that the rate laws can be expressed as follows:

$$pH < 2 \qquad k_{obs} = k_1[H^+] + k_2 \qquad (3)$$

$$pH > 2 \qquad k_{obs} = \text{almost constant} \qquad (4)$$

Dependence of Rate Constants on Ionic Strength. The effects of ionic strength on the rate constant are summarized in Table 3. The results in both media indicate that the rates decreased with the increase of ionic strengths. It has been reported that the rates of the reaction between vanadium(II) and vanadium(IV) increase with ionic strength, and are in good agreement with the extended form of Debye-Hückel's equation. Since the rate of reaction between a cation and a cation system may be increased by an anion which is used for adjusting ionic strength and which decreases the effective charge of the reaction,[4,19] it can be expected that the anion suppresses the rate of reaction between anionic oxidizing agent and the cation which forms an ion-paired species. The rates obtained are interpreted by assuming that vanadium(II) formed an ion-paired species with perchlorate ion. The larger rate constants obtained in sulfate medium are thought to indicate that the reaction proceeds mainly by another oxidation path as mentioned below.

TABLE 3. EFFECT OF IONIC STRENGTH ON k_{obs} AT 25°C

19) J. P. Candlin, J. Halpern and S. Nakamura, *J. Amer. Chem. Soc.*, **85**, 2517 (1963).

the results, the rates in various acid solutions were found to be first-order with respect to nitrate ion concentrations and are expressed by

$$k_{obs} = k_3[NO_3^-] \quad (5)$$

As indicated in Fig. 5, the increasing rate with pH above 3.5 in perchlorate medium is confirmed from the relation between the lines 3 and 4 in Fig. 6.

In sulfate medium, the rate increased with sulfate ion concentration and the intercepts of straight lines shown in Fig. 7 are not zero. This indicates that nitrate-ion-independent terms of the rate constants appeared. Even in sulfate medium, the rates were, however, first-order with respect to the nitrate ion concentration. The rate law is

$$k_{obs} = k_4 + k_5[NO_3^-] \quad (6)$$

When nitrate ion was not present in the solution, the diffusion current of vanadium(II) was almost constant for about 30 min, showing that no oxidation occurred by other oxidizing agents such as oxygen in the air. It was therefore concluded that the nitrate-ion-independent term was characteristic of the oxidation in the presence of sulfate ion, in which a sulfato-complex or an ion-paired species was oxidized faster than V^{2+} (hydrated).

After completion of oxidation, the polarograms indicated that the vanadium(III) concentration was about 50% of that of the initial vanadium(II). Since the polarographic wave in large excess of nitrate ion involved the catalytic wave,[20] the species of the reaction product vanadium(III) could not be determined. However, the diffusion current was not affected by vanadium(III) species.

Measurements of Visible Absorption Spectra. It was difficult to measure the rate of oxidation in a weakly acidic solution as used for the polarographic studies because of the small extinction coefficients of vanadium(II) and vanadium(III), and of the high acidity of vanadium(II) stock solution.[21] When sodium nitrate was added to the solution containing 2×10^{-2} M vanadium(II), the solution immediately exhibited a brown color, which gradually changed to green. Hydrogen ion in the vanadium(II) stock solution could be decreased somewhat by employing the experimental condition that hydrogen ion was reduced on zinc amalgam. When sodium nitrate was added to this solution, the brown color developed was so stable that absorption spectra could be measured. The spectra showed a peak at 425 mμ similar to that of the

intermediate VOV^{4+} of the reaction between vanadium(II) and vanadium(IV).[14] Because of a large molar extinction coefficient of this species, it was possible to follow the rate of reaction producing VOV^{4+} in almost the same composition as used for the polarographic measurements. As indicated in Fig. 8, the absorbance at 425 mμ increased both with sulfate ion concentration and with decrease in hydrogen ion. Newton and Baker found that the rate of the reaction between vanadium(II) and vanadium(IV) increased to some extent with a small amount of sulfate ion, and the reaction yielded the intermediate VOV^{4+} which decomposed to monomer in a strongly acidic solution.[14] The time dependence of absorption at 425 mμ in perchlorate medium gave the decomposition rate of the dimer VOV^{4+} to monomer. The half-life time at pH 2.59 was about 1.8 hr. The resulting solution exhibited a yellow green color which was mainly due to the absorption of vanadium(III) monomer. The result indicates that there was a reaction path between vanadium(II) and vanadium(IV) in the oxidation by nitrate ion. It was therefore considered that nitrate ion mainly acted as a one-electron oxidizing agent in strongly acidic solutions and as a two-electron one in weakly acidic solution,[22] and that vanadium(IV) produced by a single two-electron oxidation then reacted with vanadium(II) to yield the dimer. Since vanadium(III) yielded the dimer above pH 2, the dimer was not produced only by the reaction between vanadium(II) and vanadium(IV). Accordingly the oxidation in weakly acidic solutions did not always proceed by a single two-electron oxidation path.

In the present work, the rate constant of the oxidation of vanadium(III) by nitrate ion polarographically measured at pH 1.33 was smaller than 7.7×10^{-5} sec^{-1} at 1.84×10^{-2} M nitrate ion, and this rate was considerably slow compared with that of vanadium(II) by nitrate ion. When sodium nitrate was added to a strongly acidic vanadium(II) solution, the solution first developed a green color which changed to blue corresponding to the absorption of VO^{2+}. This indicates that almost all vanadium ions were once in +3 oxidation state during the course of oxidation reaction, and the polarographic measurements, therefore, followed the overall oxidation of vanadium(II) to vanadium(III).

Effects of Sulfate and Halide Ion on the Rates. The typical effects of anions on the rates of oxidation are shown in Fig. 9. The rate increased with sulfate ion and became almost constant above 0.10 M sulfate ion. The results indicate that above this sulfate ion concentration almost all of vanadium(II) formed a sulfato-complex or an ion-paired species, and the rate of oxidation of this species was not affected any more by increasing sulfate ion concentration. Newton and Baker reported that the rate of the reaction between vanadium(II) and vanadium(IV) increased by adding 4×10^{-3} M sulfate ion. This increase is probably connected with the activation process.[4] These facts lead to the conclusion that the dimer in sulfate medium may be $VOV(SO_4)^{2+}$ and was fairly stable in the solution as discussed in the absorption experiments. It is also considered from the results given in Fig. 9 that a sulfato-complex or an ion-paired species was oxidized faster than V^{2+} (hydrated).

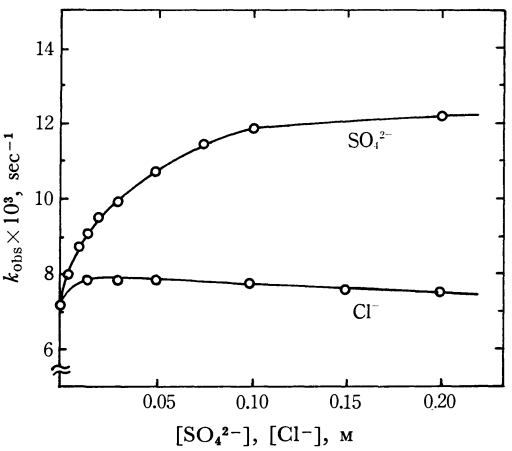

Fig. 9. Effects of sulfate and chloride ion on first-order rate constant at pH∼4.4.
Initial concentration: *ca.* 8×10^{-4} M vanadium(II), 1.84×10^{-2} M sodium nitrate

The half-wave potentials, reversibility and oxidation rates of vanadium(II) by nitrate ion are summarized in Table 4. The half-wave potential in fluoride solution indicates that vanadium(III) formed a fluoro-complex,[13] and the oxidation rate was too fast to be measured by the polarographic method. The polarographic measurements of oxidation in halide solutions, except fluoride, gave almost the same rate constants as in perchlorate medium. From these half-wave potentials, it was considered that only weak complexing took place and therefore the rates were not so much affected by halide ion concentration. However, as shown in Fig. 9, the rate increases with a small amount of chloride ion and becomes gradually suppressed above 2.5×10^{-2} M chloride ion. It has been found that the reaction between vanadium(II) and vanadium(IV) is catalyzed by chloride ion, vanadium(IV) in the presence of a large amount of chloride ion forms a chloro-complex, and the chloride ion does not increase the rate any more.[4]

The reversibility increased from fluoride to iodide solution as shown in Table 4. It was found in the oxidation of titanium(III) by chlorate ion that the smaller the rate constant, the lower the

reversibility.[23] However, the oxidation rates by nitrate ion increased with sulfate ion and the reversibility were lower than those in perchlorate medium. Although the rates in halide solutions, except fluoride, gave almost the same rate constants, reversibility was markedly varied. The discrepancies can be explained as follows: 1) the electrochemical oxidation product in sulfate medium may be so stable that the product makes the electrode reaction irreversible; 2) in halide solutions, the electron transfer of electrode reaction may be accelerated by halide ion specifically adsorbed on mercury.

Infrared Determination of Gaseous Products. When sodium nitrate was added to acidic vanadium(II) solutions, the solution immediately developed a brown color which gradually turned to green, yielding gaseous products. The gases produced in a vacuum line were collected in a gas cell using liquid nitrogen and determined by measuring their infrared spectra. The results are shown in Table 5. They indicate that NO and N_2O were predominant products in the ratio of 3 : 1.[25,26] However, this ratio in the polarographic measurements is considered to be more favorable to NO because of the large excess of nitrate ion. HNO_2 and NO_2 found in perchlorate medium might be produced by the oxidation of NO with oxygen in the traps, and their amounts negligibly small. The gaseous products immediately generated by the reaction between vanadium(II) and nitrite ion were also detected as NO and N_2O. The oxidizing power of nitrite ion was so strong that vanadium(IV) in acidic solution was easily oxidized to vanadium(V). Since there was such a low oxidation state of nitrogen as N_2O, it was expected that vanadium(II) would be oxidized by NO gas. NO gas easily produced by adding sodium nitrite to ferrous sulfate in sulfuric acid was bubbled through a vanadium(II) solution. The infrared spectrum of gas collected in the gas cell indicated the presence of N_2O. No N_2O was detected from the original NO gas. The solution bubbled for 3 hr developed a blue color corresponding to the absorption of vanadium(IV). The facts varified that vanadium(II) was oxidized to vanadium(IV) by NO gas, and the rate was very slow. However, all reactions investigated by the polarographic method were carried out with a considerable excess of nitrate ion to obtain feasible rates. Therefore, the amount of N_2O produced in the reaction was negligible with respect to the amount of NO. The gaseous products did not affect the time dependence of the diffusion current.

s : strong w : weak

Reaction Mechanism. The changes of diffusion currents measured in a large excess of vanadium(II) over nitrate ion showed that the amount of vanadium(II) ions oxidized by nitrate ions was approximately four times larger than that of nitrate ions consumed. In fact, the ratio of vanadium(II) to nitrate ion was 3.7 : 1 in perchlorate medium and 3.9 : 1 in sulfate medium. Therefore, overall oxidation of vanadium(II) by nitrate ion is

$$8V^{2+} + 2NO_3^- + 10H^+ \rightarrow 8V^{3+} + N_2O + 5H_2O$$

The reaction processes involved the oxidation paths of vanadium(II) by vanadium(IV), NO_2^- and NO as mentioned above. Guymon and Spence reported that NO was a major product in the oxidation of molybdenum(V) by nitrate ion and that NO^+ was assumed to be the reactive intermediate.[10] For the oxidation of vanadium(II) by nitrate ion in

the present work, NO^+ was also assumed to be present as a reactive intermediate, and the following possible mechanisms in perchlorate medium were proposed.

$$V^{2+} + NO_3^- + H^+ \xrightarrow{k_I} V^{3+} + NO_2 + OH^- \quad (I)$$

$$V^{2+} + NO_3^- \xrightarrow{k_{II}} VO^{2+} + NO_2^- \quad (II)$$

$$V^{2+} + VO^{2+} \longrightarrow VOV^{4+} \quad (III)$$

$$2NO_2 \rightleftharpoons N_2O_4 \quad (IV)$$

$$N_2O_4 \rightleftharpoons NO^+ + NO_3^- \quad (V)$$

$$V^{2+} + NO^+ \longrightarrow V^{3+} + NO \quad (VI)$$

$$V^{2+} + NO_2^- + 2H^+ \longrightarrow V^{3+} + NO + H_2O \quad (VII)$$

$$2V^{2+} + 2NO + 2H^+ \longrightarrow 2V^{3+} + N_2O + H_2O \quad (VIII)$$

The oxidation rate corresponding to reaction(VII) was polarographically measured and gave a second-order rate constant of 3×10^2 M^{-1}·sec^{-1} at pH 4.70. Thus, the rate of reaction (VII) is very fast and gaseous products such as NO and N_2O were generated. Frank and Spence investigated the oxidation of molybdenum(V) by nitrite ion, and found that the rate law was dependent on nitrite ion and hydrogen ion, but independent of molybdenum (V).[27] This leads to the conclusion that nitrite ions are in the following equilibrium:

$$H^+ + NO_2^- \rightleftharpoons HNO_2 \quad (IX)$$

$$H^+ + HNO_2 \rightleftharpoons NO^+ + H_2O \quad (X)$$

The true oxidation path of reaction(VII) was therefore considered to be the same as that of reaction(VI). Reaction (I) was the predominant oxidation path in strongly acidic solutions and reaction(II) in weakly acidic solutions. The polarographic determination of the reaction between vanadium(II) and vanadium(IV) was performed, and the rate constant obtained at pH 1.66 was 0.545 M^{-1}·sec^{-1}, indicating that the rate was almost the same as that by nitrate ion.

Applying the steady-state condition to NO_2, NO_2^-, N_2O_4, NO^+, and VO^{2+}, the following rate law is obtained.

$$-d[V(II)]/dt=(2k_I[H^+] + 3k_{II})[V^{2+}][NO_3^-] \quad (7)$$

When hydrogen ion concentrations are low, that is, pH>2, Eq. (7) can be written as

$$-d[V(II)]/dt = 3k_{II}[V^{2+}][NO_3^-] \quad (8)$$

These formulas are in good agreement with the experimental rate laws, and the proposed mechanism is in line with kinetic data.

In sulfate medium, the following equilibrium between vanadium(II) and sulfate ion may exist below 0.1 M sulfate ion.

$$V^{2+} + SO_4^{2-} \rightleftharpoons VSO_4 \quad (XI)$$

where VSO_4 shows a sulfato-complex or an ion-paired species. The oxidation rate of this species is faster than that in perchlorate medium, and the following oxidation paths may be involved.

$$VSO_4 + NO_3^- + H^+ \longrightarrow VSO_4^+ + NO_2 + OH^- \quad (I')$$

$$VSO_4 + NO_3^- \longrightarrow VOSO_4 + NO_2^- \quad (II')$$

$$V^{2+} + VOSO_4 \longrightarrow VOV(SO_4)^{2+} \quad (III')$$

As mentioned in the visible absorption experiments, the stable dimer of vanadium(III) in sulfate medium might be produced by reaction (III). However, it is difficult from the present data to interpret the nitrate-ion-independent term k_4 in Eq. (6), so that further work for the oxidation in sulfate medium is necessary.

Conocchioli *et al.* investigated the oxidation of iron(II) by hypochlorate ion and suggested that iron(IV) was produced as an intermediate by a single two-electron oxidation.[28] Oxidation of vanadium(II) by thallium(III) proceeds mainly by a single two-electron step.[5] When vanadium (II) was oxidized by hydrogen peroxide and oxygen, about 30% and 60%, respectively, vanadium(III) was formed by the reaction between vanadium(II) and vanadium (IV).[3] The results obtained for the oxidation of vanadium(II) by nitrate ion might show that reactions (I) and (II) proceed by one-electron oxidation, and reactions (II) and (III) by two-electron one, the latter occurring mainly in weakly acidic solutions, particularly in sulfate medium. The two-electron oxidation would also be possible in the reaction between vanadium(II) and nitrate ion. However, when sodium nitrite was added to acidic vanadium(II) solution, the solution did not exhibit a brown color. This shows that nitrate ion acted as a one-electron oxidizing agent.

The energy of activation was determined by measuring the rate of overall reactions at five temperatures, 15, 20, 25, 30, and 38°C.[29] The results obtained are shown in Table 6.

Table 6. Activation enthalpy and entropy of overall reaction at $\mu=0.50$

The Polarography of Alkyl Hydroperoxides in an Aqueous Solution

Shigeo HAYANO and Noriko SHINOZUKA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November, 17, 1969)

The polarographic behavior of alkyl hydroperoxides was studied. *n*-Propyl, *n*-butyl, *n*-hexyl, and *n*-octyl hydroperoxide in an aqueous solution all show diffusion-controlled irreversible waves. The effect of the pH on the $E_{1/2}$ and $n\alpha$ values is very small. The length of the alkyl group has a marked effect on $E_{1/2}$ and $n\alpha$. The longer the chain length of the alkyl group, the larger the value of $n\alpha$ and the more positive the $E_{1/2}$. The linear free-energy relationship was found for the four alkyl hydroperoxides examined. The relation of Taft's polar substituent coefficient to $E_{1/2}$ has a negative reaction constant, which indicates a reaction promoted by high electron density in the reactive group. The electrode process seems to be the rupture of the -O–O- bond, followed by the protonation of the ions produced on the electrode.

Polarography is a versatile electrometric method that offers one of the best techniques for peroxide analysis. As most organic peroxides are polarographically reducible, their polarographic behavior has been studied for twenty years.[1-6] The electrode process may be a two-electron transfer, which leads to the rupture of the -O–O- bond, thus forming an OH group:[7]

$$ROOR + 2e + 2H \rightarrow ROH + ROH$$

The details of the above reaction have been discussed recently,[8,9] but have not yet been confirmed. The available data about the reaction of alkyl hydroperoxides provided by different authors are not sufficient for systematic discussion.

This paper will describe the polarographic behavior of the lower alkyl hydroperoxides (*n*-propyl, *n*-butyl, *n*-hexyl, and *n*-octyl hydroperoxides) synthesized in our laboratory and will discuss the electrode process in relation to the polarographic data and the organic structure. The relation of Taft's substituent coefficient to the $E_{1/2}$ values of the four compounds shows a linear line, the slope of which has a negative sign.

Experimental

All the alkyl hydroperoxides examined, *n*-propyl, *n*-butyl *n*-hexyl, and *n*-octyl hydroperoxide, were synthesized by the use of alkylmethane sulfonates.[10] The active oxygen values were determined by iodometric titration. The hydrogen peroxide and contaminated peroxides were checked by thin-layer chromatography.

Britton-Robinson's buffer solution was deaerated by N_2 bubbling for about 30 min; an alcoholic solution of a hydroperoxide was added to it with a microsyringe or a micropiette, and then N_2 was again bubbled in for a few minutes. The alcohol content was within 10 vol%.

A YEW POL-11-type polarograph (Yokogawa Denki Co.) was used for recording the d.c. polarograms. The pH of the solution was measured with a Toa Dempa PM-5A pH meter. The dropping electrode had the following characteristics: $m=2.07$ mg/sec, $t=3.58$ sec (in pure water, open circuit). No decomposition of the sample could be detected during the measurements. All the measurements were carried out at 25°C.

Results and Discussion

1) Shape of Polarographic Waves. With the four hydroperoxides examined, ill-defined waves were obtained. The wave shape indicates the irreversible nature of the step; this was confirmed by low peak height of the a.c. polarography. In both acid and alkaline solutions, the limiting currents were proportional to the hydroperoxide concentration. The half-wave potential was constant for hydroperoxide concentrations of 10^{-5}—10^{-4} M. The limiting current has a linear relation-

ship with the square root of the Hg height. The temperature coefficient of the limiting current is about 1% between 15—35°C. These results indicate that the limiting current is diffusion-controlled.

2) Dependence of Apparent $E_{1/2}$ on pH. The apparent $E_{1/2}$ values at various pH values are shown in Fig. 1. All the compounds shift with the half-wave potential more negative as the pH increases, but the effect of the pH is very small. As the number of carbon atoms increases, the half-wave potential shifts toward a more positive potential.

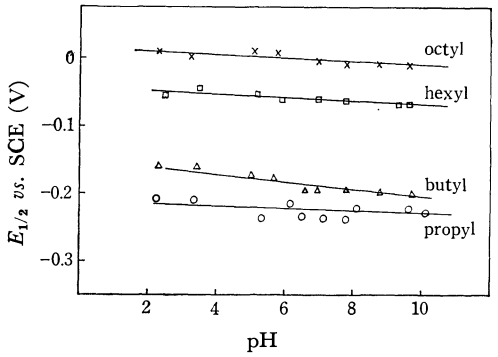

Fig. 1. Relation of $E_{1/2}$ to pH.

3) Dependence of $n\alpha$ Values on pH. As the hydroperoxides show irreversible polarographic waves, the slopes of log-plots gave $n\alpha$ values. The values of $n\alpha$ calculated at various pH are plotted in Fig. 2. Each compound seems not to change in its $n\alpha$ value with the pH of the solution. The tendency for a large alkyl group to have a large $n\alpha$ value indicates that if n=constant, a large alkyl group diminishes in polarographic irreversibility: this accords with the fact that the waves for the higher homologues are steep and well-defined.[8]

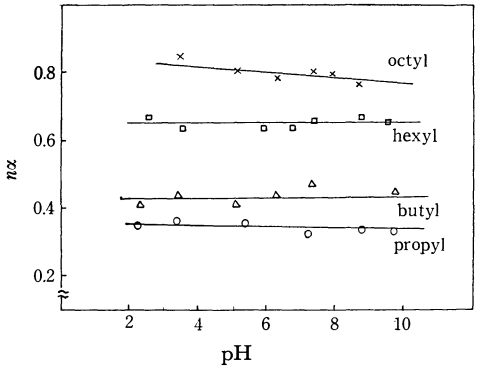

Fig. 2. Relation of $n\alpha$ to pH.

4) Effect of the Alkyl Group on $E_{1/2}$ and $n\alpha$. $E_{1/2}$ and $n\alpha$ are affected by the length of the alkyl group of the hydroperoxides. The plots of the half-wave potential and $n\alpha$ values against the chain length show a linear relation with the C_3—C_8 compounds (Figs. 3,4). The $E_{1/2}$ of C_1—C_2 hydroperoxides, quoted from Ref. (8), has a steeper slope than that of C_3—C_8.

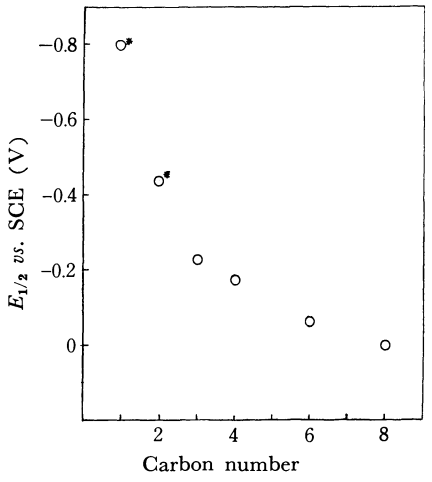

Fig. 3. Relation of $E_{1/2}$ (at pH=7) to chain length.
○*: from Ref. 8.

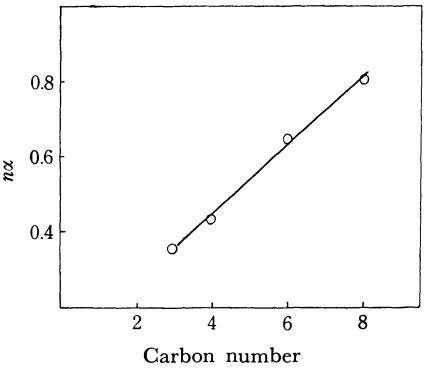

Fig. 4. Relation of $n\alpha$ to chain length.

5) The Electrode Reaction of Alkyl Hydroperoxides. The relation of the half-wave potential to Taft's polar substituent constant, σ_x*, is shown in Fig. 5. The half-wave potential of the irreversible electrode process is expressed as follows:[11]

$$E_{1/2} = E_0 + \frac{RT}{n\alpha F} \ln 0.87\, k_f^\circ \sqrt{\frac{t_1}{D}} \qquad (1)$$

$$\frac{\partial E_{1/2}}{\partial \mathrm{pH}} = -\frac{2.3RT}{\alpha F}$$

11) J. Heyrovsky and J. Kuta, "Principle of Polarography," Academic Press, New York (1966), p. 257.

where E_0 is the standard oxidation-reduction potential; R, the gas constant; T, the absolute temperature; α, the transfer coefficient; n, the number of electrons transferred in the electrode process; F, the faraday; $k_f{}^0$, the rate constant of the electrode process; t_1, the drop time, and D, the diffusion coefficient. From this equation, the linear free-energy relationship can be said to be valid when it is assumed that the value of the $dE_{1/2}/dpH$ slope and that of the transfer coefficient determined from the shape of the wave remain unchanged for all the members of the reaction series under study.[12] Therefore, strictly speaking, only with the large alkyl-group hydroperoxides which may have almost the same α values can a linear correlation be expected.

Recently Zuman has reported[13] that, in some instances, $dE_{1/2}/dpH$ and $RT/\alpha nF$ are approximately linear function of the substituent constant, $\sigma_x{}^*$. In some other cases, plots of $(E_{1/2}\cdot dE_{1/2}/dpH)$ or $(E_{1/2}\cdot RT/\alpha nF)$ against $\sigma_x{}^*$ show a better correlation than the $E_{1/2}$–$\sigma_x{}^*$ plots. On the other hand, in alkyl hydroperoxides, plots of $E_{1/2}\cdot RT/\alpha nF$ against $\sigma_x{}^*$ do not show any better correlation.

From the negative reaction constant in Fig. 5, it can be assumed that the reaction is promoted by high-electron density on the reaction group. The independence of the half-wave potential on pH suggests that the proton does not directly participate in the electrode process. The fact that in such aprotic solvent as acetonitrile and dimethylformamide the waves elongate and become ill-defined, can be interpreted in terms of the increased irreversibility in aprotic solvents. This indicates a proton contribution to the overall reaction.

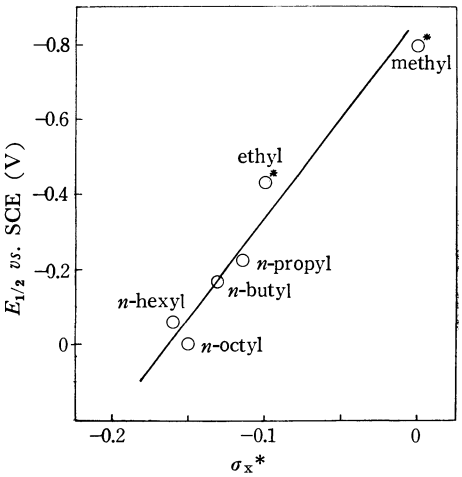

Fig. 5. Relation of $E_{1/2}$ to Taft polar substitution constant $\sigma_x{}^*$.
○*: from Ref. 8.

From the facts described above, it seems likely that the electrode process is as follows:

$$ROOH + 2e \xrightarrow{slow} RO^- + OH^-$$

$$OH^- + RO^- + 2H \xrightarrow{fast} ROH + H_2O$$

Polarographic Behaviors and Potentiostatic Determination of Kinetic Parameters for the Electrode Reaction of *trans*-1,2-Cyclohexanediaminetetraacetatochromate(III) Complexes

Nobuyuki TANAKA, Takeshi TOMITA and Akifumi YAMADA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received November 21, 1969)

The polarogographic behaviors of *trans*-1,2-cyclohexanediaminetetraacetatochromate(III) complex have been studied. The complex is reduced reversibly at the dropping mercury electrode in the solution which contains 0.4 M sodium chloride, 0.1 M acetate buffer and 2×10^{-6} M polyoxyethylene lauryl ether. The kinetic parameters of this oxidation-reduction process have been determined from the potentiostatic measurements at 25°C. The measured parameters are: the standard potential ($E_0)_{ms}=-1.198$ V *vs.* SCE, the standard rate constant $(k_s)_{ms}=2.9\times10^{-2}$ cm sec^{-1}, the transfer coefficient for cathodic process $(\alpha_c)_{ms}=0.33$ and that for anodic one $(\alpha_a)_{ms}=0.67$. The Frumkin correction for the electrical double layer has been applied to these parameters and the corrected values thus obtained are: $(E_0)_{corr}=-1.198$ V *vs.* SCE, $(k_s)_{corr}=0.93$ cm sec^{-1}, $(\alpha_c)_{corr}=0.40$ and $(\alpha_a)_{corr}=0.57$.

The theoretical treatment of the potentiostatic method for the study of fast electrode reactions and its application to the oxidation-reduction processes of Cr(II)–EDTA/Cr(III)–EDTA and Co(II)–EDTA/Co(III)–EDTA systems have been reported,[1-3] where EDTA means ethylenediaminetetraacetic acid. A ligand, *trans*-1,2-cyclohexanediaminetetraacetic acid (CyDTA), which is very similar to EDTA, also forms a stable chelate with chromium(III) ion[4] in difference of a more bulky ion.

In this report, the polarographic behaviors of Cr(III)–CyDTA have been studied and the kinetic parameters of the electrode reaction have been measured by the potentiostatic method. The Frumkin correction has been applied for the effect of electrical double layer at the electrode solution interface.

Experimental

Reagents. The stock solution of *trans*-1,2-cyclohexanediaminetetraacetatochromate(III) complex was prepared by adding the solution of hexaaquochromium(III) perchlorate (0.1 M) to the solution of disodium *trans*-1,2-cyclohexanediaminetetraacetate (0.1 M), and by heating on the water-bath for half an hour. Then, the solution was passed through a cation exchanger Dowex 50W-X8 to remove unreacted chromium ions. The concentration of the complex was determined polarographically after oxidizing chromium(III) to chromate with hydrogen peroxide.[5] All other chemicals used were of guaranteed reagent-grade.

Apparatus. Polarographic measurements were carried out with a Yokogawa Polarocorder POL-11. The potentiostat used was constructed in this laboratory and its characteristics were described previously.[3] The dropping mercury electrode used for polarographic measurements had an *m*-value of 2.02 mg sec^{-1} and a drop time t_d of 4.05 sec in 0.5 M sodium chloride solution at -0.5 V *vs.* SCE and at 63 cm mercury height. The visible absorption spectra of the solution was measured with a Hitachi EPU-2 spectrophotometer. Electrolysis at constant potential was carried out with a Yanagimoto Controlled Potential Electrolyser.

Results and Discussion

Polarographic Studies. The complex ion has two absorption maxima in the visible region at 18.3×10^3 cm^{-1} (ν_1, log $\varepsilon_1=2.05$) and 25.4×10^3 cm^{-1} (ν_2, log $\varepsilon_2=2.39$), respectively. No apparent change in visible spectra was found in the pH range from 4.2 to 7.7, and this may suggest that the predominant complex species have the ligand coordinated to the chromium(III) ion as a pentadentate or hexadentate in the same way in Cr(III)–EDTA complex.

Polarograms were obtained in a solution containing 1.0 mM Cr(III)-CyDTA, 0.4 M NaCl, 0.1 M acetate or phosphate buffer (pH 4.2 to 7.7) and 2×10^{-6} M polyoxyethylene lauryl ether (LEO) at 25°C. Examples are given in Fig. 1. As seen in Table 1, the half-wave potentials were at -1.200

5×10^{-3}% gelatin	4.67	−2.96	−1.202	62

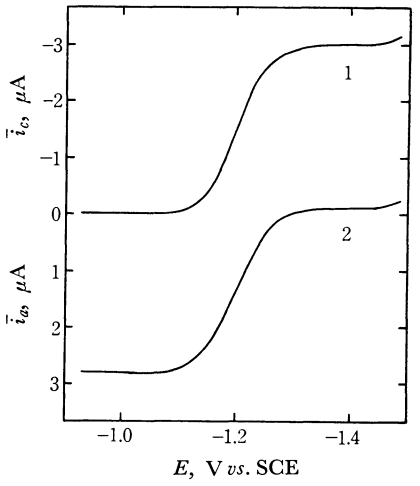

Fig. 1. Polarograms of 1.0 mM Cr-CyDTA complex in solutions of pH 4.7 containing 0.4 M NaCl, 0.1 M acetate buffer and 2×10^{-6} M LEO at 25°C: (1) Cathodic wave of Cr(III)-CyDTA; (2) anodic wave of Cr(II)-CyDTA produced by electrolytic reduction with a mercury pool electrode.

V *vs.* SCE in both cathodic and anodic processes and the limiting current, which was diffusion controlled, was of a one-electron reduction. These and the slope of log-plot indicated that the electrode processes of Cr(II, III)-CyDTA complexes are reversible. Little changes in cathodic current and $E_{1/2}$ were observed in this pH region; this may indicate that the complex species present in the solution and at the electrode surface is only one species, [Cr(III)–CyDTA]$^-$ for oxidant and [Cr(II)–CyDTA]$^{2-}$ for reductant ions.

The effect of surface-active substance on the polarographic wave was relatively small unless the concentration of the substance was too high; in the case of LEO, for example, unless its concentration exceeded about 10^{-5} M, as shown in Table 1.

Electrolysis was carried out in a deaerated solution containing 1.0 mM Cr(III)–CyDTA, 0.4 M NaCl, 0.1 M acetate buffer (pH 4.7) and 2×10^{-6} M LEO with the mercury pool electrode, the potential of which was set at −1.40 V *vs.* SCE at 25°C. A polarogram of the solution after electrolysis was given in Fig. 1, which showed a limiting diffusion current used for the determination of Cr(II)–CyDTA complex. Diffusion coefficients of Cr(III)–CyDTA and Cr(II)–CyDTA were 5.5×10^{-6} cm^2 sec^{-1} and 5.4×10^{-6} cm^2 sec^{-1}, respectively. These values are smaller than those of Cr–EDTA complexes, and seem to be reasonable because the sizes of Cr–CyDTA ions are larger than those of Cr–EDTA ions.

From these results mentioned above, the electrode process is considered as,

$$[\text{Cr(III)-CyDTA}]^- + e \rightleftarrows [\text{Cr(II)-CyDTA}]^{2-} \quad (1)$$

in which any chemical reaction, *e.g.* protonation reaction, is not involved appreciably in the range of pH 4.2 to 7.7.

Equilibrium potentials of this oxidation-reduction process were measured polarographically, using the Nernst's equation at 25°C. A straight line was obtained with a reciprocal slope of 61 mV by plotting E_e *versus* $\log\{[\text{Cr(III)–CyDTA}]/[\text{Cr(II)–CyDTA}]\}$, as shown in Fig. 2. The standard potential $(E_0)_e$ was found to be −1.199 V *vs.* SCE.

Determination of Kinetic Parameters by Means of Potentiostatic Method. When an electrode reaction is expressed as,

$$O + ne \rightleftarrows R \quad (2)$$

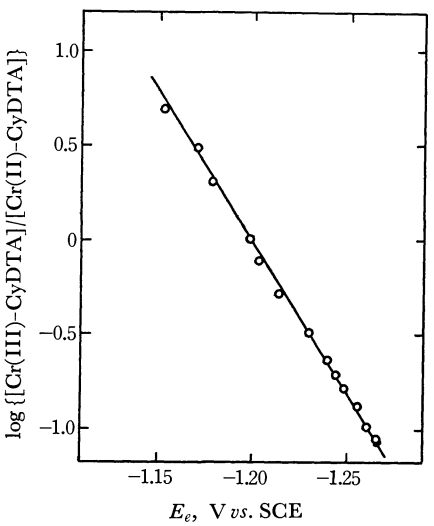

Fig. 2. Relation between equilibrium potential E_e and log{[Cr(III)-CyDTA]/[Cr(II)-CyDTA]} at 25°C. Each concentration was determined polarographically. Cr(II)-CyDTA was prepared by electrolytic reduction with a mercury pool electrode in the solution of pH 4.7 containing Cr(III)-CyDTA, 0.4 M NaCl, 0.1 M acetate buffer and 2×10^{-6} M LEO.

the relation between cathodic current i and t, time after the beginning of the electroreduction at a given potential, can be represented by the equations,[1-2]

$$\left(\frac{i}{i_d}\right)_t \Big/ \left(\frac{i}{i_d}\right)_\tau = \sqrt{\pi}\lambda_{ms}\sqrt{t}\exp(\lambda_{ms}^2 t)\operatorname{erfc}(\lambda_{ms}\sqrt{t}) \qquad \sqrt{\tau} \gg \sqrt{t} \tag{3}$$

$$(k_c)_{ms} = \lambda_{ms}\left(\frac{i}{i_d}\right)_\tau \sqrt{D_O} \tag{4}$$

$$(k_a)_{ms} = \lambda_{ms}\left\{1-\left(\frac{i}{i_d}\right)_\tau\right\}\sqrt{D_R} \tag{5}$$

where

$$\lambda_{ms} = \frac{(k_c)_{ms}}{\sqrt{D_O}} + \frac{(k_a)_{ms}}{\sqrt{D_R}} \tag{6}$$

D_O and D_R are the diffusion coefficients of oxidant and reductant, respectively. Since the ratio of $(i/i_d)_t$ to $(i/i_d)_\tau$ and time, t, are measurable, λ_{ms} can be evaluated at various potentials. The measured rate constants of the cathodic and the anodic process, $(k_c)_{ms}$ and $(k_a)_{ms}$, can be obtained with these λ_{ms} values. Kinetic parameters*1 of the electrode reaction are calculated from the relations,

$$(k_c)_{ms} = (k_s)_{ms}\exp\left[-\frac{(\alpha_c)_{ms}n\boldsymbol{F}}{\boldsymbol{RT}}(E-(E_0)_{ms})\right] \tag{7}$$

$$(k_a)_{ms} = (k_s)_{ms}\exp\left[\frac{(\alpha_a)_{ms}n\boldsymbol{F}}{\boldsymbol{RT}}(E-(E_0)_{ms})\right] \tag{8}$$

*1 The notations of parameters used here except $(k_s)_{corr}$, which corresponds practically to $(k_s)^c{}_{corr}$, are identical with those described previously.[2]

Plotting $\log(k_c)_{ms}$ against E and $\log(k_a)_{ms}$ against E (Fig. 3), the measured standard potential $(E_0)_{ms}$ can be obtained from the point of intersection of two straight lines, each slope of which gives the measured transfer coefficients $(\alpha_c)_{ms}$ and $(\alpha_a)_{ms}$ for the cathodic and the anodic process, respectively. The values of $(i/i_d)_t$ and $(i/i_d)_\tau$ which were obtained at various potentials and also those of $(k_c)_{ms}$ and $(k_a)_{ms}$ calculated therefrom are given in Table 2.

Frumkin Correction. All measured parameters involve the influence of the electrical double layer. On the assumption that neither reactant nor supporting electrolyte is specifically adsorbed, we can consider the effect of the double layer ac-

cording to the Frumkin correction.

The values of ϕ_2 potential at the outer Helmholtz plane of double layer were determined by the measurements of the differential capacity and the electrocapillary curve of the supporting electrolyte solution. The ϕ_2 potentials thus obtained were shown in Fig. 4.

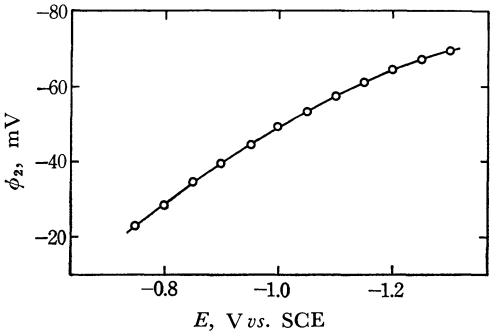

Fig. 4. Values of ϕ_2 potential at outer Helmholtz plane as a function of the electrode potential E. ϕ_2 was measured in the solution of pH 4.7 containing 0.4 M NaCl, 0.1 M acetate buffer and 2×10^{-6} M LEO at 25°C, under the assumption that no specific adsorption took place.

Arranged forms of Frumkin's equations are expressed as follows:[1]

$$(k_c)'_{ms} \equiv (k_c)_{ms}\exp\left[\frac{z_O\boldsymbol{F}}{\boldsymbol{RT}}\phi_2\right] = (k_s)_{corr}\exp\left[-\frac{(\alpha_c)_{corr}n\boldsymbol{F}}{\boldsymbol{RT}}(E-\phi_2)\right] \times\exp\left[\frac{(\alpha_c)_{corr}n\boldsymbol{F}}{\boldsymbol{RT}}(E_0)_{corr}\right] \quad (9)$$

$$(k_a)'_{ms} \equiv (k_a)_{ms}\exp\left[\frac{z_R\boldsymbol{F}}{\boldsymbol{RT}}\phi_2\right] = (k_s)_{corr}\exp\left[\frac{(\alpha_a)_{corr}n\boldsymbol{F}}{\boldsymbol{RT}}(E-\phi_2)\right] \times\exp\left[\frac{(\alpha_a)_{corr}n\boldsymbol{F}}{\boldsymbol{RT}}(E_0)_{corr}\right] \quad (10)$$

The plots of $\log(k_c)'_{ms}$ *vs.* $(E-\phi_2)$ and those of $\log(k_a)'_{ms}$ *vs.* $(E-\phi_2)$ were found to give straight lines, of which the intersection gave the corrected standard potential $(E_0)_{corr}$ and the corrected standard rate constant $(k_s)_{corr}$ and the slopes did the transfer coefficients $(\alpha_c)_{corr}$ and $(\alpha_a)_{corr}$, respectively (Fig. 5).

Kinetic parameters thus obtained are given in Table 3. The standard rate constants $(k_s)_{ms}$ and $(k_s)_{corr}$ are smaller than those of Cr–EDTA system. This may be supported by the observations that the polarographic reduction wave of Cr(III)–CyDTA complexes was more suppressed by the addition of the same amount of surface-active substances than that of Cr(III)–EDTA complexes. In this connection, it may also be interesting that on electrolysis at a constant potential, the reduced form,

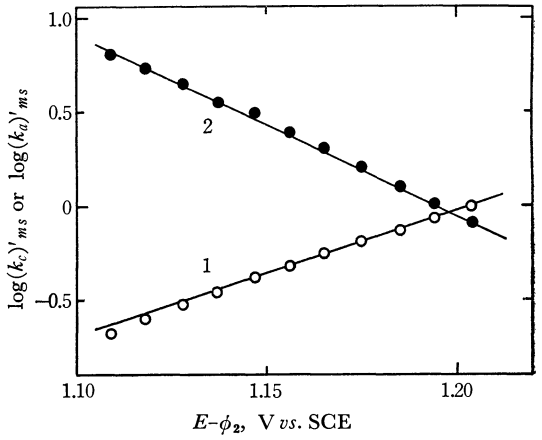

Fig. 5. (1) $\log(k_c)'_{ms}$ *vs.* $(E-\phi_2)$ and (2) $\log(k_a)'_{ms}$ *vs.* $(E-\phi_2)$ obtained with 1.0 mM Cr(III)-CyDTA in the solution of pH 4.7 containing 0.4 M NaCl, 0.1 M acetate buffer and 2×10^{-6} M LEO at 25°C. $(k_c)'_{ms}$ and $(k_a)'_{ms}$ are defined by Eqs. (9) and (10), respectively.

Table 3. Kinetic parameters of the electrode reactions of Cr(II, III)-EDTA[2] and Cr(II, III)-CyDTA systems

	Cr(II)-EDTA/ Cr(III)-EDTA	Cr(II)-CyDTA/ Cr(III)-CyDTA
$(E_0)_{ms}$, V *vs.* SCE	−1.220	−1.198
$(k_s)_{ms}$, cm sec^{-1}	0.21	0.029
$(\alpha_c)_{ms}$	0.58	0.33
$(\alpha_a)_{ms}$	0.39	0.67
$(E_0)_{corr}$, V *vs.* SCE	−1.220	−1.198
$(k_s)_{corr}$, cm sec^{-1}	17*	0.93
$(\alpha_c)_{corr}$	0.54	0.40
$(\alpha_a)_{corr}$	0.43	0.57

* This value is given for $(k_s)^c_{corr}$ in Ref. 2, which practically corresponds to $(k_s)_{corr}$ in this report.

Cr(II)–CyDTA ion, was more stable than Cr(II)–EDTA ion in the deaerated solution.

The sum of transfer coefficients, $(\alpha_c)_{ms}+(\alpha_a)_{ms}$ or $(\alpha_c)_{corr}+(\alpha_a)_{corr}$, was nearly equal to unity, and this caused $(E_0)_{ms}$ and $(E_0)_{corr}$ to be of the same value with each other.[1] Furthermore, each transfer coefficient, $(\alpha_c)_{corr}$ or $(\alpha_a)_{corr}$, seems to have a tendency to approach to 0.5 by the correction of the effect of the electrical double layer.

The polarographic half-wave potential $(E_{1/2})$, the standard potential obtained by the measurements of the equilibrium potentials, $(E_0)_e$, and those obtained by the potentiostatic method, $(E_0)_{ms}$ and $(E_0)_{corr}$, were in good agreement with each other within the experimental error.

Polarography of Halides in Dimethylformamide. III. The Chloride Ion, the Trichloromercurate Ion, and Mercuric Chloride

Yoshihisa MATSUI, Yukio KUROSAKI*1 and Yoshio DATE

Department of Agricultural Chemistry, Faculty of Agriculture, Shimane University, Nishikawazu-cho, Matsue

(Received November 27, 1969)

The polarographic behavior of the chloride ion at the dropping mercury electrode was investigated in dimethylformamide. The chloride ion gives two diffusion-controlled anodic waves. On the basis of the analysis of the waves, the first anodic wave can be ascribed to the reversible oxidation of mercury to form either the tri- or the tetrachloromercurate ion. At the more negative part of the potential in the wave, where the concentration of the chloride ion on the mercury drop is much higher than that of the mercuric ion dissolved, the higher complex species, *i.e.*, the tetrachloromercurate ion, is the main product of the electrode reaction. As the potential of the dropping electrode shifts toward less negative potentials, the concentration of the chloride ion at the electrode surface decreases more and more and the formation of the trichloromercurate ion becomes predominant. When a constant diffusion current is attained, only the trichloromercurate ion is formed and the formation of the tetrachloromercurate ion can be neglected. On the other hand, the second anodic wave can be ascribed to the reversible oxidation of mercury to mercuric chloride.

The polarographic behavior of the bromide ion, the iodide ion, and their mercuric complexes in dimethylformamide (DMF) have been reported on in previous papers.[1,2] It has been shown that each of the bromide and iodide ions gives two anodic waves; the first wave corresponds to the reversible oxidation of mercury to the trihalogenomercurate ion (HgX_3^-), and the second wave, to the reversible oxidation of mercury to mercuric halide (HgX_2).

The present investigation will deal with the mechanism of the electrode reaction of the chloride ion, the trichloromercurate ion, and mercuric chloride at the dropping mercury electrode in DMF.

Experimental

The methods of the purification of DMF and mercuric chloride and of the preparation of tetraethylammonium perchlorate and tetraethylammonium chloride were described in the previous papers.[1,2] A stock solution of tetraethylammonium trichloromercurate in DMF was prepared by adding equimolecular amounts of tetraethylammonium chloride and mercuric chloride to DMF.

The polarographic cell and the dropping mercury electrode were the same as those described previously.[1,2] D.c. polarography, controlled potential electrolysis, and conductivity measurements were carried out according to the same procedures as were used before. Likewise, all the potentials reported in the present paper refer to the aqueous saturated calomel electrode connected with the test solution by a DMF-agar salt bridge.[3]

Results and Discussion

Complex Formation between Tetraethylammonium Chloride and Mercuric Chloride in DMF. The composition of the complex ion between the chloride ion and mercuric chloride was examined in DMF by means of conductometric titration. As the previous papers showed,[1,2] information concerning the complex formation between the halide ion and the mercuric ion helps us to elucidate the mechanism of the electrode reaction of the halide ion at the dropping mercury electrode. The results are given in Fig. 1. As mercuric chloride was added to a solution of tetraethylammonium chloride in DMF, the specific conductance of the solution decreased. It attained its minimum value when the mole ratio of mercuric chloride to tetraethylammonium chloride became equal to about 0.6. This suggests that complex formation occurs in solution and that the resulting complex ion is the tetrachloromercurate ion ($HgCl_4^{2-}$). The addition of more mercuric chloride increased the specific conductance, which reached virtually a constant value when the mole ratio became equal to unity. This indicates that

the formation of the trichloromercurate ion ($HgCl_3^-$) also occurs in solution. Consequently, it is necessary to consider the formation of $HgCl_4^{2-}$, as well as those of $HgCl_3^-$ and $HgCl_2$, when the mechanism of the anodic dissolution of mercury in the presence of the chloride ion is studied in DMF.

The equivalent conductances of a few connected salts are plotted as a function of the square root of the concentration in Fig. 2. The results for tetraethylammonium chloride and tetraethylammonium trichloromercurate approximately fit the Onsager equation, indicating that these salts behave as strong electrolytes in DMF. The equivalent conductance of mercuric chloride is very low, however, and its plotting does not fit the Onsager equation, which shows that the chloride is a weak electrolyte in this medium.

D.C. Palarography. Figure 3 shows the d.c. polarograms of tetraethylammonium chloride(I), mercuric chloride(III), and their equimolar mixture, *i.e.*, tetraethylammonium trichloromercurate (II) in DMF containing 0.1 M tetraethylammonium perchlorate and 0.005% polyvinyl chloride (PVC), which was added to suppress the maximum arising on the cathodic wave of tetraethylammonium trichloromercurate or on the second cathodic wave

of mercuric chloride. The polarographic characteristics of these depolarizers at various concentrations are given in Table 1. The relation between the limiting currents and the effective heads of the dropping mercury is given in Table 2. As is shown in these tables, all the limiting currents are virtually proportional to the bulk concentrations of the corresponding depolarizers and also to the square root of the effective pressure on the mercury drop, indicating that all these waves are diffusion-controlled.

It might be considered that the mechanism of the electrolytic oxidation of mercury in the presence of the chloride ion is essentially identical with that in the presence of the bromide or iodide ion, and that it may be expressed as follows:

$$2Hg + 6Cl^- \rightleftarrows 2HgCl_3^- + 4e \quad (1)$$

$$Hg + 2HgCl_3^- \rightleftarrows 3HgCl_2 + 2e \quad (2)$$

In fact, some of the results can indeed be explained in terms of this mechanism: (1) The chloride ion gives two anodic waves, the trichloromercurate ion, two waves and anodic, cathodic, and mercuric chloride, two cathodic waves, all within the same potential region. (2) The height of the wave occurring at the more negative potential is approximately equal to twice that of the wave occurring at the more positive potential in each depolarizer.

This mechanism is also suggested by the results of the large-scale electrolysis of mercuric chloride with a controlled potential. When mercuric chloride was reduced at the potential (−0.04 V *vs.* SCE) of the plateau of the first cathodic wave, using a Hg pool cathode and a Pt plate anode, the quantity of electricity transfered per mole of the depolarizer (n) was equal to 0.77 $\boldsymbol{F}$ (calculated for Eq. (1); 0.67 $\boldsymbol{F}$); moreover, the d.c. polarogram of the catholyte agreed well with that of the trichloromercurate ion. The electroreduction of mercuric chloride at the potential (−0.62 V *vs.* SCE) of the plateau of the second cathodic wave yielded the chloride ion, the formation of which was confirmed by the d.c. polarogram of the catholyte. The value of n was equal to 2.00 $\boldsymbol{F}$ (calculated for Eqs. (1) and (2): 2.00 $\boldsymbol{F}$).

This mechanism, however, overlooks the formation of the tetrachloromercurate ion, which is clearly indicated by the conductometric titration described above. It was immediately ascertained by analyzing the d.c. polarograms of the chloride ion, that the formation of the tetrachloromercurate ion as well as that of the trichloromercurate ion must be considered. If the electrode reaction is expressed by Eqs. (1) and (2), the potential of the dropping mercury electrode is given for the first anodic wave of the chloride ion by:[1]

$$E_n = C_n + (\boldsymbol{R}T/2\boldsymbol{F}) \ln\{i/(i_d - i)^3\} \quad (3)$$

and for the second anodic wave by:

$$E_p = C_p + (\boldsymbol{R}T/2\boldsymbol{F}) \ln\{i^3/(i_d - i)^2\} \quad (4)$$

The results of the analysis of the waves are given in Fig. 4. The plot of $\log\{i^3/(i_d - i)^2\}$ against the potential for the second anodic wave gives a fairly good straight line, with a slope equal to 0.029 V (calculated for Eq. (4): 0.030 V), indicating that Eq. (2) is valid. On the other hand, the plot of $\log\{i/(i_d - i)^3\}$ against the potential for the first anodic wave became considerably curved on the less negative side. Furthermore, the slope of the

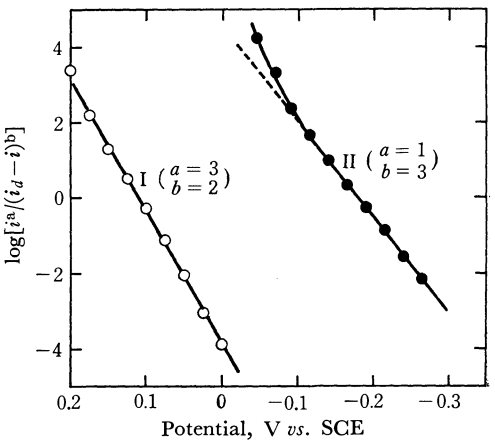

Fig. 4. Log plots for the waves of Et_4NCl.
Reciprocal slope: I, 0.029 V; II, 0.038 V

log plot (0.038 V) was somewhat greater than that expected from Eq. (3) (0.030 V).

Similar results have been reported by Given and Peover[4] in the polarographic study of lithium chloride in DMF. They assumed that the first anodic wave of the chloride ion was due to the reversible oxidation of mercury to the tetrachloromercurate ion, and they plotted log $\{i/(i_d-i)^4\}$ against the potential of the dropping mercury electrode. Their plot, however, became curved at the less negative values of the potential. They attributed the deviation of the plot to the dissociation of the tetrachloromercurate ion into the trichloromercurate ion and the chloride ion.

On the basis of these facts, we considered that the first anodic wave of the chloride ion cannot simply be ascribed to the electrochemical equilibrium expressed by Eq. (1). The tetrachloromercurate ion rather than the trichloromercurate ion is supposed to be mainly formed at the more negative part of the potential in the wave (Eqs. (5) and (6)), for here the concentration of the chloride ion on the mercury drop is much higher than that of the mercuric ion dissolved.

$$Hg \rightleftarrows Hg^{2+} + 2e \quad (5)$$

$$Hg^{2+} + 4Cl^- \rightleftarrows HgCl_4^{2-} \quad (6)$$

As the potential becomes more positive, the concentration of the mercuric ion dissolved may increase more and more and the formation of the trichloromercurate ion may become predominant (Eq. (7)):

$$Hg^{2+} + 3Cl^- \rightleftarrows HgCl_3^- \quad (7)$$

Conversely, when the trichloromercurate ion is electrolytically reduced, the tetrachloromercurate ion as well as the chloride ion may be formed at the less negative part of the potential in the cathodic wave (Eqs. (8) and (9)). Since the concentration of the trichloromercurate ion on the electrode surface may decrease with an increase in the negative potential, the formation of the tetrachloromercurate ion may be suppressed at the more negative part of the potential in the wave and the trichloromercurate ion may eventually be reduced to mercury and the chloride ion:

$$HgCl_3^- + 2e \rightleftarrows Hg + 3Cl^- \quad (8)$$

$$HgCl_3^- + Cl^- \rightleftarrows HgCl_4^{2-} \quad (9)$$

On the other hand, no data were obtained which are in conflict with the attribution of the second anodic wave of the chloride ion, as well as the anodic wave of the trichloromercurate ion and the first cathodic wave of mercuric chloride, to the electrochemical equilibrium expressed by Eq. (2).

The Equation of the More Negative Wave. If the mechanism of the anodic dissolution of mercury in the presence of Cl^- is expressed by Eqs. (5), (6), and (7), the potential at any point on the polarographic wave is given by:[5]

$$\begin{aligned} E &= C + (\boldsymbol{R}T/2\boldsymbol{F}) \ln x_0 \\ &= C' + (\boldsymbol{R}T/2\boldsymbol{F}) \ln(x_3/x_1^3) \\ &= C'' + (\boldsymbol{R}T/2\boldsymbol{F}) \ln(x_4/x_1^4) \end{aligned} \quad (10)$$

where C, C', and C'' are constant and where x_0, x_1, x_3, and x_4 are the concentrations of the simple mercuric ion, the chloride ion, the trichloromercurate ion, and the tetrachloromercurate ion respectively at the electrode surface.

Provided that a steady state is reached very quickly as the applied potential is changed, the current at any point of the wave should be equal to the sum of the rates of diffusion of the mercuric complexes formed by electrolysis. As Heyrovsky and Ilkovic[6] described, the rate of diffusion can be assumed to be directly proportional to the difference in concentration between the electrode surface and the bulk of the solution. Hence, the current should be given by:

$$i = k_3x_3 + k_4x_4 \quad (11)$$

where k_3 and k_4 are the proportionality constants of the tri- and tetrachloromercurate ions respectively, as defined by the Ilkovic equation. Likewise, the amount of the chloride ion diffusing up to the electrode surface in a unit of time should be euqal to that diffusing off from the electrode surface in the form of mercuric complexes. Hence, we obtain:

$$k_1'(*x_1 - x_1) = 3k_3x_3 + 4k_4x_4 \quad (12)$$

where k_1' is the proportionality constant of the chloride ion and where $*x_1$ is the constant concentration of the chloride ion in the bulk of the solution. The concentrations of the chloride and tetrachloromercurate ions at the electrode surface, x_1 and x_4, decrease with an increase in the anodic current of the wave, with the result that these ions are consumed for the reactions with the dissolved mercuric ion, thus forming the trichloromercurate ion. When a constant diffusion current, i_d, is attained, both x_1 and x_4 have decreased to negligibly small values. Hence, we have:

$$k_1'*x_1 = 3i_d \quad (13)$$

Eq. (13) shows that the value of k_1' is equal to three times that of the Ilkovic equation constant for the chloride ion (k_1).

By introducing Eq. (13) into Eq. (12), we obtain:

$$3i_d - k_1'x_1 = 3k_3x_3 + 4k_4x_4 \quad (14)$$

4) P. H. Given and M. E. Peover, *J. Chem. Soc.*, **1959**, 1602.

5) Since the concentrations of the species concerned are very low, we took their activity coefficients as constant for the sake of simplicity.

6) J. Heyrovsky and D. Ilkovic, *Collect. Czech. Chem. Commun.*, **7**, 198 (1935).

Since x_4 is expressed by:

$$x_4 = K_4 x_1 x_3 \tag{15}$$

where K_4 is the stepwise stability constant of the tetrachloromercurate ion, we obtain three equations for x_1, x_3, and x_4; these equations are solved as follows:

$$x_1 = (k_3/2k_1')[y - r + \{(y+r)^2 + 4ir/k_3\}^{1/2}] \tag{16}$$

$$x_3 = (1/2)[-y - r + \{(y+r)^2 + 4ir/k_3\}^{1/2}] \tag{17}$$

$$x_4 = (k_3/2k_4)[(3i_d + 2i)/k_3 + r - \{(y+r)^2 + 4ir/k_3\}^{1/2}] \tag{18}$$

where:

$$y = (3i_d - 4i)/k_3 \tag{19}$$

$$r = k_1'/k_4 K_4 \tag{20}$$

Since k_3 can be evaluated from the polarographic data, the value of y can be obtained at any point of the wave. On the other hand, the value of r is unknown; therefore, neither x_1 nor x_3 can be evaluated. However, when the plot of the potential against $\ln(x_3/x_1^3)$ calculated for an arbitrary value of r becomes linear, and when the reciprocal slope is equal to $\boldsymbol{R}T/2\boldsymbol{F}$, as is expressed by Eq. (10), the value of r must be the correct one.

Thus, as Fig. 5 shows, the linearity of the plot calculated for $r = 5 \times 10^{-4}$ M became better than that calculated for $r = \infty$ ($K_4 = 0$) and the reciprocal slope of the former (0.030 V) was in agreement with the theoretical value. In this treatment, the values of k_1' and k_3 were taken as equal to 6.63×10^{-3} and 5.28×10^{-3} A/M respectively.

The values of x_1, x_3, and x_4 calculated for $r = 5 \times 10^{-4}$ M changed with the potential of the dropping mercury electrode, as is shown in Fig. 6; the figure also clearly shows the mechanism of the electrooxidation of mercury in the presence of the chloride ion. Thus, the tetrachloromercurate ion is formed in larger quantities than the trichloromercurate ion at potentials more negative than -0.180 V *vs.* SCE. With a decrease in the negative potential, the formation of the trichloromercurate ion becomes predominant. When a constant diffusion current is attained, only the trichloromercurate ion is formed and the formation of the tetrachloromercurate ion can be neglected.

Now that the values of r and k_1' have been determined, the stepwise stability constant, K_4, of the tetrachloromercurate ion can be estimated from Eq. (20) if the value of the proportionality constant, k_4, of the tetrachloromercurate ion, as defined

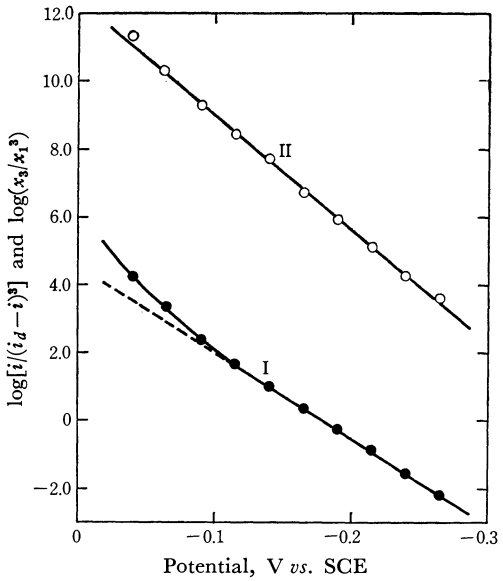

Fig. 5. Plots of $\log[i/(i_d - i)^3]$ (I) and $\log(x_3/x_1^3)$ (II) *vs.* potential for the more negative wave of Et_4NCl.

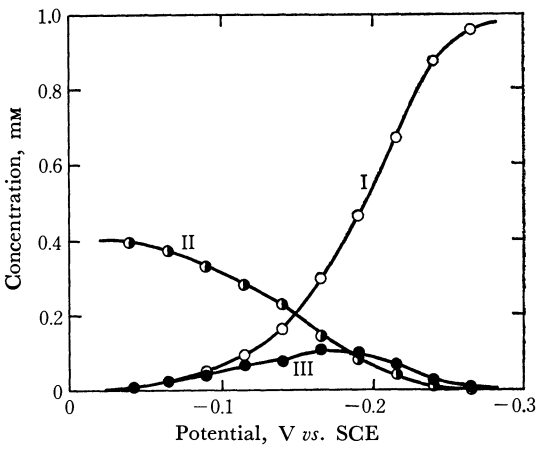

Fig. 6. Plots of the calculated concentrations of Cl^-(I), $HgCl_3^-$(II), and $HgCl_4^{2-}$(III) on the electrode surface *vs.* potential.

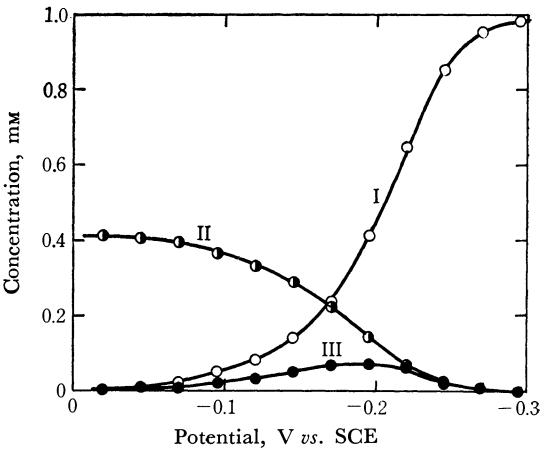

Fig. 7. Plots of the calculated concentrations of Br^-(I), $HgBr_3^-$(II), and $HgBr_4^{2-}$(III) on the electrode surface *vs.* potential.

by the Ilkovic equation, is determined. However, the value of k_4 could not be determined, because we could found no condition under which only the tetrachloromercurate ion exists as a depolarizer in the DMF solution. Assuming that k_4 is approximately equal to k_3, we can roughly estimate the value of K_4 to be 2.5×10^3 M^{-1}.

In the previous papers dealing with the polarographic behavior of the bromide ion[1] and the iodide ion,[2] the formation of the tetrahalogenomercurate ion was not considered. Indeed, it might not be necessary to consider the formation of the tetraiodomercurate ion, because the plot of log $\{i/(i_d-i)^3\}$ *vs.* the potential of the dropping mercury electrode for the first anodic wave of the iodide ion yielded a straight line of the reciprocal slope equal to 0.030 V; this is in agreement with the theoretical value obtained on the basis of the formation of the triiodomercurate ion alone. However, the reciprocal slope of such a plot for the first anodic wave of the bromide ion was equal to 0.035 V, somewhat greater than the theoretical value. Since the oxidation process was proved to be reversible, this increase in the reciprocal slope indicates that the formation of the tetrabromomercurate ion may simultaneously take place. The same method of analyzing the wave as was used for the wave of the chloride ion was applied to the first anodic wave of the bromide ion; the value of r was thus estimated to be 1×10^{-3} M ($K_4=1.3\times10^3$ M^{-1}). Figure 7 shows the change in x_1, x_3, and x_4 with the potential of the dropping mercury electrode. It is apparent that the tetrabromomercurate ion is also formed in an appreciable quantity. In the case of the wave of the iodide ion, the plot of the potential against log $(x_3/x_1{}^3)$ calculated for the r value of 1×10^{-2} M became linear and the reciprocal slope was equal to 0.0295 V, indicating that the value of K_4 for the tetraiodomercurate ion is no more than 1.3×10^2 M^{-1}.

Accordingly, it can be said that the tetrahalogenomercurate ion is always formed at the first anodic wave of any halide ion. However, the value of the K_4 of the tetraiodomercurate ion is so small that it is not necessary to consider the formation of this complex ion in the anodic dissolution of mercury in the presence of the iodide ion. On the other hand, the K_4 values of the tetrabromo- and tetrachloromercurate ions are so large that the formation of these complex ions cannot be neglected when either the bromide ion or the chloride ion is a depolarizer.

Polarography of Halides in Dimethylformamide. IV. The Stability Constants of the Halo Complexes of Mercury(II)

Yoshihisa MATSUI and Yoshio DATE

Department of Agricultural Chemistry, Faculty of Agriculture, Shimane University, Nishikawazu-cho, Matsue

(Received December 10, 1969)

The overall stability constants (β) of mercuric halide and the tri- and tetrahalogenomercurate ions in dimethylformamide containing 0.1 M tetraethylammonium perchlorate were evaluated by the polarographic method at 25°C. The values of log β obtained were: 24.16 for $HgCl_2$, 31.23 for $HgCl_3^-$, 34.57 for $HgCl_4^{2-}$, 24.17 for $HgBr_2$, 31.62 for $HgBr_3^-$, 34.73 for $HgBr_4^{2-}$, 25.93 for HgI_2, 33.34 for HgI_3^-, and 36.02 for HgI_4^{2-}.

A number of workers have evaluated the stability constants of the halo complexes of mercury(II) in an aqueous solution,[1] but only a few workers have done so in non-aqueous solutions. Ellendt and Cruse[2] have evaluated the stepwise stability constants of the tri- and tetrahalogenomercurate ions in acetonitrile by means of conductivity measurements. Given and Peover[3] and Breant and Kiet[4] have determined the overall stability constants of the tetrahalogenomercurate ion in dimethylformamide (DMF) by the polarographic method. These results show that the halo complexes of mercury(II) are generally more stable in non-aqueous solutions than in an aqueous solution.

In the previous papers of this series,[5-7] the mechanism of the electrooxidation of mercury in the presence of the halide ion was studied in DMF by means of polarography; the current-potential curve thus obtained was interpreted on the basis of the formation of complex ions of the $HgX_j^{(2-j)}$ type, where j has values from 2 to 4. In the present experiment, the overall stability constants of these complex ions were determined in DMF containing 0.1 M tetraethylammonium perchlorate by means of an analysis of the d.c. polarographic waves.

Experimental

The solvent and the supporting electrolyte used were purified as has been described previously.[6] Polarograms were obtained in a manner similar to that described before. Likewise, all the potentials reported in the present paper refer to an aqueous, saturated calomel electrode connected with a test solution by a DMF-agar salt bridge.[8]

Preparation of Solutions of Mercuric Perchlorate in DMF. According to the directions of Given and Peover,[3] mercuric perchlorate was prepared in a concentrated aqueous solution by neutralizing 60% perchloric acid with solid mercuric oxide. As a small amount of a yellow solid was precipitated, the supernatant of the mixture was pipetted out and standardized by titration against an aqueous potassium thiocyanate solution, using ferric ammonium sulfate as the indicator. Test solutions of mercuric perchlorate in DMF were then prepared from this aqueous solution. The water introduced during this procedure (*ca.* 10 mM) was not removed.

Results

The Standard Potential of Mercury in DMF. In order to evaluate the stability constants of complex ions of mercury(II) by means of polarography, it is necessary to determine the ordinary standard potential($E°$) of the mercury-mercury(II) ion half-cell,[9] which is expressed by the equation:

$$E° = E - (\boldsymbol{R}T/2\boldsymbol{F}) \ln x_0 \quad (1)$$

where x_0 is the concentration of the simple or the solvated mercury(II) ion on the dropping mercury electrode at the potential E V *vs.* SCE.[10] The value of x_0 can be obtained by:

$$x_0 = {}^*x_0 - i/k_0 \quad (2)$$

where $*x_0$ is the concentration of the mercury(II) ion in the bulk of the solution; i, the cathodic current flowing at the potential E, and k_0, the Ilkovic equation constant for the mercury(II) ion. The constant k_0, which is equal to $i_d/*x_0$, can be determined by measuring the cathodic diffusion current, i_d, flowing as a result of the reduction of the mercuric perchlorate at a given concentration, $*x_0$.

Figure 1 shows a polarogram of 0.97 mM mercuric perchlorate obtained in DMF containing 0.1 M tetraethylammonium perchlorate at 25°C. An acute maximum was observed at every concentration of the mercury(II) ion studied. The height of this maximum increased with an increase in the concentration of the depolarizer. It was suppressed only a little by the addition of polyvinyl chloride, which is known to suppress the maxima given by various metal ions in DMF.[6,11] Immediately after the maximum was passed, the current suddenly decreased and reached the plateau of the wave. The height of the plateau was nearly proportional to the concentration of the depolarizer and to the square root of the effective height of the mercury head (Table 1); this indicates that the limiting current is controlled by diffusion.

From these polarographic data, k_0 was calculated to be 3.54×10^{-3} A/M. The value of E° could be determined directly from the polarographic data of the mercuric perchlorate if no maximum wave appeared. In practice, however, the value of E° was calculated from the polarographic data concerning the anodic dissolution of mercury in DMF containing 0.1 M tetraethylammonium perchlorate. The value of E at an arbitrary current of -1 μA was found to be 0.452 ± 0.004 V *vs.* SCE, while the value of E° was calculated from Eqs. (1) and (2) as 0.557 ± 0.004 V *vs.* SCE.

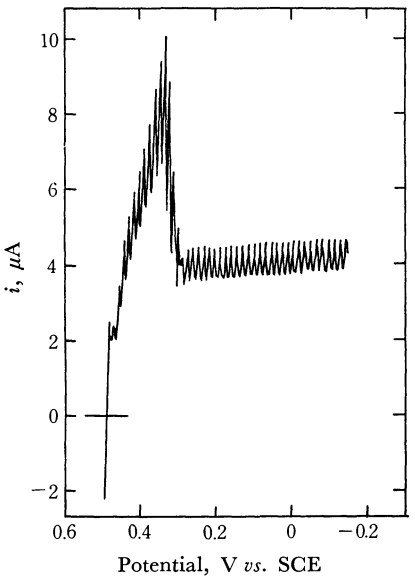

Fig. 1. Polarogram of 0.97 mM mercuric perchlorate in DMF at 25°C.

Table 1. Relation between the limiting current (i_d) of 0.97 mM mercuric perchlorate and pressure on the dropping mercury ($h_{corr.}$)

$h_{corr.}$ (cm)	i_d (μA)	$i_d/(h_{corr.})^{1/2}$
37.3	3.25	0.532
44.3	3.47	0.521
54.3	3.84	0.521
64.3	4.18	0.521
74.3	4.48	0.520

It is remarkable that the standard potential of mercury is more negative in DMF than in water ($E^\circ=0.589$ V *vs.* SCE, obtained in water at an ionic strength of 1.0 M[12]) even though the dielectric constant of DMF is lower than that of water. This indicates that the mercury(II) ion may be strongly solvated in DMF. The specific solvation of the mercury(II) ion by DMF was also suggested by the fact that the diffusion constant of the mercury(II) ion in DMF (3.92×10^{-6} cm^2 sec^{-1} at 25°C), calculated on the basis of the Ilkovic equation, was unusually small compared with that in an aqueous solution (8.2×10^{-6} cm^2 sec^{-1} at 25°C[13]). The solvated mercury(II) ion must be unstable, for it was observed that metallic mercury was separated out from the 0.1 M solution of mercuric perchlorate in DMF when it was left standing at room temperature for a few days. This may be due to the reduction of the mercury(II) ion by one-electron transfer from the solvating DMF molecules.

Evaluation of the Stability Constants of the Tri- and Tetrahalogenomercurate Ions. When the halide ion is added to a 0.1 M solution of tetraethylammonium perchlorate in DMF, two new anodic waves appear. This can be explained in terms of the formation of complexes between the halide ion and the mercury(II) ion.[5-7] The general equation, which relates the potential of the dropping mercury electrode to the current flowing when mercury is oxidized to form complex ions, is:[9]

$$E = E^\circ + (\boldsymbol{R}T/2\boldsymbol{F})\ln(i/k_c) - (\boldsymbol{R}T/2\boldsymbol{F})\ln F_0(x) \quad (3)$$

10) The concentration of the simple mercury(II) ion is, compared with that of the supporting electrolyte, so low that the activity coefficient of the former may be constant; therefore, it was assumed to be equal to one for the sake of simplicity.

where:

$$F_0(x) = 1 + \beta_1 x + \beta_2 x^2 + \cdots + \beta_j x^j \quad (4)$$

In this equation, x represents the concentration o the halide ion at the electrode surface; β_j, the overall stability constant of the complex $HgX_j^{(2-j)}$, and k_c, the Ilkovic equation constant for the complex ions. The value of k_c may vary with different complex ions, but the variation seems to be very slight and so the value was assumed to be constant throughout this series. The value of $F_0(x)$ can be readily obtained at every potential of the waves from Eq. (3), since the other terms in Eq. (3) are experimental quantities.

At the potential corresponding to the more negative of the polarographic waves given by the halide ion, only two halo complexes, *i.e.*, the tri- and tetrahalogenomercurate ions, are formed by the reactions:[7]

$$Hg + 4X^- \rightleftarrows HgX_4^{2-} + 2e \quad (5)$$

$$Hg + 3X^- \rightleftarrows HgX_3^- + 2e \quad (6)$$

The presence of the other complex ions can be disregarded. Thus,

$$F_0(x) = \beta_3 x^3 + \beta_4 x^4 \quad (7)$$

When K_4 denotes the stepwise stability constant of the tetrahalogenomercurate ion, we obtain:

$$F_0(x) = \beta_3 x^3(1 + K_4 x)$$

or:

$$\log F_0(x) = \log \beta_3 + 3 \log x + \log(1 + K_4 x) \quad (8)$$

In this equation, x can be expressed by the equation:[7]

$$x = (k_c/6k_x)[y - r + \{(y+r)^2 + 4ir/k_c\}^{1/2}] \quad (9)$$

where:

$$y = (3i_d - 4i)/k_c$$

$$r = 3k_x/k_c K_4$$

and where k_x is the Ilkovic equation constant for the halide ion. Since the terms on the right side of Eq. (9) are all experimental quantities except for r, which has been roughly estimated for every halide ion in a manner described in a previous paper,[7] the value of x can be evaluated at every potential of the waves.

Figure 2 is a plot of $\log F_0(x)$ *vs.* $\log x$ for the polarographic data of 1.0 mM tetraethylammonium chloride, where the value of r was taken to be 5×10^{-4} M. As is to be expected from Eq. (8), the plot becomes linear, with a slope of 3.0, in the region where the value of x is small enough for the term of $\log(1 + K_4 x)$ to be disregarded. Thus, the value of $\log \beta_3$, which is approximately equal to $\log F_0(x) - 3\log x$ if the term of $\log(1 + K_4 x)$ is negligible, was calculated to be 31.23. The value of $\log K_4$ was also determined to be 3.34 by the measurement of the deviation of the plot from linearity. The solid curve shown in Fig. 2 was calculated using these values for the stability constants obtained. It seems that the values can adequately account for the polarographic data.

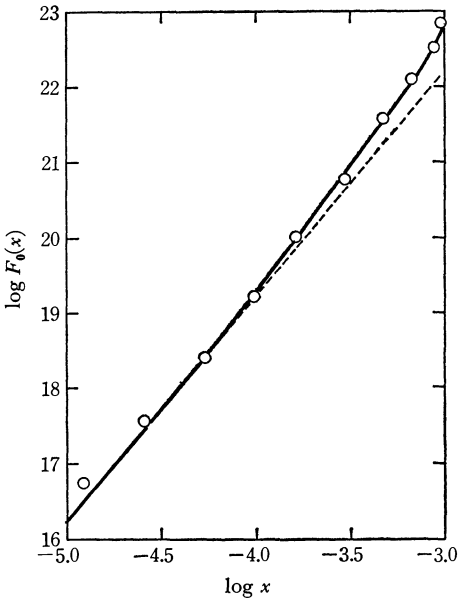

Fig. 2. Plot of $\log F_0(x)$ *vs.* $\log x$ for the more negative wave of the chloride ion.
The solid line was calculated with the stability constants in Table 2.

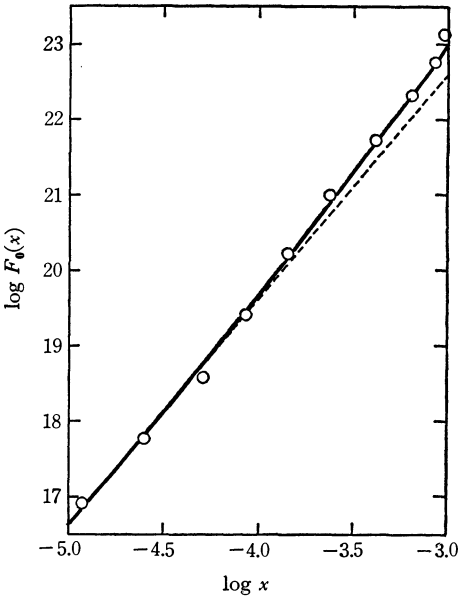

Fig. 3. Plot of $\log F_0(x)$ *vs.* $\log x$ for the more negative wave of the bromide ion.
The solid line was calculated with the stability constants in Table 2.

A similar procedure was applied to the more negative of the waves given by a 1.0-mM solution of tetraethylammonium bromide or iodide in DMF.

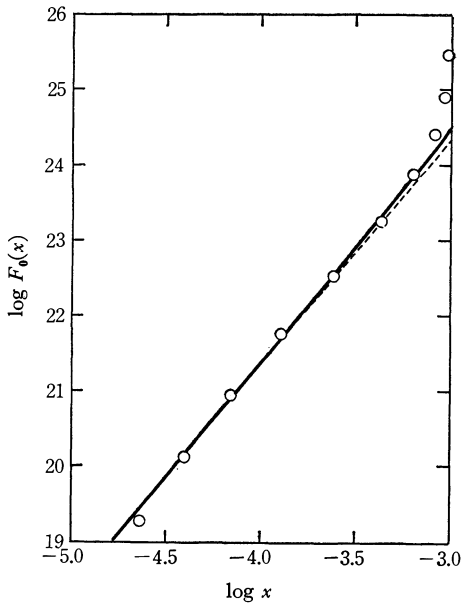

Fig. 4. Plot of log $F_0(x)$ *vs.* log x for the more negative wave of the iodide ion.
The solid line was calculated with the stability constants in Table 2.

Table 2. Stability constants of the halo complexes of mercury(II) in DMF containing 0.1 M tetraethylammonium perchlorate at 25°C

Ligand	log β_2	log K_3	log β_3	log K_4	log β_4
Cl^-	24.16	7.07	31.23	3.34	34.57
Br^-	24.17	7.45	31.62	3.11	34.73
I^-	25.93	7.41	33.34	2.68	36.02

The variation in log $F_0(x)$ with the log x value is shown in Fig. 3 for the bromide ion (r is taken as 1×10^{-3} M) and in Fig. 4 for the iodide ion (r is taken as 1×10^{-2} M). All the values of β_3, K_4, and β_4 obtained are given in Table 2. Every plot of log $F_0(x)$ *vs.* log x was found to deviate from the calculated solid curve, especially in the case of the iodide ion, in the potential range where the anodic current begins to flow. This may be due to the adsorption of the depolarizers on the electrode surface, as has previously been descrived.[6]

Evaluation of the Stability Constant of Mercuric Halide. The overall stability constant of mercuric halide can be determined more easily than those of the tri- and tetrahalogenomercurate ions. As has been described in previous papers[5-7] the more positive of the polarographic waves given by the halide ion in DMF is due to the reversible oxidation of mercury to mercuric halide. Since the concentrations of the halide ion and the tetrahalogenomercurate ion at the electrode surface become negligible at the potential corresponding to the plateau of the more negative wave, the electrode reaction at the more positive wave can be simply expressed by the equation:

$$Hg + 2HgX_3^- \rightleftarrows 3HgX_2 + 2e \qquad (10)$$

Therefore, the potential of the dropping mercury electrode at any point of this wave should be given by:

$$E = E^\circ + (\boldsymbol{R}T/2\boldsymbol{F})\ln(\beta_3^2/\beta_2^3) + (\boldsymbol{R}T/2\boldsymbol{F})\ln(x_2^3/x_3^2) \qquad (11)$$

where x_2 and x_3 are the concentrations of mercuric halide and the trihalogenomercurate ion respectively at the electrode surface. x_2 and x_3 are expressed by:

$$x_2 = 3(i-i_d)/k_c \qquad (12)$$

$$x_3 = 2(i_d'-i)/k_c \qquad (13)$$

where the current flowing at any point of the wave (i), as well as the diffusion current of the first and second anodic waves (i_d and i_d' respectively), is measured on the basis of the total anodic current. By introducing Eqs. (12) and (13) into Eq. (11) and by rearranging the resulting equation, we obtain:

$$\log\beta_2 = (1/3)\{2\boldsymbol{F}(E^\circ-E)/2.303\boldsymbol{R}T + 2\log\beta_3 + \log(27/4k_c) + \log(i-i_d)^3/(i_d'-i)^2\} \qquad (14)$$

Since the terms on the right side are either experimental quantities or known ones, the value of log β_2 can be readily calculated at any potential of the wave. As an example, the results of the calculation for the wave given by the bromide ion are given in Table 3. The mean values of log β_2 thus obtained for various halides are given in Table 2.

Table 3. Log β_2 calculated at various potentials in the more positive wave of the bromide ion

E (V *vs.* SCE)	i (μA)*	log β_2
0.056	2.31	24.19

0.231	3.10	24.22

* $i_d=2.26\,\mu$A and $i_d'=3.16\,\mu$A.

Discussion

Among the stability constants obtained in this work, only that of the tetrahalogenomercurate ion can be compared with those in earlier works, since the other constants in DMF have never been reported. Given and Peover[3] have determined the value of log β_4 to be about 30 for $HgCl_4^{2-}$ in DMF containing 1.0 M lithium perchlorate, and to be 38.79 for HgI_4^{2-} in DMF containing 0.1 M lithium perchlorate, by means of polarography at

20°C. Their procedure for determining the constants requires the measurement of the potential of the dropping mercury electrode, at an arbitrary current of $-1.0\ \mu A$, as a function of the concentration of the halide ion. In using this method, the concentration of the complexing agent in the bulk of the solution must be high enough to be effectively equal to that on the electrode surface when any slight current is flowing. Consequently, only the overall stability constant of the highest complex ion of mercury(II) can be evaluated by this procedure. Moreover, in applying this method we must pay attention to the possibility that the potential of the dropping mercury electrode at $-1\ \mu A$ can be shifted in a more negative direction by the adsorption of the depolarizer. Breant and Kiet,[4] using the same method as Given and Peover, also determined the values of log β_4 to be 32.9 for $HgCl_4^{2-}$, 35.2 for $HgBr_4^{2-}$, and 36.6 for HgI_4^{2-} in DMF containing 0.1 M perchloric acid. The values presented by them agree approximately with those in the present work, although the two sets of experimental conditions are not quite the same.

It is well known that the stabilities of the halo complexes of such metallic ions as Cu(I), Ag(I), Cd(II), and Hg(II), whose electronic configurations are representative of pseudo-inert gas ($s^2p^6d^{10}$), as opposed to those whose electronic configurations are representative of noble gas (s^2p^6), increase in an aqueous solution in the following order:

$$F^- < Cl^- < Br^- < I^-$$

This has been explained in terms of the mutual polarization of the metallic ions and ligands. The results in Table 2 show that the alteration in the stability of the complex ions with the ligands in DMF follows the same sequence as that in an aqueous solution (Table 4[1]), although the former is not so great as the latter. The difference in electronegativity between mercury and halogen ($\Delta\chi_{Hg-F}=2.1$, $\Delta\chi_{Hg-Cl}=1.1$, $\Delta\chi_{Hg-Br}=0.9$, and $\Delta\chi_{Hg-I}=0.6$[14]) indicates that all the bonds of Hg–Cl, Hg–Br, and Hg–I are rich in covalent character, and that this covalent character decreases and the ionic character increases in the following sequence:

$$Hg\text{-}I < Hg\text{-}Br < Hg\text{-}Cl < Hg\text{-}F$$

However, no such difference in bond character among them can be clearly observed in DMF. This may be due to the low dielectric constant of DMF (37.8[11]). On the other hand, the dielectric constant of water (78.54) may be high enough to distinguish the difference in bond character.

It is interesting that the values of K_4 of $HgCl_4^{2-}$, $HgBr_4^{2-}$, and HgI_4^{2-} decrease in this order. This may be related to the difference in the ionic radii of the halide ions. As has been described above, the bond between mercury and iodine is essentially covalent in character. As the value of β_3 of HgI_3^- is very large, it may be considered that each covalent Hg–I bond in HgI_3^- is readily formed without any steric hindrance from the other iodide ions. The formation of the fourth Hg–I bond, on the other hand, may be sterically hindered by the other three iodide ions already combined with the mercury(II) ion. Probably as a result, the K_4 value of HgI_4^{2-} becomes very small. As the ionic radii of I^-, Br^-, and Cl^- decrease in this order, the stepwise stability constants increase in that sequence. No such steric hindrance can be observed in an aqueous solution (Table 4), probably because, in water, the effect of the difference in bond character among Hg–Cl, Hg–Br, and Hg–I on the stability constant becomes larger than the steric effect.

cis-Tricarbonylbistriphenylphosphinemanganese and the Related Compounds*1

Hiroaki NAKAYAMA*2

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received December 6, 1969)

Tricarbonyl-methylcyclopentadienylmanganese(I) (I) gives two manganese carbonyl triphenylphosphine compounds when treated with triphenylphosphine in the presence of a sodium dispersion, with tetrahydrofuran used as the solvent. One compound is a known diamagnetic $(CH_3C_5H_4)Mn(CO)_2(PPh_3)$ (II) (38% yield) formed by a ligand substitution reaction without any change in the oxidation number of the central manganese(+1). The other compound is a novel paramagnetic manganese(0) compound, *cis*-$Mn(CO)_3(PPh_3)_2$ (III) (25% yield), which may be formed by a reductive phosphination reaction. A *cis* trigonal bipyramidal configuration, as in the case reported for $Fe(CO)_3(o\text{-}(AsMe_2)_2C_6H_4)$, is proposed for III on the basis of the results of infrared spectroscopy. The compound III gives the following derivatives: $BrMn(CO)_3(PPh_3)_2$, VI, $CH_3Mn(CO)_3(PPh_3)_2$, VII, and $Mn(CO)_3(PPh_3)_2 \cdot 1/2 \cdot CHCl_3$, VIII.

Manganese carbonyl compounds are generally prepared by reductive carbonylation methods,[1,2] in which compounds of manganese in its higher oxidation state are reduced in the presence of ligand carbon monoxide in ethereal solvents. By analogy with this, triphenylphosphine (PPh_3) can also be expected to react with the metal compounds in reductive phosphination reactions in appropriate solvents. In this experiment, methylcyclopentadienyltricarbonylmanganese(I) (I), a well-known starting material for the preparation of manganese carbonyl compounds,[2] was treated reductively with a sodium dispersion in the presence of triphenylphosphine in tetrahydrofuran(THF); a novel paramagnetic manganese(0) compounds, *cis*-tricarbonyl-bistriphenylphosphinemanganese(0) (III), and a known compound, methylcyclopentadienyldicarbonyltriphenylphosphinemanganese(I) (II), were thus obtained. The latter, II, was identical with the previously-reported compound prepared by the ultraviolet radiation reaction of I and PPh_3 in cyclohexane,[3] or by heating a mixture of I and PPh_3 without any solvent at a temperature higher than 250°C.[3] With regard to the former paramagnetic compound, III, paramagnetic pentacoordinated manganese carbonyl derivatives, which do not obey the inert gas rule, have scarcely been reported. Two examples are $Mn(CO)_4PR_3$[4] and $Mn(CO)_3$(Diphos).*3,[5]

Experimental*4

Reagents. Triphenylphosphine (PPh_3) was prepared by the method in the literature[6] and then recrystallized from ethanol. All the solvents used were distilled under a nitrogen atmosphere after ordinary purification procedures. A combustion Improver 2, Ethyl Corporation, containing a small amount of organic orange dyes, was used as methylcyclopentadienyltricarbonylmanganese(I) without any further purification. A sodium dispersion, 40% in toluene (Kawaken Fine Chemicals, Co., Ltd.), was employed.

Synthesis in THF Solvent. Compound I (9.6 g; 44 mmol) was treated with PPh_3 (23.0 g; 88 mmol) and a sodium dispersion (9.3 g, 40% in toluene; Na 160 mmol) in THF (150 ml) under a nitrogen atmosphere. When the mixture was shaken, gas evolution was observed. The shaking was continued for 7 hr, after which the sodium dispersion was filtered off. Then the filtrate and the washings were evacuated under nitrogen. The dark brown tarry residue was treated with concd. hydrochloric acid and heated on a water

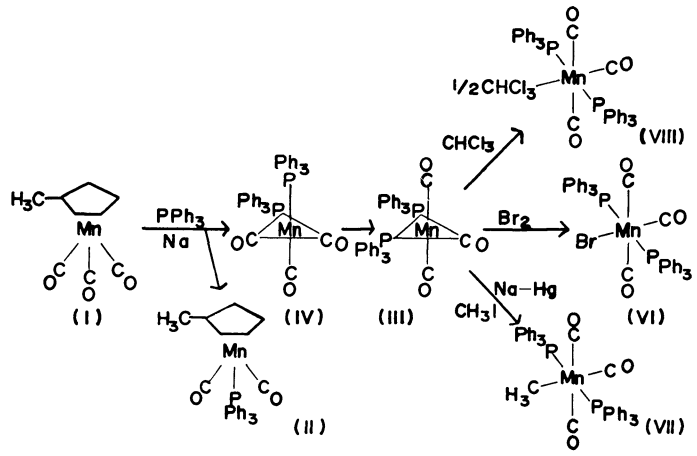

Scheme 1

bath. The residue turned into a brownish red viscous liquid; the phase of concd. hydrochloric acid was decanted away before cooling. Again concd. hydrochloric acid was added and decanted away. The residual viscous liquid was repeatedly treated with hot ethanol. Then a yellow precipitate and a brownish-red ethanol solution were obtained; they were separated by filtration. The precipitate was washed with water and then with ethanol. The crude product, tricarbonylbistriphenylphosphinemanganese, III (7.41 g, 25% yield), was recrystallized from benzene and then from acetone. The pale yellow crystals were dried *in vacuo*. A yellow chloroform adduct, $Mn(CO)_3(PPh_3)_2 \cdot 1/2\text{-}CHCl_3$, VIII, was obtained by the repeated recrystallization of III from chloroform-petroleum ether under nitrogen; it was then dried *in vacuo*. While the filtrate and the washings were combined and evaporated under reduced pressure. The crude product, methylcyclopentadienyldicarbonylmonotriphenylphosphinemanganese, II (7.75 g; 38% yield), was recrystallized from ethanol, and the resulting yellow needle crystals were measured after drying *in vacuo*. It sublimed at 100°C/10^{-4} mmHg and melted at 117°C (lit,[3] 119—20°C).

Synthesis in Dioxane Solvent. Compound I (3.35 g; 15.4 mmol) and PPh_3 (8.04 g; 30.7 mmol) were refluxed with a sodium lump (0.39 g; 17 mmol) in dioxane (55 m*l*) under a nitrogen atmosphere for 6 hr. The clear orange solution turned dark red after 30 min. After 70 min, the solution offered a clear brownish yellow color which did not change until the refluxing was stopped after 6 hr. After having been left nine days, the mixture was treated by a procedure similar to that used in the synthesis in THF. Yellow needle crystals of II were obtained in a yield of 69.4% (4.82 g), but III could not be separated in this procedure.

Synthesis in THF Solvent under Carbon Monoxide. Compound I (10.1 g; 46.1 mmol) was treated with PPh_3 (23.0 g; 88 mmol) and a sodium dispersion (16.5 g; 40% in toluene; Na 287 mmol) in THF (150 m*l*). The mixture was transferred into a 300-m*l* autoclave under a nitrogen atmosphere. The autoclave was purged twice with carbon monoxide at 60 atm and then vented to 10 atm at room temperature. It was heated to 130°C with rocking, the pressure being kept at 18 atm. When it was cooled after 6.5 hr, the barometer indicated 0 atm. The carbon monoxide was vented out, and the reaction mixture was filtered in air. The filtrate was treated by a procedure similar to that used in the synthesis under atmospheric pressure. Compound III was obtained as a yellow powder in a poor yield (44.1 mg, 0.14%); it was washed with hot ethanol, and then repeatedly with water and ethanol, and dried in air.

Reaction in THF Solvent under Atmospheric Pressure and at a Higher Temperature. Compound I (2.06 g; 9.45 mmol) and PPh_3 (5.20 g; 20 mmol) were refluxed with a sodium dispersion (1.58 g, 40% in toluene; Na 27.5 mmol) in THF (30 m*l*) under a nitrogen atmosphere for half an hour. The residual sodium was quenched with water after cooling, and phosphoric acid was added to the mixture. A suspension composed of aqueous and organic layers was thus obtained. The brown organic layer was extracted with petroleum ether; the aqueous layer was neutralized with sodium carbonate and extracted with THF. The THF extract was evacuated, and the residue was extracted with petroleum ether. The petroleum ether solution thus obtained was put together with the petroleum ether extract of the organic layer. The resulting petroleum ether solution was dried with calcium chloride and evaporated to deposit brown crystals. The crystals were dissolved with hot petroleum ether. Crystalline II was deposited instantaneously by cooling. Another brown crystal, IV, was obtained later on, although the main solute of the solution was confirmed to be II by a study of the infrared spectra.

Bromotricarbonylbistriphenylphosphinemanganese(I) (VI). Compound III (185.9 mg; 0.295 mmol) was treated with bromine (more than 29.5 mg; 0.184 mmol) in chloroform (50 m*l*). On occasional shaking, the red color turned orange, green, and at last yellow. White crystals were filtered off after 2 hr. The filtrate was evacuated to dryness. The residue was washed with diethyl ether and recrystallized from chloroform-petroleum ether. Yellowish brown crystals, VI, were thus obtained.

Methyltricarbonylbistriphenylphosphinemanganese(I) (VII). Compound III (98.5 mg; 0.149 mmol)

was treated with a sodium amalgam (prepared by dissolving 1.2 g (52 mmol) of sodium metal in 13 m*l* of mercury) in THF (35 m*l*) under a nitrogen atmosphere. The mixture was left stand with occasional shaking. The yellow color turned brown during a 4-hr period. The mercury layer was then poured off, and the THF solution was filtered. The filtrate was treated with methyl iodide (8 m*l*; 130 mmol). The color gradually turned a greyish yellow green and then a transparent, yellowish brown on leaving still. The solution was filtered and evaporated. The residue was recrystallized from benzene-petroleum ether under a nitrogen atmosphere. Yellowish brown crystals, VII, were thus obtained.

Physical Measurements. *The Molecular Weights* were determined in benzene or in methylethylketone with a Mechrolab, model 301 A, osmometer.

The Magnetic Susceptibilities were measured with Gouy balances at room temperature.*5 Cobalt(II) mercury(II) tetrathiocyanate ($\chi_g = 16.44 \pm 0.08 \times 10^{-6}$ c.g.s.e.m.u., 20°C) was used as the standard substance for III and II, while water ($\chi_g = -0.722 \times 10^{-6}$ c.g.s.e.m.u., 25°C) was used for VIII diluted with NaCl.[7]

The Infrared Spectra were recorded with Japan Optics DS-402G, Japan Optics IR-G, and Perkin Elmer model 137B Infracord recording spectrometers for the samples in the nujol mulls and KBr disks.

The ESR Spectra were recorded with a JEOL JES-118 spectrometer.

The ^1H NMR Spectra were recorded on a Varian HA-100 high-resolution spectrometer, using carbon tetrachloride as the solvent and tetramethylsilane as the internal reference.

Results and Discussion

Condition of the Synthesis. Ordinarily in the present experiment, the synthetic procedure was performed by shaking the THF solution of the reactants with a mechanical shaker at room temperature and at an atmospheric pressure of nitrogen. Two other conditions were investigated in an attempt to obtain III in a better yield and with more certainty. One of them was the reaction at so high a temperature that the sodium metal melted to react more completely with I. The THF solvent was replaced with dioxane for this purpose. Though this experiment was unsuccessful, purified II was obtained in a higher yield (69.4%) than that in the literature.[3],*6 The other reaction has at a higher temperature and at 10 atm of carbon monoxide in order to restrain the CO elimination. In this procedure, however, III was obtained in only a low yield (0.14%).

Tricarbonyl bistriphenylphosphine manganese(0) (III), $Mn(CO)_3(PPh_3)_2$. Compound III is composed of yellow, needle-like crystal readily air-oxidized in solution, although it is moderately stable against aereal oxidation in the solid state. The dilute chloroform solution of III gives no signal on an ESR spectrometer at temperature of liquid nitrogen under a nitrogen atmosphere, but it gives that of a high-spin manganese(II) compound after a short exposure to the air. Therefore, all the experiments, unless otherwise noted, were performed under a nitrogen atmosphere.

The results of the elementary analyses are listed in Table 1. The values observed on the pale yellow crystals recrystallized from benzene or from acetone do not agree well with those calculated in accordance with the formula noted above. This

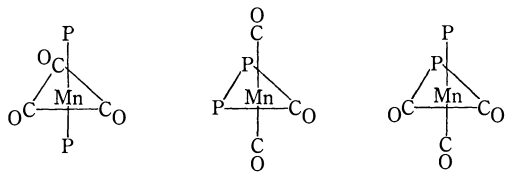
Fig. 1. Infrared spectra.

cannot be attributed to the solvation of the compound (see Table 1). Though those on the yellow crystals recrystallized from chloroform-petroleum ether agree well with the solvated formula: $Mn(CO)_3(PPh_3)_2 \cdot 1/2CHCl_3$, VIII, their infrared spectra are not identical with those of the crystals recrystallized from the former two solvents (see Table 2 and Fig. 1).

The molecular weight of III in a benzene solution (Table 1) agrees very well with that calculated according to the monomeric formula, $Mn(CO)_3(PPh_3)_2$.

The infrared spectra and the wave numbers of III and VIII are shown in Fig. 1 and in Table 2. The absence of a band at about 840 cm^{-1}, characteristic of the methylcyclopentadienyl ligand, supports the idea that the $CH_3C_5H_4$ ligand of I is replaced in III. The absorption bands observed at from 760 cm^{-1} to 680 cm^{-1} can be assigned to the CH out-of-plane deformation bands of PPh_3. Three bands (one of them a doublet) in the C–O stretching region show that three CO ligands of I are not replaced. The C–O stretching pattern of pentacoordinated $M(CO)_3L_2$ was discussed by Cotton and Parish[8] and supplied by Manuel.[9] Only one infrared active band was observed for the D_{3h} symmetrical, *trans*-disubstituted trigonal bipyramidal (TBP) complexes (at 1930 cm^{-1} for rhenium[10]).



trans (D_{3h}) *cis* (C_{2v}) *cis* (C_s)

P: PPh_3

On the other hand, three bands like III were observed for most of the *cis*-$M(CO)_3L_2$, $M(CO)_3$-(Diphos),*4 and $M(CO)_3$(Diars)*7 (see Table 2). Since the (Diphos) and (Diars) ligands cannot form a monomeric *trans*-disubstituted complex, the C_{2v}

*7 (Diars) means Me_2As *o*-$C_6H_4AsMe_2$.

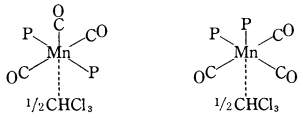
or C_s symmetrical *cis*-disubstituted TBP structures were assigned to these complexes. The band pattern of III most resembles that of $Fe(CO)_3$(Diars),[11] for every band of the former is about 40 cm^{-1} higher than the corresponding band of the latter and the second bands of both compounds are more intensive than the lowest ones. Thus, the C_{2v} symmetrical TBP configuration is most likely for $Mn(CO)_3(PPh_3)_2$, much as with $Fe(CO)_3$(Diars). Now, for both $Mn(CO)_3$(Diphos) and I, two bands have been reported, but the lower intensive band might consist of two bands overlapping accidentally. $Mn(CO)_3(PPh_3)_2 \cdot 1/2CHCl_3$, VIII, shows a C–O stretching absorption band pattern similar to those of these compounds (see Fig. 1). The structure of this adduct depends on whether the chloroform molecule is only a solvent of crystallization or a definite ligand. The appearance of the highest band suggests that a linear OC–Mn–CO skeleton is preserved.*8 Therefore, two rectangular pyramidal (RP) structures, C_{2v} or C_s symmetrical, are very likely for the mother complex. The sixth coordination site of the octahedral configuration may be occupied by half-molar chloroform, though the existence of the chemical bond is uncertain. In other words, solvation may occur on the molecular plane in one of tow possible directions relative to the mother TBP complex.



C_{2v} C_s

P: PPh_3

The magnetic susceptibilities and magnetic moments of III and VIII are listed in Table 1.*9 The value of 1.86 BM has been reported[4] for Mn-

11) H. Nigam, R. S. Nyholm and D. V. Ramana Rao, *J. Chem. Soc.*, **1959**, 1397.

*8 According to the explanation given by Angelici *et al.*[12] for the octahedral tricarbonyl complexes, the highest band can be assigned to the symmetric C–O vibration of linear OC–M–CO. C_{2v} structures (TBP and RP) and one of the RP C_s structures have this skeleton.

*9 The corrections for PPh_3 and $CHCl_3$ have been calculated to be 166 and 69 respectively on the basis of Selwood's review.[7] For three CO it was reduced from the correction given by Hieber and Freyer[3] to $-(CO)_4(PPh_3)$, 219, to 40. (All the values are in units of 10^{-6} c.g.s.e.m.u.) The formula: $\mu_{eff}=2.83\times\sqrt{\chi_M^{coor.}\times T}$ was used.

12) R. J. Angelici, F. Basolo and A. J. Poë, *J. Amer. Chem. Soc.*, **85**, 2215 (1963).

$(CO)_4(PPh_3)$, and that of 1.70 BM,[5] for $Mn(CO)_3$-(Diphos). The observed value agrees quite well with these, corresponding to one unpaired electron. This supports the idea that they are monomeric and zero valent manganese complexes, an idea which is also consistent with the observed molecular weight. In the chloroform adduct crystal VIII, the monomeric structure may be preserved for manganese because of its paramagnetism.

Two chemical reactions of III were investigated: one, its oxidation with bromine in chloroform, gave brown *trans*-$BrMn(CO)_3(PPh_3)_2$, VI, which is the usual hexa-coordinated complex. The results of CH analyses are listed in Table 1. The infrared spectra (see Table 2 and Fig. 1) are in good agreement with the results reported by Abel and Wilkinson[13] and corrected by Angelici *et al.*[14] with respect to structural assignment. The chemical shift value of the ^1H NMR spectrum (see Table 3) can be assigned to the protons of the phenyl group. The other reaction examined was the reduction of III with a sodium amalgam, followed by treatment with methyl iodide. Yellowish brown $CH_3Mn(CO)_3(PPh_3)_2$*10 VII, was thus obtained; it was identified because its infrared spectra showed a pattern similar to that of isostructural VI. Thus, the mother complex is confirmed to be *cis*-$Mn(CO)_3(PPh_3)_2$.

Methylcyclopentadienyldicarbonylmonotriphenylphosphinemanganese(I) (II), $(CH_3C_5H_4)$-$Mn(CO)_2(PPh_3)$. All the results with II are consistent with the structure reported in the literature.[3] The chemical shifts of the ^1H NMR spectra are listed in Table 3, along with the assignment of the absorptions. In the preparative reaction, sodium metal may, in the present experiment, play the same role as the ultraviolet ray in those in the literature.[3,16]

The Unidentified Yellowish Brown Crystal (IV). This was obtained by a short reaction at a higher temperature. Yellow mixture, V, noticed in the course of synthesis in dioxane consisted of II and IV judging from its infrared spectra. Three almost equi-distant intensive C–O strethcing bands are characteristic of the infrared spectra of IV (see Table 2 and Fig. 1), and their intensities are about 1 : 2 : 1. No such feature is found in I, II, or III. Shoulders on the lower side of the lower two bands are assigned to absorptions of II mixing in. In comparison with the spectra of III, the bands of IV other than the strongest center one are relatively intensive. These facts lead to two hypothetical structures for IV. One is an octahedral $Mn(CO)_3(PPh_3)_2X$, where X may be a hydrido ligand or another ligand. The other is a structural isomer of III. Neither III nor IV has a D_{3h} structure. The C_{2v} structure may be assigned to III, and the C_s structure to IV, for the weakness of the highest band in the former spectra can be attributed to the strong coupling of *trans*-2CO vibrations.*8 On the repeated recrystallization of the cruder III, the band at 1865 cm^{-1} became weak, and that at 1950 cm^{-1} intensive. This may be interpreted as resulting from the fact that the inpurity, II or IV, was taken off. However, another interpretation is possible, *i.e.*, an angular isomerization from the C_s structure to the C_{2v} one (see sheme). In the former there remains the original configuration of I for three CO, and the latter may be thermodynamically stable because of its higher symmetry. This rearrangement corresponds to the *cis-trans* isomerization of the octahedral complex for three CO ligands.[12]

The Separation of Gold, Platinum, and Palladium by Reversed-phase Partition Chromatography

Ikuko AKAZA, Toshiyasu KIBA and Tomoe KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received December 6, 1969)

For the separation of gold, platinum(IV), and palladium, and for the isolation of gold from other metals, the reversed-phase partition chromatography has been used as a column process in which TBP is adsorbed on Daiflon(polytrifluorochloroethylene moulding powder) as the stationary phase and hydrochloric acid, as the mobile phase. The separation of the above three noble metals was successfully achieved by carrying out the elution with 3—4 N HCl, and the isolation of gold was attained well of itself by virture of the fact that gold is tightly retained on the column and is only released by letting concentrated HNO_3 flow through the column. The concentration and separation of gold from various solutions, such as in the presence of a large amount of iron(III) or in the presence of 19 common metals and the above three noble metals, was achieved only by allowing gold to be retained on the column and allowing ther others to flow down with a 1 N HCl eluting solution. The behavior of the three noble metals in batch extraction was also examined under the same condition as in the partition chromatography employed here; a similarity was observed between the column and the batch extraction. The principal extracted species of the noble metals might be assumed to be a hydrated and solvated ion pair, such as $H(H_2O)_nTBP_6^+ \cdot HPtCl_6^-$.

Reversed-phase partition chromatography has been used by many investigators for the separation of various metal ions. The present authors have also carried out investigations of the reversed-phase partition chromatography (not the ion-exchange) of alkali metals,[1] alkaline earth metals,[2] and hexacyanoferrate(II) and (III)[3] and established that the technique is very useful for the mutual separation of ions. In this work, reversed-phase partition chromatography was applied to the separation of gold, platinum, and palladium from each other, and to the isolation of gold from various metals. These three noble metals are the elements which come into the soluble fraction in the process of the treatment of the noble metals with aqua regia, which is still one of the best techniques available for the separation of the platinum group.[4]

With respect to the work on the reversed-phase chromatography of the noble metals, there have been descriptions by Hu *et al.*[5,6] on the chromatography using filter paper impregnated with TBP and a developing solution of hydrochloric acid. The quantitative separation of the noble metals has never been attained by means of reversed-phase partition column chromatography.

The chromatographic investigations previously performed by the present authors[1-3] have indicated that much valuable information on the chromatographic separation could be obtained from the extraction behavior of the element in question in the same system. Many articles dealing with the solvent extraction of noble metals have been cited in a review[7] and other papers; the TBP-HCl extraction system was preferred in this study as the one most suitable for a good separation of the three metals. This selection seemed to be pertinent in respect to the results of the reversed-phase partition paper chromatography by Hu[5,6], the R_f-spectra of many metals on reversed-phase thin-layer chromatography with TBP,[8] and the distribution data on the solvent extraction of the three metals in the TBP-HCl system[9] and in the counter-current extraction.[10]

Experimental

Reagents and Equipments. *Daiflon M-300.* Trifluorochloroethylene polymer moulding powder was obtained from the Daikin Kogyo Co., Osaka, Japan. The material was ground with a mixing grinder and sieved; particles of 42—80 mesh were used.

TBP. *n*-tributyl phosphate of the reagent grade was washed twice with a 5% sodium carbonate solution of equal volume and then with water to remove any dibutyl- or monobutyl phosphate.

Metallic Salts Solutions. The solutions were prepared from metallic gold, palladium chloride, and chloroplatinic acid hexahydrate, all of analytical-reagent grade respectively.

Tracers. ^{195}Au, ^{113}Sn, ^{203}Hg, ^{59}Fe, ^{207}Bi, ^{110m}Ag, ^{65}Zn, ^{124}Sb were employed as tracers of the stable ions.

The other chemicals used were all of an analytical grade.

Column. The glass tube had a diamter of 0.92 cm and a length of 30 cm, and was equipped with a fritted glass disk at one end.

Measurement of Radioactivity. A scintillation counter, Kobe Kogyo Co., Model EA-14, with a NaI(Tl) crystal, and a Model SA-2 scaler were employed.

The other pieces of equipment such as a fraction collector and a spectrophotometer, were all those in ordinary use.

Organic Solvent for the Stationary Phase of the Column as Well as for the Batch Extraction. The TBP used in each experiment had been pre-equilibrated with hydrochloric acid of the same concentration as that of the acid used for the mobile phase in the column or the aqueous phase in the batch. No such diluent as benzene was added except when it was necessary to vary the TBP concentration of the organic phase.

Eluting Solution of the Column Extraction. Hydrochloric acid of various concentrations and concentrated nitric acid were used as the eluting solutions; they had been pre-equilibrated with TBP or TBP-benzene. These solutions were also used in the batch-extraction experiments as an aqueous phase.

Test Solution. Hydrochloric acid of various concentrations and of varying volumes, each portions containing 0.5 mg of a metal ion, was prepared; in this case, the concentration of hydrochloric acid was adjusted to be the same as that of the eluting solution for the column or the aqueous phase in the batch extraction.

Experimental Procedure. *The Stationary Phase of the Column.* A 5.5-g portion of Daiflon was placed in an Erlenmyer flask fitted with a stopper, and 6 m*l* of the organic solvent, prepared as above, was poured onto it. This volume of the organic solvent had been established previously to be an adsorbable amount of TBP on Daiflon.[3] The stoppered flask was shaken gently by hand until the content became homogeneous; then it was left standing over three hours. The product was then slurried with an eluting solution and packed in a column tube by gentle pressing with a glass rod every time a small portion of the slurry was added. After the column had then been washed with an eluting solution with the acidity same as the test solution, a 5 m*l* or 3 m*l* portion of the test solution was allowed to soak into the column bed at the rate of about 0.25 m*l*/min. The elution was carried out with a suitable eluting solution at the rate of 0.5 m*l*/min. The effluent was collected in suitable fractions, and the metal ion in each fraction was determined. In this study the colorimetric methods of platinum with $SnCl_2$ and of palladium with dimethylglyoxime were adopted. The gold was estimated colorimetrically with rhodamine B or radiometrically with ^{195}Au. When radioactive tracers, involving gold and other elements; were employed, all being mixed together, the nuclide separated in a fraction was identified by taking its γ-ray spectra with a 200-channel pulse-height analyzer, not only by counting the radioactivity with a scintillation counter.

Rusults and Discussion

Preliminary Experiments. *Behavior of Au, Pt, and Pd in the Batch Extraction.* The distribution behavior of the three metals was examined between the TBP adsorbed on Daiflon and an aqueous solution, not by means of liquid-liquid extraction between TBP and hydrochloric acid, in search of good conditions for separation. In this case, 4.6 g of Daiflon, adsorbing 5 m*l* of TBP, and 15 m*l* of a hydrochloric acid solution containing 0.5 mg of the metal were employed. The contents of a stoppered flask were gently shaken for a while, set aside a while, then poured them on a coarse glass filter. The aqueous solution coming through the filter was submitted to the determination of the metal ions in it. Gold shows a very high distribution in TBP on Daiflon, so this measurement method can not be applied in the case of gold. Therefore, the distribution ratio of gold was estimated only by an

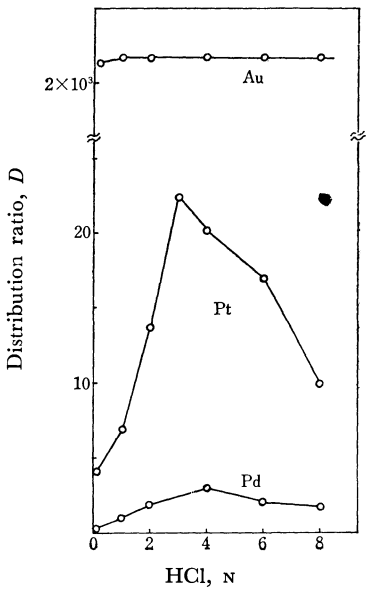

Fig. 1. The distribution curves of Au, Pt and Pd in the batch extraction.

ordinary liquid-liquid extraction between 5 m*l* of TBP and 15 m*l* of the aqueous solution. The results are shown in Fig. 1, from which the optimum condition for the mutual separation of the metals may be seen to be in the range of acidity between 3 to 4.

Chromatographic Behavior of Individual Ions. With 3 m*l* of a test solution containing only one of the three metals, the chromatographic behavior of the metal ion was examined by means of elution with hydrochloric acid of various concentrations. The results are shown in Fig. 2, where gold is omitted because of its absence in the effluent. Gold showed so high a distribution in TBP on the column that, even after as much as 1 *l* of the eluting solution had passed through, gold did not appear in the effluent. Thus, the separation of the three metals seemed to be attained satisfactorily by elution with 3—4 N hydrochloric acid.

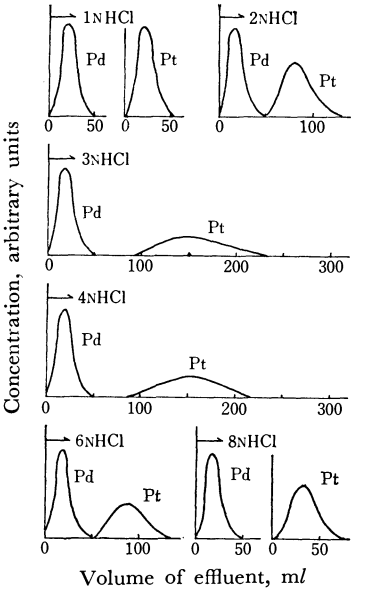

Fig. 2. The chromatographic behavior of individual ions. Gold was not eluted even after 1 *l* of eluting solution flowed.

Test solution: 3 m*l* containing metal of 0.5 mg.

Separation of Au, Pt, and Pd in the Presence of Fe(III). With the help of the results obtained for an individual ion, the separation from a test solution containing all three metals was carried out by elution with 3—4 N hydrochloric acid. Gold, which was tightly retained on the column, could be at last removed from the column by passing through concentrated nitric acid. The features of this elution scheme are shown in Fig. 3. Some interesting applications of this separation are also shown in Fig. 4, in which: (a) the quantity of each metal is in proportion to its Clarke

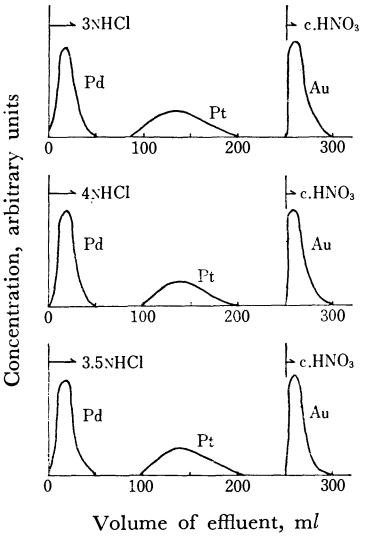

Fig. 3. The separation of Au, Pt and Pd from a mixed solution.

Test solution: 5 m*l* containing 0.5 mg of each metal.

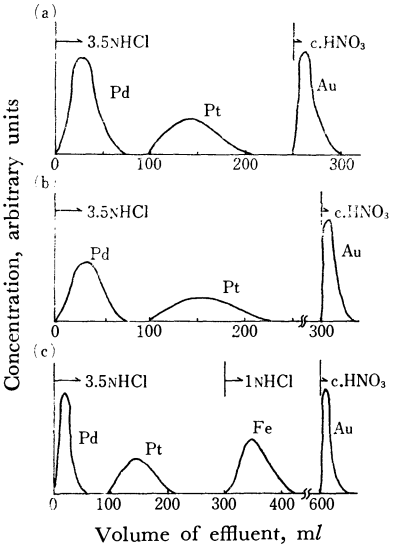

Fig. 4. The separation of Au, Pt and Pd from a mixed solution.

number, (b) there is separation from a test solution of large a volume such as 50 m*l*, and (c) there is the separation of the three noble metals in the presence of iron(III). In the last case, iron(III) could be eluted with 1 N hydrochloric acid after the elution of Pd and Pt with 3.5 N hydrochloric acid. This seems to be very noticeable because

iron(III) is an ion which has a high distribution ratio in an ordinary TBP-HCl extraction system and is apt to exist in various samples as an impurity. All in the above experiments, gold could not be eluted by elution with hydrochloric acid, but instead was retained on the column tightly; therefore, a minute amount of gold could be successfully concentrated and separated by this column technique. As an example, 200 m*l* of a test solution containing 0.5 mg of gold and 6 g of iron(III) was adjusted to 1 N of a hydrochloric acid solution and allowed to flow through the column; followed by elution with 500 m*l* of 1 N hydrochloric acid. The iron(III) in the effluent was determined colorimetrically by the thiocyanate method, and gold(III) was detected by the tracer method with γ-counting. It was found that the gold was retained on the column completely; was concentrated and separated from a large amount of iron(III). With the elution of concentrated nitric acid, the gold could also be recovered quantitatively in the effluent. This method might be used in the chemical analysis of gold-plating materials.

Separation of Gold from Many Other Metals. To confirm the above use of this method, 50 m*l* of a test solution of 1 N hydrochloric acid was prepared, in which 0.5-mg portions of each of the following metal ions were put: Sn(IV), Hg(II), Fe(III), Zn, Bi, Ag, Co, Sb(III), Cd, Cu, Ni, Al, Mn, Pb, Ca, Sr, Ba, Mg, Pd, Pt, and Au(III). The test solution was soaked on the column, and then 950 m*l* of 1 N hydrochloric acid eluting solution was passed through. After examining all of the fractions of the effluent, it was found that only two metal ions, Au(III) and Sn(IV), were retained on the column. Then, Sn(IV) was released from the column by passing through 300 m*l* of 1 N nitric acid, and there after. Au was eluted by concentrated nitric acid. From the distribution data of the liquid-liquid extraction in the TBP-HCl system, it had been established that none of the metal ions except Sn(IV), Hg(II), Fe(III), Bi(III), Ag, Zn and Sb(III) participated in the extraction,[9] therefore, in this study the radioactive tracers of the latter seven metals and Au(III) were preferentially employed in order to detect the behavior of these metal ions. Thallium(III) is only the ion, the distribution ratio of which is so close to that of Au(III) in the TBP-2 N HCl extraction, but it was omitted in this experiment because of the lack of its γ-emitting tracer. It seems that this separation method can be used for various purposes, such as the milking of ^{195}Pt from ^{195}Au and the preparation of carrier-free ^{199}Au from irradiated platinum. The applications will be described elsewhere.

The Distribution Ratio in the Chromatographic Column and That in the Batch Extraction of the Same System. The distribution ratio in the column extraction can be calculated

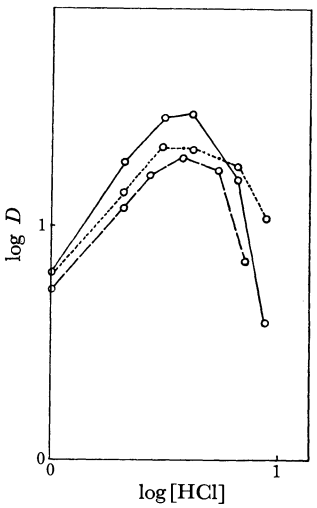

Fig. 5. Dependence of the distribution ratio of Pt on the concentration of HCl.

Solid line: Column chromatography

Dotted line: Batch method

by the following equation by putting the data of the elution into it: $D=(E-F)/B$, where E is the volume of the effluent before the emergence of the peak of the curve; B, the volume of the stationary phase, and F, the volume of the mobile phase. In the present column, B was 6 m*l* and F was 6.4 m*l*; 0.5 mg of platinum was loaded on and eluted with hydrochloric acid of varying concentrations. The TBP concentration of the stationary phase was also varied by diluting the organic solvent with benzene.

Thus, the dependence of the distribution ratio on the hydrochloric acid concentration of the aqueous phase, log D *vs.* log [HCl], and that on the TBP concentration of the organic phase, log D *vs.* log [TBP], were found to be as shown in Fig. 5 and Fig. 6 respectively. Along with these experiments, two other extractions were carried out by the batch system: a liquid-liquid extraction between each 5-m*l* portin of the aqueous and the organic phases, and a liquid—TBP on Daiflon extraction between 15 m*l* of the aqueous phase and 5 m*l* of the organic phase held on the adsorbent. From the distribution data thus obtained, log D *vs.* log [HCl] and log D *vs.* log [TBP] were also obtained; they are shown in Fig. 5 and Fig. 6. From the figures, it can be seen that platinum behaves similarily in all the above three extraction processes, and the chromatographic data can contribute to a knowledge of the distribution behavior of the metal ion. The lowering of the distribution ratio in the range of higher acid concentrations in Fig. 5 raises some questions to the extraction mechanism and the extracted species, but it is assumed to be caused by the competition between hydrochloric acid and the platinum ion in the extraction with TBP. Therefore, when the concentration of the chloride ion was fixed at 4 M by adding lithium chloride, the lowering of the distribution disappeared and log D *vs.* log [HCl] showed a straight line with a slope unity, as shown in Fig. 7.

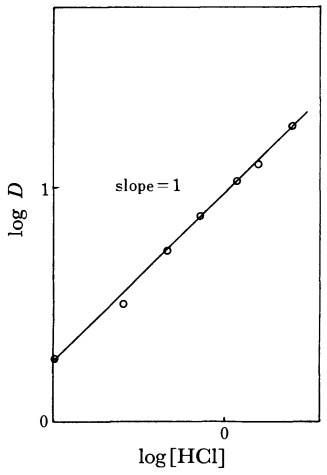

Fig. 7 Dependence of distribution ratio of Pt on the concentration of HCl.

[Cl⁻] is adjusted to 4 M with LiCl

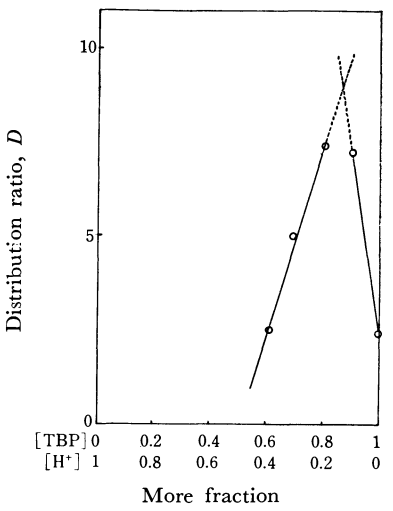

Fig. 8. Distribution of Pt under continuous variation of [TBP] and [HCl].

[Cl⁻] is kept at 4 M with LiCl
[TBP] and [HCl] are 0—3.66 M each

At last, it may be of interest to establish the extracted species of platinum in this TBP-HCl system since the species in the organic phase has not been stated anywhere. A continuous-variation method was applied to the extraction system with two variables of TBP and hydrochloric acid concentrations with a fixed concentration of 4 M lithium chloride in the aqueous phase. As is shown in Fig. 8, the maximum distribution appears at the [H] : [TBP] ratio of 1 : 6; this fact agrees well with the results shown in Figs. 5, 6, and 7. In consequence of this distribution study, though it was far from ideal, the main extracted species may be assumed to be an ion-associated one, $H(H_2O)_nTBP_6{}^+HPtCl_6{}^-$, especially in view of a previous paper concerning the extraction of metals and mineral acids,[11] and Ref. 8.

The expense of the present research was met in part by a Grant for Scientific Research from the Ministry of Education, to which the authors' thanks are due.

Electronic Absorption Spectra of Zero-Valent* Tris-(2,2′-bipyridine) Metal Complexes

Youkoh KAIZU, Takanori YAZAKI, Yasuo TORII and Hiroshi KOBAYASHI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 8, 1969)

Electronic absorption spectra of zero-valent tris(2,2′-bipyridine) metal complexes of the first transition metals from titanium to cobalt have been studied. These spectra give a criterion to determine whether the central metal atom or the ligand is trapping the electrons furnished by reducing reagents upon syntheses of the complexes, if the absorption spectra of the coordinating negative ions are fairly free from the influence of the configuration interactions by the "ligand-metal" charge transfer excited states and/or by the "metal-ligand" ones. The vanadium complex is concluded as a complex of the metal atom in zero oxidation state and neutral bipyridine molecules, where the 'metal-ligand' charge transfer bands are observed. The iron- and the manganese-complexes are ionic complexes of the metal ion in a non-zero oxidation state and the negative ions of bipyridine, where the (π–π^*) absorption bands of coordinating bipyridine negative ion are observed. On the basis of their spectral character, the complexes of the other transition metals might be assigned to be a hybrid of the two typical electron traps given above.

Stabilization of complexes with a metal of lower oxidation states, $Cr(CO)_6$ for example, is well interpreted as due to the strong pi-bondings between the metal atom and the ligand molecules. The former acts as a dπ electron donor while the latter as acceptors by use of vacant anti-bonding pi-molecular orbitals of lower energy.[1] It is well known that 2,2′-bipyridine (bipy) is one of the ligands which stabilize the lower oxidation states of metals. Recently a large number of tris-bipyridine metal complexes of lower valency have been prepared by Herzog and his coworkers, and others.[2] We showed evidence of pi-bonding between the central metal atom and the ligand in the tris-bipyridine metal (II) complexes and also in the trisphenanthroline ones.[3] It might be expected that the lower the oxidation state, the more stable the pi-bonding. Although the essential role of pi-bonding in the stabilization of lower oxidation states of metals in such complexes as zero-valent bipyridine complexes should be appreciably important as was pointed out by Orgel and Jϕrgensen,[4,5] the existence of an isostructural zero-valent aluminum complexes, which is described as a complex of Al^{3+} coordinated by bipyridine negative ions, namely [Al(III)$(bipy^-)_3$], should not be overlooked, even if there exists a crucial pi-electron delocalization effect between Al^{3+} and the coordinating bipyridine negative ions.

Electron trapping seems to happen mainly in the central metal atom in the case of comparatively stable lower valency complexes of the first transition metals, *e.g.* $[Cr(I)(bipy)_3]^+$. However, the existence of coordinating negative ion, or electron trapping ligand, seems to be possible even in the first transition metal complexes depending upon the electron trapping powers of the central metal atom and the ligands.

Since bipyridine is a strong σ-donating ligand, the positive charge of the central metal ion, even in an essentially ionic complex, is almost neutralized with σ-electron charge donated by the nitrogens of the coordinating bipyridine. However, since what we discuss here is not the charge distribution of the σ-bonds in the zero-valent com-

*1 In this paper, the term "valency" stands for a net charge (electrovalency) of the complex as a whole. Therefore "zero-valent" means that no net charge is accompanied by the complex. The term "oxidation state" or "oxidation number" stands for a degree of electron detachment of the central metal or a formal charge of the central metal.

plexes but the majority trapping of the extra electrons furnished by reducing reagents upon synthesis of the zero-valent complexes, the notations such as $[Al(III)(bipy^{-})_3]^0$ or $[Al(0)(bipy)_3]^0$, roughly show majority population of the molecular orbital trapping the extra electrons but not anything about the degree of σ-electroneutrality.

Analysis of ESR spectra and electronic absorption spectra give a means to determine whether the central metal atom or the ligands trap electrons. For this purpose, however, only effective magnetic moments have been measured and optical spectrum has been reported in only a few cases.[6] As far as the zero-valent complexes are concerned, only the spectrum of the iron complex[7] and the ESR of the vanadium complex[8] have been published.

In this paper, the electronic absorption spectra of the zero-valent tris-bipyridine complexes of the first transition metals from Ti to Co are presented, and the actual oxidation states of the central metals are discussed based on their absorption spectra.

Experimental

The tris-bipyridine complexes such as $[Ti(bipy)_3]$, $[V(bipy)_3]$, $[Cr(bipy)_3]$, $[Mn(bipy)_3]$, $[Fe(bipy)_3]$, and $[Co(bipy)_3]$ were prepared by the method of Herzog *et al.*[2a-2d, 9-11] The compounds were identified by elementary analysis of metal.

Tris(4,4'-dimethylbipyridine)vanadium was prepared in 50% methanol solution by the reduction of $[V(4dmbip)_3](ClO_4)_2$[3] with magnesium powder and purified by extraction with tetrahydrofuran (THF) or benzene. The compound was a blue-violet crystalline substance. Found: V, 8.31%. Calcd for $[V(4dmbip)_3]$: V, 8.44%.

Tris(5,5'-dimethylbipyridine) vanadium was prepared in 60% methanol solution by the reduction of $[V(5dmbip)_3](ClO_4)_2$[3] with magnesium powder and purified by extraction with THF. The compound was a blue-violet crystalline substance and less soluble in organic solvents than $[V(4dmbip)_3]$ and $[V(bipy)_3]$. Found: V, 8.11%. Calcd for $[V(5dmbip)_3]$: V, 8.44%.

Measurement of electronic absorption spectra. Sample solutions for spectral measurement were prepared by the method described in a previous paper.[12] Electronic absorption spectra were measured in quartz cells with light path of 0.1 cm and 1 cm, using a Shimadzu multipurpose recording spectrophotometer model MPS-50.

Results and Discussion

The electronic absorption spectra of the zero-valent tris-bipyridine complexes are given in Figs. 1—3. The general feature of their absorption spectra in the near infrared region is very diffuse and intense. Intense absorption appears in a lower wave number region than those observed for the corresponding tris-bipyridine complexes of divalent metal ions. These diffuse and intense bands might be assigned to the "metal to ligand" charge transfer bands fairly strongly red-shifted by the central metal atom M(0) with smaller ionization potential, whereas this type of charge transfer bands are usually observed in the visible region

for the corresponding tris-bipyridine complexes of such metal ions as V(II), Cr(II) and Fe(II).[3] The assignment is based on the assumption that the oxidation number of the central metals is zero, in other words the central metal atom captures electrons given by reducing reagents. On the other hand, tris(bipyridine)aluminum complex is interpreted by an approximate charge distribution such as $[Al(III)(bipy^-)_3]$,[13] since it shows an absorption spectrum very close to that observed for sodium bipyridinate and also gives ESR spectrum with a free spin g-value of 2.0037. An aluminum cation is coordinated by three bipyridine negative ions rather than an aluminum atom of zero-oxidation number is coordinated by ordinary bipyridine molecules, even if pi-electron delocalization effects between the central metal and the coordinating bipyridine are appreciable. It has also been reported for $Na[Fe(bipy)_3]$ to show similar properties.[14] In this case, the actual oxidation state of the central ion is not minus one but much more positive and the ligands are trapping a sufficient part of pi-electrons. Since these complexes are made of bipyridine negative ions coordinating to an ionic metal species, the absorption bands which appear in the near infrared region could be assigned to the (π–π^*) transitions of the coordinating bipyridine negative ion rather than the charge transfer bands mentioned above. Actually they give rise to a very similar feature to

13) Y. Torii, S. Murasato, Y. Kaizu and H. Kobayashi, to be published.

14) C. Mahon and W. L. Reynolds, *Inorg. Chem.*, **6**, 1927 (1967).

that of the bipyridine ion in alkaline salts. Among the formally zero-valent compounds of the first transition metals, $[Fe(bipy)_3]$ and $[Mn(bipy)_3]$ show a similar spectrum to that of (Na^+bipy^-) (Fig. 3). The iron complex is not so stable in solvents and decomposes so easily to Fe metal and bipyridine that $\log \varepsilon$ could not be quantitatively determined. The spectrum in the ultraviolet region could not be given because of superposing absorption bands due to the bipyridine set free in the solution (Fig. 3).

We might conclude that the Fe- and the Mn-compounds are regarded as ionic complexes of metal cation and bipyridine negative ion, $bipy^-$. The actual, but not formal, oxidation states of the central metals of these complexes could not be zero. However, molecular orbital calculations and direct experimental determinations are desirable. The Ti-, V-, Cr- and Co-compounds show another type of absorption spectra different from those for the Fe- and Mn-compounds. König interpreted his ESR spectra of the V-compound on the basis of a remarkable difference between the optical spectra observed for the V-compound and (Na^+bipy^-), assuming that trapped electrons are localized at the central metal and can not be delocalized around the ligands. Such a difference, however remarkable, does not always give a criterion when the (π–π^*) transition bands of the coordinating negative ion are drastically changed by a superposition and/or a mixing of "metal to ligand" or "ligand to metal" charge transfer bands.

In a previous paper, it was shown that small perturbations such as introduction of CH_3 group to the ligand, namely introduction of two methyl groups to the bipyridine in 4 dmbip and 5 dmbip, for example, show quite opposite spectral shifts for the "metal-ligand" charge transfer bands and the (π–π^*) transition bands of the coordinating negative ion at the lowest wave number region.[12] The charge transfer bands shift to the lower wave number in the order, 5 dmbip, bipy, 4 dmbip, while the (π–π^*) transitions of the bipyridine negative ions at the lowest wave number shift to the higher wave number in the order, 5 dmbip, bipy, 4 dmbip, which is similar to the usual (π–π^*) transitions of the bipyridines. As is shown in Fig. 2, the absorption band at the lowest wavenumber of the V-compounds shifts towards the lower wavenumber in the order, 5 dmbip, bipy, 4 dmbip. This small perturbation technique gives the criterion that the lowest wave number band of the V-compounds is due not to a (π–π^*) transition but to a "metal-ligand" charge transfer transition. This rejects the possibility of a coordinating negative ion in the case of the V-compound. We conclude that the vanadium traps electrons and is in zero oxidation state.

The Ti-compound shows a similar absorption spectrum to that of the V-compound at the near infrared and visible regions (Fig. 1). In the ultraviolet region, however, the spectra of the compounds are not identical. The absorption bands at the adjacent region of 30000 cm^{-1} are due to the (π–π^*) transition of the coordinated bipyridine. In the case of the tris-bipyridine compounds of metal(II), or metal(III), the total shift of these absorption bands ranges over several hundred wavenumbers varying with the central metal ion among the first transition metals. On the contrary, the corresponding absorption bands of the Ti-compound are observed to shift several thousand wave numbers in a comparison with the V-compound (Figs. 1 and 2): Although the (π–π^*) transition of the coordinating bipyridine changes very much in the Ti-compound, the fact that the absorption bands at the lowest wave number appear in the region lower than 10000 cm^{-1} and resemble that of the V-compound makes us conclude that the Ti-compound consists of neutral bipyridine but not negative ions. In the zero-valent complex discussed in the paper, the electron delocalization between the central metal dπ-orbitals and the ligand antibonding molecular orbitals should be appreciable even in the ground state. Since the antibonding pi-orbitals of the coordinating bipyridine is donated dπ-electron by the central metal through so-called back-donation, the (π–π^*) transitions of the coordinating bipyridine should be much modified. This type of large pi-interactions between the metal dπ-orbitals and the ligand antibonding pi-orbitals can explain not only the spectral behavior of the coordinating bipyridine but also the diamagnetism of the Ti-compound.[2a] As Fig. 1 shows, the Cr- and the Co-compounds give visible and near infrared spectra similar to those observed for the Ti-compound and the V-compound, while in the ultraviolet region, they are different from those observed for the V-compound.

Zero-valent tris-bipyridine compounds of the first transition metals can be formally classified on the basis of spectral criterion of the electronic structure: The V-compound is a complex of the metal of zero oxidation state and neutral ligands, while the Fe- and Mn-compounds are ionic complexes of the metal of non-zero oxidation state and negative ion ligands. The others seem to be in between.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2072—2075 (1970)

The Syntheses and Properties of the Complexes of Boron with Ethylenediaminetetraacetic Acid and Its Analogs*1

Mitsuhisa NAKATANI, Yoshiaki TAKAHASHI, Akira OUCHI and Kunihiko WATANUKI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received December 11, 1969)

Two compounds of boron with ethylenediaminetetraacetic acid, $H_6EDTA(BF_4)_2$ and $H_4EDTA\text{-}(BF_3)_2$, as well as complexes with cyclohexanediaminetetraacetic acid and nitrilotriacetic acid, have been synthesized. Their properties, including their infrared and ultraviolet spectroscopic data, have been investigated and discussed.

The syntheses and the properties of the ethylenediaminetetraacetato chelates of a large number of metals have been reported in detail.[1] The boron complexes of ethylenediaminetetraacetic acid (H_4EDTA) or other aminopolycarboxylic acids, however, have not yet been reported on. Since Gay-Lussac[2] prepared the addition compound between ammonia and boron trifluoride, $H_3N\text{-}BF_3$, about 160 years ago, a large number of complexes have been prepared by a reaction between boron trifluoride and a variety of nitrogen compounds, such as amines, imines, amides, nitriles, and nitrogen-containing hetero cyclics.[3-5] The lone-pair electrons on the nitrogen atom in these compounds readily form a coordination bond with an acceptor boron trifluoride. The carboxylic acids are less easily coordinated with boron, but some acetic acid have also been reported.[6,7] However, the coordinate compounds of boron with such aminocarboxylic acids as ethylenediaminetetraacetic acid (H_4EDTA), cyclohexanediaminetetraacetic acid (H_4CDTA), and nitrilotriacetic acid (H_3NTA) have not yet been reported on. Therefore, it seemed that it would be interesting to investigate whether or not these acids coordinate with the boron trifluoride.

Experimental

Materials and Instruments. The H_4EDTA, H_4CDTA, and H_3NTA that were used in this experiment were of all of an analytical grade. The 45% ethylether solution of boron trifluoride ethyl etherate ($BF_3\text{-}(C_2H_5)_2O$) and the acetonitrile were of an EP grade. All of them were used without further purification.

The infrared spectra were obtained by a KBr-disc or nujol-mull procedure using a Japan Spectroscopic Co. DS 403 G infrared spectrophotometer. The electronic spectra were obtained with a Hitachi EPS-2 automatic recording spectrophotometer. The pH was measured with a Toa Electronic Co. pH meter, model HM-5A.

Synthesis of the Ethylenediaminetetraacetic Acid Adduct of Boron Trifluoride, $H_4EDTA(BF_3)_2$. Two grams (0.007 mol) of H_4EDTA and 6 m*l* (0.02 mol BF_3) of a 45% ether solution of $BF_3\text{-}(C_2H_5)_2O$ were mixed with 10 m*l* of acetonitrile containing a small amount of water (about 0.3 m*l*). The mixture was warmed on a water bath for a few minutes and then dissolved. A small amount of insoluble residue was filtered off, and the filtrate was refluxed for about 2 hr. A white precipitate was thus obtained. The product was filtered off, washed well with acetonitrile and ethyl ether successively, and dried in a vacuum at room temperature. The yield was about 1.9 g (65% calculated for H_4EDTA).

Found: C, 28.08; H, 4.26; N, 6.57; B, 4.79; F, 25.83%. Calcd for $C_{10}H_{16}N_2O_8B_2F_6$: C, 28.04; H, 3.74; N, 6.54; B, 5.05; F, 26.64%.

Synthesis of Ethylenediaminetetraacetic Acidium Tetrafluoroborate, $H_6EDTA(BF_4)_2$. The acetonitrile solution of H_4EDTA and boron trifluoride ethyl etherate obtained by the former synthesis process was allowed to stand for one day at room temperature without refluxing. The white precipitate thus obtained was filtered off, washed well with acetonitrile and ethyl ether successively, and then dried in a vacuum at room tem-

perature. The yield was about 80% (calculated for H_4EDTA).

Found: C, 25.99; H, 3.87; N, 6.06; B, 3.94; F, 32.29%. Calcd for $C_{10}H_{18}N_2O_8B_2F_8$: C, 26.57; H, 3.88; N, 5.99; B, 4.62; F, 32.48%.

Synthesis of the Cyclohexanediaminetetraacetic Acid Adduct of Boron Trifluoride, $H_4CDTA(BF_3)$. About 0.5 g (0.0015 mol) of H_4CDTA, about 0.7 m*l* (0.0025 mol BF_3) of a 45% ether solution of BF_3-$(C_2H_5)_2O$, and 1 m*l* of acetonitrile were mixed and dissolved; water was not necessarily added. The solution was refluxed on a water bath for about 1 hr. After the removal of the solvent and the excess of BF_3-$(C_2H_5)_2O$ under reduced pressure, about 10 m*l* of ethyl ether was added to the brown residue. The white precipitate thus obtained was washed well with acetonitrile and ethyl ether before being dried in a vacuum at room temperature. The yield was about 0.13 g (20% calculated for H_4-CDTA).

Found: C, 39.49; H, 5.81; N, 6.21; B, 2.10; F, 14.06%. Calcd for $C_{14}H_{22}N_2O_8BF_3$: C, 40.60; H, 5.36; N, 6.76; B, 2.61; F, 13.76%.

Synthesis of Nitrilotriacetato Boron (NTA·B). The method of synthesizing $H_4EDTA(BF_3)_2$ was used. The yield was about 15% (calculated for H_3NTA).

Found: C, 34.58; H, 3.12; N, 6.99; B, 4.98%. Calcd for $C_6H_6NO_6B$: C, 36.22; H, 3.04; N, 7.04; B, 5.43%.

Results and Discussion

Typical patterns of the infrared spectra of these complexes are shown in Fig. 1, while the alkalimetric titration curve of $H_6EDTA(BF_4)_2$ in an aqueous solution is shown in Fig. 2.

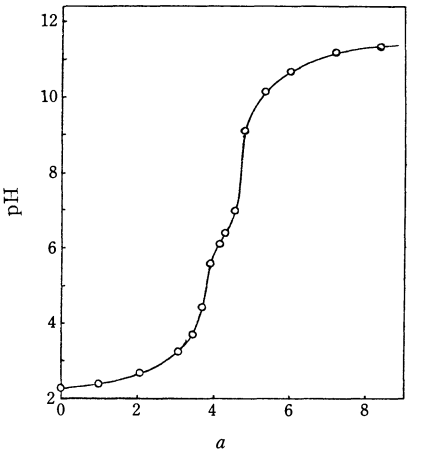

Fig. 2. Alkalimetric titration curve of $H_6EDTA(BF_4)_2$ in aqueous solution.

a = NaOH/$H_6EDTA(BF_4)_2$

Many papers have been published about the infrared spectra of ethylenediaminetetraacetato complexes as well as free acid.[8] According to these papers, the antisymmetric stretching bands of the uncoordinated and unionized carboxyl group of EDTA appears in the 1750—1700 cm^{-1} region, whereas that of the coordinated one appears in the 1650—1590 cm^{-1} region. The band of the free acid appears at 1690 cm^{-1}, and Novak and his co-workers deduced that two protonated nitrogen atoms and two $(-COOHOOC-)^-$ groups seem

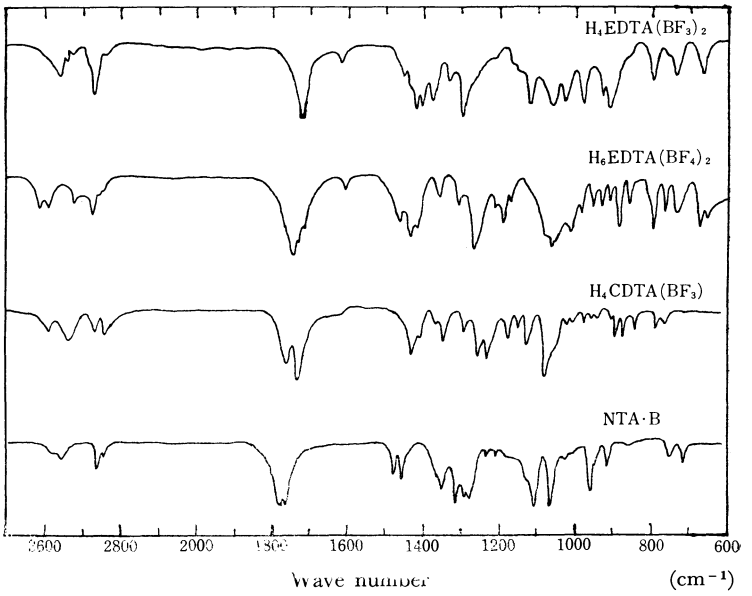

Fig. 1. Infrared spectra of the boron compounds.

8) K. Nakamoto, "Infrared Spectra of Inorganic Coordination Compounds," John Wiley & Sons, New York, N.Y. (1963), p. 205.

to exist in the free acid.[9] The fully protonated salt of ethylenediaminetetraacetic acid, $H_6EDTA \cdot Cl_2$, was also prepared by the reaction between ethylenediaminetetraacetic acid and hydrogen chloride.[10] The infrared spectra of the compound have a strong, characteristic absorption band near 1740 cm^{-1}; this can probably be assigned to the carboxyl groups attached to the protonated nitrogen atoms. There is also a broad band in the 3300—2000 cm^{-1} region; this is probably the OH stretching band of a carboxyl group.[9]

The assignments of the infrared absorption bands of $H_4EDTA(BF_3)_2$ were made with reference to the data about H_4EDTA, its metal complexes, and other B-N compounds. Therefore, the assignments are only tentative. The antisymmetric stretching band of the carboxyl group of this compound appears at 1725 cm^{-1}; this wave number is about 35 cm^{-1} higher than that of the free acid. This is probably due to the effect of coordinated boron trifluoride, which is a strong Lewis acid and which may be expected to have the same effect as a proton bonded to the nitrogen atom, as in the case of $H_6EDTA \cdot Cl_2$. Therefore, no carboxyl group of this complex seem to be coordinated with boron.

The bands near 1100 cm^{-1} are identified as B-F stretching bands following the examples given by Kreutzberger of amine adducts,[11] by Taylor of ammonia and trimethylamine adducts,[12] and by Paterson of hydrazine adducts.[13] The B-N stretching bands may be overlapping in this last case too.

A fresh aqueous solution of the complex does not give positive results in qualitative tests for the tetrafluoroborate ion using potassium chloride[3] or using nitron (1,4-diphenyl-3,5-endoanilinodihydrotriazole).[14] Therefore, the boron atoms of this compound are expected to bond with EDTA, probably with its nitrogen atoms, although no direct proof from the infrared spectra has yet been obtained.

Some peaks of the infrared spectra of $H_6EDTA(BF_4)_2$ have also been assigned by comparing them with those of $H_6EDTA \cdot Cl_2$. The strong bands at 1740—1720 cm^{-1}, the antisymmetric stretching band of the carboxyl group, and the broad band at 3200—2400 cm^{-1}, probably overlapping one of the stretching bands of N^+–H and OH, are visible. Consequently, a proton probably bonds to each nitrogen atoms of ethylenediaminetetraacetic acid, and this makes the stretching band of the carboxyl group shift to the higher-wave-number side, as in the case of $H_6EDTA \cdot Cl_2$. The other broad bands appearing in the 1100—1000 cm^{-1} region seem to be due to the B-F stretching bands of the tetrafluoroborate ion, BF_4^-, because the alkali salts show the same peak, as has been reported by Cote.[15] The broadening of this band was explained by Greenwood in term of the site symmetry and the isotope effect of the ion.[16]

The presence of the BF_4^- ion was also established by qualitative tests using potassium chloride or nitron.[3,14]

The alkalimetric titration curve of this compound, shown in Fig. 2, indicates that one mole of this compound immediately decomposes to two moles of tetrafluoroboric acid and one mole of H_4EDTA. In reality, if the solution is concentrated, a white precipitate of H_4EDTA appears. The former is a strong acid, and its hydrolysis in an aqueous solution, $BF_4^- + H_2O \rightarrow BF_3(OH)^- + HF$, is negligible during the titration, altough it may be gradually decomposed. Therefore, the inflexion point corresponds with the neutralization of two moles of HBF_4 and one mole of H_4EDTA (only to H_2EDTA^{2-}). On the other hand, boron trifluoride is rapidly hydrolysed in an aqueous solution, and the concentrations of BF_4^- and other various ionic species increase faster.[17] The acidity gradually increase during the alkalimetric titration process. In reality, in the alkalimetric titration of $H_4EDTA(BF_3)_2$ it took a long time before the equilibrium was attained after alkali was added.

Debye-Scherrer X-ray powder diffraction patterns of both $H_4EDTA(BF_3)_2$ and $H_6EDTA(BF_4)_2$ were obtained, but they were completely different from each other.

Although the attempt to recrystallize these compounds has not yet been successful, each compound seems to be nearly pure, since two products which were not only analytically but also infrared-spectroscopically characterized were reproducibly obtained in each synthesis of the compounds, even when the mole ratio of the starting materials was changed from 1 : 20 to 1 : 3.

The infrared spectra of $H_4CDTA(BF_3)$ in general resemble those of cyclohexanediaminetetraacetic acid.

The antisymmetric bands of the carboxyl group appear at 1760 and 1730 cm^{-1}, whereas the bands

of the free acid appear at 1597 cm^{-1} and in the 1750—1700 cm^{-1} region (three peaks). The stretching band of B-F appears at 1100—1050 cm^{-1}. Probably the B-N band is also overlapping there.

Therefore, the structure of this complex seems to resemble $H_4EDTA(BF_3)_2$.

The infrared spectra of nitrilotriacetic acid and its metal complexes have been investigated in detail.[18,19] On the basis of all these results, the assignments of the spectra of the complex were made as follows. The antisymmetric stretching band of the carboxyl group of this compound appears at 1770 cm^{-1}, about 40 cm^{-1} higher than that of the corresponding band of the free acid (1728 cm^{-1}). This shift is probably due to the effect of the B-O and B-N bonds, which have a strong covalent character. The two strong bands at 1105 and 1070 cm^{-1} seem to be C-N and B-N stretching bands respectively. This complex is very stable towards hydrolysis because the electron shell of boron is filled with the electrons donated by the coordinated nitrogen atom. Others of the same type of compound, boroxazolidines, triethanolamine borate, for example, also show a high resistance to hydration.[20,21] Judging from these results, the ligand seems to work as a tetradentate in this complex.

Alcoholic or aqueous solution of neither $H_4EDTA(BF_3)_2$ nor $H_6EDTA(BF_4)_2$ show any peaks in the ultraviolet region, probably because of the solvolytic decomposition. However, their acetonitrile solutions show a characteristic maxima at 38200 cm^{-1} and two shoulders at about 38200 and 41000 cm^{-1}. As these compounds are only slightly soluble in a solvent, the molar extinction coefficients have not yet been determined. When the solutions were boiled for a while or allowed to stand for a few hours at room temperature, the 39400 cm^{-1} and 41000 cm^{-1}, remained. This is probably due to the solvolysis of the complex. The cyclohexanediaminetetraacetato complex shows almost the same ultraviolet spectra. The nitrilotriacetato complex is insoluble and so its spectra were not examined.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2076—2079 (1970)

Chemical Effects Associated with the β-Decay Process. V. Kinetic Studies of the Chemical Behavior of the ^{144}Pr Formed by the Decay of the ^{144}Ce(III)-Ethylenediaminetetraacetate and ^{144}Ce(III)-*trans*-1,2-Diaminocyclohexane-*N*,*N*′-tetraacetate

Takanobu SHIOKAWA, Hiroaki KIDO and Takashi OMORI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received December 13, 1969)

The chemical effects associated with the β^--decay of ^{144}Ce(III)-aminopolycarboxylate complexes have been further investigated. The chemical behavior of ^{144}Pr was analyzed kinetically on the basis of the isotopic exchange-reaction mechanism. The formation of the intermediate complex produced by an intramolecular electron transfer of the ^{144}Pr(IV)-aminopolycarboxylate following the β^--decay of ^{144}Ce(III) complex was also confirmed. In the ethylenediaminetetraacetate and *trans*-1,2-diaminocyclohexane-*N*,*N*′-tetraacetate systems, the values for the bond-rupture of the daughter complex ions are fairly much larger than in the diethylenetriaminepentaacetate system, suggesting that a kinetically-excited intermediate complex decomposes to a free ion to some extent.

In the β^--decay of the ^{144}Ce(III)-ethylenediaminetetraacetate(^{144}Ce(III)-EDTA) complex, the formation of an intermediate complex has been proposed on the basis of kinetic treatments.[1,2] Further investigation of the ^{144}Ce(III)-diethylenetriaminepentaacetate(^{144}Ce(III)-DTPA) complex revealed that an exhaustive bond-rupture of the daughter complex ion involves 25 per cent of the ^{144}Pr formed by the decay of the parent complex.[3]

Recently, Glentworth and Wright[4] have reported on the chemical behavior of ^{144}Pr/^{143}Pr in the aminopolycarboxylate complexes, and have proposed that a substantial fraction of the break-up of ^{144}Pr/^{143}Pr results in the multiple charging of the daughter complex as a result of the internal conversion of γ-rays and electron shake-off, as has already been pointed out in our previous papers.[2,3] However, the deactivation processes do not seem to have been established.

In order to confirm the stabilization process of ^{144}Pr on the basis of our model, the chemical behavior of ^{144}Pr was investigated in the ^{144}Ce(III)-*trans*-1,2-diaminocyclohexane-*N*,*N*′-tetraacetate (^{144}Ce(III)-DCTA) complex system. Furthermore, some additional experiments in the EDTA complex system were carried out.

Experimental

G.R.-grade EDTA and DCTA were used without further purification. The chelating agent solutions were standardized against a standard zinc(II) solution by volumetric titration, using Eriochrome Black T as an indicator. All the other chemicals and the experimental procedures employed here were substantially the same as those described previously.[2]

Results

Isotopic Exchange Reaction. Kinetic experiments on the exchange reaction,

$$^{144}Ce^{3+} + CeY^- \rightleftarrows {}^{144}CeY^- + Ce^{3+} \quad (1)$$

in the pH range from 4 to 7 at 25°C and at 5°C were carried out; here, Y^{4-} indicates the tetravalent EDTA and DCTA anions. The exchange rate between the uncomplexed cerium(III) ion and cerium(III)-aminopolycarboxylate can be expressed as follows:

For the EDTA complex system:

$$R = k_{Ce}[H^+][CeY^-] \quad (2)$$

For the DCTA complex system:

$$R = k_{Ce}[H^+][CeY^-] + k'_{Ce}[CeY^-] \quad (3)$$

The isotopic exchange rate constants, k_{Pr} and k'_{Pr}, for the analogous systems of praseodymium(III) have also been calculated using the equilibrium constant, K, for the substitution reaction[3]:

$$^{144}Ce^{3+} + PrY^- \rightleftarrows {}^{144}CeY^- + Pr^{3+} \quad (4)$$

The equilibrium constants, K, were obtained as 0.47_7 for the EDTA complex system and 0.47_2 for the DCTA complex system. The isotopic exchange rate constants for these systems are summarized in Table 1.

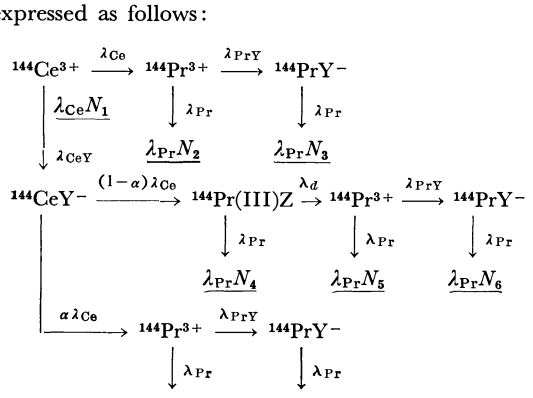
Chemical Behavior of ^{144}Pr. After complete equilibration with respect to ^{144}Ce in the systems represented by Eqs. (1) and (4) had been attained chemically, the yield of ^{144}Pr(III)-aminopolycarboxylate ($^{144}PrY^-$-yield) was obtained as a function of pH at 25° and 5°C. The $^{144}PrY^-$-yield is defined as the ratio of the γ-activity of the eluate to the total γ-activity. The results are shown in Figs. 1—4. In these experiments, the praseodymium ions are carrier-free when the carriers of the Ce(III) ion and Ce(III)-aminopolycarboxylate exist in aqueous solutions, and *vice versa*.

In both the systems, the $^{144}PrY^-$-yield decreases gradually with the pH, while in the DCTA complex system it seems to be constant in the higher pH regions. On the contrary, all the $^{144}PrY^-$-yield curves in the lower pH region exhibit asymptotic approaches to the equilibrium values, as is to be expected from the equilibrium constants of Reaction (4).

Discussion

The chemical behavior of the ^{144}Pr formed by the decay of ^{144}Ce(III)-DTPA was successfully explained on the basis of kinetic considerations as follows.[3] The praseodymium(IV)-DTPA complex was promptly reduced by an intramolecular electron-transfer. The trivalent ^{144}Pr, which remains complexed with a degradated DTPA radical, decomposes to a free ion by the dissociation in the substitution reaction. The uncomplexed ^{144}Pr(III) ion is also produced directly by an exhaustive decomposition of the daughter complex ion, without any formation of the intermediate. These stabilization processes of ^{144}Pr are considered to be valid also in the aminopolycarboxylate complex systems studied in this paper. Thus, the chain reactions for the stabilization of ^{144}Pr can be expressed as follows:



(6)

where λ_{Ce} and λ_{Pr} are the decay constants of ^{144}Ce and ^{144}Pr respectively, where λ_{CeY} and λ_{PrY} denote the respective exchange-rate constants of $^{144}Ce^{3+}$ and $^{144}Pr^{3+}$ with the aminopolycarboxylate complex, where λ_d is the decomposition rate constant of the intermediate (^{144}Pr(III)Z), and where α is the ratio of bond-rupture, which is defined as the ratio of the $^{144}Pr^{3+}$ produced directly from ^{144}Ce-(III)-aminopolycarboxylate without any formation of the intermediate possessing a finite life-time.

In Eq. (6), the fractions of $\lambda_{Pr}N_3$, $\lambda_{Pr}N_4$, $\lambda_{Pr}N_6$, and $\lambda_{Pr}N_8$ give the $^{144}PrY^-$-yield, supposing that, upon separation, the intermediate complex is not adsorbed on the ion-exchange resin. When the chemical equilibrium with respect to ^{144}Ce had been attained, and when the ^{144}Pr initially present had decayed out, the $^{144}PrY^-$-yield was obtained; therefore, the solution of Bateman's equation[5] for the respective fractions are given for the system ascribed by Eq. (1) as follows:

$$\lambda_{Pr}N_3 = \lambda_{Ce}N_1 \cdot \frac{\lambda_{PrY}}{\lambda_{Pr}+\lambda_{PrY}} \cdot \frac{[Ce^{3+}]_e}{[Ce^{3+}]_e+[CeY^-]_e} \times \frac{[^{144}PrY^-]_e}{[^{144}Pr^{3+}]_e+[^{144}PrY^-]_e} \quad (7)$$

$$\lambda_{Pr}N_4 = \lambda_{Ce}N_1 \cdot \frac{(1-\alpha)\lambda_{Pr}}{\lambda_{Pr}+\lambda_d} \cdot \frac{[CeY^-]_e}{[Ce^{3+}]_e+[CeY^-]_e} \quad (8)$$

$$\lambda_{Pr}N_6 = \lambda_{Ce}N_1 \cdot \frac{(1-\alpha)\lambda_{PrY}\lambda_d}{(\lambda_{Pr}+\lambda_{PrY})(\lambda_{Pr}+\lambda_d)} \times \frac{[CeY^-]_e}{[Ce^{3+}]_e+[CeY^-]_e} \cdot \frac{[^{144}PrY^-]_e}{[^{144}Pr^{3+}]_e+[^{144}PrY^-]_e} \quad (9)$$

$$\lambda_{Pr}N_8 = \lambda_{Ce}N_1 \cdot \frac{\alpha\lambda_{PrY}}{\lambda_{Pr}+\lambda_{PrY}} \cdot \frac{[CeY^-]_e}{[Ce^{3+}]_e+[CeY^-]_e} \times \frac{[^{144}PrY^-]_e}{[^{144}Pr^{3+}]_e+[^{144}PrY^-]_e} \quad (10)$$

where the effect of the disintegration of ^{144}Ce can be ignored. For the system expressed by Eq. (4), analogous equations are derived by exchanging the terms involving the concentrations of the metal ions. Thus, the $^{144}PrY^-$-yield is given by the sum of Eqs. (7)—(10); that is,

$$^{144}PrY^-\text{-yield}(\%) = \frac{\lambda_{Pr}(N_3+N_4+N_6+N_8)}{\lambda_{Ce}N_1} \times 100 \quad (11)$$

Since the values for λ_{Pr} and λ_{PrY} have already been established, the values for λ_d and α can be obtained by inserting the experimental values for the $^{144}PrY^-$-yields.

It was found that the ratio of the bond-rupture, α, is a constant independent of the temperature, while the λ_d depends on the temperature and is affected by the concentration of the hydrogen ion;

$$\lambda_d = k_d[H^+] \quad (12)$$

The values for the decomposition rate constant, k_d, of the intermediate, Pr(III)Z, and for the α thus obtained are summarized in Table 2, together with the data obtained in the DTPA complex system.[3] The experimental and calculated values

(5°C)	$(5 \pm 2) \times 10^4$	
DCTA (25°C)	$(3 \pm 1) \times 10^4$	0.75
(5°C)	$(8 \pm 3) \times 10^3$	
DTPA (25°C)	$(5 \pm 2) \times 10^4$	0.25
(5°C)	$(2 \pm 1) \times 10^4$	

* $\lambda_d = k_d[H^+]$

for the $^{144}PrY^-$-yields are compared in Figs. 1—4.

The bond rupture of the daughter complex may be caused by the formation of a multiply-charged ^{144}Pr ion due to electron shake-off and the internal conversion of γ-rays, followed by the Auger process. In the DTPA-complex system, the ratio of the bond rupture of 0.25 corresponds to the extent of the formation of the multiply-charged ^{144}Pr ion. In the EDTA- and DCTA-complex systems, the ratios of the bond rupture of 0.70 and 0.75 respectively are much larger than that in the DTPA complex system, indicating that there is involved another process, without any formation of a stable intermediate. This process may be accounted possibly by the recoil effect. In the β^--decay of ^{144}Ce, the recoil energies imparted to free ^{144}Pr atoms range from 0 to 1.6 eV. The probability of bond rupture as a result of recoil only is very small; however, a significant fraction of the β^--decay of ^{144}Ce would leave the daughter complex in a kinetically-excited state. Thus, by taking into consideration the fact that the activation energies for the decomposition of the intermediate are estimated to be about 10 kcal/mol, it is reasonable that the kinetically-excited decomposition of the intermediate should take place, resulting in the formation of the uncomplexed $^{144}Pr(III)$ ion.

In the DTPA-complex system, the kinetically-excited decomposition of the intermediate was not observed. The differences in the chemical behavior of ^{144}Pr in the DTPA complex system from that in the EDTA and DCTA complex systems may be attributed to the difference in the molecular structures of the chelates; that is, the EDTA and DCTA are hexadentate chelating agents, while the DTPA is an octadentate.

In view of the decomposition mechanism and rate constants, the stabilization processes of ^{144}Pr proposed in the DTPA-complex system[3] are further confirmed in the EDTA- and DCTA-complex systems. In addition, a new process of the kinetically-excited decomposition of the intermediate is proposed. The stabilization processes of ^{144}Pr are shown schematically in Fig. 5.

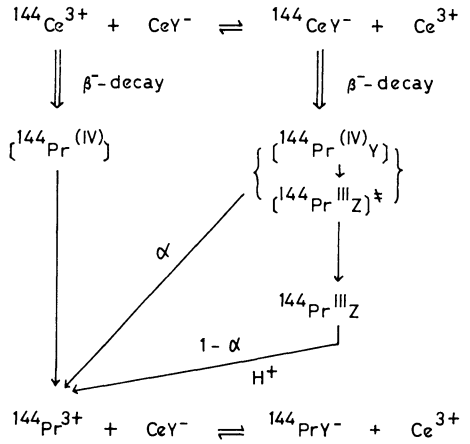

Fig. 5. Stabilization processes of ^{144}Pr produced by β^--decay of ^{144}Ce in the aminopolycarboxylate complex system.

Pyrolysis-Gas Chromatographic Analysis of Vinylchloride-Vinylacetate Copolymer

Tadaoki OKUMOTO

Engineering Department, Nagoya Rubber Co., Ltd., Haruhi-mura, Nishikasugai-gun, Aichi

and Tsugio TAKEUCHI and Shin TSUGE

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received December 15, 1969)

Pyrolysis-gas chromatography was applied to rapid and precise determination of vinylchloride-vinylacetate copolymer by use of the yields of acetic acid and of benzene. The separation column was filled with packing of polymer beads (porapak Q) which are free from deterioration by hydrogen chloride evolved during the thermal degradation of copolymers. Relative yields of acetic acid, which originated from the side chains of the polymer and corresponded to vinylacetate content, and of benzene, formed mainly from successive vinylchloride units, were calculated from the relative peak area appearing on the pyrogram by making relative sensitivity correction for the flame ionization detector. By this method the composition of copolymer can be determined using 0.5—2.0 mg of sample with mean absolute deviation 0.5—0.4 wt%, with the yields of acetic acid and of benzene.

The copolymer of vinylchloride and vinylacetate (VC-VAc) shows different properties according to vinylacetate content. With the increase of vinylacetate content, solubility and adhesive affinity are imporved, and softening point is lowered. Analysis of the copolymer has mostly been carried out by means of IR, NMR and chemical determination of chlorine. A few qualitative works on the analysis of the copolymer by pyrolysis-gas chromatography (PGC), have been reported.[1-3] This is partly associated with the fact that hydrogen chloride evolved during the degradation of the polymer deteriorates the separating column, and has no sensitivity to the flame ionization detector.

Barlow *et al.*[3] reported on the analysis of the copolymer at the relatively high pyrolysis temperature of 580°C, using a hot-filament-type pyrolyzer and Katharometer detector (thermal conductivity detector). They performed the analysis with the peaks of hydrogen chloride and acetic acid on pyrogram of the copolymer with about 2% standard deviation.

In our previous works,[4,5] we characterized the microstructure of chlorine-containing polymers by PGC in which NaOH-precut column was used to adsorb hydrogen chloride evolved during the degradation of polymers.

We have worked out an analytical method for determining the composition of vinylchloride-vinylacetate copolymer with the use of PGC without NaOH-precut column.

Experimental

Materials. VC-VAc copolymers synthesized by suspension polymerization were used as samples.

The content of vinylacetate in the copolymer ranged from 0.5 to 15.7 wt% which was determined by the usual chemical analysis of chlorine.

Apparatus. A heated furnace type pyrolyzer, Hitachi KP-1, whose structure is almost the same as that used previously works[4-6] was used to decompose the polymers. It was directly attached to the inlet port of a gas chromatograph, Hitachi F6-D with flame ionization detectors.

In order to minimize the change of the pyrolysis temperature, which disturbs the reproducibility, a voltage stabilyzer was used for the pyrolyzer.

An optimum pyrolysis temperature 430°C was chosen in order to obtain characteristic, reproducible and sharp pyrograms.

A sample weighing 0.5—2.0 mg was pyrolyzed under a flow of carrier gas (N_2) at the pyrolysis temperature for 1 min. This was sufficient to achieve complete pyrolysis of the polymers.

Gas Chromatographic Conditions. Gas chromatographic analysis was carried out under the following conditions.

Column: Stainless steel tube (3 mm diam. × 0.5 m

1) Y. Mashiko, A. Echizen and A. Nakao, *Kogyo Kagaku Zasshi*, **68**, 1206 (1965).

length),

Packing: Polymer beads with porosity (Porapak Q; 120—150 mesh),

Temperature programing: 120—230°C, (7°C/min) isothermal after 230°C,

Carrier gas: N_2 1.0 kg/cm² inlet pressure (55 ml/min at room temperature),

Hydrogen flame: H_2 0.7 kg/cm², air 1.0 kg/cm².

Polymer beads (Porapak Q) without liquid phase and NaOH-precut column were packed in the separating column, which is not deteriorated by acidic products such as hydrogen chloride or acetic acid.

Identification of the peaks appearing on the pyrograms was carried out with the use of the retention data of various pure substances which are expected to be formed from the degradation of the polymers.

Results and Discussion

Figure 1 shows typical pyrograms of VC-VAc copolymer, PVAc (polyvinylacetate) and PVC (polyvinylchloride) at the pyrolysis temperature 430°C.

PVC yields benzene and a small amount of toluene. These degradation products are formed by dehydrochlorination reaction followed by cyclization of polymer structure.[4] On the other hand, PVAc[7] yields acetic acid and a small amount of benzene. In this case, there exist competitive thermal reactions, namely scission of the main chain followed by elimination of acetic acid and the formation of polyene structure followed by cyclization to benzene.

Although both mechanisms yield acetic acid, the former is predominant judging from the relatively small amount of benzene on pyrogram.

As might be expected from the above degradation mechanisms of PVC and PVAc, the copolymers with high content of VAc yield mainly acetic acid and a little benzene, whereas those with high content of VC yield mainly benzene.

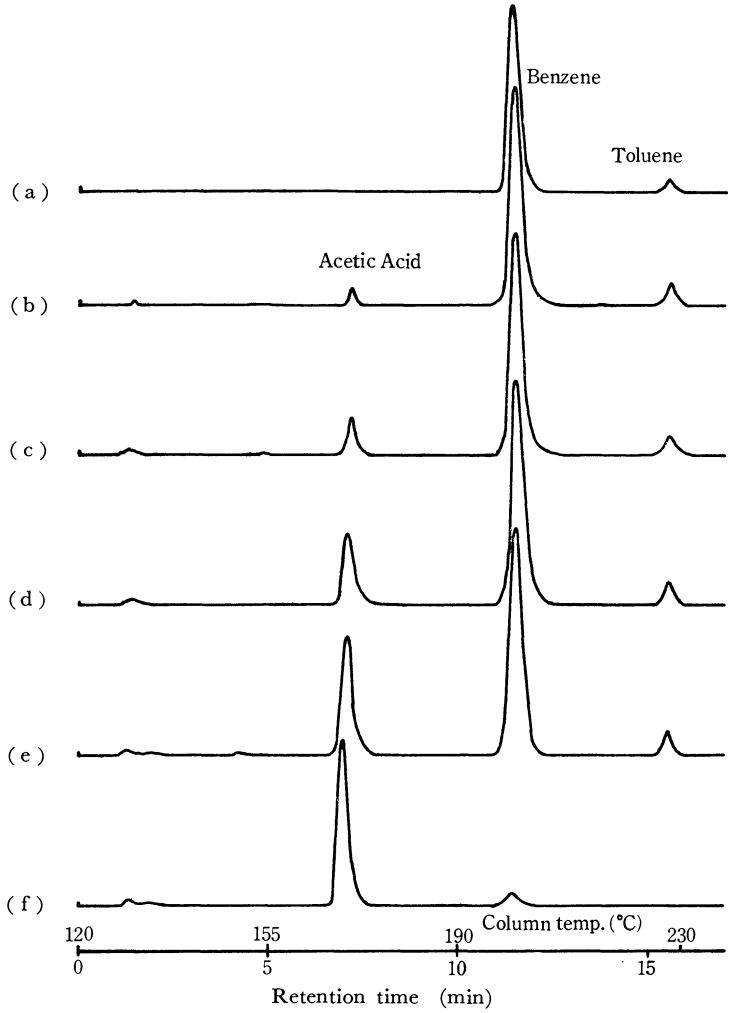

Fig. 1. Pyrogram of vinylchloride-vinylacetate copolymer at 430°C.
(a) PVC; (b)—(e) VC-VAc copolymer (VAc=2.9 (b), 5.5 (c), 11.6 (d) and 15.7 (e) wt%); (f) PVAc

For the sake of simplicity, a small amount of toluene observed with PVC and copolymers was converted into benzene in the calculation and added to the observed yield of benzene. One mole of benzene was considered to correspond to three moles of successive VC-unit, whereas one mole of acetic acid to one mole of VAc-unit.

Figure 2 shows the relation between the relative yields of acetic acid and benzene and the composition of vinylacetate (wt%). The plots (● and ▲) represent the observed values, and the solid line is obtained by the method of least squares.

The linear relations can be represented as follows:

(A) Yield of acetic acid

$$Y = 2.21\,X + 5.2 \qquad (1)$$

(B) Yield of benzene

$$Y' = 2.36\,X' - 140.1 \qquad (2)$$

where X and X' are vinylacetate and vinylchloride contents in copolymer (wt%), respectively, and $X+X'=100$. Y and Y' are the observed relative yields of acetic acid and benzene (wt%), respectively. Precision data are listed in Table 1.

With the use of Eqs. (1) and (2), the composition of vinylacetate in copolymer can be determined with mean absolute deviation 0.5 and 0.4 wt% respectively, with the yields of acetic acid and of benzene.

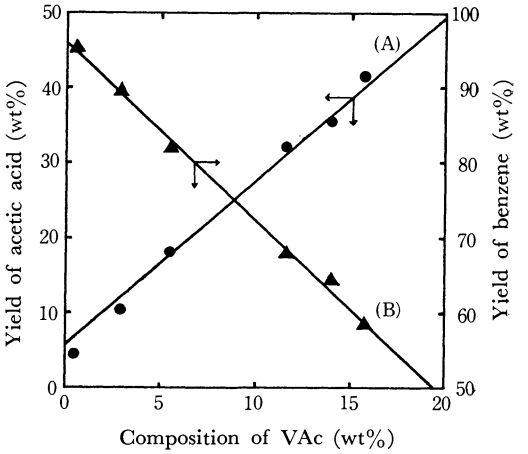

Fig. 2. Relationship between yields of acetic acid and of benzene, and composition of VAc.
(A) acetic acid; (B) benzene

Pyrolysis-gas chromatography was successfully applied to rapid and precise determination of composition of polymer evolving such acidic products as hydrogen chloride and acetic acid during its thermal decomposition without trapping the acidic substances.

On the Polarographic Limiting Current of Solubilized Dye in Nonionic Surfactant Solutions

Shigeo HAYANO and Noriko SHINOZUKA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 24, 1969)

The nature of the limiting current of the reduction of solubilized dye with nonionic surfactants on a mercury-drop electrode was examined. The solution of anthraquinone derivatives solubilized in an aqueous solution of a nonionic surfactant showed a proportionality of the limiting current to the dye concentration. The linear dependence of the current on the square-root of the mercury-column height, the solpe of the log-plot, and the *i-t* curves indicated the limiting current to be diffusion-controlled. From the *i-t* curve measurements, the acceleration of the instantaneous current at the end of the mercury-drop growth was observed with the polyoxyethylene nonylphenylether and Triton X-100. This can be interpreted in relation to the reorientation of the surfactant molecules.

A previous paper treated[1] the polarographic reduction of the disperse-dyes solubilized in nonionic surfactant solutions in which the electrode process is diffusion-controlled. In that case, a linear relation of the limiting current to the dye concentration was assumed, but it could not be established.

In this paper, the nature of the limiting current of the solubilized dye will be examined in further detail in a system which shows a proportionality of the limiting current to the dye concentration.

Experimental

The 1-amino-2-methoxy-4-hydroxy anthraquinone was obtained by the recrystallization of a sample dye received through the courtesy of the Sumitomo Chemical Industry Co. from an ethanol-water mixture. Polyoxyethylene nonylphenyl ether (NP-$\overline{10}$, NP-$\overline{9}$), polyoxyethylene lauryl ether (L-$\bar{9}$), and Triton-X-100 (TX-100) were used as nonionic surfactants.

The solubilization and the polarographic procedure were the same as in the previous paper except that the solution was not irradiated with supersonic waves in this study.

The current-time curves were measured with a potentiostat (Hokuto Denko Co., Ltd.) and a XY-5121-type synchroscope (Iwasaki Tushinki Co., Ltd.) or a XY-recorder (Yokogawa Denki Co., Ltd.).

Results and Discussion

Relation of the Limiting Current to Dye Concentration. The solubilized dye in all four surfactant solutions showed a well-defined wave. $E_{1/2}$ is -0.625 V (*vs.* SCE), a value which accords with the peak potential of the ac polarogram. The dependence of the limiting current on the dye concentration is shown in Fig. 1. The linear relationship was obtained with a surfactant concentration of between 10^{-3} and 10^{-1} M. This proves that the diffusion coefficient of the surfactant micelle with the dye molecule is not affected by the surfactant concentration or the dye concentration. The value of the diffusion coefficient increases with an increase in the molecular weight of the surfactant, (NP-$\overline{10}$>L-$\bar{9}$>TX-100). The values are in accord with the volumes of these surfactant micelles, all of which have almost the same aggregation number, about 100.[2]

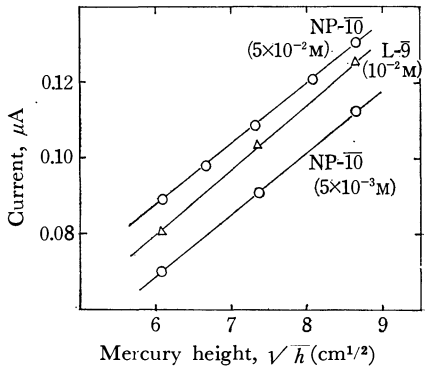

Fig. 2. Dependence of current on mercury height.

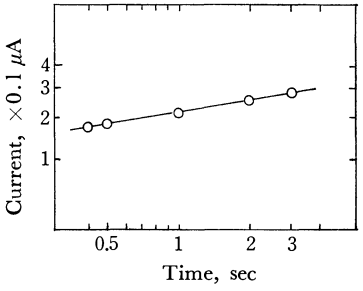

Fig. 3. log-Plots of *i-t* curve.
(L-9: 6×10^{-2} M, Dye: 2.2×10^{-4} M, at -0.7 V)

The Nature of the Limiting Current. The linear dependence of the current on the square-root of the mercury-column height indicates that the limiting current is diffusion-controlled (Fig. 2). Furthermore, the *i-t* curves of the dye at the potential of the current-plateau show the relation of $i \propto t^{1/6}$ (Fig. 3).

The log-plot of the current against the potential gives a straight line with a slope of about 30 mV/log unit, showing that the reversibility of the reduction of solubilized dye is not affected by the solubilization with surfactants.

Current-time Curves. During the measurement of the *i-t* curves, a marked current increase, an increase which gave rise to a hump on the limiting current, was observed when the mercury head was lowered or/and the surfactant concentration was decreased at potentials between -0.8 and -1.3 V (Fig. 4). The log-plots of the curve showed that the current was diffusion-controlled until there was a marked current increase. This phenomenon was not found with the L-9 surfactant in various concentrations or at various mercury-column heights. The following analysis of the curve indicates that the time of the sudden current increase corresponds to the constant surface area of a mercury drop.

The surface area of a mercury drop at time t is given as follows:[3]

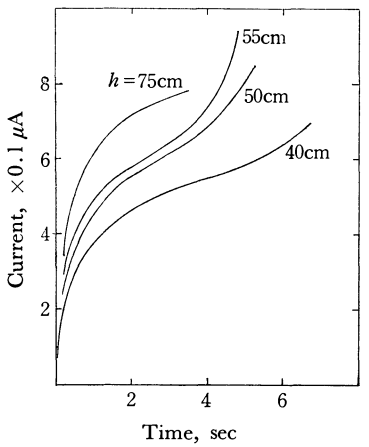

Fig. 4. Dependence of *i-t* curves on mercury height.
(NP-10: 5×10^{-2} M, Dye: 2.6×10^{-4} M at -0.8 V)

TABLE 1. DEPENDENCE OF THE TIME OF SUDDEN CURRENT INCREASE ON MERCURY COLUMN HEIGHT

Mercur height (cm)	t (sec)	$(Pt)^{2/3}$
75.5	2.2	30.2
65.5	2.5	29.9
55.5	2.9	29.5
45.5	3.5	29.3
40.5	4.1	30.1

$$a = 0.85m^{2/3}t^{2/3}$$

As the mercury flow rate, m, is proportional to the height of the mercury head, "P", and as P is easy to measure, "a" is written as,

$$a = kP^{2/3}t^{2/3} \qquad k\text{: constant}$$

From the *i-t* curves, the $(Pt)^{2/3}$ values, where t is the time at which the current increases, were calculated; they are listed in Table 1. The constant $(Pt)^{2/3}$ means that the current increases when the mercury surface attains a constant area.

It is known that surface-active cations accelerate the reduction of anions and that anionic surfactants accelerate the reduction of cations.[4] Such acceleration as in the case of a charged-type depolarizer with an ionic surfactant can be interpreted in terms of a change in the ϕ-potential due to adsorption. On the other hand, for a neutral depolarizer with a nonionic surfactant system, no acceleration has yet been reported.

Recently, Jehring has discussed the reorientation of the surfactant on mercury by means of ac polarography and has concluded that, with NP-10, a unimolecularly-dispersed surfactant is reoriented to a micelle or its hydrophilic portion extends toward

mercury in the potential range of -0.85——-1.1 V *vs.* SCE.[5] The potential range of its appearance, the dependence on the concentration of the surfactant, and the presence of a phenyl group in the surfactant molecule were the same as in this study.

From ac polarograms it is evident that surfactant molecules are adsorbed on the electrode; therefore, the above results can be interpreted as showing that the adsorbed surfactant molecules are reoriented when the mercury-drop surface reaches a certain size. The value of the area corresponding to the reorientation varies with the applied potential, the kind of surfactant, and the surfactant concentration. For a 5×10^{-2} M solution of NP-10 at -0.8 V, the value is 2.34×10^{-2} cm^2; this is reasonable compared with the value, 2.23×10^{-2} cm^2, that corresponds to the approximate monolayer coverage of Triton -X-100.[6] The accelerated current may be related to the reorientation of the surfactant molecules.

It is interesting to note that, although the electrode reaction of the solubilized dye occurs at a potential where the surfactant is strongly adsorbed, the current is diffusion-controlled and the reversibility of the reduction is not affected.

Work is now in progress to investigate the effect of micelles on the electrode reaction of the solubilizate and the adsorption of surfactant molecules on the electrode.

Multidentate Ligand Substitution Reactions. XI. Substitution Reactions of Nickel(II) Complexes of Diethylenetriamine and Ethylenediaminemonoacetic Acid with Diethylenetriaminepentaacetic Acid and of Nickel(II) Complexes of Diethylenetriamine and Ethylenediamine with Cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic Acid

Mutsuo KODAMA, Yuki FUJII and Teiko UEDA

Department of Chemistry, Ibaraki University, Bunkyo, Mito, Ibaraki

(Received January 21, 1970)

The kinetics of substitution reactions of nickel(II) complexes of diethylenetriamine and ethylenediaminemonoacetic acid with diethylenetriaminepentaacetic acid and those of diethylenetriamine and ethylenediamine with cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic acid were studied systematically by using the polarographic technique. All the reactions studied were found to be first-order with respect to the attacking group and also first-order with respect to the nickel(II) complex of diethylenetriamine, ethylenediamine, or ethylenediaminemonoacetic acid with a 1-to-1 composition. From a comparison of the relative rate constants determined experimentally with those calculated on the basis of a postulated reaction intermediate, the reaction mechanism was described in detail. All the reactions were concluded to proceed through the mixed ligand complex reaction intermediates which are characterized as having two nitrogen (amino) groups of displaced ethylenediamine, diethylenetriamine, or ethylenediaminemonoacetate ions bonded to the nickel(II) ion. This finding is contrary to the observation obtained by Rorabacher and Margerum from their kinetic study of the exchange reaction of the ethylenediaminetetraacetate anion with nickel(II) complexes of triethylenetetramine and tetraethylenepentamine.

In previous papers,[1-3] we have studied the kinetics of nucleophilic substitution reactions involving nickel(II) and cobalt(II) complexes of ethylenediaminetetraacetic acid (EDTA) and its related substances. From a comparison of the rate constants, the reaction intermediate for these substitution reactions was characterized as having one

2) M. Kodama, C. Sasaki and T. Noda, *ibid.*, **41**, 2033 (1968).
3) M. Kodama, C. Sasaki and K. Miyamoto, *ibid.*, **42**, 163 (1969).

nitrogen (amino) group and one acetate group of displaced aminopolycarboxylate anions bonded to the metal(II) ion (Glycinate mechanism). The nucleophilic substitution reactions involving nickel-(II)-aspartate and iminodiacetate complexes were also found to proceed through a reaction intermediate with a glycinate group bonded to the nickel(II) ion.[4] Rorabacher and Margerum studied the substitution reactions involving nickel-(II) complexes of polyamines.[5] In their kinetic studies of the displacement of triethylenetetramine and tetraethylenepentamine by the EDTA anion, they proposed a reaction intermediate in which the released polyamine forms two five-membered rings with the nickel(II) ion through three nitrogen groups. The ethylenediaminemonoacetate (EDMA) ion, in whose complexation reaction with metal ions two nitrogen groups and one acetate group can function as donor groups, was also found to be displaced from its nickel(II) complex by diethylenetriaminepentaacetic acid (DTPA) at a measurable rate. In general, the nickel(II)-nitrogen bond rupture is much slower than the nickel(II)-oxygen bond rupture.

Therefore, the nucleophilic substitution reactions involving the nickel(II)-EDMA complex can hardly be expected to proceed through a glycinate reaction mechanism. On the other hand, if the nucleophilic substitution reaction of the nickel(II)-ethylenediamine (En) complex also proceeds through a mixed ligand complex intermediate, because of steric requirements the reaction intermediate can be expected to have a structure in which a bidentate ethylenediamine occupies two of the six octahedral coordination sites of the nickel (II) ion. Thus, the substitution reaction involving an En complex would have a different reaction intermediate from those of the other polyamine complexes. In the experiments reported in this paper, we studied the kinetics of the substitution reactions of the nickel(II) complexes of diethylenetriamine (Dien) and EDMA with DTPA and of those of Dien and En with cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (CyDTA) and determined the reaction mechanism and rate constants for these reactions. From comparisons of the rate constants determined experimentally and from calculations based on the relative stability of the mixed ligand complex intermediate and the electrostatic interaction between the entering group and the reactant (nickel(II) complex), the structure of the reaction intermediates in the substitution reactions involving nickel(II)-EDMA, Dien, and En complexes were determined.

Experimental

Reagents. A nickel(II) nitrate solution was prepared by dissolving a known amount of metallic nickel (99.99% pure) in dilute nitric acid (1+1) and by then removing the excess nitric acid by distillation under reduced pressure. The preparation and recrystallization of EDMA dihydrochloride have been described previously.[6] The En and Dien were purified by distillation under reduced pressure. The DTPA and CyDTA were recrystallized twice from their aqueous solutions by adding a suitable amount of pure ethanol. The other reagents were of analytical reagent grades and were used without further purification.

Apparatus and Experimental Procedures. All the d.c. polarograms and current-time curves were

recorded automatically by means of a Yanagimoto pen-recording polarograph, PA-102, or a Hitachi recorder, QPD-54. The characteristics of the dropping mercury electrode (DME) used in this study have been described previously.[7] For all the spectrophotometric measurements, a Hitachi EPS-3 recording spectrophotometer with a pair of 1-cm quartz cells was used. The rate of the substitution reaction was determined by measuring the change in the diffusion current of anodic waves due to the decrease in the uncomplexed DTPA or CyDTA concentration with time. In this study, all the measurements were conducted in solutions with an ionic strength of 0.30. In order to adjust the ionic strength, sodium perchlorate (the EDMA system) or potassium nitrate (the En and Dien systems) was used. In the kinetic study, measurements were made in solutions containing a large excess of complexed and uncomplexed EDMA, En, or Dien over DTPA or CyDTA in the pH range from 8.30 to 10.0 at 25°C. Therefore, all the substitution reactions could be treated as pseudo first-order reactions and no buffer reagent was required to maintain the solution's pH constant over the entire pH range covered. All the experimental procedures employed were the same as had previously been described.[7]

Results and Discussion

Spectrophotometric Determination of Formation Constants of the Nickel (II)-Ethylenediaminemonoacetate Complex. As EDMA has two amino groups and one acetate group, it can act as a tridentate ligand in the complexation with metal ions. Therefore, in order to complete the octahedral coordination sphere of a nickel(II) ion, two molecules of EDMA are required. Thus, the nickel(II) ion is expected to form complexes of 1-to-1 and 1-to-2 compositions with EDMA. In Fig. 1, typical absorption curves of the nickel-(II) ion in the EDMA solution are reproduced. In this study, we tried to determined the stability constants of the nickel(II)-EDMA complexes spectrophotometrically. If the total concentration of nickel(II) ions is kept constant throughout the experiment, the concentrations of complexed and uncomplexed nickel(II) ions in a solution containing an equimolar EDMA can be represented by the following equations:

$$[NiX^+] = \frac{A - A_{Ni}}{\varepsilon_{NiX} - \varepsilon_{Ni}} \quad (1)$$

$$[Ni^{2+}] = \frac{A_{NiX} - A}{\varepsilon_{NiX} - \varepsilon_{Ni}} \quad (2)$$

where ε's denote molar extinction coefficients, where $[Ni^{2+}]$ and $[NiX^+]$ are the concentrations of uncomplexed and complexed nickel(II) ions respectively, and where A, A_{NiX} and A_{Ni} are, respectively, the absorbance of the solutions in which complexed and uncomplexed nickel(II) ions coexist, in which all the nickel(II) ions exist in the form of NiX^+, and in which there is no EDMA. Since the concentration of uncomplexed EDMA is identical with that of the uncomplexed nickel(II) ion, the conditional formation constant of the nickel(II)-EDMA complex with a 1-to-1 composition, K'_{NiX}, is given by:

$$K'_{NiX} = \frac{K_{NiX}}{(\alpha_H)_X} = \frac{(A - A_{Ni})(\varepsilon_{NiX} - \varepsilon_{Ni})}{(A_{NiX} - A)^2} \quad (3)$$

where $(\alpha_H)_X$ is the (α_H) value of EDMA, and K_{NiX}, the formation constant of NiX^+.

Equation (3) clearly indicates that, by plotting $\log[(A-A_{Ni})(\varepsilon_{NiX}-\varepsilon_{Ni})/(A_{NiX}-A)^2]$ *vs.* $\log(\alpha_H)_X$, one can obtain a linear relation with a slope of -1.0 and that the $\log(\alpha_H)_X$ value at $\log[(A-A_{Ni})(\varepsilon_{NiX}-\varepsilon_{Ni})/(A_{NiX}-A)^2]$=zero corresponds to the $\log K_{NiX}$ value. To prepare an equimolar solution of nickel(II) ions and EDMA, we used a known amount of pure crystals of ethylenediaminemonoacetatotriaquonickel(II) chloride synthesized in our laboratory.*1 With the aid of Eq. (3), the experimental data were analyzed. The results are illustarated in Fig. 2. From the intercept of the linear relation in Fig. 2, the $\log K_{NiX}$ value was estimated to be 10.44. With an increase in the uncomplexed EDMA concentration and an increased pH value, the absorbance of the nickel (II) solution increases and the absorption curve's maxima shift to shorter wavelengths. This can be ascribed to the formation of a complex with a 1-to-2 ratio. If both the complex with a 1-to-2 ratio and that with a 1-to-1 ratio are formed, and if the uncomplexed nickel(II)-ion concentration can be disregarded as compared with the complexed nickel(II)-ion concentration, the following

*1 The preparation of ethylenediaminemonoacetatotriaquonickel(II) chloride will be described elsewhere.

relation can be derived thermodynamically for a solution containing an excess of EDMA over the nickel(II) ion:

$$\log \frac{K_2}{(\alpha_H)_X} = \log \frac{(A-A_{NiX})(\varepsilon_{NiX_2}-\varepsilon_{NiX})}{\left((A_{NiX_2}-A)\{([X]_t-2[Ni]_t)(\varepsilon_{NiX_2}-\varepsilon_{NiX})+(A_{NiX_2}-A)\}\right)} \quad (4)$$

where K_2 is defined as $[NiX_2^0]/[NiX^+]\cdot[X^-]$, where $[X]_t$ and $[Ni]_t$ denote the total concentrations of EDMA and nickel(II) ions respectively, where A_{NiX_2} means the absorbance of a solution where all the nickel(II) ions exist exclusively in the form of NiX_2^0, and where ε_{NiX_2} is the molar extinction coefficient of NiX_2. Equation (4) varified experimentally. As is illustrated in Fig. 3, the plot of the right-hand side of Eq. (4) against $\log(\alpha_H)_X$ gave a linear relation with a slope of -1.0. From this linear relation, the $\log K_2$ value was determined to be 6.34. The presence of chloride ions has no effect on the absorbance or the location of the maximum. This clearly indicates that the nickel(II) ion does not enter into the mixed ligand complex involving the chloride ion under the present experimental conditions. The numerical values determined are given in Table 1.

Kinetics Study of Substitution Reaction of Nickel(II) Complexes of Dien and EDMA with DTPA and Those of Dien and En with CyDTA. As was found in the substitution reaction of the nickel(II)-NTA complex with DTPA,[7] the linear relations passing through the point of origin could be obtained by plotting the $\log(i_0/i_t)$ against time, t, in all the substitution reactions studied in the present paper

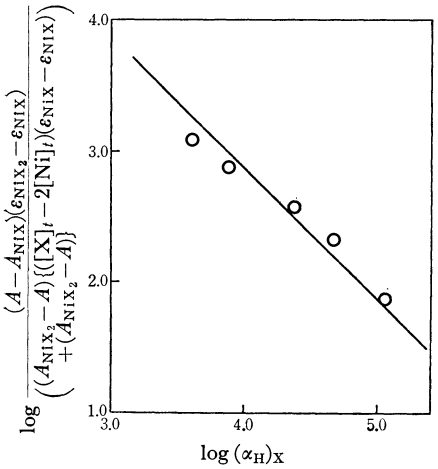

Fig. 3. The plot of $\log[(A-A_{NiX})(\varepsilon_{NiX_2}-\varepsilon_{NiX})/(A_{NiX_2}-A)\{([X]_t-2[Ni]_t)(\varepsilon_{NiX_2}-\varepsilon_{NiX})+(A_{NiX_2}-A)\}]$ against $\log(\alpha_H)_X$.

ε_{NIX}	5.98	3.31
ε_{NIX2}	—	9.80

(these results are not shown). Here, i_0 and i_t denote the wave heights of DTPA or Cy-DTA wave at time $t=0$ and $t=t$ respectively. When the other experimental conditions were kept constant, the slope of the above linear relation was not influenced by the addition of the nickel(II)-DTPA or CyDTA complex, and it was independent of the initial concentration of DTPA or CyDTA. These facts clearly indicate that the forward reaction is much faster than the backward reaction, and that the dissociation of the nickel(II) complex of Dien, EDMA, or En is not involved in any of the present substitution reactions. Therefore, the log-plot slope multiplied by 2.303 is equal to the apparent rate constant, k^+_{ap}, of the forward reaction. Furthermore, in solutions of a given pH and a given initial concentration of DTPA or CyDTA, the log-plot slope was exactly proportional to the concentration of the nickel(II)-EDMA, En, or Dien complex with a 1-to-1 ratio. The results are given in Table 2. Dien and EDMA act as tridentate

ligands in the complex formation reaction. Therefore, the concentration of the nickel(II) complex of Dien or EDMA with a 1-to-1 ratio can be expressed by $[Ni]_t/[1+K_2[X]_f/(\alpha_H)_X]$. Here, $[X]_f$ and $(\alpha_H)_X$ denote the concentration of uncomplexed Dien or EDMA and the (α_H) value of Dien or EDMA, and K_2 is the second successive formation constant of the nickel(II)-EDMA or Dien complex. On the other hand, in the nickel(II)-En system, the concentration of the nickel(II)-En complex with a 1-to-1 ratio is given by $[Ni]_t/[1+K_2\cdot[X]_f/(\alpha_H)_X+K_2\cdot K_3\cdot[X]_f^2/(\alpha_H)_X^2]$. Here, K_2 and K_3 are the second and third successive formation constants of the nickel(II)-En complexes. As is illustrated in Figs. 4 and 5, the product of the apparent rate constant, k^+_{ap}, and $(\alpha_H)_Z(1+K_2\cdot[X]_f/(\alpha_H)_X)/[Ni]_t$(Dien and EDMA systems) or $(\alpha_H)_Z(1+K_2[X]_f/(\alpha_H)_X+K_2\cdot K_3\cdot[X]^2_f/(\alpha_H)^2_X)/[Ni]_t$ (En system) was found to be a linear function of the hydrogen ion concentration and is given by

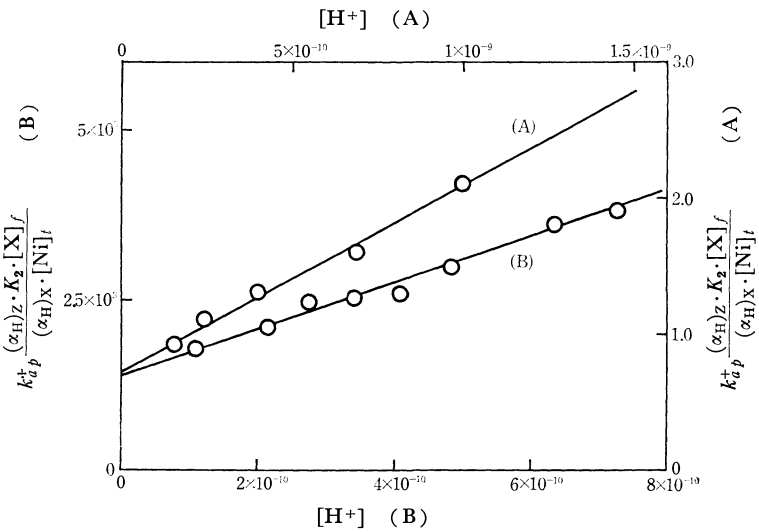

Fig. 5. The plot of $k_{ap}^{+}(\alpha_H)_Z K_2 \cdot [X]_f/(\alpha_H)_X[Ni]_t$ against the hydrogen ion concentration.
μ=0.30, 25°C
Initial concentration of DTPA=0.40 mM
Concentration of nickel(II) ion=10.0 mM
A: Ni(II)-Dien system
Total concentration of Dien=30.0 mM
B: Ni(II)-EDMA system
Total concentration of EDMA=30.0 mM

Eq. (5a) or (5b):

$$k_{ap}^{+}(\alpha_H)_Z \cdot \left(1 + \frac{K_2 \cdot [X]_f}{(\alpha_H)_X}\right) \frac{1}{[Ni]_t} = k_\alpha^{+} + k_\beta^{+}[H^+] \quad (5a)$$

$$k_{ap}^{+}(\alpha_H)_Z \cdot \left(1 + \frac{K_2 \cdot [X]_f}{(\alpha_H)_X} + \frac{K_2 \cdot K_3 \cdot [X]_f^2}{(\alpha_H)_X^2}\right) \cdot \frac{1}{[Ni]_t} = k_a^{+} + k_b^{+}[H^+] \quad (5b)$$

Here, $(\alpha_H)_Z$ in Eqs. (5a) and (5b) is the (α_H) value of DTPA or CyDTA, and $1+K_2 \cdot [X]_f/(\alpha_H)_X$ in Eq. (5a) and $1+K_2 \cdot [X]_f/(\alpha_H)_X+K_2 \cdot K_3 \cdot [X]_f^2/(\alpha_H)^2_X$ in Eq. (5b) are practically identical with $K_2 \cdot [X]_f/(\alpha_H)_X$ and $K_2 \cdot K_3 \cdot [X]_f^2/(\alpha_H)_X^2$ respectively under the present experimental conditions. From the above data, we may conclude that the mechanism of the substitution reactions of the nickel(II)-EDMA or Dien complex and that involving the nickel(II)-En complex can be expressed by (A) and (B) respectively:

(A) i) $NiX^{2-a} + Z^{m-} \overset{k_1^{+}}{\rightleftharpoons} NiZ^{2-m} + X^{a-}$

$\Big\Updownarrow$ rapid

NiX_2^{2-2a}

ii) $NiX^{2-a} + HZ^{1-m} \overset{k_2^{+}}{\rightleftharpoons} NiZ^{2-m} + HX^{1-a}$

$\Big\Updownarrow$ rapid

NiX_2^{2-2a}

where NiX_2^{2-2a} denotes 1-to-2 complex of Dien or EDMA and where Z^{m-} means a completely-deprotonated DTPA or CyDTA anion.

(B) i) $NiX^{2+} + Z^{4-} \overset{k_1^{+}}{\rightleftharpoons} NiZ^{2-} + X^{0}$

$\Big\Updownarrow$ rapid

$NiX_2^{2+} \overset{\text{rapid}}{\rightleftharpoons} NiX_3^{2+}$

ii) $NiX^{2+} + HZ^{3-} \overset{k_2^{+}}{\rightleftharpoons} NiZ^{2-} + HX^{+}$

$\Big\Updownarrow$ rapid

NiX_2^{2+}

$\Big\Updownarrow$ rapid

NiX_3^{2+}

From the above reaction mechanisms, it is very clear that k_α^{+} and k_a^{+} can be equated with k_1^{+}, and k_β^{+} and k_b^{+} with k_2^{+}/K_d. Here, K_d denotes the K_4 of CyDTA or the K_5 of DTPA. The possibility of the formation of a mixed ligand complex of nickel(II) ions involving the CyDTA anion and En can be eliminated, because the addition of En had no effect on the absorption curve of the nickel(II)-CyDTA complex. The rate constant, k_1^{+} and k_2^{+}, were determined from the linear relations shown in Figs. 4 and 5: they are listed, together with the k_2^{+} value determined for the substitution reaction of the nickel(II)-iminodiacetate (IDA) complex with DTPA, in Table 3.

8) D. W. Margerum, D. B. Rorabacher and J. F. Clarke, Jr., *Inorg. Chem.*, **2**, 667 (1963).

Table 3. Rate constants

System	k_1^+ $M^{-1}\,sec^{-1}$	k_2^+ $M^{-1}\,sec^{-1}$
Ni(II)-IDA - DTPA	3.8×10^4	6.13×10^3
Ni(II)-EDMA - DTPA	$1.3_6\times10^3$	2.58×10^2
Ni(II)-Dien - DTPA	7.2×10^5	9.80×10^4
Ni(II)-En - CyDTA	7.2×10^4	1.23×10^4
Ni(II)-Dien - CyDTA	3.8×10^4	2.97×10^1

The substitution reactions of the nickel(II)-Dien and -En complexes are much faster than their dissolication rates.[8] This clearly indicates that the presence of DTPA or CyDTA in a solution effectively aids in the removal of the Dien and En from the coordination sphere of the nickel(II) ion. To perform this function, DTPA and CyDTA may form coordination bonds with the nickel(II) ion prior to the complete dissociation of the Dien or En from the nickel(II) ion. As in the case of the reactions of Eriochrom Black T (BT) with nickel(II) and cobalt(II)-aminopolycarboxylic acids, this mechanism indicates the formation of mixed ligand intermediate complexes involving Dien or En, and DTPA or CyDTA, anion. If the substitution reaction of CyDTA with the nickel-(II)-Dien complex has a reaction intermediate quite different from that of the reaction with the nickel(II)-En complex, the rate constants of the former reaction can not reasonably be compared with those for the latter reaction. However, if the reaction with the nickel(II)-Dien complex proceeds through a reaction intermediate quite similar to that through which the reaction with the nickel(II)-En complex proceeds, the relative rate constant determined experimentally can be compared with that estimated on the basis of the proposed reaction intermediate.

In Fig. 6, the structures of some possible reaction intermediates are shown. As in the cases of the reactions of BT with the nickel(II) and cobalt(II)-EDTA and -EDTA-OH complexes,[2] the rate-

constant ratios between the reaction of CyDTA with the nickel(II)-Dien complex and that with the nickel(II)-En complex were calculated on the assumption that the rates for breaking Dien and En from their mixed ligand complex intermediates are the same. In the calculation of the rate constant ratio, the stability constants of 2.34×10^{7} and 3.55×10^{10} ($\mu=0.30$) were used for the nickel(II)-En and -Dien complexes respectively, with a 1-to-1 ratio. The additional stability due to the statistical effect was also taken into account.[9] These results are listed in Table 4, together with those obtained experimentally. The calculated ratio based on structure I agrees best with the observed ratio. This finding is contrary to the observation of Rorabacher and Margerum obtained in their kinetics study of the displacement of polyamine from its nickel(II) complex by the EDTA anion.[5]

In the case of the reaction of the nickel(II)-EDMA complex, the following are considered to be possible reaction intermediates (Fig. 7). The

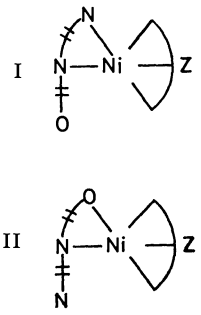

Fig. 7. Reaction intermediates for the substitution reaction of nickel-EDMA complex.

one in which only the acetate group of the displaced EDMA anion is bonded to the nickel(II) ion can be eliminated, because the nickel(II)-oxygen(acetate) bond rupture is much faster than the nickel(II)-nitrogen (amino) bond rupture[9]; hence, at least one nickel(II)-nitrogen bond rupture should be involved in the rate-determining step. Furthermore, in considering the conclusion that the reactions of the nickel(II)-aspartate and -IDA complexes with CyDTA and DTPA proceed through glycinate intermediates, the reaction intermediate having only one nitrogen group of displaced EDMA bonded to the nickel(II) ion seems unlikely. If the substitution reaction of the nickel(II)-EDMA complex with DTPA also has a glycinate mechanism, a comparison of its rate constant with that of the reaction of nickel(II)-IDA complex should be possible. The rate-constant ratio calculated on the basis of a glycinate reaction intermediate occurring between the reaction of DTPA with the nickel(II)-EDMA complex and that with the nickel(II)-IDA complex is $1 : 1.34_{6}\times 10^{3}$. In a calculation of the relative stability of the reaction intermediate, stability constants of 1.29×10^{8} and 2.75×10^{10} ($\mu=0.30$) were used for the nickel(II)-IDA and -EDMA complexes respectively, with a 1-to-1 ratio. Here, additional stabilities due to statistical and electrostatic factors were also taken into account.[9] As is clear from the data in Table 4, there is no close agreement between the calculated ratio and the observed ratio for either elementary reaction pathway, i) or ii). As was mentioned by Margerum *et al.* in their kinetic study of the formation reactions of nickel(II)-triethylenetetramine and tetraethylenepentamine complexes,[8] the electrostatic interaction between the entering group and the reactant (the nickel(II) complex) should also be taken into consideration. If the above electrostatic contribution to the rates of the reactions of nickel(II)-IDA and -EDMA complexes can be evaluated by means of Eq. (27) in Ref. (7), the rate-constant ratios for the two elementary reaction pathways, i) and ii), can be calculated to be 1 : 4.27 and 1 : 1, respectively. Even when the electrostatic interaction between the DTPA anion and the nickel(II)-IDA or -EDMA complex is taken into consideration, there is no close agreement between the calculated rate-constant ratio and the observed ratio. This disagreement clearly eliminates the possibility of a glycinate reaction mechanism (Structure II). As in the case of reactions of CyDTA with the nickel(II)-Dien and En complexes, if the reaction of DTPA with the nickel(II)-EDMA complex proceed through reaction intermediate I, the rate-constant ratios for k_1^{+} and k_2^{+} between the reaction of DTPA with the nickel(II)-Dien complex and that with the nickel(II)-EDMA complex can be estimated to be $6.63\times10^{2} : 1$ and $1.55\times10^{2} : 1$ respectively. Of course, the additional stability of the reaction intermediate due to the statistical and electrostatic effects and the contribution of electrostatic interaction between the attacking group and the nickel(II)-EDMA or -Dien complex were also taken into consideration. The agreement between the observed ratio and the calculated ratio can be regarded as satisfactory. From the results discussed in this paper, it can safely be concluded that the nucleophilic substitution reaction involving the nickel(II)-EDMA complex proceeds through a reaction intermediate in which the displaced EDMA anion is bonded to the nickel(II) ion through two nitrogen groups. This is a reasonable conclusion, because the nickel(II)-oxygen (acetate) bond cleavage is much faster than the nickel(II)-nitrogen (amino) bond cleavage.

The present authors wish to express their heartfelt thanks to the Ministry of Education for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2093—2095 (1970)

Intramolecular Electron-transfer Reactions of Ethylenediaminetetraacetatocobaltate(III) and Its Related Complexes in Solid State

Kenzo NAGASE

Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Sendai

and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received January 23, 1970)

Electron transfer from a ligand to a central cobalt(III) in solid state was investigated by following the change of the valence state of coblat(III) to cobalt(II). The reaction was carried out in a vacuum as a function of sample amount, temperature and nature of a ligand and an outer-sphere cation. The electron-transfer reaction followed the first-order rate law. An outer-sphere cation had a slight effect on the reaction of the complex ion. The kinetic parameters obtained for potassium ethylenediaminetetraacetatocobaltate(III) ($E_a=38$ kcal/mol, $A=10^{14}$) differed greatly from those for potassium propylenediaminetetraacetatocobaltate(III), potassium cyclohexanediaminetetraacetatocobaltate(III) and potassium trimethylenediaminetetraacetatocobaltate(III) ($E_a\simeq 22$ kcal/mol, $A\simeq 10^6$). The kinetic behavior of the pentadentate complex, potassium hydrogen halogenoethylenediaminetetraacetatocobaltate(III), was compared with that of the hexadentate complex, potassium ethylenediaminetetraacetatocobaltate(III).

The electron-transfer reactions of cobalt(III) complexes in solid state were discussed in detail by Tanaka *et al.*[1] They proposed that the values of the activation energies increased in parallel with the increase of the ligand field.

However, it is considered that the electron-transfer reaction depends on the structure of the ligand in addition to the electronic state of the complex ion.

In the present study, a series of diaminotetraacetatocobaltate(III) complexes whose electronic spectra are almost the same but structure different were adopted, and their structural effects on the electron-transfer reaction were discussed.

Experimental

Materials. Potassium ethylenediaminetetraacetatocobaltate(III) dihydrate, K[Coedta]$2H_2O$,[2] potassium propylenediaminetetraacetatocobaltate(III) dihydrate, K[Copdta]$2H_2O$,[3] potassium cyclohexanediaminetetraacetatocobaltate(III) trihydrate, K[Cocydta]$3H_2O$,[4] potassium trimethylenediaminetetraacetatocobaltate(III) dihydrate, K[Cotrdta]$2H_2O$,[5] potassium hydrogen chloroethylenediaminetetraacetatocobaltate(III) monohydrate, K[CoCledtaH]H_2O[6], and potassium hydrogen bromoethylenediaminetetraacetatocobaltate(III) dihydrate, K[CoBredtaH]$2H_2O$,[7] were prepared according to the methods given in literature.

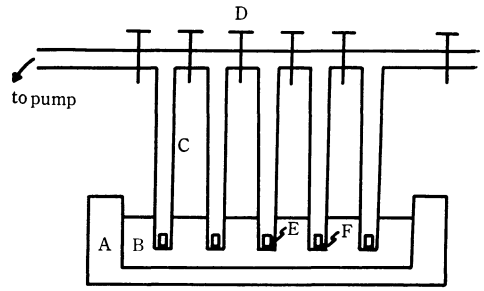

Fig. 1. Schematic diagram of apparatus: (A) bath, (B) silicone oil, (C) reaction tube, (D) cock, (E) crucible and (F) sample.

Apparatus and Procedure. Figure 1 shows the apparatus used for the thermal treatment. Samples which were smaller than 100 mesh in size weighed 2 to 4 mg in each kinetic measurement and the temperature of the sample was controlled in a range of ± 0.3°C by means of a silicone oil bath. The system was continu-

ously evacuated by a rotary pump during the reaction. Every one hour, the heated sample was taken out of the reaction tube and dissolved in a 25 ml deaerated solution containing 0.5 M potassium chloride. A Yanagimoto PR-2 pen-recording polarograph was used for the determination of cobalt(III) content in the solution.

Results and Discussion

The decomposition processes of diaminotetraacetatocobaltate(III) complexes were investigated by thermogravimetric analysis, gas evolution analysis and polarographic analysis. For example, the process for potassium ethylenediaminetetraacetatocobaltate(III) in a vacuum is given by the equations

$$K[Co^{III}\,edta]2\,H_2O \xrightarrow[\sim 50°C]{\text{dehydration}} K[Co^{III}\,edta] + 2\,H_2O \quad (1)$$

$$K[Co^{III}\,edta] \xrightarrow[\sim 170°C]{\text{electron transfer}} K[Co^{II}(edta')] \quad (2)$$

$$K[Co^{II}(edta')] \xrightarrow{\text{decarbonation}} \text{Products containing cobalt(II)} + CO_2 \quad (3)$$

where edta' represents the edta radical which was formed by the electron transfer from an edta to a central cobalt(III). The rate of reaction (2) was followed by the measurement of the change of the valence state of cobalt(III) to cobalt(II).

The Order of the Electron-transfer Reaction. The measurements which were carried out with various initial amounts of the sample confirmed, as shown in Fig. 2, the relation given by the equation

$$-dN/dt = kN \quad (4)$$

where N represents the number of cobalt(III) ions in the heated sample and k the rate constant. Equation (4) is modified to

$$2.303 \log x = -kt \quad (5)$$

where x is the mole fraction of cobalt(III) in the sample. A plot of $\log x$ *versus* time was made for each complex and nearly straight lines were obtained. The plots for K[Cocydta] are shown in Fig. 3 as an example.

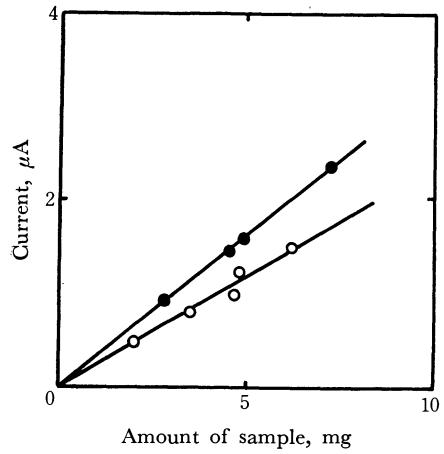

Fig. 2. Determination of cobalt(III) content for Na[Coedta] (●) before and (○) after heating at 172°C for 5 hr.

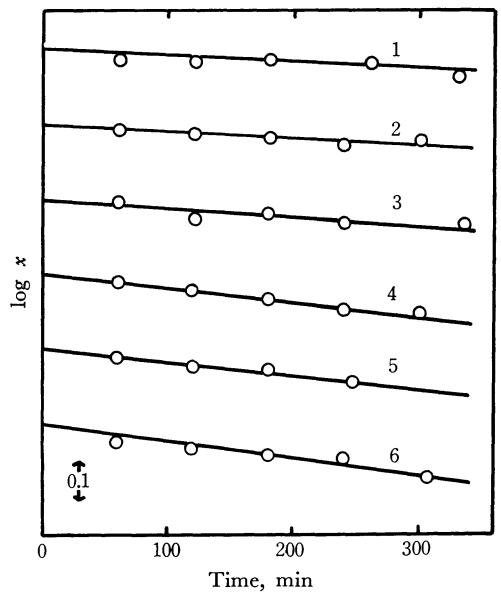

Fig. 3. Plots of log x *versus* time for K[Cocydta] at various temperatures: (1) 190, (2) 192, (3) 196, (4) 200, (5) 203 and (6) 204°C.

From these results, it is confirmed that the electron-transfer reaction follows the first-order rate law.

Effects of Outer-sphere Cations on the Electron-transfer Reaction. The kinetic parameters of ammonium, sodium and potassium salts of ethylenediaminetetraacetatocobaltate(III) are given in Table 1. The temperatures at which the rate constants are equal to 1×10^{-5} sec^{-1} are almost the same among these complexes, but the activation energies (E_a) and frequency factors (A) are slightly different. Therefore, a precise comparison of the kinetic behavior of the complex ion should be made among the complexes containing the same outer-sphere ion.

TABLE 1. EFFECTS OF OUTER-SPHERE CATION ON THE ELECTRON-TRANSFER REACTION OF EDTA COMPLEX

Complex	Temp., °C ($k = 1 \times 10^{-5}$ sec^{-1})	E_a kcal/mol	A
NH_4[Coedta]	171	43	10^{16}
Na[Coedta]	170	41	10^{15}
K[Coedta]	171	38	10^{14}

Kinetic Studies of K[Coedta], K[Copdta], K[Cocydta] and K[Cotrdta]. The first-order rate constants for potassium salts of ethylenediaminetetraacetatocobaltate(III) and its related complexes were determined from the plots of log x *versus* time. The order of the temperatures at which the rate constant is equal to 1×10^{-5} sec^{-1} is as follows:

$$\text{K[Coedta]} < \text{K[Cotrdta]} < \text{K[Cocydta]} < \text{K[Copdta]}$$

This suggests that the rate depends considerably on the nature of the ligand. The activation energies and frequency factors were obtained from the temperature dependence of the rate. The kinetic parameters obtained are given in Table 2. It is noticed that the kinetic parameters of EDTA complex are considerably higher than those of PDTA, CyDTA and TRDTA complexes, which are almost the same.

Table 2. Kinetic parameters of the electron-transfer reaction for various cobalt(III) complexes in solid state

Complex	Temp., °C ($k = 1\times10^{-5}$ sec^{-1})	E_a kcal/mol	A
K[Coedta]	171	38	10^{14}
K[Copdta]	199	22	10^{5}
K[Cocydta]	194	24	10^{6}
K[Cotrdta]	187	23	10^{6}

According to a previous paper,[1] the activation energies of the electron-transfer reaction of cobalt(III) complexes are somewhat lower than the energies of the A band of their absorption spectra and the frequency factors are smaller than the normal values for a first-order reaction, 10^{13}. From this conclusion, the values expected for EDTA, PDTA, CyDTA and TRDTA complexes are $E_a=$ 20 to 25 kcal/mol and $A=10^5$ to 10^8.

Electron transfer from a ligand to a central cobalt(III) will occur after reorganization of the structure of the cobalt complex in the formation of the transition state. Such a rearrangement in the complex containing polydentate ligand will be caused by increasing the bond distance and by varying the direction of the coordinated atom. The latter will be caused by the twist of the chelate ring as observed in racemization. From the steric relationship, the twist is easy for the EDTA complex but difficult for the other three. The difficulty of the twist for the PDTA complex results from the repulsion between methyl hydrogen atoms and methylene hydrogen atoms. The twist of the chelate ring in the CyDTA complex is impossible since the chelate ring involving two nitrogen atoms is fixed by a cyclohexane ring. In the TRDTA complex, the six-membered chelate ring is formed in contrast with the EDTA, PDTA and CyDTA complexes. The difficulty of the twist for the TRDTA complex has been reported by Ogino *et al.*[8] It is supposed that the activation energy and the frequency factor of the electron-transfer reaction are higher for the twist mechanism than for the mechanism by which the chelate ring is fixed. Therefore, the difference between kinetic parameters obtained for the EDTA complex and those for the other three may be due to whether the twist of the chelate ring is possible or not.

Kinetic Studies of Potassium Hydrogen Halogenoethylenediaminetetraacetatocobaltate(III). The kinetic parameters of the pentadentate complex, K[CoCledtaH] and K[CoBredtaH], are given in Table 3. The order of the temperatures at which the rate constant is equal to 1×10^{-5} sec^{-1} was as follows:

Table 3. Kinetic parameters of the pentadentate cobalt(III) complexes

Complex	Temp., °C ($k = 1\times10^{-5}$ sec^{-1})	E_a kcal/mol	A
K[CoCledtaH]	158	33	10^{11}
K[CoBredtaH]	144	28	10^{10}

$$\text{K[CoBredtaH]} < \text{K[CoCledtaH]} < \text{K[Coedta]}$$

This order suggests that the rate of the electron-transfer reaction was increased by substituting a halide ion for a carboxyl group. Also, the activation energies were decreased in the order

$$\text{K[Coedta]} > \text{K[CoCledtaH]} > \text{K[CoBredtaH]}.$$

These facts may be explained by the following:

i) The chelate ring of the pentadentate complex will twist more easily than that of the hexadentate complex.

ii) The energies of ligand field splitting and charge transfer from ligand to metal are lower in the order K[Coedta]>K[CoCledtaH]>K[CoBredtaH].

The authors wish to express their hearty thanks to Dr. Hiroshi Ogino for the supply of K[Cotrdta]–$2H_2O$. They also thank the Ministry of Education for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2096—2102 (1970)

The Adsorption of 2,2′-Bipyridine and Its Ferrous Complex on the the Dropping Mercury Electrode

Hiromiti SAWAMOTO*1

Chemistry Institute, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received January 26, 1970)

The adsorption of 2,2′-bipyridine and its ferrous complex $[Fe(bip)_3]^{2+}$ onto the electrode has been studied both by the electrocapillary method and the impedance-bridge method. Electrocapillary curves were obtained by the drop-time method. A peculiar shape was observed in the electrocapillary curve of $[Fe(bip)_3]^{2+}$, which was corrected for in the further thermodynamic treatment by taking into account the data obtained with an impedance bridge. It was found that 2,2′-bipyridine is adsorbed flat in the more positive region. At more negative potentials, the adsorption is also flat at low concentrations of 2,2′-bipyridine, but becomes perpendicular beyond 2×10^{-3} M. The $[Fe(bip)_3]^{2+}$ adsorption can be accounted for by a Langmuir isotherm. However, the isotherm for 2,2′-bipyridine adsorption varies with the potential, which can be explained in terms of the change in the adsorption structure.

The adsorption of organic compounds at the mercury electrode—solution interface has been studied for many years, mainly by the electrocapillary method and by the impedance-bridge method.[1] Attempts have been made to give a generalized interpretation of the adsorption of simple organic compounds, such as alcohols, and rather successful results have been obtained.[2] However, the adsorption of more complex organic compounds is difficult to interpret by such a generalized theory, and many complicated phenomena have been observed. For instance, certain anionic surface-active substances, such as alkyl sulfate ions, have been found to show three or four peaks in their differential capacity - potential curves.[3] In these cases, the differential capacity during a drop-life changes in a very complicated way.[4] It has also been found that the adsorption isotherms of pyridine and its derivatives vary remarkably with the electrode potential.[2,5-7]

The adsorption of organic compounds can also be studied by a.c. polarography (tensammetry), by which curves similar to the capacity - potential curves measured by the impedance-bridge method can be obtained automatically.[8] Using the a.c. polarographic method, the present author and his co-workers studied the adsorption of oxine and its derivatives and found that they showed peculiar non-faradaic peaks which were not typical of the adsorption - desorption of organic compounds.[9-13] When metal ions, such as copper and zinc, were added to the solution, the peaks disappeared by forming chelates with oxines, showing that the behavior of oxine and its derivatives differed from that of their chelates. This fact was used to detect the end point of titration of very dilute solutions of metal ions with oxines.[9-13] Scarcely a.c. polarographic (tensammetric) studies of the adsorption of chelate compounds have been reported. The present author has studied, in a previous report,[14] the a.c. polarographic behavior of chelates of 2,2′-bipyridine and 1,10-phenanthroline with metal ions, such as iron, zinc, and nickel. He found that, unlike the case of oxine chelates, these chelates

show typical adsorption - desorption peaks.

The present study was undertaken to investigate in more detail the above studies. The adsorption of 2,2'-bipyridine and its ferrous complex in 0.5 M KCl was measured by the impedance-bridge method and by the electrocapillary method. The a.c. polarographic method was used as an auxiliary method. The surface excess and the adsorption isotherms of these adsorbates have been obtained, and their adsorption structures have then been deduced from these results. Special attention was paid to the abnormal shape observed in the electrocapillary curves of $[Fe(bip)_3]^{2+}$ ions.

Experimental

The measurement of the differential capacity with an impedance-bridge has been described previously.[4] The bridge was balanced at the end of the life of a mercury drop. The tensammetric measurement with an a.c. polarograph has also been described previously.[13] Electrocapillary curves were usually obtained by the drop-time method. The drop time was determined by measuring the time of ten drops with a stop watch. The accuracy of the measurement of the drop time was within ± 0.01 sec, which corresponds to an interfacial tension of about ± 1 dyn/cm at the mercury/electrolyte phase boundary. The reproducibility of the dropping mercury electrode was checked before each measurement in a 0.5 M potassium chloride solution. All the chemicals were of analytical-reagent grades and were used without further purification. Drying 2,2'-bipyridine in a desiccator under reduced pressure caused no weight change. The concentration of the ferrous sulfate solution was determined gravimetrically. $[Fe(bip)_3]^{2+}$ was prepared by mixing equivalent amounts of 2,2'-bipyridine and ferrous sulfate.

Results and Discussion

Electrocapillary Curves. Among the methods for obtaining electrocapillary curves, the measurement with a Lippman electrometer is most reliable for thermodynamic treatment, but it is rather tedious, especially in the presence of organic compounds. Drop time - potential curves usually measured in polarography, on the other hand, can easily be converted to electrocapillary curves by using such relations as are shown by Eqs. (1) and (2) and can be used for further thermodynamic treatment. The relation in Eq. (1) was used by Tate, and that in Eq. (2), by Corbusier and Gierst:[15]

$$\gamma = \frac{\gamma_{ref}}{t_{ref}} t \tag{1}$$

$$\Delta\gamma = K^* \frac{\gamma_{ref}}{t_{ref}} \Delta t = 0.973 \frac{\gamma_{ref}}{t_{ref}} \Delta t \tag{2}$$

In these equations, γ and t are the interfacial tension and the drop time respectively. γ_{ref} is a known interfacial tension under the conditions chosen as a reference, and t_{ref} is the drop time obtained under the same conditions as γ_{ref}. $\Delta\gamma$ is equal to $\gamma - \gamma_{ref}$, and Δt, to $t - t_{ref}$. In the present report, the value of the interfacial tension obtained by Devanathan and Peries[16] at a potential of the electrocapillary maximum was used as γ_{ref}. K^* is a constant; a value of 0.973 was obtained experimentally by Corbusier and Gierst.[15]

The interfacial tension can also be obtained by a double integration of the differential capacity, C:

$$\iint_{Ez}^{E} C \mathrm{d}^2E = \gamma(E_z) - \gamma \tag{3}$$

where E is the electrode potential, where E_z is the potential of zero charge, and where $\gamma(E_z)$ is the known interfacial tension at E_z.

The electrocapillary curves were obtained in 0.5 M potassium chloride solutions containing various concentrations of 2,2'-bipyridine by using Eqs. (1), (2), and (3); they are compared in Fig. 1. The results obtained from Eq. (3) show slightly larger values than those obtained from Eqs. (1) and (2) in the cathodic potential region. Such differences in the presence of organic compounds have also been reported by Parsons and Zobel.[17]

●: calculated from Eq. (3)

The results obtained from Eqs. (1) and (2) coincide well, but in the calculation from Eq. (2) the value of K^* was assumed to be 0.973, as had been obtained experimentally by Corbusier and Gierst;[15]

this value may not be applicable to the present dropping mercury electrode. For these reasons, the electrocapillary curves described below were obtained from Eq. (1). More detailed results on the electrocapillary curves in the presence of 2,2′-bipyridine are shown in Fig. 2.

The electrocapillary curves in the presence of $[Fe(bip)_3]^{2+}$ are shown in Fig. 3. The curves obtained in the concentration range between 5×10^{-5} M and 3×10^{-4} M show a peculiar depression in the cathodic potential range, while those obtained for $[Fe(bip)_3]^{2+}$ concentrations below 5×10^{-5} M or above 3×10^{-4} M show no such depression

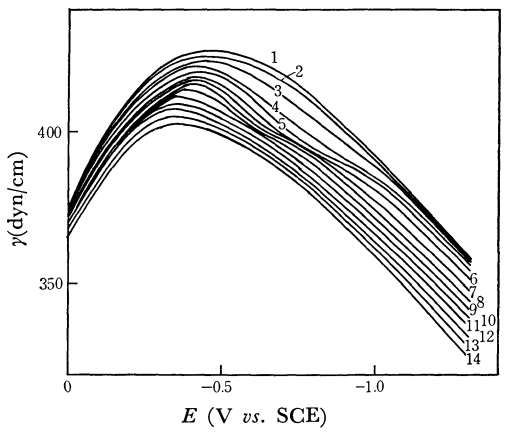

Fig. 3. Electrocapillary curves of $[Fe(bip)_3]^{2+}$ in 0.5 M KCl.
$[Fe(bip)_3]^{2+}$ concentration: 1, 0; 2, 2×10^{-5} M; 3, 3×10^{-4} M; 4, 5×10^{-5} M; 5, 7×10^{-5} M; 6, 10^{-4} M; 7, 2×10^{-4} M; 8, 3×10^{-4} M; 9, 5×10^{-4} M; 10, 7×10^{-4} M; 11, 10^{-3} M; 12, 1.4×10^{-3} M; 13, 2×10^{-3} M; 14, 3×10^{-3} M

and have normal shapes. This appearance of the depression in the electrocapillary curves is a peculiar phenomenon, because the two differentiations of the interfacial tension with respect to the potential causes a negative capacity.

It has been reported that such an abnormal depression of the electrocapillary curves was observed at a dropping mercury electrode at the potential at which the polarographic maximum appeared, but it was not observed with a Lippmann electrometer.[18] When an organic compound is reduced and gives a reductant which is strongly adsorbed onto the electrode surface, a sudden decrease in the interfacial tension is also observed at the potential at which reduction occurs.[19] In the present case, however, no faradaic current was observed in the abnormal region, as is shown in Fig. 4. As to the abnormal depression of the electrocapillary curve in the absence of electrolytic processes, only one example has been observed in anhydrous acetic acid,[20] and none in an aqueous solution.

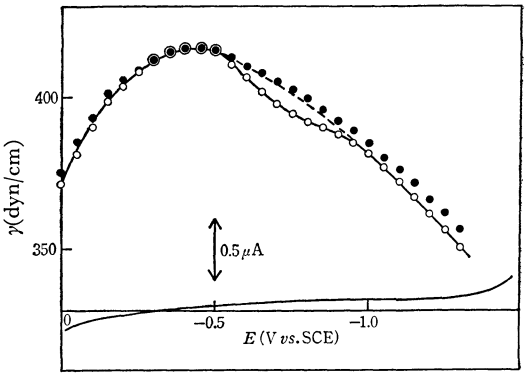

Fig. 4. Electrocapillary curve of 10^{-4} M $[Fe(bip)_3]^{2+}$ in 0.5 M KCl and its d.c. polarogram.
○: calculated from Eq. (1)
●: calculated from Eq. (3)
Dotted line shows the method of correction for the abnormal depression.

In order to test the effect of the sulfate ion introduced as $FeSO_4$ in 0.5 M potassium chloride, ferrous chloride was used instead of ferrous sulfate. As this electrocapillary curve showed the same abnormality, the effect of the sulfate ion can be disregarded.

The electrocapillary curve in the presence of both 2,2′-bipyridine and $[Fe(bip)_3]^{2+}$ also showed an abnormality at 2,2′-bipyridine concentrations above 10^{-4} M. This fact might show that the presence of both 2,2′-bipyridine and $[Fe(bip)_3]^{2+}$ is

18) J. Heyrovsky and J. Kuta, "Principles of Polarography," Academic Press, New York (1966), p. 23.

20) G. B. Bachman and M. J. Astle, *J. Amer. Chem. Soc.*, **64**, 2177 (1942).

the cause of the abnormal phenomena, and that the species obtained as a result of the dissociation of $[Fe(bip)_3]^{2+}$ might be responsible for it. However, from the calculation of the dissociation of $[Fe(bip)_3]^{2+}$ previously described,[13,21] it was found that $[Fe(bip)_3]^{2+}$ is not so dissociated as to affect the electrocapillary curves. Though the electrocapillary curve of the mixture of $[Fe(bip)_3]^{2+}$ and 2,2'-bipyridine coincides with that of $[Fe(bip)_3]^{2+}$, their C - E curves differ markedly from each other, showing that the causes of the abnormalities are not identical.

From these results, it can be concluded that the abnormality of the electrocapillary curves in the presence of $[Fe(bip)_3]^{2+}$ is not due to the presence of both $[Fe(bip)_3]^{2+}$ and 2,2'-bipyridine resulting from the dissociation of the complex in solution, though the real cause of this abnormality is still uncertain.

The electrocapillary curves calculated from Eq. (3) using the data of the impedance-bridge measurements showed no abnormality, as is shown in Fig. 4. Therefore, a correction shown by a dotted line in Fig. 4 will be made in the following discussion for the abnormality.

Adsorption Structure. The surface excess, Γ, of an adsorbed species can be obtained from the Gibbs adsorption equation:

$$\Gamma = -\left(\frac{\partial \gamma}{\partial \mu}\right)_{E,T} = -\frac{1}{2.303RT}\left(\frac{\partial \gamma}{\partial \log c}\right)_{E,T} \quad (4)$$

where μ and c are, respectively, the chemical potential and the concentration of the adsorbate in solution; R, the gas constant, and T, the absolute temperature. The value of $(\partial\gamma/\partial \log c)_{E,T}$ can be obtained by graphically differentiating the γ-$\log c$ curve as is shown in Fig. 5.

Potentials: 1, −0.2 V; 2, −0.4 V; 3, −0.6 V; 4, −0.8 V; 5, −1.0 V; 6, −1.2 V

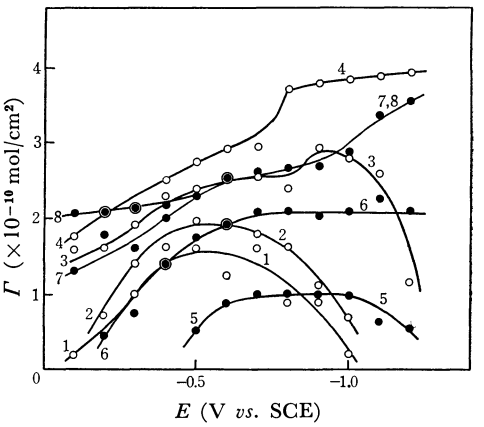

Fig. 6. Variation of surface excess with electrode potentials at different concentrations of (a) 2,2'-bipyridine and (b) $[Fe(bip)_3]^{2+}$ in 0.5 M KCl.
(a): 1, 2×10^{-5} M; 2, 10^{-4} M; 3, 10^{-3} M 4, 3×10^{-3} M
(b): 5, 2×10^{-5} M; 6, 10^{-4} M; 7, 10^{-3} M 8, 3×10^{-3} M

The variation of the surface excess with the electrode potential is shown in Fig. 6 for 2,2'-bipyridine and $[Fe(bip)_3]^{2+}$. At low concentrations of 2,2'-bipyridine, the curves are almost symmetrical, as in the case of typical neutral molecules (curves 1 and 2). The surface excess is at its maximum at the point of zero charge and decreases almost to zero at sufficiently anodic or cathodic potentials. However, as the concentration increases, asymmetrical curves are obtained whose maximum is located at a considerably negative potential (curves 3 and 4). If the 3.9×10^{-10} mol/cm² obtained from curve 4 in Fig. 6 is assumed to be the saturated surface excess for the monolayer adsorption of 2,2'-bipyridine, the area occupied by its single molecule can be calculated as 42.5 Å²/mol. The area of the electrode occupied by a molecule of α-naphthol, which is considered to be smaller than that of 2,2'-bipyridine, has been reported[22] to be 66 Å² when it is adsorbed in parallel to the electrode and 26 Å² when adsorbed perpendicularly. This shows that, at negative potentials, 2,2'-bipyridine cannot be adsorped in parallel to the electrode if a monolayer is assumed. Therefore, the adsorption of 2,2'-bipyridine at negative potentials (about −1.0 V) seems to be in multilayers or perpendicular to the electrode in a monolayer.

$[Fe(bip)_3]^{2+}$ at low concentrations is not adsorbed at sufficiently positive potentials (curves 5 and 6). At high concentrations, however, it is adsorbed in all the potential regions investigated, and the surface excess is especially large in negative regions (curves 7 and 8). This shows that [Fe-

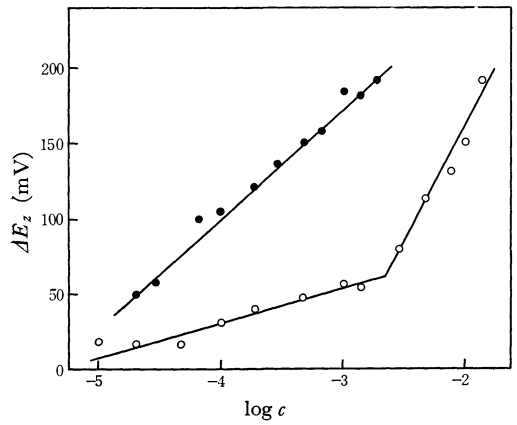

Fig. 7. Shifts of the potential of zero charge with the logarithms of adsorbate concentration in 0.5 M KCl.
○: 2,2'-bipyridine
●: $[Fe(bip)_3]^{2+}$

$(bip)_3]^{2+}$ has a character of the organic cation.

The shifts of the potential of zero charge (ΔE_z) with the logarithms of the concentrations of the adsorbates in 0.5 M KCl are shown in Fig. 7. In Fig. 7, $\Delta E_z = E_z^0 - E_z$, and E_z^0 is the potential of zero charge of the 0.5 M KCl solution, while E_z is that in a solution containing 2,2'-bipyridine or $[Fe(bip)_3]^{2+}$. The potentials of zero charge were determined from the electrocapillary curves. The change in E_z with the change in the concentration of an inorganic anion can be explained by the Esin and Markov effect,[23] which predicts that E_z will vary linearly with the logarithm of the activity of the anion. Barradas *et al.*[24] studied this effect with uncharged organic molecules and got linear relations between E_z and the logarithms of the concentrations of the organic molecules. In Fig. 7, E_z in the presence of $[Fe(bip)_3]^{2+}$ varies linearly with the logarithm of its concentration, as in the case of other inorganic ions, while the $E_z - \log c$ curve in the presence of 2,2'-bipyridine consists of two lines with different slopes. The lines cross each other at about 2×10^{-3} M, indicating a change in the structure of the adsorbed layer at this concentration.

The differential capacity - potential curves in the presence of 2,2'-bipyridine, shown in Fig. 8, do not show typical peaks, but the depression of the curves from that of the base solution indicates that 2,2'-bipyridine is adsorbed in this potential region. Above 2×10^{-3} M of 2,2'-bipyridine, a hump is observed in the adsorption region, indicating that two different adsorption structures exist on the two sides of the hump. The deep depression of the

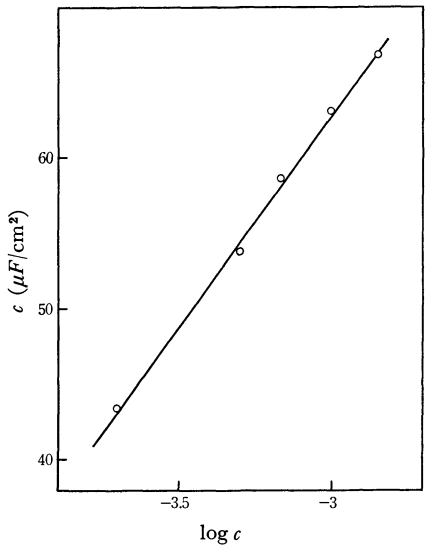

Fig. 10. Dependence of the height of capacity peak on concentration of $[Fe(bip)_3]^{2+}$.

are shown in Fig. 9. When compared with the curves in Fig. 8, distinct peaks are observed at about −0.4 V, and the capacity in the adsorption potential region is smaller in this case. As is shown in Fig. 10, the peak height varies linearly with the logarithm of the concentration. This is a characteristic trend of the adsorption - desorption peak.[2]

On the basis of the above studies, the adsorption structure can be deduced. It is preferable to assume a monolayer if there is no sure evidence for multilayers, as has been found in the case of the adsorption of certain anionic surface-active substances.[3,4] In low concentrations, 2,2'-bipyridine is adsorbed flat throughout the adsorption regions. Beyond 2×10^{-3} M, though it is still adsorbed flat in the more positive region, in the more negative region it is adsorbed perpendicularly to the electrode, probably because of the specific adsorption of nitrogen atoms onto the mercury electrode. The

boundary of the two adsorption regions is not very distinct, so a hump is observed instead of a peak in the differential capacity - potential curves. Although the reason for the abnormal behavior of the electrocapillary curves of $[Fe(bip)_3]^{2+}$ is not yet certain, it is supposed to have only one adsorption region. As the chemical structure of $[Fe(bip)_3]^{2+}$ is almost symmetrical, the change in the orientation of the adsorbed ion cannot be considered as in the case of 2,2'-bipyridine.

Adsorption Isotherms. The surface excesses Γ of 2,2'-bipyridine and $[Fe(bip)_3]^{2+}$ at various potentials were plotted against their concentrations in the bulk of the solution. The results are shown in Figs. 11 and 12. From the figures, the isotherm for $[Fe(bip)_3]^{2+}$ is found to be of the Langmuir type, while that for 2,2'-bipyridine is not so simple and varies considerably with the electrode potential, as has been found in the case of pyridine and its derivatives.[2,5-7]

Among the many isotherms proposed up to now,[25] the Langmuir isotherm (Eq. (5)) is most commonly been used;

$$Bc = \frac{\theta}{1-\theta} \tag{5}$$

where B is the constant of the adsorption equilibrium; c, the concentration of the organic compound, $\theta=\Gamma/\Gamma_m$, the fraction of the coverage, and Γ_m, the limiting value of Γ at $c\to\infty$. Recently, however, the following Frumkin isotherm[2] has often been used:

$$Bc = \frac{\theta}{1-\theta}\exp(-2a\theta) \tag{6}$$

where a is the attraction constant, a quantity characterizing the interaction between the adsorbed particles. If a is equal to zero, Eq. (6) is converted to Eq. (5). A comparison of the experimental results with the theoretical expectations becomes much easier when Eq. (6) is modified as Eq. (7):

25) P. Delahay, "Double Layer and Electrode Kinetics," Interscience Publishers, New York (1965), p. 83.

$$\frac{c}{c_{\theta=0.5}} = \frac{\theta}{1-\theta}\exp\left[a(1-2\theta)\right] \qquad (7)$$

where $c_{\theta=0.5}$ is the concentration at which θ becomes equal to 0.5. Supposing that the Γ_m of 2,2′-bipyridine is 3.9×10^{-10} mol/cm² and that the Γ_m of $[Fe(bip)_3]^{2+}$ is 3.5×10^{-10} mol/cm², the relations of $c/c_{\theta=0.5}$ and θ were calculated; they are plotted in Figs. 13 and 14. The value of a determined from these figures is between 0 and −3 for $[Fe(bip)_3]^{2+}$, while that for 2,2′-bipyridine changes from −5 at −0.2 V to +2.5 at −1.2 V. Damaskin[26] explained the adsorption of pyridine by using the Frumkin isotherms, but he did not explain why a changed considerably with the electrode potential.

Now, from the results of the investigation of the adsorption structure of 2,2′-bipyridine, the change in a with the potential can be explained in the following way, by means of the change in the adsorption structure with the potential. In the more positive potential regions, 2,2′-bipyridine is adsorbed flat onto the electrode surface as a result of the π-electron - electrode interaction. In this case, the isotherm shown by curve 1 in Fig. 13 is obtained, and a negative attraction constant is obtained from it. In the more negative potentials, however, 2,2′-bipyridine at low concentrations is scarcely adsorbed because of the repulsion between the π-electron and the electrode. However, when the concentration is increased, it is adsorbed in a large amount perpendicularly to the electrode, resulting in an adsorption isotherm with a positive attraction constant, as in curve (8) of Fig. 13. As one adsorption structure changes in relation to another with an electrode potential, the isotherm changes between the two extreme cases with the electrode potential.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2103—2109 (1970)

Trimethylenediamine Complexes. II. Some *cis-trans* Isomeric Pairs of Diacidobis(trimethylenediamine)cobalt(III) Complexes*[1]

Hiroshi KAWAGUCHI and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received January 31, 1970)

Isomeric pairs of *cis*- and *trans*-dinitro-, diisothiocyanato- and cyanosulfito-bis(trimethylenediamine)cobalt(III) complexes, and *cis*-nitronitritobis(trimethylenediamine)cobalt(III) nitrite were synthesized. Their electronic and infrared spectra were compared with each other to assign their structures. The *cis*-diisothiocyanatobis(trimethylenediamine)cobalt(III) complex was resolved into optically active isomers by means of potassium antimony(III) (+)-tartrate. The circular dichroism spectra of this dissymmetric complex were measured and discussed in relation to its absolute configuration which was recently determined by X-ray analysis.

Several diacidobis(trimethylenediamine)cobalt(III) complexes were derived from *trans*-dichlorobis(trimethylenediamine)cobalt(III) chloride by the ligand substitution reactions in methanol, and all of them were assumed to have the *trans* configuration on the basis of their infrared data.[1] It is curious that there are very few reports on trimethylenediamine complexes. No example of *cis-trans* isomeric pairs of the diacidobis(trimethylenediamine)cobalt(III) complex is known. We tried to prepare these compounds and report three such pairs obtained so far.

Experimental

***cis*-Dinitrobis(trimethylenediamine) cobalt(III) Nitrite.** Five grams of *trans*-$[CoCl_2tn_2]Cl$ was dissolved in a small quantity of hot water, to which 12 g of potassium nitrite was added. The solution was heated for about 3 hr and then kept standing overnight at room temperature. Crude precipitate was recrystallized from water, washed with water and then with acetone and dried in air. Orange-yellow crystals (3.5 g) were obtained.

Found: C, 20.60; H, 5.88; N, 27.11%. Calcd for $C_6H_{20}N_7O_6Co=[Co(NO_2)_2tn_2]NO_2$: C, 20.88; H, 5.84; N, 27.40%.

The same compound was also obtained by heating an aqueous solution of *trans*-$[Co(NO_2)_2tn_2]NO_2$ for a few hours.

When excess sodium nitrite was added to an aqueous solution of $[CoCO_3tn_2]Cl$ and kept standing for 4 days at room temperature, or heated for 3 hr on a hot water bath, color of the solution turned from purple to reddish brown, and orange-yellow crystals appeared which were recrystallized from hot water. The infrared spectrum of this specimen was also identical with that of *cis*-$[Co(NO_2)_2tn_2]NO_2$ prepared by the above method.

***cis*-Nitronitritobis(trimethylenediamine)cobalt(III) Nitrite.** Five grams of *trans*-$[CoCl_2tn_2]Cl$ was dissolved in a small quantity of hot water, to which 12 g of potassium nitrite was added. The solution was heated for about 1 hr and then cooled for a few hours. Deposited crystals were washed with cold water and then with methanol and dried. Orange yellow crystals (3.1 g) were obtained.

Found: C, 20.88; H, 6.10; N, 27.46%.

***cis*-Diisothiocyanatobis(trimethylenediamine)-cobalt(III) Thiocyanate.** To a hot aqueous solution (*ca.* 70 m*l*) of *trans*-$[CoCl_2tn_2]Cl$ (5 g) was added gradually an aqueous solution (*ca.* 30 m*l*) of potassium thiocyanate (15 g). When the solution was heated for about 15 min, orange red crystals precipitated which were filtered off after cooling in ice for 2 hr, and recrystallized from hot water. Yield: 3.0 g.

Found: C, 28.41; H, 5.36; N, 25.53%. Calcd for $C_9H_{20}N_7S_3Co=[Co(NCS)_2tn_2]SCN$: C, 28.34; H, 5.29; N, 25.70%.

trans-Dinitro- and *trans*-diisothiocyanato-complexes were derived from *trans*-$[CoCl_2tn_2]Cl$ by the ligand substitution reactions in methanol as reported[1].

***cis*-Cyanosulfitobis(trimethylenediamine)cobalt(III).** This compound was prepared by following the method which Ohkawa, Hidaka and Shimura[2] had employed in synthesizing *cis*-$[CoCN(SO_3)en_2]$. To a 10 % aqueous solution of $Na_3[Co(CN)_2(SO_3)_2(NH_3)_2]\cdot 6H_2O$ (10 g), 10 g of trimethylenediamine was added. The solution was heated on a hot water bath for 5—10 hr, and then concentrated by slow evaporation to separate yellow brown crystals (1.1 g).

Found: C, 26.93; H, 6.75; N, 22.03%. Calcd for $C_7H_{20}N_5SO_3Co=[CoCN(SO_3)tn_2]$: C, 26.84; H, 6.49; N, 22.36%.

Sodium Disulfitobis(trimethylenediamine)-cobaltate(III) Trihydrate. Baldwin's method[3] of preparing the corresponding ethylenediamine complex

*1 Partly presented at the 10th International Conference on the Coordination Chemistry, Nikko, Japan, September, 1967.

1) H. Kawaguchi, N. Yano and S. Kawaguchi, This Bulletin, **42**, 136 (1969).

2) K. Ohkawa, J. Hidaka and Y. Shimura, *ibid.*, **39**, 1715 (1966).

3) M. E. Baldwin, *J. Chem. Soc.*, **1961**, 3123.

was followed. Five grams of sodium sulfite was dissolved in *ca.* 50 m*l* of hot water, to which 3 g of solid *trans*-$[CoCl_2tn_2]Cl$ was added. Orange yellow precipitate resulted, which was filtered off and recrystallized from water by adding sodium sulfite solution and ethanol.

Found: C, 16.29; H, 6.09; N, 12.86%. Calcd for $C_6H_{26}N_4S_2O_9CoNa = Na[Co(SO_3)_2tn_2]\cdot 3H_2O$: C, 16.22; H, 5.90; N, 12.61%.

Chlorosulfitobis(trimethylenediamine)cobalt(III) Monohydrate. $Na[Co(SO_3)_2tn_2]\cdot 3H_2O$ was kneaded with concentrated hydrochloric acid. Sulfur dioxide gas was evolved and the color changed to pink. The solid mass was washed with methanol, dissolved in 6 N hydrochloric acid, and recrystallized by adding methanol to this solution.

Found: C, 21.34; H, 6.72; N, 16.34%. Calcd for $C_6H_{22}N_4SO_4ClCo = [CoCl(SO_3)tn_2]\cdot H_2O$: C, 21.15; H, 6.51; N, 16.44%.

***trans* - Cyanosulfitobis(trimethylenediamine) - cobalt(III) Monohydrate.** To a 10% aqueous solution of $[CoCl(SO_3)tn_2]\cdot H_2O$ was added a concentrated solution of equimolar potassium cyanide. Yellow brown precipitate was produced but dissolved again upon prolonged stirring. To this solution five or six times the volume of ethanol was added and kept at 0°C. Yellow brown needles separated were recrystallized from water by adding ethanol. This method of preparation is analogous to that for the corresponding ethylenediamine complex.[4]

Found: C, 25.23; H, 6.79; N, 20.99%. Calcd for $C_7H_{22}N_5SO_4Co = [CoCN(SO_3)tn_2]\cdot H_2O$: C, 25.38; H, 6.69; N, 21.14%.

***cis* - Dicyanobis(trimethylenediamine)cobalt(III) Thiosulfate.** Yellow needles were obtained according to the method of Ohkawa *et al.*[5]

Found: C, 30.45; H, 6.49; N, 26.39%. Calcd for $C_{16}H_{40}N_{12}S_2O_3Co_2 = [Co(CN)_2tn_2]_2S_2O_3$: C, 30.47; H, 6.39; N, 26.66%.

***cis*-Chloroaquobis(trimethylenediamine)cobalt-(III) Chloride.** Two grams of carbonatobis(trimethylenediamine)cobalt(III) chloride monohydrate, which had been synthesized according to Werner's method,[6] was wetted with several drops of water and cooled with ice and salt. To this mass was added cold concentrated hydrochloric acid drop by drop until the evolution of carbon dioxide ceased. The purple solution was cooled with ice and salt and cold acetone was added to separate pink power. The product was filtered off, washed with cold acetone and dried over phosphorus pentaoxide *in vacuo*.

Found: C, 21.73; H, 6.82; N, 16.53; Cl, 31.60; H_2O (by the Karl Fischer method), 5.23%. Calcd for $C_6H_{22}N_4OCl_3Co = [CoCl(H_2O)tn_2]Cl_2$: C, 21.30; H, 6.69; N, 16.56; Cl, 32.09; H_2O, 5.44%.

The Optical Resolution of *cis*-$[Co(NCS)_2tn_2]SCN$. The sample was dissolved in a minimum quantity of water, to which large excess of potassium iodide was added and cooled with ice to precipitate *cis*-$[Co(NCS)_2tn_2]I$. Two grams of this iodide was mixed with 0.74 g (equimolar) of silver acetate in the presence of a small amount of water. A small quantity of cold water was added and silver iodide was filtered off. To the filtrate was added 0.74 g (half molar) of potassium antimony-(III)(+)-tartrate and the solution was kept standing overnight in an ice bath. Separated $(-)_D$-*cis*-$[Co(NCS)_2tn_2][Sb(+)\text{-tart}]$ was dissolved again in a minimum volume of water. A large excess of potassium iodide was added and the solution was cooled in an ice bath to precipitate $(-)_D$-*cis*-$[Co(NCS)_2tn_2]I$. The optical-active compound was treated with silver acetate again. After silver iodide was filtered off, excess potassium thiocyanate was added to the filtrate to precipitate $(-)_D$-*cis*-$[Co(NCS)_2tn_2]SCN$.

Spectral Measurements. Electronic absorption spectra were measured by means of a Hitachi spectrophotometer model EPS-2. Infrared absorption spectra in the region from 4000 through 650 cm^{-1} were measured with a Hitachi infrared spectrophotometer EPI-2, and those in 700—200 cm^{-1} with a Hitachi grating infrared spectrophotometer EPI-L. The optical rotatory dispersion curve was determined by means of a Yanagimoto spectropolarimeter model ORD-185 and the circular dichroism curve with a Roussel-Jouan dichrograph.

Results and Discussion

Hughes and McWhinnie[7] compared the infrared spectra of various *cis*- and *trans*-diacidobis-(ethylenediamine)cobalt(III) complexes in the lower frequency region and reported that the Co–N (en) stretching peaks in the 600—500 cm^{-1} region

were most helpful in diagnosing the geometrical configuration. In Figs. 1, 2 and 3 are presented the infrared absorption bands in the lower frequency region of the three isomeric pairs of compounds we prepared. The infrared absorption bands of these complexes are rather simple in comparison with those of diacidobis(ethylenediamine) complexes reported by Hughes and McWhinnie.[7] In the present case, too, spectra of *cis* and *trans* isomers are not identical, but the former are more complicated than the latter.

Although the reaction between *trans*-$[CoCl_2tn_2]$-Cl and excess potassium nitrite in hot methanol gave *trans*-$[Co(NO_2)_2tn_2]NO_2$, the same reaction in hot water resulted in a *cis* isomer. The *trans* form shows a single peak of Co–N(tn) stretching at 531 cm^{-1}, but the *cis* isomer two peaks at 531 and 524 cm^{-1}. In the synthetic study of this system an interesting phenomenon was observed. When a concentrated aqueous solution of excess potassium nitrite was added under stirring to an aqueous solution of *trans*-$[CoCl_2tn_2]Cl$ at room temperature or even at 0°C, yellow precipitate separated at first which was identified as potassium hexanitrocobaltate(III). However, prolonged agitation of the reaction mixture resulted in a gradual decrease of the yellow compound and increase of an orange brown precipitate which was *trans*-$[Co(NO_2)_2tn_2]NO_2$. It seems strange that two molecules of trimethylenediamine easily displaced by nitrite anions actually make a counter-attack and replace the nitrite groups. Such reactions have never been recognized in bis(ethylenediamine)cobalt(III) complexes.

It should also be noted that in reactions between hexanitrocobaltate(III) and trimethylenediamine, *trans*-$[Co(NO_2)_2tn_2]NO_2$ precipitates at room temperature, but the corresponding *cis* complex is formed at higher temperatures. If crystals of the *trans* form is redissolved in water and heated, the *cis* form is obtained. However, the reverse isomerization from *cis* to *trans* has not yet been realized.

When the heating time was relatively short, *e.g.* 1 hr, the reaction between *trans*-$[CoCl_2tn_2]Cl$ and excess potassium nitrite in water gave orange crystals. Analytical data of this compound agree with those for the dinitro complex, but its infrared spectra differ from those of *cis*- and *trans*-$[Co(NO_2)_2tn_2]NO_2$. As shown in Fig. 1 two peaks due to the Co-N(tn) stretching vibration are observed at 529 and 516 cm^{-1} suggesting the *cis* configuration of this compound. Absorption due to the wagging vibration of the nitro group[8] appears as a single peak both for *cis* and *trans* dinitro complexes. However, three peaks are observed for the new compound. A strong peak exists at 1170 cm^{-1} which is not shown by dinitro complexes and disappears on heating. The results strongly suggest that this compound is a linkage isomer, *cis*-$[CoNO_2(ONO)tn_2]NO_2$. As reported previously, *trans*-$[CoCl(ONO)tn_2]Cl$ is labile and isomerizes quickly in

methanol and so the absorption spectrum could not be observed at room temperature. The *cis*-nitronitrito compound, on the other hand, is rather inert and the isomerization to the dinitro isomer is slow even in a hot aqueous solution.

The absorption spectra of *cis*- and *trans*-[Co$(NO_2)_2tn_2]NO_2$ and *cis*-[$CoNO_2(ONO)tn_2]NO_2$ in methanol are presented in Fig. 4. It seems unlikely that the *cis*- and *trans*- dinitro complexes show practically identical spectra. The *cis-trans* isomerization equilibrium cannot possibly be attained so quickly in methanol at room temperature. The transmission spectra of solid specimen of both compounds, measured by the Nujol mull method, are also identical. The first band of the nitro-nitrito complex lies at the slightly longer wavelength side than that of the dinitro isomer (Table 1). The same trend is observed for the corresponding ethylenediamine complexes.[9]

The absorption spectra of *cis*- and *trans*-[Co$(NCS)_2tn_2]SCN$ are shown in Fig. 5. The first band of the *trans* isomer lies on the longer wavelength side than that of the *cis* isomer. This is contrary to the observation on the corresponding ethylenediamine complexes.[10] When *cis*-[Co$(NCS)_2tn_2]SCN$ was dissolved in methanol, heated for a few hours, and then concentrated by evaporation, crystals of the *trans* isomer were obtained. Reverse isomerization from *trans* to *cis* was not possible.

$(SO_3)tn_2]$ in the region of 600—500 cm^{-1} are complicated and less diagnostic than those for dinitro and diisothiocyanato complexes (Fig. 3). The *cis* isomer has four peaks in this region, while the *trans* isomer three. The electronic absorption spectra of these compounds also resemble each other as shown in Fig. 6.

The absorption maxima of the new compounds reported here are summarized in Table 1 together with those of the corresponding ethylenediamine complexes. As in a previous paper,[1] the first band of each trimethylenediamine complex lies at the longer wavelength side than that of the corresponding ethylenediamine complex, indicating that the ligand field of trimethylenediamine is weaker than that of ethylenediamine.

Efforts to prepare *cis*-dichlorobis(trimethylenediamine)cobalt(III) complex have not been successful so far. Treatment of $[CoCO_3tn_2]Cl$ with concentrated hydrochloric acid at low temperatures resulted in a pink-colored compound $[CoCl(H_2O)tn_2]Cl_2$, which is unstable and changes gradually to the green dichloro complex. The infrared absorption curve of this chloroaquo complex in the potassium bromide region is complicated as shown in Fig. 7 suggesting a possible *cis* configuration. In this connection the spectrum of *cis*-$[Co(CN)_2tn_2]_2S_2O_3$ is also included in Fig. 7. Unfortunately the corresponding *trans* isomer has not been obtained so far, and the comparison of IR curves of this isomeric pair is not possible, but the splitting of the Co–N(tn) stretching band may be reconciled with the *cis* assignment by Ohkawa, *et al.*[5]

Hughes and McWinnie[7] compared several methods of diagnosing the geometrical configurations of diacidobis(ethylenediamine)cobalt(III) complexes, and showed that Baldwin's method[11] utilizing the CH_2 rocking peaks was the best among them. In Table 2 are summarized the CH_2 rocking peaks shown by bis(trimethylenediamine)-cobalt(III) complexes discussed in this paper. Baldwin's criterion is successful in these examples except for one case, *cis* compounds showing two

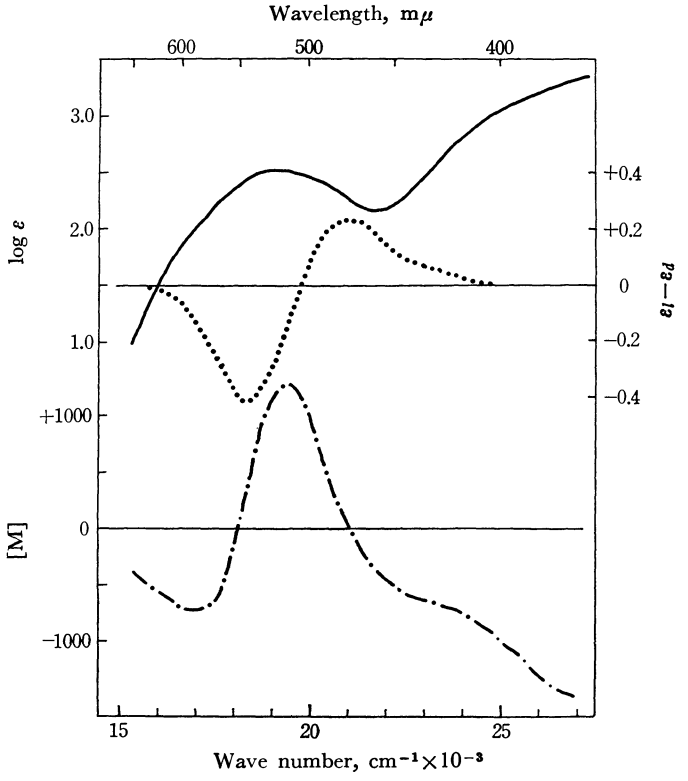

Fig. 8. Absorption(——), circular dichroism(····), and optical rotatory dispersion(·—·) curves of $(-)_D$-*cis*-$[Co(NCS)_2tn_2]SCN$ in water.

peaks while the *trans* isomers only one. The compound $[CoCl(H_2O)tn_2]Cl_2$, which was tentatively concluded to have the *cis* configuration, shows a single peak at 888 cm^{-1} violating Baldwin's empirical rule.

To establish the *cis* configuration unequivocally we tried to resolve the *cis* compounds into their optical isomers, but have succeeded only in the case of *cis*-$[Co(NCS)_2tn_2]SCN$. In Fig. 8 are shown the rotatory dispersion and circular dichroism curves of the optically active isomer. The molar rotations were calculated as follows:

$$[M]^{23}_{546} = +275°;\ [M]^{23}_{589} = -725°$$

The first example of the optically active cobalt(III) trimethylenediamine complex is $(-)_D$-$Cotn_3^{3+}$ prepared by Woldby,[12] which was shown by Saito and his coworkers[13] to have the same absolute configuration as the $(+)_D$-$Coen_3^{3+}$ ion,[14] namely Λ[15] or $P(C_2)$.[16] The crystal structure of the diastereoisomer $(-)_D$-$[Co(NCS)_2tn_2][Sb(+)$-tart]$\cdot 2H_2O$ has recently been studied and the absolute configuration of this dissymmetric complex cation was revealed to be Λ or $P(C_2)$, too.[17]

In recent years the circular dichroism spectra of a number of dissymmetric trigonal complexes have been measured and discussed in relation to their absolute configurations.[16] It was suggested[16,18] that trigonal d^3 and d^6 complexes have the same absolute configuration as $(+)_D$-$Coen_3^{3+}$ if the spin-allowed transition of lowest energy has an E_a component with a positive rotatory power. Beddoe and Mason[19] showed that the E_a component in $(-)_D$-$Cotn_3^{3+}$ has a positive rotational strength at longer wavelength, indicating that the spectroscopic criterion for the absolute configuration of trigonal metal complexes containing five-membered chelate rings may be successfully applicable to the trisdiamine complexes containing six-membered chelate rings. Consistent CD band assignments were also given by Gollogly and Hawkins to the enantiomeric $(+)_D$-$Cotn_3^{3+}$ ion.[20]

The relationship of absolute configuration to the optical activity of dissymmetric trigonal complexes have been extended to the *cis*-series of the bisethylenediamine complexes of cobalt(III). It was concluded that for the *cis*-complexes with the $P(C_2)$ configuration the major of the two CD bands mainly due to the E_a component of the parent trigonal complex has a positive sign and is displaced less than the minor band from the reference frequency of the $Coen_3^{3+}$ absorption.[21] The absolute configuration of $(+)_D$-$Co(CN)_2en_2^+$ was determined by Matsumoto *et al.*[22] to be Λ or P-(C_2) in accordance with this assignment by McCaffery *et al.*[23]

As shown in Fig. 8 $(-)_D$-$Co(NCS)_2tn_2^+$ gives two CD bands in the region of the long wavelength absorption band. The absolute rotational strengths of the bisdiamine complexes are usually smaller than those of the parent trisdiamine complexes owing to the reduced chelation,[24] but in the present case the CD bands of $(-)_D$-$Co(NCS)_2tn_2^+$ are more than twice as intense as those of $(-)_D$-$Cotn_3^{3+}$ (Fig. 9). If the above spectroscopic criterion concerning the absolute configurations of the bisethylenediaminecobalt(III) complexes can be extended to the bistrimethylenediamine complexes, the negative and the positive CD bands in Fig. 9 must be assigned to the A_2 and the E_a transitions in $(-)_D$-$Cotn_3^{3+}$, respectively. The positive high-energy component (E_a parentage) is displaced only by 850 cm^{-1} from the reference frequency of the $Cotn_3^{3+}$ absorption, but the negative low-energy component (A_2 parentage) is much farther displaced (1850 cm^{-1}). Thus the frequency displacement criterion holds in this case, but the relative band-area criterion fails since the negative component is larger than the positive one.

Another method of identifying the CD bands due to E_a and A_2 transition is based upon the observation that, in the presence of polarizable oxyanions such as phosphate, the areas of E_a and A_2 bands in the trigonal complexes are diminished and enhanced, respectively.[25,26] Of the various oxyanions investigated, selenite was found to be particularly convenient, producing large changes in the band area.[27] This ion-pairing effect was

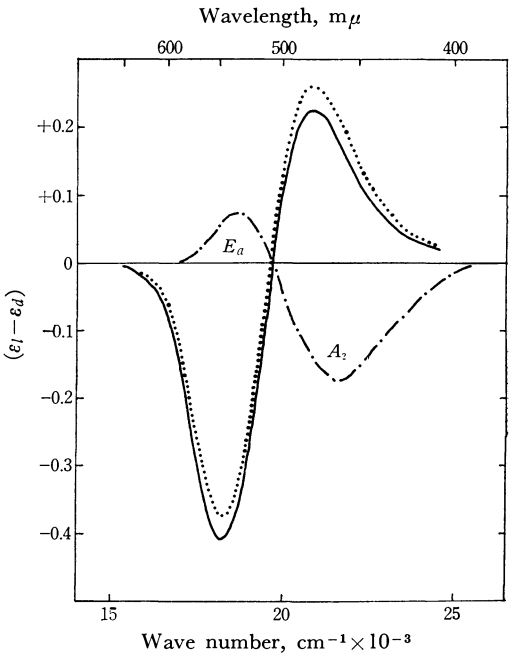

Fig. 9. Circular dichroism curves of $(-)_D$-*cis*-$[Co(NCS)_2tn_2]ClO_4$ in water(——) and in 0.05 M aqueous sodium selenite(· · · ·), and of $(-)_D$-$[Cotn_3](ClO_4)_3$ in water(— · —).

successfully applied in the case of $Cotn_3^{3+}$ ion,[19,20] but now gives inconsistent results to $(-)_D$-$Co(NCS)_2tn_2^+$. As shown in Fig. 9 the effect of selenite addition upon the CD band areas is small but obvious. The negative low-energy component is diminished and the positive high-energy component enhanced indicating that they are of E_a and A_2 trigonal parentage, respectively. Thus the CD bands assignment based on the outer-sphere coordination effect contradicts with the above assignment based on the empirical relationship between spectroscopic and configurational assignments. It is not certain at present which of them fails in the case of the bistrimethylenediamine complex, but the ion-pairing method might be less reliable. Further investigations of other dissymmetric trimethylenediamine complexes are desired.

The authors are grateful to Dr. Jinsai Hidaka of Osaka University for his help in the measurements of ORD and CD spectra and to Dr. Junnosuke Fujita of Tohoku University for his valuable discussion. Thanks are also due to Mr. Jun-ichi Gohda and Miss Takeko Inoue for organic elemental analyses and IR measurements.

Application of the AC Polarographic Method to the Microdetermination of the Sulfide Ion by the Methylene Blue Procedure*1

Kiyoshi HASEBE and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received February 4, 1970)

A new AC polarographic method utilizing the methylene-blue procedure was used for the determination of the sulfide ion. By means of dimethyl-*p*-phenylenediamine sulfate and iron(III) alum, the sulfide ion is converted quantitatively into methylene blue in the sulfuric-acid milieu. The methylene blue thus formed shows a prominent and reproducible AC peak, which can be suitably utilized for the indirect microdetermination of the sulfide ion. Halide ions interfere with the determination, however.

The methylene blue method is very useful for the microdetermination of sulfur. The method[1-8] consists of the photometry of the methylene blue formed by the reaction of the sulfide ion with dimethyl-*p*-phenylenediamine in the presence of the ferric ion.

The present authors tried to apply the AC polarographic method to the microdetermination of the sulfide ion by methylene-blue procedure. Although this method is found to be a little inferior to spectrophotometry as to sensitivity, the AC polarographic peaks are very prominent and reproducible and are sufficient for use in the determination of microamounts of the sulfide ion.

Experimental

Apparatus. The polarograph used was a Yanagimoto pen recording polarograph, model PA-102. The capillary characteristics at an 80-cm mercury column height were: $m=1.10_6$ mg/sec in pure water and $t=$ 4.90 sec in the polarographic solution at 0.00 V *vs.* mercury pool. The polarographic cell was thermostated to 25±0.1°C.

All the absorbance measurements were carried out by the aid of a Shimadzu photoelectric spectrophotometer, model QV-50, using 1-cm glass cells. The measurement of pH was made with a Hitachi-Horiba, model D-5, glass electrode pH meter.

Reagents. The 10^{-2} M dimethyl-*p*-phenylenediamine solutions were prepared freshly for each use by dissolving its salts (Wako Chemicals Co.), namely, hydrochloride (special grade) and its sulfate (first grade), in a 0.1 M sulfuric acid milieu. Methylene blue (for microscopy, E. Merck AG), and all the other reagents used were of analytical-reagent quality. The sodium sulfide solution was prepared afresh each day and was stored in a stoppered brown bottle protected from light. The 10^{-2} M iron(II) solution was prepared by dissolving 3.921 g of Mohr's salt in 1 *l* of 0.1 M sulfuric acid. The 10^{-2} M iron(III) solution was prepared by dissolving iron alum in 1 *l* of 0.1 M sulfuric acid.

Results

Effect of Supporting Electrolyte. As is well known methylene blue gives an adsorption prewave in DC polarography and the corresponding AC peak is remarkably prominent, suggesting a very high analytical sensitivity. The methylene-blue method, which utilizes the formation of methylene blue by the reaction of the sulfide ion with dimethyl-*p*-phenylenediamine in the presence of the ferric ion, has been carried out mainly in hydrochloric acid milieus.[1,2,4-6] The methylene-blue reaction proceeds as follows:

$$2NH_2C_6H_4N(CH_3)_2 + 6Fe^{3+} + H_2S \longrightarrow$$
$$\text{Methylene blue}^+ + 6Fe^{2+} + NH_4^+ + 4H^+$$

First of all, the effects of the various supporting electrolytes were studied. It was found that hydrochloric acid is not suitable as a supporting electrolyte for the determination of methylene blue, because the anodic peak of chloride ion partially overlaps that of methylene blue. In a 0.1 M sulfuric acid milieu and also in a solution which is 0.1 M in sulfuric acid and 0.1 M in sodium acetate, well-defined AC peak of methylene blue was ob-

served.

Effect of Ferric and Ferrous Ions. For the conversion of the sulfide ion into methylene blue, the ferric ion is employed as the oxidizing agent. Hence, the effect of the excess ferric ion and the ferrous ion produced on the methylene-blue polarogram should be investigated. Figures 1 and 2 illustrate the DC and AC polarograms with the supporting electrolyte, that is, 0.1 M sulfuric acid and also in sodium acetate.

Curve (a) in Fig. 1 represents the DC polarogram of the blank solution, curve (b) was recorded after the addition of iron(III) in 5×10^{-4} M to the test solution, and curve (c) was recorded with a test solution containing the ferric ion and methylene blue in 5×10^{-5} M. When 0.1 M sulfuric acid alone is employed as the supporting electrolyte, the reduction wave of methylene blue in the DC polarogram appears *ca.* 0.3 V from the ferric ion wave, while in the AC polarography methylene blue shows a prominent peak which is not effected by the ferric ion. Therefore, the supporting electrolyte of 0.1 M sulfuric acid was employed, thereafter.

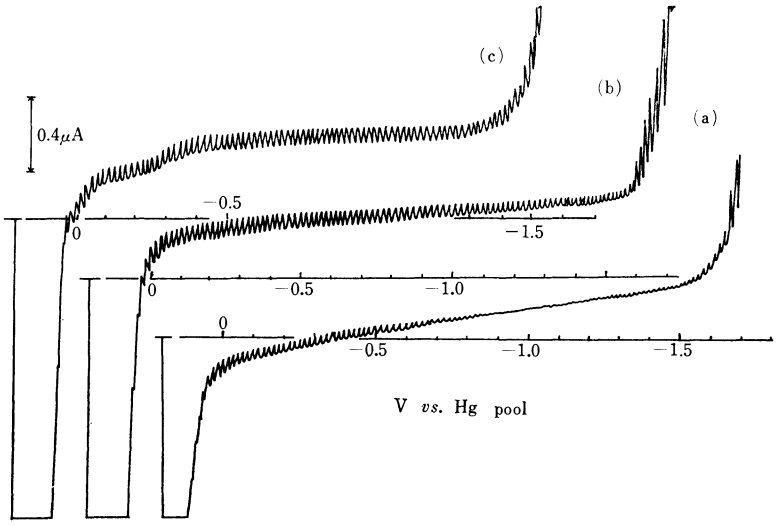

Fig. 1. Typical DC polarograms of methylene blue (Merck AG) and ferric ion.
Supporting electrolyte: (a) 0.1 M H_2SO_4+0.1 M NaOAc, (b) (a)+5×10^{-4} M Fe^{3+}, (c) (b)+5×10^{-5} M methylene blue. Parallel capacitance: 50 μF

Parallel capacitance: 0.05 μF.

Effect of Anions on the AC Peak of Methylene Blue. According to many authors,[2,6] the hydrochloride of dimethyl-*p*-phenylenediamine has widely been used for the color reaction forming methylene blue. When dimethyl-*p*-phenylenediamine was used, the anodic wave of the chloride ion interferes with the methylene-blue determination by the polarographic method. As the concentration of the chloride ion increases, the interference becomes especially remarkable.

Figure 3 compares polarograms of methylene blue as synthesized by dimethyl-*p*-phenylenediamine hydrochloride (a) and its sulfate (b). The prominent chloride peak appears near to the methylene blue wave. The use of sulfate is, needless to say, more advantageous than that of hydrochloride. As is well known, iodide reduces methylene blue to the leuco form, and chloride and, more strongly, the bromide ion suppress the methylene-blue peak height, as has been reported in our previous study.[9]

Effect of the Sulfuric Acid Concentration. The color development due to the formation of methylene blue from the sulfide ion and dimethyl-*p*-phenylenediamine in the presence of the ferric ion should be performed in a sulfuric acid milieu, because the chloride ion interferes with the polarographic determination of methylene blue.

The relationship between the concentration of sulfuric acid and absorbance of methylene blue, or the AC polarographic peak, was investigated. According to Rabinowitch and Epstein,[10] methylene blue exists in monomer and dimer forms in solution. On the other hand, Oka and Matsuo,[4] who discussed in detail the behavior of methylene blue in a hydrochloric acid milieu, reported the association of methylene blue with hydrochloric acid as indicated by the new absorption band at 735 mμ. Figure 4 shows the variation in the absorption spectrum of methylene blue with the sulfuric acid concentration. The new maximum in absorbance curves at 740 mμ *vs.* the reagent blank clearly shows another form of methylene blue in a sulfuric acid milieu. This maximum can be interpreted as resulting from the association of methylene blue with sulfuric acid. Thus, it is important to select a suitable acid concentration.

Figure 5 shows the relationship between the AC polarographic peak height and the sulfuric acid concentration. It can readily be seen that the optimum polarographic concentration of sulfuric acid is at 0.1—0.2 M.

Effect of the Ferric Ion Concentration and Deaeration on the AC Polarographic Peak. By applying the constant initial concentration of the sulfide ion of 4×10^{-4} M in the reaction mix-

Table 1. Analysis of means

Relationship between the AC peak height of methylene blue and ferric ion concn. with and without deaeration.

Ferric ion concn., M	AC peak height, μσ	
	With deaeration	Without deaeration
1×10^{-3}	132±15.6	133±15.6
5×10^{-4}	213±20.8	205±26.0
	(208, 224, 208)*	(204, 196, 216)*
1×10^{-4}	113± 5.20	111±10.4

Confidence limits 95%; * Figures in parentheses represent individual values. Parallel capacitance 0.05 μF.

The initial concentration in the reaction mixture: 4×10^{-5} M S^{2-}, 5×10^{-3} M dimethyl-*p*-phenylenediamine.

F-test shows that there is no significant difference between two variances: $F(2, 2, 0.025)=39.0>F_0=1.18$, *t*-test shows that there is no significant difference between two means: $t(4, 0.05)=2.77>t_0=1.17$.

ture, the effect of the ferric-ion concentration on the synthesis of methylene blue was studied.

Table 1 shows the relationship between the AC polarographic peak heights of methylene blue and the initial concentration of the ferric ion without deaeration. The optimum concentration of the ferric ion was found to be 5×10^{-4} M in the reaction mixture. With the ferric ion concentration of 5×10^{-4} M, the two means of obtaining the AC peak heights, with and without dissolved oxygen, were analyzed statistically. Consequently, it can be concluded that there is no significant difference between the AC peak heights obtained with and without deaeration.

Effect of the Dimethyl-*p*-phenylenediamine Concentration. The dimethyl-*p*-phenylenediamine in the electrolysis solution showed no AC peak. The optimum concentration of dimethyl-*p*-phenylenediamine was determined by employing various concentrations of the diamine from 1×10^{-4} to 8×10^{-3} M. Figure 6 shows the change in the AC polarograms of methylene blue at various

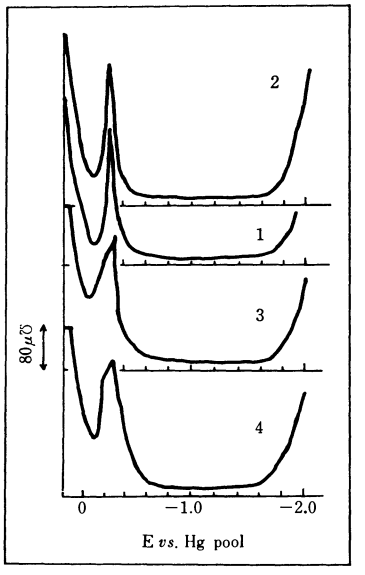

Fig. 6. Effect of dimethyl-*p*-phenylenediamine concentration on the AC polarographic peak.
Concentration in the reaction mixture is: 4×10^{-5} M S^{2-}; 5×10^{-4} M Fe^{3+}.
The diamine concentration is: (1) 5×10^{-4} M; (2) 1×10^{-3} M; (3) 5×10^{-3} M; (4) 8×10^{-3} M.

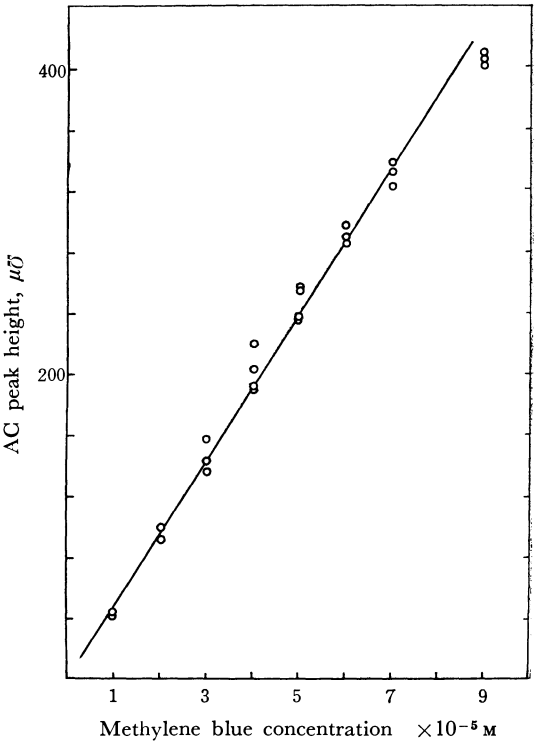

Fig. 7. Calibration curve of methylene blue.
AC peak height is plotted against the concentration of synthesized methylene blue in the electrolysis solution.

diamine concentrations.

It can be seen that 5×10^{-4} M or 1×10^{-3} M of dimethyl-*p*-phenylenediamine is most suitable for the determination of the sulfide ion. However, no peak of methylene blue appeared with 1×10^{-4} M diamine. The diamine in concentrations higher than 5×10^{-3} M interferes with the methylene blue peak, as Fig. 6 shows.

Effect of the Standing Time. At room temperature, no change in the AC polarographic peak height of methylene blue was observed over a period of 24 hr.

Established Procedure. The procedure for the sulfide determination has been established to be as follows:

To 0.5 m*l* of 2 M sulfuric acid in a 10-m*l* volumetric flask, add 0.5—1 m*l* of 10^{-2} M dimethyl-*p*-phenylenediamine in 0.1 M sulfuric acid and 0.5—0.6 m*l* of 10^{-2} M iron(III) ammonium sulfate. Add the sample solution containing the sulfide ion to the reagent mixture, shake, let stand for 15—20 min and then fill up to the mark with water. Record the AC polarogram without deaeration.

Calibration Curve. The relationship between the AC polarographic peak height of the synthesized methylene blue and the original amount of the sulfide ion was studied. The results are shown in Fig. 7.

It is possible to determine the sulfide ion, namely, methylene blue, from 1×10^{-5} M to 9×10^{-5} M in the electrolysis solution, as is shown in Fig. 7.

Discussion

It has been said that the degree of methylene-blue color development changes slightly with the sequence of reagent addition.[2,4,5] In the AC polarography, however, no significant difference could be seen by any change in reagent addition.

Breyer and Hacobian[11, 12] have reported that the sulfide ion gave a good AC polarographic peak in a supporting electrolyte of 1 M sodium hydroxide and that a linear calibration curve was obtained in the concentration range from 10^{-4} to 10^{-3} M. However, the direct determination of sulfide ion is much less sensitive than the present indirect method.

Mössbauer Effect of ^{119}Sn in Some Organotin Compounds*1

Clive WYNTER and Louis CHANDLER

Environmental Sciences Department, Rutgers University, New Brunswick, New Jersey, U.S.A.

(Received December 1, 1969)

Mössbauer, NMR, and infrared spectroscopy have been applied to the study of a number of organometallic tin compounds containing one or more tin manganese pentacarbonyl bonds. For the $(CH_3)_{4-n}Sn[Mn(CO)_5]_n$ series ($n=0$ to 3) a linear relation between the Mössbauer isomer shift and the number of manganese pentacarbonyl ligand was consistent with the partial isomer shift theory of ^{119}Sn. A linear relation between the Mössbauer isomer shift and the methyl proton NMR chemical shift was also observed for this series. A plot of the isomer shift (δ_0) *versus* the number of p holes (h_p) for organotin manganese pentacarbonyl compounds established a relation $\delta_0 = 1.23 + 0.53\, h_p$ for sp^3 hybridized tin. From isomer shift systematics a value of ($\Delta R/R$) for ^{119}Sn was calculated to be 1.2×10^{-4}.

The preparation and properties of some mixed metal carbonyl compounds of the type $R_{4-n}Sn[Mn(CO)_5]_n$ were R=Cl, Br, C_6H_5, CH_3 and $n=0$ to 3 have been reported by Gorsich.[1] Clark and Tsai,[2] and Jetz and his co-workers[3] have studies the tin manganese bond by IR and NMR spectroscopy. Later, Graham,[4] using the Cotton-Kraihanzel (CK) approximate force constant method, separated the inductive and mesomeric effects in these types of compounds. The Mössbauer effect of a variety of these tin-transition metal bonds in organometallic compounds have been studied by Karasev[5] and his group to obtain information on the nature of the Sn–$Mn(CO)_5$ interaction, the tin-alkyl sites and the local symmetry of $Mn(CO)_5$ group in the compounds. Values of electron density at the nucleus were obtained from Ruby *et al.*[6] correlation diagram of electron density at the nucleus and the isomer shift. From this a value of ($\Delta R/R$) is obtained.

Experimental

The compounds reported in Table 1 save the monomethyl tin tris manganese pentacarbonyl, were synthesized by Gorsich's procedure.[1] A new method utilizing an inert N_2 atmosphere because of the air sensitivity of the manganese pentacarbonyl dimer was used to prepare the monomethyl tin tris manganese pentacarbonyl. An approximately 1% Na amalgam (0.5 g Na and 50 g Hg) was reacted with 2 g (5.1 mmol) $Mn_2(CO)_{10}$ dissolved in 30 m*l* of dried tetrahydrofuran. The reaction mixture was stirred for 1 hr with a magnetic stirrer and the resulting $Na^+[Mn(CO)_5]^-$ solution was decanted off from the Hg. The latter solution was mixed with 0.82 g (3.4 mmol) $MeSnCl_3$ dissolved in 4 m*l* of THF and stirred for three hours. The solid residue was filtered off and the THF solvent was removed from the mother liquor with a water aspirator. The solid residue was extracted with a 1 : 2 by volume water - THF mixture and the crude product was recovered by removing the THF from the organic layer. This yellow solid was recrystallized from *n*-hexane.

All the compounds studied gave satisfactory analytical data.

The Mössbauer spectra of these compounds at 80°K were obtained in transmission geometry with a $Ba^{119m}SnO_3$ source at room temperature. In addition proton magnetic resonance and IR spectroscopic data were taken.

Results and Discussion

In Table 1 the Mössbauer parameters of the ^{119}Sn compounds prepared in this laboratory are reported. The quadrupole splitting in these compounds save triphenyl tin manganese pentacarbonyl are due to p holes in the "perfect" s state of sp^3 configuration arising from a disparity between the electronegativity of the R (Cl, Br, CH_3) group and the manganese pentacarbonyl radical. The question of why there is no observed quadrupole splitting in triphenyl tin manganese pentacarbonyl although there is a "p" electron defect (h_p=0.57) which is larger than in the trimethyl tin manganese pentacarbonyl (h_p=0.42) where there is a measurable quadrupole splitting is still not resolved. A reasonable guess is that the presence of the π electron clouds in the phenyl rings compensates for the field inhomogeneity at the tin nucleus and hence there is no resolvable quadrupole interaction.

Particularly interesting is the $(CH_3)_{4-n}Sn[Mn(CO)_5]_n$ series where n=0 to 3. The electrical environment around the metal atom in tetramethyl tin gives rise to the expected zero quadrupole splitting, whereas the trimethyl, the dimethyl and the monomethyl tin congeners show an almost constant quadrupole splitting of approximately

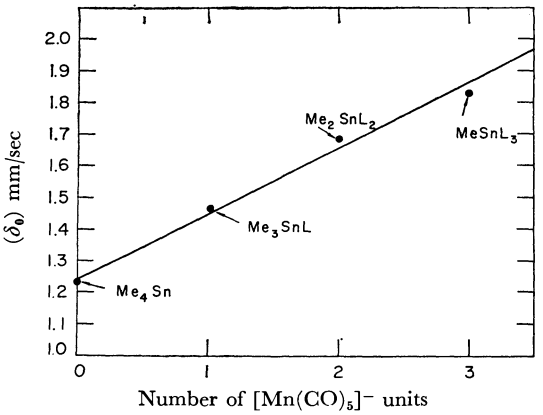

Fig. 1. A plot of the isomer shift *versus* the number of substituted $[Mn(CO)_5]$ ligand for the $(CH_3)_{4-n}Sn[Mn(CO)_5]_n$ series. (n=0 to 3)

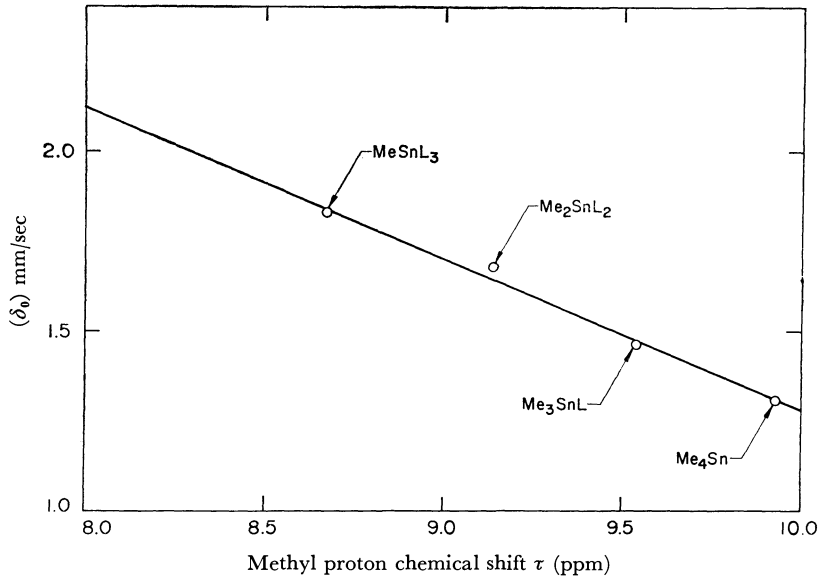

Fig. 2. Graph of the Mössbauer isomer shift *versus* the methyl proton NMR shift for the $(CH_3)_{4-n}Sn[Mn(CO)_5]_n$.

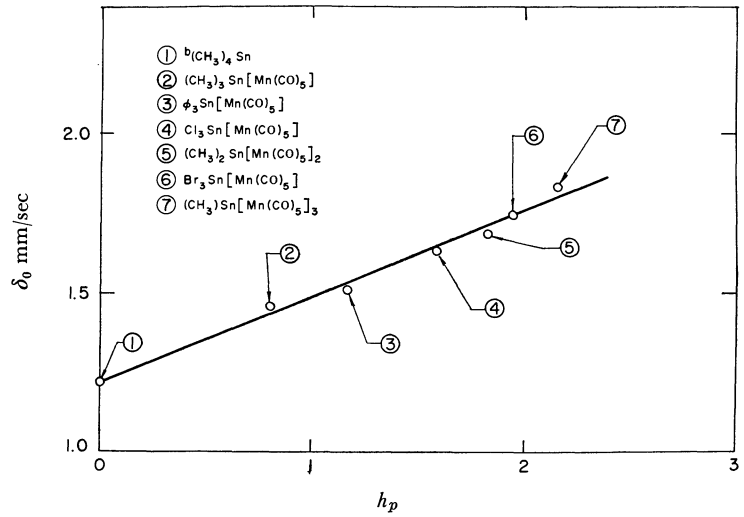

Fig. 3. A plot of the ismer shift δ_0 *versus* the number of p holes h_p for tin manganese pentacarbonyl compounds.

1 mm/sec. This lack of variance is explained by the disparity yet closeness of the group electronegativety of the $[Mn(CO)_5]$ ligand of 2.01 compared to the methyl group of 2.54.

Figure 1 shows a linear plot of the isomer shift δ_0 *versus* the number of $[Mn(CO)_5]$ ligands in the series $(CH_3)_{4-n}Sn[Mn(CO)_5]_n$, where $n=0$ to 3. This in fact lends proof to the partial isomer shift theory of tin and leads to the simple equation.

$$\delta_0(\text{relative to } BaSnO_3) = 1.23 + 0.19n \qquad (1)$$

Another interesting feature of this series is seen in Fig. 2. It establishes a linear relation between the Mössbauer isomer shift (δ_0) and the proton NMR shift τ (ppm). Holmes and Kaesz[7] have correlated the coupling constant $A_{^{119}Sn^H}$ with %5*s* character. This correlation does not work for this series and may be due to hydrogen bonding of the methyl protons in juxtaposition with oxygen of the manganese pentacarbonyl moiety. Evidence for change in local C_{4v} symmetry of the bulky manganese pentacarbonyl ligand in the monomethyl tin tris manganese pentacarbonyl derivative was furnished by the drastic change in the relative intensity of the $[2A_I+E]$ bands. It is possible that smaller changes of this sort in the other member of this series may not be detected by infrared techniques.

Spijkerman[8] has calibrated the %5*s* character and the Mössbauer chemical shift. From the measured isomer shift, %5*s* character of all compounds in this work was estimated, and electronic configurations and number of p holes h_p assuming a constant sp^3 hybridization calculated. These are shown in Table 3. Figure 3 shows a plot of the isomer shift δ_0 *versus* the number of p holes h_p leads to a linear relationship $\delta_0=1.23+0.53\ h_p$ for sp^3 hybridized tin.

Table 3. Derived parameters from the isomer shifts of ^{119}Sn compounds

Compounds	Electronic configuration	Number of p holes h_p	% 5*s* character
$Cl_3Sn[Mn(CO)_5]$	$5s^{0.745}5p^{2.22}$	0.78	34
$Br_3Sn[Mn(CO)_5]$	$5s^{0.685}5p^{2.04}$	0.96	37
$\phi_3Sn[Mn(CO)_5]$	$5s^{0.815}5p^{2.43}$	0.57	31
$(CH_3)_4Sn$	$5s^1\ 5p^3$	0.00	25

Ruby *et al.*[6] has correlated the electron density $\psi^2(0)/a_0^3$ at the nucleus and the isomer shift for ^{119}Sn. From this data values of $\psi^2(0)/a_0^3$ were obtained and a value of $\Delta R/R=1.2\times10^{-4}$ calculated. This agrees with the value obtained by their group and some previously reported values.

Further work is in progress to clear up any ambiguities in the phenyl tin manganese pentacarbonyl series.

Reactive Species in the Explosion of Silver Acetylide. II. Reaction with Olefins

Ko Taki

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received June 12, 1969)

The reaction of the reactive species in the explosion of silver acetylide with olefins was investigated. The main produst is acetylene. On the basis of the results of experiments on the effects of the pressure and the distance from the explosion position, the C_3 and C_4 products in the reaction with ethylene may be considered to be produced from a common precursor. The C_4 products consist mainly of vinylacetylene and diacetylene. The formation processes of the products may consist of the decomposition of the adducts of the C_2 species. The reaction with C_4 olefins gives benzene, cyclopentadiene, and other products.

In the previous paper[1] the reaction of the reactive species in the explosion of silver acetylide with saturated hydrocarbons has been reported. From the distribution[1] of the products and from the variation[1] in the ratio of C_2H_4 to C_2H_2 in various phases, it was assumed[1] that the diatomic carbon (C_2) was one of the reactive species in the explosion.

In this paper the reaction of the reactive species in the explosion of silver acetylide with olefins and their reaction processes were investigated. This reaction will be compared with the reaction of a carbon atom produced by the nuclear recoil reaction[2,3] and with the reaction of a carbon vapor produced by the carbon arc[4,5] in this paper.

Experimental

The experimental procedure and the explosion technique were essentially the same as those reported in the previous paper. The olefins (Takachiho Co., Ltd.) were used without further purification. The analyses were performed by gas chromatography using silica gel, squalane, and polyethylene glycol columns. The quantitative analyses were carried out by the internal standard system, using neopentane and chlorobenzene as standards.

Results and Discussion

In the reaction with olefins, the main product is acetylene, as has previously been described in connection with the reaction with saturated hydrocarbons.[1] This is similar to the reaction of the free carbon atom in the recoil reaction.[2] Therefore, the formation of C_3 compounds in the gas-phase reaction with the C_2 substrate may suggest that one of the reactive species is monatomic carbon. However, the yield of C_3 compounds is not high as compared with that of C_4 compounds,*1 as is shown in Table 1. Moreover, with the change in substrate from ethane to acetylene, the yields of C_3 compounds decrease, but those of C_4 compounds increase.

Table 1. C_3 and C_4 product yields in the reaction with ethane, ethylene and acetylene in the gas phase

Ag_2C_2 0.10 g
Substrate $2.3-2.5\times10^{-4}$ mol
Product $\times10^{-6}$ mol

Substrate	Product		Ratio	
	C_3	C_4	C_3/C_4	C_4H_2/C_4H_4
Ethane	2.2	1.1	2.0	1.0
Ethylene	0.51	1.9	0.3	1.3
Acetylene	0.05	3.6	0.013	7.0

These results are quite different from those with the recoil reaction[6] and the reaction of carbon vapor. In the recoil reaction,[2] as is shown in Table 2, C_3 compounds are produced in quite a large yield, and in the reaction of carbon vapor C_1 insertion intermediate and spiropentane deri-

Table 2. In the recoil reaction, C_3 and C_4 product yield% in the reaction with ethane and ethylene[2,3]

Substrate	Product C_3%	Product C_4%	Ratio C_3/C_4
Ethane	12.5	—	—
Ethylene	27.1	10.8	2.5
Ethylene liq. −130°C	21.7	9.9	2.2
Ethylene solid −196°C	22.1	15.8	1.2

vatives[7,8] are produced in the reactions with saturated hydrocarbon and olefins respectively.

On the basis of the above results, it may be suggested that the reactitive species include not only monatomic carbon but also other carbon oligomers. By the reaction with ethylene, C_4 compounds were obtained, but higher hydrocarbons were not obtained; therefore, C_2 may be the most probable reactive species, as was suggested in the previous paper.[1] C_3 and C_4 compounds are given in the reaction of C_1 or C_2 with ethane, ethylene, and acetylene as follows:

$$\left.\begin{matrix}C_1\\C_2\end{matrix}\right\} + C_2\ \text{Substrate} \rightarrow \begin{cases}[C_2\ \text{Substrate}\ C_1]^* \rightarrow C_3\ \text{Compounds}\\ [C_2\ \text{Substrate}\ C_2]^* \rightarrow C_4\ \text{Compounds}\end{cases}$$

Reaction with Ethylene under Various Conditions. In order to examine the reaction process, a further experiment was carried out with an ethylene substrate. In the solid phase, as is shown in Table 3, and in the gas-phase reaction the main products are acetylene and C_3 and C_4 compounds. The yields of acetylene and of the C_3 and C_4 compounds increase with the ethylene pressure but the C_3/C_4 and C_4/C_2H_2 ratios are almost constant, as is shown in Figs. 1 and 2. The C_3/C_4 ratio does not depend on the distance from the explosion position,*2 as is shown in Fig. 3. Moderation of the reactive species by helium gas gave the same results. These experimental results suggest that the acetylene and C_3 and C_4 compounds may be produced from a common precursor.

Table 3. Product yields in the solid phase reaction with ethylene

Ag_2C_2 0.10 g

Ethylene 2.2—2.5×10^{-4} mol

Product	Yield×10^{-6} mol
Methane	2.5—2.7
Ethane	0.14—0.24
Acetylene	41.6—65.6
Propylene	0.43
C_3 Products	0.51
Butadiene	0.12
Ethylacetylene	0.03
Vinylacetylene	0.63
Diacetylene	0.83
C_4 Products	1.72
C_3/C_4	0.30
C_4H_2/C_4H_4	1.3

The Formation Process of C_4 Compounds. C_4 compounds consist of vinylacetylene and diacetylene,*3 and the sum of their yields increases with the ethylene pressure, as has been mentioned before. However, the ratio of diacetylene to vinylacetylene decreases with the ethylene pressure, as is shown in Fig. 4. Helium gas moderation also brought about a decrease in the C_4H_2/C_4H_4 ratio. From these facts, it may be considered that the formation processes of C_4 compounds depend on the deactivation condition of the adduct ($C_2H_4C_2$), which may be an energy-rich C_2-insertion intermediate(C_4H_4). The adduct easily gives vinylacetylene upon deactivation at a high pressure, but the adduct decomposes easily to diacetylene at a low pressure according to these reactions:

$$C_2H_4 + C_2 \rightarrow$$

$$[C_2H_4C_2]^* \begin{cases} \longrightarrow \text{acetylene}\\ \xrightarrow{\text{high pressure}} \text{vinylacetylene}\\ \xrightarrow{\text{low pressure}} \text{diacetylene}\end{cases}$$

This mechanism is also supported by the fact that the ratio of diacetylene to vinylacetylene decreases with the increase in the distance from the explosion position in the solid-phase reaction, as is shown in Fig. 5.

Harris and Skell[10] reported recently that the C_4 species (tetra atomic carbon) in carbon vapor is the precursor of the C_4 products in the reaction

*2 The explosion technique as a function of the distance from silver acetylide was also described in the previous paper.[1]

*3 The C_4 compounds were identified as vinylacetylene and diacetylene on the basis of the evidence that the catalytic hydrogenation gave *n*-butane gas chromatographically and that the retention times of these compounds on three different columns, polyethylene glycol 1000, squalane, and apiezone L columns, were the same as those of authentic vinylacetylene and authentic diacetylene. The authentic vinylacetylene was kindly given by Dr. S. Horiie (Denki Kagaku Co.), the authentic diacetylene was prepared following Ref. 9, and the catalyst, PtO_2, was kindly provided by Dr. K. Taya (Rikagaku Kenkyu Sho).

of various hydrocarbons. The C_4 compounds have been ethylacetylene, methylallene, 1,3-butadiene, and vinylacetylene, but diacetylene has been found only in trace quantities. In the present reaction, because of the high yield of diacetylene, C_4 compounds seem unlikely to be yielded from the reaction of the C_4 species (tetra-atomic carbon).

Reaction with C_3 and C_4 Olefins. The yields of acetylene, ethylene, cyclopentadiene, diacetylene, vinylacetylene, and benzene in reactions with various C_3 and C_4 olefins are listed in Tables 4, 5, and 6. From the fact that the reactions with isobutene and with isobutane give benzene (the yield is not high), benzene may be formed in the process of the decomposition of adducts. However, the benzene yield depends on the structure of the substrate, for the reactions with 1,3-butadiene and with 1-butene give high yields*4 of benzene. From the above facts, benzene may

*4 The yields of benzene from *cis*-butene and *trans*-butene are almost the same. In this case, the structure of the substrates does not seem to have any effect on the formation of benzene. The reason for this is not clear, but the formation of benzene might be caused by the addition of the C_2 species to the terminal double bond in the molecule and the resulting adduct may undergo cyclization; therefore, the formation might be interpreted in terms of the position of the double bond in the molecule.

Table 4. Vinylacetylene, diacetylene, cyclopentadiene and benzene yields in the solid phase reaction with C_4 olefins

be considered to be formed not only by the decomposition of adducts, but also by the cycloaddition to substrates. In the reaction with C_3 olefins, it is not clear whether diacetylene and vinylacetylene are formed by the reaction of C_1 or of C_2 species. The diacetylene yield is higher in allene and methylacetylene than in propane. On the other hand, the vinylacetylene yield is higher in propane than in allene. This fact indicates that the yields of diacetylene and vinylacetylene are affected by the structure of the substrate. The cyclopentadiene yield is also affected by the structure of the substrate, as is shown in Table 6.

The benzene formation in the reaction with C_3 olefins, and the cyclopentadiene formation in the reaction with C_4 olefins may be considered to be the reactions of the C_3 and C_1 species respectively, but the details are still not clear.

In the reaction of carbon vapor from the carbon arc[11] with ethylene, acetylene is not a main product, while in the reaction of carbon atoms from a recoil reaction[2] acetylene is a main product. Although the reaction of carbon vapor from the carbon arc deals with the reaction of carbon atoms complexed[11] by surface material rather than with the reaction of free carbon atoms, the facts that the acetylene yield diminishes sharply[12] as the carbon atoms from the recoil reaction are thermalized by a moderator and as the adducts are efficiently de-excited confirms that there is indeed no discrepancy in the two reactions. Moreover, the

11) P. S. Skell and R. R. Engle, *J. Amer. Chem. Soc.*, **87**, 1135 (1965).

12) J. E. Nicholas, C. MacKay and R. Wolfgang, *ibid.*, **87**, 3008 (1965).

yield of C_3 products is higher than that of C_4 products. On the other hand, in the present work the main products in the reaction with ethylene are acetylene and C_4 products. The C_3 products are too small in quantity as compared with the C_4 products. The difference in the results may be considered to be caused by the difference in the reactive species in the carbon vapor.

In conclusion, C_2 may be considered to be one of the reactive species in the explosion of silver acetylide. The primary step is the addition of reactive species to the substrate; the resulting adduct undergoes a secondary process to give the final products. However, the steps of the formation of benzene depend on the structure of the substrate.

The author wishes to thank Professor Shunsuke Murahashi (Osaka University) for his useful suggestions and encouragement, Miss K. Motegi for her efforts in the analysis of the reaction products, and Dr. M. Imamura and Dr. M. Matsui for their helpful discussions and suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2123—2129 (1970)

The Synthesis and Polymerization of Vinyl- and Isopropenyl-*s*-triazines

Yasuo YUKI,*1 Toshio KAKURAI and Tatsuya NOGUCHI

Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 4, 1969)

Some new vinyl monomers with an amino-*s*-triazinyl group were synthesized. 2,4-Amino- and substituted amino-6-vinyl-*s*-triazines were synthesized by the reaction of the substituted biguanides with acrylyl chloride, while 2-amino-4-substituted amino-6-isopropenyl-*s*-triazines were prepared from the substituted biguanides with methyl methacrylate. It has been found that vinyl-*s*-triazines thermally polymerized immediately after melting and gave insoluble polymers. Polymers with amino-*s*-triazinyl groups in the side chain were obtained by the radical polymerization of some vinyl- and isopropenyl-*s*-triazines. The copolymerization of these monomers with styrene has been investigated in dimethyl sulfoxide using α,α'-azobisisobutyronitrile as an initiator. The monomer reactivity ratios were determined, and the Q and e values for these vinyl-*s*-triazines were calculated. Some discussions are presented.

A vinyl monomer with an amino-*s*-triazine ring is interesting as a reactive monomer. Overberger and Shapiro[1,2] have reported on the synthesis and polymerization of 2,4-diamino-6-vinyl-*s*-triazine and 2-amino-4-anilino-6-vinyl-*s*-triazine from the reaction of biguanide and phenylbiguanide respectively with acrylyl chloride. Thurston[3] has reported on the reaction of biguanide with methyl methacrylate to give 2,4-diamino-6-isopropenyl-*s*-triazine. We have repeated these synthesis and, in addition, synthesized various vinyl- and isopropenyl-*s*-triazines.

The polymerizations of 2,4-diamino-6-vinyl-*s*-triazine and 2-amino-4-*o*-toluidino-6-vinyl-*s*-triazine have previously been reported.[4,5] Continuing the studies of vinyl-*s*-triazines, the homopolymerization and copolymerization of several vinyl- and isopropenyl-*s*-triazines have now been investigated. In particular, the copolymerization with styrene was studied. The copolymerization of 2,4-diamino-6-vinyl-*s*-triazine hydrochloride with styrene will also be reported here.

Experimental

Materials. The aliphatic biguanides were prepared by the method of Kono and Odo.[6] The aromatic biguanides were prepared by the method of Cohn[7] from the reaction of dicyanodiamide with aromatic amines hydrochlorides in hot water. The styrene was purified by the usual method and was distilled again before use. The initiator, α,α'-azobisisobutyronitrile (AIBN), was a commercial material. The

dimethyl sulfoxide (DMSO) was fractionally distilled under reduced pressure in the presence of nitrogen. All the other reagents were commercially available and were used after purification if necessary.

2-Amino-4-anilino-6-methyl-s-triazine. Phenylbiguanide (1.77 g, 0.01 mol) was dissolved in 4 m*l* of methanol, and then 3.7 g (0.05 mol) of methyl acetate were added. After the reaction mixture had then been allowed to stand for five days at room temperature, the methanol and excess methyl acetate were removed. The residue was washed with water to give 1.2 g (60%) of a product which melted at 173—175°C.

The other 2,4-disubstituted-6-methyl-*s*-triazines were prepared in a similar manner.

2-Amino-4-anilino-6-isopropenyl-s-triazine. To a solution of 17.7 g (0.1 mol) of phenylbiguanide in 50 m*l* of methanol, we added 15.0 g (0.15 mol) of methyl methacrylate. After the reaction mixture had been allowed to stand for six days at room temperature, the methanol was removed and water was added to give 7.1 g (34%) of a white product. The product was recrystallized from a methanol-water mixture, mp 174—175.5°C.

The other 2,4-disubstituted-6-isopropenyl-*s*-triazines were prepared in a similar manner.

2-Amino-4-anilino-6-vinyl-s-triazine. 2-Amino-4-anilino-6-vinyl-*s*-triazine and the other 2,4-disubstituted-6-vinyl-*s*-triazines were prepared in a manner similar to that previously described.[5]

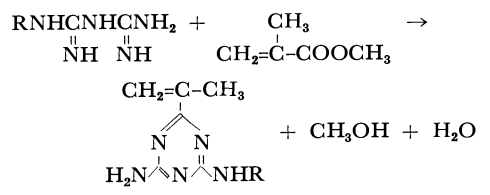
Procedure. All the polymerization experiments were carried out in a DMSO solution by AIBN at 60°C in a glass tube sealed under a vacuum. Methanol was used as a precipitant. The composition of the copolymer was calculated from the carbon and nitrogen contents.

Results and Discussion

Preparation of Monomers. The synthesis of 2,4-amino- or substituted amino-6-substituted-*s*-triazines was effected by the reaction of substituted biguanides with carboxylic acid derivatives (acid esters or acid chlorides).[8]

Methyl-*s*-triazines were synthesized for the model compounds of vinyl-*s*-triazines according to the directions of Overberger and Shapiro.[9] The results are shown in Table 1.

Isopropenyl-*s*-triazines were given by the reaction of substituted biguanides with methyl methacrylate in methanol,



The results are shown in Table 2.

Vinyl-*s*-triazines were prepared from the reaction of the substituted biguanides with acrylyl chloride in acetone at a low temperature, as has previously been reported in the case of 2-amino-4-*o*-toluidino-6-vinyl-*s*-triazine.[5] The results are shown in Table 3.

The UV absorption data of *s*-triazines determined in ethanol are given in Table 4. When 2- and 4-substituents are amino or alkyl amino groups, the vinyl- and isopropenyl-*s*-triazines show a bathochromic shift compared with methyl-*s*-triazines. This is probably due to the conjugation of the double bond with the triazine nucleus. On the other hand, when the 4-substituents are aryl amino groups, the vinyl- and isopropenyl-*s*-triazines show a hypsochromic shift. Overberger and Shapiro[11] found this same effect on 2-amino-4-anilino-6-vinyl-*s*-triazine. These results indicate little conjugation of 4-aryl amino groups.

The thermal behavior of vinyl- and isopropenyl-*s*-triazines was studied by the techniques of differential thermal analysis (DTA) and thermogravimetric analysis (TGA). 2,4-Diamino-6-vinyl-*s*-triazine was reported to be decomposed without melting at 300—310°C[1] Figure 1 shows the DTA and TGA curves of 2,4-diamino-6-vinyl-*s*-triazine. It was found that 2,4-diamino-6-vinyl-*s*-triazine was gradually sublimed above 170°C and was thermally polymerized at about 260°C without melting. This thermally-polymerized product was insoluble, but it swelled in formic acid. Its IR spectrum was identical with that of the polymer obtained by the solution polymerization using AIBN in DMSO.[4] All the other vinyl-*s*-triazines,

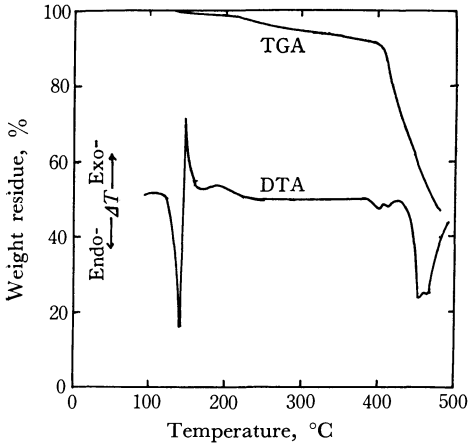

Fig. 2. Thermal analysis of 2-amino-4-*N*-methylanilino-6-vinyl-*s*-triazine in air.
TGA (5°C/min), DTA (20°C/min)

which gave a sharp melting point, were found, by a study of DTA and TGA curves, to polymerize immediately after melting. The curves of 2-amino-4-*N*-methylanilino-6-vinyl-*s*-triazine are shown in Fig. 2 as a typical example. After the exotherm, no double-bond absorption was observed in the IR spectra of the heated samples. This polymer was also insoluble. On the other hand, no thermal polymerization of isopropenyl-*s*-triazines was observed, even after its melting.

Polymerization. The results of the homopolymerization of some vinyl- and isopropenyl-*s*-triazines by AIBN in DMSO are presented in Tables 5 and 6 respectively. Poly-2-amino-4-methylamino-6-vinyl-*s*-triazine and poly-2,4-diamino-6-isopropenyl-*s*-triazine were insoluble in common organic solvents, but they were soluble in formic acid, acetic acid, and mineral acid. The polymerization of 2-amino-4-dimethylamino-6-vinyl-*s*-triazine proceeded homogeneously, but the polymer isolated was insoluble in DMSO. The polymers containing aryl amino groups were soluble in DMSO, DMF, DMA, and dioxane.

b) C=0.2 g/d*l*, at 30°C.

Copolymerization. The copolymerization of vinyl- and isopropenyl-*s*-triazines with styrene were carried out at 60°C in DMSO. The polymerization conditions were as follows; $[M_1]+[M_2]=0.20$ mol/*l* and [AIBN]=1.35×10^{-3} mol/*l*. The polymerization proceeded homogeneously. The rates of copolymerization decreased as the styrene contents in the monomer mixtures increased. The relationship between the composition of the monomer feeds and that of the copolymers is summarized in Tables 7 and 8. The copolymerization of 2,4-dianilino-6-vinyl-*s*-triazine with styrene gave a colloidal solution when the reaction mixture was poured in methanol, and the copolymer was not isolated quantitatively.

The η_{sp}/C values of several copolymers were measured in DMSO and in formic acid. The η_{sp}/C values of the copolymers in formic acid increased as the *s*-triazine content in copolymers increased.

The copolymers of 2,4-diamino-6-vinyl-*s*-triazine hydrochloride with styrene were not precipitated in methanol, but they were isolated by the addition of aqueous ammonia. The results are shown in Table 7. On the basis of these data, the

b) Insoluble.

monomer-copolymer composition curves are drawn in Fig. 3; they are shown in comparison with the free base previously reported on.[4]

The monomer reactivity ratios were determined by the method of Fineman and Ross.*2 The values obtained are given in Tables 9 and 10. Assuming $Q=1.0$ and $e=-0.8$ for styrene, the Q-e values for vinyl- and isopropenyl-*s*-triazines were calculated. These are summed up in Table 9 for vinyl-*s*-triazines and in Table 10 for isopropenyl-*s*-triazines.

In general, the *s*-triazinyl group acts as an electron-withdrawing group because of the electron-attracting character of nitrogen atoms. This is why 2,4-dimethyl-6-vinyl-*s*-triazine has a positive e value.[12] However, the negative e values obtained for 2,4-amino and alkylamino derivatives may be due to the presence of two strong electron-donating groups attached to the triazine ring. The

*2 In the case of copolymerization of 2,4-diamino-6-vinyl-*s*-triazine hydrochloride with styrene, the integral method of Mayo and Lewis was used.

slight effect of the *p*-substituents of substituted anilino groups on the e values and the positive e values of these monomers show a weak conjugation of anilino groups with a double bond through the triazine nucleus; these results coincide with those of the UV spectra.

The positive e value of 2,4-diamino-6-vinyl-*s*-triazine hydrochloride shows that the *s*-triazinyl cation is a strong electron-withdrawing group. It is very interesting to be able to change the Q-e values easily by using the salt of the monomer.

The authors wish to thank Mr. T. Saito of the Tokyo Institute of Technology for his elementary analysis.

Polyamides and Polyureas Containing *s*-Triazine Rings

Yasuo YUKI,*1 Shoji SAKURAI, Toshio KAKURAI and Tatsuya NOGUCHI

Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 4, 1969)

Several new aromatic diamines containing *s*-triazine rings were prepared by the reaction of the related dinitro-compounds prepared from biguanide derivatives and carboxylic acid chlorides. Polyamides and polyureas containing amino-*s*-triazine were synthesized by the polycondensation of these diamines with dicarboxylic acid chlorides and diisocyanates respectively. Their preparations and physical properties are described.

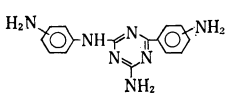
Among many studies for preparing thermally-stable organic polymers, the syntheses of polyamides containing heterocyclic rings from dicarboxylic acid chlorides and diamines with heterocyclic rings have been reported recently.[1)]

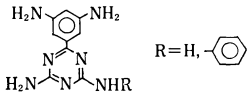
$$NH_2R(Het)R'NH_2 + ClCOR''COCl \longrightarrow$$
$$-(-NHR(Het)R'NHCOR''CO-)- + 2HCl$$

where Het is a heterocyclic ring.

This paper will describe the preparation of several new aromatic diamines, polyamides, and polyureas containing *s*-triazine rings.

Diamines of two types were prepared, that is, 2-amino-4-aminoanilino-6-aminophenyl-*s*-triazine and 2-amino-4-amino- or anilino-6-(3,5-diaminophenyl)-*s*-triazine. The former gave the polymers containing *s*-triazine in a main chain, while the latter gave the polymers containing it in a side chain.

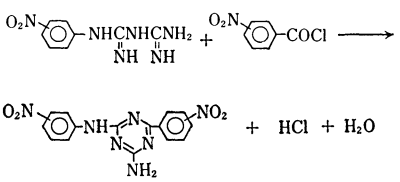




An amino group on *s*-triazine has a character like that of an amino group in the amide group because of the electron-attraction of the *s*-triazine ring, and it does not react with carboxylic acid chloride at low temperatures.[2)] In this study, an amino group on *s*-triazine was found not to be subject to a reaction with carboxylic acid chloride or isocyanate.

Results and Discussion

Preparation of Diamines. It is well known that 2-amino-4-substituted amino-6-substituted-*s*-triazines can be prepared by the reaction of substituted biguanides with carboxylic acid chlorides. The dinitro-compounds containing *s*-triazine rings were thus synthesized. 2-Amino-4-nitroanilino-6-nitrophenyl-*s*-triazine was prepared in a good yield by the reaction of nitrophenylbiguanide with nitrobenzoyl chloride. The reaction can be written as follows;



2-Amino-4-amino- or anilino-6-(3,5-dinitrophenyl)-*s*-triazine was prepared from biguanide or phenylbiguanide and 3,5-dinitrobenzoyl chloride.

These dinitro-compounds were then reduced to give diamines with tin and hydrochloric acid in ethanol. Some physical and analytical data of the reduced products are shown in Table 1. The yields were almost quantitative except in the case of 2,4-diamino-6-(3,5-diaminophenyl)-*s*-triazine (17%). Thurston[3)] has reported the synthesis of 2-amino-4-*p*-aminoanilino-6-*p*-aminophenyl-*s*-triazine dihydrochlorides.

A comparison of the UV spectra of these diamines and of 2-amino-4-anilino-6-phenyl-*s*-triazine (λ_{max} =260 mμ, ε=43.4×10^3 in ethanol[4)]) indicated the bathochromic effect of the *p*-aminophenyl group attached directly to the triazine ring.

Preparation of Polyamides. The low-temperature-solution polycondensation using organic

polar solvents is well known to be effective in preparing high-molecular-weight polyamides from aromatic diamines and dicarboxylic acid chlorides. This procedure was used here. The diamines used are described in Table 1; the carboxylic acid chlorides used were terephthaloyl chloride, isophthaloyl chloride, and adipoyl chloride.

The results of the preparation of polyamides by the solution polycondensation using dimethylacetamide (DMA) as a solvent are shown in Table 2. The polyamides were obtained almost quantitatively and were all a white powder except the No. 1 (yellow) and 2 (yellow) polymers. Poly-*m*-phenylene isophthalamide was prepared for the purpose of comparison.

Properties of Polyamides. Figure 1 shows the IR spectra of several polyamides. The spectra of the model compound, 2-amino-4-anilino-6-*p*-benzamidophenyl-*s*-triazine, and 2-amino-4-*p*-aminoanilino-6-*p*-aminophenyl-*s*-triazine are also shown. The bands at 815, 1390, and 1500—1600 cm^{-1} are characteristic of the amino-*s*-triazine ring. In polyamides and the model compound, the bands of amide I and amide II are masked by

the broad bands of amino-*s*-triazine, but the band of amide III at 1320 cm^{-1} is present.

The solubilities of the polyamides are shown in Table 3. These polyamides were soluble in DMF, DMSO, DMA, and sulfuric acid, but were insoluble in the usual organic solvents. These results show that these polymers are linear and that the amino group on *s*-triazine is free.

The thermal stabilities of these polyamides were determined by thermogravimetric analysis (TGA) and by differential thermal analysis (DTA). The TGA curves of some typical polymers are shown in Fig. 2. The TGA curves of the Nos. 2, 4, 5, 7, and 8 polymers are like of No. 1, those of Nos. 6 and 9 were like that of No. 3, and those of Nos. 10, 12, and 13 were like that of No. 11. The aromatic polyamides containing *s*-triazines in the main chain showed a good thermal stability and began to decompose above 450°C. On the other hand, those containing *s*-triazines in the side chain gradually decomposed above 300°C, like poly-*m*-phenylene isophthalamide. The data of the thermal analysis of polyamides are summed up in Table 4.

showed low viscosity values except in the case No. 16.

The solubility of these polyureas was like that of the above polyamide, and they were soluble in DMSO, DMA, DMF, formic acid, acetic acid, and mineral acid.

The TGA curves of these polyureas are shown in Fig. 3. The thermal stability of polyureas was inferior to that of polyamides.

Experimental

Materials. The arylbiguanides were prepared by the reaction of dicyanodiamide with related arylamine hydrochlorides following the method of Cohn.[5] The biguanide was prepared by the method of Odo.[6] All the other reagents were commercially available and were used after purification if necessary.

2-Amino-4-p-nitroanilino-6-p-nitrophenyl-s-triazine. A suspension of 33 g (0.15 mol) of *p*-nitrophenylbiguanide in 300 m*l* of acetone was treated with 25 g (0.135 mol) of *p*-nitrobenzoyl chloride, and then 7.5 g (0.135 mol) of potassium hydroxide in water were added. Stirring and cooling at 0—5°C were continued during the reaction. After the acetone had then been removed, the yellow precipitate was separated and washed with hot water. The product was given almost quantitatively; 47.5 g, mp 300°C. (Found: N, 27.95%; Calcd.: N, 27.75%)

The other dinitro-compounds were prepared in a similar manner.

2-Amino-4-p-aminoanilino-6-p-aminophenyl-s-triazine. By stirring and refluxing, to a suspension of 11.5 g (0.033 mol) of the above dinitro-compound and 17.5 g (0.15 mol) tin in 100 m*l* of ethanol we added, drop by drop over 1-hr period, 100 m*l* of 12 N hydrochloric acid. The reaction mixture became clear and then formed a precipitate. When the precipitate was separated, dissolved in water, and treated with strong alkali, a white precipitate was also given. The product was separated; 9.0 g (93%), mp 231—231.5°C

The reduction of the other dinitro-compounds was carried out in a similar manner.

Preparation of Polyamides. In a 100-m*l*, three-necked flask equipped with a stirrer and a nitrogen inlet, we placed 7 m*l* of DMA, 0.300 g of 2-amino-4-*p*-aminoanilino-6-*p*-aminophenyl-*s*-triazine, and 0.15 g of lithium chloride; then 0.216 g of terephthaloyl chloride was gradually added at 25°C. After 8 hr, the reaction mixture was poured into methanol. The polymer was isolated, washed with water, dipped in a dilute alkali solution, repeatedly washed again with water and methanol, and dried. The polymer obtained amounted to 0.429 g.

6) K. Kono and K. Odo, *Yuki Gosei Kagaku Kyokai Shi*, **20**, 649 (1962).

The other polyamides and polyureas were treated in a similar manner.

Preparation of the Model Compound. 2-Amino-4-anilino-6-*p*-nitrophenyl-*s*-triazine was prepared by the reaction of phenylbiguanide with *p*-nitrobenzoyl chloride; yellow powder, mp 206.5—208°C.

Found: C, 58.25; H, 4.13; N, 27.43%. Calcd for $C_{15}H_{12}N_6O_2$: C, 58.04; H, 3.89; N, 27.27%.

2-Amino-4-anilino-6-*p*-aminophenyl-*s*-triazine was given by the reaction of the nitro-compound with tin and hydrochloric acid in ethanol; mp 200.5—201.5°C.

The model compound, 2-amino-4-anilino-6-*p*-benzamidophenyl-*s*-triazine, was prepared by the reaction of the above amine with benzoyl chloride by a method of preparation similar to that used for the polyamides; mp 222—222.5°C, 69%. The results of elementary analysis agreed with the value calculated for semi-hydrate.

Found: C, 67.63; H, 4.70; N, 21.19%. Calcd for $C_{22}H_{18}N_6O \cdot \frac{1}{2}H_2O$: C, 67.51; H, 4.89; N, 21.47%.

The authors wish to thank Mr. T. Saito of Tokyo Institute of Technology for his elementary analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2134—2137 (1970)

Synthesis of 1,3-Thiazine Derivatives from 2-Iminocyclopentanedithiocarboxylic Acid[1)]

Motomu MURAOKA*[1], Masataka YOKOYAMA*[2], Kiyoko YAMAMOTO*[3], and Tatsuo TAKESHIMA*[2]

Department of Chemistry, Faculty of Science, Josai Uuiversity, Sakado, Saitama, and The Institute of Physical and Chemical Research, Yamatomachi, Saitama

(Received October 11, 1969)

Several new 3-substituted and 3,3-disubstituted-1,3,4,5,6,7-hexahydro-1-thioxocyclopenta[*d*]-[1,3]thiazines were obtained by the reactions of 2-iminocyclopentanedithiocarboxylic acid with some aldehydes and ketones. Some intermediate compounds in these reactions such as 2-amino-2-[2-(piperonylidenamino)-1-cyclopenten-1-yl]thiocarbonylthiocyclopentanedithiocarboxylic acid, 2-amino-2-[2-(vanillylidenamino)-1-cyclopenten-1-yl]thiocarbonylthiocyclopentanedithiocarboxylic acid, and 2-amino-2-[2-(4-methoxybenzylidenamino)-1-cyclopenten-1-yl]thiocarbonylthiocyclopentanedithiocarboxylic acid could be isolated.

Several new 1,3-thiazine derivatives were synthesized by the reactions of 2-iminocyclopentanedithiocarboxylic acid (I) with carbonyl compounds. Compound I was isolated as the intermediate during the course of synthesis of 1,3,4,5,6,7-hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine-3-spirocyclopentane. The coupling reactions of I with ketones were partly reported.[2)]

The reactions in question were effected by acid or base, and 3-substituted and 3,3-disubstituted-1,3,4,5,6,7-hexahydro-1-thioxocyclopenta[*d*][1,3]-thiazines (III) were produced. Aliphatic and alicyclic ketones, in the presence of morpholine,[2)] easily reacted with I to give respective thiazine derivatives. However, aldehydes and acetophenone under the same conditions did not afford the expected products.

On treatment with sulfuric acid in place of morpholine, we have found that aldehydes such as piperonal, vanillin, anisaldehyde, acetaldehyde, salicylaldehyde, benzaldehyde, *o*-methoxy or *p*-hydroxybenzaldehyde and *p*-tolualdehyde as well as ketones such as acetophenone, methyl ethyl ketone and acetone reacted with I to afford the corresponding thiazine derivatives III. This paper deals with the results.

Evidence for the structures of IIIa—j was provided by comparison of their IR, UV and NMR spectra with those of known 1,2,5,6,7,8-hexahydro-4-thioxo-4*H*-3,1-benzo[*d*]thiazine-2-spirocyclohexane, 2-ethyl-2,4,5-trimethyl-2,3-dihydro-6-thioxo-6*H*-1,3-thiazine, and 3,3-dimethyl-1,3,4,5,6,7-hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine.[2-4)] The doublet near δ 6.15 (J=4—6 Hz) was assigned to a C-3 proton, and thus structures

III were proposed as the corresponding thiazine structures.

It was shown that the reaction of methyl ethyl ketone with I was abortive.[2] However, the present experiment revealed that 3-ethyl-3-methyl-1,3,4,5,6,7 - hexahydro-1-thioxocyclopenta[*d*][1, 3]-thiazine IIIk, had a molecule of water of crystallization which was lost on heating at 138°C under reduced pressure and thus was of a different physical nature. Likewise, the thiazine derivatives IIIa and IIIj which were obtained by the reactions of I with piperonal and *p*-tolualdehyde, respectively, also had a molecule of water of crystallization which was lost on heating at 110°C under reduced pressure.

Under the acidic conditions, piperonal, vanillin and anisaldehyde gave respective intermediate compounds IIa, IIb and IIc at low temperature which changed to IIIa—b on treatment with sulfuric acid. Compound IIc was resistant to conversion into IIIc.

Structures IIa, IIb and IIc were assigned by spectral data (see Experimental).

Experimental

2-Amino-2-[2-(piperonylidenamino)-1 - cyclopenten-1-yl]thiocarbonylthiocyclopentanedithiocarboxylic acid (IIa). A solution of I (4.1 g), piperonal (4 g) and sulfuric acid (96%, 1 g) in 150 m*l* of methanol was allowed to stand for 5 min at room temperature. The yellow material was collected, washed with methanol and recrystallized from methanol-*N*,*N*-dimethylformamide. Yellow long plates (IIa): yield 4.6 g, 70%; mp 211—214°C with dec. (slow heating), 215—220°C with dec. (rapid heating); UV λ_{max}^{MeOH} 311, 397 mμ (log ε=4.04, 4.32); IR (KBr) 3380 (m, NH_2), 3296 (s, NH_2), 1609 (s, δ NH_2), 1600 (vs, C=N), 1500 (s, ring), 1486 (s, ring), 1475 cm^{-1} (m, ring); NMR (CF_3COOH) δ 9.00 (br, 1H, S<u>H</u>), 7.08 (m, 4H, $C_6\underline{H}_3$ and C<u>H</u>=N), 6.30 (s, 2H, $OC\underline{H}_2O$), 3.03 (m, 9H, C-1, 3,5,3',5' $\underline{H}_2$), 2.20(m, 4H, C-4,4'$\underline{H}_2$); NMR (CD_3SOCD_3) δ 10.80 (br, *ca.* 2H, N<u>H</u>$_2$), 9.00 (br, *ca.* 1H, S<u>H</u>); Found: C, 53.56; H, 5.09; N, 6.18; S, 28.36%. Calcd for $C_{20}H_{22}N_2S_4O_2$: C, 53.30; H, 4.92; N, 6.22; S, 28.45%.

NMR absorptions of NH_2 and SH in CD_3SOCD_3 disappeared by addition of deuterium oxide.

Conversion of IIa into IIIa. A mixture of IIa (1 g), sulfuric acid (96%, 400 mg) and 50 m*l* of methanol was refluxed for *ca.* 1 hr until a clear solution was obtained. After cooling, a yellowish orange material was collected and recrystallized from *N*,*N*-dimethylformamide-water as yellowish orange long plates: mp 177—178°C, undepressed on admixture with an authentic specimen; yield 500 mg, 77%. IR and UV spectra of both specimens also were identical.

2-Amino-2- [2-(vanillylidenamino)-1-cyclopenten-1-yl]thiocarbonylthiocyclopentanedithiocarboxylic acid (IIb). To an ice-cold solution of I (4.7 g) and vanillin (5 g) in methanol (130 m*l*), sulfuric acid (96%, 2 g) was added and the solution was kept at 0°C for 5 min. The resulting yellow material was recrystallized from acetone-water. Yellow long plates (IIb): yield 5.2 g, 77%; mp 190—192°C with dec. (slow heat-

ing), 199—201°C with dec. (rapid heating); UV λ_{max}^{MeOH} 308, 397 mμ (log ε=4.13, 4.30); IR ($CHCl_3$) 3320 (m, NH_2), 3260 (m, NH_2), 1614 (s, δ NH_2), 1603 (vs, C=N), 1510 (m, ring), 1500 (m, ring), 1472 cm^{-1} (m, ring); NMR (CF_3COOH) δ 8.97 (br, 1H, SH), 7.30 (m, 4H, C_6H_3 and CH=N), 6.12 (s, 1H, OH), 4.04 (s, 3H, OCH_3), 3.08 (m, 9H, C-1,3,5,3′,5′ H_2), 2.23 (m, 4H, C-4,4′ H_2); NMR (CD_3SOCD_3) δ 10.86 (br, *ca.* 2H, NH_2), 8.97 (br, *ca.* 1H, SH); Found: C, 53.13; H, 5.49; N, 6.16; S, 28.53%. Calcd for $C_{20}H_{24}N_2S_4O_2$: C, 53.07; H, 5.35; N, 6.19; S, 28.32%.

Conversion of IIb into IIIb. A mixture of IIb (1 g), sulfuric acid (96%, 0.5 g), *N,N*-dimethylformamide (25 m*l*) and methanol (50 m*l*) was refluxed for 15 min and allowed to stand at room temperature for 2 hr and then was added water. The resulting material was recrystallized from *N,N*-dimethylformamide-water as orange prisms: yield 400 mg, 62%; mp 229—238°C with dec., undepressed by addition of an authentic specimen. UV and IR spectra of both specimens also were identical.

2 - Amino - 2 - [2-(4-methoxybenzylidenamino)-1-cyclopenten-1-yl]thiocarbonylthiocyclopentanedithiocarboxylic acid (IIc). To an ice-cold solution of I (2.5 g) and anisaldehyde (2.5 g) in methanol (100 m*l*), sulfuric acid (96%, 1 g) was added and kept at 0°C for 10 min. The reaction mixture was worked up as above. Yellow long plates (IIc): yield 3 g, 88%; mp 209—214°C with dec. (slow heating), 213—223°C with dec. (rapid heating); UV λ_{max}^{MeOH} 275, 392 mμ (log ε=4.15, 4.27); IR (KBr) 3389 (m, NH_2), 3294 (s, NH_2), 1607 (vs. C=N), 1510 (s, ring), 1450 cm^{-1} (s, ring); NMR (CF_3COOH) δ 9.50 (br, 1H, SH), 7.18 (m, 5H, C_6H_4 and CH=N), 4.03 (s, 3H, OCH_3), 3.07 (m, 9H, C-1,3,5,3′,5′ H_2), 2.27 (m, 4H, C-4,4′ H_2); NMR (CD_3SOCD_3) δ 10.81 (br, *ca.* 2H, NH_2), 8.97 (br, *ca.* 1H, SH); Found: C, 54.96; H, 5.70; N, 6.53; S, 29.14%. Calcd for $C_{20}H_{24}N_2S_4O$: C, 55.02; H, 5.54; N, 6.42; S, 29.36%.

3 - (3,4 - Methylenedioxyphenyl) - 1,3,4,5,6,7-hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine(IIIa). A solution of I (2 g), piperonal (2 g) and sulfuric acid (96%, 1 g) in methanol (100 m*l*) was refluxed for 35 min. The resulting material was collected and recrystallized from *N,N*-dimethylformamide-water and dried at 110°C under reduced pressure for 1 day to give yellowish orange plates (IIIa): yield 3.6 g, 92%; mp 178—179°C; UV λ_{max}^{EtOH} 341, 408 mμ (log ε=4.00, 4.61); IR ($CHCl_3$) 3406 (s, NH), 1541 (s, conjd C=C), 1520 (s, ring), 1506 (vs, ring), 1446 cm^{-1} (s, ring); NMR (CF_3COOH) δ 9.42 (br, 1H, NH), 7.02 (m, 3H, C_6H_3), 6.14 (d, 1H, *J*=4 Hz, C-3 H), 6.07 (s, 2H, OCH_2O), 3.05 (m, 4H, C-5,7 H_2). 2.37 (m, 2H, C-6 H_2); Found: C, 57.86; H, 4.46; N, 4.79; S. 22.08%. Calcd for $C_{14}H_{13}NS_2O_2$: C, 57.71; H, 4.50; N, 4.81; S, 21.99%.

3-(3-Methoxy-4-hydroxyphenyl)-1,3,4,5,6,7-hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine (IIIb). A solution of I (2.5 g), vanillin (2.5 g) and sulfuric acid (96%, 1 g) in methanol (60 m*l*) was refluxed for 1 hr. The resulting material was worked up as above. Light lustrous orange prisms (IIIb): yield 4.1 g, 89%; mp 229—239°C with dec. (slow heating), 237—250°C with dec. (rapid heating); UV λ_{max}^{EtOH} 340, 408 mμ (log ε=3.93, 4.32); IR ($CHCl_3$) 3365 (s, NH), 1560 (s, conjd C=C), 1505 (vs. ring), 1444 cm^{-1} (m, ring); NMR (CF_3COOH) δ 9.50 (br, 1H, NH), 7.12 (m, 3H, C_6H_3), 6.15 (d, *J*=4 Hz, C-3 H), 3.97 (s, 3H, OCH_3), 3.00 (m, 4H, C-5,7 H_2), 2.36 (m, 2H, C-6 H_2); NMR (CD_3SOCD_3) δ 9.60 (s, 1H, OH), 9.37 (br, 1H, NH); Found: C, 57.31; H, 5.09; N, 4.80; S, 21.60%. Calcd for $C_{14}H_{15}NS_2O_2$: C, 57.32; H, 5.16; N, 4.78; S, 21.85 %.

3 - (4 - Methoxyphenyl) - 1,3,4,5,6,7 - hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine (IIIc). To a hot solution of I (2.5 g) and anisaldehyde (2.5 g) in methanol (100 m*l*), was added sulfuric acid (96%, 1 g) and refluxed for 30 min. The resulting mixture was worked up as above. Red long prisms (IIIc): yield 3.5 g, 81%; mp 179—180°C; UV λ_{max}^{EtOH} 341, 408 mμ (log ε=3.70, 4.08): IR ($CHCl_3$) 3410 (s, NH), 1545 (s, conjd C=C), 1515 cm^{-1} (vs. ring): NMR (CF_3COOH) δ 9.39 (br, 1H, NH), 7.34 (q, 4H, C_6H_4), 6.17 (d, 1H, *J*=4 Hz, C-3 H), 4.08 (s, 3H, OCH_3), 3.03 (m, 4H, C-5,7 H_2), 2.38 (m, 2H, C-6 H_2); Found: C, 60.66; H, 5.34; N, 5.15; S, 23.13%. Calcd for $C_{14}H_{15}NS_2O$: C, 60.62; H, 5.45; N, 5.05; S, 23.11%.

3 - Methyl - 1,3,4,5,6,7 - hexahydro -1- thioxocyclopenta[*d*][1,3]thiazine (IIId). A solution of I (5 g), acetaldehyde (5 g) and sulfuric acid (96%, 2 g) in methanol (150 m*l*) was allowed to stand at room temperature for 64 hr. The resulting reaction mixture was concentrated under reduced pressure and then water was added. The purple material which separated from the solution was recrystallized from methanol-water. Light orange plates (IIId): yield 4.5 g, 78%; mp 128—129°C; UV λ_{max}^{EtOH} 337, 405 mμ (log ε=3.72, 4.26); IR ($CHCl_3$), 3405 (s, NH), 1550 (vs, conjd C=C), 1515 cm^{-1} (vs. ring); NMR (CF_3COOH) δ 9.40 (br, 1H, NH), 5.17 (m, 1H, C-3 H), 2.92 (m, 4H, C-5,7 H_2), 2.25 (m, 2H, C-6 H_2), 1.85 (d, 3H, CH_3); Found: C, 51.83; H, 5.83; N, 7.62; S, 34.87%. Calcd for $C_8H_{11}NS_2$: C, 51.85; H, 5.99; N, 7.55; S, 34.61%.

3-Methyl-3-phenyl-1,3,4,5,6,7-hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine (IIIe). A mixture of I (5 g), acetophenone (5 g), sulfuric acid (96%, 2 g) and methanol (150 m*l*) was refluxed for 3 hr and the reaction mixture was worked up as above. Light orange plates (IIIe): yield 1.6 g, 19.5%; mp 183—184°C (remelted at 195—197°C); UV λ_{max}^{EtOH} 340, 407 mμ (log ε=3.70, 4.30); IR ($CHCl_3$) 3400 (m, NH), 1550 (vs. conjd C=C), 1522 cm^{-1} (s, ring); NMR (CF_3COOH) δ 9.66 (br, 1H, NH), 7.51 (s, 5H, C_6H_5), 3.03 (m, 4H, C-5,7 H_2), 2.31 (m, 2H, C-6 H_2), 2.28 (s, 3H, CH_3); Found: C, 64.41; H, 5.77; N, 5.40; S, 24.73%. Calcd for $C_{14}H_{15}NS_2$: C, 64.32; H, 5.79; N, 5.36; S, 24.53%.

3 - (2 - Hydroxyphenyl) - 1,3,4,5,6,7 - hexahydro - 1-thioxocyclopenta[*d*][1,3]thiazine (IIIf). A solution of I (2 g), salicylaldehyde (2 g) and sulfuric acid (96%, 1 g) in methanol (70 m*l*) was refluxed for 10 min and then allowed to stand at room temperature for 1 hr. The reaction mixture was concentrated under reduced pressure, then water was added. The resulting red material was recrystallized from methanol-water. Red long plates (IIIf): yield 2.2 g, 67%; mp 201—215°C with dec. (slow heating), 211—227°C with dec. (rapid heating); UV λ_{max}^{EtOH} 341, 408 mμ (log ε=3.87, 4.20); IR ($CHCl_3$) 3260 (s, OH), 3160 (s, br, NH), 1560 (s, conjd C=C), 1495 cm^{-1} (vs. ring); NMR (CF_3COOH) δ 9.43 (s, br, 2H, OH and NH), 7.28 (m, 4H, C_6H_4), 6.58 (d, 1H, *J*=5 Hz, C-3 H), 3.02 (m, 4H, C-5,7 H_2), 2.35 (m, 2H, C-6 H_2); Found: C, 59.46; H, 4.92;

N, 5.25; S, 23.95%. Calcd for $C_{13}H_{13}NS_2O$: C, 59.28, H, 4.98; N, 5.32; S, 24.34%.

3-Phenyl-1,3,4,5,6,7-hexahydro-1- thioxocyclopenta[*d*][1,3]thiazine (IIIg). A solution of I (5 g), benzaldehyde (5 g) and sulfuric acid (96%, 2 g) in methanol (150 m*l*) was refluxed for 2 hr. The resulting material was recrystallized from methanol. Red prisms (IIIg): yield 5.1 g, 66%; mp 199—200°C; UV λ_{max}^{EtOH} 340, 408 mμ (log ε=3.86, 4.28); IR ($CHCl_3$) 3400 (s, NH), 1546 (vs. conjd C=C), 1515 cm^{-1} (s, ring); NMR (CF_3COOH) δ 9.45 (br, 1H, N<u>H</u>), 7.49 (m, 5H, $C_6\underline{H}_5$), 6.13 (d, 1H, J=4 Hz, C-3 <u>H</u>), 2.97 (m, 4H, C-5,7 $\underline{H}_2$), 2.31 (m, 2H, C-6 $\underline{H}_2$); Found: C, 63.06; H, 5.11; N, 5.70; S, 25.79%. Calcd for $C_{13}H_{13}NS_2$: C, 63.12; H, 5.30; N, 5.66; S, 25.92%.

3 - (2 - Methoxypehnyl) - 1,3,4,5,6,7 - hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine (IIIh). A mixture of I (5 g), *o*-methoxybenzaldehyde (5 g), sulfuric acid (96%, 2 g) and methanol (150 m*l*) was refluxed for 30 min and worked up as above. Light thick plates (IIIh): yield 5.3 g, 61%; mp 201°C; UV λ_{max}^{EtOH} 341, 408 mμ (log ε=3.88, 4.29); IR ($CHCl_3$) 3410 (s, NH), 1547 (vs. conjd C=C), 1510 cm^{-1} (s, ring); NMR (CF_3COOH) δ 9.35 (br, 1H, N<u>H</u>), 7.28 (m, 4H, $C_6\underline{H}_4$), 6.56 (d, 1H, J=6 Hz, C-3 <u>H</u>), 3.97 (s, 3H, $OC\underline{H}_3$), 3.00 (m, 4H, C-5,7 $\underline{H}_2$), 2.36 (m, 2H, C-6 $\underline{H}_2$); Found: C, 60.73; H, 5.57; N, 5.10; S, 23.10%. Calcd for $C_{14}H_{15}NS_2O$: C, 60.62; H, 5.45; N, 5.05; S, 23.11%

3 - (4 - Hydroxyphenyl) - 1,3,4,5,6,7 - hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine (IIIi). A mixture of I (5 g), *p*-hydroxybenzaldehyde (5 g), sulfuric acid (96%, 2 g) and methanol (150 m*l*) was allowed to stand at room temperature for 30 min and worked up as above. Orange prisms (IIIi): yield 6.4 g, 77%; mp, 197—213°C with dec. (slow heating), 211—220°C with dec. (rapid heating); UV λ_{max}^{EtOH} 340, 408 mμ (log ε=3.88, 4.28); IR ($CHCl_3$) 3268 (s, OH), 3100 (m, br, NH), 1566 (s, conjd C=C), 1512 cm^{-1} (vs. ring); NMR (CF_3COOH) δ 9.49 (br, 1H, N<u>H</u>), 7.27 (q, 4H, $C_6\underline{H}_4$), 6.18 (d, 1H, J=4 Hz, C-3 <u>H</u>), 3.00 (m, 4H, C-5,7 $\underline{H}_2$), 2.31 (m, 2H, C-6 $\underline{H}_2$); Found: C, 59.28; H, 4.83; N, 5.33; S, 24.37%. Calcd for $C_{13}H_{13}NS_2O$: C, 59.28; H, 4.98; N, 5.32; S, 24.34%.

3 - (p-Tolyl) - 1,3,4,5,6,7-hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine(IIIj). A mixture of I (3 g), *p*-tolualdehyde (3 g), sulfuric acid (96%, 1 g) and methanol (100 m*l*) was refluxed for 30 min and then water was added. The solution was allowed to stand at room temperature for 12 hr. The resulting crystalline material was recrystallized from methanol and dried at 110°C under reduced pressure. Light orange prisms (IIIj): yield 2.3 g, 44%; mp 176—177°C; UV λ_{max}^{EtOH} 340, 408 mμ (log ε=3.91, 4.34); IR ($CHCl_3$) 3420 (s, NH), 1545 (s, conjd C=C), 1515 cm^{-1} (vs. ring); NMR (CF_3COOH) δ 9.50 (br, 1H, N<u>H</u>), 7.40 (s, 4H, $C_6\underline{H}_4$), 6.17 (d, 1H, J=3 Hz, C-3 <u>H</u>), 3.08 (m, 4H, C-5,7 $\underline{H}_2$), 2.42 (s, 3H, $C\underline{H}_3$), 2.38 (m, 2H, C-6 $\underline{H}_2$); Found: C, 64.58; H, 6.05; N, 5.36; S, 24.23%. Calcd. for $C_4H_{15}NS_2$: C, 64.32; H, 5.79; N, 5.36; S, 24.53%.

3-Ethyl-3-methyl-1,3,4,5,6,7-hexahydro-1-thioxocyclopenta[*d*][1,3]thiazine(IIIk). A mixture of I (5 g), methyl ethyl ketone (22 g), morpholine (15 g) and ethanol (100 m*l*) was refluxed for 10 hr. The white precipitates which separated from the solution were filtrated, the filtrate was concentrated under reduced pressure and then water was added. The resulting yellow material was recrystallized from ethanol-water and dried at 138°C under reduced pressure for 1 day. Yellow plates (IIIk): yield 4.4 g, 67%; mp 173—174°C; UV λ_{max}^{EtOH} 336, 406 mμ (log ε=3.68, 4.25); IR (KBr) 3180 (s, NH), 1565 (m, conjd C=C), 1520 cm^{-1} (vs. ring); NMR (CD_3COCD_3) δ 9.40 (br, 1H, N<u>H</u>), 3.00 (m, 4H, C-5,7 $\underline{H}_2$), 2.25 (m, 4H, C-6 $\underline{H}_2$ and $C\underline{H}_2CH_3$), 1.85 (s, 3H, $C\underline{H}_3$). 1.15 (t, 3<u>H</u>, $CH_2C\underline{H}_3$); Found: C, 56.53; H, 7.00; N, 6.54; S, 29.99%. Calcd for $C_{10}H_{15}NS_2$: C, 56.32; H, 7.09; N, 6.57; S, 30.01%.

Compound IIIk was also obtained by refluxing a mixture of I (5 g), methyl ethyl ketone (5 g), sulfuric acid (96%, 2 g) and methanol (100 m*l*) for 1 hr; the yield was 57%.

3,3 - Dimethyl - 1,3,4,5,6,7 - hexahydro - 1 - thioxocyclopenta[*d*][1,3]thiazine (IIIl). A mixture of I (2.5 g), acetone (3 g), sulfuric acid (96%, 1 g) and methanol (100 m*l*) was refluxed for 1.5 hr and then worked up as above: yield 51%, mp 172—173°C, undepressed on admixture with an authentic specimen. IR and UV absorption spectra of IIIl were also identical with those of authentic specimen.[2)]

The authors are grateful to Dr. Hiroshi Midorikawa for his support of this work. They also wish to thank Dr. Toshio Hayashi, Miss Makiko Akano and Mr. Ichigaku Nagayama for their advice and assistance.

(Received October 15, 1969)

α-Cyanoglycidic ester derivatives have been prepared from alkylidenecyanoacetic esters with hydrogen peroxide. The NMR technique has been applied to the study of the geometric configurations of the stereoisomeric mixture of the glycidic esters. It has been found that the β-methyl protons *cis* to the ester group respond at a higher field than do the *trans* protons.

Our search for practical methods of determining the geometric configurations of α-cyano-β-alkoxy-β-alkylacrilic esters[1] and alkylidenecyanoacetic esters[2] led to a study of nuclear magnetic resonance spectroscopy. During these studies it became apparent that the NMR non-equivalence of signals arising from geometrically-related groups of β-methylglycidic-ester derivatives which possess an oxirane ring replaced by four different groups could also serve such a purpose. Recently, Valente and Woffhagen[3] have introduced the use of this technique in the determination of the geometric configuration of β-phenylglycidic esters. We wish now to report on the chemical shifts for a number of α-cyano and α-carbamoyl-β-methyl-β-alkylglycidic esters which were gathered in order to delineate the scope of the NMR method for determining the geometric configuration.

Various conditions for epoxidation are described in the literature. The epoxidation of an alkene-bearing carbonyl substituent by a usual reagent, such as peroxy benzoic or peroxyacetic acid, is generally very slow.[4] The treatment of α,β-unsaturated nitrile with hydrogen peroxide under alkaline conditions results in the formation of epoxyamide rather than epoxynitrile.[5] We have found that the direct epoxidation of alkylidenecyanoacetic esters with hydrogen peroxide without a catalyst is satisfactory in giving the corresponding epoxynitriles. By refluxing a solution of the alkylidenecyanoacetic ester in aqueous alcohol with a small excess of 30% hydrogen peroxide for varying lengths of time, good yields of eight 2-cyano-3-methylglycidic ester derivatives (compounds I-VIII) have been obtained. That all of these compounds except 2-cyano-2,3-epoxybutanoic esters are mixtures of *cis-trans* isomers is confirmed by their NMR spectra. Table 1 shows the most important features of the NMR spectra of compounds I—VIII. The synthetic steps are shown in Chart 1.

Chart 1

The resonance positions of the methyl protons of the methoxycarbonyl group were always located in the 3.94±0.01 ppm range, while those of the methylene and methyl protons of the ethoxycarbonyl group always appeared in the 4.36±0.01 ppm and 1.37±0.01 ppm ranges respectively. The replacement of the methoxycarbonyl group by the ethoxycarbonyl group has practically no effect on the chemical shifts of the β-methyl group in the corresponding ester. Similar results have been observed in alkylidenecyanoacetic esters by some of the present authors.[2]

In the α-cyano-β,β-dimethylglycidic ester (II), the signals due to two β-methyl groups were at 1.69 and 1.47 ppm. This result indicated that the magnitude of such a chemical-shift difference was sufficient to be of practical value in the quantitative determination of geometrical isomers. In the epoxy ester, III—VIII, made by the epoxidation of alkylidenecyanoacetic esters (*cis-trans* mixture[6]), the spectra show two signals of an unequal intensity, separated by about 0.22—0.25 ppm, for the β-methyl protons. These results indicate that they contain both geometric isomers. After the products had been repeatedly distilled, their NMR showed the same pattern. It was desirable that the spectra be correlated with structures on the bases of the known configuration of the *cis* and *trans* epoxides.[7] However, no stereoisomers of a known configuration of β-alkylglycidic esters were available. Attempts to separate stereoisomers of these esters by gas and thin-layer chromatographies were unsuccessful.

In the preceding paper,[2] it was shown that the relative stabilities of the stereoisomeres of alkylidenecyanoacetic esters can be determined by means of the simple steric interaction between the β-alkyl substituent and the alkoxycarbonyl group. A similar effect may be expected for the epoxy esters. In the compounds III—VIII, models show that the *cis* configurations are to be favored over the *trans*. On the basis of this consideration, the more intense of the two signals of the β-methyl group can be assigned to the *cis* isomer, and the less intense, to the *trans*.

It is known that the ethylidenecyanoacetic ester produced by the condensation of acetaldehyde with the cyanoacetic ester is only the *trans* isomer from the NMR spectrum.[8] We have attempted to convert the *trans* isomer into the *cis* isomer. However, so far our attempts have been unsuccessful. The *trans* ethylidenecyanoacetic ester was converted into the 2-cyano-2,3-epoxybutanoic ester (I) by refluxing it with excess hydrogen peroxide or by treating it with a calculated amount of hydrogen peroxide at room temperature under alkaline conditions. The NMR spectra of the products show only one β-methyl doublet (1.65 ppm) (Fig. 1). This resonance position corresponds to that of the methyl protons at a lower field in other epoxy esters. In the case of compound I, it seems reasonable to say that the methyl group prefers a *trans* orientation, for there is a substantial difference in the steric requirements of the methyl and hydrogen groups. Thus, the result supports the structural assignment that the *trans* β-methyl group responds at a lower field than does the *cis* β-methyl group.

The methyl 1-methylpropylidenecyanoacetate used in the other experiments was prepared by the condensation of methyl ethyl ketone with cyanoacetic acid,[8] followed by esterification with diazomethane. From the NMR spectrum of the product, it has been concluded that the ester is the *cis* isomer and not a mixture of the two geometric isomers. The *cis* ester underwent 30% isomerization to the *trans* ester when refluxed in an aqueous methanol solution for six hours (NMR analysis of the product mixture). After ten hours refluxing, 47% isomerization had taken place. A longer refluxing gave no change in the *trans-cis* ratio. A more rapid isomerization of *cis* to *trans* takes place in the reaction mixture containing 0.1 N alkali. Therefore, owing to experimental difficulties arising

6) Following the notation given in Ref. 2.

7) The isomeric forms of a series of the esters are denoted as (i) *cis* (in which the β-methyl and alkoxycarbonyl groups are both on the same side of the C(—O)C bond) and (ii) *trans* (in which these groups are on opposite sides).

8) M. J. Hamelin, *C. R. Acad. Sc. Paris*, Ser. C **263**, 553 (1966).

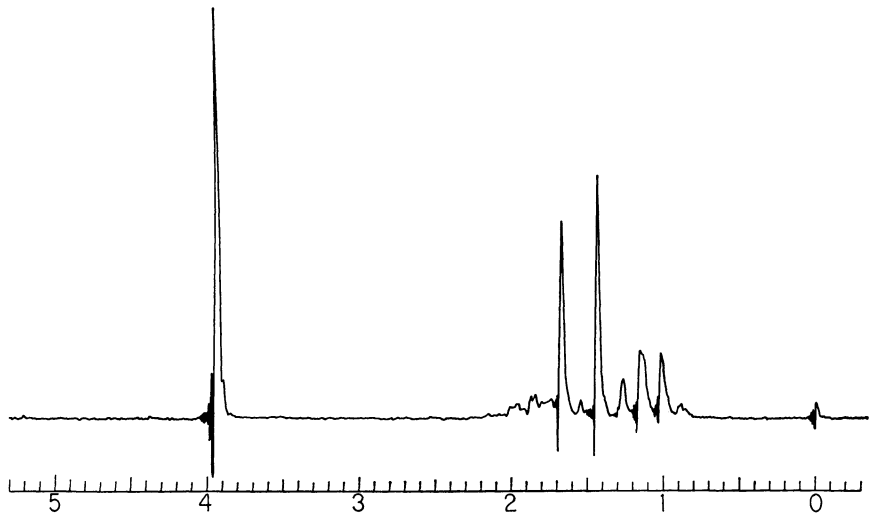

Fig. 2. The NMR spectrum of methyl 2-cyano-3-methyl-2,3-epoxyvalerate.

from the fast isomerization of the starting material, we could not obtain the pure *cis* epoxy ester.

As a typical example, the present authors analyzed the spectrum of methyl 2-cyano-3-methyl-2,3-epoxyvalerate (IIIa) (Fig. 2). The β-methyl signal appears as a doublet of an unequal intensity, with the more intense signal at the higher field (1.66 and 1.44 ppm). The intensity ratio from the analysis of the β-methylene multiplet was less certain. The γ-methyl protons appear as a doublet of an unequal intensity, with the more intense signal at the lower field (1.15 and 1.01 ppm). On the basis of the evidence just given, the more intense signal of the β-methyl protons can be assigned to that of the *cis* isomer, and the weaker signal, to that of the *trans*.

Table 2 shows the isomeric compositions of six epoxy esters and their starting unsaturated esters, which were estimated from the integration of the area under the appropriate NMR signals. The composition is little affected by the reaction conditions except in the case of VIII. Methyl 2-cyano-2,3-epoxy-3,5,5-trimethylcaproate (VIII) (*trans* percentage 60) was prepared from methyl 2-cyano-3,5,5-trimethylhexanoate (*trans* percentage 47) by heating it (70—80°C) with 30% hydrogen peroxide, while VIII (*trans* percentage 38) was obtained from the same starting ester in the presence of sodium bicarbonate at room temperature. It has already been pointed out that the *trans* isomer of this unsaturated ester is much increased by heating it to 71°C (*trans* percentage 61).[2] Accordingly, the results (Table 2) show that the *cis-trans* ratios of the products are almost the same as those of the starting materials.

On the other hand, it is known that the epoxidation of alkylidenecyanoacetic esters under alkaline conditions results in the formation of epoxy-

** Following the method given in Ref. 2.

amides rather than epoxynitriles.[9] In the present study, the epoxynitrile was converted into epoxyamide by hydration with hydrogen peroxide in the presence of alkali. These compounds also possess an oxirane ring substituted by four different groups. Therefore, it would be interesting to use the above technique in the determination of the geometric configurations of these compounds. The NMR data are listed in Table 1.

The NMR absorptions of the β-methyl protons of the two isomers (*cis* and *trans*) were well separated, but the ratios could not be accurately determined (except for the case of XVII) from the relative areas of the two signals because of their overlap with the signals of the other alkyl groups. Therefore, when the difference in the steric requirements of the methyl and alkyl groups is relatively small, it is hard to assign signals to the two isomers by the above method.

By the epoxidation of *trans* ethyl ethylidenecyanoacetate or the hydration of *trans* ethyl 2-cyano-2,3-epoxybutyrate, ethyl 2-carbamoyl-2,3-epoxybutyrate (IX) was obtained. That this compound is a pure stereoisomer is confirmed by its NMR spectrum. The spectrum showed β-methyl protons at 1.45 ppm. This resonance position corresponds to those of signals of the lower fields of other epoxyamides (X—XII, XV) in which *cis* isomers coexist with *trans* isomers. In methyl 2-carbamoyl-2,3-epoxy-3,4,4-trimethylvalerate (XVI), prepared from the corresponding unsaturated nitrile (*trans* : *cis*=2 : 98). the only signal due to the β-methyl protons is at 1.32 ppm. In methyl 2-carbamoyl-2,3-epoxy-3,5,5-trimethylcaproate (XVII), prepared from methyl 2-cyano-2,3-epoxy-3,5,5-trimethylcaproate (VIII) (*trans* : *cis*=40 : 60), the signals due to the β-methyl protons are at 1.52 and 1.46 ppm, with the signal at the higher field much the more intense. Since there is a substantial difference between the steric requirements of methyl and hydrogen, *tert*-butyl and methyl, and neopentyl and methyl groups, it appears that the methyl group in IX, the *tert*-butyl group in XVI, and the neopentyl group in XVII prefer a *trans* orientation. By fractional crystallization, methyl 2-carbamoyl-3,4-dimethyl-2,3-epoxyvalerate (XIII) (*cis-trans* mixture) gave one isomer which was confirmed by the NMR spectrum (β-methyl protons: at 1.27 ppm). With the above data in hand, a tentative assignment of the configuration may be made. In the nine epoxyamides discussed here, the signals due to the β-methyl protons are at a higher field when they are *cis* to the ester group, and at a lower field when they are *trans*.

In the preceding papers the authors determined the geometric configurations of $R_1R_2C=C(CN)-COOR_3$ on the basis of the assumption[2] that the response for the β-methyl protons is at a higher field in the *trans* than in the *cis* configuration with respect to the ester group. The β-methyl group is more deshielded in the *cis* than in the *trans* arrangements. This trend is not followed in the case of the epoxy esters discussed here. The β-methyl protons *cis* to the ester group respond at a higher field than do the *trans* β-methyl protons because the former is more shielded. These observations can be explained consistently by considering the magnetic anisotropy of the carbonyl group. It is well established that protons located in or near the carbonyl plane experience additional deshielding, while additional shielding is observed for protons out of the plane.

Experimental

NMR Spectra. All the NMR spectra were taken with a JNM-C-60 high-resolution NMR spectrometer working at 60 MHz at a temperature of 19—20°C. The samples were examined in a chloroform solution, using tetramethylsilane as the internal reference. The chemical shifts are given as ppm downfield from tetramethylsilane.

Alkylidenecyanoacetic Esters. The ethyl ethylidenecyanoacetate was prepared according to the method of Popp and Catala.[10] The other unsaturated esters were prepared according to the method of Cope.[11] The methyl 1-methylpropylidenecyanoacetate (*cis*) was prepared by the condensation of methyl ethyl ketone with cyanoacetic acid, followed by esterification with diazomethane according to the method of Hamelin.[8]

Epoxidation of Alkylidenecyanoacetic Esters. A. A mixture of the alkylidenecyanoacetic ester (0.1 mol), 30% hydrogen peroxide (0.2 mol), and alcohol (30 ml) was refluxed for 7 hr on a water bath. To the

mixture water (100 m*l*) was added, and then it was extracted with chloroform. After the removal of the solvent, the residual oil was distilled to give epoxy nitrile.

B. To a flask equipped with a thermometer, a dropping funnel, and a stirrer, the alkylidenecyanoacetic ester (0.1 mol), sodium bicarbonate (0.05 mol), and alcohol (30 m*l*) were added. Into this 30% hydrogen peroxide (0.2 mol) was stirred, drop by drop, at room temperature. After stirring for 3 hr, the mixture was allowed to stand overnight. To the solution thus obtained we added water (100 m*l*), and then it was extracted with chloroform. After the removal of the solvent, the residual oil was distilled in a vaccum to give epoxy nitrile. The properties of the products are shown in Table 3.

Reaction of Epoxy Nitriles I—VIII with Hydrogen Peroxide. To the products (I-VIII) obtained above (0.01 mol) in alcohol (5 m*l*), we added 30% hydrogen peroxide (0.05 mol) and sodium tungstate dihydrate (0.005 mol). The mixture was then kept for 3 hr at 70—80°C on a water bath. After the removal of the solvent, the residue was extracted by the use of chloroform, and then the solvent was evaporated. The oily residue was shaken with petroleum ether to give colorless crystals (epoxy amides IX—XV, XVII).

Epoxy amide XVI was prepared from methyl 2-cyano-3,4,4-trimethylpentenoate[2] according to the method of the present authors.[12]

These epoxy amides were used for the measurement of the NMR spectra without further purification because the *cis-trans* ratios were affected by recrystallization. The samples were recrystallized from chloroform-petroleum ether prior to analyses.

Methyl 2-Carbamoyl-3,4-dimethyl-2,3-epoxyvalerate (XIII-*cis*). Compound XIII (*cis-trans* mixture) was prepared according to the general procedure. The repeated recrystallization of the product from chloroform-petroleum ether gave colorless needles; mp 135—136°C (NMR: β-methyl, 1.27 ppm).

Found: C, 53.99; H, 7.14; N, 6.95%. Calcd for $C_9H_{15}O_4N$: C, 53.72; H, 7.51; N, 6.96%.

The authors wish to express their hearty thanks to Professors Taro Hayashi and Tatsuo Takeshima for their kind advice and encouragement, and to Dr. Toshio Hayashi for his valuable discussions. Thanks are also due to Dr. Haruo Homma and his staff for their microanalyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2143—2152 (1970)

Stereochemistry and Mechanism of Catalytic Hydrogenation and Hydrogenolysis. III.*1 Catalytic Hydrogenolysis of Benzyl-type Alcohols and Their Derivatives*2

Sekio MITSUI, Shin IMAIZUMI and Yasuyoshi ESASHI*3

Department of Applied Science, Faculty of Engineering, Tohoku University, Aramaki, Aoba, Sendai-shi

(Received October 25, 1969)

In order to obtain evidence for the mechanism we proposed of the catalytic hydrogenolysis of benzyl-type alcohols and their methyl ethers, optically active 2-phenyl-2-butanol (Ia), 2-phenyl-2-methoxybutane (IIa), ethyl atrolactate (Ib), and ethyl 2-phenyl-2-methoxypropionate (IIb) were hydrogenolyzed over Raney nickel and Pd(H) catalysts under hydrogen or helium atmosphere in an ethanol solution. In all cases, the hydrogenolysis proceeded stereoselectively with retention of configuration over Raney nickel catalyst but with inversion of configuration over palladium catalyst. A reverse stereoselectivity was observed when the benzyl alcohols (Ia and 2-phenyl-1,2-dihydroxypropane (Ic)) and methyl ethers (IIa) and (IIb) were hydrogenolyzed in the presence or absence of various additives over nickel catalysts. It was also found that the hydrogenolysis of benzyl alcohols always proceeds with retention of configuration over nickel catalyst containing sodium hydroxide. Various binary mixtures of Ia, IIa, Ib and IIb were hydrogenolyzed competitively over Raney nickel and Pd(H) catalysts. The order of relative rates was found to be Ia$\gtrsim$Ib$>$IIa$\gtrsim$IIb over Raney nickel, and IIa$\gtrsim$Ia$\gg$IIb$\gtrsim$Ib over Pd(H) catalyst. The results support our mechanism. The catalytic hydrogenolysis is a competitive reaction of two courses (S_Ni type and S_N2 type reactions), and the stereoselectivity reflects the difference of the free energy levels of the transition states to form π-benzylic complexes. The free energy levels of the corresponding transition states depend on stereoelectronic factor, affinity of substituents for catalyst metal, catalyst hindrance and electronic effects of substituents. The acetates (IVa) and (IVb) of Ia and IIa were hydrogenolyzed with inversion of configuration over nickel and palladium catalysts, whereas the stereoselectivity of the hydrogenolysis of the benzoate (V) of IIa depended on the kind of catalyst. The results are also explained on the basis of our mechanism.

We have shown[1] that the catalytic hydrogenolysis of optically active benzyl alcohols and their methyl ethers proceeds stereoselectivity under moderate conditions in an ethanol solution and the stereochemical results are correlated with the nature of the catalyst; the hydrogenolysis proceeds with retention over Raney nickel, cobalt, and copper catalysts but with inversion over palladium and platinum catalysts. From these results, we suggested that the hydrogenolysis proceeds through sterically different chemisorbed states of substrates which depend on the kind of catalyst metal.[1,2]

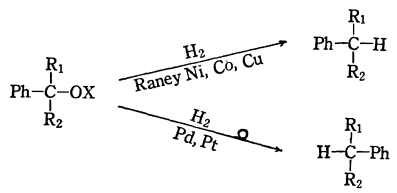
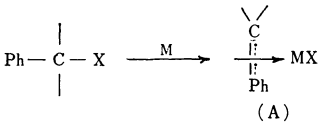
Khan, McQuillin and Jardine[3] proposed a mechanism different from ours in which the reaction proceeds *via* the same intermediate(A) over any

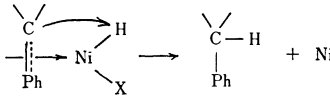


X=H or CH_3

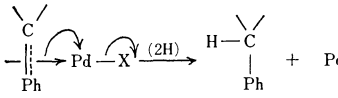
catalyst metal, followed by hydrogen transfer with retention or inversion of configuration depending on the chemical nature of catalyst metal. They considered that nickel-carbon bond is displaced by hydrogen with retention(1), but palladium-carbon bond is displaced by hydrogen in a type of nucleophilic substitution with inversion (2), since the hydrogen supply could be critical by the faster hydrogenolysis over palladium than over nickel and because of the polarization of palladium-carbon bond. Garbisch, Jr., *et al.* offered a mechanism of the hydrogenolysis. However, no detailed process of the formation of inversed product was given.[4]



(A)



(1)



(2)

The purpose of the present study is to make a more detailed examination of the hydrogenolysis of optically active benzyl alcohols and their methyl ethers over nickel and palladium catalysts under various conditions, and to improve the mechanism from the results of this study.

Results

Catalysts. W-4 Raney nickel, "reduced nickel," 5% palladium on charcoal, Raney palladium, and "palladium hydride[5]" were used as catalysts.

The reduced nickel catalyst was prepared by reduction of finely powdered nickel oxide with hydrogen stream at about 300°C. It seems likely that no alkaline substances are contained in the catalyst, since the nickel oxide for the starting material was prepared by thermal decomposition of nickel nitrate.

The palladium hydride catalyst was prepared as follows: An aqueous solution of palladium chloride (5 per cent) was reduced with hydrogen. The metal formed was washed with water until free from chloride ion. The palladium was oxidized for one hour at 400—500°C in atmosphere and then the resulting oxide was reduced by hydrogen in an ethanol suspension. Oxidation and reduction were repeated several times until the volume of consumed hydrogen became nearly constant. The oxide consumed a greater amount of hydrogen than necessary for reduction to metal. It may be assumed that about 80 per cent of palladium was converted into palladium hydride, if all of the occluded hydrogen was consumed to form hydride. The symbols Pd(H) and $Pd(H_{0.4})$ will be used to denote the above catalyst and palladium respectively which occludes 40 per cent of the calculated amount of hydrogen corresponding to PdH.

Hydrogenolysis of Benzyl Alcohols and Their Methyl Ethers. The ethanol solution of optically active 2-phenyl-2-butanol (Ia), 1-phenyl-2-methoxybutane (IIa), ethyl atrolactate (Ib), and ethyl 2-phenyl-2-methoxypropionate (IIb) was hydrogenolyzed to 2-phenylbutane (IIIa) and ethyl 2-phenylpropionate (IIIb), respectively, over Raney nickel, Pd(H) and $Pd(H_{0.4})$ under various conditions. The results are summarized in Tables 1 and 2. In all cases, the hydrogenolysis proceeded stereoselectively with retention of configuration over Raney nickel catalyst but with inversion of configuration over palladium catalyst, the results being the same as those reported on hydrogenolysis using other palladium catalyst under ordinary reaction conditions. It is to be noted that the stereoselective inversion occurred in the hydrogenolysis over Pd(H) and $Pd(H_{0.4})$ but the retention was observed over Raney nickel not only under hydrogen atmosphere but also under helium atmosphere.

In the case of Raney nickel catalyst, the stereoselectivity of hydrogenolysis of benzyl alcohols (Ia) and (Ib) remained unaltered by the addition of

sodium hydroxide. On the other hand, Tables 3 and 4 clearly reveal a decrease in the proportion of the retention of configuration in the cases of methyl ethers (IIa) and (IIb) when the amount of sodium hydroxide added increased. A similar trend in the stereoselectivity was also obtained when alkali halide were added instead of sodium hydroxide.

In order to see why the benzyl alcohols were hydrogenolyzed with retension of configuration over Raney nickel catalyst in any reaction conditions, "reduced nickel" was used as nickel catalyst which contains no alkaline substance. Hydrogenolysis proceeded only at elevated temperature, and stereoselectivity depended on the structure of benzyl alcohols as shown in Tables 3 and 4. Hydrogenolysis proceeded with predominantly retention of configuration in the case of Ib, but with predominantly inversion of configuration in the cases of Ia, IIa and 2-phenyl-1,2-dihydroxypropane (Ic). Ia was hydrogenolyzed with retention of configuration under the conditions where a trace amount of sodium hydroxide is present (Table 3).

These results suggest that the stereoselectivity of hydrogenolysis of benzyl alcohols and their methyl ethers over nickel catalyst is correlated with the structure of substrates, the kind of nickel catalyst and additives, and that an alkaline substance which is contained inevitably over Raney nickel catalyst acts as an effective factor in the stereospecific hydrogenolysis of benzyl alcohols with retention of configuration.

Competitive Hydrogenolysis of the Benzyl Alcohols(Ia) and (Ib) and Their Methyl Ethers (IIa) and (IIb). The order of relative rates of hydrogenolysis of the substrates was found to be Ia$\gtrsim$Ib$>$IIa$\gtrsim$IIb over Raney nickel catalyst, and IIa$\gtrsim$Ia$\gg$IIb$\gtrsim$Ib over Pd(H) catalyst at room temperature and atmospheric pressure in an ethanol solution. Various binary mixtures of Ia, Ib, IIa and IIb were hydrogenolyzed competitively over both catalysts under the same condition as in individual hydrogenolysis. The results are summarized in Table 5. The competitive rates in hydrogenolysis of the binary mixture of Ia and Ib were similar over Raney nickel catalyst, whereas Ia was more rapidly hydrogenolyzed than Ib over Pd(H) catalyst. In the case of the binary mixture of Ib and IIb, Ib reacted more readily than IIb over Raney nickel catalyst, while a reverse relation was observed over Pd(H) catalyst. The same competitive rates were observed in the binary mixtures of IIa and IIb, and Ia and II a,respectively.

Discussion

Mechanism of the Hydrogenolysis of Benzyl-type Alcohols and Their Methyl Ethers. Khan *et al.* considered that the hydrogenolysis of benzyl alcohols and their methyl ethers over palladium catalyst proceeds with the inversion of configuration, since the hydrogen supply could be critical by rapid hydrogenolysis, *i.e.*, the intermediate (A) reacts with hydrogen from the opposite side of the catalyst surface by a deficiency of adsorbed hydrogen.[3] This prompted us to investigate the hydrogenolysis under various reaction conditions, especially over Pd(H) under helium atmosphere.

The results summarized in Tables 1 and 2 show that the stereoselectivity is independent of the kind of atmosphere. Thus, the hydrogenolysis over Pd(H) and Pd($H_{0.4}$) proceeded with the stereo-

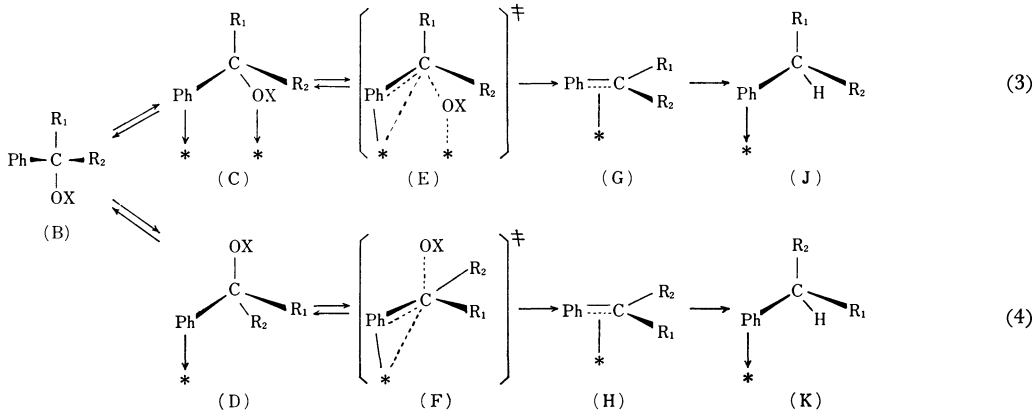
specific inversion of configuration not only under hydrogen atmosphere but also under helium atmosphere, in which no hydrogen is detected by means of vapor phase chromatographic analysis in the gas phase during the reaction. These results suggest that the hydrogen which takes part in the hydrogenolysis attackes an adsorbed substrate from the side of catalyst surface. Thus, the results are not in line with the consideration of Khan *et al.*,[3)] but support our mechanism.[1,2)]

It seems that the hydrogenolysis proceeds through π-adsorption of the phenyl group, followed by the formation of a π-benzylic complex with the catalyst. This complex formation will be similar to that of a π-allylic complex with transition-metal catalysts. In the transition state, thus, there is a change toward sp^2-hybridization at the benzylic carbon with the carbon-oxygen bond becoming labile. The leaving group is finally eliminated by combination with surface hydrogen π-benzylic complex being formed.[6)]

From the results, the mechanism of hydrogenolysis of benzyl-type alcohols (I) and their methyl ethers (II) may be described as follows: The substrate (B) is adsorbed over the catalyst surface. An electron attacks nucleophilically the adsorbed substrates (C) and (D) from the surface of the catalyst, and then π-benzylic intermediates (G) and (H) are produced through transition states (E) and (F), respectively. The resulting intermediates (G) and (H) decompose to the adsorbed products

6) J. J. Rooney, F. G. Gault and C. Kemball, *Proc. Chem. Soc.*, **1960**, 407; F. G. Gault, J. J. Rooney and C. Kemball, *J. Catal.*, **1**, 255 (1962); J. J. Rooney, *ibid.*, **2**, 53 (1963); J. J. Rooney and G. Webb, *ibid.*, **3**, 488 (1964); J. J. Rooney, *Chem. Brit.*, **2**, 242 (1966).



(J) and (K) by hydrogen from the surface of the catalyst with retention of configuration.

The intermediates (G) and (H) are identical in the half-hydrogenated state in the catalytic hydrogenation of styrene derivatives.[7] It has been reported that the intermediate readily decomposes to the adsorbed product by hydrogen from the catalyst surface with the retention of configuration not only over nickel catalyst but also over palladium catalyst.[7] Therefore, it seems that the stereoselectivity of hydrogenolysis is not determined by the step of the decomposition of the intermediates (G) and (H) with hydrogen.

The fact that the hydrogenolysis of I and II over palladium catalyst proceeds with the stereoselective inversion of configuration under all reaction conditions (Tables 1 and 2), suggests that the stereoselectivity is not determined by the step of the adsorption of the substrate in the mechanism. It is unlikely that both Ia and Ib are adsorbed only in one form (D) over palladium catalyst.

Therefore, the stereoselectivity over palladium catalysts may be determined by the difference in the free-energy levels of the transition states (E) and (F) to form π-benzylic complexes in the two courses (Reactions (3) and (4)), since the above results suggest that the activation energies for the cleavage of carbon-oxygen bond (C→G, and D→H) is larger than that for the adsorption of the substrate (B→C, and B→D) and that for the decomposition of carbon-metal bond of the π-benzylic complex to the adsorbed products (G→J, and H→K).

The mechanism is supported by the results of hydrogenolysis of the benzyl alcohol derivatives such as *cis*- and *trans*-1-phenylcyclohexane-1,2-diol, their monoacetates and diacetates, containing an eliminable substituents in β-position.[8]

The results of the palladium catalyzed hydrogenolysis of I and II suggest that the free energy of transition state (F) is lower than that of (E). This may be due to the fact that reaction (4) in which an electron attacks nucleophilically the asymmetric carbon from the opposite side of the leaving hydroxyl or methoxyl groups, *i.e.*, from the catalyst surface, (S_N2 type reaction on catalyst) has an advantage of fulfilling the stereoelectrical requirement in contrast with reaction (2) in which the leaving group is displaced in the same side (S_Ni type reaction on catalyst) in the same way as in homogeneous nucleophilic substitution reaction on carbon.

In the case of Raney nickel catalyst, the hydrogenolysis of I and II proceeds with the retention of configuration. Thus, the fact that the course of reaction (3) is preferable to that of reaction (4) may be due to the strong affinity of the leaving group for Raney nickel catalyst. It is well known that nickel has a strong affinity for oxygen.[9] Accordingly, Raney nickel may adsorb the groups containing oxygen more than palladium. Thus the free enrgy level of the transition state(E) may be lower than that of (F), since the strong chemisorption of the sterically small leaving groups, such as hydroxyl or methoxyl, decreases not only free energy level of adsorption state(C) but also the activation energy from (C) to intermediate(G).

The Effect of Additives over Nickel Catalysts. It was reported that the stereoselectivity of hydrogenolysis of the phenyl ether[10] of Ib and epoxides[1e,11] depended on the presence or ab-

sence of an additive over catalyst. However, the effect of an additive for I and II has not been studied. The mechanism presented here suggests that the reverse stereoselectivity may also be observed over nickel catalyst if the hydrogenolysis of I and II carried out under the reaction conditions which weaken the adsorption of substrate over the catalyst. In fact, the reverse stereoselectivity was observed under several reaction conditions as seen in Tables 3 and 4. Thus, the inversed product is produced predominantly by the addition of sodium hydroxide or alkali halides over Raney nickel catalyst in the hydrogenolysis of methyl ethers (IIa) and (IIb). The results may be expalined by assuming that the additives act as a catalyst poison which weakens the adsorption of substrate over the catalyst. Then the course of reaction (4) will become more advantageous to that of reaction (3) over the poisoned nickel catalyst, since hydrogenolysis may be retarded by the additives, especially in (3) which needs a strong adsorption of the leaving group.

On the other hand, the stereoselectivity of hydrogenolysis of benzyl alcohols over Raney nickel catalyst is not affected by the additives. The divergent result can be ascribed to the effect of alkaline substance contained inevitably in Raney nickel catalyst, because the inversed product is formed predominantly in the hydrogenolysis of Ia over reduced nickel catalyst but the retained product is produced in the presence of sodium hydroxide over the same catalyst (Table 3). Benzyl alcohols differ from their methyl ethers in having free hydroxyl group, and in forming their alkoxide anions with alkali over the catalyst. Therefore, the reaction of course (4) is disfavored by the decrease of the electronegativity of the leaving group, *i.e.*, by the resonance effect of the anion, resulting in the selective hydrogenolysis through course (3).

As seen in Table 3, methyl ether (IIa) was hydrogenolyzed with the inversion of configuration over the reduced nickel catalyst in contrast to the case over Raney nickel catalyst. However, it is clear that the activity of the reduced nickel catalyst is lower than that of Raney nickel catalyst because the former acts as a hydrogenolysis catalyst only at an elevated temperature. It is likely from these results that the reduced nickel behaves like the catalyst poisoned with substances other than alkali. Thus, it is assumed that the hydrogenolysis of Ia proceeds predominantly with the inversion of configuration over the reduced nickel catalyst similar to the case of IIa. It is evident that alkali acts as an effective factor for the stereoselectivity of the hydrogenolysis of benzyl alcohols because Ia is hydrogenolyzed with retention of configuration in the presence of sodium hydroxide over the reduced nickel catalyst. The result may be explained from the formation of the alkoxide anions of the benzyl alcohols with alkali over the catalyst as described before. A similar effect of sodium hydroxide has been observed in the hydrogenolysis of 2-methyl-2-phenylazilidine over palladium catalyst.[12]

In the case of ethyl atrolactate (Ib), hydrogenolysis proceeded predominantly with the retention of configuration over the reduced nickel catalyst, but the stereoselectivity was low compared with the case of Raney nickel catalyst, and decreased by the addition of potassium bromide (Table 4). Thus, it is clear that the tendency of variation of stereoselectivity is similar to that observed in the case of Ia, but the degree of variation is slight. It appears to depend on the structure of benzyl alcohols. The structure of Ib differs from that of Ia only in having the ethoxycarbonyl group instead of the ethyl group. It is clear that the bulkiness and electronegativity of the ethoxycarbonyl group are greater than those of the ethyl group, and that if the reaction proceeds *via* course (4), the ethoxycarbonyl group of Ib must be placed to the side of the catalyst surface, whereas the ethoxycarbonyl group in the reaction *via* course (3) may or may not be placed thus. The results suggest that the effect of the catalyst hindrance of the ethoxycarbonyl is larger than the electronic effect in its adsorbed state for the hydrogenolysis of Ib.

This consideration is in line with the results of the competitive hydrogenolysis of various binary mixtures of the substrates (Ia, Ib, IIa and IIb), *i.e.*, as shown in Table 5, Ia and IIa are more rapidly hydrogenolyzed than Ib and IIb, respectively, over Pd(H) catalyst, in which the hydrogenolysis proceeds with the inversion of the configuration, whereas similar rates were observed in the case of Raney nickel catalyst, in which the hydrogenolysis proceeds with the retention of the configuration.

The consideration is supported by the fact that the hydrogenolysis of 2-phenyl-1,2-dihydroxypropane (Ic) which had sterically smaller methylol group than ethoxycarbonyl group of Ib proceeds with the inversion of the configuration over reduced nickel catalyst (Table 4), similarly as in Ia.

The results led us to the conclusion that the stereoselectivity of the catalytic hydrogenolysis of benzyl alcohols and their methyl ethers depends on the difference in the free energy levels of the transition states (E) and (F). The free energy levels of E and F depend on such factors as stereoelectronic factor, affinity of substituents for catalyst metal, catalyst hindrance, and electronic effects

of substituents.

Hydrogenolysis of Benzyl Acetates and Benzoates. Let us consider the stereochemistry of the hydrogenolysis of other derivatives of benzyl alcohols.

The hydrogenolysis of the acetates (IVa) and (IVb) proceeded with the inversion of configuration under all reaction conditions (Table 6), the results being the same as those reported in the hydrogenolysis of IVb[13] and of other benzyl acetates.[3,4,14] The stereoselectivity of hydrogenolysis of benzoate (V) depended on the kind of catalyst.

The results of benzoate(V) cannot be explained by the consideration of Khan *et al.*[3] that hydrogenolysis of the benzyl derivatives, such as acetate and benzoate, having a strongly electronegative leaving group proceeds with the inversion of configuration *via* course (2). These results may be also explained on the basis of our mechanism of the hydrogenolysis of I and II.

The fact that the acetates are hydrogenolyzed with the stereospecific inversion of configuration over both nickel and palladium catalyst suggests clearly that stereoselectivity is not determined by the difference of the step to form the adsorption states (C and D), since the acetoxyl and ethoxycarbonyl groups may be adsorbed with greater facility over the catalyst than the alkyl group. Thus, stereoselectivity may be correlated with the difference in the free energy levels of the transition states (E) and (F) to form the π-benzyl intermediates (G) and (H), in analogy with the cases of hydrogenolysis of I and II.

It is considered that S_N2 type reaction on catalyst in the hydrogenolysis of benzyl acetates proceeds with greater facility than that of benzyl alcohols and their methyl ethers, because the acetoxyl group of the acetates has a strong electron attractive nature. It seems likely therefore, that the hydrogenolysis of benzyl acetates proceeds generally with the inversion of configuration *via* course (4) under all reaction conditions.

The stereoselectivity of hydrogenolysis of benzoate (V) depended on the reaction conditions (Table 6). Thus, the hydrogenolysis proceeded predominantly with the retention of configuration over Pd(H) catalyst, but the reverse stereoselectivity was observed over palladium on charcoal, Raney palladium and Raney nickel catalysts.

These results suggest that the difference of the activation energy between the two courses (3) and (4) for V is smaller than that for the acetate(IVb). Although the benzoyloxyl group of V unquestionably possesses a stronger affinity with the catalyst and a larger catalyst hindrance than those of the acetoxyl group of IVb, the effect of the former may be larger for the hydrogenolysis of V, compared with the case of IVb, because both the carbonyl and the phenyl of the benzoyloxyl group are π-adsorbed. These effects are similar to those of the phenyl group of the phenyl ether of Ib.[10] Thus, the strong chemisorption of the benzoyloxyl group is expected to facilitate course (3) in line with the hydrogenolysis of I and II over Raney nickel catalyst. Consequently, differing from the case of acetates (IV) the stereoselectivity of hydrogenolysis of V may depend on the reaction conditions.

When a catalyst which has many suitable pores such as Raney catalyst is used, hydrogenolysis with an inversion of configuration over two phases of the catalyst surface cannot be ruled out, in analogy with the hydrogenolysis of phenyl ether[10] of Ib, since the benzoyloxyl group has a planar structure containing π-electrons, and asymmetric carbon-oxygen bond of the substrate is able to rotate freely. It is assumed that the reaction *via* this adsorption state has a smaller activation energy than that *via* the other adsorption states. Needless to say, this reaction course is included in course (4).

When the benzoyloxyl and phenyl groups of the benzoate(V) are adsorbed strongly over the catalyst, partial participation of the radical cleavage reaction on catalyst is made possible, giving a racemic product.[2,13] These factors may further complicate the stereoselectivity of hydrogenolysis of V.

Recently a similar variable stereoselectivity has been also found in the Raney nickel catalyzed desulfuration of benzylsulfone derivatives by Grimm and Bonner.[15] It is assumed that desulfuration, in analogy with the hydrogenolysis of the benzoate, may be also complicated by the participation of many reaction courses which depend on the structure of substrate and reaction conditions.

16) D. J. Cram, *J. Amer. Chem. Soc.*, **74**, 2149 (1952).

(V),[13] $[\alpha]_D^{20}+34.6°$ (*c* 9.1, ethanol), 91.9% optical purity; S(+)-2-phenyl-1,2-dihydroxypropane(Ic),[1b] $[\alpha]_D^{16}+5.1°$ (*c* 1.96, ethanol), 84% optical purity.

Hydrogenolysis. Hydrogenolysis was carried out in 20 m*l* of ethanol containing a known amount of substrate, catalyst and additive. The catalyst was filtered. In the cases of Ia, IIa and IVa, 200 m*l* of water was added to the filtrate, and then extracted with ether. The ether layer was washed with a saturated sodium bicarbonate solution and was dried over anhydrous calcium chloride, and the solvent was removed. 2-Phenylbutane (IIIa) was then separated from the residual oil by distillation (bp 60°C/15 mmHg) or by vapor phase chromatography (2 m of column packed with a polyethylene glycol-4000 on 30—60 mesh firebrick). In the cases of Ib and IIb, the solvent was distilled, and ethyl 2-phenylpropionate (IIIb) was then separated from the residual oil by vapor phase chromatography. In the cases of IVb and V, the solvent was distilled. The residual oil was taken up in ether and extracted with a saturated sodium bicarbonate solution. The alkaline insoluble material was dried over anhydrous sodium sulfate, and the solvent removed. IIIb was then separated from the residual oil by vapor phase chromatography. In the case of Ic, the solvent was distilled. The residual oil was distilled at reduced pressure to give 2-phenyl-1-propanol (IIIc), bp 120°C/21 mmHg.

The stereochemical results are shown in Tables 1, 2, 3, 4, and 6.

Competitive Hydrogenolysis. Hydrogenolysis was carried out with each of the individual substrates and their various binary mixtures under atmospheric pressure and at room temperature (20°C). For the hydrogenolysis of the individual substrates, 10 m*l* of ethanol and 0.004 mol of the substrate were used. Hydrogenolysis of the binary mixtures of the substrates was carried out with an ethanol solution (10 m*l*) of the two substrates concerned. The concentration of each substrate was approximately 0.2 molar. Catalyst weights were 1 g of Raney nickel (wet) and 1 g of Pd (H) for each run. Small amounts of samples were extracted through a silicone rubber stopper with a hypodermic syringe at suitable intervals and analyzed by glcp procedures (45 m Golay column coated with polyethylene glycol-4000). The results are shown in Table 5.

2-Cyclohexylbutane (IIIa'). R(−)-2-Phenylbutane ($[\alpha]_D^{21}-15.4°$ (benzene), optical purity 54.8%) was hydrogenated over platinum catalyst in ethanol under hydrogen at an ordinary temperature and pressure until the hydrogen was no longer adsorbed. The catalyst was filtered and rinsed with ether. Water and ether were added to the filtrate, and ether layer was dried over anhydrous calcium chloride, and then the solvent was removed. The residual oil distilled at reduced pressure gave R(+)-2-cyclohexylbutane (IIIa'), bp 60°C/ 15 mmHg, $[\alpha]_D^{25}+1.95°$ (benzene). The specific rotation of the optically pure IIIa' is calculated to be $[\alpha]_D$ 3.56° (benzene).

Sulfilimine. II. IR, UV and NMR Spectroscopic Studies

Kenji TSUJIHARA, Naomichi FURUKAWA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received October 30, 1969)

The physical properties of several *N*-*p*-tolylsulfonylsulfilimines were studied by means of infrared, ultraviolet and NMR spectroscopic determinations. Four characteristic infrared absorption bands due to both sulfonyl and sulfilimino groups are observed and those due to both N–S(IV) and N–S(VI) stretching vibrations appear at nearly the same positions and overlap with each other. The ultraviolet spectra suggest that the sulfilimino group is not an electron donor but an electron acceptor group when conjugated with a phenyl ring and could be used to measure the pK_a value of methyl-*p*-methoxyphenyl derivative. The NMR chemical shift of methyl protons attached to the S atom of *S*-methyl-*S*-*p*-tolyl derivative appears at 2.81 ppm, whereas the shifts of the corresponding sulfoxide and the sulfone groups appear at 2.69 and 3.04 ppm, respectively. From these results, it seems that the N–S(IV) bond of *N*-*p*-tolylsulfonylsulfilimine is of semipolar character while the charges on the S(IV) atom and the N atom are delocalized substantially with strong $d\pi$ conjugation into S(IV)–N–S(VI) bondings.

Sulfilimines have been known as sulfur-nitrogen ylides or ylenes. The *N*-acyl derivatives are especially well known compounds and their IR,[1] UV,[2] and X-ray data[3] have been accumulated in recent years.

The configuration of *N*-sulfonylsulfilimine is not established, though the S–N bond has been postulated from IR spectroscopic study[1] to have a double bond character. We have examined IR, UV and NMR spectra of various *N*-sulfonylsulfilimines. This paper will describe the new data and their relation to a preferable structure for *N*-sulfonylsulfilimine.

Results and Discussion

IR Spectra of *N*-*p*-Tolylsulfonylsulfilimines. The IR spectra of several *N*-*p*-tolylsulfonylsulfilimines are taken in KBr disks and shown in Table 1. All the sulfilimines have four strong characteristic IR absorption bands at around 930—980, 1070—1090, 1130—1140 and 1260—1280 cm^{-1} respectively (Fig. 1). The latter two bands, 1130—1140 and 1260—1280 cm^{-1} are well assigned to those of both symmetrical and asymmetrical stretching vibrations due to SO_2 group. The first band, 930—980 cm^{-1} has been assigned to the stretching vibration due to N–S(IV) group by Kucsman *et al.*,[1] though there are controversies in the assignment of the absorption of S–N stretching vibration.[4-6] The second band, 1070—1090 cm^{-1}, which appears in all arylsulfonamides was revealed by Tanaka *et al.* to be not of the S–N stretching absorption band from a study of the IR spectra of various sulfonamides, sulfonic acids, sulfones and other related compounds.[5]

N-*p*-Tolylsulfonylsulfilimine may be formulated by either the ylide structure, the ylene structure or by the resonance hybrid of both.

Ylide type Ylene type

Kucsman *et al.* favor the ylene structure on the basis of IR spectroscopic observations.[1] They argue that the $\bar{\nu}$ SO_2*[1] band in sulfilimine appears at a wave number considerably higher than that in sulfonate ($\bar{\nu}$ SO_3=1120 cm^{-1}) although it might

be predicted that both SO_2 bands in the system $-SO_2-N^{\ominus}-$ and $-SO_2-O^{\ominus}$ would appear in the same region. A shift of 40—50 cm^{-1} toward a lower wave number of $\bar{\nu}$ SO_2 band in sulfilimine than that in sulfonamide or sulfone is also too small to be ascribed to the ylide structure.

However, a comparison of the two systems may not be appropriate and the shift of 40—50 cm^{-1} toward the lower wave number of SO_2 band is too large to be caused only by the electronic effect of sulfilimino group. We examined the IR spectra of sodium *N*-chloro-*p*-tolylsulfonylsulfonamide (chloramine T) which is considered to have the system $-SO_2-N^{\ominus}-$. IR spectra of *p*-tolylsulfonamide, chloramine T and *S,S*-dimethyl-*N*-*p*-tolylsulfonylsulfilimine are shown in Fig. 1. Chloramine T has four characteristic intense bands at 1255 ($\nu_{as}SO_2$), 1130 (ν_sSO_2), 1083 and 929 cm^{-1}. The whole spectrum does not resemble that of the sulfonamide but is very similar to that of sulfilimine except for the band at 929 cm^{-1} which is less intense than that of *S,S*-dimethyl-*N*-*p*-tolylsulfonylsulfilimine at 943 cm^{-1}.

The characteristic IR absorption bands of several sulfilimines, chloramine T and other related compounds are listed in Table 2. The values of $\bar{\nu}$ SO_2 of sulfilimines (1190—1210 cm^{-1}) are similar to the value of chloramine T anion (1193 cm^{-1}) but different from that of sulfonamide (1243 cm^{-1}) and

sulfones (1238—1247 cm^{-1}). The value of $\bar{\nu}$ SO_2 of sulfoximine (I) produced by the oxidation of sulfilimine is close to that of sulfonamide but not to that of sulfilimine or chloramine T. This fact seems to be supported by the S=N double bond character of sulfoximine.[7]

The results suggest that sulfilimine and chloramine T anion have similar electronic environments around the SO_2 group, and *N*-*p*-tolylsulfonyl sulfilimine would be represented better by the ylide structure than by the ylene structure.

Recently, an X-ray crystallographic study of *S*,*S*-dimethyl-*N*-methylsulfonylsulfilimine has revealed that the bond length of N–S(IV) and N–S(VI) are 1.63 and 1.58 Å respectively,[3] which are normal values for N–S distance of sulfonamide such as *N*-phenylmethanesulfonamide[9] or sulfamide.[10] The result undoubtedly supports the consideration that the S–N bond is of semipolar nature.

$$(CH_3)_2S \qquad SO_2CH_3$$
$$1.63\ \text{Å} \diagdown \quad \diagup 1.58\ \text{Å}$$
$$N$$

The stretching vibrations of the N–S(IV) and the N–S(VI) bonds can be calculated simply by the following equation[11] using the values 1.63 and 1.58 Å, and the values 878 and 971 cm^{-1} are obtained.

$$\nu = \frac{1}{2\pi c}\left(\frac{f}{M_n \cdot M_s/M_n + M_s}\right)^{1/2}, \quad f = \frac{1.86 \times 10^5}{(r-0.88)^3}$$

where

ν: the stretching frequency (cm^{-1})
c: the velocity of light (cm/sec)
f: the force constant of bond (dyn/cm)
r: the bond length (Å)
M_n and M_s: the mass of N atom and S atom respectively (g)

N-*p*-Tolylsulfonylsulfilimine has only one very intense band around 930—980 cm^{-1} whose intensity is stronger than those of the SO_2 bands and the S–N stretching vibration of chloramine T (see Fig. 1). Thus, both bands due to both N–S(IV) and N–S(VI) stretching are considered to apper at the same or nearly the same position and would overlap each other.

UV Spectra of *N*-*p*-Tolylsulfonylsulfilimines. UV spectra of several *N*-*p*-tolylsulfonylsulfilimines are shown in Table 3. All the sulfilimines except those having *p*-amino or *p*-methoxyphenyl group give UV spectra having the maximum absorption bands (λ_{max}) at around 228 mμ with intensities (log ε_{max}) between 4.06 and 4.35.

There is practically no shift of λ_{max} when R_1 and R_2 change from dialkyl to alkylpheny or diphenyl. This suggests that the maximum absorption bands at around 228 mμ are the ^1L_a bands due to the phenyl ring of *p*-tolylsulfonyl group connected to sulfilimine group, since λ_{max} and log ε_{max} between *S*,*S*-dialkyl-*N*-*p*-tolylsulfonylsulfilimine and *p*-tolylsulfonamide having the ^1L_a band at 225 mμ are very similar.

If the S(IV)–N bond of *N*-*p*-tolylsulfonylsulfilimine has a normal double bond character, the resonance interaction between the S=N bond and the adjacent phenyl ring shown below, would lead the λ_{max} to a red-shift.

7) S–N bond of sulfoximine is considered to be of double bond character from the following evidence. i) S–N bond length obtained from X-ray analysis is appropriate for S=N double bond distance. 1.56 Å for methionine sulfoximine; B. W. Christensen and A. Kjaer, *Chem. Commun.*, **1969**, 169. 1.53 Å for methyl-*p*-nitrophenyl sulfoximine; A. Shimada, K. Hirotsu and K. Iwama, unpublished work. ii) The substituent effect of pK_a of arylmethylsulfoximine does not obey σ^+ value but σ value; S. Oae, K. Tsujihara and N. Furukawa, *Chem. Ind.* (London), **1968**, 1569.

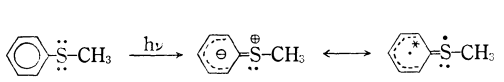
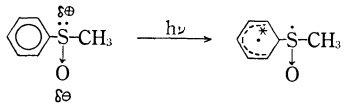
Fig. 2

Lack of such a red-shift suggests that the S(IV)–N bond in sulfilimine cannot be of the usual double bond character. This resonance interaction between the lone pair electrons on the S atom with phenyl ring is well known in sulfides.[12]



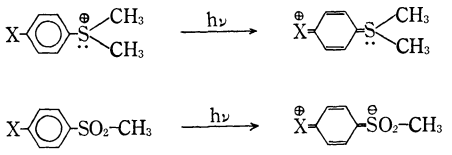
Even in the case of sulfoxides having both a lone electron pair and a somewhat positive charge on the S atom, this resonance interaction is observed.[12] In this case, however, the resonance interaction is not as large as in the case of sulfide, since the positive



charge on the sulfoxide sulfur atom increases the energy required to excite an electron on the lone pair.

As the positive charge on the S atom becomes larger, this resonance interaction of the lone electron pair with phenyl ring would become difficult, and when the S atom bears a discrete positive charge such as in sulfonium salts, this type of resonance interaction is no longer observed.[12]

In this case, resonance involving the donation of electrons from an occupied orbital in phenyl ring into a vacant $d\pi$ orbital of the S atom would be observed. This type of interaction is known to occur in sulfones attached to a phenyl ring and occasionally in sulfoxides having a pheny ring substituted with an electron-releasing group such as amino or methoxyl group.[12]



In the case of *N*-*p*-tolylsulfonylsulfilimine the lone electron pair would be bound somewhat tightly on the S atom and not readily excited to the energy level of *d* orbitals, because the λ_{max} and log ε_{max} of *p*-nitrophenyl or *p*-ammoniumphenyl-methylsulfilimine (σ_p of *p*-NO_2 and *p*-$NH_3\oplus$ are 0.778 and 0.60 respectively) scarcely alter when solvent changes from methanol or dilute sulfuric acid to 75% sulfuric acid in which sulfilimine is protonated with sulfuric acid and bears a discrete positive change on the S atom (see Table 4).

This observation indicates that the S atom of *N*-*p*-tolylsulfonylsulfilimine would bear a considerable positive charge which makes the lone electron pair tightly bound on the S atom.

UV spectra of *S*-aryl-*S*-methyl-*N*-*p*-tolylsulfonylsulfilimine in various solvents are shown in Table 4.

The maximum band of *S*-methyl-*S*-*p*-methoxyphenylsulfilimine (σ_p^+ of *p*-CH_3O is -0.778) at 239 mμ is shifted to 232 mμ with a shoulder at 242 mμ when solvent changes from methanol to water.

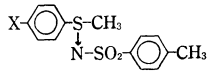
TABLE 4. UV SPECTRA OF ARYLMETHYLSULFILIMINES



X	Solvent	λ_{max}	log ε_{max}	σ_p (σ_p^+)
H	CH_3OH	226	4.26	0
	H_2O	226	4.26	
	75%-H_2SO_4	230	4.27	
CH_3	CH_3OH	230	4.32	−0.170(−0.311)
Cl	CH_3OH	231	4.37	0.227(0.114)
NO_2	CH_3OH	230	4.21	0.778(0.790)
		255 (shoulder)	(3.96)	
	75%-H_2SO_4	235	4.23	
		254 (shoulder)	(4.07)	
OCH_3	CH_3OH	239	4.30	−0.268(−0.778)
	H_2O	232	4.25	
		242 (shoulder)		
	75%-H_2SO_4	234	4.19	
		267	4.02	
NH_2	CH_3OH	222	4.17	−0.66 (−1.3)
		275	4.27	
NH_3^+	2%-H_2SO_4	226	4.21	+0.60
	75%-H_2SO_4	228	4.24	

The increase of the concentration of sulfuric acid gives a bathochromic shift to the shoulder at 242 mμ while in 75% sulfuric acid the sulfilimine gives two isolated bands at 234 and 267 mμ. This observation obviously indicates that there is some resonance interaction between *p*-methoxyphenyl ring and the somewhat positively charged S atom, while the resonanse interaction becomes stronger when the sulfilimine group is protonated with sulfuric acid and bears a discrete positive change on the S atom as shown in Fig. 3.

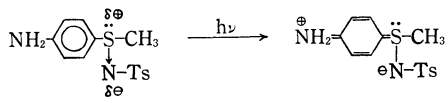
(Ts: *p*-$CH_3C_6H_4SO_2$–)

Fig. 3

This type of resonance interaction can be more clearly observed in the case of *S*-*p*-aminophenyl-*S*-methylsulfilimine (σ_p^+ of *p*-NH_2 is −1.3): namely, in methanol solution in addition to 222 mμ band due to *p*-tolylsulfonyl group 275 mμ band appears and completely disappears when solvent is changed to 2% sulfuric acid in which amino group is completely protonated.

This clearly indicates that *p*-aminophenyl ring interacts with the S atom bearing somewhat positive charge as shown below.

The fact that the resonance interaction involving the donation of electrons from an occupied orbital of the phenyl ring into a vacant $d\pi$ orbital of the S



(Ts: *p*-$CH_3C_6H_4SO_2$–)

atom occurs obviously in the case of sulfilimines having an electron releasing substituent such as amino or methoxyl group, indicates that the S atom of sulfilimine possesses an appreciable positive charge.

The resonance interaction which involves the donation of electrons from the lone electron pair of the S atom into an unoccupied orbital of the benzene ring would not occur, since the UV spectra of *p*-ammoniumphenyl- and *p*-nitrophenylmethylsulfilimine are not altered when sulfilimine group protonated and bears a discrete positive charge on the S atom.

This suggests that the S(IV)–N bond is not a discrete double bond, and there is at least some positive charge on the S atom to bind the lone pair electrons tightly on the atom. From these results the S(IV)–N bond in *N*-*p*-tolylsulfonylsulfilimine is considered to be a semipolar rather than a double bond. The negative charge on the N atom is considered to be delocalized over the SO_2 and the sulfilimine groups. *p*-Methoxyphenylmethylsulfilimine gave two isolated bands at 234 and 267 mμ in aqueous sulfuric

acid. The latter band has been considered to be due to the resonance interaction between *p*-methoxyphenyl ring and the S atom having a discrete positive charge as shown in Fig. 3.

It is of interest that this observation can be used to determine the basicity of N atom of the sulfilimine group. The basicity of sulfilimine is shown in the following equation.

$$pK_a = H_0 + \log \frac{C_{B^+}}{C_A}$$

where

H_0: the acidity function

C_A and C_{B^+}: the concentrations of sulfilimine and protonated sulfilimine respectively.

When the decrease of 242 mμ band or the increase of 267 mμ band is measured, the pK_a value can be obtained from the H_0 when the sulfilimino group is half protonated. The value of pK_a of *S,S-p*-methoxyphenylmethyl-*N*-*p*-tolylsulfonylsulfilimine thus obtained is -1.78 and this value is considerably larger than that of *p*-tolylsulfonamide ($pK_a = -3.30$).[13] This fact indicates that the electron density on the N atom is increased in the form of a coordination of the lone electron pair of the S atom to the N atom.

NMR Chemical Shifts of *N*-*p*-Tolylsulfonylsulfilimines. The chemical shifts of sulfilimines are measured from TMS internal standard as a reference peak in $CDCl_3$.

N-*p*-Tolylsulfonylsulfilimine has an asymmetric center which may give the chemical shift difference between the protons of an adjacent methyl or methylene group, and the AB-type NMR spectrum due to magnetically non-equivalent protons is expected to be observed.

Actually benzyl protons of *S*-benzyl-*S*-phenyl-*N*-*p*-tolylsulfonylsulfilimine appear as double doublet ($J_{AB} = 13$ Hz). The chemical shifts of methyl protons attached to the S(IV) atom of *S*-methyl-*S*-*p*-tolylsulfilimine, sulfoxide and sulfone are 2.81, 2.69, 3.04 ppm respectively. This indicates that the sulfilimino group is somewhat more electron-withdrawing than the sulfoxide group but less than the sulfone group, while a substantial positive charge is centered on the S(IV) atom of *N*-*p*-tolylsulfonylsulfilimine.

From these IR, UV, NMR spectroscopic studies together with X-ray crystallographic data, *N*-*p*-tolylsulfonylsulfilimine is considered to be represented better by the ylide structure in which the charges on the S atom and the N atom are considerably delocalized with strong $d\pi$ conjugation into S(IV)–N–S(VI) bondings. Therefore the S–N bond of sulfilimino group is considered to be essentially semipolar.

Experimental

Preparation of Sulfilimines. All the *N*-*p*-tolylsulfonylsulfilimines were prepared from the reaction of corresponding sulfides and chloramine T by the same procedure described previously.[14] The melting points of sulfilimines are listed in Table 1.

Measurement of the Basicity of *S*-Methyl-*S*-*p*-methoxyphenyl-*N*-*p*-tolylsulfonylsulfilimine. UV spectra of *S*-methyl-*S*-*p*-methoxyphenyl-*N*-*p*-tolylsulfonylsulfilimine were taken in sulfuric acid of several concentrations (from 0% to 75%). Increase of the concentration of sulfuric acid gave a bathochromic shift for the shoulder at 242 mμ. In 75% sulfuric acid the sulfilimine gave two isolated bands at 234 and 267 mμ, but above 75% the pattern of the spectrum no longer altered. The height of the spectrum at the suitable wavelength, for instance 266 mμ was used for calculation of the concentration in the equation

$$pK_a = H_0 + n \log \frac{C_{B^\oplus}}{C_A} = H_0 + n \log \frac{h - h_0}{h_{75} - h}$$

where

H_0: acidity function

n: constant (1.0 for Hammet base)

h, h_0 and h_{75}; height of spectrum at 266 mμ

h; at an arbitrary concentration of sulfuric acid

h_0; at 0% sulfuric acid (no protonation)

h_{75}; at 75% sulfuric acid (completely protonated)

The pK_a value was obtained from the H_0 when the sulfilimine group is half protonated ($\log(h-h_0/h_{75}-h)=0$), see Fig. 4.

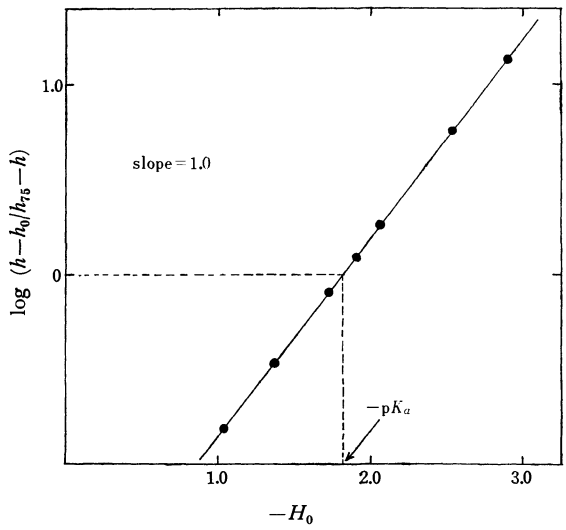

Fig. 4. Relations of $-H_0$ and log $(h-h_0/h_{75}-h)$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2159—2161 (1970)

The Preparation of α-Amino-α-benzylmercaptopropionic Acid Derivatives

Akira KANEDA and Rokuro SUDO

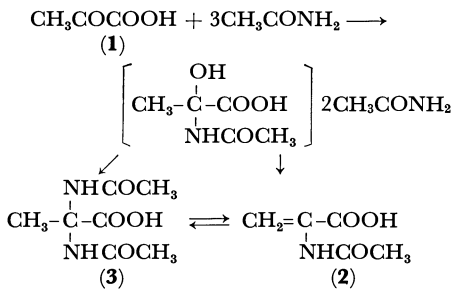
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received November 11, 1969)

The preparation of *N*-acyl derivatives of α-amino-α-benzylmercaptopropionic acid was investigated. It is described that pyruvic acid was treated with amides to afford *N*-acyl-α-amino-α-hydroxypropionic acids, which were then substituted into *N*-acyl-α-amino-α-benzylmercaptopropionic acids. In another experiment, Steglich's method was improved in order to afford three *N*-acyl derivatives of α-amino-α-benzylmercaptopropionic acid in a better yield.

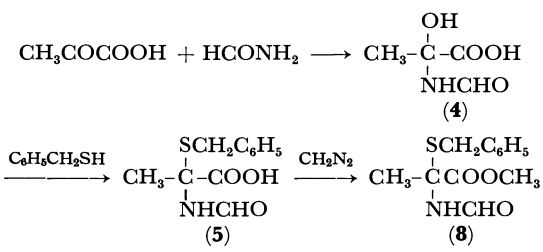
α-Amino-α-mercaptocarboxylic acid has not been isolated in a pure form, and only two methods for the preparation of its derivatives have been reported by Steglich[1] and by Shemiyakin.[2] This paper will report a simple method for the preparation of α-amino-α-benzylmercaptopropionic acid derivatives from pyruvic acid and also an improvement of Steglich's method to give a better yield.

It has been described[3] that pyruvic acid (**1**) was heated with acetamide to give α-acetamidoacrylic acid (**2**) and α,α-diacetamidopropionic acid (**3**), which were produced through the intermediate, a complex of α-acetamido-α-hydroxypropionic acid acetamide.

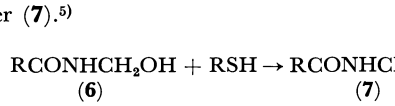


On the other hand, Shieve[4] reported that adding formamide to pyruvic acid (**1**) yielded α-formamido-α-hydroxypropionic acid (**4**), which was then isolated in a pure form.

When the acid **4** was refluxed with benzyl mercaptan in a benzene solution by means of the use of a water separator for 3 hr, 1 mol of water was separated and α-formamido-α-benzylmercaptopropionic acid (**5**) was obtained in a good yield.



The structure of Compound **5** was characterized by elementary analysis and by a study of its IR and NMR spectrum. This reaction process was supported by the fact that carbinolamine (**6**) was replaced by mercaptan to give aminomethyl thioether (**7**).[5]



After the α-formamido-α-benzylmercaptopropionic acid (**5**) had been neutralized with a sodium bicarbonate solution, it was converted to its methyl ester with diazomethane.

On the other hand, pyruvic acid (**1**) did not react with urethane at room temperature, unlike the case of formamide. However, when pyruvic acid was refluxed with urethane in a benzene solution, it gave α-ethoxycarbonylaminoacrylic acid (**9**). Thus, pyruvic acid, urethane, and benzyl mercaptan were heated together under 60°C for 3 hr; α-ethoxycarbonylamino-α-benzylmercaptopropionic acid (**10**) was thus obtained.

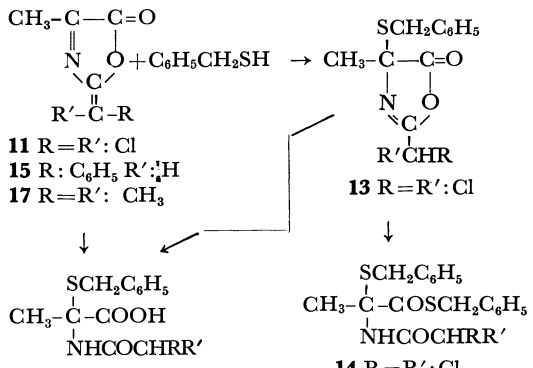
5) H. E. Zaugg, "Organic Reactions," Vol. 14, (1965), p. 113.

Similarly, acetamide and chloroacetamide did not give α-amino-α-mercaptocarboxylic derivative, but α-acetamidoacrylic acid and α,α-diacetamidopropionic acid derivatives were formed.

Moreover, another method was investigated. Steglich[1] has described how the mercaptolysis of 2-dichloromethylene-4-methy-3-oxazolin-5-one (**11**) with ethyl mercaptan in an acetic acid solution containing hydrogen bromide gave α-dichloroacetamido-α-ethylmercaptopropionic acid and its ethyl thioester at the same time.

In our study, however, when **11** was treated with benzyl mercaptan in a solvent such as methylene-dichloride or tetrahydrofuran (THF) under neutral conditions and at room temperature, it gave only 2-dichloromethylene-4-methyl-4-benzylmercapto-2-oxazolin-5-one (**13**) and no further addition of mercaptan was observed. In an acetic acid solution however, Compound **13** reacted with another molecule of mercaptan to give α-dichloroacetamido-α-benzylmercaptopropionic acid benzyl thioester (**14**). Compound **13** was hydrolyzed, in an acetic acid solution, into α-dichloroacetamido-α-benzylmercaptopropionic acid (**12**), which was also obtained directly in low yields by the reaction of **11** with benzyl mercaptan in an acetic acid solution containing a small amount of water. Similarly, 2-benzylidene-4-methyl-3-oxazolin-5-one (**15**) also reacted with benzyl mercaptan in a THF solution; subsequent hydrolysis gave α-phenylacetamido-α-benzylacetamido-α-benzylmercaptopropionic acid (**16**), and in the case of 2-isopropylidene-4-methyl-3-oxazolin-5-one (**17**) it did not react with benzyl mercaptan in an acetic acid or THF solution, but in an acetic acid solution containing hydrogen bromide, α-isobutyrylamido-α-benzylmercaptopropionic acid (**18**) was obtained.



Experimental

α-Formamido-α-hydroxypropionic Acid (4). This was prepared by the method of Shieve;[4] mp 53°C, yield 98%.

α-Formamido-α-benzylmercaptopropionic Acid (5). A benzene solution (50 m*l*) of **4** (6.6 g, 1/20 mol) was heated with benzyl mercaptan (6.2 g, 1/20 mol) under refluxing for 3 hr. After cooling, the solvent was removed and the residue was treated with a sodium bicarbonate solution. The water layer was washed with ether and acidified with dilute hydrochloric acid under cooling. An oily substance was thus separated and crystallized. Recrystallization from ethanol gave white needles with a mp of 148—149°C; yield 18 g (75%). IR bands (KBr), 3290 cm^{-1} (NH), 1685, 1705 cm^{-1} (COOH), 720 cm^{-1} (C_6H_5). NMR spectrum (DMSO, TMS as internal reference), τ 8.26 (3H, singlet) for CH_3, τ 6.12 (2H, doublet) for S-$CH_2C_6H_5$, τ 2.61 (5H, singlet) for C_6H_5, τ 1.90 (1H, singlet) for NH. This compound was hydrolyzed to pyruvic acid and benzyl mercaptan under refluxing for 1 hr in water. In an attempted debenzylation and deacylation, it was unsuccessful in isolating α-mercapto-α-amino acid itself in a pure form.

Methyl α-Formamido-α-benzylmercaptopropionate (8). To a solution of 2.39 g (1/100 mol) of **5** in ether, was added, drop by drop, a solution of diazomethane in ether until nitrogen-gas ceased to be evolved. The mixture was stirred at room temperature for 0.5 hr, and the excess diazomethane was treated with a small quantity of acetic acid. The mixture was then concentrated under reduced pressure. The residue was washed with a saturated sodium bicarbonate solution, extracted with ethyl acetate, and dried over anhydrous sodium sulfate. The evaporation of the organic layer afforded 2.40 g (95%) of a methyl ester of **5**. Recrystallization from dibutyl ether gave colorless crystals; mp 57—58°C. IR (KBr) 3290 cm^{-1} (NH), 1730 cm^{-1} ($COOCH_3$), 1665 cm^{-1} (CONHR), 700, 720 cm^{-1} (C_6H_5).

Found: C, 57.05; H, 6.25; N, 5.74%. Calcd for $C_{12}H_{15}NO_3S$: C, 56.91; H, 5.97; N, 5.53%.

α-Ethoxycarbonylamino-α-benzylmercaptopropionic Acid (10). Pyruvic acid (4.4 g, 1/20 mol) and ethyl carbamate (4.4 g, 1/20 mol) were dissolved in 50 m*l* of benzene. The solution was heated at 40°C for 1 hr, and then benzyl mercaptan (6.2 g, 1/20 mol) was added to this solution. The mixture was heated for 2 hr at 60°C. After the removal of the benzene, the residue was treated with a sodium bicarbonate solution. The water layer was washed with ether and then acidified with dilute hydrochloric acid under cooling. An oily substance which separated gradually crystallized on cooling. Recrystallization from ethylene dichloride-cyclohexane gave colorless prisms with a mp of 90—91°C; yield 8.2 g (58%). IR bands (KBr), 3300 cm^{-1} (NH), 1939 cm^{-1} ($COOC_2H_5$), 1660 cm^{-1} (COOH), 715 cm^{-1} (C_6H_5). NMR spectrum ($CDCl_3$, TMS as internal reference), τ 8.78 (3H, triplet) for CH_2CH_3, τ 8.06 (3H, singlet) for CH_3, τ 6.10 (2H, singlet) for S-CH_2-C_6H_5, τ 5.88 (2H, quartet) for CH_2CH_3, τ 2.15 (5H, singlet) for C_6H_5, τ 2.15 (1H, singlet) for COOH.

2-Dichloromethylene-4-methyl-3-oxazolin-5-one (11). This was prepared by the method of Steglich;[1] mp 77°C, yield 78%.

2-Benzylidene-4-methyl-3-oxazolin-5-one (15). This was prepared by the method of Filler;[6] mp 110—

6) R. Filler and E. J. Piasek, *J. Org. Chem.*, **28**, 221 (1963).

115°C, yield 85%.

2-Isopropylidene-4-methyl-3-oxazolin-5-one (17). This was prepared by the method of Bergmann;[7] bp 56°C/1.5 mmHg, yield 62%.

2-Dichloromethylene-4-methyl-4-benzylmercapto-2-oxazolin-5-one (13). In 50 m*l* of ethylene dichloride **11** (9.0 g, 1/20 mol) was dissolved, and to this solution was added benzyl mercaptan (12.4 g, 1.0 mol). The resulting solution was kept at room temperature for 24 hr. After the evaporation of the solvent, the residual benzyl mercaptan was removed by distillation under reduced pressure. The residue was chromatographed on an alumina column in benzene to afford a syrup. This syrup could not be distilled and crystallized; yield, 11.0 g (62%). IR bands (liquid film), 1805 (C=O) and 1650 cm^{-1} (C=N). NMR bands ($CDCl_3$, TMS was used as the internal reference), τ 7.84 (3H, singlet) for CH_3, τ 6.18 (2H, singlet) for $C_6H_5CH_2$, τ 4.01 (1H, singlet) for $CHCl_2$, and τ 2.72 (5H, singlet) for $C_6H_5CH_2$.

Found: C, 47.66; H, 3.74; N, 4.36%. Calcd for $C_{12}H_{11}O_2SNCl_2$: C, 47.37; H, 3.62; N, 4.61%.

α-Dichloroacetamido-α-benzylmercaptopropionic Acid-*S*-Benzylester (14). To a solution of **13** (6.1 g, 1/50 mol) in 50 ml of acetic acid was added 2.5 g (1/50 mol) of benzyl mercaptan. The resulting mixture was kept at room temperature for 48 hr. After the evaporation of the solvent, the residue was chromatographed on an alumina column in benzene to afford a crude product, which was recrystallized from isopropyl alcohol to give colorless prisms; mp 94—95°C, yield 4.2 g (50%). IR bands (KBr), 1690 cm^{-1} ($COSCH_2C_6H_5$), 1680 and 1560 cm^{-1} (CONH).

Found: C, 53.48; H, 4.54; N, 3.42%. Calcd for $C_{19}H_{19}O_2NS_2Cl_2$: C, 53.25; H, 4.44; N, 3.27%.

α-Dichloroacetamido-α-benzylmercaptopropionic Acid (12). a) In 50 m*l* of acetic acid containing a small amount of water was dissolved 6.1 g (1/50 mol) of **13**. The resulting mixture was kept at room temperature for 48 hr. After the evaporation of the solvent, the oily residue was dissolved in a sodium bicarbonate solution and washed with ether. The aqueous solution was acidified with dilute hydrochloric acid under cooling. An oily substance which separated crystallized standing. The crystals were recrystallized from acetic acid to give colorless prisms; mp 166—167°C, yield 4.2 g (65%). IR bands (KBr), 3300 cm^{-1} (NH), 1713 cm^{-1} (COOH), 1685 and 1542 cm^{-1} (CONH).

b) To a solution of **11** (9.0 g, 1/20 mol) in 50 m*l* of acetic acid was added 6.2 g (1/20 mol) of benzyl mercaptan and a small amount of water. The resulting mixture was kept at room temperature for 2 days and they treated by a procedure similar to a) above to yield compound **12**.

α-Phenylacetamido-α-benzylmercaptopropionic Acid (16). To a solution of **15** (9.5 g 1/20 mol) in 50 m*l* of THF was added 6.2 g (1/20 mol) of benzyl mercaptan. The resulting mixture was kept at room temperature for 24 hr. After the removal of the solvent, the residue was dissolved in a mixture of 30 m*l* of acetic acid and 10 m*l* of water, and the resulting mixture was heated for 5 hr. After the removal of the acetic acid, the residue was neutralized with a sodium bicarbonate solution. This solution was acidified with dilute hydrochloric acid to give crystals. Recrystallization from ethyl acetate gave colorless crystals; mp 157—158°C, yield 11 g (66.7%). IR bands (KBr), 3300 cm^{-1} (NH), 1710 cm^{-1} (COOH), 1628 and 1516 cm^{-1} (NHCO).

α-Isobutyrylamido-α-benzylmercaptopropionic Acid (18). In an acetic acid solution containing 20% hydrogen bromide **17** was treated by a procedure similar to **16**. The recrystallization of a crude product from ethylene dichloride gave colorless prisms; mp 114—115°C, yield 40%. IR bands (KBr), 3330 cm^{-1} (NH), 1730 cm^{-1} (COOH) and 1615 cm^{-1} (NHCO).

Photoreaction of Acetoacetate

Masaru TADA, Tadayoshi KOKUBO and Tadashi SATO

School of Science and Engineering, Waseda University, Shinjuku, Tokyo

(Received November 14, 1969)

Methyl acetoacetate was irradiated in the presence of cyclohexene to afford methyl 3-cyclohexyl-3-hydroxybutyrate (VIII), methyl 3-cyclohexenyl-3-hydroxybutyrate (IX), two oxetanes (Xa and Xb), and cyclohexene dimers. In contrast to acetylacetone, acetoacetate behaves as a saturated ketone rather than as an α,β-unsaturated ester on photoreaction. We concluded that the n-π^* excitation of the enol-form of β-dicarbonyl compound is responsible for photo-cycloaddition, and no effective n–π^* excitation is accesisble on irradiaron of the enol-form of acetoacetate, since the enol form of acetoacetate has its n–π^* and π–π^* absorptions in the same region.

Ultraviolet irradiation of saturated ketone in the presence of olefin gives oxetanes. β-Diketone and olefin, on the other hand, give cyclobutanes under the same condition.

Bradshaw[1] reported the formation of oxetane I, unsaturated alcohol II, and olefin dimer III on irradiation of acetone in the presence of cyclohexene. De Mayo and Takeshita[2] reported that irradiation of acetylacetone in the presence of cyclohexene afforded cyclobutane derivative IV, which was transformed to diketone V by heat. This feature of 1,3-diketone can be accounted for by the excitation of the enol-form of acetylacetone, which is the predominant species under the reaction condition. β-Ketoester is also well known to enolize to a reasonably high extent in non-polar solvents.[3] If the enol-form of β-ketoester is responsible for the photo-cycloaddition, we may expect the formation of hydroxyester VI.

Our purpose in this work was to pursue the behaviour of acetoacetic ester, as saturated ketone or unsaturated ester, on irradiation in the presence of olefin.

Results and Discussion

Irradiation of methyl acetoacetate and cyclohexene with a high pressure mercury lamp gave products which were separated into C_{12}-hydrocarbons and addition products between methyl acetoacetate and cyclohexene. The structures of C_{12}-hydrocarbons were assigned to be the two isomers of tricyclododecanes (VIIa and VIIb) and bicyclohexenyl (III) respectively. The structures of VIIa and VIIb were deduced mainly from the mass spectra which showed peaks at $m/e=164$ (molecular peak), 82, and 67 for both isomers. The last two peaks are characteristic of cyclohexene[4] which is formed by the ring opening of the tricyclododecanes. Hydrocarbon III was identified with bicyclohexenyl which was unambiguously synthesized. The fraction of the adducts between acetoacetate and cyclohexene consists mostly of four components; saturated hydroxy ester VIII, unsaturated hydroxy ester IX, and two isomers of oxetanes Xa and Xb in the ratio of *ca.* 1.0 : 1.5: 2.4 : 2.2.

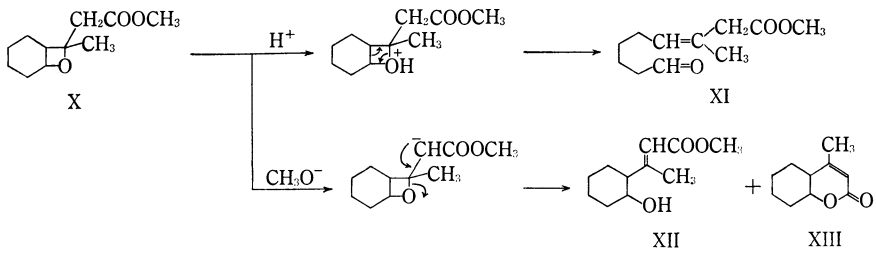

Fig. 1. Chemical behaviour of the oxetanes toward acid and base.

by the Reformatsky reaction between acetylcyclohexane and methyl bromoacetate. The structure of adduct IX was deduced to be methyl 3-(2-cyclohexenyl)-3-hydroxybutyrate from IR and NMR spectra, and was confirmed by the formation of adduct VIII by hydrogenation.

The oxetane-structures of adducts Xa and Xb were indicated by characteristic NMR signals[1] at 4.65 ppm due to the hydrogens attached to $C_6(H_a)$, and was further confirmed by the chemical behaviour toward acid and base. Acid treatment of the mixture of Xa and Xb gives two isomers of aldehyde XIa and XIb (IR: 2720, 1725 cm^{-1}, NMR: 9.62 ppm) besides a small amount of methyl acetoacetate and cyclohexene (Fig. 1). The cleavage of oxetane by acid is well known.[5] Base treatment of Xa and Xb, on the other hand, produces the hydroxyester XII (3470, and 1725 cm^{-1}) and δ-lactone XIII (1710 cm^{-1}).

NMR signals of oxetane at 4.65 ppm due to H_a are a sextet with a half-band width of 14 Hz for Xa (Fig. 2) and a quintet with a half-band width of 17 Hz for Xb, respectively. Spin decoupling between C_5-methylene (H_c and H_d) and H_a of Xa gives a doublet for H_a with a coupling constant 7 Hz (J_{ab}). Oxetane Xb gives essentially the same result except for the coupling constant between H_a and H_b being 8 Hz.

These values of J_{ab} suggest that H_a and H_b are *cis* and the oxetane rings are *cis*-fused to cyclohexane ring. This feature is further supported by the half-band width of H_a-signal and the coupling constant between H_a and C_5-methylene: $J_{ac}=J_{ad}=2.5$ Hz for Xa, and $J_{ac}=J_{ad}=4.0$ Hz for Xb. If the ring junction were *trans*, both H_a and H_b would have to occupy *quasi*-axial conformation with respect to the cyclohexane ring. In this case H_a and one of the hydrogen of C_5-methylene (H_c or H_d) must be in the relation of *trans quasi*-diaxial regardless of the conformation of the cyclohexane ring, and the larger half-band width would be observed.[6] Thus the two oxetanes must be configurational isomers at C_8. The chemical shifts of methyls (1.50 ppm for Xa and 1.33 ppm for Xb)[1] and methylene bearing carbomethoxy groups (2.60 ppm for Xa and 2.72 ppm for Xb) are in good accordance with the struc-

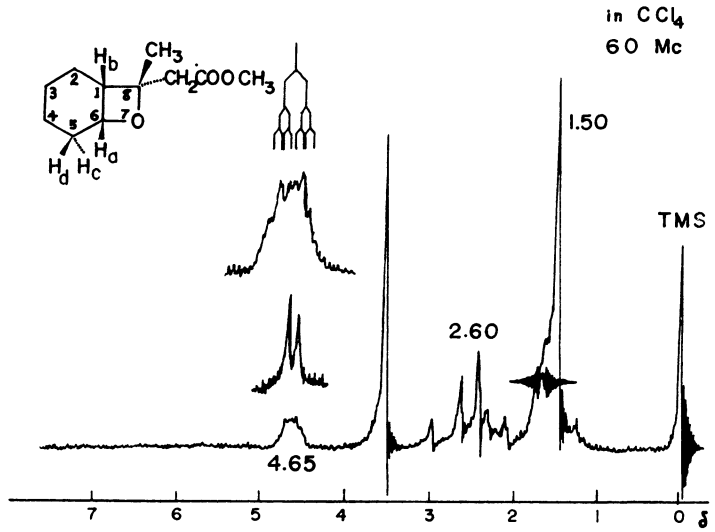

Fig. 2. NMR spectrum of oxetane Xa.

6) N. S. Bhacca and D. H. Williams, "Applications of NMR Spectroscopy in Organic Chemistry: Illustrations from the Steroid Field," Holden-Day, Inc., San Francisco (1964), p. 51.

tures Xa and Xb. The anisotropic effect of C_1–C_2 bond would shift to a higher field the signals of the group which is *cis* to the C_1–C_2 bond. None of the *trans* isomers other than these *cis*-oxetanes was detected at least from VPC analysis.

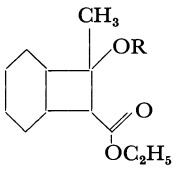
Types of products III, IX, Xa and Xb correspond to the irradiation products between acetone and cyclohexene reported by Bradshaw.[1] Thus the keto-form of acetoacetate must be responsible for the present photoreaction. We may expect the formation of adduct VI in the same fasion with acetylacetone, if the enol-form of acetoacetate is responsible in photoreaction. No such adduct, however, could be detected and the enol-form must be inert to the photo-cycloaddition under these irradiation.

During the course of confirming the inertness of the enol-form, the following results were obtained.

1) Irradiation of acetoacetate and cyclohexene in *n*-hexane, instead of benzene, gave the same results as in the case of the irradiation of the mixture in benzene, except for the lack of tricyclododecane (VII) in the product-mixture. Tricyclododecane was formed by the sensitization effect of benzene.

2) Irradiation with a low pressure mercury lamp (emitting strong line at 2537 Å) resulted in the production of the adducts in poor yield.

3) The enol-form of ethyl acetoacetate was fixed by making its ether (*β*-ethoxycrotonate), and acetate (*β*-acetoxycrotonate). Irradiation of these derivatives in the presence of cyclohexene did not give the expected adducts XIV and XV.



XIV: R=C_2H_5

XV: R=$COCH_3$

In view of these facts, it can be concluded that the enol-form of acetoacetate does not undergo cycloaddition at least by π–π^* excitation (246 mμ). Though n–π^* excitation of the enol-form might cause the cycloaddition, the effective n–π^* excited state is inaccessible in these systems.

Although acetylacetone (*ca.* 96% enol in *n*-hexane)[3] has a single absorption band at 272 mμ (Fig. 3), its enol ether discriminates the n–π^* band (308 mμ; ε=70) from the π–π^* band (248 mμ; ε=15900). Though we can not observe a distinct absorption maximum, the enol-form of acetylacetone must have n–π^* band in the same region as in the n–π^* band of its enol ether (308 mμ). This n–π^* excitation is believed to be responsible for the cycloaddition giving adduct IV though without rigorous evidence.[2] On the other hand, acetoacetate and its enol ether have π–π^* absorption at 246 mμ (due to enol-form, 51% in *n*-hexane)[3] and 230 mμ respectively, in *n*-hexane, and the n–π^*

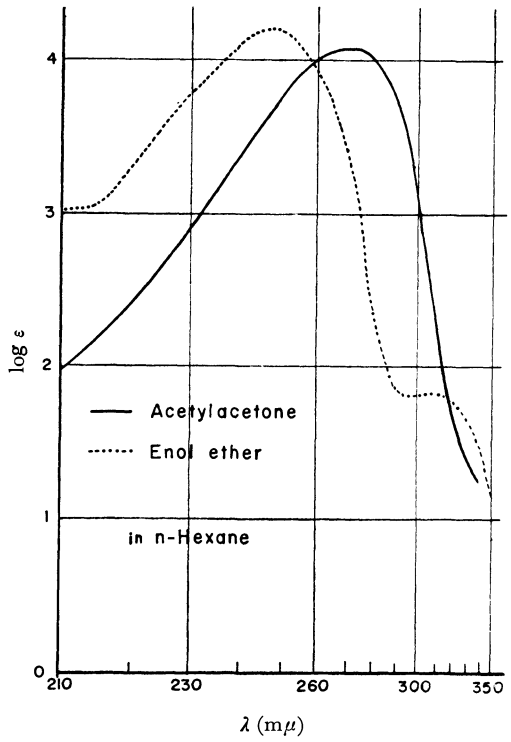


Fig. 3. UV spectra of acetylacetone and its enol ether.

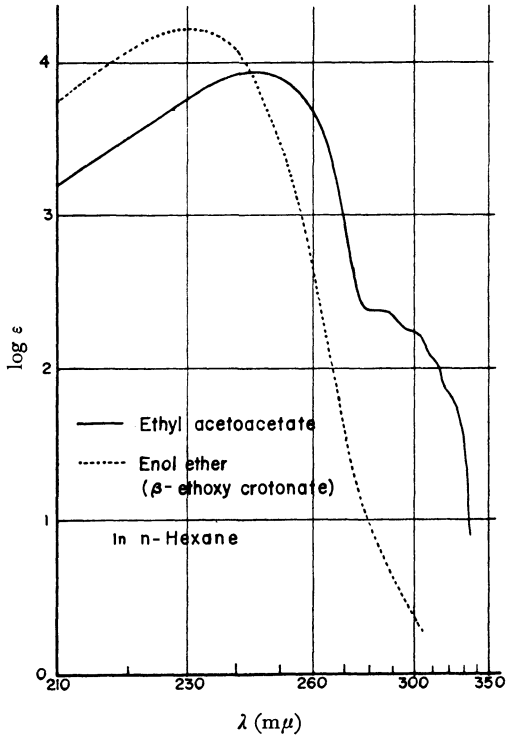

Fig. 4. UV spectra of ethyl acetoacetate and its enol ether.

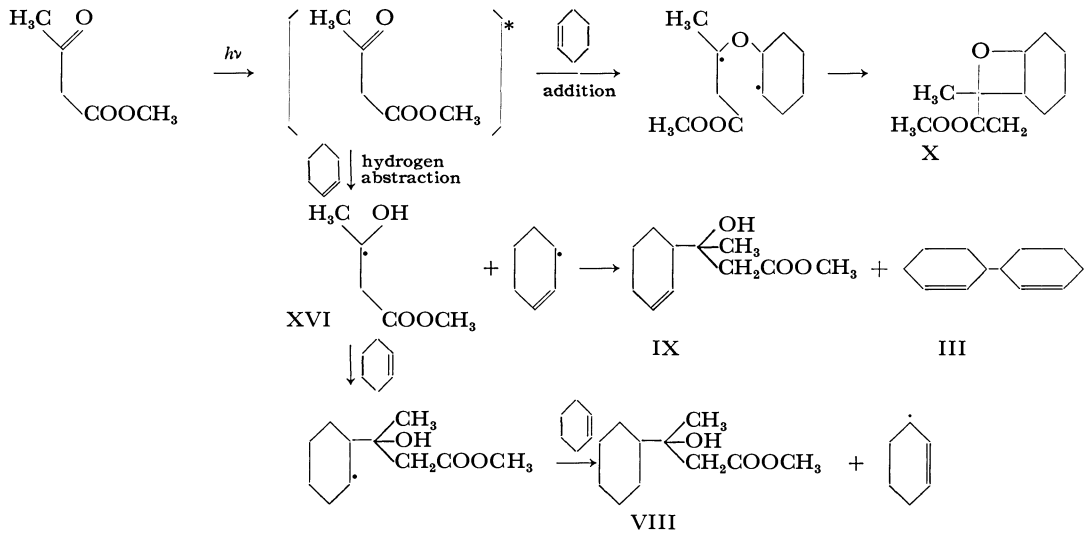

Fig. 5. Reaction scheme.

band of the enol-form can not be observed in both cases. An α,β-unsaturated ester usually has an n–π^* absorption around 240 mμ which is buried under the strong π–π^* absorption.[7] Attachment of hydroxy at β-position of α,β-unsaturated ester shifts the π–π^* absorption to longer wave length (*ca.* 40 mμ), while it possibly affects the n–π^* absorption a little.[8] The n–π^* absorption of the enol-form of acetoacetate, therefore, might be located in the same region as in its π–π^* absorption and the effective excited state (n–π^*) for the photo-cycloaddition can not be achieved.

UV spectrum of acetoacetate in n-hexane shows an absorption at 246 mμ (ε=8100) due to the π–π^* excitation of the enol-form and the shoulder at 285 mμ (ε=68) due to the n–π^* excitation of the keto-form. The latter excitation takes part in the formation of oxetane and the hydrogen abstraction from cyclohexene.

On the basis of the above discussion, the reaction of acetoacetate with cyclohexene can be rationalized as a process involving the n–π^* excitation of the keto-form of acetoacetate and can be represented by the scheme in Fig. 5. Formation of the saturated alcohol VIII can be envisaged by the initial coupling of the radical intermediate XVI and cyclohexene. The mechanism involving the coupling of cyclohexyl radical and the radical XVI can be eliminated by the fact that no bicyclohexyl can be detected in the reaction products.

Bicyclohexenyl (III) must originate from the coupling of two cyclohexenyl radicals formed by hydrogen abstraction. Formation of tricyclododecane (VII) is attributable to the sensitization by benzene used as solvent. This sensitization can be shown by the fact that cyclohexene itself gave VII on irradiation in benzene and the irradiation of acetoacetate and cyclohexene in n-hexane, instead of benezne, gave no tricyclododecane.

Experimental

Irradiation of Methyl Acetoacetate and Cyclohexene. Methyl acetoacetate (29.0 g) and cyclohexene (82.0 g) in 350 m*l* of benzene were internally irradiated with a 450 W high pressure mercury lamp (USHIO UM-452) through a quartz immersion well in the conventional manner. Most of acetoacetate disappeared after irradiation for 14 hr and the solvent was removed under reduced pressure.

Separation and Structure of Photo-products. The crude products were distilled into two fractions, A: bp 40—50°C/1.5 mmHg, 2.4 g, and B: bp 80—90°C/1.5 mmHg, 21.8 g. Fraction A showed mainly three peaks at 7.0 (VIIa), 8.5 (VIIb), and 14.5 min (III) in the ratio of 1 : 3 : 1 on VPC analysis (2.2 m×6 mm, 10% PEG-20M on Chromosorb-W, 140°C). These products were separated and purified by preparative VPC. VIIa and VIIb were deduced to be tricyclo[6.4.0.$0^{2,7}$]dodecane. Product III was identified with the authentic sample of bicyclohexenyl.

VIIa. Mass: strong peaks at m/e=164 (M^+, $C_{12}H_{20}$), 82, 81, and 67 (base peak). IR (neat): 2850, 1445, 1340, 950 and 910 cm^{-1}. NMR (CCl_4): no olefinic hydrogen.

VIIb. Found: C, 87.62; H, 12.23%. Calcd for $C_{12}H_{20}$: C, 87.73; H, 12.27%. Mass: strong peaks at m/e=164 (M^+, $C_{12}H_{20}$), 82 (base peak), 81, and 67. IR (neat): 2850, 1449, 1320, 917, and 873 cm^{-1}. NMR (CCl_4): no olefinic hydrogen.

III. Found: C, 88.52; H, 11.17%. Calcd for $C_{12}H_{18}$: C, 88.82; H, 11.18%. IR (neat): 3010, 1650, 1435, 730, and 650 cm^{-1}. NMR (CCl_4): 5.6 ppm (4H, -CH=CH-).

Fraction B contains the adducts between acetoacetate and cyclohexene and shows four peaks at 13.4 (VIII),

14.3 (IX), 16.3 (Xa), and 20.0 min (Xb) in the ratio of 1.0 : 1.5 : 2.4 : 2.2 on VPC analysis (2.5 m×6 mm, 10% PEG-20M on Chromosorb-W, 180°C). These adducts were separated by preparative VPC.

VIII. Found: C, 66.17; H, 9.90%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%. IR (neat): 3560, 1717, 1200, 1005, and 893 cm^{-1}. NMR (CCl_4):*1 3.63 ($-OCH_3$), 3.2 (-OH), 2.35 (q, J_{ab}=15 Hz, $-CH_2-COO-$), 1.10 ($-CH_3$), 0.8—2.0 ppm (11H).

IX. Found: C, 66.92; H, 9.43%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. IR (neat): 3550, 3020, 1720, 1205, 1005, 893, and 725 cm^{-1}. NMR (CCl_4): 5.67 (diffused d, J=5 Hz, -CH=CH-), 3.63 ($-OCH_3$), 3.3 (-OH), 2.38 (q, J_{ab}=15 Hz, $-CH_2-COO-$), 1.2—2.3 (7H), 1.16 and 1.09 ppm ($-CH_3$, 1.5H for each of the two peaks, both singlet due to the diastereomeric nature of IX).

Xa. Found: C, 66.35; H, 8.89%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. IR (neat): 1740, 1195, 1095, 995, 953, 925, and 883 cm^{-1}. NMR (CCl_4): 4.65 (sextet, >CH-O-), 3.60 ($-OCH_3$), 2.60 (q, J_{ab}=16 Hz, $-CH_2-COO-$), 2.4 (multiplet, >CH-), 1.50 ($-CH_3$), 1.2—1.9 ppm (8H).

Xb. Found: C, 66.32; H, 9.16%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. Mass: m/e=198 (M^+, $C_{11}H_{18}O_3$). IR (neat): 1740, 1195, 1092, 1008, 940, and 885 cm^{-1}. NMR (CCl_4): 4.65 (quintet, >CH-O-), 3.60 ($-OCH_3$), 2.72 (q, J_{ab}=15 Hz, $-CH_2-COO-$), 2.6 (multiplet, >CH-), 1.33 ($-CH_3$), and 1.2—1.9 ppm (8H).

Irradiation of Methyl Acetoacetate and Cyclohexene in *n*-Hexane. Methyl acetoacetate (3.94 g) and cyclohexene (14.0 g) in 100 m*l* of purified *n*-hexane were internally irradiated with a 100 W high pressure mercury lamp (Rikosha, UVL-700) through a quartz jacket. After irradiation for 40 hr, most of the starting acetoacetate disappeared and VPC analysis showed that the composition of the adducts was the same as that from the irradiation using benzene as solvent.

Irradiation of Enol-ether of Methyl Acetoacetate. A mixture of ethyl β-ethoxycrotonate[9] (1.0 g), cyclohexene (3.0 g) and 10 m*l* of *n*-hexane was placed in a quartz tube and was externally irradiated with a 450 W high pressure mercury lamp. VPC analysis showed that essentially no change had occured in the starting mixture.

Irradiation by a Low Pressure Lamp. Methyl acetoacetate (3.94 g) and cyclohexene (14.0 g) in 100 m*l* of *n*-hexane were internally irradiated with a 30 W low pressure mercury lamp (Rikosha UVL-300). After irradiation for 6.5 hr, VPC analysis showed that less than two per cent of the starting ester had been converted to the photo-products.

Synthesis of Bicyclohexenyl (III). Bicyclohexenyl was synthesized by an allyl coupling of 3-bromocyclohexene *via* its Grignard reagent. The reaction was carried out in the conventional manner to prepare the Grignard reagent. A mixture of 3-bromocyclohexene (6.50 g), magnesium tunings (1.07 g) and catalytic amount of iodine in dry ether (50 m*l*) was stirred overnight at room temperature under nitrogen. Work up in the usual manner and alumina chromatography gave bicyclohexenyl (1.0 g), which was identical with the product III on IR and VPC analysis.

Found: C, 88.69; H, 11.28%. Calcd for $C_{12}H_{18}$: C, 88.82; H, 11.18%.

Methyl 3-Cyclohexyl-3-hydroxybutyrate (VIII). Acetylcyclohexane (2.58 g) and freshly distilled methyl bromoacetate (3.06 g) were dissolved in 20 m*l* of dry benzene - toluene (1 : 1). To the solution was added activated zinc powder (1.31 g) and trace amount of iodine, and the reaction mixture was refluxed for 3 hr. To the reaction mixture was added dilute sulfuric acid after cooling and the organic layer was separated. The aqueous layer was further extracted with benzene, and the combined extract was washed with aqueous sodium bicarbonate and water. Evaporation of the solvent and distillation of the products after drying over magnesium sulfate gave methyl 3-cyclohexyl-3-hydroxybutyrate; bp 98—99°C/2.5 mmHg, 1.05 g (25% yield). This product was identical with the adduct VIII on IR, NMR, and VPC analysis.

Hydrogenation of the Adduct (IX). The 1 : 1 mixture of the adducts VIII and IX (400 mg) in 5 m*l* of ethanol was hydrogenated over 10% palladium - charcoal (40 mg) in the usual manner. The product consists only of the adduct VIII on IR, NMR, and VPC analysis.

Base Treatment of Oxetanes (X). The mixture of the photo-adducts (4.30 g) was dissolved in 140 m*l* of 1% sodium methoxide - methanol and was stirred overnight at room temperature. After neutralization of the reaction mixture by bubbling carbon dioxide, the solvent was evaporated and the products were dissolved in ether. Distillation under reduced pressure separated the intact adducts (VIII and IX) (fraction A; bp 95—97°C/2.0 mmHg, 1.40 g) and the degradation products (XII and XIII) from oxetanes (fraction B; bp 110—120°C/2.0 mmHg, 1.20 g). No oxetane was detected in the product-mixture. Fraction A accompanied a small amount of the α,β-unsaturated esters which were formed from the adducts VIII and IX. Fraction B consisted of hydroxy-α,β-unsaturated esters (XII) and δ-lactone XIII, which were formed by the ring opening of the oxetanes, in the ratio of 1 : 1. XII and XIII were separated and purified by preparative VPC (2.2 m ×6 mm, 10% PEG-20 M on Chromosorb-W, 200°C).

XII. Found: C, 66.25; H, 8.77%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. Mass: m/e=198 (M^+, $C_{11}H_{18}O_3$). IR (neat): 3470, 1725, 1642, 980, and 865 cm^{-1}. NMR (CCl_4): 5.65 (q, J=1.0 Hz, =CH-), 4.06 (diffused, >CH-O-), 3.66 ($-OCH_3$), 2.17 (d, J=1.0 Hz, $-CH_3$), and 1.2—2.4 ppm (10H).

XIII. Mass: m/e=166 (M^+, $C_{10}H_{14}O_2$). IR (neat): 1710, 1640, 990, and 856 cm^{-1}. NMR (CCl_4): 5.60 (q, J=1.5 Hz, =CH-), 4.40 (multiplet, >CH-O-), 1.95 (d, J=1.5 Hz, $-CH_3$), and 2.3—1.0 ppm (9H).

Acid Treatment of Oxetanes (X). A mixture of the photo-adducts (2.40 g) in 50 m*l* of methylene chloride was treated with *p*-toluenesulfonic acid (50 mg), and the mixture was stirred overnight at room temperature. The solvent was removed after neutralization of the solution with aqueous sodium bicarbonate and drying over magnesium sulfate. VPC analysis showed that the alcohol (VIII and IX) persisted on acid treatment and the oxetanes (X) were converted into aldehydes (XIa and XIb) in *ca.* 70% yield and to the hydroxy-α,β-unsaturated esters (XII), which were also formed by base treatment, in *ca.* 30% yield. The aldehydes

*1 The following abbreviations were used to show signal patterns. s: singlet, d: doublet, t: triplet, q: quartet.

9) E. E. Smissman and A. N. Voldeng, *J. Org. Chem.*, **29**, 3161 (1964).

were separated by distillation under reduced pressure (bp 90—100°C/2.0 mmHg) from the products-mixture and were purified by preparative VPC (2.2 m × 6 mm, 10% PEG-20M on Chromosorb-W, 200°C).

XIa. Found: C, 66.65; H, 9.28%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. IR (CCl_4): 2720, 1740, 1725, 1205, 1170, and 1015 cm^{-1}. NMR (CCl_4): 9.62 (t, J=2.0 Hz, -CHO), 5.32 (t, J=7.0 Hz, =CH-), 3.58 ($-OCH_3$), 2.90 (s, $-CH_2-COO-$), 2.36 (t, J=7.0 Hz, $-CH_2\diagdown C=O$), 1.98 (t, J=7.0 Hz, $-CH_2\diagdown C=$), 1.75 ($-CH_3$), and 1.2—1.7 ppm (4H).

XIb. Found: C, 66.28; H, 9.05. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%. IR (CCl_4): 2720, 1740, 1725, 1260, 1160, and 1015 cm^{-1}. NMR (CCl_4): 9.62 (t, J=2.0 Hz, -CHO), 5.16 (t, J=7.0 Hz, =CH-), 3.58 ($-OCH_3$), 2.86 (s, $-CH_2-COO-$), 2.36 (t, J=7.0 Hz, $-CH_2\diagdown C=O$), 2.00 (t, J=7.0 Hz, $-CH_2\diagdown C=$), 1.66 ($-CH_3$), and 1.2—1.7 ppm (4H).

Aldehydes XIa and XIb were also formed during the VPC analysis when Chromosorb-P, instead of Chromosorb-W, was used as support for liquid phase (10% PEG-20M on Chromosorb-P, 160°C).

Reactions of Some Olefins with *N*-Chlorourea in the Presence of Acetonitrile

Yasuo WADA

Koei Chemical Co., 645, *Hanaten, Jyoto-ku, Osaka*

and Ryohei ODA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received November 24, 1969)

A new three-component reaction of *N*-chlorourea, olefins and acetonitrile is reported. Styrene gives *N*-(1-ureidoethylidene)-2-choro-1-phenylethylamine, *N*-(2-chloro-1-phenylethyl)acetamide and 4-phenyl-2-oxazolidone. Addition proceeds in a Markovnikov manner as shown by structural evidence. Cyclohexene gives *N*-(1-ureiodoethylidene)-2-chlorocyclohexylamine and *N*-(2-chlorocyclohexyl)acetamide. The stereochemistry of the reaction has been shown to be *trans* as demonstrated by chemical and physical evidence. Mechanisms for the reaction are proposed.

The chemistry of *N*-chlorourea given in literature is restricted predominantly to aqueous or alcoholic systems. In these cases *N*-chlorourea acts simply as a mild chlorinating or oxidizing agent. The present paper describes a new type of three-component reactions of *N*-chlorourea for the synthesis of *N*-(1-ureidoalkylidene)-2-chloroalkylamines and *N*-(2-chloroalkyl)amides. The synthesis involves interaction of *N*-chlorourea and olefin in the presence of a nitrile to give *N*-(1-ureidoalkylidene)-2-chloroalkylamine and imidochloride that can be hydrolyzed to an *N*-(2-chloroalkyl)amide.

In 1948, Ritter and co-workers discovered the reaction of nitriles with olefins in strongly acidic media to form *N*-substituted amides.[1,2]

The reaction can be explained to proceed *via* carbonium ion which is formed by addition of proton to olefins. Cairns and co-workers have discovered that halonium ion which is formed by addition of positive halogen to olefins can react with nitriles to form *N*-substituted amide.[3]

We have found the reaction of *N*-chlorourea with olefins in the presence of nitrile. The reaction has been shown to proceed in two steps.

The first step gives *N*-(1-ureidoalkylidene)-2-chloroalkylamine, chloroimide chloride and chlorinated hydrocarbon arising from the original olefin, and the second step gives an *N*-(2-chloroalkyl)-amide by the hydrolysis of chloroimide chloride.

The interaction of *N*-chlorourea and olefin in the presence of nitrile is postulated to proceed as follows:

$$NH_2CONHCl \longrightarrow Cl^+ + NH_2CONH^- \quad (1)$$

$$RCH=CH_2 + Cl^+ \longrightarrow RC^+HCH_2Cl \quad (2)$$

$$RC^+HCH_2Cl \xrightarrow{R'CN} RCHCH_2Cl \quad (3)$$

$$\qquad\qquad\qquad\qquad\qquad\qquad\quad \underset{+}{N}{=}CR' \quad [I]$$

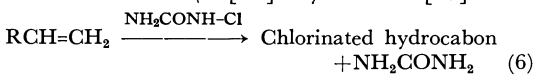
(5)

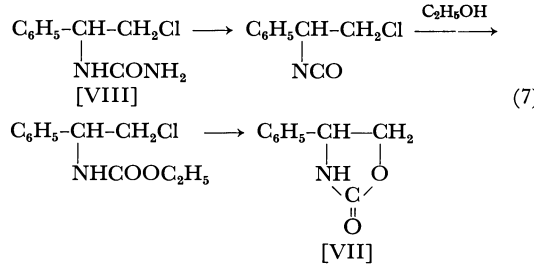


(6)

The chlorine attached to nitrogen has a positive halogen character and attacks olefin as an acidic substance Cl^+ to form a carbonium ion RC^+HCH_2Cl which may combine with nitrile. The carbonium ion [I] can be stabilized by reaction (4) with a negative ion NH_2CONH^- to produce *N*-(1-ureidoalkylidene)-2-chloroalkylamine [II]. [II] was isolated and analyzed but could not be hydrolyzed to *N*-(2-chloroalkyl)amide [IV]. Therefore, [IV] is not a hydrolyzed product of [II]. It is supposed that the carbonium ion [I] can also be stabilized by reaction (5) with a negative ion Cl^- derived from hydrogen chloride which is present in reaction medium as an impurity to produce chloroimide chloride [III]. [III] could not be isolated. But as reported by Cairns,[3] *N*-(2-chloroalkyl)amide is probably a hydrolyzed product of [III]. Reactions (4) and (5) are competing reactions and the products [II] and [IV] are expected. This interaction is a special case of the so-called Ritter reaction.[1,2]

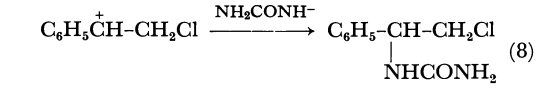
We have studied the interaction of *N*-chlorourea with styrene and cyclohexene in the presence of acetonitrile.

Styrene reacted with *N*-chlorourea and acetonitrile at 10°C within 2.5 hr to give *N*-(1-ureidoethylidene)-2-chloro-1-phenylethylamine [V] and *N*-(2-chloro-1-phenylethyl)acetamide [VI] after treating the reaction product with water. The reaction mixture was evaporated *in vacuo*, the residue was treated with water, and the aqueous solution was extracted with benzene. From the organic layer *N*-(2-chloro-1-phenylethyl)acetamide [VI] was obtained by vacuum distillation. Neutralization of the aqueous layer with sodium hydroxide resulted in immediate precipitation of *N*-(1-ureidoethylidene)-2-chloro-1-phenylethylamine [V]. It was separated by filtration, washed with water and analyzed correctly. On evaporation of the aqueous filtrate, extraction of the residue with ethyl alcohol and distillation of the extract *in vacuo*, 4-phenyl-2-oxazolidone [VII] was obtained in poor yield. It is well known that isocyanates are formed on heating urea derivatives. Hassner and coworkers[4] have shown that 4-phenyl-2-oxazolidone can be obtained by heating β-iodoalkane isocyanate with alcohol. Katchalsky and co-workers[5] have also shown that β-halocarbamate may be converted to 2-oxazolidone by pyrolysis at 120—200°C. A reaction scheme consistent with the obtained product is as follows:



(7)

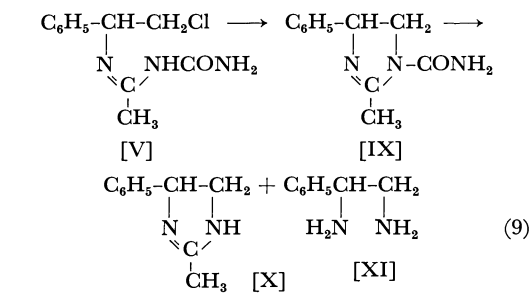
This suggests that the carbonium ion $R\overset{+}{C}HCH_2Cl$ was stabilized by NH_2CONH^- to produce *N*-(2-chloro-1-phenylethyl)urea [VIII].



(8)

4-Phenyl-2-oxazolidone [VII] was characterized by identity of its melting point (137—137.5°C) and infrared spectrum with that of the known authentic compound prepared from styrene and iodine isocyanate followed by reaction with ethyl alcohol.[4] For 5-phenyl-2-oxazolidone the reported melting point is 88.8—90.2°C.[6]

The direction of addition is such that Cl^+ ion combines with the less substituted carbon. The composition and the structure of *N*-(1-ureidoethylidene)-2-chloro-1-phenylethylamine [V] were established by elemental analysis and infrared spectra. The spectrum shows essentially the patterns of urea, C–Cl, monosubstituted benzene and C=N bond. The structure of [V] was also established by its conversion, on treatment with aqueous sodium hydroxide solution, to 1-aminocarbonyl-2-methyl-4-phenyl-2-imidazoline [IX] and further to 2-methyl-4-phenylimidazoline [X] and 1,2-diaminoethylbenzene [XI].



(9)

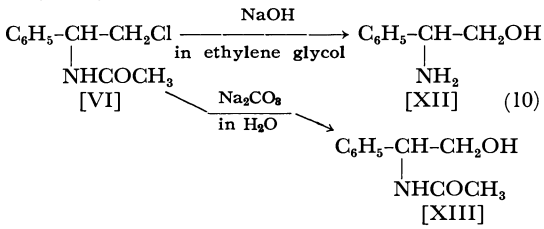
4) A. Hassner, M. E. Lobber and C. Heathcock, *J. Org. Chem.*, **32**, 540 (1967).

5) E. Katchalsky and D. B. Ishai, *ibid.*, **15**, 1067 (1950).

6) M. S. Newman and A. Kutner, *J. Amer. Chem. Soc.*, **73**, 4199 (1951).

[V] was found to be highly unstable to base hydrolysis or heat, and converted to [IX] at room temperature and more rapidly at elevated temperature. For example, when [V] was allowed to stand for one month at room temperature, complete isomerization to [IX] hydrochloride occurred. A more satisfactory procedure for the preparation of [IX] was to treat [V] with sodium hydroxide solution at elevated temperature for several minutes. A new compound [V], which was isolated and purified only by washing with cold water, had a melting point of 97—99°C and its elemental analysis corresponded to the empirical formula $C_{11}H_{14}N_3ClO$. When it was recrystallized from boiling water, however, a different substance having a melting point of 119—119.5°C was obtained. Elemental analysis of this compound corresponds to a value for [V] plus a mol of water, and infrared absorption bands at 3480 and 1130 cm^{-1} indicate the presence of C–OH.

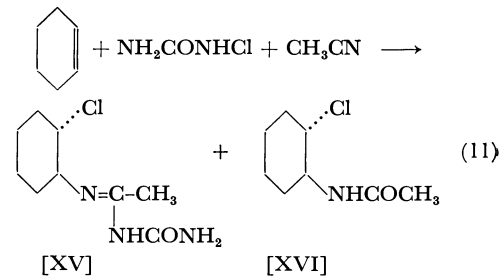
N-(2-chloro-1-phenylethyl)acetamide [VI] was confirmed by coincidence of its melting point with that of the known compound.[7] The NMR spectrum of [VI] indicates a doublet at τ 6.18 (2H, CH_2Cl), a multiplet at 5.5 (1H, CHN) owing to additional splitting by NH, a single peak at 2.68 (5H, aromatic protons), a typically broad peak at 4.7 (the proton on nitrogen) and a triplet at 7.95 (3H, CH_3). The structure of [VI] was also established by its conversion to the known 2-hydroxyl-1-phenylethylamine [XII], picrate of [XII] and hydrochloride of [XII]. An isomeric *N*-(2-chloro-2-phenylethyl)acetamide should yield 2-phenyl-2-hydroxyethylamine.



(10)

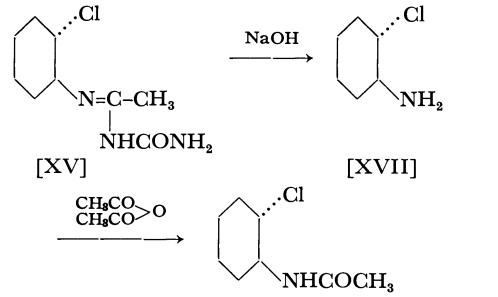
[VI] was also treated with sodium carbonate in water to give *N*-(2-hydroxy-1-phenylethyl)acetamide [XIII] having a melting point 123—124°C.[8] Lusskin and Ritter[7] reported the preparation of 2-methyl-4-phenyl-2-oxazoline having a melting point 120°C on treating chloroacetamide with potassium hydroxide at 60—65°C for 90 sec in ethyl alcohol. But the product obtained by the same reaction was a liquid having a boiling point of 96—96.5°C/5mmHg. Its infrared spectrum and elemental analysis correspond to those of 2-methyl-4-phenyl-2-oxazoline [XIV]. The hydrochloride of [XIV] had mp 145—146°C.

Cyclohexene reacted with *N*-chlorourea in the presence of acetonitrile to give *N*-(1-ureidoethylidene)-*trans*-2-chlorocyclohexylamine [XV] and *N*-(*trans*-2-chlorocyclohexyl)acetamide [XVI].



(11)

[XV] precipitated from the reaction mixture as a white solid. The filtrate was evaporated *in vacuo* to yield a very viscous semi-solid. This substance could not be recrystallized nor distilled. When it was treated with boiling water, [XVI] was obtained as white crystalline material. Reaction of cyclohexene with *N*-chlorourea and acetonitrile could yield *cis*- or *trans*-isomer. The stereochemistry of the reaction was shown to be *trans*, consistent with the ring opening of the intermediate halonium ion.[9] Thus, the product was identified as [XV] and [XVI]. The composition and structure of [XV] were established by elemental analysis and infrared spectra. The spectrum shows essentially the patterns of urea, C=N and *trans* C–Cl. The structure of [XV] was also established by its conversion to known *trans*-2-chlorocyclohexylamine [XVII] and further to *N*-(*trans*-2-chlorocyclohexyl)-acetamide [XVI].



(12)

2-Chlorocyclohexylamine may exist in two diastereoisomeric forms. The infrared spectrum of [XVII], with a stretching vibration of C–Cl at 728 cm^{-1}, was identical with that reported by Yoshida[10] for *trans*. On standing at room temperature for several days, it partly decomposed to form a solid material. This confirms the previous observation for this compound.[11] The acetylated

7) R. M. Lusskin with J. J. Ritter, *ibid.*, **72**, 5577 (1950).

8) The melting point of [XIII] was reported as 114—116°C by R. M. Lusskin and J. J. Ritter.[7]

9) A. Hassner, L. A. Levy and R. Gault, *Tetrahedron Lett.*, **1966**, 3119 (1966).

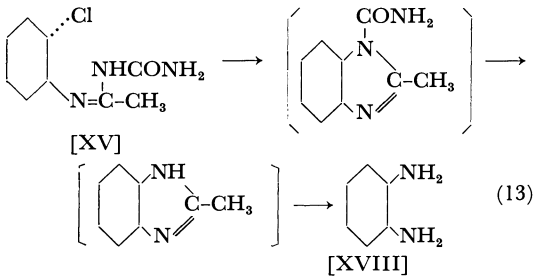
product of [XVII] was characterized by identity of its melting point with that of [XVI]. 1,2-Diaminocyclohexane [XVIII] was also obtained on treating [XV] with sodium hydroxide in poor yield. A reaction scheme consistent with the obtained product is as follows:



(13)

[XV] may react with sodium hydroxide to give [XVIII] *via* intermediates, imidazoline derivatives. [XVIII] reacted so readily with carbon dioxide that it was immediately converted to the picrate and subjected to analysis. [XV] was hydrogenated on treatment with sodium borohydride in ether to give *N*-(1-ureidoethyl)cyclohexylamine [XIX].

N-(*trans*-2-chlorocyclohexyl)acetamide [XVI] was confirmed by coincidence of its melting point (127.5°C) with that of the reported compound.[3] The infrared spectrum of [XVI] indicates a peak at 730 cm^{-1} based on stretching vibration of *trans* C–Cl.[10] The NMR spectrum of [XVI], in $CDCl_3$, had bands at τ 4.0 (the proton on nitrogen), 6.2 (doublet, 1H, CHCl), 7.07 (singlet, 1H, CHN), 8.0 (singlet, 3H, CH_3) and 7.7—8.87 (multiplet, cyclohexyl protons). [XVI] was hydrolyzed on treatment with aqueous hydrochloric acid solution to give *cis*-2-hydroxycyclohexylamine[3] [XX]. [XVI] was also hydrolyzed with sodium carbonate in aqueous solution or aqueous ammonium hydroxide solution to give *N*-(*cis*-2-hydroxycyclohexyl)-acetamide[12] [XXI], which was further hydrolyzed to give [XX]. [XX] was acetylated by acetic anhydride to give [XXI].[13]

13) M. Mousseron and R. Jacquier, *Bull. Soc. Chim. Fr.*, **1950**, 238.

[XX], on standing at room temperature for several days, darkened and finally turned to a tarry matter. The structure of [XX] was confirmed by coincidence of the melting point of its hydrochloride (184—185°C) with that of the reported compound.[13] The infrared spectrum of [XX] had an absorption at 945 cm^{-1} based on *cis* C–O bond.[14] The NMR spectrum of [XX], in $CDCl_3$, had bands at τ 6.3 (singlet, 1H, CHO), 7.2 (singlet, 1H, CHN), 7.35 (the proton on nitrogen), 8.45 (1H, OH) and 8.55 (cyclohexyl protons). The spectrum was identical with that reported by Pavia and co-workers[15] for *cis*. Further proof of [XX] was demonstrated by its conversion to [XXI] having a melting point 145—146°C.[16] The melting point of *trans*-isomer was reported as 126—127°C.[16]

Experimental

All reagents were redistilled before use. Acetonitrile was predried over potassium hydroxide and distilled over calcium hydride. All the melting points are uncorrected. IR spectra were measured in KBr pellets or in liquid state using a Hitachi Model EPI-G3 IR spectrometer. NMR spectra were obtained using dilute solutions in CCl_4 or $CDCl_3$. Tetramethylsilane was used as an internal standard and chemical shifts are expressed in "tau" scale.

Reaction of *N*-Chlorourea with Styrene in the Presence of Acetonitrile. Simultaneous formation of *N*-(1-ureidoethylidene)-2-chloro-1-phenylethylamine[V], *N*-(2-chloro-1-phenylethyl)acetamide [VI] and 4-phenyl-2-oxazolidone [VII]. The compounds can be prepared from *N*-chlorourea or, more simply, from urea and chlorine forming *N*-chlorourea directly in the reaction solution.

A suspension of 0.6 mol (36 g) of pulverized urea in 450 m*l* of acetonitrile was cooled to 0°C and chlorinated while being stirred rapidly. Gas introduction was discontinued as soon as 0.3 mol (21.3 g) of chlorine had been absorbed. The resulting clear, colorless solution was stirred for an additional 30 min. The solution was purged with and kept under nitrogen atmosphere. A solution of 0.3 mol (31.2 g) of styrene in 100 m*l* of acetonitrile was then added dropwise over a period of 1 hr while maintaining the temperature at 10°C by external cooling. After the addition was complete, the reaction mixture was stirred for about 2 hr at 10°C until an HI test failed to produce iodine. The reaction mixture was allowed to separate into two phases. From the viscous lower phase was recovered urea after neutralizing with sodium hydroxide. The upper acetonitrile phase was then placed in a vacuum distillation flask to remove acetonitrile. The resulting viscous, pale yellow liquid was then poured into 300 m*l* of water, stirred vigorously for 20 min, and then shaken with benzene. The upper organic phase was separated and dried over

anhydrous $MgSO_4$. After removing benzene and chlorinated styrene, the residue was distilled *in vacuo* to yield 14 g (23.6%) of *N*-(2-chloro-1-phenylethyl)acetamide, bp 121—127°C/1.2 mmHg, as a colorless liquid. The distillate solidified upon standing. Recrystallization from benzene gave colorless leaflets melting at 98—99.5°C (lit, mp 100°C,[7] 103—104°C[3]).

Found: C, 60.31; H, 6.28; Cl, 17.58; N, 6.94%. Calcd for $C_{10}H_{12}ClNO$: C, 60.76; H, 6.11; Cl, 17.93; N, 7.08%.

IR: 3310 (NH), 1650 (C=O), 1530 (amide II), 770, 695 (mono subst. benzene) and 725 cm^{-1} (C–Cl); NMR: τ 2.68 (phenyl, singlet), 4.7 (NH, broad peak), 5.5 (CHN, multiplet), 6.18 (CH_2Cl, doublet) and 7.95 (CH_3, triplet).

The lower aqueous phase was made alkaline (pH≒8.5) with NaOH and the resulting white precipitate was separated by filtration, washed with a large amount of cold water and dried *in vacuo* to yield 22 g (30.6%) of *N*-(1-ureidoethylidene)-2-chloro-1-phenylethylamine having a melting point 97—99°C (dec.). Insoluble in cold water, ethyl alcohol and benzene, soluble in hot water and hot ethyl alcohol. If allowed to stand for one month at room temperature, it became liquid and then resolidified.

Found: C, 54.44; H, 5.88; Cl, 15.12; N, 17.19%. Calcd for $C_{11}H_{14}ClN_3O$: C, 55.11; H, 5.88; Cl, 14.79; N, 17.52%.

IR: 3400, 3240, 3120 (NH), 1730 (C=O), 1625 (C=N), 1520 (amide II), 765, 700 (mono subst. benzene) and 710 cm^{-1} (C–Cl).

The filtrate was concentrated *in vacuo*, the residue extracted with ethyl alcohol and the extract distilled *in vacuo* to yield 1.5 g of 4-phenyl-2-oxazolidone, bp 150—160°C/1.5 mmHg. An analytical sample, mp 137—137.5°C (lit,[4] mp 138—139.5°C), was obtained by recrystallization from water. The compound gave a mp 137—137.5°C in admixture with authentic sample (mp 137.5—138°C, prepared according to the method of Hassner, Lobber and Heathcock[4]).

Found: C, 66.17; H, 5.62; N, 8.70%. Calcd for $C_9H_9NO_2$: C, 66.24; H, 5.55; N, 8.58%.

IR: 3270 (NH), 1750, 1720 (C=O), 1230, 1040 (ester) and 760, 700 cm^{-1} (mono subst. benzene).

Reaction of *N*-Chlorourea with Cyclohexene in the Presence of Acetonitrile. Simultaneous formation of *N*-(1-ureidoethylidene)-*trans*-2-chlorocyclohexylamine [XV] and *N*-(*trans*-2-chlorocyclohexyl)acetamide [XVI]. A solution of 0.3 mol of *N*-chlorourea in acetonitrile was prepared as described above. Cyclohexene (0.3 mol, 24.6 g) in acetonitrile (70 m*l*) and the *N*-chlorourea solution were reacted in a similar manner. The resulting precipitate was separated by filtration, washed with cold water, ethyl alcohol and ethyl ether. Recrystallization from hot water produced 22.5 g of white precipitate melting at 174.5—175°C (dec.), soluble in hot water, insoluble in benzene and ethyl alcohol. This product was dissolved in 60 m*l* of hot water, and the solution was made alkaline with KOH (pH≒10). After cooling the solution, the resulting precipitate was separated by filtration, washed with water and dried *in vacuo* to yield 18.5 g (28.3%) of *N*-(1-ureidoethylidene)-*trans*-2-chlorocyclohexylamine. An analytical sample, mp 113.5—114.5°C, was obtained by recrystallization from ethyl alcohol, soluble in ethyl alcohol, benzene and hot water, insoluble in ethyl ether and cold water.

Found: C, 49.28; H, 7.27; Cl, 16.70; N, 19.18%. Calcd for $C_9H_{16}ClN_3O$: C, 49.65; H, 7.40; Cl, 16.28; N, 19.30%.

IR: 3430, 3250, 3100 (NH), 1700 (C=O), 1660 (C=N), 1560 (amide II) and 730 cm^{-1} (*trans* C–Cl).

The picrate of [XV] was prepared and had mp 193°C after recrystallization from ethyl alcohol.

Found: C, 40.30; H, 4.27; Cl, 8.17; N, 18.79%. Calcd for $C_{15}H_{19}ClN_6O_8$: C, 40.32; H, 4.28; Cl, 7.93; N, 18.80%.

The filtrate from the above product was allowed to separate into two phases. From the viscous lower phase was recovered urea after neutralizing with NaOH. The upper acetonitrile phase was placed in a vacuum distillation flask to remove acetonitrile, cyclohexene and chlorinated cyclohexene. The residue was poured into 500 m*l* of water, stirred vigorously for 30 min at 90°C. The solution was then cooled to room temperature, and the resulting white needles were separated by filtration, dried *in vacuo* to give 20 g (38%) of crude *N*-(*trans*-2-chlorocyclohexyl)acetamide [XVI]. After recrystallization from benzene twice, pure [XVI] having a melting point of 127.5°C (bp 110—116°C/0.8 mmHg) was obtained. The reported melting point for this compound is 129—130°C;[3] for *cis*-isomer the melting point is 98°C.[13]

Found: C, 54.81; H, 8.02; Cl, 20.11; N, 8.03%. Calcd for $C_8H_{14}ClNO$: C, 54.70; H, 8.03; Cl. 20.18; N, 7.97%.

IR: 3200 (NH), 1630 (C=O), 1560 (amide II), and 730 cm^{-1} (*trans* C–Cl); NMR: τ 4.0 (NH, broad peak), 6.2 (CHCl, doublet), 7.07 (CHN, singlet), 7.7—8.8 (cyclohexyl protons, multiplet) and 8.0 (CH_3, singlet).

2-Hydroxy-1-phenylethylamine [XII]. Twenty grams of *N*-(2-chloro-1-phenylethyl)acetamide was refluxed with a solution consisting of 19 g of aqueous 45% NaOH solution and 48 m*l* of ethyleneglycol on an oil bath for 5 hr. After cooling the solution, the precipitate was filtered, the filtrate was acidified with HCl and then evaporated to dryness. Cold aqueous 50% NaOH solution was added to the residue and the resulting oil was extracted with ether. The ethereal extracts were dried over anhydrous $MgSO_4$, ether was removed *in vacuo* and the residue distilled *in vacuo*. 2-Hydroxy-1-phenylethylamine (9 g, 65%), bp 102—108°C/1.5 mmHg (lit,[17] bp 104—106°C/1 mmHg) was obtained, which solidified to a white solid, mp 51—52°C (lit,[17] mp 48—49.5°C).

Found: C, 69.78; H, 8.11; N, 10.20%. Calcd for $C_8H_{11}NO$: C, 70.04; H, 8.08; N, 10.21%.

IR: 3400 (OH), 3300, 1610 (NH), 1055 (C–O) and 765, 705 cm^{-1} (mono subst. benzene).

The picrate of [XII] had mp 204—204.5°C after recrystallization from ethyl alcohol. The reported melting point for this compound is 205—206°C;[18] for 2-hydroxy-2-phenylethylamine-picrate the melting point is 158°C.[19]

Found: C, 46.17; H, 4.03; N, 15.12%. Calcd for $C_{14}H_{14}N_4O_8$: C, 45.90; H, 3.85; N, 15.29%.

The hydrochloride, prepared by addition of dry HCl

gas to an alcoholic solution of the free base and recrystallization from ethyl alcohol, melted at 131—132°C, resolidified and subsequently remelted at 145°C. The results confirm those reported for this compound[3] (melts at 132—135°C, resolidifies and remelts at 147—149°C). The reported melting point for 2-hydroxy-2-phenylethylamine hydrochloride is 213°C.[20]

N-(2-Hydroxy-1-phenylethyl)acetamide [XIII]. Five grams of N-(2-chloro-1-phenylethyl)acetamide and a solution of 3.5 g of Na_2CO_3 in 75 ml of water were allowed to stand for 12 hr at room temperature and then refluxed for 1 hr. The solution was extracted with ethyl acetate. After removal of ethylacetate, the residue was recrystallized from benzene-ethyl alcohol to yield 3 g (66%) of white crystals, having a new mp 123—124°C (lit,[7] mp 114—116°C).

Found: C, 66.81; H, 7.38; N, 7.79%. Calcd for $C_{10}H_{13}NO_2$: C, 67.01; H, 7.31; N, 7.81%.

IR: 3350 (OH), 3140 (NH), 1650 (C=O), 1560 (amide II), 1055(C-O) and 760, 700 cm^{-1} (mono subst. benzene).

2-Methyl-4-phenyl-2-oxazoline [XIV]. N-(2-chloro-1-phenylethyl)-acetamide (0.1 mol, 19.7 g) was mixed 90 sec at 60—65°C with 0.1 mol (5.6 g) of KOH in 200 ml of ethyl alcohol. One gram of $NaHCO_3$ was added and the solution was filtered. After removal of ethyl alcohol, the residue was distilled *in vacuo* to yield 7 g (44%) of the product, bp 96—96.5°C/5 mmHg (lit,[7] mp 120°C).

Found: C, 73.94; H, 6.85; N, 8.62%. Calcd for $C_{10}H_{11}NO$: C, 74.50; H, 6.87; N, 8.68%.

IR: 1670 (C=N), 1230, 990 (C-O) and 760, 700 cm^{-1} (mono subst. benzene).

The hydrochloride, prepared by addition of dry HCl gas to an alcoholic solution of [XIV], had mp 145—146°C (lit,[3] 160.5—161°C).

IR: 2720—2400, 1980 ($C=N^+H$), 1745 ($C=N^+$), 1240, 1060, 1050(C-O) and 765, 700cm^{-1} (mono subst. benzene).

N-(1-Ureido-1-hydroxyethyl)-2-chloro-1-phenylethylamine. N-(1-Ureidoethylidene)-2-chloro-1-phenyl ethylamine was recrystallized from water. A white precipitate melting at 119—119.5°C was obtained.

Found: C, 51.28; H, 6.43; Cl, 13.80; N, 16.40%. Calcd for $C_{11}H_{16}ClN_3O_2$: C, 51.26; H, 6.25; Cl, 13.75; N, 16.30%.

1-Aminocarbonyl-2-methyl-4-phenyl-2-imidazoline [IX]. Twenty grams of N-(1-ureidoethylidene)-2-chloro-1-phenylethylamine were mixed for 30 min at 50°C with 200 ml of aqueous 40% NaOH solution. The precipitate was separated by filtration, washed with cold water and dried *in vacuo* to yield 9 g (53%) of [IX] melting at 76—76.3°C.

IR: 3200 (NH), 1680 (C=O), 1640 (C=N), 1620 (amide II) and 755, 695 cm^{-1} (mono subst. benzene).

The picrate of [IX] had mp 139—140°C after recrystallization from ethyl alcohol.

Found: C, 47.17; H, 3.68; N, 19.39%. Calcd for $C_{17}H_{16}N_6O_8$: C, 47.22; H, 3.73; N, 19.43%.

2-Methyl-4-phenyl-2-imidazoline [X] and 1,2-Diaminoethylbenzene [XI]. Twenty-five grams of 1-aminocarbonyl-2-methyl-4-phenyl-2-imidazoline were refluxed with 90 ml of aqueous 40% NaOH solution for 2.5 hr and the resulting mixture was extracted with chloroform. The extracts were dried over anhydrous $MgSO_4$, concentrated *in vacuo* and the residue was distilled *in vacuo* to yield the following two fractions:

Cut-1, bp 95—117°C/1.5mmHg, 7 g

Cut-2, bp 135—136°C/1.5mmHg, 3 g (lit,[21] bp 121—122°C/0.2mmHg)

Cut-1 was redistilled *in vacuo* to yield pure 1,2-diaminoethylbenzene, bp 85—88°C/1.0 mmHg (lit,[22] bp 243—246°C/760 mmHg).

Found: C, 70.17; H, 8.95; N, 20.39%. Calcd for $C_8H_{12}N_2$: C, 70.55; H, 8.88; N, 20.56%.

IR: 3300, 3100, 1605, 880 (NH) and 750, 700 cm^{-1} (mono subst. benzene).

The picrate of [XI] had mp 165.5—166.5°C after recrystallization from ethyl alcohol (lit,[22] mp 160°C).

Found: C, 45.94; H, 4.09; N, 18.93%. Calcd for $C_{14}H_{15}N_5O_7$: C, 46.03; H, 4.13; N, 19.17%.

Cut-2. solidified upon standing and had mp 78.5—79°C.

Found: C, 75.08; H, 7.68; N, 17.16%. Calcd for $C_{10}H_{12}N_2$ [X]: C, 74.96; H, 7.54; N, 17.48%.

IR: 3200, 3120 (NH), 1620 (C=N, NH) and 755, 700 cm^{-1} (mono subst. benzene).

The picrate of [X] had mp 131.5—132.5°C after recrystallization from ethyl alcohol.

Found: C, 49.13; H, 3.78; N, 17.65%. Calcd for $C_{16}H_{15}N_5O_7$: C, 49.36; H, 3.88; N, 17.98%.

***cis*-2-Hydroxycyclohexylamine [XX].** Ten grams of N-(*trans*-2-chlorocyclohexyl)acetamide were refluxed with 100 ml of aqueous 20% HCl solution for 2 hr. The mixture was made alkaline with NaOH and subjected to steam distillation. The distillate was acidified with HCl and evaporated to dryness. Cold aqueous 50% NaOH solution was added to the residue. The resulting oil was extracted with ether. The etheral extracts were dried over anhydrous $MgSO_4$, concentrated *in vacuo* and the residue was distilled *in vacuo* to yield 4 g (61%) of *cis*-2-hydroxycyclohexylamine, bp 98—99°C/12 mmHg, which solidified upon standing. An analytical sample, mp 76.5—78°C, was obtained by recrystallization from ether. The product darkened on prolonged standing in air. The reported melting point for this compound is 107—108°C,[13] 72—73°C,[16] 71—72°C[12]; for *trans*-isomer the melting point is 66—67°C.[13]

Found: C, 62.25; H, 11.74; N, 12.10%. Calcd for $C_6H_{13}NO$: C, 62.57; H, 11.37; N, 12.16%.

IR: 3400 (OH), 3300, 3100, 1615 (NH), 990, 965 and 945 cm^{-1} (*cis* C-O); NMR: τ 6.3 (CHO, singlet), 7.2 CHN, singlet), 7.35 (NH_2, singlet), 8.45 (OH, singlet) and 8.55 (cyclohexyl protons).

The hydrochloride, prepared by addition of dry HCl gas to an alcoholic solution of the free base, melted at 183—184°C after recrystallization from ethyl alcohol. The reported melting point for this compound is 184—185°C[13]; for *trans* isomer the melting point is 175°C.[13]

N-(*cis*-2-Hydroxycyclohexyl)acetamide [XXI] from N-(*trans*-2-Chlorocyclohexyl)acetamide [XVI]. Five grams of N-(*trans*-2-chlorocyclohexyl)-acetamide and a solution of 3.5 g of Na_2CO_3 in 75 ml of water were allowed to stand for 12 hr at room tempera-

ture and then refluxed for 1 hr. The solution was extracted with ethyl acetate. After removal of the solvent the residue was recrystallized from benzene-ethyl alcohol to yield 2.5 g (55%) of *N*-(*cis*-2-hydroxycyclohexyl)-acetamide as a colorless plate, mp 145—146°C. The reported melting point for this compound is 146—147°C;[13,16] for *trans* isomer the melting point is 126—127°C.[16] The same result was obtained by treating [XVI] with aqueous 20% NH_4OH solution.

***cis*-2-Hydroxycyclohexylamine Hydrochloride from *N*-(*cis*-2-Hydroxycyclohexyl)acetamide.** Ten grams of *N*-(2-hydroxycyclohexyl)acetamide were refluxed with 60 m*l* of aqueous 20% HCl solution for 2 hr, and distilled *in vacuo* to dryness. The residue was recrystallized from ethyl alcohol to yield 6 g (62%) of colorless crystals, mp 183—185°C.

***N*-(*cis*-2-Hydroxycyclohexyl)acetamide [XXI] from *cis*-2-Hydroxycyclohexylamine [XX].** A solution of five grams of *cis*-2-hydroxycyclohexylamine in 20 m*l* of ethyl alcohol was added dropwise to 50 m*l* of acetic anhydride. The white precipitate was separated by filtration, recrystallized from ethyl acetate to yield 5.5 g (80%) of colorless plates, mp 145.5—146°C. The compound gave a mp 145—146°C in admixture with the sample in the preceding example prepared from *N*-(*trans*-2-chlorocyclohexyl)acetamide [XVI].

Found: C, 60.97; H, 9.78; N, 8.91%. Calcd for $C_8H_{15}NO_2$: C, 61.11; H, 9.61; N, 8.90%.

IR: 3350 (OH), 3100 (NH), 1650 (C=O), 1545 (amide II) and 985 cm^{-1} (*cis* C–O).

***N*-(1-Ureidoethyl)cyclohexylamine [XIX].** Five grams of $NaBH_4$ were added to 6.5 g of *N*-(1-ureidoethylidene)-*trans*-2-chlorocyclohexylamine [XV] solution in 150 m*l* of methyl alcohol over a period of 1 hr at 15°C. After the addition was complete, the reaction mixture was stirred for 1 hr at 15°C, then 1 hr at 40—50°C. The solution was treated with 5 m*l* of acetone, concentrated *in vacuo* to dryness and the residue extracted with ether. After drying with anhydrous $MgSO_4$, the ether was removed *in vacuo* and the resulting precipitate was separated by filtration. Recrystallization from ether gave white precipitate melting at 162—162.5°C.

Found: C, 58.31; H, 9.81; N, 22.56%. Calcd for $C_9H_{19}N_3O$: C, 58.34; H, 10.33; N, 22.68%.

IR: 3350, 3200 (NH), 1660 (C=O), 1605 (NH) and 1540 cm^{-1} (amide II).

***trans*-2-Chlorocyclohexylamine [XVII] and 1,2-Diaminocyclohexane [XVIII].** Twenty-eight grams of *N*-(1-ureidoethylidene)-2-chlorocyclohexylamine was refluxed with a solution consisting of 21 g of NaOH in 26 m*l* of water and 70 m*l* of ethylene glycol on a oil bath for 3 hr. The solution was acidified with HCl, filtered and the filtrate was evaporated to dryness *in vacuo*. Cold aqueous 50% NaOH solution was added to the residue and the resulting oil was extracted with ether. The ethereal extracts were dried over anhydrous $MgSO_4$, concentrated *in vacuo* and the residue was distilled *in vacuo* to yield the following two fractions:

Cut-1 [XVII] bp 62/9—63.5°C/8 mmHg, 4.5 g (26%) (lit,[11] bp 69°C/12 mmHg)

Cut-2 [XVIII] bp 115—121°C/3.5 mmHg, 1.0 g (7%) (lit,[23] 36—38°C/0.05 mmHg)

Cut-1 was a colorless oil when it was freshly distilled. But on standing at room temperature for several days, it decomposed to give a deposit of crystals. The result is in line with that reported for this compound.[11] IR: 3370, 3270, 1605 (NH) and 728 cm^{-1} (C–Cl).

The hydrochloride, prepared by addition of dry HCl gas to an alcoholic solution of the freshly distilled free base, melted at 208—210°C after recrystallization from ethyl alcohol. The reported melting point is 205—207°C,[24] 213—214°C;[3] the *cis*-isomer is reported to melt at 185—186°C.[16]

On being treated with acetic anhydride, the freshly distilled free base [XVII] was converted to the *N*-(*trans*-2-chlorocyclohexyl)acetamide. Recrystallization from ethyl acetate gave white needles melting at 128.5—129°C. There was no depression of melting point on admixture with the sample in the preceding example prepared from cyclohexene, *N*-chlorourea and acetonitrile.

Cut-2, obtained as a colorless oil, absorbed carbon dioxide rapidly on exposure to atmosphere as indicated by the immediate formation of solid on the surface. It was dissolved in ethyl alcohol and the solution was added to a picric acid solution in ethyl alcohol. A yellow solid precipitated immediately, the precipitate was washed with ethyl alcohol and analyzed. It became dark by heating at 220—260°C.

Found: C, 37.60; H, 3.70; N, 19.62%. Calcd for $C_6H_{14}N_2 \cdot 2C_6H_3N_3O_7$: C, 37.77; H, 3.52; N, 19.57%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2174—2176 (1970)

The Characterization of Malloprenol and Its Ester with Linolenic Acid Isolated from the Leaves of *Mallotus japonicus*

Toshiharu NODA, Teruo TAKE, Tetsuo WATANABE and Jinnosuke ABE

Research Institute, Toyo Jozo Co., Ltd., Ohito, Tagata, Shizuoka

(Received December 3, 1969)

An isoprenoid alcohol (I) and the ester with linolenic acid (II) isolated from *Mallotus japonicus* of *Euphorbiaceae* were investigated. The trivial name "mallophenol" was proposed to describe the prenol (I). Nuclear magnetic resonence studies showed that the prenol contained one *trans* and six *cis* internal isoprene residues, and a *cis* 'OH-terminal' isoprene residue.

Mallotus japonicus is a deciduous tree of the *Euphorbiaceae* which has long been used in Japan as a gastrointestinal drug. In the studies of this plant, the presence of bergenin,[1] rutin,[2] and some fatty acids,[3] but not linolenic acid, has been reported.

From the nonpolar fractions of the methanol extracts of leaves which has been collected in Ohito and Nagaoka-cho, Shizuoka Prefecture, in September and October, 1968, malloprenol (I) and the ester with linolenic acid (II) were isolated. The nonpolar fractions of the extracts were then chromatographed on silica gel to give malloprenol and the ester with linolenic acid, which was less polar than the malloprenol (I). The malloprenol (I) is a colorless oil, $n_D^{23.5}$ 1.5038. The molecular formula, $C_{45}H_{74}O$ (mol wt, 631.0), was deduced from the analytical data and from the molecular weight*1 of (I) (the obsd mol wt, 652) and its derivatives. The IR spectra showed absorptions at 3325, 1005, and 1665 cm^{-1}, thus confirming the presence of a primary hydroxyl group and isolated double bonds. In the UV spectrum, there was no absorption longer than 210 mμ. The malloprenol (I) gave the acetate (III), with acetic anhydride-pyridine, $C_{47}H_{76}O_2$ (mol wt, 673.28, obsd mol wt, 669, 667), or (IV) with *p*-bromobenzoylchloride-pyridine, $C_{52}H_{77}O_2Br$ (mol wt, 814.05; obsd mol wt, 854). In the IR spectra there was no hydroxyl band, but there did appear a strong absorption of the carbonyl group at 1740 cm^{-1} in (III) and at 1730 cm^{-1} in (IV). The primary hydroxyl group in (I) was easily oxidized with the chromium trioxide-pyridine complex to give the aldehyde (V), $C_{45}H_{72}O$ (mol wt, 629.02; obsd mol wt 645). In the IR spectrum, there were absorptions of the formyl group (2740 and 1670 cm^{-1}) and the conjugated double bond (1620 cm^{-1}). The formyl proton appeared at 9.90 ppm (1H, d, J=8Hz) in the NMR spectrum. The strong absorption at 231 mμ in the UV spectrum confirmed that Compound I was a primary allylic alcohol. Compound V gave the 2,4-dinitrophenylhydrazone as a reddish oil, $C_{51}H_{76}O_4N_4$ (mol wt, 809.15; obsd mol wt, 833). From the ozonization of the malloprenol (I), followed by the reductive decomposition of the ozonide, levulinaldehyde and acetone were isolated as their 2,4-dinitrophenylhydrazones. From the above results, it appeared that malloprenol was an isoprenoid alcohol.

The NMR spectrum of (I) resembles those of solanesol[4] (all *trans*) and castaprenol-11, -12 and -15.[5] There are two peaks at 1.60 and 1.68 ppm with a shoulder at 1.73 ppm in Compound I. The relative areas under the two peaks are about six and twenty-four protons (including the shoulder at 1.73 ppm) respectively. The peak at 1.60 ppm can be assigned to two methyl groups of one internal and one ω-terminal *trans* isoprene residues. The eight methyl group at 1.68 ppm show the seven methyl groups of the six internal and one ω-*cis* isoprene residues and one methyl group of the *cis* 'OH-terminal' isoprene residue (as shoulder at 1.73 ppm.[5]) The olefinic protons give a broad peak at 5.13 ppm (8H) and a triplet at 5.42 ppm (1H, J=7Hz), corresponding to the proton on the β-carbon to the hydroxyl-group coupling with the α-methylene protons to the hydroxyl group, which appear at 4.11 ppm (2H, J=7Hz) in the malloprenol (I).

From the above observations, the prenol can be said to contain a *cis* 'OH-terminal' isoprene residue

(shoulder at 1.73 ppm), one internal *trans* isoprene residue (1.60 ppm), and, of necessity, methyl groups both *cis* and *trans* to the olefinic proton in the *ω*-isoprene residue (*cis*: 1.68 ppm; *trans*: 1.60 ppm). Six of the other isoprene rdsidues are internal *cis* (1.68 ppm). In Compounds III and IV, the metyl groups of the *cis* 'OH-terminal' isoprene residue appeared at 1.75 and 1.77 ppm respectively. The allylic methylene protons appeared as two peaks, at 2.02—2.05 and 2.07—2.08 ppm, in Compounds (I—IV).

$$\begin{array}{l} \qquad\quad CH_3 \\ \qquad\quad | \\ H\text{-}(CH_2\text{-}C\text{=}CH\text{-}CH_2)_9\text{-}OR \end{array}$$

I: R=H

II: R=$CH_3(CH_2\text{-}CH\text{=}CH)_3\text{-}CH_2(CH_2)_6\cdot CO$-

The ester (II), $n_D^{19.5}$ 1.5057, showed strong absorptions at 1740 and 1170 cm^{-1}, but no hydroxyl band in its IR spectrum. The alkaline hydrolysis of the ester gave the components, an alcohol, and an acid. The NMR and IR spectra of the alcohol were the same as those of the malloprenol (I) in all respects. The acid afforded the methyl ester (VI) with diazomethane. The ester (VI) (M^+/e 292) was identified as methyl linolenate (mol wt, 292.44) by a study of its GLC, IR, and NMR spectra.

Experimental

The IR spectra were recorded on a Hitachi Grating Infrared Spectrometer EPI G-2; the UV spectra, on a Hitachi Recording Spectrophotometer EPS-3, and the NMR spectra, on a Hitachi Nuclear Magnetic Resonance Spectrometer R-20. The chemical shifts were measured on the δ scale relative to TMS as the internal standard (δ=0).

Extraction and Isolation of Malloprenol I and the Ester with Linolenic Acid (II). Dried leaves (5.1 kg) were extracted with methanol (75 *l*) at room temperature for two weeks. The methanol extract was then concentrated to 5 *l*, and water (5 *l*) was added. The solution was subsequently extracted with light petroleum ether. The evaporation of the solvent left a tarry residue (205 g), which was then chromatographed on silica gel. Ligroin/benzene (6:1) eluted fractions which gave dark brown spots (R_f 0.7) with a concentrated sulfuric acid spray on chromatoplates developed with ligroin/benzene (4:1). The fractions were combined and evaporated, and the residue was repeatedly chromatographed to give a colorless oil, (II) (1.7 g), which showed a single spot on TLC, $n_D^{17.5}$ 1.5057; Found: C, 84.85; H, 11.51%. Calcd for $C_{63}H_{102}O_2$: C, 84.88; H, 11.53%. IR: 3020, 1665, 840 (C=C), 1740, 1170 cm^{-1} ($OCOCH_3$). $\delta_{ppm}^{CDCl_3}$ 0.98 (3H, t, J=7.5 Hz, $C\underline{H}_3CH_2$-), 1.33 [10H, (-$C\underline{H}_2$)$_5$-CH_2COO-], 1.60(6H, $C\underline{H}_3\rangle C\text{=}C\langle H$), 1.67 (24H, $C\underline{H}_3\rangle C\text{=}C\rangle H$), 2.03—2.08(32H, -$C\underline{H}_2$-C=CH), 2.08(4H, $C\underline{H}_2$-CH=CH), 4.55(2H, d, J=7.5 Hz, C=CH-$C\underline{H}_2$-OH), 5.13(8H, C=C$\underline{H}$-CH_2).

Benzene subsequently eluted fractions which gave dark brown spots (R_f 0.4) with a concentrated sulfuric acid spary on chromatoplates developed with benzene. After the evaporation of the solvent, the residue was rechromatographed several times to give a colorless oil, (I) (30 g), which showed a single spot on reversed-phase partition TLC on paraffin-impregnated kieselgel (impregnated with 5%, v/v, liquid paraffin in petroleum ether) with acetone - water (23 : 2, v/v) saturated with paraffin as the mobile phase,[6] $n_D^{23.5}$ 1.5038. Found: C, 85.70; H, 11.72%; mol wt, 652. Calcd for $C_{45}H_{74}O$; C, 85.64; H, 11.82%; mol wt, 631.04. IR: 3325, 1090 (OH), 3025, 1665, 840 (C=C), 2970, 2925, 2850, 1450, 1375 cm^{-1} (-CH_2-, -CH_3). $\delta_{ppm}^{CDCl_3}$: 1.31 (1H, -$CH_2O\underline{H}$), 1.60 (6H, $C\underline{H}_3\rangle C\text{=}C\langle H$), 1.68 (24H, $C\underline{H}_3\rangle C\text{=}C\rangle H$), 2.02 and 2.07 (32H, -$C\underline{H}_2$-CH=C), 4.06 (2H, d, J= 7 Hz, C=CH-$C\underline{H}_2$-OH), 5.13 (8H, C=C$\underline{H}$-CH_2-), 5.42 (1H, t, J=7 Hz, C=C$\underline{H}$-CH_2-OH).

Monoacetate (III). The malloprenol (I) (590 mg) in 0.5 m*l* of pyridine was treated with 0.5 m*l* of acetic anhydride and then allowed to stand overnight. To the reaction mixture 15 m*l* of water were then added, and the oily product was extracted with benzene to give 522 mg of the crude acetate. Using silica-gel chromatography and elution with petroleum ether/benzene (1 : 1), 485 mg of III was obtained; $n_D^{22.5}$ 1.5047. Found: C, 83.52; H, 11.32%; mol wt, 669, 667. Calcd for $C_{47}H_{76}O_2$: C, 83.86; H, 11.38%; mol wt, 673.08. IR: 3025, 1660, 835 (C=C), 1740, 1230 cm^{-1} ($OCOCH_3$).

***p*-Bromobenzoate (IV).** The malloprenol (I) (500 mg) in 1.5 m*l* of pyridine was treated with 510 mg of *p*-bromobenzoyl chloride and then allowed to stand overnight at room temperature. To the reaction mixture, 20 m*l* of benzene were then added, after which the precipitate was filtered off and the filtrate was washed with a $NaHCO_3$ solution, 0.5N HCl, and water. After the removal of the solvent, the residue (581 mg) was chromatographed on silica gel (20 g) to give 508 mg of (IV); $n_D^{22.5}$ 1.5267. Found: C, 77.20; H, 9.73; Br, 9.70%; mol wt, 854. Calcd for $C_{52}H_{77}O_2Br$: C, 76.72; H, 9.73; Br, 9.82%; mol wt, 814.05. IR: 3030, 1665, 850 (C=C), 1730, 1590, 1270, 760 cm^{-1} (benzyl).

The Aldehyde V and Its 2,4-dinitrophenylhydrazone. To a CrO_3-pyridine complex (CrO_3 1 g, pyridine 10 m*l*) we added 1.5 g of I in 6 m*l* of pyridine with cooling at 0°; the mixture was then allowed to stand for an hour at room temperature. The reaction mixture was filtered, and the dark brown solid remaining was washed with pyridine. The combined pyridine solution was diluted with water and extracted with benzene. After drying (Na_2SO_4), the solvent was removed and the residue was chromatographed on silica gel (35 g) to give 975 mg of V; $n_D^{22.5}$ 1.5126. Found; C, 85.77; H, 11.46%; mol wt, 645. Calcd for $C_{45}H_{72}O$: C, 85.92; H, 11.54%; mol wt, 629.02. IR: 2740, 1670, 1620 cm^{-1} (C=C-CHO). λ_{max} 231 mμ (ε=1.38×10^4 in cyclohexane). $\delta_{ppm}^{CDCl_3}$ 5.86 (1H, d, J=8 Hz, C=C$\underline{H}$-CHO), 9.90 (1H, d, J=8 Hz, C=CH-C$\underline{H}$O). To 156 mg of (V), 2,4-dinitrophenylhydrazine in an EtOH solution was added; after dilution with water, a reddish oily product was extracted with benzene. After the removal of the solvent, the residue (195 mg) was chromatographed on silica gel to give 166 mg of the 2,4-dinitrophenylhydrazone.

Found: C, 75.64; H, 9.51; N, 6.57%; mol wt, 833. Calcd for $C_{51}H_{76}O_4N_4$: C, 75.70; H, 9.47; N, 6.92%; mol wt, 809.15.

6) K. J. Sone, A R. Wellburn, F. W. Hemming and J. F. Pennock, *ibid.*, **102**, 325 (1967).

Ozonolysis of the Malloprenol (I). A solution of 1.554 g of the malloprenol (I) in 150 m*l* of ethyl acetate was ozonized at −70°C until the solution became blue. The solvent was then removed *in vacuo* to give the ozonide as a pale yellow oil. To the ozonide 200 m*l* of water and 15 g of zinc dust were added and then decomposed by heating them at 95°C for 8 hr. To this reaction mixture, nitrogen gas was blown and the volatile component was collected as its 2,4-dinitrophenylhydrazone (64 mg; mp 117—119°C).

Found: C, 45.23; H, 3.99; N, 23.33%; Calcd for $C_9H_{10}N_4O_4$: C, 45.38; H, 4.23; N, 23.52%. No depression of mp was noted with an authentic sample of acetone 2,4-dinitrophenylhydrazone. After the filtration of the zinc dust, 500 m*l* of 2N HCl saturated with 2,4-dinitrophenylhydrazine was added to the filtrate. The precipitate was collected and crystallized from dimethylformamide to give 559 mg of fine needles; mp 245—246°C. Found: C, 44.25; H, 3.28; N, 24.17%. Calcd for $C_{17}H_{16}O_8N_8$: C, 44.35; H, 3.50; N, 24.34%. No depression of mp was noted with an authentic sample of levulinaldehyde 2,4-dinitrophenylhydrazone.

Alkaline Hydrolysis of II.] To the solution of II (600 mg) in 20 m*l* of benzene we added 20 m*l* of alcoholic 1N KOH, after which the mixture was refluxed for 4 hr. The organic solvents were then evaporated, leaving a residue which was dissolved in 30 m*l* of water and extracted with light petroleum ether to give a colorless oil (498 mg). The oil was identical with (I) in all respects. The aqueous solution was acidified with 1N HCl and extracted with ether to give 114 mg of a colorless oil which was esterified with diazomethane to give 105 mg of (VI); M^+/e 292. IR: 3025, 1650, 725 (C=C), 1745, 1175 cm^{-1} ($COOCH_3$). $\delta_{ppm}^{CDCl_3}$ 0.97 (3H, t, J=6.8 Hz, CH_3CH_2), 1.27—1.33 [10H, $-(CH_2)_5-CH_2COOCH_3$], 2.81 (4H, $CH_2-CH=CH$), 3.67 (3H, s, $COOCH_3$), 5.3—5.5 [6H, $(CH_2-CH=CH)_3$].

The authors wish to express their thanks to Mr. Hajime Takeuchi and Mr. Katsutoshi Ota of this Institute for their elemental analysis and for the measurements of the molecular weight.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2176—2181 (1970)

A Study of Acyl Migration in Gallacetophenones

Kazu KUROSAWA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received December 13, 1969)

3,4-Diacetoxy-2-hydroxyacetophenone, 3,4-dibenzoyloxy-2-hydroxyacetophenone and 3,4-bis(*p*-nitrobenzoyloxy)-2-hydroxyacetophenone gave corresponding 2,3-diacyl-4-methoxyacetophenones on treatment either with diazomethane or with dimethyl sulfate in the presence of potassium carbonate in acetone. Structure determination of the methylation product and also the methylation reaction of 3,4-dimethanesulfonyloxy-2-hydroxyacetophenone and 3,4-bis(*p*-toluenesulfonyloxy)-2-hydroxyacetophenone are reported.

In the course of synthetic studies of isoflavans, Gallacetophenone diacetate, mp 106—107°C,[1] was prepared as a synthetic intermediate material.[1] The structure of the diacetate was first elucidated by Perkin and Storey[1] as 2,4-diacetate on the basis of alkaline degradation of the gallacetophenone mono methyl ether, mp 132—133°C, derived from the diacetate. This ether, they claimed, afforded 2-methylpyrogallol (**6**), indicating the position of the hydroxyl group at 3. The identification, however, had been made by comparison of the melting point of the "2-methylpyrogallol diacetate" (60—63°C) only, whereas an authentic 2-methylpyrogallol diacetate has a mp 51—54°C and 1-methylpyrogallol diacetate has a mp 91—93°C.[3]

The IR spectrum of the diacetate showed a carbonyl absorption at 1648 cm^{-1}, which is slightly higher than those of other *o*-hydroxyacetophenones such as 3-acetoxy-2-hydroxy-4-methoxyacetophenone (**2b**) and 2,3-dihydroxy-4-methoxyacetophenone (**9**). Nevertheless, it is obviously a hydrogen bonded carbonyl when compared with the carbonyl absorptions of 2,3-diacetoxy-4-methoxyacetophenone (**3a**), 3-hydroxy-2,4-dimethoxyacetophenone (**10**) and 3-acetoxy-2,4-dimethoxyacetophenone (**4b**), in which *o*-hydroxyl group is absent (see Table 1). On the other hand, the NMR spectrum of the diacetate exhibited a proton signal at a lower field (δ 12.10)

which disappeared on deutration. The chemical shift is also characteristic to a hydrogen bonded *o*-hydroxyl proton as observed on *o*-hydroxyacetophenones, **9** and **2b**, while a *m*-hydroxyl proton in the compounds, **9** and **10**, appeared at a higher field (see Table 2). From this spectroscopic evidence, it is quite clear that the structure of the diacetate is neither 2,4-diacetate nor 2,3-diacetate, but undoubtedly 3,4-diacetate (**2a**) (see Fig. 1).

Diacetate (**2a**) gave a diacetyl mono methylgallacetophenone, mp 150—151°C,[1] on treatment with diazomethane, structure of which had been shown as 2,4-diacetoxy-3-methoxyacetophenone. However, this structure is also incorrect and should be revised as 2,3-diacetoxy-4-methoxyacetophenone (**3a**) by the following evidence. Diacetyl mono methylgallacetophenone was hydrolyzed to give gallacetophenone mono methyl ether, mp 132—133°C,[1] which was considered to be "2,4-dihydroxy-3-methoxyacetophenone." However, this ether was, in fact, 2,3-dihydroxy-4-methoxyacetophenone (**9**), being identical with an authentic sample, mp 132—133°C,[4] and differs from 2,4-dihydroxy-3-methoxyacetpohenone (**8**), mp 75—76°C,[5] and 3,4-dihydroxy-2-methoxyacetophenone (**7**), mp 84—85°C. It follows therefore that the two acetyl groups can be located at the position-2 and -3 in **3a**. This was further confirmed by acetylation of **9**, which gave an identical acetate, mp 150—151°C, with **3a**. The reaction could be explained in terms of a double acetyl migration during methylation. Acyl migration is fairly frequently observed in alicyclic and polyaromatic system[1,6] and extensively reviewed by Akahori[7] recently.

Various gallacetophenone 3,4-diesters (**2d**, **2e**, **2g**, **2h**) (Fig. 1) were prepared by partial esterification of Gallacetophenone (**1**) with acid anhydride or with acid chloride in pyridine (see Table 3). The position of the hydroxyl group is confirmed as ortho to the carbonyl by the presence of a hydrogen bonded carbonyl in the IR spectra and the presence of the proton signal at a lower field in the NMR spectra (see Tables 1 and 2).

Methylation of 3,4-dibenzoyloxy-2-hydroxyacetophenone (**2d**), mp 108—109°C, and 3,4-bis(*p*-nitrobenzoyloxy)-2-hydroxyacetophenone (**2e**), mp 208—209°C, gave mono methyl ethers (**3d**), mp 186—187°C,[8] and **3e**, mp 181—182°C, which were

a) Obtained by methylation.
b) Obtained by the esterification of corresponding monomethyl gallacetophenone.

found to be identical with those obtained by benzoylation of **9**. This indicates that the same type of benzoyl migration did occur in the reaction. In the case of **2e**, another product, mp 151—152°C, was isolated and found to be 2,4-dimethoxy-3-(*p*-nitrobenzoyloxy)acetophenone (**3f**), structure of which was confirmed by the independent synthesis of **3f** from **9**. 3-Acetoxy-2-hydroxy-4-methoxyacetophenone (**2b**), mp 122—123°C,[9] gave 3-acetoxy-2,4-dimethoxyacetophenone (**4b**), mp 112—113°C,[10] which was hydrolyzed to 3-hydroxy-2,4-dimethoxyacetophenone (**10**), mp 79—80°C,[11] indicating that the acetyl group could not migrate unless another acetyl group was present at the position-4. 3,4-Dimethanesulfonyloxy-2-hydroxyacetophenone (**2g**), mp 142—143°C, and 3,4-bis(*p*-

9) W. J. Horton and M. G. Scott, *J. Org. Chem.*, **20**, 1221 (1961).

11) Beilstein's Handbuch der Organischen Chemie, **8**, II, 440 (1948).

toluenesulfonyloxy)-2-hydroxyacetophenone (**2h**), mp 151—152°C,[1] yielded 3,4-dimethanesulfonyloxy-2-methoxyacetophenone (**4g**), mp 116—117°C, and 3,4-bis(*p*-toluenesulfonyloxy)-2-methoxyacetophenone (**4h**), mp 118—119°C,[1] respectively. These sulfonates were found to be identical with those prepared from 3,4-dihydroxy-2-methoxyacetophenone (**7**), mp 84—85°C. These experiments showed that the sulfonate group did not migrate in the reaction. The results are summarized in Tables 3 and 4.

It is interesting to note that acyl migration did occur not in the sulfonates but in the carboxylic esters in the methylation. It is presumably due to the fact that O–CO bond is readily cleaved by the participation of the hydroxyl group at the neighboring position, whereas O–SO_2 bond cannot be cleaved under the condition used. Although an intermolecular reaction mechanism could not be ruled out,[12] the methylation reaction seems to proceed *via* cyclic intermediates (II and IV in Fig. 2). Anion (I) can be in equilibrium with anion (III) and anion (V) *via* the cyclic intermediates in the cases R are acetyl, benzoyl and *p*-nitrobenzoyl, and V is then methylated preferentially, as it is sterically less hindered. On the other hand, when methanesulfonyl and *p*-toluenesulfonyl groups are involved, the neighboring hydroxyl group cannot attack them and I is directly methylated. Methylation with diazomethane can also be accounted for by the same mechanism: the first step of the reaction is the capture of the proton on the hydroxyl group with diazomethane molecule, providing the anion (I), and then I is rearranged to anion (V) which is methylated.

The fact that the mono *p*-nitrobenzoate (**3f**) was obtained in the methylation of **2e** is queer. It seems that the bis-*p*-nitrobenzoate (**3e**) could be hydrolyzed with moisture and then methylated with excess dimethylsulfate present. Further investigation on this point is necessary.

Methylation of 3,4-bis(*p*-methoxybenzoyloxy)-2-hydroxyacetophenone was examined under similar conditions. However, the product has not been isolated in crystalline form as yet.

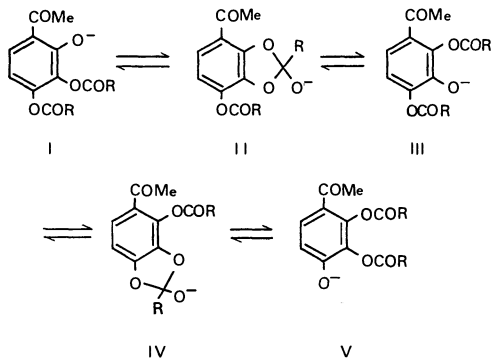

Fig. 2

Experimental

Measurements. IR spectra were recorded with JASCO Model DS 403G, a grating infrared spectrometer. Melting points were determined with Yanagimoto melting point apparatus. NMR spectra were obtained on a Varian A60 NMR spectrometer and JEOL JNM C 60H spectrometer using TMS as an internal standard.

Esterification of Gallacetophenones. a) Gallacetophenone (1 mmol) was treated with a mixture of acid anhydride (from 3 to 11 mmol) and pyridine (from 1 to 3 m*l*) at temperatures, room temperature — 120°C, for 3—24 hr. The reaction mixture was poured into ice water and the precipitates were collected. The crude ester was recrystallized from ethanol. b) Gallacetophenone (1 mmol) was dissolved in pyridine (from 1 to 3 m*l*) and treated with acid chloride (from 2 to 4.1 mmol) at temperatures 0—120°C for a period of time shown in Table 3. Working up in a similar manner to the above, a pure ester was obtained.

Methylation of Gallacetophenone. a) Gallacetophenone (1 mmol) was treated with a mixture of dimethyl sulfate (from 1.6 to 11.5 mmol) and potassium carbonate in acetone (30 to 40 m*l*). The reaction mixture was heated under reflux for a period of time shown in Table 4. After acetone was distilled off, the residue was triturated with water and the solid was collected. It was recrystallized from ethanol.

b) Gallacetophenone (1 mmol) was treated with distilled diazomethane at 0°C for 12 hr. After removal of the excess diazomethane and ether, the resulting solid was recrystallized from ethanol (see Table 4).

Preparation of Gallacetophenone (1), Gallacetophenone Monomethyl Ethers (7), (8) and (9), and 2,4-Dimethyl Ether (10). *Gallacetophenone (1).* The modified Nencki reaction of pyrogallol with boron trifluoride-acetic acid complex gave colourless needles (90%), mp 173°C.

2,3-Dihydroxy-4-methoxyacetophenone (9). 1-Methylpyrogallol[3] (4.0 g) was heated with boron trifluoride-acetic acid complex (12 m*l*) on a steam bath for an hour. The reaction mixture was poured into hot 2N hydrochloric acid (200 m*l*) and allowed to crystallize. This yielded colourless needles (4.0 g, 77%), mp 132—133°C (after sublimation) (lit,[4] mp 132—133°C).

2,4-Dihydroxy-3-methoxyacetophenone (8). 2-Methylpyrogallol[13] (839 mg) was heated with boron trifluoride-acetic acid complex (3 m*l*) on a steam bath for 30 min. The reaction mixture was poured into ice water and the precipitates were collected. Recrystallization of the crude material from water gave colourless leaves (928 mg, 85%), mp 75—76°C (lit,[5] mp 75°C).

3,4-Dibenzyloxy-2-hydroxyacetophenone (2c). A mixture of Gallacetophenone (**1**) (2 g), benzyl chloride (3.0 g), sodium iodide (4.0 g), and sodium bicarbonate (17 g) in acetone (71 m*l*) containing ethanol (6 m*l*), was heated under reflux for 19 hr. After removal of the acetone and the ethanol under reduced pressure, the residue was

12) T. H. Thompson and R. S. Wright, *J. Org. Chem.*, **26**, 4686 (1961).

13) Beilstein's Handbuch der Organischen Chemie, **6**, 1081 (1923).

triturated with water and then extracted with chloroform. The chloroform evaporated and the resulting liquid was allowed to crystallize in benzene. Recrystallization from ethanol gave colourless needles (2.01 g, 48%), mp 114—115°C (lit,[5] mp 113—114°C).

*3,4-Dibenzyloxy-2-methoxyacetophenone (**4c**).* 3,4-Dibenzyloxy-2-hydroxyacetophenone (**2c**) (4.9 g) was heated with a mixture of dimethyl sulfate (5.0 g) and potassium carbonate (6.0 g) in methyl ethyl ketone (100 m*l*) under reflux for 24 hr. After removal of the methyl ethyl ketone under reduced pressure, the residue extracted with chloroform. The chloroform was removed and the residue was crystallized from ethanol to give colourless plates (4.5 g, 88%), mp 62—63°C.

*3,4-Dihydroxy-2-methoxyacetophenone (**7**).* 3,4-Dibenzyloxy-2-methoxyacetophenone (**4c**) (1.14 g) was debenzylated with 15% hydrogen chloride-ethanol (20 m*l*), heating on a steam bath for an hour. Excess hydrogen chloride-ethanol was removed under reduced pressure and the resulting coloured liquid was separated on a silica column (Wakogel, C100, 100 g) with chloroform as an eluant. From a slow running fraction the required 3,4-dihydroxy-2-methoxyacetophenone (**7**) was crystallized on concentration, which was recrystallized from chloroform to give colourless needles (128 mg, 22%), mp 84—85°C.

*3-Hydroxy-2,4-dimethoxyacetophenone (**10**).* 3-Acetoxy-2,4-dimethoxyacetophenone (**4b**) (200 mg) was hydrolyzed with 2N hydrochloric acid (6 m*l*) in methanol (6 m*l*) under reflux for an hour. After removal of excess acid and methanol, the resulting solid was recrystallized from a mixture of benzene and light petroleum (30/70) to give micro crystals (130 mg, 78%), mp 79—80°C (lit,[11] mp 79—80°C).

The author wishes to thank Professor S. Sasaki, of Miyagi University of Education, JEOL Co., Ltd., and Dr. Y. Nakadaira, of Tohoku University for measuring the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2181—2186 (1970)

The Reactions of 1-Tropylazulenes with Phosphorus Pentachloride

Takashi TODA and Akira YAMANOUCHI[1)]

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received December 18, 1969)

The reactions of three 1-tropylazulenes——ethyl 2-acetamido-3-(cycloheptatrien-7-yl)azulen-1-carboxylate (I), 2-chloro-1-(cycloheptatrien-7-yl)azulene (II) and ethyl 3-(cycloheptatrien-7-yl)-azulen-1-carboxylate (III)——with phosphorus pentachloride were investigated. The reactions of I and II gave ethyl 2-acetamidoazulen-1-carboxylate and 1,2,3-trichloroazulene respectively. On the other hand, III afforded ethyl 3-chloroazulen-1-carboxylate (IV) and (3-ethoxycarbonylazulen-1-yl)tropylium perchlorate (V). The thermal isomerization of III formed *ca.* 2:3 mixtures of ethyl 3-(cycloheptatrien-3-yl)azulen-1-carboxylate (IV) and ethyl 3-(cycloheptatrien-1-yl)azulen-1-carboxylate (VII), but not ethyl 3-(cycloheptatrien-2-yl)azulen-1-carboxylate. The treatment of the above mixtures with phosphorus pentachloride raised the yield of V; however, IV was also obtained. The sodium borohydride reduction of V gave *ca.* 2:3 mixtures of VI and VII.

Syntheses of 1-tropylazulenes have been reported by Hafner and his coworkers,[2)] by Anderson and Replogle,[3)] and by the present authors.[4)] Although attempts to synthesise azulenyltropylium ions by means of the hydride abstraction of tropylazulenes have been carried out,[2,3)] there are no reports in the literature that azulenyltropylium ions have been successfully isolated in a pure state. Azulenyltropylium ions are of interest because of their possible canonical formulae, *e.g.*, the azulenyltropylium-ion type (A) and the condensed fulvalene-tropylium-ion type (B), as is shown in Fig. 1. The contribution of which canonical formula is more important is the first question. Secondly, if those types of ions are synthesized, they should be useful potential key intermediates for synthesizing non-benzenoid polycondensed aromatics, corresponding to benzanthracene, pentacene, *etc.*, in benzenoid polycondensed aromatics. Also, it is interesting to compare their properties with those of 1-azulenylfulvenes (C),[5)]

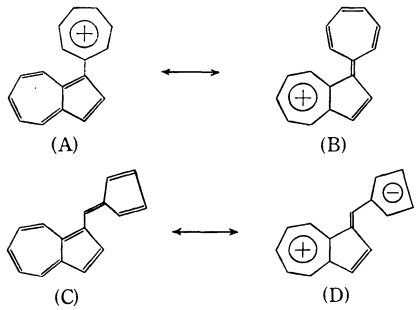

Fig. 1

which possess a (D)-type canonical formula.

In order to study the influence of substituents on azulene nuclei for hydride abstraction reactions and the stability of the formed azulenyltropylium ions, hydride abstraction reactions of three different kinds of tropylazulenes[4]——ethyl 2-acetamido-3-(cycloheptatrien-7-yl)azulen-1-carboxylate (I), 2-chloro-1-(cycloheptatrin-7-yl)azulene (II), and ethyl 3-(cycloheptatrin-7-yl)azulen-1-carboxylate (III)——were investigated. Bromination-dehydrobromination,[6] triphenylmethyl ions,[7] and phosphorus pentachloride[8] have been previously used for hydride abstraction reactions of tropylidenes. In this report, phosphorus pentachloride will be employed.

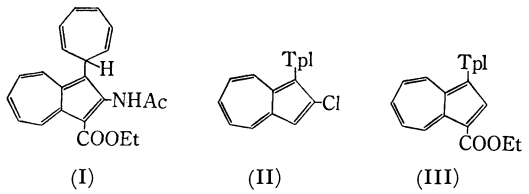

Fig. 2

The reaction of I with phosphorus pentachloride in anhydrous carbon tetrachloride afforded ethyl 2-acetamidoazulen-1-carboxylate[9] besides some intractable resinous substances. However, an attempt to isolate the removed tropylium ion as perchlorate was unsuccessful. Also, when II was treated as above, 1,2,3-trichloroazulene[9] was obtained in a 35% yield, but no other clear resultants could be identified.

The action of phosphorus pentachloride on III gave two substances, (IV) and (V). The elemental analysis ($C_{13}H_{11}O_2Cl$) and the IR spectrum (1655

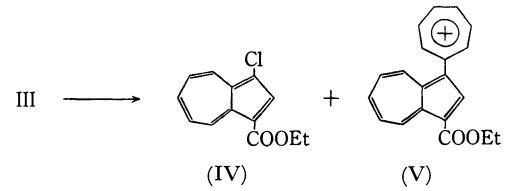

Fig. 3

cm^{-1}) of IV indicated that its structure is ethyl 3-chloroazulen-1-carboxylate. The hydrolysis and subsequent decarboxylation of IV gave 1-chloroazulene.[10] V was isolated as perchlorate salt from the water layer. The results of the elemental analysis of V are consistent with the molecular formula of ($C_{20}H_{17}O_6Cl$), and a new strong absorption band at 763 cm^{-1}, with a weakening of the 748 cm^{-1} band of III (which possesses the characteristic, very strong bands at 780, 748, and 708 cm^{-1}), is observed in the IR spectrum of V.[11] V also shows a broad strong band at 1080 cm^{-1}; presumably, this band is due to the Cl–O vibrations of the perchlorate anion.[12] Therefore, hydride abstraction must have occurred and the structure of V is (3-ethoxycarbonylazulen-1-yl)tropylium perchlorate. V is stable in air at room temperature and can be recrystallized from alcohol, but it burns explosively when heated.

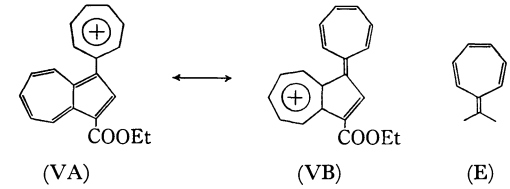

Fig. 4

As has been mentioned above, V possesses VA- and VB-type canonical formulae. If VB is the important canonical formula, the UV and a visible spectra of V should show spectra analogous to those of heptafulvenes (E). However, the spectra of V, although lacking the fine structure in the visible region, are similar to those of III, but not to those of heptafulvenes,[13] as is shown in Fig. 4. Thus,

-------- III —— V ---- VI

-·-·-· 8,8-Dicyano-2,3-dimethoxyheptafulvene[13c]

the contribution of the VB-type canonical formula is not important. Also, from the stereochemical point of view, this is rather reasonable, for if V takes a VB-type structure, the interference between the C_4-hydrogen of the azulene nucleus and the C_2-hydrogen of the tropylium moiety is fairly large.

The above reaction sometimes afforded a neutral substance (mp 181°C) which showed, in its IR spectrum, a strong absorption band at 1640 cm^{-1} beside the ester carbonyl band. This is presumably ethyl 3-(troponyl)azulen-1-carboxylate, which is formed from V by the attack of water and the following disproportionation reaction.[14] However, we did not obtain this in a quantity sufficient to investigate it further.

The reaction of III with chlorine was carried out for the purpose of obtaining V by chlorination-dehydrochlorination reaction. The results were the formation of IV and the recorvery of the starting substance, plus some resinous substances. Therefore, only the exchange reaction of the chlorine cation with the tropyl group occurred. Analogous types of reactions were observed when several 1-tropylazulenes were treated with cationoid reagents.[4]

The formation of 1,2,3-trichloroazulene from II and that of IV from III with phosphorus pentachloride can also be explained as exchange reactions of the chlorine cation with the tropyl groups of the above compounds, for phosphorus pentachloride is said to exist as a PCl_4^+-PCl_6^- complex[15] and it seems possible that the PCl_4^+ moiety dissociates to Cl^+ and PCl_3. The tetrachlorophosphonium cation or the formed chlorine cation then attacks the C_1- and C_3-positions of the azulene nucleus to form 1,2,3-trichloroazulene and IV respectively.[16]

Although 1-azulenyltropylium ion was obtained in the pure state, the yield of the ion was unsatisfactory because of the formation of IV as a by-product. The formation of IV can be explained as follows; if a tropyl group is attached to azulene by its C_7-position (allylic carbon), the exchange reaction takes place more readily than the hydride abstraction reaction. Therefore, if a tropyl group is attached to azulene by a carbon atom (vinyl carbon) other than C_7, the cleavage of the vinyl-carbon bond should not so easy. For this purpose, the thermal isomerization reactions of III was studied, as were the hydride abstraction reactions of the obtained isomers of III.

The thermal isomerization reactions of several different types of tropylidenes have been investigated by ter Borg *et al.*,[17] by the present au-

thors,[18] and by Murry and Kaplan;[19] the results have shown that a 1,5-hydrogen shift occurs in all cases. III was heated under a nitrogen atmosphere, and the reactions were followed by NMR spectroscopy. The methyne hydrogen of the tropyl group of III appears as a triplet (J=5.5 Hz) at 3.20 ppm in its NMR spectrum. When III was heated at 150°C, the triplet disappeared gradually and a new triplet (J=7.0 Hz) appeared at 2.38 ppm. After the disappearance of the triplet at 3.20 ppm, another new peak (doublet, J=7.5 Hz) appeared, at 2.80 ppm while the triplet at 2.38 ppm reached a maximum intensity and then decreased in intensity. The ratio of the intensities of the triplet at 2.38 ppm and the doublet at 2.80 ppm reached equilibrium (about 2:3) after *ca.* 20 hr, and no change was observed. The above peaks could be assigned to the methylene hydrogens of the tropyl groups of ethyl 3-(cycloheptatrien-3-yl)azulen-1-carboxylate (VI) and ethyl 3-(cycloheptatrien-1-yl)azulen-1-carboxylate (VII) respectively. The assignement can also be explained reasonably as follows. VI is formed from III by a 1,5-thermal hydrogen shift of the tropyl group, and then VII is formed from VI by the same procedure. The coupling constants and patterns of the above compounds are also reasonable in view of the assigned structures. Prolonged heating or heating at elevated temperature caused the formation of resinous substances, but no formation of (cycloheptatrien-2-yl)-azulene (VIII)-type isomers could be observed. Some examples of the obtained results are listed in the table.

Although the IR spectrum of III shows characteristic absorption bands at 708, 748, and 780

cm^{-1}, the band at 708 cm^{-1} becomes very weak as the isomerization proceeds and a new, strong band appears at 730 cm^{-1}.

When the mixtures of VI and VII were treated with phosphorus pentachloride under the same conditions as in the case of III, the yield of V was raised to 50—55%. However, IV was surprisingly obtained in a 20—25% yield. These are very interesting results. The explanation was first thought to be as follows: the protons which are formed as the reaction proceeds react with VI and VII to form III, as is shown in Fig. 6, and then the exchange reaction of the tropyl group of the formed III takes place, thus giving IV. However, the treatment of the mixtures of VI and VII with hydrogen chloride under the present reaction conditions did not provide any evidence of the formation of III or ethyl azulen-1-carboxylate. The second possible mechanism of this reaction is that the attack of the chlorine cation takes place at the C_3-position of the azulene nucleus, and then the isomerization and elimination of the tropyl group occurs, either step by step or simultaneously, to give IV. Further investigation of the reaction mechanism is in progress.

The metal - hydride reductions of tropylium ions have been reported to give mixtures of several different kinds of tropylidenes by Vol'pin *et al.*,[20] and by Conrow.[21] Also, Anderson and Replogle[3] reported the formation of 1-chloro-3-(cycloheptatrien-7-yl)azulene by the reduction of the 1-(3-chloroazulen-1-yl)tropylium ion with sodium borohydride. However, they did not isolate the chloroazulenetropylium ion which was used for reduction, and the reduction product was identified only by means of its UV and visible spectra.

The sodium borohydride reduction of V gave only 2 : 3 mixtures of VI and VII, as shown by an investigation of the IR and NMR spectra of the reduction products, but the formation of III was not observed. According to Conrow,[21] the hydride reduction of the methyltropylium ion gave mixtures of 1-methyl-, 2-methyl-, and 3-methyl-tropylidenes in more than a 95% yield and the yield of 7-methyltropylidene was about 2%. The formation of a large amount of a 7-tropyl-type compound does not seem reasonable either from the point of view of the thermodynamical stability of the resultants and the steric requirements of the reaction.

The results of the reduction of V, together with the consideration of the spectroscopic properties of V mentioned above, support the idea that the structure of V is (3-ethoxycarbonylazulen-1-yl)-tropylium perchlorate.

Experimental[22]

Hydride Abstraction Reaction of I. Into a suspension of 0.60 g of phosphorus pentachloride in 20 m*l* of anhydrous carbon tetrachloride, a solution of 0.50 g of I in 5 m*l* of anhydrous carbon tetrachloride was stirred, and then stirring was continued for 6 hr. The reaction mixture was poured into 30 m*l* of cold water, and the water layer was extracted with benzene. After separation, the combined organic layers were dried over sodium sulfate, separated from the drying reagent, and concentrated *in vacuo*; the residue was dissolved in benzene and submitted to chromatography. The first eluate gave 89 mg of dark red prisms (mp 141—142°C, which did not show any mixed-melting-point depression with ethyl 2-acetamidoazulen-1-carboxylate[9]); the second eluate gave 9 mg of violet crystalline substances (mp 111—112°C), and the third gave 23 mg of violet, crystalline substances (mp 146—182°C), the rest was composed of 156 mg of resinous, oily substances. The second crystalline substances show a positive Beilstein test: however, further purification of the second and the third eluates failed to provide pure substances.

The addition of 60% perchloric acid to the water layer did not give any crystalline substances.

Hydride Abstraction Reaction of II. A solution of II in 5 m*l* of anhydrous carbon tetrachloride and 1.0 g of phosphorus pentachloride in 20 m*l* of carbon tetrachloride was treated as above. Cyclohexane eluates of the chromatography gave 173 mg of dark blue, crystalline substances (mp 120—124°C). Recrystallization from ethyl acetate raised its melting point to 137°C; yield, 140 mg. A mixed-melting-point determination of this and 1,2,3-trichloroazulene[9] failed to show any depression.

Found: C, 51.70; H, 2.20%. Calcd for $C_{10}H_5Cl_3$: C, 51.88; H, 2.18%.

The water layer did not give any crystalline substances after the addition of 60% perchloric acid.

Hydride Abstraction Reaction of III. Into a suspension of 1.13 g of phosphorus pentachloride in 25 m*l* of anhydrous carbon tetrachloride, a solution of 0.78 g of III in 5 m*l* of carbon tetrachloride was stirred, and then the stirring was continued for 1.5 hrs. After the reaction, the reaction mixture was treated as above. The organic layer gave blue black needles (mp 62°C), after chromatography and recrystallization from cyclohexane; yield, 133 mg.

Found: C, 66.27; H, 4.30%. Calcd for $C_{13}H_{11}O_2Cl$: C, 66.30; H, 4.75%.

The addition of 60% perchloric acid to the water layer formed dark brown precipitates. The precipitates were then separated by filtration and dried in a desiccator to give 0.40 g of a dark brown powder (mp 180—182°C (dec.)). Recrystallization from alcohol raised its melting point to 205°C (dec.), and this crystalline substance vigorously burned when heated in air.

Found: C, 61.71; H, 4.30%. Calcd for $C_{20}H_{17}O_6Cl$: C, 61.79; H, 4.41%.

λ_{max}^{MeOH}, mμ (log ε); 238 (4.43), 305 (4.54), 382 (3.94), and 536 (3.49).

Hydride Abstraction Reaction of the Mixtures of VI and VII. From 0.50 g of the mixtures of VI and VII, 0.34 g of V was obtained when the reaction was carried out as above. From the organic layer, 85 mg of IV were obtained; the rest was composed of resinous, oily substances which did not give any pure substances upon further purification. The average yields of IV and V from the mixture were 20—25% and 50—55% respectively, and no remarkable change was observed when the ratio of VI and VII in the starting mixtures was changed.

Sometimes a few mg of dark blue, crystalline substances (mp 181°C) were obtained from the organic layer; these substances showed a strong absorption band at 1640 cm^{-1} (KBr pellet) besides the ester carbonyl band at 1675 cm^{-1}.

Hydrolysis and Decarboxylation of IV, 1-Chloroazolene. A solution of 50 mg of IV and 38 mg of potassium hydroxide in 3 m*l* of alcohol and 1 m*l* of water was heated under reflux for 4 hr, and then 5 m*l* of cold water were added. The pH of the solution was adjusted to *ca.* 3.0 with 6N hydrochloric acid to give 32 mg of dark violet precipitates (mp 225°C (dec.)) after having been dried *in vacuo*. The precipitates were heated in a sublimation apparatus for decarboxylation at 190°C (3 mmHg), and the blue oil thus formed was chromatographed on alumina. The cyclohexane eluate gave 21 mg of a blue oil, and its IR spectrum was superimposable upon that of 1-chloroazulene prepared by the authentic method.[10] The treatment of the oil with trinitrobenzene gave dark brown needles (mp 132—133°C) from benzene (reported, mp *ca.* 105°C).[10]

Found: C,51.26; H, 2.58; N, 10.66%. Calcd for $C_{16}H_{10}O_6N_3Cl$: C, 51.14; H, 2.68; N, 11.19%.

Reaction of III with Chlorine. To a solution of 116 mg of III in 10 m*l* of anhydrous carbon tetrachloride, 30 mg of chlorine in 0.25 m*l* of anhydrous carbon tetrachloride were added, then the mixture was allowed to stand overnight. After the solvent has then been removed, 142 mg of an oily substance were obtained; the oil was submitted to chromatography. The benzene eluate gave 88 mg of a dark blue oil, and the ethyl acetate eluate gave 24 mg of a black tar. Rechromatography of the first eluate by petroleum ether-cyclohexane (4 : 1) gave 35 mg of dark blue, crystalline substances (mp 61°C) from cyclohexane as the first eluate, and, as the second eluate, 25 mg of

21) K. Conrow, *J. Amer. Chem. Soc.*, **83**, 2343 (1961).
22) All melting points are uncorrected.

a violet oil. The former was identical with ethyl 3-chloroazulene-1-carboxylate (IV), and the latter was the recovered starting materials, as determined by a comparison of their IR spectra with those of the respective authentic samples.

Thermal Isomerization of III. III (0.51 g) was heated under a nitrogen stream at 130°C for 2 hr without any solvent; after heating, the resultant substance was chromatographed on alumina. The benzene eluate gave 0.51 g of dark blue-violet oil. The results of the elemental analysis of the resultant are as follows:

Found: C, 82.56; H, 6.38%. Calcd for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

The ratio of the isomers was determined by measuring the areas of the methine and methylene hydrogens of mixtures of the isomers. The NMR spectra were measured with *ca.* 10% solutions of each resultant in carbon tetrachloride, with TMS as the internal standard, using a Varian A-60-type spectrometer. Some examples of the obtained results are listed in the table.

About 2 : 3 mixtures of VI and VII were obtained when the isomerization was carried out at 150°C for *ca.* 20 hr. However, when heating was continued for more than 15 hr at 190°C, VI and VII amounted to *ca.* 56%, with the rest being a polymer which could be separated from VI and VII by means of alumina chromatography.

Sodium Borohydride Reduction of V. Into a solution of 0.20 g of V in 5 m*l* of acetonitrile, a solution of 40 mg of sodium borohydride in 2 m*l* of acetonitrile was stirred in small portions. The color of the solution changed from a dark reddish violet to brown; then 40 more mg of borohydride were added, thus causing the color of the solution to change from brown to a greenish violet. The solution was then allowed to stand at room temperature for 30 min with stirring, and water was added. The water layer was extracted with petroleum ether; the combined organic layers were then washed with water and dried over sodium sulfate, and the drying reagent was separated by filtration. The petroleum ether was removed to give 155 mg of a greenish-brown oil; the obtained oil was chromatographed on alumina. A light petroleum - benzene (9 : 1) eluate afforded 109 mg of a greenish-violet oil the IR and NMR spectra of which were identical with those of the 2 : 3 mixtures of VI and VII.

The authors wish to express their gratitude to Professor Tetsuo Nozoe for his kind encouragement and interest, to Miss Ayako Iwanaga, Miss Mutsuko Suzuki, and Mrs. Ei Arai for their elemental analyses, and to Miss Yoriko Terui and Mr. Iwao Miura for their measurement of the spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2186—2191 (1970)

The Catalytic Dehydrogenation, Dehydroxylation and Dehydroxymethylation of Benzyl Alcohol. I. The Scope and the Kinetic Study

Masayoshi ISHIGE,*1 Koji SAKAI, Masatoshi KAWAI and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received December 23, 1969)

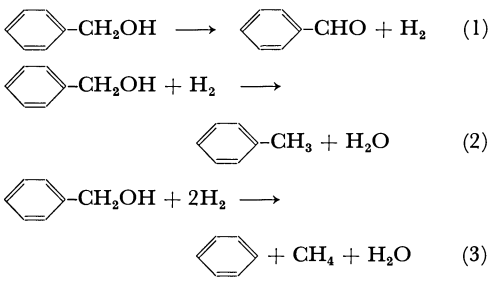
Benzyl alcohol was dehydrogenated to benzaldehyde when it was heated in the presence of various metal catalysts. It was found that the dehydrogenation was accompanied by a reductive dehydroxylation and dehydroxymethylation which led to the production of toluene and benzene respectively. The compositions of the products, which mainly consisted of benzaldehyde, toluene, and benzene, were greatly affected by the chemical nature of the catalysts used. The results of the reactions in a sealed tube or in an authoclave suggested that a pseudo-equilibrium between benzyl alcohol and benzaldehyde was attained during the reaction in a closed system. The formation of CO_2, CH_4, and other hydrocarbons as gaseous products was also observed. From these results, the catalytic dehydrogenation, dehydroxylation, and dehydroxymethylation were assumed to proceed competitively *via* a certain metal benzyl complex which is formed as an adsorbed transition complex upon the catalyst metal.

It has previously been reported[1] that a novel redox reaction was observed between benzyl alcohol and some kinds of unsaturated organic compounds, such as styrene and mesityl oxide, in the presence of nickel catalysts. In these reactions, benzyl alcohol was mainly converted into benzaldehyde by dehydrogenation (Eq. (1)), but reductive dehydroxylation (Eq. (2)) and dehydroxymethylation

*1 Present address: Chemical Laboratory, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo.

1) K. Sakai, T. Ito and K. Watanabe, This Bulletin, **39**, 2230 (1966).

(Eq. (3)) were also found to take place to some extent.



The behavior of benzyl alcohol in these reactions was considered to be much more complicated; for example, in addition to the formation of CH_4, the generation of CO_2 and of some other gaseous hydrocarbons was observed. Furthermore, the composition of the products from the alcohol was characteristically affected by the nature of the catalysts used. Nishimura[2] has also shown that the reactivity and selectivity in the hydrogenation of benzyl alcohol are dependent upon the species of the catalysts used. Thus, the study of the dehydrogenation, dehydroxylation and dehydroxymethylation of benzyl alcohol may provide an insight into the nature of the reactivity and selectivity in catalysis. For a further investigation of the relation between the catalytic reaction and the nature of the catalysts, the reactions of benzyl alcohol have been studied in the presence of various kinds of solid catalysts, including metals and metal oxides.

Results and Discussion

Benzyl alcohol afforded benzaldehyde, toluene, and benzene when heated at 140—180°C with various metal catalysts. In addition, the generation of CO_2, CH_4, and some other hydrocarbons was observed, accompanied by the formation of benzene by dehydroxymethylation.

Some experiments were carried out by refluxing under ordinary pressure; in these experiments, when the refluxing was continued for a long time, a change in the quality of the catalyst was necessarily brought

2) S. Nishimura and M. Hama, *ibid.*, **39**, 2467 (1966); S. Nishimura, *ibid.*, **32**, 103 (1959); **32**, 1158 (1959).

about by the reaction with the benzaldehyde and/or benzoic acid which was formed during the reaction. The other experiments were practiced in a sealed tube or in an autoclave in order to avoid the volatilization and oxidation of the products. After the reaction was over, the reaction mixture was analyzed by gas chromatography. The results of representative experiments are summarized in Tables 1 and 2. The catalysts used were precipitated nickel (ppt-Ni), precipitated copper (ppt-Cu), Raney nickel (R-Ni), Urushibara nickel A (U-Ni-A), stabilized nickel (S-Ni), copper chromium oxide ($Cu_2Cr_2O_5$), nickel chromium oxide ($Ni_2Cr_2O_5$), zinc chromium oxide ($ZnCr_2O_4$), aluminum oxide (Al_2O_3), and nickel oxide (NiO).

The activities of these catalysts are represented in terms of the corresponding first-order rate constants of the catalytic reaction of the alcohol (k_{alc}), which were approximately calculated from the amount of unreacted alcohol. From these results, it was found that the activity of ppt-Ni is much better in dehydrogenation rather than those of the other catalysts, and that the compositions of the reaction products vary remarkably depending upon the species of the catalysts; for example, the mol percentage of toluene in the products was not very different between the different nickel catalysts used, whereas the formation of benzene was markedly influenced by the kind of catalyst, the relative yield being suppressed in the following order: S-Ni> R-Ni>U-Ni-A>ppt-Ni. It is noteworthy that benzene was not produced in the presence of metal oxide catalysts, such as $Cu_2Cr_2O_5$, $ZnCr_2O_4$, and Al_2O_3. From the viewpoint of the formation of benzene during the reaction, the catalysts used can be roughly classified into three categories: (a) the catalysts, such as S-Ni and R-Ni (W-7), which afford a large quantity of benzene. They are mainly composed of nickel crystals or crystallites; (b) the catalysts, such as ppt-Ni and U-Ni-A, which give a small quantity of benzene. Ppt-Ni, which is the precursor of U-Ni-A, is supposed to have the surface structure of an alloy-like crystal composed of nickel and zinc,[3] and (c) ppt-Cu or oxide-type catalysts which exhibit no activity giving benzene. Considering these facts, it can be assumed that the nickel crystals are generally effective in the formation of benzene.

With a veiw to getting further information on the process of the reactions of benzyl alcohol, the change in the composition of the reaction mixture was followed by gas-chromatographic analysis at successive intervals. The results of the reaction, in which benzyl alcohol was refluxed under orindary pressure in the presence of S–Ni (S 10), are shown in Fig. 1; those of the same reaction practiced in a sealed tube are illustrated in Fig. 2. Figures 1 and 2 indicate that the alcohol always reacts in the

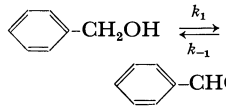
first order. In the reaction in a sealed tube, benzaldehyde and benzene increased successively in the early stages, but the rate of their formation was found to decline after the elapse of 12 hr, while toluene went on increasing.

In the redox reaction shown in Eq. (4), the rate constant of the oxidation of the alcohol (k_1) was supposed to be smaller than that of the reverse reaction (k_{-1}), because the oxidation potential of benzaldehyde is comparatively high.[4]



$$\text{-CHO} + H_2 \quad (k_1 < k_{-1}) \qquad (4)$$

Thus, in the state of equilibrium between benzyl alcohol and benzaldehyde, the alcohol may be predominant. Therefore, in the closed reaction system, the reduction of benzaldehyde, which corresponds to the reverse reaction in Eq. (4), may proceed concurrently with the dehydrogenation of benzyl alcohol until the pseudo-equilibrium shown in Eq. (4) is attained in the reaction system. The consumption of hydrogen produced by the dehydrogenation of benzyl alcohol will lead to the disadvantageous reductive dehydroxylation and dehydroxymethylation of the alcohol according to Eqs. (2) and (3). Of these competitive reactions, the latter was found to be more strongly suppressed (Fig. 2). This is conceivable not only because the C–C bond is more difficult to hydrogenolyze than the C–O bond, but also because the dehydroxymethylation (Eq. (3)) requires twice as much hydrogen as does dehydroxylation (Eq. (2)).

One piece of evidence leading to this conclusion comes from the results of the reactions carried out with various amounts of a nickel catalyst (S-Ni) in sealed tubes; the influence of the change in the amount of catalyst in the reactions is summarized in Table 3 and Fig. 3. As is shown in Fig. 3, a linear proportionality was observed between the amount of the catalyst and the logarithm of the rate constant. The linear relation equation can be approximately represented as follows:

$$\log k_{alc} = 6.20 \times 10^{-2} \cdot W - 2.20 \qquad (5)$$

where W is the weight of the catalyst (in gram).

The composition of each product in the reaction mixture of the above reactions is given in Fig. 4. It can be found from Figs. 3 and 4 that the rate constant of the overall reaction of benzyl alcohol and the yields of toluene and benzene increased with an increase in the amount of the catalyst. However, the yield of benzaldehyde decreased in spite of the increase in the rate of the overall reaction of benzyl alcohol. Therefore, it may be

assumed that the faster the dehydragenation reaction proceeds due to an increase in the amount of the catalyst, the more readily the pseudo-equilibrium shown in Eq. (4) will be attained, resulting in the promotion of the formation of benzene and toluene.

Other experiments to observe the effect of the amount of the catalyst were carried out by refluxing benzyl alcohol under ordinary pressure. The results are shown in Table 4 and Fig. 5. A linear relationship was similarly observed between the rate constant of the overall reaction of benzyl alcohol and the amount of the catalyst. The relation can be represented as in the following equation:

$$k_{alc} = 2.21 \times 10^{-3} \cdot W \qquad (6)$$

In contrast to the results in a closed reaction system, the decrease in the formation of benzaldehyde with the increase in the catalyst amount (see Fig. 4) was observed in an open reaction system under ordinary pressure. Thus, it was found that hydrogen plays an important role in determining the compositions of the products. In the closed reaction system, the high pressure of hydrogen, which is brought about by the dehydrogenation, necessarily leads to a decrease in the final yield of benzaldehyde. On the other hand, it may be advantageous to promote the formation of toluene and benzene by the reductive dehydroxylation and dehydroxymethylation. This consideration is fairly consistent with the results of another experiment in which the variation in the composition of the products under various hydrogen pressures was observed (Fig. 6). Consequently, it was concluded that the selectivity of this reaction is dependent not only upon the nature of the catalyst used, but also upon the pressure of hydrogen in the reaction system.

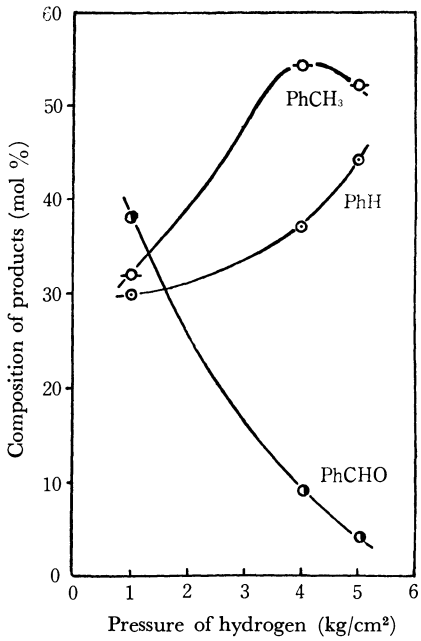

Fig. 6. The composition of products by the catalytic reactions of benzyl alcohol under varied pressure of hydrogen.
benzyl alcohol 24 ml; catalyst: stabilized nickel 4 g

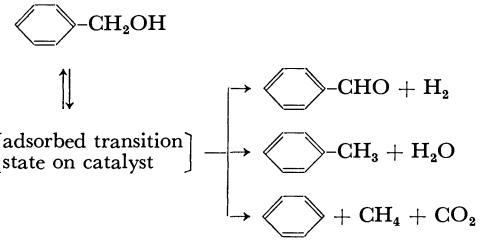
It was established that benzaldehyde cannot be an intermediate in the formation of toluene or benzene, because the benzaldehyde itself was completely recovered unchanged when it was heated in the presence of a nickel catalyst in a sealed tube for more than 24 hr. The formation of methane in the dehydroxymethylation of primary alcohol has already been reported.[5] In the present study the generation of a small quantity of another gaseuous hydrocarbon besides methane was observed by gas-

5) V. N. Ipatieff, G. Czajkowski and H. Pines, *ibid.*, **73**, 4098 (1951); H. Pines, H. G. Rodenberg and V. N. Ipatieff, *ibid.*, **76**, 771 (1954); H. Pines, M. Shamaiengar and W. S. Postle, *ibid.*, **77**, 5099 (1955).

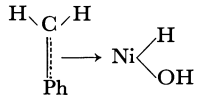
chromatographic analysis; it was assumed to be either ethane or propane on the basis of its retention time. The formaldehyde, which might be expected in dehydroxymethylation, could not be detected by any test with 2,4-dinitrophenylhydrazine, Fehling's solution, and Schiff's reagent.

It is noticeable that the generation of carbon dioxide was observed as another by-product of the dehydroxymethylation. Carbon dioxide was detected by gas-chromatographic analysis and by the formation of a $BaCO_3$ precipitate when a gaseous product was introduced into a saturated aqueous solution of $Ba(OH)_2$.

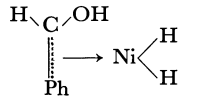
The mode of the adsorption of benzyl alcohol on the catalyst and the mechanism of the catalytic reaction are not entirely clear, but it is considered that the general scheme of the reaction may well be represented as follows, assuming the intervention of an adsorbed transition state on the catalyst:



McQuillin *et al.*[6] have proposed a mechanism of the hydrogenolysis of benzylic compounds in which the reaction was presumed to proceed through a metal benzyl complex. If the formation of a π-benzyl complex intermediate in hydrogenolysis is established, it is conceivable that a similar complex, at least one of nickel, is involved in the dehydroxymethylation and dehydroxylation of benzyl alcohol in the presence of a catalyst. This consideration seems to be fairly consistent with the complicated reaction course of benzyl alcohol. Since nickel metal plays an important role in the cleavage of α-carbon from the benzene ring by dehydroxymethylation reaction, a strong interaction of nickel with the phenyl group may be expected in the adsorbed transition complex. Considering the simultaneous formation of CO_2 and CH_4 in the dehydroxymethylation, and the high yield of cyclohexylmethanol in the hydrogenation,[2,7] of benzyl alcohol, it was supposed that the formation of a π-benzyl intermediate involves the removal of either a hydrogen atom or a hydroxyl group from α-carbon, thus giving a metal benzyl complex, I or II :



(I)



(II)

The preference for the alternative removal of either the hydrogen or hydroxyl group is probably dependent upon the chemical nature of the catalyst metal and on the reaction conditions. From the fact that scarcely no formation of benzene was observed when precipitated copper or oxide-type catalysts were used, it is reasonable to consider that the reaction in the presence of these catalysts might take place through another reaction path, without any formation of the metal complex.

Experimental

Benzyl Alcohol. Commercial benzyl alcohol of an extra pure degree was refined by distillation. The fraction boiling at 100—101°C/20 mmHg was collected. The sample was proved to be pure by gas chromatography.

The Reaction under Ordinary Pressure. In a 50-m*l* three-necked flask fitted with a Dimroth condenser and a thermometer was placed 6 m*l* of benzyl alcohol (6.25 g). The flask was then heated to 160°C, and 1.0 g of a catalyst was added through a side-neck when the contents reached a constant temperature.

Small portions of the reaction mixture were periodically taken out with a pipet and analyzed by gas chromatography: column, 1 m of 30% Silicone grease DC on Celite 480 (30—40 meshes) and 2 m*l* of 20% Apiezon grease on Chromosorb W (60—80 meshes); column temp., 150—163°C; flow rate, 40—60 m*l*/min; carrier gas, H_2.

The Reaction in a Sealed Tube. Benzyl alcohol (2.00 m*l*) and a catalyst (0.333 g) were heated at 157°C for 24 hr in a sealed tube. After the reaction was over, the tube was cooled by ice; then the reaction mixture was analyzed by gas chromatography immediately after the tube was opened. For the kinetic study in a closed reaction system, several sealed tubes with the same contents were prepared. The tubes were succesively taken out from the heating bath at adequate intervals and the reaction mixture was analyzed as has been mentioned above.

The Reaction in an Autoclave. Benzyl alcohol (24 m*l*) and a catalyst (4 g) were placed in a 200-m*l* autoclave. After the air in the autoclave had been completely displaced by hydrogen gas, the mixture was heated at 155°C for 24 hr under 1.0 kg/cm^2 pressure of hydrogen without stirring. After the reaction was over, portions of the gaseous product were introduced into various kinds of reagents in order to detect the formation of CO_2 and formaldehyde. The liquid products were analyzed by gas chromatography. Some of the gaseous products were also detected by gas chromatography.

The authors wish to express their hearty thanks to Dr. Ken-ichi Watanabe for his helpful encouragement.

The Hydroformylation of Nitroalkenes with Rhodium Carbonyl

Masahiko TAKESADA and Hachiro WAKAMATSU

Central Research Laboratories, AJINOMOTO CO., INC., Kawasaki

(Received January 7, 1970)

The hydroformylation of butenes in nitrobenzene or nitroethane gives C_5-aldehydes in an excellent yield in the presence of tetrarhodium dodecarbonyl, but in only a poor yield in the presence of dicobalt octacarbonyl. Under hydroformylation conditions, nitrobenzene is hydrogenated to aniline above 150°C with rhodium carbonyl and at 125°C with cobalt carbonyl. The hydroformylation of nitroalkenes with rhodium carbonyl is described. 4-Nitrostyrene gives isomeric (4-nitrophenyl)-propionaldehydes in a 96% yield. 3-Nitropropene-1 gives C_4-nitroaldehydes, mostly 2-methyl-3-nitropropionaldehyde, in a 96% yield. However, no reaction of nitroethylene occurred below 140°C.

It has been already established that nitrobenzene is hydrogenated to give aniline under hydroformylation conditions at an elevated temperature and in the presence of cobalt carbonyl.[1,2] However, no study has been reported on the hydroformylation of nitroalkenes. In this paper, the hydroformylation of butenes in a solvent of nitro compounds will be described, together with the hydrogenation of nitrobenzene under hydroformylation conditions in the presence of cobalt and rhodium carbonyl. The hydroformylations of nitroethylene, 3-nitropropene-1, and 4-nitrostyrene will also be described.

Results and Discussion

Hydroformylation of Butenes. The results of the hydroformylation of butenes in a solvent of various nitro compounds are shown in Table 1. In the reaction of butene-1 with a mixture of carbon monoxide and hydrogen in nitrobenzene in the presence of dicobalt octacarbonyl, the absorption of the gas started at 120°C and more than 2 moles of the gas were consumed per mole of butene-1. However, the yield of C_5-aldehydes was only 37% and the ratio of 2-methylbutyraldehyde to *n*-valeraldehyde was 1.0 to 1.40. The yield and the isomeric ratio of the products in this system are different from those of the hydroformylation of butene-1 in benzene, where the yield of the aldehydes and the isomeric ratio were reported to be 89% and 0.23 respectively.[3] The poor yield of the aldehydes in nitrobenzene is probably due to further reactions of the aldehydes with the aniline formed from nitrobenzene under hydroformylation conditions.

TABLE 1. HYDROFORMYLATION OF BUTENES

Reaction conditions[a]					Product	
Olefin	Catalyst	Solvent	Temp. °C	Time min	Yield of aldehydes %	Ratio of isomers[c] B/N
Butene-1	Co	Nitrobenzene	120	170	37	1.40
	Rh	Nitrobenzene	60	41	95	1.19
	Rh	Nitroethane	60	42	94	1.24
	Rh	Benzene	60	33	94	1.26
trans-Butene-2	Rh[b]	Nitrobenzene	60	100	93	100
	Rh[3]	Benzene	60	120	91.4	∞

a) Other reaction conditions:
Butenes: 100 mmol, solvent: 45 ml, pressure: 200 kg/cm², $[Rh(CO)_3]_4$: 50 mg or $[Co(CO)_4]_2$: 145 mg.
b) $[Rh(CO)_3]_4$: 80 mg.
c) B: 2-methyl-butyraldehyde. N: *n*-valeraldehyde.

1) I. Wender, H. Greenfield, S. Meltin and M. Orchin, *J. Amer. Chem. Soc.*, **74**, 4079 (1952).
2) S. Murahashi, S. Horiie and T. Joh, *Nippon Kagaku Zasshi*, **79**, 68 (1958).
3) H. Wakamatsu, *ibid.*, **85**, 227(1964).

In the presence of tetrarhodium dodecacarbonyl in place of dicobalt octacarbonyl, the hydroformylation of butenes gave C_5-aldehydes in an excellent yield even in nitrobenzene or nitroethane, and the amount of gas consumed was almost the theoretical value for hydroformylation. On the hydroformylation of butene-1 or *trans*-butene-2 with rhodium carbonyl under milder conditions, there are no significant differences in the yield and isomeric distribution of the aldehydes between the benzene and the nitrobenzene used as solvents.

Hydrogenation of Nitrobenzene. In order to elucidate the catalytic activity of cobalt and rhodium carbonyl for the hydrogenation of nitro compounds to amino derivatives under hydroformylation conditions, the hydrogenation of nitrobenzene was studied. The results are shown in Table 2.

Table 2. Hydrogenation of nitrobenzene

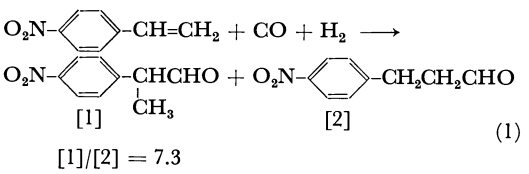
Catalyst	Reaction conditions: Solvent	Temp. °C	Time min	Yield of aniline %
Co[a)]	Benzene	125	30	100
Rh[a)]	Benzene	180	140	94
Rh[b)]	—	150—154	105	96

Other reaction conditions:
a) Nitrobenzene (80 mmol)+benzene: 40 m*l*, pressure: 250 kg/cm² ($CO+H_2$), $[Rh(CO)_3]_4$: 73 mg or $[Co(CO)_4]_2$: 465 mg.
b) Nitrobenzene: 30 m*l*, pressure: 182 kg/cm² ($CO+H_2$), $[Rh(CO)_3]_4$: 80 mg.

Nitrobenzene is hydrogenated to aniline under hydroformylation conditions at 125°C with cobalt carbonyl as shown in Table 2. Rhodium carbonyl also catalyzed the hydrogenation of nitrobenzene above 150°C without a solvent or at 180°C in benzene, but at lower temperatures no reaction took place. A higher temperature is required for the hydrogenation of nitro groups with rhodium carbonyl than with cobalt carbonyl.

Hydroformylation of Nitroalkenes with Rhodium Carbonyl. In view of the above results, it may be expected that the hydroformylation of nitroalkenes to nitroaldehydes proceeds without hydrogenating the nitro group below 150°C with rhodium carbonyl. The hydroformylation of nitroalkenes was carried out with tetrarhodium dodecacarbonyl as a catalyst.

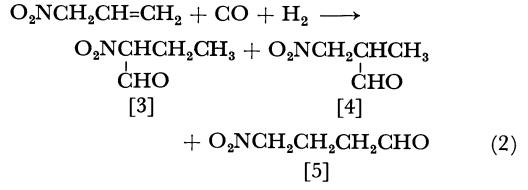
The hydroformylation of 4-nitrostyrene in benzene gave (4-nitrophenyl)-propionaldehydes in a 96% yield. By means of PMR study, the (4-nitrophenyl)-propionaldehydes thus produced were found to be a mixture of two isomers, [1] and [2]. The ratio of [1] to [2] was determined to be 7.3. This ratio is somewhat smaller than those of the 2-phenyl-propionaldehyde to the 3-phenyl-propionaldehyde produced by the hydroformylation of



[1]/[2] = 7.3 (1)

styrene, of which ratios are 11.9 at 60°C and 13.8 at 70°C.[4] Thus, the nitro substitution on styrene is observed to induce a change in the isomeric distribution of the products, probably because of the electron-withdrawing effect of the substituent.[5]

The hydroformylation of 3-nitropropene-1 proceeded smoothly at 60°C and gave C_4-nitroaldehydes in a 96% yield. Although the formation of three isomeric aldehydes was anticipated, it was found by



(2)

PMR that 2-methyl-3-nitropropionaldehyde, [4], was the predominant product and that the amounts of the other isomers were very small. On the hydroformylation of propene with rhodium carbonyl at 40°C, the ratio of the isobutyraldehyde to the *n*-butyraldehyde produced is 1.0 to 1.25.[3] There is a great difference in the isomeric distribution of the reaction products between 3-nitropropene-1 and propene. It is clear that a nitro-group on the olefin has a great effect on the isomeric distribution. This effect may be explained in terms of the interaction of the nitro group with rhodium in the intermediate step of the reaction, although further work on the intermediate is required to clarify this interesting observation.

Similarly, when nitroethylene was treated with a mixture of carbon monoxide and hydrogen, no absorption of the gas was observed below 140°C. When this is compared with the reaction of 3-nitropropene-1, it seems reasonable to consider that the inactiveness of nitroethylene to hydroformylation is to be ascribed to the possible deviation of the nature of the carbon-carbon double bond in nitroethylene, which may originate from the conjugation with a nitro group.

Experimental

All the melting points were uncorrected. The PMR spectra were obtained at room temperature on a Varian A-60 spectrometer, using tetramethylsilane as an internal standard. The IR spectra were recorded on a Perkin Elmer 21 spectrometer. Gas-liquid chromatographic

5) M. Kainosho, M. Takesada and H. Wakamatsu, the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

analyses were carried out with a Shimadzu GC-2B apparatus.

Materials. The nitrobenzene and nitroethane were obtained commercially and were rectified before use. The nitroethylene[6] and 4-nitrostyrene[7] were prepared in the manner as described in the literature. The 3-nitropropene-1 was synthesized according to the method of Askennasy[8] and was purified by fractional distillation using diphenyl ether as a diluent.

Quantitative Analyses of Aldehydes. The amount of aldehydes produced was determined by the method described previously.[3]

Hydroformylation of Butenes. The reaction and the determination of the ratio of the isomeric aldehydes were carried out in the manner described previously.[3]

Hydrogenation of Nitrobenzene. The hydrogenation was carried out similarly to the hydroformylation of butenes. The quantitative analyses of aniline were carried out by gas-liquid chromatography.

Hydroformylation of 4-Nitrostyrene. A solution (50 m*l*) of 4.7 g of 4-nitrostyrene in benzene, 88 mg of tetrarhodium dodecacarbonyl, and a small amount of hydroquinone were put into an 100 m*l*-autoclave. The mixture was then shaken for 30 min at 60—70°C under the pressure (203 kg/cm²) of an equimolar mixture of carbon monoxide and hydrogen. A part of the reaction mixture (36.6 m*l*) was concentrated to give a crystalline residue. By the fractional distillation of the residue, 3.3 g of [1] was obtained; bp 142.5—144°C/1 mmHg, mp 42—43°C recrystallized from ether (lit,[9] mp 43°C).

Found: C, 59.96; H, 5.19; N, 7.61%. Calcd for $C_9H_9NO_3$: C, 60.32; H, 5.06; N, 7.82%.

IR: 2822, 2722 (CHO), 1724 (C=O), 1519, 1352 (NO_2) cm^{-1}.

PMR (in CCl_4): 8.50 τ (doublet) for CH_3, 6.19 τ (broad quartet) for CH, 2.20 τ (multiplet) for the aromatic protons, 0.20 τ (doublet) for CHO.

The PMR spectra of the reaction mixture were obtained and the ratio of the isomeric aldehydes was calculated according to Eq. 3:

$$[1]/[2] = 4A/C = 4B/3C \quad (3)$$

A : relative intensity of the CH proton in [1], 7.02 τ.
B : relative intensity of the CH_3 protons in [1], 8.92 τ.
C : relative intensity of the CH_2 protons in [2], 7.4—8.2 τ (multiplet).

Hydroformylation of 3-Nitropropene-1. A solution (25 m*l*) of 4.4 g of 3-nitropropene-1 in benzene, 50 mg of tetrarhodium dodecacarbonyl, and a small amount of hydroquinone were put into a 50 m*l*-autoclave and then the mixture was shaken for 20 min at 60°C under the pressure (200 kg/cm²) of an equimolar mixture of carbon monoxide and hydrogen. A part of the reaction mixture (17 m*l*) was concentrated, and the residue was fractionally distilled to give 2.8 g of [4]; bp 74—75.5°C/1 mmHg, $n_D^{21.5}$ 1.4428.

Found: C, 41.19; H, 6.26; N, 12.04%. Calcd for $C_4H_7NO_3$: C, 41.02; H, 6.03; N, 11.96%.

IR: 2846, 2746 (CHO), 1723 (C=O), 1555, 1384 (NO_2) cm^{-1}.

PMR (in benzene): 9.27 τ (doublet) for CH_3, 7.42 τ (multiplet) for CH, 5.92 τ (multiplet) for CH_2, 0.78 τ (singlet) for CHO.

2,4-Dinitrophenylhydrazone: yellow needles, mp 138—139°C recrystallized from ethanol.

Found: C, 40.44; H, 4.46; N, 23.77%. Calcd for $C_{10}H_{11}N_5O_6$: C, 40.40; H, 3.73; N, 23.57%.

The PMR spectrum of the reaction mixture was virtually identical with that of [4].

The encouragement and support of Dr. Toichi Yoshida are gratefully acknowledged. The authors wish also to thank Dr. Asao Nakamura for his helpful discussion of the PMR studies, and Mrs. Keiko Terao and Mr. Nobuyoshi Kitamura for their technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2195—2198 (1970)

The Stereoselectivity of the Methylcarbenoid of Zinc in the Reaction with Styrene, Indene, and Naphthalene

Jun NISHIMURA, Junji FURUKAWA and Nariyoshi KAWABATA*1

Department of Synthetic Chemistry, Kyoto University, Kyoto

(Received January 7, 1970)

The stereoselectivity of the methylcarbenoid generated from diethylzinc and ethylidene iodide was investigated in the reactions with styrene, indene, and naphthalene. 1-Methyl-2-phenylcyclopropanes (*cis*/*trans*=4.1) were obtained from styrene in a 13% yield. Indene gave exclusively the *endo*-isomer of 6-methyl-2,3-benzobicyclo[3.1.0]hex-2-ene in a 28% yield. From naphthalene, three isomers of 5,8-dimethyl-2,3-benzotricyclo[5.1.0.$0^{4,6}$]oct-2-ene were obtained favorably to the *syn*-form, as in the cases with styrene and indene, but two isomers of 7-methyl-2,3-benzobicyclo[4.1.0]-hepta-2,4-diene were formed favorably to the *anti*-form. This *anti*-selectivity was explained by the step-by-step addition mechanism which had previously been proposed for the ring-expansion reaction of alkylbenzene by the methylcarbenoid.

The stereoselectivity of unsymmetrically-substituted carbenes and carbenoids in the reaction with olefins is an interesting problem. Alkyl-,[1] phenyl-,[2] halo-,[3] phenylthio-,[4] and phenylselenocarbenes[5] and their carbenoids generally exhibit *syn*-selectivity.*2 On the other hand, alkoxy-,[6] phenoxy-,[7] carboalkoxy-,[8] and trimethylsilylcarbenes[9] and their carbenoids show *anti*-selectivity. The present authors have previously reported that the methylcarbenoid of zinc generated from diethylzinc and ethylidene iodide generally exhibits *syn*-selectivity.[1e] In general, a delicate balance of steric and electrostatic interactions among the substituents of olefins and of carbenoids in a three-centered transition state determines the stereoselectivity of the cycloaddition.[2c,d,3a,c,e]

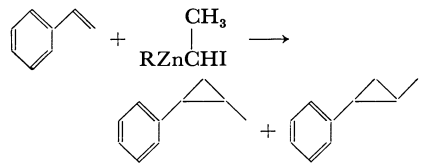
c) Simmons and Smith (*J. Amer. Chem. Soc.*, **81**, 4256 (1959)) reported bp 78—79°C/20 mmHg and n_D^{25}

A highly polarizable group attached to olefin is expected to increase the *syn*-selectivity of the cycloaddition. In order to examine this effect, the reactions of the methylcarbenoid with styrene, indene and naphthalene were investigated. The results are summarized in Table 1.

The reaction of styrene with twice as much of the methylcarbenoid in *n*-heptane at 80°C for 10 hours yielded a 4.1 : 1 mixture of *cis*- and *trans*-1-methyl-2-phenylcyclopropane. The *syn*-selectivity of the methylcarbenoid is higher in this reaction than in that with cyclohexene.*3

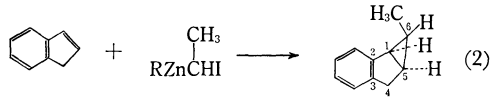


(1)

1 **2**

The structures were determined from the PMR spectra on the basis of the facts that the *cis*-methyl protons are more shielded than the *trans*-methyl protons by the anisotropy of the benzene ring[2b)] and that the absorption of the aromatic protons of the *trans*-isomer*4 becomes broader than that of the *cis*-isomer due to the shielding of an *ortho*-proton by the cyclopropane ring in a preferred conformation of the *trans*-isomer.[10)] The difference in the chemical shift between *cis*- and *trans*-methyl protons is observed to be 0.40 Hz. The aromatic proton resonances of the *cis*-isomer form a narrow band with a half-width of 1.8 Hz centered at τ 2.89. The *trans*-isomer exhibits broad highly split aromatic proton resonances extending from τ 2.7 to 3.3.

The reaction of the methylcarbenoid with indene yielded exclusively the *endo*-isomer of 6-methyl-2,3-benzobicyclo[3.1.0]hex-2-ene (**3**)



(2)

3

The PMR absorption due to the methyl protons appeared as a doublet (J=6.0 Hz) at τ 9.43. This chemical shift is higher than those of methyl groups in 1-methyl-2-phenylcyclopropanes, which appear at τ 8.8—9.2. The result can be explained by the fixing of the methyl group in the shielding region of the anisotropy by the benzene ring. The absorption due to H_1 appeared at τ 7.60 as a triplet (J=7.0 Hz). This result indicates that H_1 couples with two equivalent protons, *i.e.*, H_5 and H_6 are placed in the *cis* position with respect to H_1. These PMR findings show that the product is the *endo*-isomer.

The reactions of the methylcarbenoid with styrene and indene gave methylcyclopropanes more favorably to the *syn*-form than that with cyclohexene.*3 This result may be attributable to the large electrostatic interaction between the highly-polarizable phenyl group of olefin and the methyl group of the carbenoid. The highly *syn*-selective formation of 6-methyl-2,3-benzobicyclo[3.1.0]hex-2-ene from indene may be explained by a steric effect. The

*3 The reaction of cyclohexene with methylcarbenoid gave a 1.5 : 1 mixture of *endo*- and *exo*-7-methylnorcarane.[1e)]

*4 The structural assignment of the *trans*-isomer was also made by comparing its IR spectrum with that of the authentic sample, which was prepared in a *ca.* 50% yield by the reaction of *trans*-1-phenylpropene with diethylzinc and methylene iodide.[11)]

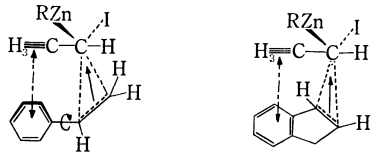
heptane (100 ml) at 80°C for 10 hr.

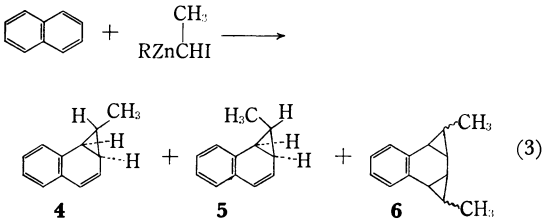
1.5204 for *cis*, *trans*-mixture.

steric interaction between the phenyl group of indene and the methyl group of carbenoid would be less than in the case of the reaction with styrene, and a strong electrostatic interaction between the phenyl group of indene and the methyl group of carbenoid



can be expected at a sufficiently close range.

A high *syn*-selectivity of the methylcarbenoid in the reaction with naphthalene, as with indene, would be expected if the reactions proceeded in a concerted mechanism similar to that proposed for the Simmons-Smith reaction.[12] 7-Methyl-2,3-benzobicyclo[4.1.0]hepta-2,4-diene and 5,8-dimethyl-2,3-benzotricyclo[5.1.0.$0^{4,6}$]oct-2-ene were obtained by reaction (3).



(3)

4 **5** **6**

Three kinds of 5,8-dimethyl-2,3-benzotricyclo-[5.1.0.$0^{4,6}$]oct-2-ene (**6**) were isolated, and their structures were determined to be *exo,exo-*, *exo,endo-*, and *endo,endo*-dimethyl isomers by comparing the PMR absorption of methyl groups.*5 The ratio of these isomers is given in Table 1. The ratio of the *syn*-methyl group to the *anti*-methyl group in these di-adducts (**6**) was calculated from the isomer ratios to be 1.9. This result indicates the *syn*-selective addition of methylcarbenoid to the mono-adducts (**4** and **5**). On the other hand, the mono-adducts (**4** and **5**) were not separated by glpc, although the two kinds of methyl groups were observed in the PMR spectrum (Fig. 1).*6

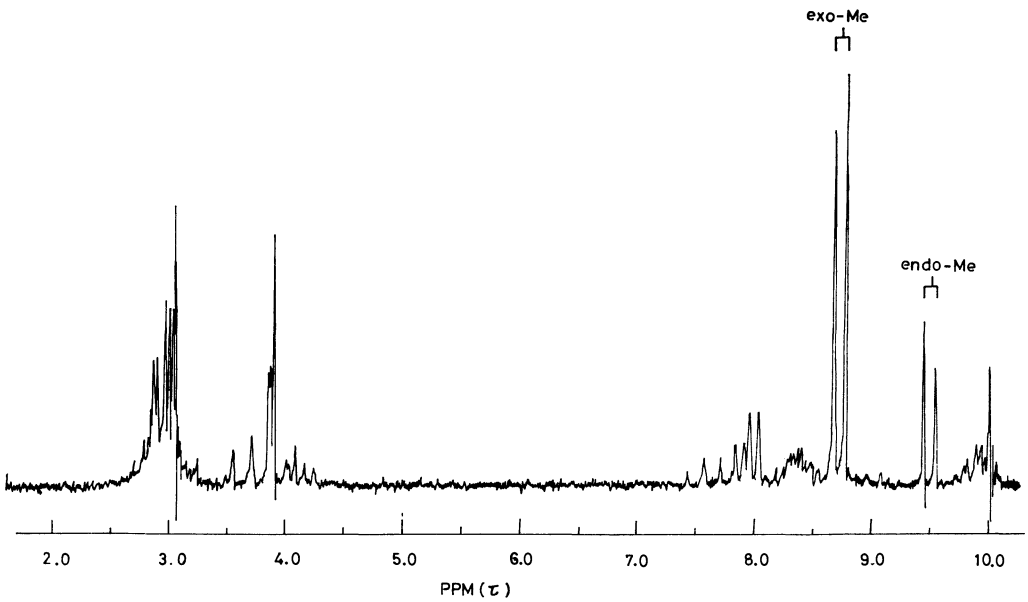


Fig. 1. The PMR spectrum of 7-methyl-2,3-benzobicyclo[4.1.0]hepta-2,4-diene (**4** and **5**).

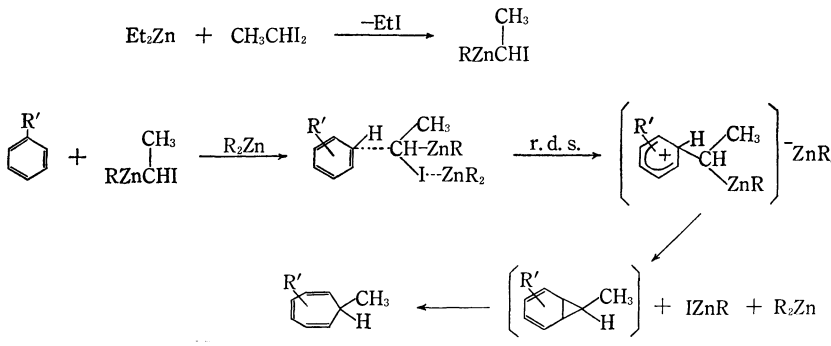
12) a) H. E. Simmons and R. D. Smith, *J. Amer. Chem. Soc.*, **81**, 4256 (1959); b) G. Wittig and F. Wingler, *Chem. Ber.*, **97**, 2146 (1964).

*5 See Experimental Section.

*6 The spectrum is similar to that of 2,3-benzonorcaradiene-2,4-carboxylic acid reported by Huisgen *et al.* (*Chem. Ber.*, **94**, 2332 (1961)).

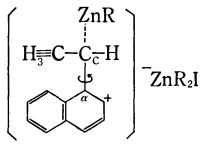


Scheme 1

One doublet peak (J=6.0 Hz), at τ 9.50, was assigned to an *endo*-methyl group, and the other one (J=6.0 Hz), at τ 8.73, to an *exo*-methyl group, by comparison with the chemical shift of the methyl group in compound (**3**). The *exo*-/*endo*-isomer ratio thus determined was 3.5, which suggests the *anti*-selective addition of methylcarbenoid to naphthalene, contrary to the above expectation.*7 This difference in the selectivity of reaction (3) from reactions (1) and (2) suggests that the mechanism of reaction (3) is different from the concerted one which was proposed for the Simmons-Smith reaction.[12] Previously, the present authors have reported that the essential features of the cycloaddition of zinc carbenoid prepared from *gem*-diiodoalkane and diethylzinc to olefin are similar to that of the Simmons-Smith reaction.[11] On the other hand, the present authors have also reported the step-by-step mechanism (Scheme 1) for the ring expansion of alkylbenzenes by methylcarbenoid.[13]

Reaction (3) may proceed by a mechanism similar to that shown in Scheme 1. The *anti*-selectivity in reaction (3) may be due to free rotation around the C_α—C_c bond in a σ-complex (**7**), which may enhance the formation of the thermodynamically more stable *exo*-isomer.*8

In a previous paper, the σ-complex formation step was concluded to determine the rate of the ring expansion.[13] The formation of *endo*- and *exo*-7-methyl-2,3-benzobicyclo[4.1.0]hepta-2,4-diene



7

in reaction (3) may support the idea of the presence of a transient norcaradiene in the ring expansion reaction.

Experimental

The analyses were performed at the Elemental Analysis Center of Kyoto University. The infrared and mass spectra were recorded on a Hitachi EPI-G spectrophotometer and a Hitachi mass spectrometer, Model RMS-4, respectively. The PMR spectra were taken on a Varian Model A-60, in carbon tetrachloride, using tetramethylsilane as the internal standard. The vapor-phase chromatograms were obtained on a Shimadzu GC-2C gas chromatograph. All the boiling points were uncorrected.

Materials and Procedure. The styrene and the indene were purified by distillation before use. Reagent-grade naphthalene was used without further purification. *n*-Heptane was purified by distillation over sodium metal. The other reagents and procedure are the same as have been described in previous papers.[1e,11]

The reactions with styrene and indene gave higher-boiling materials other than listed in Table 1 in a *ca.* 10% yield. The PMR spectra of the material showed the characteristic absorption for cycloheptatrienes at τ 3—5.

5,8-Dimethyl-2,3-benzotricyclo[5.1.0.0^{4,6}]oct-2-ene (6). The fraction (bp 110—112°C/11 mmHg) of the reaction mixture with naphthalene showed three peaks on glpc analysis conducted under these conditions: 2.25 m of Apiezon-L grease and 3.75 m of Silicone DC 550, 200°C. The ratio was 1 : 9.6 : 3.9, in the order of the retention times. These three isomers were isolated by glpc. The PMR spectra of these isomers showed two kinds of methyl groups. The peaks at τ 9.0—9.1 were assigned to the *endo*-methyl group, and those at τ 8.8—8.9 to the *exo*-one, on the basis of the effect by the anisotropy of the benzene ring. These three isomers were determined to be *exo*,*exo*-, *exo*,*endo*-, and *endo*,*endo*-isomers. The configurations of the tricyclo-ring were not confirmed.

*7 The *anti*-selective formation of the mono-adducts can be concluded even if only the *endo*-isomer (**4**) further reacts with methylcarbenoid to give three kinds of di-adducts, because the ratio of di-adducts to mono-adducts was 1 : 2 (Table 1).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2199—2204 (1970)

Studies of Peptide Antibiotics. XX. Synthesis of Tyrocidine B[1]

Kenji KUROMIZU and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received January 9, 1970)

A cyclic decapeptide, *cyclo*-(L-Trp-D-Phe-L-Asn-L-Gln-L-Tyr-L-Val-L-Orn-L-Leu-D-Phe-L-Pro-) (XVIII), having the amino acid sequence of natural tyrocidine B has been synthesized. *p*-Methoxybenzyloxycarbonyl-Trp-D-Phe-OH was transformed into an acyldipeptide hydroxysuccinimide ester by reagents of hydroxysuccinimide-dicyclohexylcarbodiimide, and the acyldipeptide ester obtained was coupled with a neutral octapeptide. An acyldecapeptide acid thus obtained was subjected to the cyclization reaction. The antibacterial activity of the synthetic product (XVIII) toward Gram positive microorganisms is found to be nearly the same as that of synthetic tyrocidine A, indicating that the L-phenylalanine residue in tyrocidine A can be replaced by L-tryptophan without causing decrease in activity.

In 1940 Hotchkiss and Dubos discovered a basic polypeptide antibiotics named tyrocidine from autolyzed cultures of *Bacillus brevis*.[2] By means of countercurrent distribution,[3] Battersby and Craig showed that the crystalline tyrocidine hydrochloride contained at least three major components, tyrocidine A (TA), B (TB) and C. In 1955 King and Craig isolated a crystalline hydrochloride of TB and determined its amino acid composition.[4] The same authors determined its structure shown as TB in Fig. 1[5] by analyses on partial hydrolyzate with hydrochloric acid.[6]

The synthesis of a linear heptapeptide, Z-Val-Orn(δ-Ts)-Leu-Phe-Pro-Trp-Phe-OMe, related to TB has been described by Zahn and Brandenburg,[7] but the total synthesis of TB has never been accomplished. There are no reports on the quantitative feature of antibacterial activity nor data of measurements such as specific rotation and melting point on the natural TB.

→L-Val-L-Orn-L-Leu-D-Phe-L-Pro—
—L-Tyr-L-Gln-L-Asn-D-Phe-L-X←

Fig. 1. Structures of tyrocidine A (TA) and B (TB).
X represents an amino acid residue such as Phe (TA) and Trp (TB or XVIII).

We reported the syntheses of TA,[8] tyrocidine C,[9] and E,[10] and have been attempting to synthesize other components of the tyrocidine family. This paper will describe the synthesis of the cyclic decapeptide hydrochloride (XVIII·HCl) having the amino acid sequence of TB, and the chemical and biological properties of the synthetic product.

Figure 2 indicates the scheme for the synthesis of the cyclic decapeptide (XVIII). The synthesis of a tripeptide derivative, Z(OMe)-Asn-Gln-Tyr-$NHNH_2$ (VII), was achieved by stepwise elongation from the carboxyl toward the amino end as shown in Fig. 2. The condensation of the azide derived from the tripeptide derivative (VII) with a neutral pentapeptide (XI) gave an acyloctapeptide acid (XII) in 87% yield. Action of trifluoroacetic acid on XII afforded amorphous trifluoroacetate of a neutral octapeptide (XIII) in an almost quantitative yield.

The synthesis of an acyldecapeptide acid (XIV) was achieved as follows. *p*-Methoxybenzyloxycar-

bonyldipeptide acid (IV) (1.2 equiv.) was treated with HOSu (1.4 equiv.) and DCC (1.1 equiv.). The acyldipeptide active ester, Z(OMe)-Trp-D-Phe-OSu, thus obtained was coupled with the neutral octapeptide (XIII) (1 equiv.) in the presence of triethylamine (1 equiv.) to afford the acyldecapeptide acid (XIV) in 70% yield. It was assumed that no racemization occurred on the D-Phe residue of H-Trp-D-Phe-Asn- sequence in XIV. Weygand *et al.* indicated that no racemization on a C-terminal amino acid residue in an acylpeptide acid was observed when the acylpeptide acid was treated with HOSu and DCC and subsequently the acylpeptide hydroxysuccinimide ester was coupled with an amine component.[11] Several investigators recognized also that the procedure with reagents of HOSu-DCC safely avoided racemization.[12,13] Furthermore, it was observed that the use of HOSu-DCC under the same conditions for preparation of acyldecapeptide acid (XIV) caused no racemization by an assay method using an amino acid analyzer.[13]

The protected cyclic decapeptide (XVII) was prepared as follows. Acyldecapeptide acid (XIV) was transformed to an acyldecapeptide *p*-nitrophenyl ester (XV), and its *p*-methoxybenzyloxycarbonyl group was removed by the action of trifluoroacetic acid. The cyclization reaction of the

decapeptide ester (XVI) gave a benzyloxycarbonyl-substituted cyclic decapeptide (XVII); its yield was 43% from XIV. The molecular weight determination demonstrated that the molecular size of XVII corresponded to that of cyclic decapeptide.

The hydrogenation of XVII in the presence of an equivalent amount of hydrogen chloride in methanol afforded the crystalline cyclic decapeptide hydrochloride (XVIII·HCl) in 78% yield. The homogeneity of XVIII was confirmed by elemental analysis, chromatography using several different methods (Figs. 5 and 6) and amino acid analysis. The antibacterial activities of XVIII toward several microorganisms are listed in Table 1. It was found that the degree of the activities of XVIII toward the Gram positive microorganisms was nearly the same as that of TA, indicating that the L-Phe residue in a TA molecule can be replaced with the L-Trp without seriously influencing the activity.

Experimental

Melting points were uncorrected. The optical rotations were determined with a Yanagimoto Photometric Polarimeter, OR-20 type. Thin layer chromatography was performed on Merck silica gel G with the following solvent systems: R_f^1, *n*-butanol - acetic acid - pyridine - water 4 : 1 :1 : 2 v/v; R_f^2, chloroform - methanol 5 : 1 v/v. Paper chromatography was performed on Toyo Roshi No. 52 with the following solvent systems: R_f^{I}, *n*-butanol - acetic acid - pyridine - water 4 : 1 : 1 : 2 v/v; R_f^{II}, *n*-butanol - formic acid - water 15 : 3 : 2 v/v. Spots of materials possessing free amino groups on a thin layer plate were detected by spraying ninhydrin, and those of the amino group-blocked materials, by spraying 47% hydrobromic acid and then ninhydrin. Prior to analysis, the compounds were dried over phosphorus pentoxide at 60°C and 2 mmHg to a constant weight unless otherwise described.

Z(OMe)-Trp-OH·DCHA (I). To a chilled solution of L-tryptophan (10.2 g, 50 mmol) and 2N sodium hydroxide (25 m*l*) were added *p*-methoxybenzyloxycarbonyl chloride in ether[14] (15 m*l*, 60 mmol) and 2N sodium hydroxide (30 m*l*) portionwise at −5°C. After 2 hr, the reaction mixture was extracted with ether and acidified with 0.5M citric acid solution at 0°C. The oily material formed was extracted with ethyl acetate. The organic layer was washed with water, dried over sodium sulfate and evaporated *in vacuo*. The residual oil was dissolved in ether (200 m*l*) and dicyclohexylamine (9.98 ml, 50 mmol) was added. The resulting crystals were collected by filtration, and recrystallized from ethanol - ethyl acetate - ether; yield, 19.6 g (71%); mp 151—152°C; $[\alpha]_D^{20}$ +11.5° (*c* 1, methanol); R_f^2 0.54.

Found: C, 69.55; H, 7.83; N, 7.59%. Calcd for $C_{20}H_{20}O_5N_2 \cdot C_{12}H_{23}N$: C, 69.91; H, 7.88; N, 7.64%.

H-D-Phe-OBzl·TsOH (II). A mixture of D-phenylalanine (16.5 g), *p*-toluenesulfonic acid monohydrate (20.9 g), benzyl alcohol (50 m*l*) and benzene (100 m*l*) was heated following the general procedure by Izumiya and Makisumi.[15] Yield, 36.8 g (86%); mp 166—167°C; $[\alpha]_D^{20}$ +7.5° (*c* 2, DMF) (Found: C, 64.53; H, 5.80; N, 3.26%). Reported values for the L-isomer; mp 165°C[16] and 170.5—171.5°C;[17] $[\alpha]_D$ +7.2° (DMF)[16,18] and −7.2° (methanol).[17]

Z(OMe)-Trp-D-Phe-OBzl (III). To a solution of I (2.75 g, 5 mmol) and II (2.14 g, 5 mmol) in chloroform (20 m*l*) was added DCC (1.04 g, 5 mmol) at 0°C. After being stirred for 3 hr at 0°C, the reaction mixture was left to stand overnight at room temperature. The mixture was then evaporated *in vacuo*, and ethyl acetate was added to the residue. The filtrate from dicyclohexylurea was washed successively with 10% citric acid, 4% sodium bicarbonate solution and water, and then dried over sodium sulfate. The filtrate was evaporated *in vacuo* and the residue was crystallized by the addition of ether. It was recrystallized from ethyl acetate - ether - petroleum ether; yield, 2.49 g (82%); mp 137—139°C; $[\alpha]_D^{20}$ +3.6° (*c* 0.5, methanol); R_f^1 0.92, R_f^2 0.80.

Found: C, 71.47; H, 5.96; N, 6.85%. Calcd for $C_{36}H_{35}O_6N_3$: C, 71.38; H, 5.83; N, 6.93%.

Z(OMe)-Trp-D-Phe-OH (IV). To a solution of III (1.66 g, 2.75 mmol) in methanol (5 m*l*) and dioxane (8 m*l*) was added N sodium hydroxide (5.5 m*l*). The solution was allowed to stand for 2 hr at room temperature. After the addition of water (8 m*l*), the solution was acidified with 0.5M citric acid under cooling, and concentrated *in vacuo* to remove organic solvent at 10—15°C. After the addition of water (80 m*l*), the mixture was stored in a refrigerator for several hours and the crystals were collected by filtration. The product was recrystallized from methanol - ether - petroleum ether; yield, 1.14 g (80%); mp 84—86°C; $[\alpha]_D^{20}$ −25.0° (*c* 0.24, methanol); R_f^2 0.46.

Found: C, 65.10; H, 5.75; N, 7.63%. Calcd for $C_{29}H_{29}O_6N_3 \cdot H_2O$: C, 65.27; H, 5.85; N, 7.87%.

H-Gln-Tyr-OEt·HCl (V). A solution of Z-Gln-Tyr-OEt[8] (6.89 g, 14.5 mmol) dissolved in DMF (60 ml) containing N ethanolic hydrogen chloride (16 ml) was hydrogenated in the presence of palladium black. The filtrate from the catalyst was evaporated *in vacuo*, and the residual crystals were collected by filtration with the aid of ether. It was recrystallized from *n*-butanol - ether - petroleum ether; yield, 5.15 g (94%); mp 157—158°C; $[\alpha]_D^{20}$ +22.4° (*c* 1, methanol); R_f^1 0.67.

Found: C, 51.42; H, 6.47; N, 11.01%. Calcd for $C_{16}H_{23}O_5N_3 \cdot HCl$: C, 51.40; H, 6.47; N, 11.24%.

Z(OMe)-Asn-Gln-Tyr-OEt (VI). To a solution of V (4.51 g, 11.3 mmol) dissolved in DMF (20 ml) and triethylamine (1.58 ml) was added Z(OMe)-Asn-ONp[19] (4.17 g, 10 mmol) in DMF (10 ml). After the solution had been stood overnight at room temperature, it was concentrated *in vacuo* and diluted with water (300 ml). The crystalline product deposited was collected by filtration and washed successively with 10% citric acid, 3% sodium bicarbonate solution and water. It was recrystallized from DMF-ether; yield, 3.90 g (63%); mp 213—214°C (decomp.); $[\alpha]_D^{20}$ −5.5° (*c* 1, DMF); R_f^1 0.84.

Found: C, 55.49; H, 6.11; N, 11.02%. Calcd for $C_{29}H_{37}O_{10}N_5 \cdot \frac{1}{2}H_2O$: C, 55.75; H, 6.13; N, 11.21%.

Z(OMe)-Asn-Gln-Tyr-NHNH$_2$ (VII). A solution of VI (3.55 g, 5.8 mmol) and hydrazine hydrate (5.58 ml, 115 mmol) in DMF (30 ml) was allowed to stand at room temperature for 2 days. The solution was then concentrated *in vacuo* in order to remove excess hydrazine, after which water (300 ml) was added to the residual solution; the resulting product was collected by filtration. It was recrystallized from DMF - ether - petroleum ether; yield, 3.3 g (95%); mp 243°C (decomp.); $[\alpha]_D^{20}$ −11.0° (*c* 1, DMSO); R_f^1 0.68.

Found: C, 53.19; H, 6.00; N, 16.50%. Calcd for $C_{27}H_{35}O_9N_7 \cdot 1/2H_2O$: C, 53.10; H, 5.94; N, 16.06%.

Z-Leu-D-Phe-OBzl (VIII). Z-L-Leu-OH·DCHA (8.95 g, 20 mmol) and II (8.55 g, 20 mmol) in chloroform (80 ml) were treated with DCC (4.14 g, 20 mmol) as described for the preparation of III. The product was recrystallized from ethanol - ether; yield, 8.22 g (79%); mp 131°C; R_f^1 0.98, R_f^2 0.78; $[\alpha]_D^{20}$ −2.0° (*c* 0.5, methanol).

Found: C, 71.72; H, 6.95; N, 5.54%. Calcd for $C_{30}H_{34}O_5N_2$: C, 7.69; H, 6.82; N, 5.57%.

Z-Leu-D-Phe-NHNH$_2$ (IX). A solution of VIII (8.25 g, 1.57 mmol) and hydrazine hydrate (15 ml) in DMF (90 ml) was treated as described for the preparation of VII. The product was recrystallized from DMF - ether - petroleum ether; yield, 6.00 g (90%); mp 162—163°C; R_f^2 0.57; $[\alpha]_D^{20}$ +3.4° (*c* 1, DMF) (Found: C, 64.72; H, 7.18; N, 13.29%). Erlanger *et al.* prepared IX from Z-Leu-D-Phe-OMe and hydrazine; mp 166°C.[20]

Z-Leu-D-Phe-Pro-OEt (X). To a solution of IX (5.34 g, 12 mmol) dissolved in a mixture of DMF (5 ml) - acetic acid (50 ml) - N hydrochloric acid (13.2 ml) were added 2N sodium nitrite (6.6 ml) and N hydrochloric acid (13.2 ml) at −5°C. After it had stood for 5 min, cold water (900 ml) was added to the solution. The azide precipitated was collected by filtration and washed with cold 3% sodium bicarbonate solution and water. After it had been dried in a vacuum desiccator, the azide was added to a chilled solution of H-Pro-OEt·TsOH (3.94 g, 12.5 mmol) dissolved in a mixture of triethylamine (1.7 ml, 12.5 mmol) and DMF (50 ml). After it had been stirred for 2 days at 0°C, the solution was evaporated *in vacuo* and the residue was dissolved in ethyl acetate (80 ml). The solution was washed with 2% hydrochloric acid, 3% sodium bicarbonate solution and water, dried over sodium sulfate, and evaporated to dryness; yield of oil, 4.93 g (76%); R_f^2 0.81. This compound was used for the preparation of H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH·HCl (XI·HCl) as described in literature.[21]

Z(OMe)-Asn-Gln-Tyr-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH (XII). To a solution of VII (0.722 g, 1.2 mmol) in a mixture of DMF (5 ml) and DMSO (10 ml) were added N ethanolic hydrogen chloride (2.4 ml) and isoamyl nitrite[22] (0.162 ml, 1.2 mmol) at −5°C. After 5 min, triethylamine (0.336 ml, 2.4 mmol) was added to this solution. To the solution containing the azide was added a mixture of XI·HCl (0.978 g, 1.25 mmol) and triethylamine (0.344 ml, 2.5 mmol) in DMF (8 ml). The reaction mixture was stirred for 3 days at 0°C and evaporated *in vacuo* to a small volume (about 10 ml). After the addition of N ethanolic hydrogen chloride (1.2 ml) and water (150 ml), the percipitate was collected and recrystallized from DMF - ether - petroleum ether; yield, 1.35 g (87%); mp 226—227°C; R_f^1 0.85; $[\alpha]_D^{25}$ −22.2° (*c* 1, DMF).

Found: C, 59.03; H, 6.88; N, 11.67%. Calcd for $C_{65}H_{85}O_{17}N_{11} \cdot 2H_2O$: C, 58.77; H, 6.75; N, 11.60%.

The homogeneity of this product was established further by paper chromatography and paper electrophoresis after hydrogenolysis; R_f^I 0.78 and R_f 0.99× GS.[23]

H-Asn-Gln-Tyr-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH·CF$_3$-COOH (XIII·CF$_3$COOH). To a mixture of XII (1.55 g, 1.2 mmol) and anisole (1 ml) was added trifluoroacetic acid (8 ml) at −5°C. When swirled, the reaction mixture changed to a clear solution within some 10 min. After 25 min, the solution was evaporated *in vacuo* at 0°C and the oily residue was triturated with ether. The solid formed was collected by filtration and washed with ether; yield, 1.45 g (97%). The homogeneity of this product was confirmed by paper chromatography in which only one spot was detected; R_f^I 0.85. The material was used in the next reaction without further purification.

Z(OMe)-Trp-D-Phe-Asn-Gln-Tyr-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH (XIV). To a chilled solution of IV (0.805 g, 1.56 mmol) in ethyl acetate (10 ml) were added HOSu (0.207 g, 1.8 mmol) and DCC (0.297 g, 1.44 mmol) at 0°C. After the mixture had been stirred for 3 hr at 0°C, dicyclohexylurea precipitated was

filtered off and washed with cold ethyl acetate. The filtrate was evaporated to dryness *in vacuo* at 0°C and the residue was dissolved in cold DMF (5 m*l*). To the solution was added a mixture of XIII·CF_3COOH (1.45 g, 1.27 mmol) in DMF (10 m*l*) and triethylamine (0.356 m*l*) at 0°C. After the stirring of the reaction mixture had been continued for 5 hr at 0°C and for additional 2 hr at room temperature, the mixture was concentrated *in vacuo* to a small volume and the residue was treated with 0.5M citric acid (30 m*l*). The product was collected by filtration and recrystallized from DMF-ethyl acetate - ether; yield, 1.35 g (70%); mp 215—216°C (decomp.); $[\alpha]_D^{20}$ +33.1° (*c* 1, DMF); R_f^1 0.79.

Found: C, 61.26; H, 6.42; N, 11.85%. Calcd for $C_{85}H_{104}O_{19}N_{14}\cdot 2H_2O$: C, 61.42; H, 6.55; N, 11.80%.

The homogeneity of this material was further established by paper chromatography and paper electrophoresis after hydrogenolysis, in which only one spot was detected; R_f^I 0.69 and R_f 1.1×GS.[23]

Detection of Possible Racemization in the Coupling by HOSu-DCC Reagents. The conditions (reaction times, temperatures, mole ratios of reagents, and others) for the coupling reaction were the same as described above. Z-Gly-L-Ala-OH (1.2 equiv.) in DMF was transformed to the corresponding hydroxysuccinimide ester with HOSu (1.4 equiv.) and DCC (1.1 equiv.). To the hydroxysuccinimide ester was added H-L-Leu-OBzl (1 equiv.) in DMF. After evaporation, the residue was dissolved in ethyl acetate. The solution was washed with 2% hydrochloric acid and 4% sodium bicarbonate solution, and dried over sodium sulfate. The filtrate was subjected to hydrogenolysis and a part of the hydrogenated material was analyzed by the amino acid analyzer as described previously,[13] the extent of racemization was calculated as less than 0.1%.

Z(OMe)-Trp-D-Phe-Asn-Gln-Tyr-Val-Orn(δ-Z)-Leu-D-Phe-Pro-ONp (XV). To a solution of XIV (1.05 g, 0.65 mmol) dissolved in DMF (5 m*l*) and pyridine (5 m*l*) was added di-*p*-nitrophenyl sulfite (2.10 g, 6.5 mmol). The faintly yellow solution was allowed to stand for 18 hr at room temperature and then evaporated *in vacuo*. The oily residue was triturated several times with a mixture of ether and petroleum ether (1 : 1 v/v). The solid was collected by filtration and washed with a mixture of ether and petroleum ether until the yellow color could not be discerned upon the addition of N sodium hydroxide to the filtrate. The *p*-nitrophenyl ester content of this product (yield, 1.123 g) was estimated to be 105% measuring the optical density at 412 mμ with the solvent of DMF and N sodium hydroxide (1 : 1 v/v).[24] The product was used for the next reaction without further purification.

H-Trp-D-Phe-Asn-Gln-Tyr-Val-Orn(δ-Z)-Leu-D-Phe-Pro-ONp·CF_3COOH (XVI·CF_3COOH). To a mixture of XV (1.12 g), anisole (1.2 m*l*) and 2-mercaptoethanol (0.12 m*l*) was added trifluoroacetic acid (12 m*l*) at −5°C. When swirled, the suspension turned to a clear solution within 10 min. The solution was evaporated *in vacuo* at 0°C and the oily residue was triturated with ether. The solid was collected by filtration and washed with ether (yield, 1.092 g). This was used as such in the next step.

***cyclo*-(Trp-D-Phe-Asn-Gln-Tyr-Val-Orn(δ-Z)-Leu-D-Phe-Pro-) (XVII).** XVI·CF_3COOH (1.092 g) was dissolved in a mixture of DMF (15 m*l*) and acetic acid (0.5 m*l*). The solution was stirred drop by drop into pyridine (200 m*l*) kept at 55—60°C over 5 hr, stirring being continued for additional 3 hr at the same temperature. After the solvent had been removed, the residue was dissolved in 100 m*l* of a mixture of methanol - dioxane - water (1 : 2 : 1 v/v). This solution was passed successively through columns (1.5×12 cm) of Amberlite IRC-50 (H^+ form) and Amberlite IR45 (OH^- form). The columns were washed with the same solvent. The filtrate and washings were combined (total 300 m*l*) and then evaporated to dryness *in vacuo*. The residual product was collected by filtration with the aid of water and recrystallized from DMF-ether; yield, 0.715 g (43% from XIV); mp 198—200°C; $[\alpha]_D^{20}$ −86.9° (*c* 0.5, methanol); R_f^1 0.98, R_f^2 0.62; amino acid ratio in acid hydrolysate, Phe 1.99, Asp 0.98, Glu 1.02, Tyr 0.91, Val 0.97, Orn 1.00, Leu 1.00, Pro 0.99.[25]

Found: C, 61.79; H, 6.58; N, 13.05%; mol wt 1450.[26] Calcd for $C_{76}H_{94}O_{15}N_{14}\cdot 2H_2O$: C, 61.68; H, 6.68; N, 13.25%; mol wt, 1479.

***cyclo*-(Trp-D-Phe-Asn-Gln-Tyr-Val-Orn-Leu-D-Phe-Pro-) Hydrochloride (XVIII·HCl).** A solution of XVII (144 mg, 0.1 mmol) dissolved 0.02N methanolic hydrogen chloride (6 m*l*) was subjected to hydrogenolysis in the presence of palladium black. After 3.5 hr, the filtrate from the catalyst was evaporated to dryness *in vacuo* and ether (4 m*l*) was added to yield crystals (yield, 120 mg). Recrystallization from methanol - ether - petroleum ether gave 111 mg (78%) as the desiccator-dried product (XVIII·HCl·$5H_2O$); mp 236—237° (decomp.); $[\alpha]_D^{20}$ −93.0° (*c* 0.5, methanol).

Found: C, 56.71; H, 6.82; N, 13.62%. Calcd for $C_{68}H_{88}O_{13}N_{14}\cdot HCl\cdot 5H_2O$: C, 56.87; H, 6.95; N, 13.66%.

This desiccator-dried sample lost 6.4% of its weight after being dried for 4 hr at 110°C, 2 mmHg. Calcd for $5H_2O$: 6.3%.

Determination of Homogeneity of XVIII. The homogeneity of the compound XVIII·HCl·$5H_2O$ was ascertained further as follows. Data for TA or gramicidin S dihydrochloride (GS·2HCl) as the reference peptides are also indicated. *(a) TLC.* One spot with the com-

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2204—2208 (1970)

On the Study of Various Reductions of 2-Benzoylcyclopentene-1-carboxylic Acid

Katsuo OHKATA and Terukiyo HANAFUSA

Chemistry Department, Faculty of Science, Hiroshima University, Higashisenda-cho, Hiroshima

(Received January 13, 1970)

It was found that the Clemmensen reduction of 2-benzoylcyclopentene-1-carboxylic acid (**2a**) did not give rise to 2-benzylcyclopentene-1-carboxylic acid (**1**), but to a mixture of *cis*- and *trans*-2-benzylcyclopentane-1-carboxylic acid (**6a** and **7a**) contrary to the description in literature. Unsaturated acid (**1**) was obtained as a major product by the Wolff-Kishner-Huang-Minlon reduction of **2a** accompanied with 1-carboxy-6-phenylbicyclo[3.1.0]hexane (**8**). The reduction of **2a** with zinc dust in acetic acid and the reduction of the methyl ester (**2b**) by way of its thioketal were also investigated.

Organic chemists have long been interested in selective reduction of conjugated unsaturated carbonyl compounds. A large number of such selective procedures have been published.[1] Since the preparation of 2-benzylcyclopentene-1-carboxylic acid (**1**) was necessary during the course of the other investigations, various reduction procedures of 2-

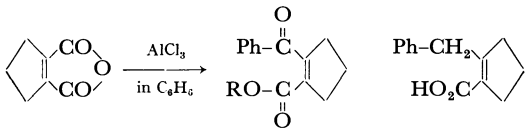
benzoylcyclopentene-1-carboxylic acid derivatives (**2a** and **2b**) were carried out. It may be interesting to study the reduction of this compound because a double bond is placed between a carbonyl group and a carboxyl group. The results will be described in this paper.

Results and Discussion

In 1950 Sengupta and Saha reported the synthesis of the unsaturated keto-acid (**2a**) by the Friedel-Crafts condensation of cyclopentene-1,2-dicarboxylic acid anhydride (**3**) with benzene.[2] They also reported that the Clemmensen reduction of **2a** gave an oil, bp 170—173°C/4 mmHg, which was assigned as the unsaturated acid (**1**). The assignment was based on further reaction sequence including dehydrogenation step into 2,3-trimethylenenaphthalene (**4**).



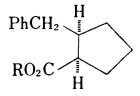
(**3**) (**2a**) R: H (**2b**) CH_3 (**1**)

We repeated the synthesis of unsaturated keto-acid (**2a**) according to Saha's method. The IR and NMR spectra of the product support the above postulated formula. Its reduction with $NaBH_4$ gave a hydroxy-acid (**5**), mp 118—119°C, in high yield. It showed a sharp singlet characteristic for benzylic α-hydrogen at $\tau=3.83$ along with other signals in its NMR spectrum. The results confirmed the presence of a tetrasubstituted double bond adjacent to the benzylic hydroxyl group.

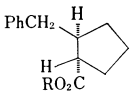
(**4**) (**5**)

The Clemmensen reduction of **2a**[1a] was carried out with zinc amalgam in concentrated hydrochloric acid and toluene for 30 hr. IR and NMR spectra of the product oil, bp 153—154°C/2 mmHg, suggested that the product was not an α,β-unsaturated acid as reported by Sengupta and Saha but a mixture of saturated acids. Thus, the product was transformed to methyl esters with diazomethane. Vapor phase chromatography of the esters revealed that they consisted of two components, the ratio being about 1 : 2. The predominant component was purified by preparative VPC, followed by elemental analysis.

It was shown that the analytical result was consistent not with the calculated value for the unsaturated ester, $C_{13}H_{16}O_2$, but for the saturated ester, $C_{13}H_{18}O_2$. From these data it may be evident that both a carbonyl group and a double bond in the unsaturated keto-acid (**2a**) were reduced in the Clemmensen reduction to give a mixture of *cis*- and *trans*-2-benzylcyclopentane carboxylic acids, **6a** and **7a** respectively.



(**6a**) R: H (**6b**) CH_3



(**7a**) R: H (**7b**) CH_3

Another selective reduction for α,β-unsaturated ketone is desulfurization of its thioketal with excess of Raney-Ni.[1b] Methyl ester (**2b**) of the unsaturated keto-acid was converted into the ethylene thioketal, followed by treatment with large excess of Raney-Ni. Without further purification the oil was subjected to careful VPC analysis. It was then found that the ester was also a mixture of two components identical with the products obtained by the Clemmensen reduction. In this case, however, the ratio of two geometric isomers was reversed, *viz.*, 2 : 1.

The Wolff-Kishner-Huang-Minlon reduction is also a useful procedure for selective reduction of a carbonyl group in an unsaturated ketone.[1c] A number of such examples have been reported.[3] Keto-acid (**2a**) was treated with hydrazine hydrate in concentrated alkaline solution mixed with triethylene glycol, followed by heating the reaction mixture to 220°C for 5 hr. The product thus obtained was a mixture of solids and an oil. The former was readily purified by recrystallization from a mixture of ether and light petroleum as colorless crystals, mp 121—122°C. By its IR spectrum it was suggested that the compound was an α,β-unsaturated acid. In its NMR spectrum, it showed a sharp singlet at $\tau=2.78$ due to five aromatic protons and a characteristic singlet at $\tau=7.53$ for two benzylic protons adjacent to a tetrasubstituted double bond, along with other signals. From these data and elemental analysis the crystalline product was identified as 2-benzyl-1-cyclopentene-1-carboxylic acid (**1**).

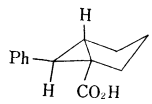
This unsaturated acid (**1**) was then hydrogenated in glacial acetic acid using the Adams catalyst to give a saturated acid. Its methyl ester was subjected to VPC analysis proving that the ester thus obtained consisted of mainly one isomer contaminated with a small quantity of the other. Since catalytic hydrogenation should preferentially give rise to *cis* isomer, the main product in this hydro-

2) S. C. Sengupta and N. N. Saha, *Current Sci.* (India), **19**, 381 (1950); S. C. S. Gupta and N. N. Saha, *J. Indian Chem. Soc.*, **29**, 331 (1952).

3) A. Furst, R. C. Berlo and S. Hooton, *Chem. Rev.*, **65**, 51 (1965).

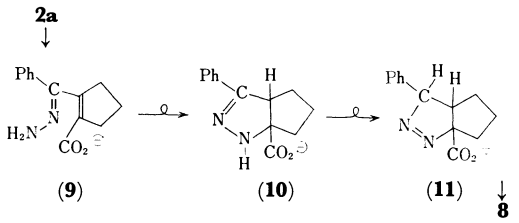
genation experiment could be characterized as *cis*-2-benzylcyclopentane-1-carboxylic acid (**6a**). From a comparison of the chromatogram of this methyl ester with that obtained by the above two other types of reductions, it may be evident that *trans* isomer (**7a**) predominated in the Clemmensen reduction product and that *cis* isomer (**6b**) predominated in desulfurization of thioketal.

The latter oil produced by the Wolff-Kishner-Huang-Minlon reduction was converted into its methyl ester with diazomethane and was purified by preparative VPC. From both the elemental analysis and spectra data of this methyl ester it was suggested that the compound could be characterized as 1-carboxy-6-phenylbicyclo[3.1.0]hexane (**8**). It may be noted in its NMR spectrum that a doublet at $\tau=7.10$ with $J=9$ cps for one proton was assigned to benzylic cyclopropane ring proton and that a multiplet centered at $\tau=9.85$ for one proton to the other cyclopropane ring proton attached to the bridge head.



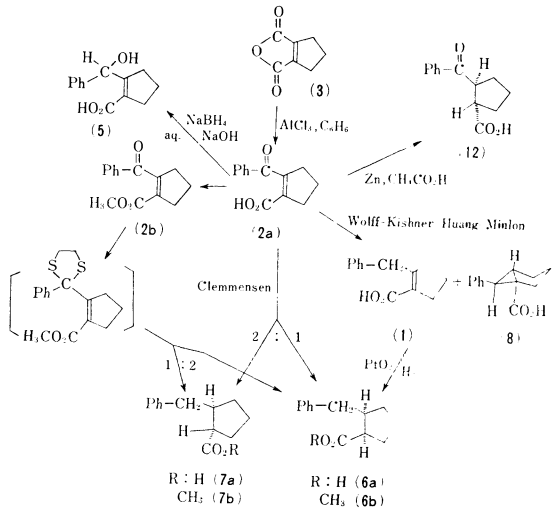
(**8**)

In analogy to the other examples[4] it seems that the intermediate hydrazone (**9**) might partially rearrange to pyrazoline derivatives (**10** and **11**), in which nitrogen molecule would be eliminated by heating the reaction mixture at higher temperature to form cyclopropane ring. Further experiments to establish the structure of **8** have not been performed.



The unsaturated dione in which a double bond is inserted between two carbonyl groups has usually been reduced with zinc dust in glacial acetic acid to give a saturated dione[5] A similar result was observed in the reduction procedure of an unsaturated keto-acid in which a double bond is placed between a carbonyl group and a carboxyl group.[6] Unsaturated keto-acid (**2a**) was treated with zinc dust in glacial acetic acid under reflux for 2 hr. The reaction product, mp 80—82°C, was characterized as 2-benzoylcyclopentane-1-carboxylic acid (**12**) by spectral results and elemental analysis. Since this compound was recovered unchanged from its reaction with aqueous sodium hydroxide solution under reflux, stereochemically, the above product is assumed to be a thermodynamically more stable *trans* isomer.

All the results in the various reductions of substrates (**2a** and **2b**) are summarized in the following chart.



Experimental

2-Benzoylcyclopentene-1-carboxylic Acid (2a). A 200 m*l* three-necked round-bottomed flask was fitted with a mechanical stirrer, a 50 m*l* dropping funnel, a thermometer and a reflux condenser protected from the moisture in the air by means of a calcium chloride tube and also connected with a gas trap for disposing of evolved hydrogen chloride. In the flask was placed 28 g of anhydrous aluminum chloride and 40 m*l* of dry benzene. Ten and a half g of 1-cyclopentene-1,2-dicarboxylic acid anhydride (**3**)[2] was added dropwise into the flask immersed in an ice-water bath at such a rate that addition was complete in about a half hour. The reaction mixture was stirred at 0—5°C for 3 hr, at room temperature for 10 hr and then at 40—50°C for 2 hr. Cooling the resulting reaction mixture to room temperature, the mixture was poured slowly into a mixture of 100 g of ice and 50 m*l* of 6N hydrochloric acid with stirring. The light brown precipitate was separated, collected on a Buchner funnel and washed with two portions each of 10 m*l* of benzene and of 20 m*l* of water. After drying the precipitate was dissolved in a 100 m*l* of 10% sodium carbonate solution at 50°C. The solution was filtered and the filtrate was acidified with 6N hydrochloric acid. The precipitate thus formed was filtered and then washed with two portions of 20 m*l* of warm water. The final product was recrystallized from a mixed solvent of methanol and benzene. Fourteen grams of 2-benzoylcyclopentene-1-carboxylic acid (**2a**),

mp 184—185°C (lit,[2] 181—182°C), was obtained in 85% yield. IR (Nujol), 1680, 1660, 1650 and 720 cm^{-1}; NMR ($CDCl_3$), τ, 7.6—7.8 (m, 2H, $-CH_2-$), 7.21 (t, J=7 Hz, 4H, $-CH_2-C=C$), 2.0—2.6 (m, 5H, C_6H_5), 1.56 (s, 1H, CO_2H).

The Reduction of 2a with Sodium Borohydride. Into 20 m*l* of 5% aqueous sodium hydroxide solution which contained 5 g of **2a** was added 1.9 g of $NaBH_4$ dissolved in 20 m*l* of water, then the mixture was heated at 65°C for 30 min. Twenty m*l* of aqueous sodium hydroxide solution was added and the reaction solution was heated under reflux for 1 hr. After cooling the solution was acidified with dilute hydrochloric acid to pH 3. Crude 2-(α-hydroxybenzyl)-cyclopentene-1-carboxylic acid (**5**), mp 116—119°C, was obtained in 89% yield (4.5 g). Its recrystallization from benzene gave pure sample, mp 118—119°C. IR (Nujol), 3270, 1660, 730 and 690 cm^{-1}; NMR ($CDCl_3$), τ 7.9—8.5 (m, 2H, $-CH_2-$), 7.0—7.7 (d. t, J=7 Hz, 4H, $-CH_2-C=C$), 4.83 (s, 1H, CH–O–), 2.3—2.7 (m, 7H, C_6H_5, OH, CO_2H).

Found: C, 71.54; H, 6.47%. Calcd for $C_{13}H_{14}O_3$: C, 71.59; H, 6.66%.

Clemmensen Reduction of 2a. Amalgamated zinc was prepared by shaking a mixture consisting of 32.6 g of mossy zinc, 3.2 g of mercuric chloride, 50 m*l* of water and 1.5 m*l* of concentrated hydrochloric acid for 3 min. On decanting the mixture, the following reagents were added in turn into the flask: 10 m*l* of water, 50 m*l* of concentrated hydrochloric acid, 15 m*l* of toluene and 10.8 g of **2a**. The reaction mixture was boiled with vigorous stirring for 30 hr. Three 10 m*l* portions of concentrated hydrochloric acid were added at approximately 6 hr intervals during the reaction. After cooling, the aqueous layer was diluted with 200 m*l* of water and extracted with three 20 m*l* portions of ether. The organic layer was washed with water and dried over anhydrous sodium sulfate. The solvent was removed, then 7.6 g of oily product was obtained by distillation, bp 153—156°C/12 mmHg, in 75% yield. IR (neat), 1690, 750 and 710 cm^{-1}; NMR (CCl_4), τ 7.8—8.9 (m, 6H, $-CH_2-$), 7.0—7.8 (m, 4H, $-CH_2Ph$, –CH–), 2.90 (s, 5H, C_6H_5), −1.65 (s, 1H, CO_2H). Its methyl ester was prepared with diazomethane. It was found by VPC analysis that the ester consisted of two components: retention time, 9.2 and 10.0 min; column, SE 30, 1 m, oven temp, 155°C, carrier gas flow rate, N_2, 40 m*l*/min, area ratio, 2 : 1 respectively. The major product was purified by preparative VPC.

Found: C, 77.08; H, 8.23%. Calcd for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31%.

Reduction of 2b by Way of Its Thioketal. 212 mg of crude methyl 2-benzoylcyclopentane-1-carboxylate (**2b**) prepared from **2a** and diazomethane, and, 310 mg of ethanedithiol were dissolved in 10 m*l* of chloroform, then dry hydrogen chloride was passed into the solution under cooling with ice water over a period of 9 hr. The resulting solution was washed with water, 5% aqueous sodium carbonate solution and water again. Organic layer was dried over anhydrous sodium sulfate. Removing the solvent under reduced pressure, 180 mg of thioketal was obtained. The substance was heated with 3 g of Raney-Ni in 4 m*l* absolute ethanol under reflux for 30 hr. After the reaction mixture was filtered and the solvent was removed under reduced pressure, 91 mg of the crude product was obtained. It was confirmed from VPC analysis that the product was a mixture of two components identical with the Clemmensen reduction product, but their ratio was reversed, namely 1 : 2. In the preparation of the above thioketal, anhydrous zinc chloride could be used instead of dry hydrogen chloride.

Wolff-Kishner-Huang-Minlon Reduction of 2a. A 100 m*l* three-necked round-bottomed flask was fitted with a thermometer and a take-off condenser equipped with a stopcock which might be opened to permit distillation. In the flask were placed 60 m*l* of triethylene glycol and 7.0 g of potassium hydroxide. The mixture was carefully heated with swirling under nitrogen in an oil bath until potassium hydroxide was dissolved. Then 10.8 g of powdered acid (**1a**) was dissolved into the solution under nitrogen atmosphere at 100°C. Further 7.6 m*l* of 80% hydrazine hydrate was added at 80°C and the mixture was heated at 100—120°C for 1 hr. After distilled water was removed from the take-off condenser, the flask was rapidly heated until reflux began. Boiling was continued for 5 hr. The reaction mixture was poured into 50 m*l* of water after cooling, then filtered off. The filtrate was washed with two portions of 20 m*l* of ligroin and acidified with 6N hydrochloric acid. The acidified mixture was extracted with three 30 m*l* of ligroin. The combined organic layer was washed with two portions of 20 m*l* of water and dried over anhydrous sodium sulfate. After most of the solvent was removed under reduced pressure, 5 m*l* of light petroleum was added to the residue. After it had been stood in a refrigerator, solids were precipitated. Collected colorless solids weighed 5.1 g and melted between 90 and 95°C. It was recrystallized repeatedly from the mixed solvent of ether and light petroleum to give a pure sample, mp 121—122°C, which was assigned as 2-benzylcyclopentene-1-carboxylic acid (**1**) from its spectral and analytical results. IR (Nujol), 1670, 740 and 700 cm^{-1}; NMR (CCl_4), τ 7.7—8.6 (m, 6H, $-CH_2-$), 7.53 (s, 2H, $-CH_2Ph$), 2.78 (s, 5H, C_6H_5), 0.05 (s, 1H, CO_2H).

Found: C, 77.36; H, 7.12%. Calcd for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98%.

The crude oily product was treated with diazomethane to give a mixture of methyl esters, which was found by VPC analysis to consist of two components. The methyl ester other than the ester of **1** was purified by preparative VPC. IR (neat), 1720, 1270, 760 and 700 cm^{-1}; NMR (CCl_4), τ 9.58—10.15 (m, 1H, bridge head H), 7.55—9.00 (m, 6H, $-CH_2-$), 7.10 (d, J=8 Hz, 1H, CH–Ph), 6.38 (s, 3H, CH_3), 2.83 (s, 5H, C_6H_5).

Found: C, 77.64; H, 7.57%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

Catalytic Hydrogenation of 1. A mixture of 103 mg of 2-benzylcyclopentene-1-carboxylic acid (**1**) dissolved in 10 m*l* of glacial acetic acid and 26 mg of Adams catalyst was shaken under hydrogen atmosphere at 20°C. Eighteen m*l* of hydrogen was absorbed. After the catalyst was filtered, the solvent was removed under reduced pressure. The residue was treated with diazomethane in ether to give its methyl ester. The identity of this ester with that of minor product in the Clemmesen reduction was confirmed by VPC analysis described below.

Vapor Phase Chromatography of the Above Four Methyl Esters. The compounds, **6b**, **7b** and methylesters of **1** and **8**, were clearly separated by

VPC, using a 2 m column packed with Carbowax 20 M coated on Celite 545 in an oven heated at 225°C with a flow rate of carrier gas 40 ml/min. Under these conditions the retention times of **6b**, **7b**, **1**-Me and **8**-Me were 7.2, 6.5, 7.8 and 8.2 min respectively.

Reduction of 2a with Zinc Dust and Glacial Acetic Acid. Into a solution of 400 mg of 2-benzoylcyclopentene-1-carboxylic acid (**2a**) dissolved in 20 ml of glacial acetic acid was added 1.6 g of zinc dust. The mixture was heated under reflux with stirring for 2 hr. After cooling the miture was filtered and zinc dust washed with small portions of acetic acid. The solvent was removed under reduced pressure. 276 mg of crude product, mp 68—73°C, was obtained. The product was recrystallized from cyclohexane to give a pure sample, mp 80—83°C. IR (Nujol), 1690, 1675 and 719 cm^{-1}; NMR ($CDCl_3$), τ, 7.55—8.52 (m, 6H, $-CH_2-$), 6.20—6.75 (m, 1H, -CH-), 5.65—6.18 (m, 1H, -CH-), 1.92—2.70 (m, 5H, C_6H_5), 0.08 (s, 1H, CO_2H).

Found: C, 71.34; H, 6.54%. Calcd for $C_{13}H_{14}O_2$: C, 71.54; H, 6.47%.

Into a solution of 1 g of sodium hydroxide in 5 ml of water was dissolved 133 mg of the above crude product. The mixture was heated under reflux for 4 hr, then acidified with dilute hydrochloric acid and extracted with ether. Evaporation of the solvent gave 110 mg of recovered acid mp 67—70°C. Both the IR and NMR spectra of the recovered acid were essentially consistent with that of the pure sample (**12**).

The authors wish to express their hearty thanks to the late Professor S. Winstein, UCLA, for his encouragement throughout this work, and to Professor Kenji Fukui for his measurement of NMR spectra and to Mrs. Shinobu Imai for her earnest assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2208—2213 (1970)

Reaction of Olefin-Palladium(II) Chloride Complexes with Amides*1

Hidefumi HIRAI and Hiroaki SAWAI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received January 16, 1970)

Ethylene-palladium(II) chloride complex reacts with pyrrolidone and ε-caprolactam to produce *N*-vinylpyrrolidone and *N*-vinyl-ε-caprolactam, respectively. The yield of *N*-vinylpyrrolidone increases with increasing reaction temperature up to 120°C and decreases above 120°C owing to conversion of *N*-vinylpyrrolidone to an oily polymer through thermal polymerization. By addition of quinone, the yield increases remarkably at 25°C and 90°C. Pyrrolidone - palladium(II) chloride complex, which is too stable to react with ethylene at 25°C, reacts at 120°C to give *N*-vinylpyrrolidone. Open chain amides such as *N*-ethylacetamide, acetanilide and acetamide also react with ethylene - palladium(II) chloride complex, though the corresponding *N*-vinylamides cannot be obtained. The reaction of a styrene - palladium(II) chloride complex with pyrrolidone was also investigated.

Olefin-palladium(II) chloride complexes react with various nucleophilic reagents to form carbonyl compounds or substituted olefins.[1] Little is known about the reaction with nitrogen compounds such as amines or amides. Amine or amide forms a very stable complex with palladium(II) chloride, which would prevent or complicate the reaction. Stern and Spector reported very briefly the reaction of acetamide with propylene in the presence of palladium(II) chloride and that with ethylene-palladium(II) chloride complex.[2] Destruction of the resulting stable complexes by hydrogenation yielded *N*-isopropylacetamide and *N*-ethylacetamide, respectively.

Shortly after we had shown the formation of *N*-vinylpyrrolidone by the reaction of ethylene-palladium(II) chloride complex with pyrrolidone,[3] the process for production of ethylenylated lactams

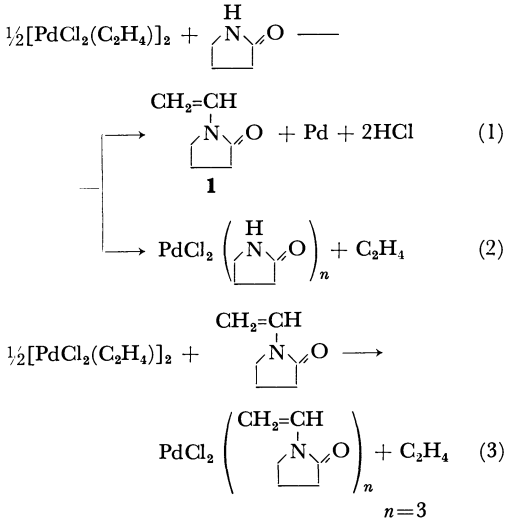
from olefins and lactams in the presence of palladium(II) chloride and cupric ion was patented.[4] This patent covered cyclic lactams such as pyrrolidone, ε-caprolactam and 2-ketopiperidone as a nucleophilic reagent, but little information on the reaction was given.

The present paper deals with the formation of *N*-vinylamides under various reaction conditions in detail to propose a reaction mechanism. The reaction of styrene-palladium(II) chloride complex with pyrrolidone is also described.

Results and Discussion

Reaction of Ethylene-Palladium(II) Chloride Complex with Pyrrolidone. Ethylene-palladium-(II) chloride complex reacted with pyrrolidone at 25°C for 2.5 hr under 10 atm of ethylene pressure to give *N*-vinylpyrrolidone (**1**) in 42 mol% yield based on palladium(II), accompanying the reduction of palladium(II) ion to the metal, as shown in Table 1. Simultaneously, a ligand substitution of the ethylene-palladium(II) chloride complex occurred to form pyrrolidone-palladium(II) chloride complex and *N*-vinylpyrrolidone-palladium(II)chloride complex. These reactions are schematically shown by the following equations.



Addition of pyridine makes **1** free from the coordination state in the reaction mixture by ligand substitution, which was confirmed by the change of color of the reaction mixture. The total yield of **1** could be determined by glpc after the addition of pyridine. As shown in Table 1, the yield of **1** increased from 24 to 42 mol% by addition of pyridine to the reaction mixture at 25°C. This means that 43% of **1** formed by reaction (1) was coordinated to palladium(II) chloride.

Table 1. Effect of temperature on the reaction of ethylene-palladium(II) chloride complex with pyrrolidone[a]

Temp. °C	Yield (mol%)[b] *N*-Vinylpyrrolidone free	*N*-Vinylpyrrolidone free+coordinated	Pd (metal)	Polymer[c] mg	Complex[d] mg
25	24	42	41	0	660(670)
60	32	51	49	0	570(590)
90	37	66	68	0	444(400)
120	65	72	77	100	240(260)
150	57	61	84	315	140(180)
180	13	13	88	500	50(150)

a) Reaction conditions: initial pressure of ethylene, 10 atm; time, 2.5 hr; [Pyrrolidone]/[Pd(II)]=4.
b) Based on palladium(II).
c) Crude substance.
d) Calculated amounts of the sum of pyrrolidone- and *N*-vinylpyrrolidone-palladium(II) chloride complexes are shown in parentheses.

Table 1 shows the effect of reaction temperature on the yields of reaction products. The yield of **1** increased with temperature and was nearly equal to that of palladium metal up to 90°C. Above 120°C, the yield of **1** decreased, while that of palladium metal increased and an oily resin of light greenish brown color resulted. The IR spectrum of this resin was identical with that of poly-*N*-vinylpyrrolidone. Elevation of temperature above 120°C promoted not only the extent of reaction (1) but also the polymerization of **1** by heat. The sum of the amount of pyrrolidone-palladium(II) chloride complex and that of *N*-vinylpyrrolidone-palladium(II) chloride complex in the reaction, decreased with the rise of temperature and was in fairly good agreement with the amount of these complexes calculated from unreduced palladium(II) ion.

The effects of the addition of quinone and diphenylpicrylhydrazyl on the yield of the products are shown in Table 2. Quinone is expected to regenerate palladium(II) ion in this system, forming a redox system and inhibiting thermal polymerization of **1**. Diphenylpicrylhydrazyl is known to be an inhibitor for the polymerization. Addition of quinone increased the yield of **1** remarkably at 25°C or 90°C, but depressed the formation of palladium metal less than 38 mol%. The yield of **1** became more than 100 mol% based on the initial amount of palladium(II). It is evident that quinone acted as an oxidant for the resulting palladium(0) at these temperatures. Above 150°C, however, the yield of **1** decreased remarkably, accompanying a definite increment of the yield of palladium metal, *e.g.*, about 50 mol%. The greater the amount of quinone added, the less the yield of

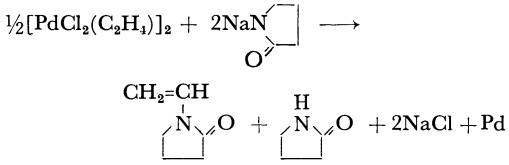
TABLE 2. EFFECT OF QUINONE ON THE REACTION OF ETHYLENE PALLADIUM(II) CHLORIDE COMPLEX WITH PYRROLIDONE[a]

Temp. °C	[Quinone]/[Pd(II)] molar ratio	Yield (mol%)[b] *N*-Vinylpyrrolidone free	*N*-Vinylpyrrolidone free+coordinated	Pd (metal)	Polymer
25	2	94	173	28	—
25	4	93	174	37	—
90	2	114		38	—
90	4	114	204	38	—
150	2	15	16	87	+
150	4	4	4	93	+
160	2[c]	17	17	85	+

a) Reaction conditions: initial pressure of ethylene, 10 atm; time, 2.5 hr; [Pyrrolidone]/[Pd(II)]=4.
b) Based on palladium(II).
c) Diphenylpicrylhydrazyl was used instead of quinone.

1. It can be concluded that quinone cannot inhibit the thermal polymerization of **1**. The added diphenylpicrylhydrazyl behaved in the reaction at 160°C just as quinone, as shown in Table 2.

Ethylene-palladium(II) chloride complex reacted also with sodium pyrrolidone at 25°C for 2.5 hr under 10 atm of ethylene pressure. *N*-Vinylpyrrolidone was obtained in 6 mol% yield, accompanying the formation of pyrrolidone, which was detected by glpc in the reaction mixture. This reaction can be expressed by the following equation.



The depression of the yield is attributable to the lower solubility of sodium pyrrolidone in tetrahydrofuran.

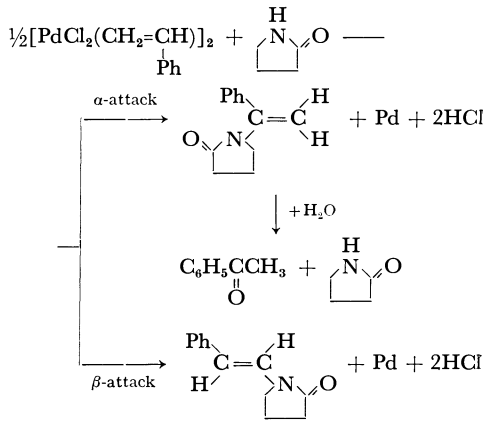
Reaction of Tris(pyrrolidone)palladium(II) Chloride Complex with Ethylene. Tris(pyrrolidone)palladium(II) chloride complex was too stable to react with ethylene at 25°C. This complex, however, was found to react with ethylene in a good yield at 120°C as shown in Table 3.

TABLE 3. REACTION OF TRIS(PYRROLIDONE)PALLADIUM(II) CHLORIDE COMPLEX WITH ETHYLENE[a]

Temp. °C	Yield (mol%)[b] *N*-Vinylpyrrolidone free	*N*-Vinylpyrrolidone free+coordinated	Pd (metal)	Polymer
25	0	0	0	—
120	62	70	69	—

a) Reaction conditions: initial pressure of ethylene, 20 atm; time, 2.5 hr.
b) Based on palladium(II).

Reaction of Styrene-Palladium(II) Chloride Complex with Pyrrolidone. Styrene-palladium(II) chloride complex reacted with pyrrolidone at 120°C for 2.5 hr, accompanied by precipitation of palladium metal in 38 mol%. Reaction products isolated by column chromatography were *trans*-β-styrilpyrrolidone, 1,4-diphenylbutadiene and acetophenone in 20, 5 and 5 mol% yield based on palladium(II), respectively. Acetophenone can be considered to be derived from α-styrilpyrrolidone by hydrolysis in the silica gel column of chromatography. The sterical unstability of α-styrylpyrrolidone would give rise to a low yield and a high susceptibility for hydrolysis. The possibility that acetophenone is formed by the reaction of styrene-palladium(II) chloride complex with water is excluded for the following reasons. No phenylacetaldehyde was formed in the present reaction, although the styrene complex is reported to react with water to yield phenylacetaldehyde and acetophenone in a molar ratio of about 1 : 2.[5] The reaction system was prevented from water contamination, and acetophenone was formed in a yield less than 1.5 mol% in a blank test.



1,4-Diphenylbutadiene has been reported to be obtained from styrene in the presence of palladium(II) ion and acetate anion.[6] Pyrrolidone probably becomes pyrrolidonium anion which can play the same role of acetate anion for the formation of 1,4-diphenylbutadiene

Reaction of Ethylene-Palladium(II) Chloride Complex with Other Amides. ε-Caprolactam, *N*-ethylacetamide, acetanilide and acetamide were allowed to react with ethylene-palladium(II) chloride complex. Table 4 shows the results of glpc

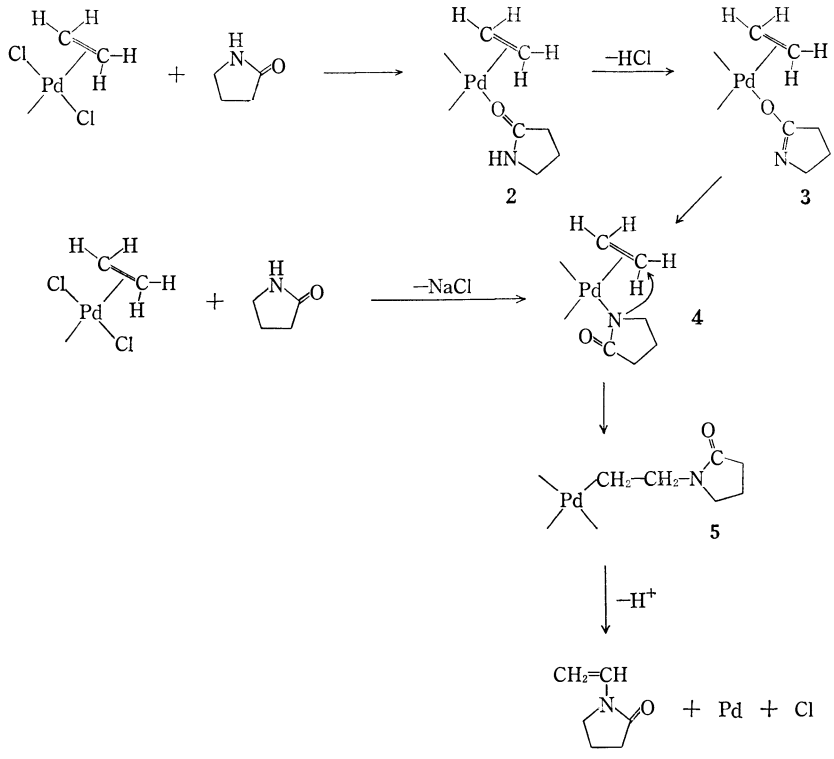
a) Reaction conditions: initial pressure of ethylene, 10 atm; time, 2.5 hr; [Amide]/[Pd(II)]=4.
b) Based on palladium(II).
c) After hydrogenation, *N*-ethylacetamide was analyzed.



Scheme 1

analysis of the reaction products. *N*-Vinyl-ε-caprolactam was obtained in 20 mol% yield at 25°C, and the yield decreased at 120°C accompanying the formation of a large amount of polymer. *N*-Vinyl-ε-caprolactam seems to polymerize thermally more easily than *N*-vinylpyrrolidone. Cyclic amides gave *N*-vinylamides in fairly good yields, while open chain secondary amides such as *N*-ethylacetamide and acetanilide could not produce the corresponding *N*-vinylamides at room temperature. The formation of palladium metal was small in these cases. At a higher reaction temperature, the corresponding oily poly-*N*-vinylamide was obtained. In the case of open chain amides, *N*-vinylamide seems to undergo hydrolysis or polymerization easily. *N*-Vinylacetanilide is reported to undergo hydrolysis very easily in the presence of acid.[7]

In the case of acetamide, the product was analyzed by glpc after hydrogenation to *N*-ethylacetamide, because no gas chromatogram of *N*-vinylacetamide could be obtained by addition of pyridine and the

7) S. Murahashi, S. Nozakura, A. Umehara and F. Nagoshi, *Kobunshi Kagaku*, **22**, 451 (1965).

authentic sample could not be prepared with the thermal decomposition of ethylidenediacetamide.[8] In the reaction mixture, only acetamide was detected by glpc. The product probably decomposed in the column of glpc. Two types of reaction products can be considered; $CH_3CH{=}NCOCH_3$ and $CH_2{=}CHNHCOCH_3$. However, further characterization was unsuccessful.

Reaction Scheme. A scheme for ethylene-palladium(II) chloride complex with pyrrolidone is proposed (Scheme 1.)

At first pyrrolidone reacts with the ethylene complex to form ethylene-pyrrolidone-palladium(II) complex (**2**). In this complex, pyrrolidone is considered to coordinate to palladium(II) ion with the carbonyl group, because the coordination of the carbonyl group of pyrrolidone in tris(pyrrolidone)palladium(II) chloride complex has been confirmed by the shift of the IR stretching band: $\Delta\, \nu_{CO}=45\ cm^{-1}$. The proton of coordinated pyrrolidone is withdrawn to form complex (**3**) which tautomerize to complex (**4**) on account of the stronger affinity of amide nitrogen anion for palladium(II) than that of alkoxy type anion. Coordinated ethylene is then inserted into the resulting Pd–N bond to give complex (**5**) which decomposes to yield **1**. Sodium pyrrolidone reacts with ethylene complex to form complex (**4**) by the exchange reaction of chloride ion with pyrrolidonium anion. Sodium pyrrolidone cannot coordinate to palladium(II) ion by the steric and the ionic effect of sodium ion. The fact that pyrrolidone-palladium(II) chloride complex could not react with ethylene at 25°C, but could at 120°C means that the elevation of temperature makes the stable pyrrolidone complex so labile as to enable ethylene to coordinate palladium(II) ion. The high temperature also activates the withdrawal of hydrogen of coordinated pyrrolidone and promotes the extent of the reaction.

The proposed scheme is essentially the same as that for the reaction of ethylene-palladium(II) chloride complex with *n*-butylamine.[9] Usually, amine or amide in a free state cannot dissociate its *N*-proton easily, while its proton in the coordination state can be withdrawn by palladium(II) ion to its strong affinity for hydrogen to result in the reaction with ethylene[9] or carbon monoxide.[10]

Experimental

Materials. Bis(benzonitrile)dichloro palladium(II) and styrene - palladium(II) chloride complex were prepared according to Kharasch.[11] *N*-Ethylacetamide was prepared from ethylamine and acetic anhydride. ε-Caprolactam, acetanilide and acetamide were of reagent grade and dried under reduced pressure. Sodium pyrrolidone was prepared from pyrrolidone and sodium hydroxide by heating on a sand bath. Tris(pyrrolidone)-palladium(II) chloride complex was prepared from bis-(benzonitrile)dichloro palladium(II) with pyrrolidone in tetrahydrofuran in a quantitative yield, and recrystallized from methanol. Tetrahydrofuran used as a solvent was dried over lithium aluminum hydride and distilled before use.

Reaction of Ethylene-Palladium(II) Chloride Complex with Pyrrolidone. Bis(benzonitrile)dichloro-palladium(II) (0.96 g, 0.0025 mol) and dry tetrahydrofuran (20 m*l*) were charged in a magnetically stirred 100 m*l*-autoclave in a slow stream of nitrogen. In the autoclave, a glass tube was used as a reactive vessel and the stirrer was made of Teflon to prevent palladium-(II) ion from reacting with steel. Ethylene-palladium-(II) chloride complex was prepared under 10 atm of ethylene pressure for half an hour with stirring. The autoclave was then opened for addition of pyrrolidone (1 m*l*, 0.01 mol) and the reaction was carried out under 10 atm of initial ethylene pressure at 25—150°C for 2.5 hr. A similar procedure was applied for the reaction with quinone or diphenylpicrylhydrazyl.

Reaction of Ethylene-Palladium(II) Chloride Complex with Sodium Pyrrolidone. Bis(benzonitrile)dichloro palladium(II) (0.96 g, 0.0025 mol), sodium pyrrolidone (1.3 g, 0.0125 mol) and dry tetrahydrofuran were placed in the autoclave. The reaction was carried out under 10 atm of ethylene pressure at 25°C for 2.5 hr.

Reaction of Tris(pyrrolidone)palladium(II) Chloride Complex with Ethylene. Tris(pyrrolidone)-palladium(II) chloride complex (1.08 g, 0.0025 mol) and dry tetrahydrofuran were charged in the autoclave. The reaction was carried out under 20 atm of initial ethylene pressure at 25 or 120°C for 2.5 hr.

Products Analysis. *N*-Vinylpyrrolidone was analyzed by glpc (a 2 m Carbowax 20 M on Diasolid A column at 160°C and a nitrogen flow rate of 55 m*l*/min) and IR. The yield data were obtained by glpc with benzonitrile as an internal standard. Glpc analysis was carried out both before and after addition of pyridine to the reaction mixture to make the product free from coordination. Other reaction products were examined as follows. The reaction mixture was filtered through a glass filter and the residue was washed with tetrahydrofuran (Filtrate I), then with methanol (Filtrate II) and finally with dimethylformamide (Filtrate III). The resulting precipitate was palladium metal and was weighed after drying. Filtrate I was concentrated under reduced pressure to a few mililiter in order to crystallize a small amount of reddish brown complex. After removal of the crystals, a large amount of ether was added to the solution to separate an oily residue which was dried under reduced pressure and weighed. The IR spectrum of this substance was essentially the same as that of poly-*N*-vinylpyrrolidone obtained commercially.

Concentration of Filtrate II gave reddish brown

crystals, which were confirmed to be a mixture of pyrrolidone-palladium(II) chloride complex and *N*-vinylpyrrolidone-palladium(II) chloride complex by IR spectrum; (3200(ν_{NH}), 2930, 2850, 1670(ν_{CO}), 1640(ν_{CO} or $\nu_{C=C}$), 1625 (ν_{CO} or $\nu_{C=C}$), 1290).

In the presence of quinone, a dark reddish brown precipitate was obtained from Filtrate III after concentration. This precipitate seems to be quinone-palladium(II) complex, but further characterization was unsuccessful.

Reaction of Styrene-Palladium(II) Chloride Complex with Pyrrolidone. Styrene-palladium(II) chloride complex (3.172 g, 0.0113 mol), styrene (2 m*l*), pyrrolidone (4.5 ml, 0.0045 mol) and dry tetrahydrofuran were charged in the autoclave. Reaction was carried out at 120°C for 2.5 hr. After the reaction, 2 m*l* of pyridine was added to the reaction mixture to make the product free from the coordination state. Then the reaction mixture was filtered through a glass filter, and the precipitate was washed with tetrahydrofuran. The filtrate was concentrated by evaporation and chromatographed on silica gel.

From the first fraction white crystals were obtained by using cyclohexane as an eluent. Recrystallization from *n*-hexane gave pure 1,4-diphenylbutadiene; mp 152—153°C (lit,[6] 149.5°C).

From the second fraction colorless liquid was obtained, which was confirmed to be acetophenone by IR and glpc.

Finally white crystals were obtained by using benzene as an eluent. Recrystallization from cyclohexane-ether gave purified *trans*-β-styrylpyrrolidone; mp 128°C (lit,[12] 129°C).

Reaction of Ethylene-Palladium(II) Chloride Complex with ε-Caprolactam, *N*-Ethylacetamide and Acetanilide. The procedure was similar to that used for the reaction of ethylene complex with pyrrolidone. Analysis of the products was carried out by glpc; A 2 m Carbowax 20 M on Diasolid A column, and a nitrogen flow rate of 60 m*l*/min, at 170°C for ε-caprolactam and acetanilide, at 122°C for *N*-ethylacetamide. The yield data were obtained by glpc with benzonitrile as an internal standard. The products were identified by comparison of gas chormatograms and IR spectra with those of authentic sample prepared according to Reppe.[13]

Reaction of Ethylene-Palladium(II) Chloride Complex with Acetamide. The reaction method was similar to that for the case of pyrrolidone. The product was analyzed by glpc; A 2 m Carbowax 20 M on Diasolid A column at 122°C and a nitrogen flow rate of 60 m*l*/min. The reaction product could not be detected by glpc, but *N*-ethylacetamide was obtained after hydrogenation of the reaction mixture catalyzed by palladium metal under 80 atm of hydrogen, as described by Stern.[2] The yield data were obtained by glpc with benzonitrile as an internal standard. The preparation of *N*-vinylacetamide as an authentic sample, reported by Ben-Ishai and Giger,[8] was unsuccessful.

Reactions of Haloferrocenes. III. The Reaction of Haloferrocenes with Copper(I) Benzenethiolate, Thiocyanate, Acetate, and Benzoate

Masaru SATO, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received January 21, 1970)

Iodoferrocene reacted with copper(I) benzenethiolate in boiling pyridine to give ferrocenyl phenyl sulfide in a quantitative yield. The reaction of iodoferrocene with copper(I) thiocyanate gave diferrocenyl disulfide. The behavior of copper(I) acetate and benzoate toward haloferrocene was found to be different from those of the other copper(I) salts: the reactions in boiling pyridine gave the corresponding ferrocenyl ester, together with a small quantity of ferrocene, while the reaction in boiling toluene produced biferrocenyl as the main product. The reaction mechanism of the ferrocenyl ester and biferrocenyl formations was discussed.

It has been shown that haloferrocene has a high reactivity in the reaction with copper(I) salts in pyridine, and that chloro-, bromo-, and cyanoferrocene were obtained in good yields from the reaction of iodoferrocene with, respectively, copper(I) chloride, bromide, and cyanide in boiling pyridine.[1] Bromoferrocene was 10^3 times more reactive than bromobenzene in the reaction with copper-

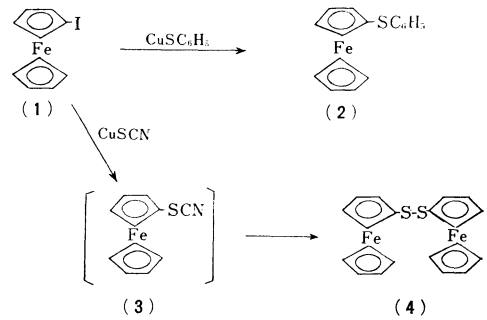
1) M. Sato, T. Ito, I. Motoyama, K. Watanabe and K. Hata, This Bulletin, **42**, 1976 (1969). Part I in this series.

(I) chloride - pyridine complex in bromobenzene.[2] According to Bunnett and Zahler,[3] the reaction of this kind is classified as a nucleophilic substitution reaction participated by transition metal through an uncertain mechanism. It is surprising that haloferrocene has a high reactivity even in the nucleophilic reaction, whereas ferrocene itself shows a much higher reactivity than benzene in an electrophilic reaction such as the Friedel-Crafts acylation. In order to elucidate the nature of this reaction, the reactions of haloferrocene with copper(I) benzenethiolate, thiocyanate, acetate, and benzoate were investigated.

Results and Discussion

The treatment of iodoferrocene (**1**) with copper(I) benzenethiolate in boiling pyridine for two hours gave ferrocenyl phenyl sulfide (**2**) in a quantitative yield. Similar results have been observed in the reaction of aryl halide with copper(I) benzenethiolate.[4] No particular high reactivity of iodoferrocene over other aryl halides was observed in this reaction, although it has been found[1] that haloferrocenes generally have a higher reactivity toward copper(I) salts than do the corresponding halobenzenes. This has been supposed to be due to the special high reactivity of benzenethiolate toward both halides. Thus, this reaction is considered to be as useful as the copper-catalyzed reaction between iodoferrocene and sodium benzenethiolate[5] for the preparation of ferrocenyl phenyl sulfide.

The reaction of iodoferrocene (**1**) with copper(I) thiocyanate in boiling pyridine for two hours gave diferrocenyl disulfide (**4**) in a 48% yield instead of the expected product, ferrocenyl thiocynate (**3**), with a 42% recovery of iodoferrocene.



It is known that aryl halides are converted to the diaryl disulfides by the action of copper(I) thiocyanate under severe conditions[6] and that aryl thiocyanates are reduced to the corresponding disulfides with copper(I) salt.[7] The formation of diferrocenyl disulfide (**4**) is probably due to the rapid reduction of the intermediary ferrocenyl thiocyanate (**3**) to the disulfide (**4**) by an excess of copper(I) salt. The reactivity of iodoferrocene toward thiocyanate seems to be usually high, since 1-bromonaphthalene hardly reacts with copper(I) thiocyanate under similar conditions.[8] This process can be used for the preparation of diferrocenyl disulfide which was previously prepared by the oxidation of ferrocenethiol.[9]

TABLE 1. THE REACTION OF HALOFERROCENE WITH COPPER(I) ACETATE AND BENZOATE
Haloferrocene: 0.005 mol; copper(I) salts: 0.01 mol; solvent: 15 ml; reaction temp.: 120°C±5°C; reaction time: 0.5 hr

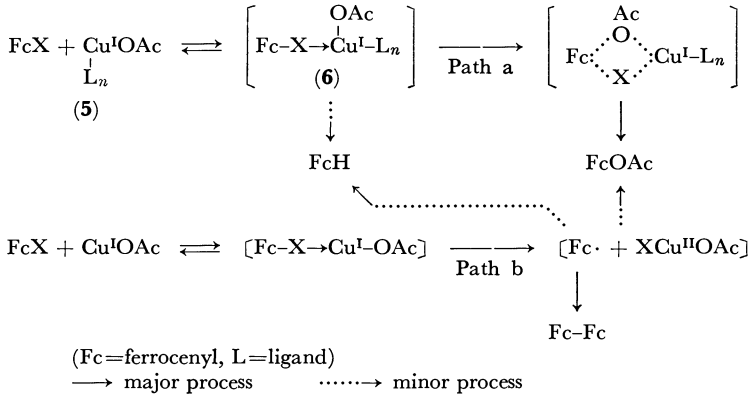

Scheme 1

The behavior of copper(I) acetate and benzoate toward haloferrocene was found to be different from that of the other salts, as is summarized in Table 1. When iodoferrocene was treated with copper(I) acetate in boiling pyridine for 0.5 hr, ferrocenyl acetate was obtained in a moderate yield, together with a small quantity of ferrocene and biferrocenyl. The formation of these by-products was not observed in the reaction described above or in the previous paper.[1] The reaction of bromo- or chloroferrocene with copper(I) acetate did not afford biferrocenyl, but it did give ferrocene in addition to ferrocenyl acetate. The reactivities of haloferrocenes toward the copper(I) acetate were in the order: FcI> FcBr>FcCl. When copper(I) benzoate, instead of copper(I) acetate, was refluxed for 0.5 hr with iodoferrocene in pyridine, ferrocenyl benzoate was similarly obtained in a moderate yield, along with traces of ferrocene and biferrocenyl. Since a considerable amount of iodoferrocene was recovered in this reaction, the reactivity of copper(I) benzoate toward iodoferrocene seems to be considerably smaller than that of copper(I) acetate.

As has been mentioned above, the reaction of haloferrocene with copper(I) acetate and benzoate in pyridine gave ferrocenyl acetate and benzoate respectively. Those results are very different from those of the halobenzene series. It has been reported that reactions of aryl halides with copper(I) acetate in pyridine generally give dehalogenation products as a sole product.[10,11] For example, naphthalene was obtained in a 60% yield by the treatment of 1-bromonaphthalene with copper(I) acetate in boiling pyridine.[10] When *o*-iodonitrobenzene, which is as reactive as iodoferrocene in the Ullmann coupling reaction,[12] was treated with copper(I) acetate in boiling pyridine, 2,2′-dinitrobiphenyl was obtained in an 84% yield, but no detectable amount of *o*-nitrophenyl acetate was produced.

The reaction of haloferrocenes with copper(I) acetate and benzoate also gave rise to the formation of ferrocene and biferrocenyl, but the formation of the latter was only observed in the reaction of iodoferrocene. The fact may be explained as follows: active copper, which was produced by the decomposition or disproportionation of copper(I) acetate, causes the coupling of iodoferrocene, just as in the reaction of iodoferrocene with active copper powder[13] prepared from copper(II) sulfate and zinc dust to give biferrocenyl. However, we cannot exclude the possibility of the process involving the reduction of iodoferrocene with copper(I) salts, followed by the coupling reaction to be described below.

The route of the reaction of haloferrocene with copper(I) acetate or benzoate in pyridine may be similar to that with the other copper(I) salts.[2] The coordination of the halogen atom of haloferrocene to the copper(I) salt-pyridine complex (**5**) may give a metastable intermediate (**6**), through which a ligand-exchange reaction leads to ferrocenyl acetate or benzoate as is shown in Path a of Scheme 1.

The fact that the dehalogenation product, *i.e.*, ferrocene, was not detected in the reaction of haloferrocene with copper(I) salts other than acetate or benzoate indicates that the existence of an acetate or benzoate ligand on the copper(I) complex (**5**) is essential for the formation of the dehalogenation product. It is considered that the dehalogenation may proceed through an intramolecular hydride shift within the intermediate complex (**6**) similar to that which was proposed by Bacon and Hill[11] in the benzene series. This consideration is supported by the fact that a larger amount of ferrocene is formed in the reaction with copper(I) acetate than with benzoate; it is possible that the hydride shift takes place more easily in the former than in the latter.

In order to examine the function of pyridine in

13) R. Q. Brewster and R. Groening, "Organic Syntheses," Coll. Vol. 2, p. 445 (1943).

these reactions, haloferrocenes were treated with copper(I) acetate or benzoate in boiling toluene (Table 1, Nos. 5, 6, and 7). In every case, the main product was biferrocenyl, while ferrocene and ferrocenyl ester were produced as minor by-products. The remarkable difference in the product ratio observed between the reactions in pyridine and those in toluene suggests that the coordinating ability of the solvent may be significant in these reactions. It has been established that the coordination of pyridine to copper(I) salt affords a copper(I) salt-pyridine complex (**5**). The reaction of haloferrocene with copper(I) acetate or benzoate was considered to proceed through this complex to afford the ferrocenyl ester as a main product. On the other hand, as the coordination of toluene must proceed through another process. During the reaction in toluene, a color change in the reaction mixture from orange to green was observed as the reaction proceeded. This is probably due to the formation of some copper(II) species. As no such color change was observed by refluxing copper(I) benzoate alone in toluene, the coexistence of haloferrocene seems to be necessary for the formation of the copper(II) species. On the basis of the results presented above, Path b in Scheme 1 was assumed to be a possible process: haloferrocene is reduced by some participation of copper(I) acetate or benzoate (for instance, the unstable complex-formation shown in Scheme 1) to give a ferrocenyl radical, which may interact with the excess of the salt to form ferrocenylcopper species. The ferrocenyl radicals thus formed couple with each other to give biferrocenyl, on the one hand, and abstract an acetoxy group from copper(II) acetate to give ferrocenyl acetate, on the other hand.

A similar process has been proposed for the reduction of benzyl chloride with copper(I) ion[14] or chrom(II) ion.[15] It is not apparent, however, whether or not the formation of the ferrocenyl ester is exclusively due to the process involving the ferrocenyl radical. Perhaps the ligand-exchange process through complex-formation discussed above will simultaneously contribute to the formation of the ester.[16]

Considering the results of the reactions of haloferrocenes with various copper(I) salt-pyridine complexes described in the present paper, together with those described in the previous paper,[1] it was found that the affinity of various ligands to ferrocene nucleus was in the following order: $SC_6H_5 > Cl > Br > CN > OAc > OBz > SCN$. It was also reconfirmed that haloferrocenes have a higher reactivity toward various copper(I) salt-pyridine complexes than do halobenzenes.

Experimental

Materials. Iodoferrocene was prepared from chloromercuriferrocene by a modification of a previously-reported procedure.[1] Bromoferrocene and chloroferrocene were prepared by the procedure described in a previous paper.[1] Copper(I) benzenethiolate,[4] thiocyanate,[17] acetate,[18] and benzoate[16] were prepared according to the literatures. Pyridine was distilled just before use after desiccation over potassium hydroxide.

Ferrocenyl Phenyl Sulfide. Iodoferrocene (1.56 g, 0.005 mol) and copper(I) benzenethiolate (1.73 g, 0.01 mol) were refluxed for 2 hr in 15 m*l* of pyridine. After the reaction had been completed, 80 m*l* of benzene was poured into the hot reaction mixture. The precipitate thus formed was filtered and washed with benzene. The combined benzene solution was repeatedly washed with water until the aqueous layer became neutral; then the solution was dried over anhydrous magnesium sulfate. After benzene had been evaporated off, the residue was chromatographed on alumina with hexane - benzene (1 : 1) to give 1.6 g of yellow crystals, which were then recrystallized from hexane - benzene, mp 110.0—110.5°C (lit, 111.5—112°C). Finally, 1.38 g (93.9% yield) of ferrocenyl phenyl sulfide were obtained.

The Reaction of Iodoferrocene with Copper(I) Thiocyanate in Pyridine. A mixture of 1.56 g (0.005 mol) of iodoferrocene, 1.22 g (0.01 mol) of copper(I) thiocyanate, and 15 m*l* of pyridine was refluxed for 2 hr under an atmosphere of nitrogen. Then, 80 m*l* of ether was added and the reaction mixture was filtered. The filtrate was washed with water, then with 2N hydrochloric acid to remove pyridine, and again with water. After the removal of the solvent, the residue was chromatographed on alumina. Iodoferrocene (0.65 g, 41.7%) was recovered, and diferrocenyl disulfide (0.52 g, 47.9%) was obtained as yellow crystals, which were subsequently recrystallized from hexane - benzene, mp 190—191°C (lit, 192°C,[9] 192—193°C[5]).

A General Procedure for the Reactions of Haloferrocenes with Copper(I) Acetate or Benzoate in Pyridine. Haloferrocene (0.005 mol) was refluxed, together with copper(I) acetate or benzoate (0.01 mol), in 15 m*l* of pyridine under an atmosphere of nitrogen. After 30 min, 80 m*l* of ether was added to the cooled reaction mixture, and then the mixture was filtered. The filtrate thus obtained was washed successively with water, 2N hydrochloric acid, and again with water, and then dried over anhydrous magnesium sulfate. After the removal of the solvent under reduced pressure, the residue was separated into individual compounds by chromatography.

Procedure for Exp. 1 in Table 1. The reaction product was chromatographed on silica gel with hexane - benzene (2 : 1). The product obtained from the first fraction was again chromatographed on alumina with the same solvent to give 0.24 g of yellow crystals and 0.04 g (4.3% yield) of biferrocenyl. The gas-chromatographic analysis of the former was carried out under the conditions described in a previous paper,[2] and the yellow crystalline substance was found to be a mixture

17) R. L. Demmerle, W. A. Taebel and W. F. Anderson, *Ind. Eng. Chem.*, **42**, 2 (1950).

18) M. Calvin and W. K. Wilmarth, *J. Amer. Chem. Soc.*, **78**, 1301 (1956).

of ferrocene (0.19 g, 20.0% yield) and chloroferrocene (0.05 g, 4.5% yield). The second fraction of chromatography gave ferrocenyl acetate (0.76 g, 62.3% yield), which was subsequently recrystallized from hexane, mp 66—67.5°C (lit,[19] 64.5—66.5°C).

The Reaction of Iodoferrocene with Copper(I) Benzoate in Toluene. (Table 1, Exp. 6). Iodoferrocene (1.56 g, 0.005 mol) was refluxed with copper(I) benzoate (1.85 g, 0.01 mol) in 20 m*l* of toluene under an atmosphere of nitrogen. After 30 min, the cooled reaction mixture was extracted with benzene by using a Soxhlet extractor. The concentration of the extract under reduced pressure, followed by filtration, gave orange crystals (0.56 g), which were identified as biferrocenyl on the basis of their melting point (238—240°C, lit,[12] 240—241°C) and their IR spectrum. The residue obtained from the filtrate on evaporation was chromatographed on silica gel with hexane-benzene (2:1). The first fraction was again chromatographed on alumina with the same solvent to give a trace of ferrocene and 0.06 g of biferrocenyl. The second fraction afforded 0.37 g (24.2% yield) of ferrocenyl benzoate. The total yield of biferrocenyl amounted to 0.62 g (67.0%).

The Reaction of *o*-Iodonitrobenzene with Copper(I) Acetate in Pyridine. The residue obtained from the reaction of *o*-iodonitrobenzene with copper(I) acetate under the conditions described above in the general procedure was chromatographed on silica gel with hexane-benzene (2:1) to give 0.12 g of a yellow liquid as a first fraction and 0.51 g (83.6%) of 2,2′-dinitrobiphenyl as a second fraction. The yellow liquid obtained from the first fraction was supposed to be a mixture of nitrobenzene and *o*-iodonitrobenzene, though attempts at identification failed because of the difficulty of separation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2217—2222 (1970)

Studies on Fluorene Derivatives. XXVI.[1] Radical Reactions in the Copyrolysis of Thermally-reactive Tribiphenylenepropanes

Kazuo Suzuki, Masahiro Minabe, Shozo Kubota* and Taro Isobe*

Department of Industrial Chemistry, Faculty of Technology, Utsunomiya University, Ishii-cho, Utsunomiya
* *Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira-cho, Sendai*

(Received January 30, 1970)

The pyrolyses of thermally-reactive tribiphenylenepropanes (mp 293°C (dec) or 257°C (dec)) in the presence of thermally-reactive 2,7,2′,7′,2″,7″-hexabromotribiphenylenepropane (mp 318—320°C (dec)) were investigated. Hydrocarbons, 2′,7′,2″,7″-tetrabromotribiphenylenepropane, 2,7-dibromo-9,9′-bifluorenyl, and -bifluorenylidene were obtained as pyrolysates from the respective thermal reactions, probably from intermolecular radical disproportionation reactions. In addition, 2,7,2′,7′-tetrabromo-9,9′-bifluorenyl, -bifluorenylidene, 2,7-dibromo-fluorene, and -fluorenone from hexabromotribiphenylenepropane, and 9,9′-bifluorenyl, -bifluorenylidene, fluorene, and fluorenone from tribiphenylenepropanes were formed by intramolecular reactions attributed to radical formation in the pyrolysis of each substrate. The pyrolyses of both tribiphenylenepropanes, 9,9′-bifluorenyl and 2,7,2′,7′,2″,7″-hexabromotribiphenylenepropane, were observed in a differential scanning calorimeter. The thermogram of tribiphenylenepropane (mp 257°C) is similar to that of 9,9′-bifluorenyl; the first endothermic peak corresponds to the melting point, and the second, broad one seems to be due to the slow formation of 9,9′-bifluorenylidene from 9,9′-bifluorenyl by means of a dehydrogenation process. In the thermogram of tribiphenylenepropane (mp 293°C), the first endothermic peak is the melting point, while the second, small one is probably caused by the overlapping of exothermic and endothermic peaks due to radical reactions during the formation and pyrolysis of tribiphenylenepropane (257°C). The thermal homolyses of solid tribiphenylenepropane isomers or those in a silicon oil solution were examined by ESR, which confirmed the radical formation in the pyrolyses.

Tribiphenylenepropanes were obtained by the Michael reaction[2] of 9,9′-bifluorenylidene (**3**) and

1) XXV of this series: K. Suzuki, M. Minabe, M. Fujimoto and N. Nohara, This Bulletin, **42**, 1609 (1969).

2) a) K. Suzuki, *Nippon Kagaku Zasshi*, **70**, 189 (1949). b) L. A. Pinck and G. E. Hilbert, *J. Amer. Chem. Soc.*, **68**, 2014 (1946).

fluorene (**13**), by the condensation of **13** with sodium amide, and by other reactions.[3] One of the isomers (mp 257°C (dec)), (**2**), is converted to the other (mp 293°C (dec)), (**1**), by the action of *N*-bromosuccinimide or Triton B.[4] We have found that the reverse process occurs during pyrolysis.

Compound **1** gave two isomers, **2** and **3**, and 9,9′-bifluorenyl (**4**) by pyrolysis, while **2** gave **3** and **4**.[2a] Additionally, 2,7,2′,7′,2″,7″-hexabromotribiphenylenepropane (**5**) yielded 2,7,2′,7′-tetrabromo-9,9′-bifluorenyl (**6**), -bifluorenylidene (**7**), and 2,7-dibromofluorenone (**12**) by pyrolysis.[5] Previously, homolytic fission was proposed as the mechanism for the formation of **2**, **3**, **4**, **6**, and **7**.[6]

The current investigation deals with the confirmation of the reaction products formed by intermolecular radical reactions during the thermolyses of tribiphenylenepropanes in the presence of **5**.

In a preliminary experiment,[2a] **13** and fluorenone (**14**) could not be isolated. A re-investigation of the pyrolysis of tribiphenylenepropane isomers showed that **1** gave **2**, **3**, **4**, **13**, and **14**, while **2** gave **3**,**4**, **13**, and **14**, as confirmed by gas-chromatographic analysis. The data are listed in Table 1.

Moreover, for the purpose of studying the thermal behavior, a differential scanning calorimeter (DSC) was employed which showed exothermic or endothermic peaks depending on the combination of physical and chemical changes proceeding at the reaction temperature. The formation of free radicals was confirmed by ESR.

Compounds **4**, **1**, **2**, and **5** are thermally-active species, each possessing two active methine groups. Under the pyrolytic conditions, the six carbon-bromine bonds in **5** are more stable than the 9-9′-9″ carbon-carbon covalent bonds in tribiphenylenepropanes.

Accordingly, the pyrolysates, **2**, 2′,7′,2″,7″-tetrabromotribiphenylenepropane (**8**), **6**, **7**, 2,7-dibromo-9,9′-bifluorenyl (**9**), -bifluorenylidene (**10**), **3**, 2,7-dibromofluorene (**11**), **12**, **13**, and **14** were observed by the copyrolysis of **1** and **5** at 320—330°C. Also, by the same process, **8**, **6**, **7**, **9**, **10**, **3**, **4**, **11**, **12**, **13**, **14**, and 2% of recovered **2** were obtained by the copyrolysis of **2** and **5** at 330—340°C.

In view of these results, it appears that all compounds participate in the fission of 9-9′-9″ carbon-carbon bonds in tribiphenylenepropanes. Moreover, the formation of the three structures, **8**, **9**, and **10**, can be explained in terms of intermolecular free radical reactions based on the thermal homolyses between the two different bromo- and nonbromo-tribiphenylenepropanes precursors. Schemes I and II summarize the pyrolytic pathways suggested for

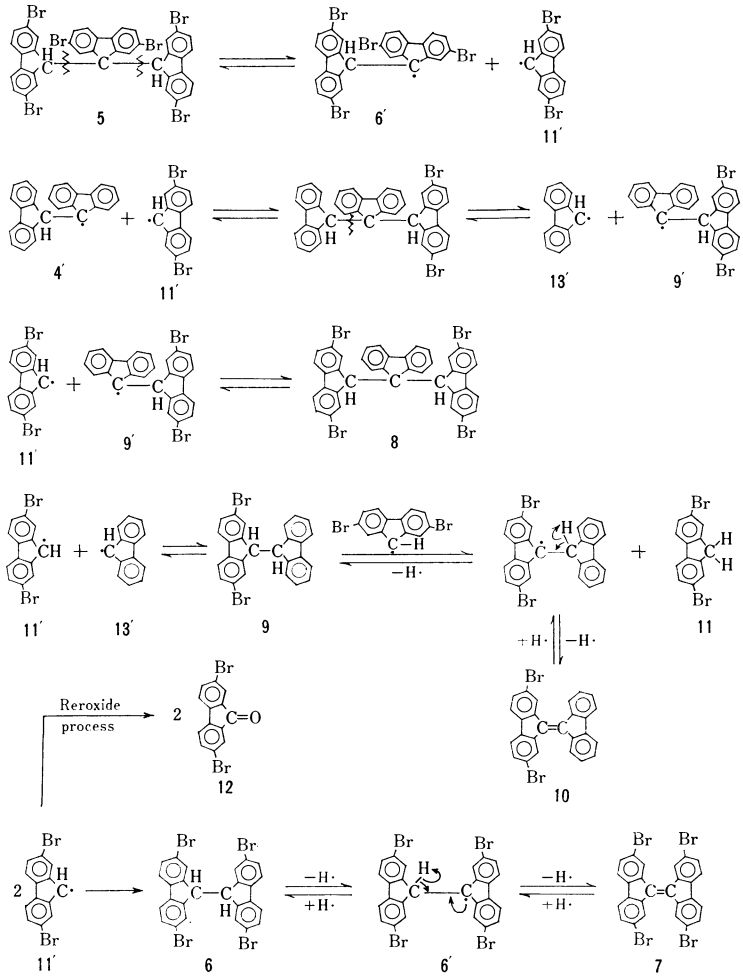

Scheme II. Pyrolyses of tribiphenylenepropanes in the presence of 2,7,2′,7′,2″,7″-hexabromotribiphenylenepropane (**5**).
(Compounds **6**, **7**, **8**, **9**, **10**, **11** and **12** were isolated.)

the formation of these compounds.

The 9-fluorenyl (**13′**) and 9-fluorenyl-9′-fluorenylidene (**4′**) radicals were presumably formed in the initial homolytic fission of **1** or **2**. A coupling reaction of **13′** could occur in the melt to give **4**, while the unsaturated hydrocarbon, **3**, may have been formed by dehydrogenation during the pyrolytic process.[2a] The formation of **13** can be explained by hydrogen abstraction from **4′** or **4** by **13′** during the formation of **3** and/or by reaction of **13′** with a hydrogen radical.

Tribiphenylenepropane (mp 257°C), (**2**), may be formed by a re-combination of the **4′** and **13′** radicals in a different steric configuration from that of the compound with a mp of 293°C (**1**). The coupling product of **4′** could not isolated; if this were formed, it might lead to the formation of **3** and **13′** by pyrolysis.

In addition, **14** was probably formed from **13′**, in the presence of trace amounts of air, *via* a peroxide mechanism by simple scission on the oxygen-oxygen bond to radicals analogous to that which would occur in peroxide, as is indicated in Scheme I.

Accordingly, the formation of compounds **6**, **7**, and **11** seems reasonable in these instances by combinations of free radical species; this is analogous with the reaction of tribiphenylenepropane, as is illustrated in Scheme II. Likewise, the formation of **12** may be similar to the case of **14**.

Our interpretation is that compound **8** is presumably formed by a combination of dissociation and coupling during the thermal reaction. The free radicals, **4′** and 2,7-dibromo-9-fluorenyl (**11′**), produce by coupling the intermediate, 2′,7′-dibromotribiphenylenepropane,[7] which may then

7) 2′,7′-Dibromotribiphenylenepropane led to 2′,7′,2″,7″-tetrabromotribiphenylenepropane (**8**) and other correlated compounds by pyrolytic reactions (see Ref. 3a).

dissociate into **13′** and 2,7-dibromo-9-fluorenyl-9′-fluorenylidene (**9′**) radicals. Thus, **8** is formed by the reaction of **11′** and **9′** radicals. In addition, **9** may have been formed by a radical reaction of **11′** and **13′**; further, **10** could conceivably result from **9** by a process analogous to that in the case of **3**.

The pyrolysates, **13**, **14**, **4**, and **3**, from **1** or **2**, in order of their retention times, were confirmed by gas-chromatographic analysis. Differential scanning calorimetry was employed to study the thermal behavior of the reactive **1**, **2**, **4**, and **5** on the basis of the pyrolyses described above. These results are illustrated in Fig. 1.

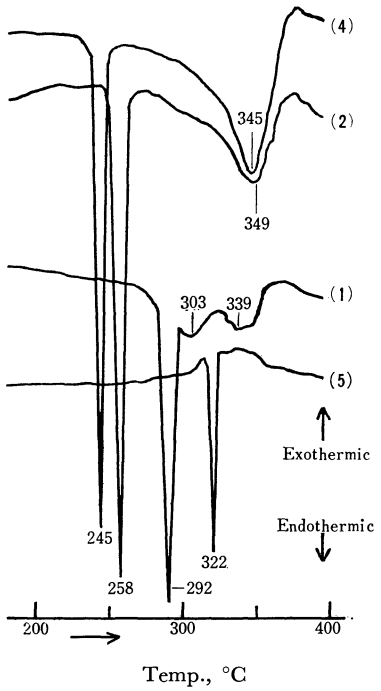

Fig. 1. Differential scanning calorimeter thermograms of **1**, **2**, **4** and **5**.

In the (4) thermogram, **4** (mp 246°C), one of the pyrolysates from **1** or **2**, can be seen to melt at the first endothermic peak (245°C), while the second, broad peak (345°C, dark red) is probably the major constituent due to the slow formation of **3** (red needles) from **4** by dehydrogenation. Moreover, the pyrolysis of **4** is known to form **3**.[2a] In this connection, the application of the DTA method to the pyrolysis of **4** has previously been reported by Lewis and Edstrom,[8] but the curves were not clear.

The two major endothermic peaks for the (2) thermogram are similar to those of **4**; the first peak corresponds to the melting point (red) at about 258°C, but a relatively slow pyrolysis[9] at the melting point was observed, unlike the case with **1**.

8) I. C. Lewis and T. Edstrom, *J. Org. Chem.*, **28**, 2050 (1963).

9) See Table 1, Run 3, for example.

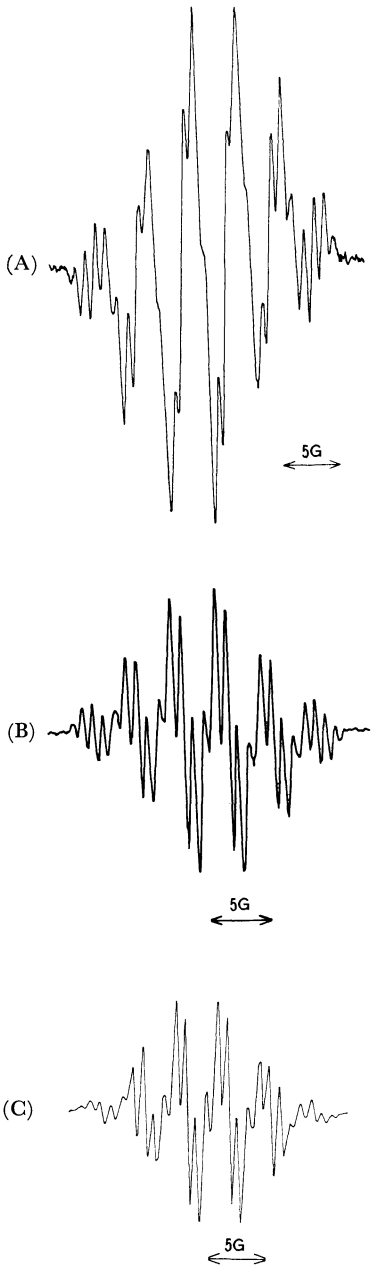

Fig. 2. Experimental spectra generated from the tribiphenylenepropane (**1**).
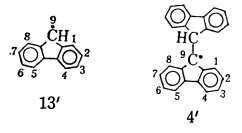
(A): 280°C
(B): 286°C in silicon oil solution
(C): Simulated pattern of **4′** or **13′**; 5H (1, 3, 6, 8 and 9)=3.67 gauss; 4H (2, 4, 5 and 7)=0.82 gauss; line width=0.65 gauss



Subsequently, the slope curves suggest that the melting depression can be attributed to the progressive formation of compounds **3**, **4**, **13**, and **14** with an elevation of the temperature after the melting peaks. In addition, the broader endothermic peak (349°C) suggests that the **4**→**3** transformation is taking place.

In the thermogram of **1**, the slope curves at 200—280°C as the thermolyses increase with an elevation in the temperature. Indeed, the pyrolysis was accompanied by a readily observable red color change in addition to the temperature rise. Thus, the melting peak (292°C) is relatively small compared with that of **2**, although equal weights of the **1** and **2** isomers were used. The results of ESR show that the pyrolyses of tribiphenylenepropane isomers begin at about 200°C. The first, small peak (303°C) after the melting point suggests the formation of **2** from **1** with a consequent pyrolysis of **2** (mp 257°C), as has been described above. Accordingly, the peaks overlap as a result of compensation by exothermic and endothermic peaks. The endothermic peak (339°C) might correspond to the formation of **3** from **4**.

Although the sample weight of **5** used was roughly equal to those of **1** or **2**, the melting peak (322°C) of **5** is comparatively small; **5**, therefore, corresponds to double the molecular weight.

The solid compounds, **1**, **2**, and **4**, were degassed and their ESR spectra were measured in the range from about 200°C to near their melting points. The signals obtained from each sample were very similar. A typical pattern of **1** is shown in Fig. 2. The signal measured in a silicon oil solution is in sharp contrast to that observed in a solid sample. The same results were observed in a squalane solution instead of in the silicon oil.

As is shown by the simulation calculations, these spectra can be explained in terms of the hyperfine interaction with five equivalent protons with a large splitting constant and four equivalent protons with a small splitting constant. These splitting constants may be attributed to the two radicals, **4′** and/or **13′** (see Fig. 2). Previously Dalton and Liebman[10] observed the fluorenyl radical, **13′**, generated from 9-diazofluorene in decalin at 170°C. The ESR spectra observed in the present work are, however, in poor agreement with those observed by Dalton *et al.* Therefore, the radical is conceivably **4′** rather than **13′**.

Experimental

All the melting points are uncorrected.

The gc data were obtained with a JGC-810FP apparatus (Japan Electron Optics Lab. Co., Ltd.), using a column containing 10% Silicone SE-30 on Chromosorb W-AW. During analysis, the column temperature was programmed at 304°C, while the detector and injector temperatures were maintained at 340°C and 400°C respectively. Samples **1** and **2** were used as 2% chloroform solutions.

The infrared spectra were recorded as KBr pellets using a JASCO model IR-G spectrophotometer (Japan Spectroscopic Co., Ltd.).

Differential scanning calorimeter. The instrument used in this investigation was of the Desktop type, 8001-CS (Rigaku Denki Co., Ltd.), was equipped with α-aluminum oxide as a standard sample, and had a sensitivity of ±4 mcal/sec. The experiments were run at atmospheric pressure in air at a heating rate of 10°C per minute. Samples **4** (13.3 mg), **1** (18.1 mg), **2** (18.1 mg), and **5** (18.2 mg) were pyrolyzed in sealed aluminum pans (o.d., 5.0 mm; height, 2.0 mm; thickness, 5/100 mm) with aluminum covers (5/100 mm) which were packed with a sample clipper.

The ESR spectrometer used was an X-band JES-3BSX-type apparatus (Japan Electron Optics Lab. Co., Ltd.) with a 100-KHz-field modulation and a variable-temperature insert dewar.

Pyrolysis of Tribiphenylenepropane (1). Finely-powdered **1** (4.94 g or 0.01 mol) was placed in a 300-m*l* Erlenmeyer flask attached to an air condenser. The flask was then heated in a salt-bath to 305—308°C with shaking for 5 min. After 3—4 min, the reactant was a red melt.

After the content of the flask had resolidified, it was ground to a fine powder; this powder was then extracted with 50 m*l* of boiling cyclohexane. The residual portion (mp 245—270°C) was recrystallized from benzene to give 3.52 g (71%) of **2** (mp 257°C (dec)). Upon the evaporation of the benzene mother liquor to a small volume, 0.53 g (11%) of **1** (mp 292—293°C (dec)) was recovered.

The dilution of the last benzene mother liquor with ethanol afforded a yellow precipitate, which was recrystallized from benzene to give 0.14 g (3%) of **4** (mp 243—244°C). The residue from the evaporation of the benzene-ethanol mother solution to dryness was recrystallized from ethanol to give 0.06 g of **3** (mp 185—186°C).

The concentration of the cyclohexane extract to a small volume afforded 0.35 g of **3** (mp 184—185°C). Then the cyclohexane mother solution was evaporated to dryness and the residue was sublimed *in vacuo* at a bath temperature of 140°C, yielding 0.02 g (0.4%) of **13** (mp 110—112°C) and 0.02 g (0.4%) of **14** (mp 77—79°C), which were separated by column chromatography in benzene on alumina. The unsublimable material was recrystallized from benzene to give 0.13 g (total 0.54 g, 11%) of **3** (mp 183—185°C).

Pyrolyses of Tribiphenylenepropane (1) in the Presence of 2,7,2′,7′,2″,7″-Hexabromotribiphenylenepropane (5). Finely-powdered **1** (3.00 g; 0.006 mol) and 2.90 g (0.003 mol) of **5** were placed in a 300-m*l* Erlenmeyer flask attached to an upright air condenser. When the mixture was heated at 320—330°C for 5 min, it yielded a red pyrolysate after a few minutes.

The powdered product was extracted with 80 m*l* of boiling cyclohexane. The fractional recrystallization of the residue part from 130 m*l* of refluxing benzene yielded 0.06 g of **7** (mp 423—424°C (dec)), 0.05 g of **6** (mp 318—319°C), 0.06 g of **8** (mp 313—314°C (dec)), 0.04 g

Table 1. Reaction products in pyrolyses of tribiphenylenepropanes under different conditions

Run	Substrates		Reaction conditions °C×min	Products, g (%)					Recvd. g (%)
	Compds.	g (mol)		**2**	**4**	**3**	**13**	**14**	
1	**1**	4.94 (0.01)	295—300×3.5	0.94 (18)	0.04 (1)	0.11 (2)	0.01 (0.2)	0.12 (2)	3.58 (73)
2	**1**	4.94 (0.01)	305—308×5	3.52 (71)	0.14 (3)	0.54 (11)	0.02 (0.4)	0.02 (0.4)	0.53 (11)
3	**2**	4.94 (0.01)	265—267×5		0.02 (0.4)	0.02 (0.4)	trace	0.01 (0.2)	4.55 (92)
4	**2**	4.94 (0.01)	280—285×10		0.07 (1)	0.09 (2)	0.0014	0.04 (0.7)	4.45 (90)
5	**2**	4.94 (0.01)	260—290×20		2.33 (47)	0.61 (12)	0.20 (4)	0.28 (5)	1.11 (23)
6	**4**	6.6 (0.02)	Rm. temp.→390 (for 40) 390×5			0.66 (10)	1.90 (29)	0.38 (5)	0.80 (12)

of **9** (mp 265—266°C), and 0.10 g of recovered **5** (mp 318—320°C (dec)). These substances were deposited in the order of their decreasing solubilities by the removal of the benzene.

The cyclohexane extract was concentrated to a small volume. The following orange-red crystalline crops were filtered off: 0.19 g (total 0.25 g) of **8** (mp 313—314°C (dec)), 0.51 g (total 0.55 g) of **9** (mp 267—268°C), 0.08 g of **2** (mp 255—257°C (dec)), (no halogen), 0.24 g of **10** (mp 243—244°C), 1.57 g of **3** (mp 182—185°C), 0.17 g of **12** (mp 201—202°C), and a recovered 0.04 g (total 0.14 g) of **5** (mp 315—317°C (dec)). Fractional recrystallization from ethyl acetate was also employed.

The last cyclohexane mother solution was chromatographed on an alumina column. The eluant was evaporated to dryness, and the residue was fractionaly sublimed to 160°C under reduced pressure; 0.03 g of **13** (mp 108—110°C) and 0.01 g of **11** (mp 158—161°C) were thus separated. Fractions of 0.36 g of **14** (mp 79—80°C), (no halogen) and 0.05 g (total 0.22 g) of **12** (mp 195—197°C) were isolated from the yellow-absorbed band on the alumina column by established methods.

Pyrolyses of Tribiphenylenepropane (2) in the Presence of 2,7,2′,7′,2″,7″-Hexabromotribiphenyleneпropane (5). A mixture of 3.00 g (0.006 mol) of **2** and **5** (2.90 g, 0.003 mol) was pyrolyzed at 330—340°C for 3 min in an atmosphere of nitrogen. The reaction products were then worked up in a manner similar to those employed in the **1** and **5** reactions. Thus 0.13 g of **7** (mp 428°C (dec)), 0.18 g of **8** (mp 312—314°C (dec)), 0.35 g of **6** (mp 316—317°C), 1.28 g of **9** (mp 268—270°C), 0.33 g of **4** (mp 240—241°C), 0.04 g of **10** (mp 238—240°C), 0.03 g of **13** (mp 111°C), 0.33 g of **14** (mp 79—80°C), 0.04 g of **11** (mp 161—163°C), 0.05 g of **12** (mp 199—201°C), and 0.11 g of **3** (mp 180—182°C) were isolated. In addition, 0.08 g of **5** and 0.64 g of **2** were recovered.

All the pyrolysates were known compounds which were identified by a comparison of their melting points, mixed melting points, and infrared absorption spectra with those of authentic samples.

The authors wish to express their gratitude to Drs. John and Elizabeth Weisburger of the National Institutes of Health, U. S. A., for supplying editorial assistance. Thanks are also due to Mr. Koichi Kubo for measurements of the electron spin resonance, Mr. Fumio Funatani of the Japan Electron Optics Lab. Co., Ltd., for his gas chromatographic analyses, and to Mr. Kimio Satoh of the Rigaku Denki Co., Ltd., for his measurements with the differential scanning calorimeter.

This work was supported in part by a grant-in-aid from the Ministry of Education, for which the authors wish to express their appreciation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2223—2229 (1970)

Chemical Constituents of *Alnus firma* (BETULACEAE). I. Phenyl Propane Derivatives Isolated from *Alnus firma*

Yoshinori ASAKAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

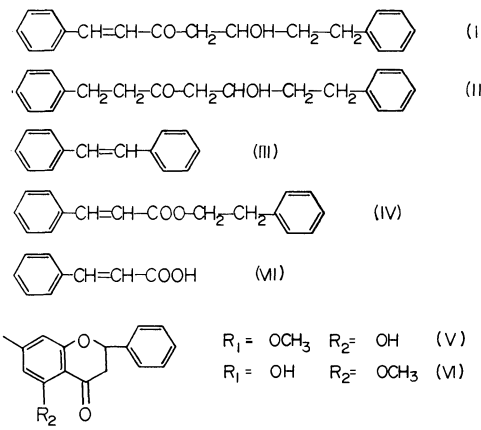
(Received February 2, 1970)

Viscous substances extracted from young shoots of *Alnus firma* were investigated, and two new hydroxyketones, named yashabushiketol (I) and dihydroyashabushiketol (II), *trans*-stilbene (III), β-phenylethyl cinnamate (IV), pinostrobin (V), alpinetin (VI), cinnamic acid (VII), paraffin hydrocarbons (*n*-, anteiso and iso) and triglycerides were identified on the basis of the chemical and spectral data. The biosynthetic pathways of the above aromatic compounds were discussed.

Alnus firma (the Japanese name is Yashabushi), which grown on poor and waste land, is a deciduous plant and a member of the birch-tree family (BETULACEAE). It is known that this plant can be used as an erosion-control plant and that its young shoots (Catkin) and leaves secrete viscous substances, late in February in Japan. No reports on the chemical constituents of *Alnus* genera have yet been presented, though. In the course of the investigation of the benzene extract of the viscous material on the young shoots, two new hydroxyketones, which possess a phenyl propane skeleton, were isolated, together with five related aromatic compounds. The present communication will be concerned with the structure elucidation and the biosynthetic pathways of these seven aromatic compounds, and with the detection of paraffin hydrocarbons and triglycerides.

Results and Discussion

The extraction of the young shoots with benzene gave a dark green, viscous material. After the removal of the acidic and phenolic constituents, the neutral portion was fractionated into three parts by silica-gel chromatography using *n*-hexane, benzene, and ethyl acetate as the eluting agents.



Yashabushiketol (I). 1,7-Diphenyl-5-hydroxy-1-hepten-3-one. Compound (I) was isolated as colorless needles by ethyl acetate extraction from the fractions. This compound (mp 59.5—60.5°C (from *n*-hexane), $[\alpha]_D^{20}$ +29.0°, R_f=0.14 on TLC) gives positive coloration with 2,4-DNP and with alkali-alkyl xanthate. The molecular formula of compound (I) was established as $C_{19}H_{20}O_2$ from a high-resolution mass spectrum. The UV spectrum shows λ_{max}^{EtOH} 217 mμ (log ε, 4.38), 227 (3.90) and 289 (4.18), suggesting the presence of cinnamoyl chromophore (Ar–CH=CH–CO).[1] The IR spectrum shows absorption bands at 1703 cm^{-1} (α,β-unsaturated carbonyl group), 3090, 3050, 1607, 1490, 1447, 752, and 702 cm^{-1} (monosubstituted benzene-ring), 3400 and 1100 cm^{-1} (secondary hydroxyl group), 1410 cm^{-1} (active methylene), and 3025, 1678 and 980 cm^{-1} (*trans* double bond). The NMR spectrum of I contains the following signals: a typical AB-type doublet at 7.61 and 6.71 ppm (J_{AB}=16 Hz, 1H, each) assignable to *trans* ethylenic protons of the cinnamoyl group, two overlapped singlets, at 7.27 and 7.25 ppm, accounted for by two monosubstituted benzene-ring protons (10H), a quintet at 4.07 ppm (J=7 Hz, 1H of –CH–) attributable to the presence of the $-CH_2-CHOH-CH_2-$ grouping, a complex multiplet located between 2.70 and 2.90 ppm (2H, of $-CH_2-$) assignable to the presence of the $-CO-CH_2-CHOH-$ grouping,[2,3] a triplet at 2.60 ppm (J=7 Hz, 2H of Ar–$C\underline{H}_2-$) due to the $Ar-CH_2-CH_2-$ group, a quartet at 1.89 ppm (J=7 Hz, 2H of –CH–$C\underline{H}_2-CH_2-$) due to the $-CHOH-CH_2-CH_2-$ group, and a broad singlet at 3.20 ppm (1H), which disappeared on

1) A. I. Scott, "Interpretation of the Ultraviolet Spectra of Natural Products," Pergamon Press, Oxford (1964), p. 115.

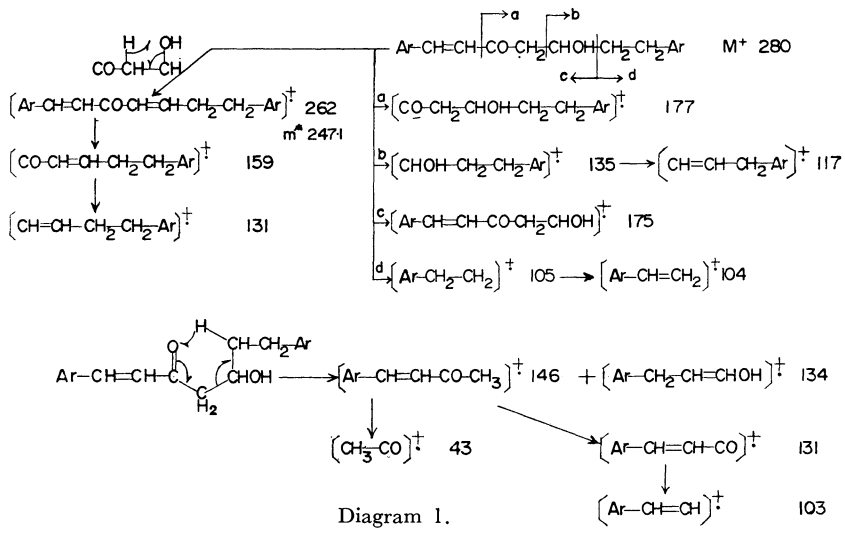


Diagram 1.

equilibration with D_2O, assignable to a hydroxy group. When I in pyridine was treated with acetic anhydride, a yellow, viscous monoacetate was obtained (IR: 1735, 1239 and 1028 cm^{-1}). That a hydroxyl group of I was secondary was proved by the fact that 4.07 ppm (quin. $J=7$ Hz, 1H) was shifted to 5.40 ppm (quin. $J=7$ Hz, 1H) after the acetylation of I.[4] Ketol (I) contains one double bond, as it absorbed one mole equivalent of hydrogen on catalytic hydrogenation over an Adams' catalyst in acetic acid and produced a dihydroderivative, $C_{19}H_{22}O_2$ (M^+ 282), mp 36.0—37.0°C, $R_f=0.25$. The IR spectrum of the dihydroderivative does not exhibit absorption bands at 3025, 1678, 1574, and 980 cm^{-1}, nor could the two doublet signals of the NMR spectrum at 7.61 and 6.71 ppm be seen. From the above chemical and spectral evidence, the following partial structures may be suggested. The ketol (I) contains the molecular

ion at *m/e* 280 ($C_{19}H_{20}O_2$ from the high-resolution mass measurements), the base peak at *m/e* 91 corresponding to a tropyrium ion, and a prominent ion corresponding to M−18 (*m/e* 262), all of which evidence indicates I to be an alcohol. The presence of characteristic ions, *m/e* 39, 51, 65, and 77 indicates I to be a monosubstituted benzene derivative. Other strong ions (*m/e* 177, 175, 159, 146, 134, 117, 105, 104, 103 and 43) in the mass spectrum may be explained as is represented in Diagram 1. The presence of the fragment ions at *m/e* 146, 134, 131, and 103 is understandable, since I, possessing a γ-hydrogen atom for a carbonyl group, undergoes β-cleavage with hydrogen transfer and the product (280→146+134) of β-cleavage is degradated by the loss of a methyl radical (146→131) and of carbon monoxide (131→103) successively. In the mass spectrum of the hydrogenated product of I, the strength of the fragment ions at *m/e* 131 decreased and the fragment of *m/e* 262 disappeared, while *m/e* 133 $(Ar\text{-}CH_2\text{-}CH_2\text{-}CO)^+$ and *m/e* 264 (M—18) newly appeared. On the basis of the above-mentioned chemical and spectral data, the structure of I was determined to be 1,7-diphenyl-5-hydroxy-1-hepten-3-one (I). We proposed the name "yashabushiketol" for this compound in a preliminary report.[5]

Dihydroyashabushiketol (II). 1,7-Diphenyl-5-hydroxy-3-heptanone. The high-resolution mass measurement of the II isolated from the ethyl acetate fraction clearly established its molecular formula as $C_{19}H_{22}O_2$. This compound, (II) (M^+ 282, mp 36.0—37.0°C (colorless needles from *n*-hexane), $R_f=0.25$), gives positive coloration with 2,4-DNP and with alkali-alkyl xanthate, and negative coloration with ferric chloride, ferric hydroxamate, and Tollens' reagent. Compound (II) is shown by its spectral properties to possess a simple ketone group

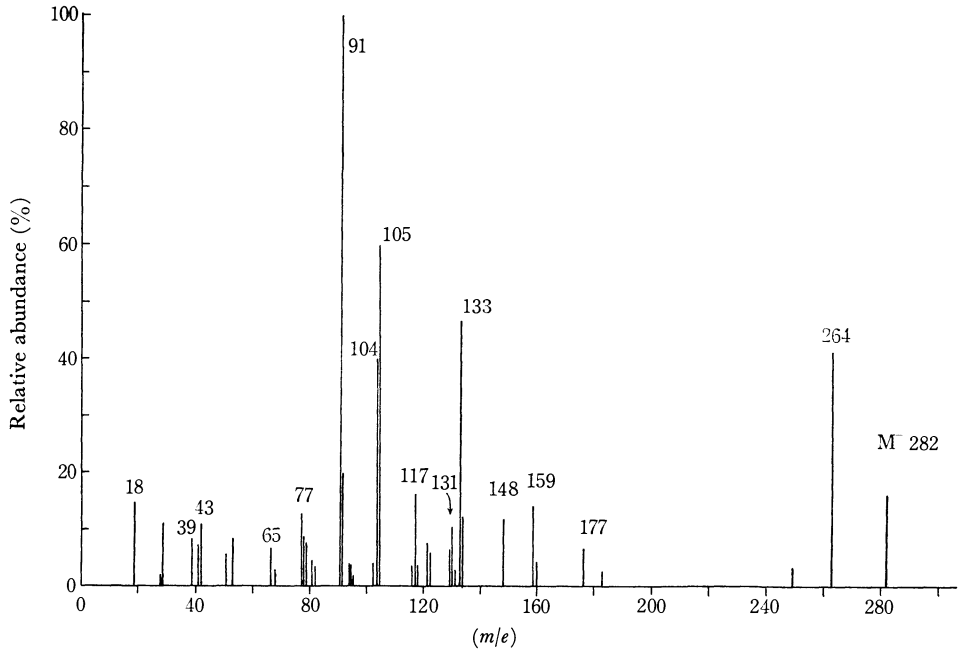

Fig. 1. Mass spectrum of dihydroyashabushiketol (1,7-diphenyl-5-hydroxy-3-heptanone).

(λ_{max}^{EtOH} 285 mμ (log ε, 2.08), ν_{max}^{liq} 1706 cm^{-1}), a mono-substituted benzene-ring (ν_{max}^{liq} 3060, 3020, 1600, 1490, 1450, 745 and 698 cm^{-1}), a non-conjugated benzene-ring (λ_{max}^{EtOH} 248 mμ (log ε, 2.50), 254 (2.53), 261 (2.54) and 268 (2.44)), active methylene (1409 cm^{-1}), and a secondary hydroxyl group (3440 and 1100 cm^{-1}). The NMR spectrum of II in $CDCl_3$ indicates signals at 7.22 ppm (s, 10H, two mono-substituted benzene-ring protons), 4.07 ppm (quin. J=7 Hz, 1H, -CH_2-C<u>H</u>OH-CH_2-), 3.10 ppm (s, 1H, O<u>H</u>), complex signals located between 2.70 and 2.90 ppm (4H, -C<u>H</u>$_2$-CO-C<u>H</u>$_2$-CHOH-), 2.55 ppm (two triplets partially overlapped, J=7 Hz, 4H, two Ar-C<u>H</u>$_2$-CH_2-) and complex multiplets located between 1.55 and 1.85 ppm (2H, -CHOH-C<u>H</u>$_2$-CH_2-). The mass spectrum (Fig. 1) of II is closely analogous to that of yashabushiketol (I). It shows the parent ion at *m/e* 282, and the base peak at *m/e* 91 corresponding to that of a tropyrium ion. An important difference between the fragmentations of these two ketols, (I) and (II), is that II possesses the molecular ion at *m/e* 282 and fragment ions at *m/e* 264 (M−18), *m/e* 148 (Ar-CH_2-CH_2-CO-CH_3)$^+$, and *m/e* 133 (Ar-CH_2-CH_2-CO)$^+$, whereas I has the molecular ion at *m/e* 280 and fragment ions at *m/e* 262 (M−18), *m/e* 146 (Ar-CH=CH-CO-CH_3)$^+$, and *m/e* 131 (Ar-CH=CH-CO)$^+$. As II has only two larger fragments and the molecular ion more than I, judging from a comparison between the mass spectra of two compounds, it seems that ketol (II) is the dihydroderivative of I. Other strong fragment ions also appear at *m/e* 177 (Ar-CH_2-CH_2-CO-CH_2-CH=OH)$^+$, *m/e* 159 (Ar-CH_2-CH_2-CO-CH=CH)$^+$ or (Ar-CH_2-CH_2-CH=CH-CO)$^+$, *m/e* 131 ($C_{10}H_{11}^+$, (Ar-CH_2-CH_2-CH=CH)$^+$ from high-resolution mass measurement), *m/e* 117 (CH=CH-CH_2-Ar)$^+$, and *m/e* 43 (CH_3-CO)$^+$. The peaks at *m/e* 39, 51, 65 and 77 constitute additional evidence for the benzene ring. These results have shown the structure of this ketol to be 1,7-diphenyl-5-hydroxy-3-heptanone (II). Furthermore, this structure was confirmed by the fact that the TLC R_f value, the mp, and the IR spectrum of II were all completely identical with those of the hydrogenated product of yashabushiketol (I). We proposed the name "dihydroyashabushiketol" for this compound in a previous communication to this bulletin.[6]

***trans*-Stilbene (III).** Colorless leaflet crystals, M$^+$ 180, mp 120.0—121.0°C, R_f=0.75, were isolated from the *n*-hexane extract. The melting point, R_f value, UV, IR, and NMR spectra of this isolated compound (III) were the same as the authentic *trans*-stilbene. There has been no report concerning the natural occurrence of *trans*-stilbene, except that Kacheler (1869) suggested the existence of stilbene on the basis of its melting point in Perubalsam oil.[7]

β-Phenylethyl Cinnamate (IV). Colorless needles (M$^+$ 252, mp 56.0—57.0°C, R_f=0.50, positive coloration with ferric hydroxamate) were isolated in a pure state (one peak, NGS 10%, 212°C) from the benzene-eluted fraction of the extract. The alkaline hydrolysis of the isolated crystals (IV) gave cinnamic acid and β-phenylethyl alcohol. The

6) Y. Asakawa, This Bulletin, **43**, 575 (1969).

7) E. Gildmeister, "Die Ätherischen Öle," Academie-Verlag, Berlin (1960), p. 413.

UV, IR and NMR spectra, the mp, the R_f value and the GLC Rt of this compound (IV) were all completely identical with those of the authentic β-phenylethyl cinnamate. It was clarified that the essential constituent with a pleasant smell in the yound shoot of *A. firma* is β-phenylethyl cinnamate, and that this compound gives rise to the viscosity of the young shoots. The only report regarding the finding of β-phenylethyl cinnamate from *Populus balsamifera* has been made by Goris and Canal.[8]

Pinostrobin (5-Hydroxy-7-methoxy-flavanone) (V). Compound (V) was isolated from the benzene-eluted fraction as colorless leaflet crystals (M^+ 270, mp 99.0—100.0°C, R_f=0.48, positive coloration with ferric chloride and with magnesium-hydrochloric acid). The mass spectrum of V is closely analogous to that of 5,7-dihydroxy flavanone.[9] When V in pyridine was treated with acetic anhydride, it gave a mono-acetate. On methylation with dimethyl sulfate, V gave pinostrobin methyl ether. The UV, IR, and NMR spectral data and the mp of the isolated original compound agreed well with those of the pinostrobin which was isolated from *Kaempferria pandurata* (ZINGIBERACEAE).[10] It is well known that pinostrobin is widely distributed in Pinaceae.[11-14]

Alipinetin (5-Methoxy-7-hydroxy-flavanone) (VI). The extensive chromatography of the phenolic portion afforded a flavanone as white needles (M^+ 270, mp 224.5—225.5°C, R_f=0.65 (benzene-methanol-acetic acid 5 : 1 : 1 vol%), negative coloration with ferric chloride and with magnesium-hydrochloric acid). The NMR spectrum of VI in trifluoroacetic acid indicates signals quite similar to those of pinostrobin. The effect upon the mass spectrum of VI is also closely analogous to that of pinostrobin and 5,7-dimethoxyflavanone. When VI was methylated, it gave pinostrobin methyl ether as fine needles. The UV and IR spectra and the mp of the isolated flavanone (VI) showed good agreement with those of alpinetin.[10]

Mongkolsuk and Dean[10] found that pinostrobin and alpinetin both occurred in *Kaempferria pandurata* (ZINGIBERACEAE) and considered that flavanoids possessing a 5-methoxy group are unusual in plants. There is no record of the coexistence of pinostrobin and alpinetin in Dicotyledoneae.

Cinnamic Acid (VII). A large quantity of colorless needles (mp 134.0—134.5°C) was isolated from the acidic portion of the extract regenerated from the sodium bicarbonate solution. The acidic compound (VII) was converted to methyl cinnamate with diazomethane. The IR and NMR spectra and the mp of the isolated acid (VII) were all completely identical with those of the authentic cinnamic acid.

In addition to the above compounds, paraffin hydrocarbons (*n*-paraffins: *n*-C_{21}—*n*-C_{33}, main component, *n*-C_{27}; anteiso: C_{22}, C_{24} and C_{26}; iso: C_{21}, C_{23} and C_{25}) and triglycerides (acid portions: saturated fatty acids, C_{16}, C_{18}, C_{20}, C_{21}, C_{22}, C_{23} and C_{24}) were tentatively identified by a comparison of the retention time with those of authentic specimens of *n*-paraffins (SE-30 2.5%, 180—300°C and 200°C) and of fatty acid methyl esters (DEGS 10%, 187°C), and by the linear relationship between the logarithm of the retention time and the number of the carbon atom of the paraffins and the fatty acid methyl esters respectively.

Biosynthetic Pathways of the Aromatic Compounds Isolated from *A. firma*. Many natural phenyl-propane derivatives have been found in organisms, and it is now recognized that the fundamental skeleton of phenyl-propane derivatives arises from phenylalanine and its congeners derived from shikimic acid and prephenic acid (these are the key compounds in this series). Birch[15] and Underhill[16] suggested that the skeletons of flavanoids and stilbenes arise from a cinnamic acid unit and three acetate units, and they assumed that, in the biosynthesis of pinosylvin (VIII), one molecule of cinnamic acid condenses with three molecules of acetic acid to give the intermediate (IX), which is then cyclized to pinosylvin carboxylic acid (X) and finally decarboxylated to give pinosylvin (VIII), as is shown in Diagram 2. This hypothesis possesses the further merit that it explains the isolation of two stilbene carboxylic acids (hydrangenic acid (XI) and phyllodulcic acid (XII)) and the coexistence of flavanoids (*e.g.*, pinocembrin (XIII) and its methyl ethers) and stilbenes (*e.g.*, pinosylvin (VIII) and its methyl ethers) in the heartwood of many pines[11] and in the buds of some species of Eucalyptus,[17] and from some of these sources cinnamic acid has been isolated. This hypothesis has been confirmed by the investigation of the biosynthesis of pinosylvin and hydrangenic acid using radioactive acetate and glucose.[18,19] Thus, it

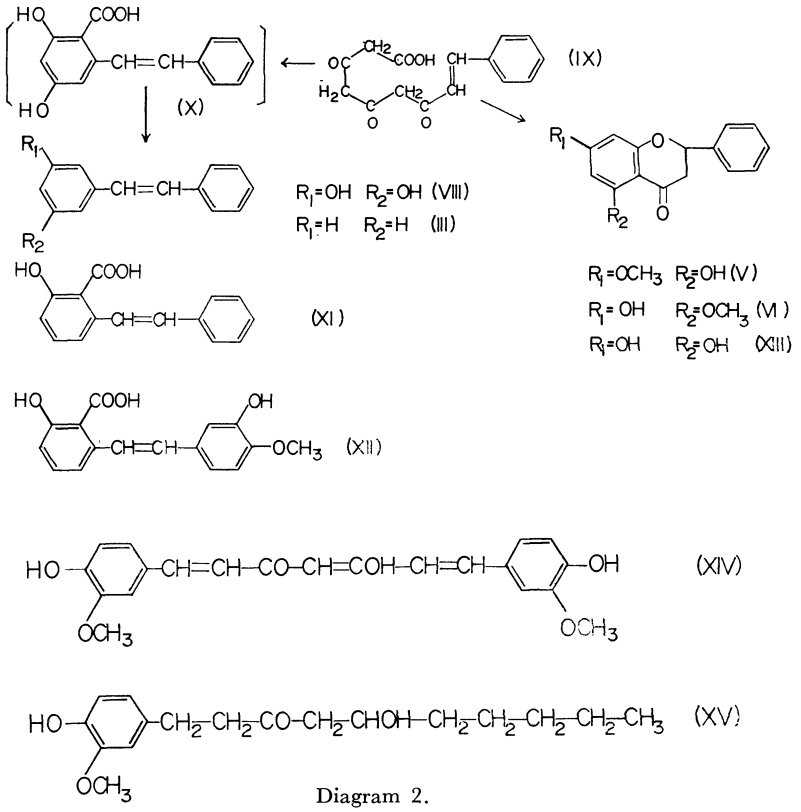

Diagram 2.

can be deduced that the *trans*-stilbene (III), *β*-phenylethyl cinnamate (IV), pinostrobin (V), and alpinetin (VI) isolated from *A. firma* result from a combination of acetic acid and shikimic acid pathways. It is noteworthy that free cinnamic acid is isolated together with pinostrobin, alpinetin, and *trans*-stilbene in this work.

There are many other natural products which also result from the condensation of cinnamic acid and acetic acid units. Thus, yashabushiketol (I) and dihydroyashabushiketol (II) are formed by the candensation of two molecules of cinnamic acid and a molecule of acetic acid. Ketol (I) and ketol (II) possess the same skeleton as the curcumin (XIV) isolated from *Curcuma longa* (ZINGIBERACEAE)[20] and are partially similar to the structure of gingeron (XV) found in *Zingiber officinalis* (ZINGIBERACEAE).[21] Recently, pinostrobin and alpinetin have been isolated from *Kaempferria pandurata* (ZINGIBERACEAE).[10] It is very interesting, from the viewpoint of biosynthesis, that the constituents isolated from *A. firma* (BETULACEAE) are closely analogous to those of ZINGIBERACEAE.

Details regarding the constituents of the cone of *A. firma* and *Alnus multinervis* (Himeyashabushi in Japan) will be reported in a later publication.

Experimental

All the melting points described are uncorrected. The IR spectra were recorded on a Perkin-Elmer model 621 grating Infrared Spectrophotometer in liquid film, in chloroform, in Nujol paste, or as KBr tablets. The NMR spectra were measured on a Varian Asssociates A-60 or Hitachi Perkin-Elmer model R-20 Spectrometer, operating at 60 MHz, and were examined in a 5—10% solution of deuterochloroform, using tetramethylsilane as the internal standard, unless otherwise indicated. The following abbreviations are used for the representation of the NMR data: s=singlet, d=doublet, t=triplet, q=quartet, bs=broad singlet, quin.=quintet, and m=multiplet. The UV spectra were measured on a Shimadzu Recording Spectrophotometer, SV 50 A type, in a 95% ethanol solution. The mass spectra were recorded on a JEOL JMS-01SG Mass Spectrometer under the following conditions: ion accel. volt, 7 kV; ionizing energy, 75 eV; ionizing current, 200 μA; vacuum, 1×10^{-7} Torr; sample temp., 110°C; chamber temp., 250°C; direct sample-introduction system with a vacuum lock. The high-resolution mass spectra were measured on a JEOL JMS-01SP high-resolution mass spectrometer under the following conditions: ionizing energy, 75 eV; direct inlet system; sample temp., 120°C; reference substance, perfluorokerocene. The gas chromatograms were measured on a Hitachi Perkin-Elmer F6-D type Gas chromatograph equipped with a flame-ionization detector. Stainless-steel columns (2 m×2 mm)

coated with SE-30 2.5%, PEG 6000 10%, NGS 10% and DEGS 10% on Diasolid L (60—80 mesh) were used. Thin-layer chromatography was carried out with Silica gel G (Merck) under the following conditions: solvent system, benzene - ethyl acetate 19 : 1 vol% unless otherwise stated; chromogenic agent, iodine vapor or mixed acid (conc. H_2SO_4: conc. HNO_3 19 : 1 vol%); developing distance, 15 cm.

Extraction and Isolation Procedure. Ninety-four kg of young shoots of *A. firma* grown in Hiroshima were collected in February and were extracted with redistilled benzene for three weeks. The evaporation of the solvent gave 5 kg of a dark-green-colored slurry. The extract (18.5 g), after the acidic and phenolic constituents has been removed by treatment with 5% sodium bicarbonate and 5% sodium hydroxide solutions, was fractionated into three portions by silica-gel chromatography using *n*-hexane, benzene, and ethyl acetate as eluting agents successively. The extract (4 g) by *n*-hexane was further chromatographed over silica gel using *n*-hexane. Likewise, the extract (7 g) by benzene and the extract (4 g) by ethyl acetate were each further chromatographed using the same solvent as before. The acidic portion (4 g) regenerated from the sodium bicarbonate solution by 5% hydrochloric acid was purified through a silica-gel column using ethyl acetate. The phenolic portion (14 g) regenerated from the sodium hydroxide solution by 5% hydrochloric acid was also chromatographed on silica gel using chloroform - acetone (19 : 1).

Yashabushiketol (I) (1,7-Diphenyl-5-hydroxy-1-hepten-3-one). From the ethyl acetate fraction, a ketol was isolated as colorless needles (150 mg); mp 59.5—60.5°C (from *n*-hexane), $[\alpha]_D^{20}$ +29.0° (*c*, 1.05 in $CHCl_3$), R_f=0.14 (benzene - ethyl acetate 19 : 1 vol%) and R_f=0.52 (the same solvent 3 : 2). This compound was identified as 1,7-diphenyl-5-hydroxy-1-hepten-3-one from the chemical and spectral evidence as has been mentioned in the "Results and Discussion" section.

Catalytic Hydrogenation of Yashabushiketol (I). Yashabushiketol (37 mg) was added to a prereduced PtO_2 catalyst (20 mg) in glacial acetic acid (1.5 m*l*). The solution was then stirred at room temperature, whereupon it absorbed one mole equivalent of hydrogen in 2 hr. The catalyst was removed by filtration, and the filtrate was evaporated *in vacuo* to take off the solvent. The resulting oily yellow substance was chromatographed on a silica-gel column using ethyl acetate to give white needles (25 mg); mp 36.0—37.0°C (after crystallization from *n*-hexane), R_f=0.25 (benzene - ethyl acetate 19 : 1). Its IR and NMR spectra agreed with those of dihydroyashabushiketol, to be discussed below.

Acetylation of Yashabushiketol (I). A solution of 20 mg of yashabushiketol in 2 m*l* of anhydrous pyridine was treated with acetic anhydride and then allowed to stand overnight. The mixture was then decomposed with ice water, and the solvent was removed *in vacuo*. The product was chromatographed on a silica-gel column using ethyl acetate to give a yellow oil (12 mg). R_f=0.5; IR spectrum; ν_{max}^{liq} 3080, 3060, 3027, 2930, 1930, 1860, 1790, 1735, 1659, 1625, 1569, 1495, 1455, 1373, 1331, 1239, 1028, 969, 748 and 749 cm^{-1}, NMR spectrum; $\delta_{ppm}^{CDCl_3}$ 5.40 (quin. J=7 Hz, 1H, $-CH_2-\underline{C}HOAc-CH_2-$), 2.04 (s, 3H, $C\underline{H}_3CO-$).

Dihydroyashabushiketol (II) (1,7-Diphenyl-5-hydroxy-3-heptanone). The repeated chromatography of the substance from ethyl acetate fractions gave colorless needles (80 mg) (mp 36.0—37.0°C (after crystallization from *n*-hexane), R_f=0.25) which were identified as 1,7-diphenyl-5-hydroxy-3-heptanone on the basis of the results of chemical and spectrometric treatment. Found: C, 83.80; H, 7.68%. Calcd for $C_{19}H_{22}O_2$: C, 83.69; H, 7.80%.

***trans*-Stilbene (III).** The crude *trans*-stilbene obtained from the *n*-hexane extract was recrystallized from ether to yield colorless leaflet crystals (20 mg); mp 120.0—121.0°C (lit,[7] 120.7°C), R_f=0.75, IR spectrum; ν_{max}^{EtOH} 3016, 1590, 1491, 1451, 755 and 690 cm^{-1} (monosubstituted benzene-ring), 959 (*trans* double bond); UV spectrum: λ_{max}^{EtOH} 228.5 mμ (log ε, 4.22), 236 (4.03), 295 (4.46), 307 (4.42) and 320 (4.23), NMR spectrum: $\delta_{ppm}^{CDCl_3}$ 7.41 (symm. m, 10H, two monosubstituted benzene-ring protons) and 7.18 (s, 2H, *trans* ethylenic protons), mass spectrum; M^+ 180 (base peak), *m/e* 179, 178, 165 (M−15, m^*=151.2), 152, 91, 89, 77, 63, 51 and 39. These data agreed with those of the authentic *trans*-stilbene. The mp was not depressed on admixture with an authentic sample.

β-Phenylethyl Cinnamate (IV). From the substance of the benzene extract, a colorless, viscous oil was obtained. This oil was then chromatographed on silica gel, using benzene, to give white crystals; repeated crystallization from *n*-hexane yielded colorless needles (1.067 g). Mp 56.5—57.0°C, R_f=0.50, UV spectrum; λ_{max}^{EtOH} 216.5 (log ε, 4.29), 223 (4.13), and 277 (4.34), IR spectrum; ν_{max}^{Nujol} 3060, 3010, 1575, 1500, 1470, 760, 695 (monosubstituted benzene-ring), 1710, 1285, 1170 (α,β-unsaturated ester), 1640, 980 (*trans* double bond), 1330, 1315, 1210, 1070, 900, 865, 750, 730 and 680 cm^{-1}, NMR spectrum; $\delta_{ppm}^{CDCl_3}$ 7.43 (bs, 5H monosubstitued benzene-ring protons), 7.30 (s, 5H, monosubstituted benzene-ring protons), 7.71 (d, J=16.2 Hz, 1H, Ar–C$\underline{H}$=CH–), 6.41 (d, J=16.2 Hz, 1H, –CH=C$\underline{H}$–CO–), 4.45 (t, J=7 Hz, 2H, O–C$\underline{H}_2$–CH_2–Ar), and 3.03 (t, J=7 Hz, 2H, $-CH_2-C\underline{H}_2$–Ar), mass spectrum; M^+ 252, *m/e* 104 (base peak, Ar–CH=CH_2)$^+$, 148, 147, 131 (Ar–CH=CH–CO)$^+$, 105 (Ar–CH_2–CH_2)$^+$, 103 (Ar–CH=CH)$^+$, 91 (C_7H_7)$^+$, 77, 65, 51 and 39, GLC Rt: 36.2 min. (NGS 10%, 212°C). All these data were completely identical with those of authentic β-phenylethyl cinnamate.

Alkaline Hydrolysis of β-Phenylethyl Cinnamate (IV). A solution of β-phenylethyl cinnamate (80 mg) in methanol was hydrolyzed with an alcoholic potassium hydroxide (about 1N). Colorless oil (10 mg) was obtained from the ether extract of the reaction mixture. The IR and GLC Rt were identical with those of authentic β-phenylethyl alcohol. White crystals (30 mg) were obtained by acidifing the potassium salt of the saponified substance with dilute hydrochloric acid. The IR and NMR spectra and the mp (134.0—135.0°C) showed the crystalline substance to be cinnamic acid.

Pinostrobin (5-Hydroxy-7-methoxyflavanone) (V). From the substance of the benzene extract, pale yellow crystals (100 mg) were obtained. Crystallization from *n*-hexane afforded colorless plates; mp 99.0—100.0°C (pinostrobin, 100°C,[10] 112—113°C[11] and 90—91°C[12]), R_f=0.48. The compound showed positive coloration with ferric chloride and with magnesium - hydrochloric acid. UV spectrum; λ_{max}^{EtOH} 215 mμ (log ε, 4.38), 228.5 (4.20), 290 (4.22) and 330 (3.50), IR spectrum: ν_{max}^{KBr} 3032, 2964, 2916, 2834, 1633, 1570, 1464, 1444, 1381, 1353, 1342, 1295, 1256, 1208, 1199,

1155, 1090, 1060, 992, 941, 890, 834, 794, 765 and 745 cm^{-1}, NMR spectrum: $\delta_{ppm}^{CDCl_3}$ 12.06 (s, 1H), 7.47 (s, 5H), 6.11 (s, 2H), 5.44 (q, J_{AX}=11 Hz, J_{BX}=5 Hz, 1H), 3.81(s, 3H), 2.99 (d, J_{AX}=11 Hz, 1H) and 2.91 (d, J_{BX}=5 Hz, 1H), mass spectrum; M^+ 270 (base peak), *m/e* 269, 193, 167, 166, 159, 138, 123, 114, 110, 104, 103, 95, 91, 78, 77, 69, 51 and 39.

Pinostrobin Monoacetate. Pale yellow crystals (15 mg), mp 142.0—144.0°C, were prepared by treating a solution of 29 mg of pinostrobin in 1 m*l* of anhydrous pyridine with 3 m*l* of acetic anhydride. R_f=0.55, IR spectrum; ν_{max}^{Nujol} 1740, 1255, 1050 (acetate band), 1655, 1600, 1550, 1430, 1325, 1310, 1260, 1240, 1190, 1145, 1020, 890, 865, 835, 760 and 695 cm^{-1}.

Methylation of Pinostrobin (V). A mixture of pinostrobin (30 mg), dimethyl sulfate (5 m*l*), pottasium carbonate (150 mg), and dry acetone (10 m*l*) was refluxed on a water bath for 48 hr to give pinostrobin methyl ether as white needles. Mp 142.0—143.0°C (pinostrobin methyl ether, 144°C[10]), R_f=0.58, IR spectrum; $\nu_{max}^{CHCl_3}$ 3025, 2955, 2950, 1979, 1895, 1670, 1600, 1570, 1460, 1430, 1370, 1340, 1320, 1270, 1209, 1180, 1110, 1070, 1040, 1030, 965, 940, 890, 860, 820, 800, 700 and 660 cm^{-1}.

Alpinetin (5-Methoxy-7-hydroxyflavanone) (VI). The phenolic portion (14 g) of the extract regenerated from the sodium hydroxide solution by hydrochloric acid was fractionated through a silica-gel column with chloroform-acetone (19 : 1 vol%); a small quantity of white crystals was thus obtained. Recrystallization from methanol gave white needles (30 mg) which showed the following properties: mp 224.5—225.0°C (alpinetin, 220°C[10] 223°C[22]), R_f=0.65 (benzene - methanol - acetic acid 5 : 1 : 1). Ferric chloride and magnesium - hydrochloric acid tests were negative. UV spectrum; λ_{max}^{EtOH} 231 (log ε, 4.08), 237 (3.98), 285 (4.21) and 310 (3.75), $\lambda_{max}^{EtOH+NaOAc}$ 230 mμ (log ε, 4.06), 237 (3.87), 252.5 (3.57), 287 (4.04) and 323 (4.15), IR spectrum; ν_{max}^{KBr} 3520, 3300, 3030, 2935, 1633, 1611, 1575, 1479, 1458, 1435, 1358, 1302, 1276, 1249, 1206, 1176, 1101, 1068, 1056, 980, 833 and 766 cm^{-1}, NMR spectrum; $\delta_{ppm}^{CF_3COOH}$ 7.51 (s, 5H), 6.47 (s, 2H), 5.71 (q, J_{AX}=11Hz, J_{BX}=6 Hz, 1H), 4.30 (s, 3H), 3.49 (d, J_{AX}=11 Hz, 1H) and 3.40 (d, J_{BX}=6 Hz, 1H), mass spectrum; M^+ 270, *m/e* 166 (base peak), 193, 167, 138, 123, 114, 104, 103, 95, 78, 77, 69, 51, 39, 18 and 17.

Methylation of Alpinetin (VI). By the same method as in methylation of pinostrobin, pinostrobin methyl ether was obtained as white crystals (14 mg). Mp 144.0—145.0°C (lit,[10] 144°C), R_f=0.58. Its IR spectrum agreed with that of pinostrobin methyl ether.

Cinnamic Acid (VII). The acidic portion (4 g) of the extract regenerated from the sodium bicarbonate solution by dilute hydrochloric acid was purified through silica-gel chromatography to give white needles (1.5 g); mp 134.0—134.5°C (from ether). The IR and NMR spectra were completely identical with those of an authentic specimen.

Paraffin Hydrocarbon. The fractions eluted with *n*-hexane yielded paraffin hydrocarbons (0.8 g). Mp 51.0—54.0°C, R_f=0.78, IR spectrum; $\nu_{max}^{CHCl_3}$ 2990, 2950, 1475, 1385, 1190, 1160, 740 and 735 cm^{-1}. *n*-Paraffins (C_{21}—C_{33}), anteiso paraffins (C_{22}, C_{24} and C_{26}) and iso paraffins (C_{21}, C_{23} and C_{25}) were tentatively identified by a comparison with the retention times of the authentic *n*-paraffins.

Triglyceride. A white crystalline mass (1.76 g) was obtained from the *n*-hexane extract. When it was recrystallized from chloroform, white crystals were obtained. Mp 76.0—77.0°C, R_f=0.6, IR spectrum; ν_{max}^{KBr} 2960, 2930, 2850, 1740, 1465, 1420, 1378, 1210, 1190, 1180, 920, 725 and 718 cm^{-1}, NMR spectrum; $\delta_{max}^{CDCl_3}$ 4.08 (m), 2.25 (m), 1.28 (s) and 0.90 (m). The alkaline hydrolysis (5% NaOH-methanol) of this mass (1.0 g) gave fatty acid mixtures (saturated, C_{16}, C_{18}, H_{20}, C_{21}, C_{22}, C_{23}, C_{24} and C_{25}) which were confirmed as methyl esters by gas chromatography (DEGS 10%, 187°C).

The author wish to express his hearty gratitude to Professor Tamon Matsuura, Professor Shuichi Hayashi and Assistant Professor Takayuki Suga of Hiroshima University for their guidance and encouragement. The author is also indebted to Mr. Fumihide Genjida for his help in this investigation. Grateful acknowledgement is also made to Professor Shô Itô of Tohoku University and Dr. Hiroshi Ishii of Shionogi Research Laboratory, Shionogi & Co., Ltd. for the measurement of NMR spectra. The author also thanks for Japan Electron Optics Co., Ltd., for high-resolution mass spectral determination.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2230—2233 (1970)

The Resolution and Rotations of *trans*-2-Aminocyclohexanecarboxylic Acids and Derivatives

Hiroyuki NOHIRA, Kenji EHARA and Akira MIYASHITA

Department of Applied Chemistry, Faculty of Science and Engineering, Saitama University, Urawa, Japan

(Received February 4, 1970)

Optically active *trans*-2-aminocyclohexanecarboxylic acids [(+)-**1** and (−)-**1**] have been prepared by a preferential crystallization of racemic *N*-benzoyl *trans*-2-aminocyclohexanecarboxylic acid [(±)-**2**]. Active **2** have been used for preparation of such active *trans*-1,2-disubstituted cyclohexanes as (+)-, and (−)-ethyl *trans*-2-aminocyclohexanecarboxylate [(+)-**3** and (−)-**3**], (+)-, and (−)-*trans*-2-aminocyclohexanemethanol [(+)-**4** and (−)-**4**], (+)-*trans*-2-bromomethylcyclohexylamine hydrobromide [(+)-**5**], and (+)- *trans*-2-methylcyclohexylamine [(+)-**6**]. Amine-nitrous acid reaction of these cyclohexylamines to give the corresponding hydroxy compounds (**7**, **8**, **9**) has also been examined. It was confirmed that the signs of optical rotations of these hydroxy compounds are the same as those of the starting amines. It has been shown that observed molecular rotations of these active 1,2-disubstituted cyclohexanes are in agreement, in sign and order of magnitude, with those calculated following Brewster's procedures presented in 1959 and in 1967.

In 1959, Brewster[1] presented a useful model for the calculation of optical rotations which has been applied to various types of optically active organic compounds.[2] Recently a more theoretical treatment has been proposed by the same author.[3] In this treatment the calculation is relatively simple in the case of 1,2-disubstituted cyclohexane systems. In this connection, Pascual[4] has reported that the observed rotation of optically active 2-hydroxycyclohexanecarboxylic acids was in good agreement with that calculated by Brewster's earlier procedure.

We also became interested in correlations between observed and calculated rotations for 2-aminocyclohexanecarboxylic acids (**1**) and their derivatives, especially rotations calculated by the procedure proposed recently. Although the racemic isomers of *cis*- and *trans*-2-aminocyclohexanecarboxylic acid are known,[5,6] there has been no investigation of their resolution.

In the present investigation, resolution of *trans*-2-aminocyclohexanecarboxylic acid [(±)-**1**] has been first realized by fractional crystallization of diastereoisomeric salts of *N*-benzoyl *trans*-2-aminocyclohexanecarboxylic acid [(±)-**2**] and an active amine, such as quinine or ephedrine. Preferential crystallization initiated by inoculation has now been found to be more convenient. When a saturated solution of (±)-**2** is carefully inoculated with a pure crystal of one of the enantiomers obtained by fractional crystallization of the diastereoisomeric salts, the crystal grows and an appreciable amount of pure crystals are separated from the racemic solution. The resulting filtrate is then saturated with addition of the racemate, and inoculation with the antipode gives another good crop of active crystals. The process can be repeated, and the optically active acids [(+)-**2** and (−)-**2**] have been prepared in large quantities.

Various optically active 1,2-disubstituted cyclohexanes have been prepared from active **2**. For example, hydrolysis of active **2** with concentrated hydrochloric acid, and then esterification with ethanol gave the active esters [(+)-**3** and (−)-**3**]. The active free amino acids [(+)-**1** and (−)-**1**] have been prepared by hydrolysis of active **3**.

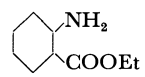
2



3

Active *trans*-2-aminocyclohexanemethanols [(+)-**4** and (−)-**4**], *trans*-2-bromomethylcyclohexylamine [(+)-**5**], and *trans*-2-methylcyclohexylamine [(+)-**6**] have been prepared by the following reaction sequence.

1) J. H. Brewster, *J. Amer. Chem. Soc.*, **81**, 5475, 5483, 5493 (1959).

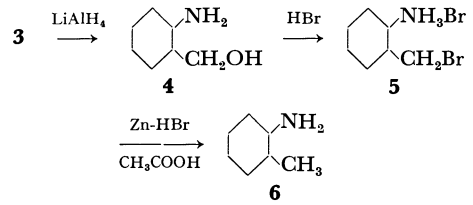
2) E. L. Eliel, "Stereochemistry of Carbon Compounds," MaGraw-Hill Book Co., Inc., New York, N. Y. (1962), p. 401.

3) J. H. Brewster, "Helix Models of Optical Activity" in "Topics in Stereochemistry," Vol. II, ed. by N. L. Allinger and E. L. Eliel, Interscience Publishers, Inc., New York, N. Y. (1967), pp. 1—72.

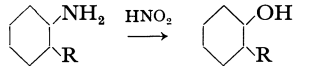
4) J. Pascual, *An. Real. Soc. Espan. Fis. Quim. Ser. B*, **63**, 727 (1967).

5) S. Hünig and H. Kahanek, *Chem. Ber.*, **86**, 518 (1953).

6) E. J. Moriconi and P. H. Mazzocchi, *J. Org. Chem.*, **31**, 1372 (1966).



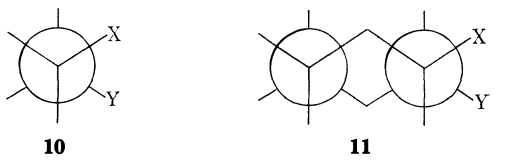
Treatment of these amines with nitrous acid gave the corresponding hydroxy derivatives:



7, R=COOH
8, R=COOEt
9, R=CH_2OH

The stereochemistry of the amine-nitrous acid reaction in cyclohexane systems has been investigated extensively. It has been shown that equatorial amines react with nitrous acid to give mainly equatorial alcohols without any alteration of configuration.[7]

In the present investigation, it was also confirmed that the signs of observed optical rotations of the hydroxy compounds obtained by the amine-nitrous acid reaction are the same as those of the starting amines. The absolute configutarion of (−)-**7** has been determined by Faixat *et al.*,[8] and the result is consistent with Brewster's model. In view of this, we might conclude that (+)-**1** and (−)-**1** have absolute configurations of 1(S), 2(S) and 1(R), 2(R), respectively.



10 **11**

Fig. 1. Dextrorotatory conformations of 1,2-disubstituted ethane and cyclohexane.

Calculation of molecular rotations $[M]_D$ of these 1,2-*trans*-disubstituted cyclohexanes was performed using Brewster's theory. According to his theory, a right-handed helical chain as X–C–C–Y in Fig. 1 makes a dextrorotatory contribution to $[M]_D$. From a summation of these conformational units, a skewed conformation of 1,2-disubstituted ethane (**10**) and 1,2-diequatorially substituted cyclohexane (**11**) give the same $[M]_D$ value. In the present calculation, it has been assumed that these 1,2-*trans*-disubstituted cyclohexanes exist in the diequatorial conformation as shown in **11**.

Table 1 shows the calculated $[M]_D$ of several 1,2-*trans*-disubstituted cyclohexanes along with observed $[M]_D$. The procedures A and B are so-called semi-

empirical.[1,2] Procedure C is a more exact theoretical treatment based on physical laws which govern the interaction between a helical conductor and electro-magnetic waves.[3]

It is worth noting that in this experiment our observed results of $[M]_D$ are in rough agreement with the results obtained by following Brewster's treatment, in which such a drastic model is assumed for molecular asymmetry as to consider a skewed chain of four atoms as a helical conductor.

Experimental

(±)-*N*-Benzoyl-*trans*-2-aminocyclohexanecarboxylic Acid [(±)-2]. (±)-*trans*-2-Aminocyclohexanecarboxylic acid [(±)-**1**] was prepared from anthranilic acid by the action of metallic sodium in isoamyl alcohol.[5,9] (±)-**2** was prepared by the reaction of (±)-**1** and benzoyl chloride in the usual way.

(−)-*N*-Benzoyl-*trans*-2-aminocyclohexanecarboxylic Acid [(−)-2]. To a mixture of 3.71 g (0.015 mol) of (±)-**2** and 5.18 g (0.016 mol) of quinine was added 130 m*l* of 70% methanol (methanol 70 and water 30 in volume). The mixture was briefly heated on a steam bath to dissolve all solid, then allowed to stand at room temperature. After 10 hr, the resulting fluffy needles were collected by filtration to give 6.0—6.5 g of salt, mp 125—130°C. Two or three recrystallizations of this material using 13—15 m*l* of 70% methanol per gram of salt gave 1.2—1.8 g of material whose properties did not change upon further recrystallization, mp 143—145°C, $[\alpha]_D^{20}$ −111.6° (*c* 2.5, ethanol).

With 3N hydrochloric acid the salt was converted into crude (−)-**2**, which was purified by recrystallization from 70% methanol to give 0.22—0.37 g (12—20%) of (−)-**2**, mp 257—258°C (in a capillary tube), subliming at near 240°C on an open plate, $[\alpha]_D^{20}$ −44.5° (*c* 0.67, ethanol).

Found: C, 68.26; H, 7.11; N, 5.71%. Calcd for $C_{14}H_{17}NO_3$: C, 67.99; H, 6.93; N, 5.66%.

l-Ephedrine salt of (−)-**2** melts at 186—188°C, $[\alpha]_D^{18}$ −39.7 (*c* 2.5, ethanol).

(+)-*N*-Benzoyl-*trans*-2-aminocyclohexanecarboxylic Acid [(+)-2]. To a mixture of 3.71 g (0.015 mol) of (±)-**2** and 2.75 g (0.015 mol) of *l*-ephedrine monohydrate was added 20 m*l* of 70% methanol. The mixture was heated on a steam bath to dissolve all solid. The solvent was then evaporated to dryness. The residue was recrystallized from 10 m*l* of 30% methanol to give 4.0—4.3 g of salt, melting at 160—175°C. Two or three recrystallizations of this material using 1.0—1.5 m*l* of 30% methanol per gram of salt gave 0.9—1.3 g of a material melting at above 190°C. With 3N hydrochloric acid the salt was converted into crude (+)-**2**, which was purified by recrystallization with 70% methanol, yielding 0.20—0.30 g (11—16%) of (+)-**2**, mp 257—258°C (in a capillary tube), subliming at near 240°C on an open plate, $[\alpha]_D^{20}$ +44.5° (*c* 0.67, ethanol).

Found: C, 68.13; H, 7.08; N, 5.75%. Calcd for $C_{14}H_{17}NO_3$: C, 67.99; H, 6.93; N, 5.66%.

The pure salt of *l*-ephedrine and (+)-**2** melts at 195—197°C, $[\alpha]_D^{18}$ +10.0° (*c* 2.5, ethanol). Quine salt of (+)-**2** melts at 122—123°C, $[\alpha]_D^{16}$ −72.3° (*c* 2.5, ethanol).

Resolution of (±)-2 by the Preferential Crystallization. A mixture of 10 g of (±)-**2** and 800 m*l* of 70% methanol was heated on a steam bath to dissolve all crystals, then cooled to a temperature of 50—60°C, and it was inoculated with 0.1 g of pure crystals of (−)-**2**. After standing at room temperature for about 10 hr, the inoculated solution was decanted and residual crystals were washed with 70% methanol to yield 0.5—0.8 g (10—14%) of (−)-**2**, mp 255—257°C, $[\alpha]_D^{18}$ −41±2° (*c* 0.67, ethanol).

The decanted solution was heated again with addition of 0.5—0.7 g of (±)-**2**, then inoculated with pure crystals of (+)-**2**, antipode of the seeds used in the preceding crystallization, to yield 1.1—1.6 g (20—30%) of (+)-**2**, mp 254—257°C, $[\alpha]_D^{18}$ +41±2° (*c* 0.67, ethanol).

The process was repeated in this way. Crystals separated by each inoculation were then put together and recrystallized from 95% ethanol to yield a pure sample of each enantiomer of **2**.

(+)-Ethyl-*trans*-2-aminocyclohexanecarboxylate [(+)-3]. A mixture of 24.7 g (0.1 mol) of (+)-**2** and 750 m*l* of concentrated hydrochloric acid was heated under reflux until crystals of (+)-**2** had completely dissolved (for 56—72 hr). The mixture was then cooled, and the resulting benzoic acid was removed by filtration. The filtrate was evaporated to dryness under reduced pressure. The residue was esterified by means of absolute ethanol and dry hydrogen chloride, and worked up in a known manner[9] to yield 14.9 g (87%) of (+)-**3**, bp 109—110°C/13 mmHg, $[\alpha]_D^{18}$ +49.7° (*c* 4, ether).

Similarly, (−)-**3** was prepared from (−)-**2** in 75—90% yield, bp 109—110°C/13 mmHg, 113—114°C/16 Hmmg, $[\alpha]_D^{17}$ −49.8° (*c* 4.5, ether).

Found: N, 8.05%. Calcd for $C_9H_{17}NO_2$: N, 8.18%.

N-Benzoyl derivative of (−)-**3** had a mp 146°C and $[\alpha]_D^{17}$ −38.5° (*c* 2, ethanol).

Found: N, 5.17%. Calcd for $C_{16}H_{21}NO_3$: N, 5.09%.

(+)-*trans*-2-Aminocyclohexanecarboxylic Acid [(+)-1]. A sample of (+)-**3** (1.0 g) was refluxed with 10 times its quantity of water (10 m*l*) for 10 hr. The solvent was then evaporated to dryness under reduced pressure. The residue was recrystallized from 70% ethanol, and dried over phosphorous pentoxide to yield a pure sample of (+)-**1** (0.5 g), mp 264°C, $[\alpha]_D^{17}$ +66.5° (*c* 2, water).

Found: N, 9.54%. Calcd for $C_7H_{13}NO_2$: N, 9.78%.

Similarily, (−)-**1** was prepared from (−)-**3**, mp 264°C, $[\alpha]_D^{16}$ −65.5° (*c* 2, water).

Found: N, 9.63%.

(+)-, (−)-, and (±)-*trans*-2-aminocyclohexanemethanol [(+)-**4**, (−)-**4**, and (±)-**4**] were prepared in 75—80% yield from (+)-**3**, (−)-**3**, and (±)-**3**, respectively, by the action of lithium aluminium hydride in ether[6] or tetrahydrofuran. (+)-**4**, bp 106—108°C/6 mmHg, mp 36—37°C, $[\alpha]_D^{28}$ +21.2° (*c* 5, ethanol). (−)-**4**, bp 98—102°C/3.5 mmHg, mp 37—38°C, $[\alpha]_D^{26}$ −21.6° (*c* 5, ethanol). (±)-**4**, bp 125—127°C/15 mmHg, mp 65—67°C (lit,[6] bp 83—85°C/1 mmHg).

N-Benzoyl derivative of (+)-**4** had a mp 151°C and $[\alpha]_D^{21}$ +41.2° (*c* 3.4, ethanol).

Found: N, 6.13%. Calcd for $C_{14}H_{19}NO_2$: N, 6.00%.

N-Benzoyl derivative of (±)-**4** had a mp 145°C.

Found: N, 5.95%.

(+)-*trans*-2-Bromomethylcyclohexylamine Hy-

9) A. Einhorn and A. Meyerberg, *Chem. Ber.*, **27**, 2467 (1894).

drobromide [(+)-5]. A mixture of 2.58 g (0.02 mol) of (+)-**4** and 10 m*l* of 47% hydrobromic acid was heated on an oil-bath at 160—170°C for 1 hr with bubbling dry hydrogen bromide gas. The temperature was finally raised to 200°C. The resulting material was purified by dissolving with ethanol and then precipitating with ether, giving 5.2 g (95%) of (+)-**5**, mp 207—208°, $[\alpha]_D^{20}$ +36.0° (*c* 3, ethanol).

Found: N, 5.33%. Calcd for $C_7H_{15}NBr_2$: N, 5.13%.

(+)-*trans*-2-Methylcyclohexylamine [(+)-6]. To a mixture of 4.1 g (0.015 mol) of (+)-**5**, 15 m*l* of acetic acid, and 15 m*l* of fuming hydrobromic acid was added slowly 2.5 g (0.038 atom) of zinc dust with stirring. The mixture was then heated under reflux for 2 hr. After removal of solvent under reduced pressure, the residue was dissolved in 10 m*l* of water. The resulting solution was treated with 12 g of sodium hydroxide and 20 m*l* of water, and extracted with three 4 m*l* portions of ether. The ethereal extract was dried (KOH), concentrated, and distilled giving 1.1 g (65%) of (+)-**6**, bp 142—144°C/758 mmHg, $[\alpha]_D^{19}$ +30.8° (*c* 10, ether).

Hydrobromide of (+)-**6** had a mp 299—301°C and $[\alpha]_D^{23}$ +23.0° (*c* 3, ethanol).

Found: N, 7.16%. Calcd for $C_7H_{16}NBr$: N, 7.22%.

N-Benzoyl derivative of (+)-**6** had a mp 164°C (lit,[10] (racemate) mp 146°C], and $[\alpha]_D^{20}$ +48.0° (*c* 5, ethanol).

Found: N, 6.22%. Calcd for $C_{14}H_{19}NO$: N, 6.45%.

(−)-*trans*-2-Hydroxycyclohexanecarboxylic acid [(−)-**7**], (−)-ethyl *trans*-2-hydroxycyclohexanecarboxylate [(−)-**8**], and (−)-*trans*-2-hydroxymethylcyclohexanol [(−)-**9**] were prepared from corresponding amines, that is, (−)-**1**, (−)-**3**, and (−)-**4**, respectively, according to a conventional method[7,8,11] in 50—60% yields. Their physical properties are listed in Table 1.

The authors are grateful to Professor J. H. Brewster and Dr. J. Tsunetsugu for their helpful suggestions and critical readings of the manuscript.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2233—2236 (1970)

Synthesis of Some New Fungicides

V. N. CHOUBEY and H. SINGH

Department of Chemistry, Banaras Hindu University, Varanasi-5, India

(Received November 25, 1969)

A number of 2-arylimino-3-aryl-4-thiazolidones and their 1,1-dioxides and 5-phenylazo derivatives have been prepared. The structure of these thiazolidones was confirmed by studying their hydrolysis products. Some of these thiazolidones were screened for their fungicidal activity against *Aspergillus niger* by agar-growth method and found to be more appropriately fungistatic and not fungicidal.

Several 4-thiazolidones and their derivatives, especially 1,1-dioxides, have been found therapeutically active as local anaesthetics,[1-3] amoebacides[4] and anticonvulsants.[5] Rout *et al.*[6-8] synthesized 2-arylimino-4-thiazolidones and their 5-substituted derivatives, and reported them to be active fungicides. Bhargava and coworkers[9-11] have demonstrated that 2-arylimino-3-aryl-4-thiazolidones with the same or different aryl groups, and 3-aryl-2,4-thiazolidiones possess considerable fungicidal activity. The acetoxymercuri derivatives of the latter were found to be the most active. Recently it has been reported that the hydrochlorides of 2-arylimino-5-methyl-4-thiazolidones[12] step the germination of spores of the fungus, *Culvularia lunata* at the concentration of 1 : 500.

In view of the significant biological applicability of the 4-thiazolidones and their 1,1-dioxides, it was thought worthwhile to synthesize 2-arylimino-3-aryl-5-substituted-4-thiazolidones (I) and 3-aryl-2-(substituted 2′-benzothiazolyl)imino-4-thiazolidones (III) as fungicides by the methods described earlier.[13-16]

where R=aryl; R′=aryl; R″=H or CH_3
Bn=substituted 2-benzothiazolyl

In this communication asymmetrical *N*-aryl-*N*′-aryl thiocarbamides, needed as starting material, were prepared by interaction of aromatic primary amines and various aryl isothiocyanates in dry benzene. These thiocarbamides on condensation with monochloroacetic (α-chloropropionic) acid in absolute ethanol in the presence of sufficient anhydrous sodium acetate (which removes HCl *in situ*) yielded the corresponding 2-arylimino-3-aryl-5-substituted-4-thiazolidones. In this case formation of two possible isomeric 4-thiazolidones (I and/or II) may be assumed from the two possible tautomeric forms of thiocarbamides undergoing reaction with monochloroacetic (or α-chloropropionic) acid. The structure of the 2-arylimino-3-aryl-5-substituted-4-thiazolidones, the position of aryl groups, has been confirmed by studying their degradation products[10,13,17] and characteristic derivatives. Likewise, synthesis of 3-aryl-2-(substituted 2′-benzothiazolyl)imino-4-thiazolidones and their structures have been confirmed. The corresponding 1,1-dioxides of some of these thiazolidones were prepared by oxidizing them with $KMnO_4$ in glacial acetic acid, and 5-phenylazo derivatives

by coupling with benzenediazonium chloride in which coupling occurs at the active methylene group.

Experimental

Asymmetrical *N*-Aryl-*N*′-aryl Thiocarbamides. A mixture of arylamine (0.1 mol) and aryl isothiocyanate (0.1 mol) in dry benzene (25 m*l*) was refluxed on a water-bath for 1—2 hr during which a solid mass was obtained. Unreacted amine and isothiocyanate were removed by washing the crude product with dil. HCl and ether respectively. It was crystallized from 95% ethanol.

2-*o*-Methoxyphenylimino-3-*α*-naphthyl-4-thiazolidone. *N*-*o*-Methoxyphenyl-*N*′-α-naphthylthiocarbamide (15.4 g), monochloroacetic acid (5 g) and anhydrous sodium acetate (8 g) in absolute ethanol (60 m*l*) were refluxed on a water-bath for 7—10 hr with occasional shaking. After distilling ethanol, the gummy product was washed with hot water which solidified on being kept overnight in contact with ice-cold water. It was crystallized from ethanol, yield 72%, mp 172°C.

Found: N, 7.92; S, 9.23%. Calcd for $C_{20}H_{16}N_2O_2S$: N, 8.05; S, 9.19%.

Similarly, other 2-arylimino-3-aryl-4-thiazolidones were synthesized. Their yields, melting points and analytical data are recorded in Table 1.

2-Arylimino-3-aryl-5-methyl-4-thiazolidones. These were prepared in a similar manner as described above, using requisite amount of α-chloropropionic acid instead of monochloroacetic acid. These were crystallized from ethanol and are reported in Table 1.

***N*-Aryl-*N*′-substituted 2-Benzothiazolylthiocarbamides.** 2-Amino-(substituted)benzothiazole (0.1 mol) and arylisothiocyanate (0.1 mol) in dry benzene (110 m*l*) were heated under reflux condenser on a water-bath for 4—20 hr. The rest of the procedure for its isolation and purification was the same as above. These thiocarbamides were crystallized from glacial acetic acid.

3-*p*-Chlorophenyl-2-(2′-benzothiazolyl)imino-4-thiazolidone. A mixture of *N*-*p*-chlorophenyl-*N*′-2-benzothiazolylthiocarbamide (3 g), monochloroacetic acid (1 g) and anhydrous sodium acetate (2 g) in absolute ethanol (60 m*l*) was refluxed on a water-bath for 8—10 hr. Excess ethanol was removed by distillation and the crude product was washed with hot water to remove unchanged reactants. It was crystallized from ethanol-acetone mixture (1 : 1), yield 80%, mp 254°C.

Found: N, 11.93; S, 17.89%. Calcd for $C_{16}H_{10}ClN_3OS_2$: N, 11.68; S, 17.80%.

Following the same procedure, various 3-*p*-chlorophenyl (or *o*-tolyl)-2-(substituted 2′-benzothiazolyl)imino-4-thiazolidones were synthesized (Table 2).

2-(*o*-Methoxyphenyl)imino-3-*m*-chlorophenyl-4-thiazolidone-1,1-dioxide. 2-*o*-Methoxyphenylimino-3-*m*-chlorophenyl-4-thiazolidone (1 g) dissolved in glacial acetic acid (20 m*l*) was treated slowly with $KMnO_4$ (1 g) solution prepared in water (45 m*l*) at 0°C. The resulting mixture was allowed to stand for some time and then sodium bisulphite solution was added to discharge the colour of potassium permanganate. The residue was washed with ice-cold water, dried and crystallized from ethanol, yield 69%, mp 148°C.

Found: N, 7.53; S, 8.94%. Calcd for $C_{16}H_{13}ClN_2O_4S$: N, 7.68; S, 8.78%.

5-Phenylazo-2-*o*-ethoxyphenylimino-3-*o*-methoxyphenyl-4-thiazolidone. To a solution of benzenediazonium chloride (prepared from 2 m*l* of aniline), cooled in a freezing mixture at 0°C, a solution of the thiazolidone (2 g) in glacial acetic acid (40 m*l*) was added in small portions with continuous stirring. The resulting reaction mixture was kept for about an hour

at 0—3°C. The precipitate formed was filtered, washed with ice-cold water and, crystallized, yield 73%, mp 77°C. Found: N, 12.44; S, 7.01%. Calcd for $C_{24}H_{22}N_4O_3S$: N, 12.56; S, 7.17%.

Fungicidal Screening. Compounds 1, 2, 3, 4, 6, 7, 9, 11, 13, 14, 15, 17, 18 and 19 (Table 1) were screened for fungicidal activity against *Aspergillus niger* by agar-growth method, incubated for 90 hr at 25°C, at concn. 1 : 1000 and 1 : 5000. It is evident from the fungicidal screening results of tested compounds that these are more appropriately fungistatic and not fungicidal.

The authors wish to express their sincere thanks to Dr. P. N. Bhargava for supervision, Professor G. B. Singh, Head, Dept. of Chemistry for providing facilities, and C.S.I.R., New Delhi, India and U.G.C., India, for awarding financial assistance to them.

Studies of Ester-Containing Surfactants. Preparation and Properties of Sodium Sulfoalkyl Alkanoates

Takeshi HIKOTA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received Junuary 20, 1970)

A series of sodium sulfoalkyl alkanoates, $RCOO(CH_2)_jSO_3Na$, were prepared by means of sodium isethionate, propane sultone, and butane sultone with normal primary fatty acid composed of 10, 11, and 12 carbon atoms respectively. The effects of the position of the ester group on the Krafft point, the critical micelle concentration (CMC), the surface tention, and the other surface and colloidal properties of these surfactants were investigated. For a given number of carbon atoms, moving the ester group from the ionic head to a more central position in the hydrocarbon chain increased the CMC value and the calcium ion stalbility, and decreased the emulsion stability and the stability to hydrolysis. However, the wetting time was not strongly influenced by the position of the ester group in these compounds. The Krafft point of these surfactants decreased as the ester group was moved to a more central position.

Many investigations have been published regarding the effect of the molecular structure on the surface and colloidal properties. For example, Stirton and his co-workers[1-4] studied the surface-active properties (the Krafft point, the critical micelle concentration, the surface tension, the detergency, the wetting time, the calcium-ion stability, *etc.*) of the sodium α-sulfo fatty ester series and observed that a good wetting agent was usually not a good detergent. Livingstone and Drogin[5] measured the CMC, the surface tension, and the detergency of alkyl thioalkyl and alkoxy alkyl sulfates. Finger and co-workers[6] measured the effect of the structure of the alkyl group in sulfate-type surfactants on the surface tension and the detergency. Previously, I have investigated the effect of the position of the ester group of alkyl sulfo acetate[7] and alkyl β-sulfo propionate[8] on the CMC, the Krafft point, and other bulk properties.

In this experiment, I prepared sodium 2-sulfoethyl alkanoates, $RCOO(CH_2)_2SO_3Na$, 3-sulfopropyl alkanoates, $RCOO(CH_2)_3SO_3Na$, and 4-sulfobutyl alkanoates, $RCOO(CH_2)_4SO_3Na$, and compared their surface-active properties in order to discuss in detail the relation between the position of the ester group and the surface activities.

Experimental

Materials. The capric and lauric acids were kindly provided by the Nippon Oil & Fat Co. The purity of each fatty acid was confirmed to be above 99% by gas chromatography. Normal undecylic acid was prepared according to the following procedure. Decyl alcohol (more than 98% pure) was chlorinated with thionyl chloride; the decyl chloride was then reacted with sodium cyanide in dimethyl sulfoxide.[9] The hydrolysis of the 1-cyanodecane by refluxing it with an excess of 35% of hydrochloric acid gave an undecylic acid. After the removal of the solvent, the residue was purified by distillation; bp 182—185°C/31 mmHg. The sodium isethionate was of a reagent grade. Propane sultone manufactured by the Shell Chemical Co. was further purified by distillation; bp 130°C/3 mmHg. The butane sultone was prepared in the following way. Acetyl chloride was gradually added to tetrahydrofuran according to the method of Cloke and Pilgrim.[10] The reaction mixture was then washed with water, and the oily layer was separated. After the esterification, the solution of δ-chlorobutyl acetate was refluxed and stirred with an aqueous solution of sodium sulfite; then most of the water was removed under reduced pressure. The residue was stirred and refluxed with the excess methanol, and hydrogen chloride was passed into the solution. The reaction mixture was cooled and filtered. The distillation of the filtrate gave a transparent, colorless, and viscous liquid; bp 146°C/17 mmHg.

Preparation of Sodium 2-Sulfoethyl Caprate. A mixture of one mole of capric acid and 1.5 mol of thionyl chloride was heated and stirred at 30°C for one hour, and then at 90°C for one hour. The reaction product, capryl chloride, was distilled under reduced pressure. After the addition of 0.35 mol of sodium isethionate to 0.4 mol of the capryl chloride, the mixture was heated a 90°C for two hours. The crude product thus obtained was recrystallized three times from methanol. Then it was extracted for 100 hr with petroleum ether in order to remove all traces of the unchanged fatty acid. The pure sodium 2-sulfoethyl caprate was obtained as a white flaky powder.

Found: C, 47.45; 4H, 7.44%. Calcd for $C_9H_{19}COO(CH_2)_2SO_3Na$: C, 47.67; H, 7.67%.

Preparation of Sodium 2-Sulfoethyl Laurate. A procedure similar to that used with sodium 2-sulfoethyl caprate was used in the preparation of sodium 2-sulfoethyl laurate from lauric acid and sodium isethionate. The salt was a white, flaky powder.

Found: C, 51.01; H, 8.15%. Calcd for $C_{11}H_{23}COO(CH_2)_2SO_3Na$: C, 50.89; H, 8.24%.

Preparation of Sodium 3-Sulfopropyl Caprate. Sodium 3-sulfopropyl alkanoates was prepared as has been described by Hirai *et al.*[11] A mixture of 0.3 mol of sodium caprate (the sodium alkanoates used in this experiment had been prepared by neutralizing fatty acid with sodium methylate in the toluene), 0.3 mol of propane sultone, and 300 m*l* of toluene was refluxed for 10 hr under stirring. The reaction mixture was then cooled and diluted with 500 m*l* of acetone. The precipitated salt was filtered and recrystallized three times from methanol. Then it was extracted for 100 hr with petroleum ether in order to remove all traces of the unchanged fatty acid. The salt was a white powder.

Found: C, 48.75; H, 7.27%. Calcd for $C_9H_{19}COO(CH_2)_3SO_3Na$: C, 49.35; H, 7.65%.

Preparation of Sodium 3-Sulfopropyl Undecylate and Laurate. The esterification of undecylic and lauric acids with propane sultone was performed in a manner similar to that used with sodium 3-sulfopropyl caprate.

Found: C, 50.90; H, 8.43%. Calcd for $C_{10}H_{21}COO(CH_2)_3SO_3Na$: C, 50.89; H, 8.24%. Found: C, 51.19; H, 8.04%. Calcd for $C_{11}H_{23}COO(CH_2)_3SO_3Na$: C, 51.19; H, 8.49%.

Preparation of Sodium 4-Sulfobutyl Caprate. Sodium 4-sulfobutyl caprate was prepared by the same procedure and with the quantities as in the preparation of the sodium 3-sulfopropyl caprate, but with the propane sultone replaced by butane sultone. The product was recrystallized three times from methanol; then it was extracted for 100 hr with petroleum ether to yield a white, flaky powder.

Found: C, 50.66; H, 8.24%. Calcd for $C_9H_{19}COO(CH_2)_4SO_3Na$: C, 50.89; H, 8.24%.

Preparation of Sodium 4-Sulfobutyl Laurate. The esterification of lauric acid with butane sultone was performed in a similar manner.

Found: C, 53.45; H, 8.89%. Calcd for $C_{11}H_{23}COO(CH_2)_4SO_3Na$: C, 53.61; H, 8.72%.

Measurements. *Krafft Point.* The Krafft point was measured by the electro conductivity method,[12] which corresponds to the estimation of the Krafft point by measuring the change in solubility with the temperature. A rapid increase in solubility at the Krafft point accompanied the rapid increase in electrical conductivity. Thus, the measurement of the change in the conductivity of the surfactant solution with the temperature in a surfactant sufficent to give a solid phase made it possible to estimate the Krafft point. The conductivity measurements were made using a Leeds and Northrup Co., No. 4197, conductivity cell and a 4866 conductivity-resistivity indicator.

Critical Micelle Concentration. The critical micelle concentration (CMC) of the aqueous solution was determined by the conductivity method at 40°C. The conductivity of the water used was about 1×10^{-6} reciprocal ohm.

Surface Tension. The surface tension of the surfactants was measured by the Wilhelmy-plate (Shimadzu Instr. Co.) method at 30°C.

Emulsion Stability. The emulsion was prepared from 10 m*l* of a 20 mmol aqueous solution of the surfactant and 5 m*l* of toluene at 40°C. The emulsifying property was determined by the time (in minutes) it took for an aqueous volume separating from the emulsion layer to reach 9 m*l*, counting from the moment of the cessation of its shaking.

Wetting Property. The wetting property was measured by using a felt 20 mm in diameter and 1 mm thick at 40°C.[13] A solution of 75 m*l* of the 20 mmol surfactant

$C_{11}H_{23}COO(CH_2)_4SO_3Na$	11C-4	below 0	0.0033	0.0025

to be tested was placed in a 150 m*l* beaker, and then the felt disk was put into the solution in such a position that the disk could run parallel to the surface of the solution. The wetting time was shown by the seconds from the moment the disk was put into the solution until the moment it stated going down.

Stability to Hydrolisys. A mixture of 10 m*l* of the 10 mmol surfactant and 10 m*l* of 2N sulfuric acid was placed in a thermostat at 40°C. The time it takes for a sample solution to be clouded as the result of hydrolysis shows the stability of the surfactant to hydrolysis.

Calcium Stability. The calcium-ion stability of a 10 mmol aqueous solution was measured by the modifide Hart method[14] using 0.1N calcium chloride.

Results and Discussion

The Krafft points of the sulfoalkyl alkanoates given in Table 1 are lower than that of surfactant with the same number of methylene groups in an alkyl chain, just as with sodium alkyl sulfate and alkyl sulfonate. This behavior suggests that the ester group introduced into the alkyl chain decreases the hydrophobic property of the hydrocarbon chain. For one series of 3-propane ester salts, 9C-3, 10C-3, and 11C-3, the Krafft point increased with the number of carbon atoms in the fatty acid chain. However, for two series with the same number of carbon atoms in the fatty acid portion, that is, 11C-2, 11C-3, and 11C-4, and 9C-2, 9C-3, and 9C-4, the Krafft point decreased with the increase in the number of methylene groups inserted between the ester group and the ionic head. For a series with the same number of carbon atoms in the surfactants, 9C-4, 10C-3, and 11C-2, the Krafft point decreased in the order of the decrease in the melting point of the corresponding fatty ester, as the ester group in the compounds was moved to a more central position. For instance, butyl caprate has a melting point of −20°C, compared with that of −10°C for the ethyl laurate of the same carbon atoms.

The CMC values of the surfactants, determined as the break points in the equivalent conductance against the concentration curves, are given in Table 1. Furthermore, the logarithm of the CMC has been plotted against the total number of methylene groups for each of the sulfoalkyl alkanoate series. For comparision, the CMC value of sodium alkyl sulfonate[15] is also presented. Figure 1, which gives examples of the plots, shows that the slopes of all of the curves (W, X, Y and Z) are parallel, following the $\log CMC = A - B \cdot N$ relationship. By measuring the horizontal distance between the curves (dotted line), one can compare the effects of the alkyl chain and of the position of the ester group on the CMC. The value of the horizontal distance was found to be 0.22 methylene groups for $\overline{WX}$ (the horizontal distance between

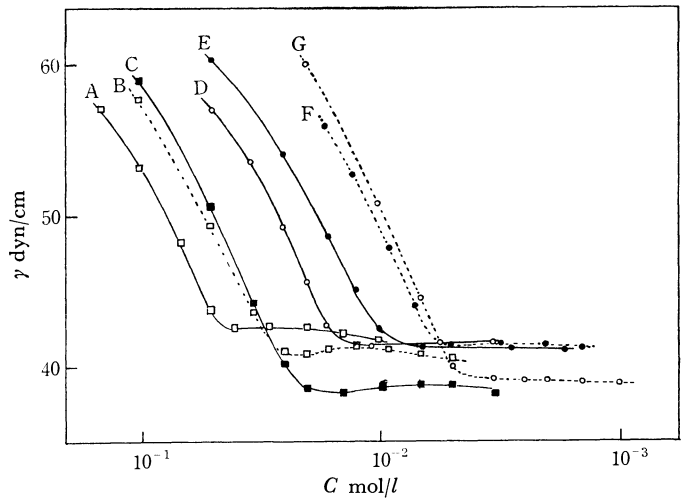

Fig. 2. Surface tension *vs.* concentration curves 11C-4 (A), 11C-3 (B), 11C-2 (C), 10C-3 (D), 9C-4 (E), 9C-3 (F) and 9C-2 (G).

the curve W and the curve X), 0.72 methylene groups for $\overline{WY}$, and 1.22 methylene groups for $\overline{WZ}$. This means that the isethionate, propane sultone, and butane sultone derivatives decrease the hydrophobic property of the hydrocarbon chain by 0.22, 0.72, and 1.22 units of the methylene group respectively with regard to the CMC value. Hence, the CMC of these surfactants increases regularly as the ester group is moved to a more central position in the chain.

The surface tension *vs.* the log concentration curve of the surfactants is shown in Fig. 2. The curve was inflected at the point which corresponds to the CMC. The CMC value estimated by means of the surface tension was in good agreement with that determined by means of the electro conductivity method, as is shown in Tables 1 and 2. The surface tension of the isethionate derivative above the CMC was about 39 dyn/cm, a little lower than that of the corresponding propane sultone and butane sultone derivatives. However, the surface tensions of these surfactants below the CMC are lower in this order: ethyl ester<propyl ester<butyl ester at the same concentration.

Table 2. Properties and stability of surfactant

Derivatives	Surface tension γ at CMC dyn/cm	Emulsion stability sec	Wetting time sec	Stability to hydrolysis min & sec
9C-2	39.10	12	3.3	43 : 51
11C-2	38.80	297	3.7	20 : 53
9C-3	41.24	146	3.8	39 : 45
10C-3	41.20	245	3.6	25 : 27
11C-3	40.40	378	4.0	18 : 39
9C-4	41.10	188	4.0	30 : 06
11C-4	42.30	442	3.5	16 : 26

The emulsion stability of the surfactants is shown in Table 2. As may be seen in the table, the emulsion stability increased with the number of the methylene group of the alkyl chain in the surfactant. For a series with the same number of methylene groups, 9C-4, 10C-3, and 11C-2, the emulsion stability increased as the ester group, was moved toward the center of the chain.

Table 3. Calcium stability and temperature

Derivative	Converted into $CaCO_3$ Temperature °C					
	10	20	30	40	50	60
9C-2	>4500	>4500	>4500	>4500	>4500	>4500
11C-2	insoluble	insoluble	260	500	1930	2380
9C-3	900	>4500	>4500	>4500	>4500	>4500
10C-3	100	700	3800	>4500	>4500	>4500
11C-3	insoluble	insoluble	100	150	700	2210
9C-4	670	>4500	>4500	>4500	>4500	>4500
11C-4	insoluble	insoluble	580	1090	2930	>4500

The wetting properties of the surfactants are shown in Table 2. These surfactants were very effective wetting agents in a distilled water solution.

The relation between the stability to hydrolysis and the chain length in the surfactant is shown in Table 2. The stability to hydrolysis decreased with the increase in the number of carbon atoms in the surfactant. The data indicates, therefore, that at the same number of the methylene group in the surfactant the relative order of stability to hydrolysis is: ethyl ester>propyl ester>butyl ester. That indicates that the sulfo group protects the ester linkage through steric hindrance.

The calcium-ion stability of the surfactants (in relation to the temperature) is shown in Table 3. It is apparent that the stability increases markedly with an increase in the temperature, but decreases with an increase in the number of methylene group in the alkyl chain length under conditions of a constant temperature. For a given number of the methylene group, moving the ester group from the terminal to a more central position in the alkyl chain increases the calcium stability. This means that the hydrophilic property of the surfactant increases with the movement of the ester group toward the the center of the chain.

The author wishes to thank Professor Kenjiro Meguro for his helpful advice, and Mr. Minori Nakamura and Miss Yōko Ohgaki for their assistance in the experiments.

The Polymerization of Dimethallylidenepentaerythritol and Dicrotylidenepentaerythritol*1

Tatsuro OUCHI, Shozo TATSUNO, Toshiharu NAKAYAMA and Masayoshi OIWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka

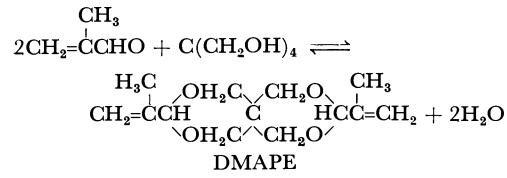
(Received September 11, 1969)

In a previous paper, the polymerization of diallylidenepentaerythritol (DAPE) has been kinetically investigated by means of degradative, effective chain transfers by the allylidene groups, and by means of cyclization by the two double bonds.[1]

This paper will deal with the polymerization of dimethallylidenepentaerythritol (DMAPE) and dicrotylidenepentaerythritol (DCPE), and with the influence of α,α'- or β,β'-methyl groups on the chain transfer and the cyclization.

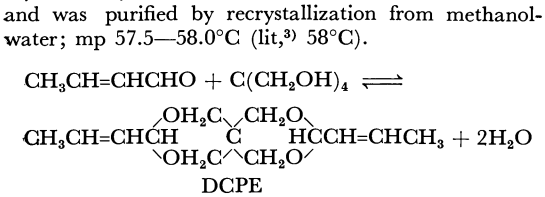
Experimental

Materials. DMAPE was prepared from methacrolein and pentaerythritol by the procedure of Komori and his co-workers,[2] using phosphoric acid - phosphorus pentoxide as the catalyst; mp 115—116°C (lit,[2] 115—116°C).



DMAPE

DCPE was prepared from crotonaldehyde and pentaerythritol by the method of Weihe and Schweitzer[3] and was purified by recrystallization from methanol-water; mp 57.5—58.0°C (lit,[3] 58°C).



DCPE

Polymerization Procedure. DMAPE and DCPE were polymerized in benzene at 80°C with benzoyl peroxide as a radical initiator. The monomer, solvent, and initiator were charged in an ampoule; after having been degassed by the freeze-thaw method, the ampoule was sealed under a vacuum. The sealed tubes were then set in a thermostated water bath; later they were taken out into a large amount of petroleum ether and the polymers were separated by using the centrifuged, after which they were dried *in vacuo*. The conversion of the polymer was less than 10%.

Measurements of the Residual Unsaturation and the Degree of Polymerization. The residual unsaturation was calculated from the bromine value (BV) according to the usual bromite-bromate method.[4]

The molecular weight of the polymer was determined by means of a vapor-pressure osmometer (Hewlett Packard Model-302) at 37°C, using benzene as the solvent.

Results and Discussion

The conditions and the results of polymerization are summarized in Tables 1 and 2. The values of residual unsaturation and degree of polymerization shown in Tables 1 and 2 are estimated by extrapolating to zero for conversion.

If the monomer concentration is kept constant, the plots of the rate of polymerization against the initiator concentration are found to be as shown in Fig. 1 by using the values listed in Tables 1 and 2. It is found that the rate of polymerization is proportional to the first power of the initiator concentration. If the relation of $([I]/R_p - a)^{-1}$ *vs.* [M] is plotted by means of the trial-and-error method, the straight-line relationship is obtained when the values are 3.0×10^3 sec (DMAPE) and 2.0×10^4 sec (DCPE) respectively (Figs. 2 and 3). Therefore, b and c values are calculated from those slopes and intercepts as follows:

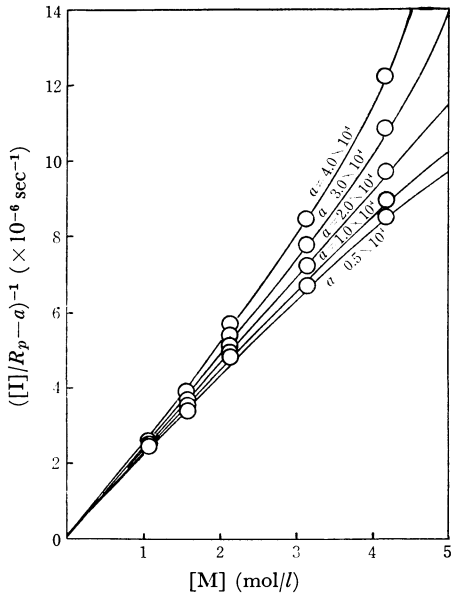

Fig. 3. Plots of $([I]/R_p-a)^{-1}$ *vs.* [M] obtained on the polymerization of DCPE.

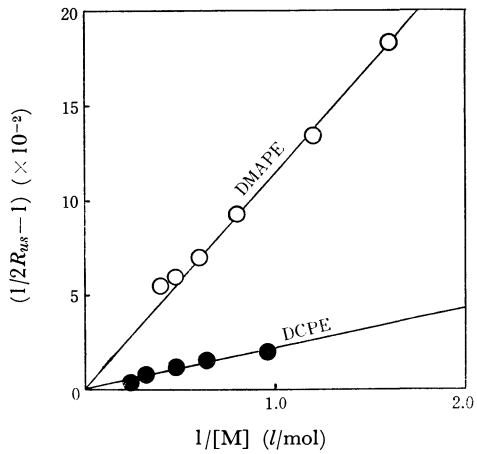

Fig. 4. Plots of $(1/2R_{us}-1)$ *vs.* 1/[M].

creases with the decrease in the monomer concentration; accordingly, there is a tendency to cyclize easily. The plots of $(1/2R_{us}-1)$ against 1/[M] are, then, shown in Fig. 4. Straight lines through the point of origin are obtained. Using their slopes, the c values of DMAPE and DCPE are computed as 0.226 mol/l and 0.044 mol/l respectively. These values agree very closely with those obtained from the trial-and-error method. Here the c value of DCPE is very small because the cyclization was sterically hindered by β,β'-methyl groups.

The degree of polymerization does not depend on the initiator concentration, but increases with the increase in the monomer concentration. It is natural that the degree of polymerization of DCPE is small, because β,β'-methyl groups influence the

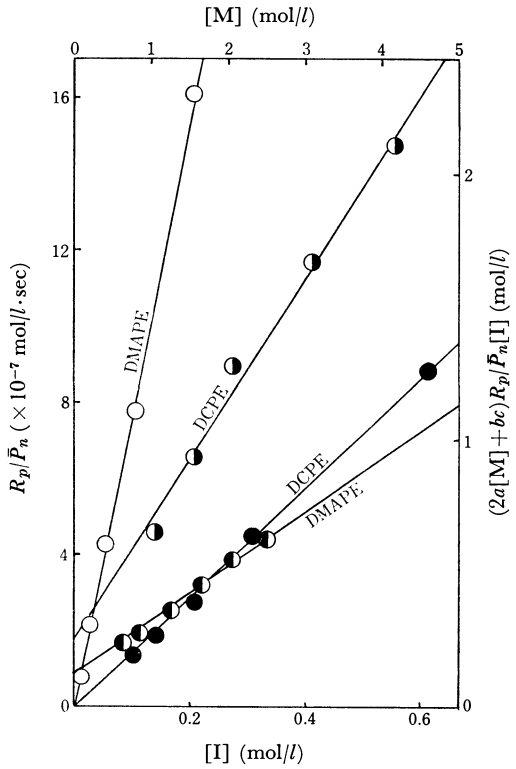

Fig. 5. Plots of $R_p/\bar{P}_n$ *vs.* [I] and $(2a[M]+bc)R_p/\bar{P}_n[I]$ *vs.* [M].

propagation and termination. The plots of $R_p/\bar{P}_n$ against [I] and of $(2a[M]+bc)R_p/\bar{P}_n[I]$ against [M] are shown in Fig. 5. Straight lines are obtained; therefore, this experimental fact seems to agree with the previous equation.[1)]

Conclusion

The polymerization of DMAPE and DCPE, which are α,α'- and β,β'-substituted derivatives of DAPE, in the initial stage were explained kinetically according to the equations suggested in a previous paper.[1)] The parameters of copolymerization for three monomers are summarized in Table 3.

Table 3. The parameters of copolymerization

Monomer	a ($\times 10^3$ sec)	b ($\times 10^4$ sec)	$\frac{k_c}{2(k_p+k_{tr}+k_{tr}^*)[M]}$
DMAPE	3.0	2.53×10	0.118
DCPE	20.0	2.00×10^3	0.022
DAPE	2.0	5.66	0.276

From the above results, it was found that $k_c/2(k_p+k_{tr}+k_{tr}^*)[M]$ were in the order of DAPE$>$DMAPE$>$DCPE, and that the cyclization was sterically hindered by methyl groups.

The a and b values varied in the following sequence:

$$\text{DAPE} < \text{DMAPE} < \text{DCPE}$$

It seemed that the degradative chain transfer occurred more readily on the methallylidene and crotylidene groups that on the allylidene group. It may be considered that allylidene groups can be resonanced easily to stabilize with methyl groups, and to hypercojugate.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2244—2245 (1970)

Photoelectrical Response of Hydrochloric Salt of Photospiran

Takao NAKAYAMA, Isamu SHIMIZU, Hiroshi KOKADO and Eiichi INOUE

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguru-ku, Tokyo

(Received November 20, 1969)

Photospirans (1,3,3-trimethylspiro[indoline-2,2′-benzopyran] and its derivatives) are transformed from a colorless form (A) to a colored form (C) by adding acid (Brönsted or Lewis acid) in organic solvents. (C) is converted to a colorless form by irradiation with either visible or UV light, and is gradually restored after irradiation is stopped.

The term "reverse photochromism" is given to photoreversible color changes.

During the course of our studies on the reverse photochromism of spiran-acid systems, an electrical response was observed when the colored species (C) in organic solvents was irradiated.

To measure the electrical current of the solution, a cell with two Al plate electrodes (10×10 mm^2) 10 mm apart was set up. The measurement was carried out under constant voltage 2 V (d.c.) by a micro-micro Ammeter (TR-84B). A high pressure mercury lamp fitted with a glass UV cut filter was used as the irradiation source.

A typical electrical current curve of the butanol solution of hydrochloric salt of spiran (1) is shown in Fig. 1.

The electronic current of the solution increased

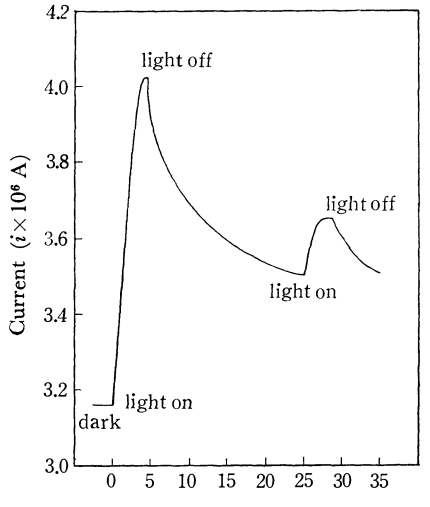

Fig. 1. Electrical current curve of the hydrochloric salt of spiran (1) in butanol.
concentration 1.7×10^{-4} mol/l
light intensity 2.1×10^{-3} W/cm^2

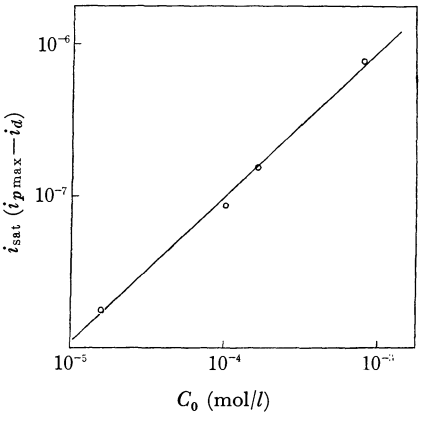

Fig. 2. Dependence of the maximum value of photocurrent on the initial concentration (C_0) of the salt.

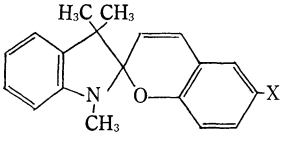
$$[\mathrm{SPH}]^+\mathrm{Cl}^- \underset{\text{thermal}}{\overset{h\nu}{\rightleftharpoons}} \mathrm{SP} + \mathrm{H}^+ + \mathrm{Cl}^- \qquad (1)$$

(C) colored (A) colorless



SP

by irradiation with light, and decreased when irradiation was stopped. The value of the saturated photo-current (i_{sat}) was proportional to the initial concentration of the salt of spiran (1) as shown in Fig. 2. The dark current of the solution also increased with concentration. Though the current decreased gradually after irradiation was stopped, it did not return to the initial value. The photocurrent of the solution is assumed to be due to the generation of electrical carriers by irradiation with light undergoing photoconversion from the colored species (C) to the colorless one (A) as shown in Eq. (1). The photo-dissociated carriers seem to be partially stabilized in solvent, and neither the color nor current of the solution returns to the initial value after irradiation is stopped.

The photoelectrical phenomena mentioned above were also observed in the solution of spiran (2).

Elimination Reactions on Solid Acid Catalysts. I. A Comparison between Silica-alumina and Alumina Catalysts in the Dehydration of Ethanol by Means of the Poisoning Method

Isao MOCHIDA, Yasuhide Anju, Akio KATO and Tetsuro SEIYAMA

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka

(Received December 15, 1969)

Silica-alumina, alumina, and alumina-boria are solid acid catalysts useful in various acid-catalyzed reactions.[1] The correlations between the acidity and the catalytic activity have been established in some reactions;[2] however, no general conclusion has yet been obtained among all the acid-catalyzed reactions.

One of the present authors has reported previously that alumina showed a characteristic behavior in contrast with silica-alumina in the reaction with methylene chloride[3] and in dehydrochlorination reactions from chloroethanes,[4] although it had a very small activity in dealkylation reactions which were explained by the protonic acidity.[5,6]

Echigoya[7] discussed the differences between these two catalysts in some reactions and explained them in terms of the acid strength and the origins of their acid sites.

The dehydration of ethanol is one of the reactions which show a distinct difference between these two catalysts, and it has been investigated for many years.[7-9] Two kinds of mechanisms have been proposed; one is the carbonium-ion mechanism,[10] and the other, the alcohoxide mechanism.[11] Pines and Pillai[12] and Jain and Pillai[13] have shown the olefin and ether formations on alumina *via* a concerted mechanism by the poisoning method, using acidic and basic inhibitors.

In the present research, the reaction mechanism was investigated by the poisoning method, using pyridine and *n*-butylamine as the basic substances and acetic acid as an acidic substance in order to clarify the differences between silica-alumina and alumina in the dehydration of ethanol. Recently,

Trambouze *et al.*[11] reported common concerted mechanisms for both alumina and silica-alumina by a similar poisoning method using tetracyanoethylene (TCNE) as the acidic substance. Very recently, Parera and Figoli[15] studied the differences between these two catalysts in the dehydration and methylation of methanol, and concluded that the active sites on silica-alumina were protonic-acid sites, whereas those on alumina were Lewis-acid sites.

Experimental

Reagents. Ethanol of a G. R. grade (Hayashi Junyaku Co.) and *n*-butylamine, pyridine, and acetic acid of an E. P. grade (Wako Junyaku Co.) were used without further purification. Isopropylbenzene was used after the removal of peroxide by an adsorption column of silica and alumina gels.[16]

Table 1. Catalysts

Abbreviation	Name	Surface area (m^2/g)	Composition	Remark

a) By precipitation of $Al(NO_3)_3$ with NH_4OH.
b) By impregnation of A with aq. NaOH.
c) By coprecipitation of $Al(NO_3)_3$ and H_3BO_3 with NH_4OH.
d) By impregnation of AB with aq. NaOH.
e) Nippon Cat, a cracking catalyst of the Shokubai Kasei Co.
f) By impregnation of SA with aq. NaOH.

Catalysts. The catalysts are listed in Table 1, together with some of their properties. They were all calcined at 550° for 8 hr in the atmosphere.

Apparatus and Procedures. An ordinary pulse technique with a hydrogen carrier gas was adopted for both reactions.[17] A 1-hr pretreatment of the catalyst was carried out in a hydrogen gas flow at 450°C. For dehydration, PEG-1500 (Gas Chro Kogyo Co.) was used in the analytical column (2 m, 70°C), and the reaction temperature was 350±2°C. The gas-chromatographic peaks of the products were broad on sodium-poisoned catalysts.[18] In this case, the products were once trapped by liquid nitrogen between the reactor and analytical column, and then they were simultaneously reevaporated for gas-chromatographic analysis. For deisopropylation, the analytical column contained 3 m of TCP (Gas Chro Kogyo Co.) and the reaction temperature was 440±2°C. The conversion was proportional to the reciprocal space velocity under a low conversion, so apparent rate constant, k, was obtained from the slope. To observe the effect of a base or acid addition, poisoning reagents were injected before the reaction. As basic inhibitors did not react with ethanol, a catalyst could then be used. In the case of acetic-acid poisoning, however, ethylacetate was formed on some catalysts, so the poisoning effect was measured over the catalysts poisoned for each observation.

Results

The Catalytic Activities of Silica-alumina, Alumina, and Their Related Catalysts in Dehydration and Deisopropylation Reactions. The catalytic activities for the dehydration of ethanol and for deisopropylation from isopropylbenzene are summarized in Table 2. The six catalysts studied may be classified into two groups: SA, SA-Na, and AB belong to one group, and A, A-Na, and AB-Na to the other group. The catalyst of

Table 2. Rates of dehydration of ethanol and deisopropylation of isopropylbenzene on various catalysts

Catalyst	A	AB	SA	A-Na	AB-Na	SA-Na
Rate (ml/min·g) ($\times 10^3$)[a]						
of ethanol disappearance	4.2	3.0	4.5	1.2	1.0	0.89
of ethylene formation	2.1	1.9	3.0	0.60	0.54	0.53
of ether formation[b]	2.1	1.1	1.5	0.60	0.48	0.36
Ratio of formation rate[c]	1.0	1.7	2.0	1.0	1.1	1.5
Rate (ml/min·m^2)	22	7.7	8.2	5.0	3.5	1.3
Rate (ml/min·m^2·Al-atom)	22	8.5	69	—	—	—
Rate of deisopropylation from isopropylbenzene (ml/min·g)[d]	1.3×10^{-1}	6.6×10^{2}	2.4×10^{3}	*	2.6	9.6×10

a) Reaction temperature: 350°C, flow rate: 90 ml/min.
b) Ethanol base.
c) Ratio of ethylene/ether in ethanol base.
d) Reaction temperature: 440°C, flow rate: 90 ml/min.
* Too small to be measured.

the former group had a considerable activity for deisopropylation and its ethylene/ether ratio was larger than unity, whereas the catalyst of the latter group had a very small activity for deisopropylation and its ethylene/ether ratio was about unity. Sodium ions poisoned the catalysts of both groups in both reactions. It is interesting that AB-Na behaved much like A.

Poisoning by Nitrogen Bases. The addition of a nitrogen base to a catalyst before the reaction retarded the dehydration reaction to an extent according to the kind of catalyst and base. The activity recovered gradually as the elution by hydrogen proceeded. These phenomena may be explained by the adsorption and desorption of the nitrogen base on acidic sites. The cases with *n*-butylamine and pyridine are shown in Figs. 1 and 2 respectively. With more basic *n*-butylamine, the dehydration was retarded more and the recovery of the catalytic activity was slower. The catalyst with a considerable activity for deisopropylation, the first group, was poisoned more severely, but A-Na or AB-Na suffered no effect. Generally speaking, the nitrogen base poisoned the ethylene formation more than the ether formation. This selective poisoning was most distinct with pyridine as an organic base and AB as a catalyst, when only the ethylene formation was retarded. Moreover, more poisoning of the sodium ion against ethylene formations on silica-alumina and alumina has been reported.[7,19]

Poisoning by Acetic Acid. The effect of an acid addition on dehydration was studied for SA, AB, and A from a viewpoint similar to that reported by Pines and Pillai[12] and by Jain and Pillai.[13] The results are shown in Fig. 3. Acetic acid also poisoned the ethylene formation more. Speaking of catalysts, they were poisoned in this order: A> AB>SA, which was just the reverse of that in the nitrogen-base poisoning. In the cases of SA and AB, the ester was found in the first pulse, but it disappeared in the second and following pulses, when the poisoning for ether formation also disappeared. On A, the ester was not found at all,

although acetic acid might be adsorbed. All sodium-poisoned catalysts except SA-Na were poisoned more severely than their original catalysts.

Discussion

As has been described in the results section, the catalysts studied were classified into two groups. As for the silica-alumina group, on which a considerable deisopropylation occurred, the dehydration may take place on the strong acid sites, as is to be expected from the fact that deisopropylation proceeded on such sites.[5-7] The decrease in activity which occurred upon the addition of a sodium ion or organic bases supports the above mechanism. The active sites may not include the basic site, which is different from the sites on the alumina group, because acetic acid had little effect on dehydration, although the phenomena became complex about AB, where parts unperturbed by the presence of boria were left. Recently, Trambouze *et al.*[14] has reported that the active sites for dehydration on silica-alumina contained basic points as well as acidic points; however, the present authors observed that TCNE poisoned the deisopropylation as well. Therefore, it is possible that the adsorption of bulky TCNE on a weak basic site retarded the reaction on an acid site. The same situation may occur in dehydration. The results on alumina suggest that the ethylene formation proceeds through a concerted mechanism on an acidic site and a basic site[9,12] including an ethoxide intermediate.[20,21] The adsorption of acetic acid on basic sites may be verified by the fact that acetic acid poisoned A-Na more severely than A. Echigoya[7] defined the Lewis acid for alumina and the Brönsted acid for silica-alumina and proposed hydrated Lewis acids as active sites on alumina for dehydration. However, the aluminum ion, which can accept ethanol in an ethoxide, is more probable as the active site, although the former part of Echigoya's definition may be true. Parera and Figoli[15] reached a similar conclusion in the reaction of methanol. These differences in the mechanism and the active site might bring about the distinct difference in the dehydrations on silica-alumina and alumina.

The esterification of ethanol with acetic acid on silica-alumina was much faster than on alumina, although the esterification may proceed on weaker acid sites than dehydration. Here an interesting difference was observed between two catalysts. The results of our investigation of this reaction in connection with dehydration will be published later.

Infrared Spectroscopic Studies on Vaska Complex using Heavy Oxygen

Kiyotomi TAKAO, Yuzo FUJIWARA, Toshinobu IMANAKA, Masao YAMAMOTO,* Kozo HIROTA* and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka
* *Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka*

(Received December 30, 1969)

Recently several transition metal complexes coordinated with molecular oxygen have been described.[1-5] With respect to iridium metal in particular, the reaction of the species having the general formula $[Ir(p\text{-}p)_2]Cl$ and $IrXCO(PPh_3)_2$ (p-p: $Ph_2PCH_2CH_2PPh_2$, X: halide) with molecular oxygen has been studied in detail.[6,7] The structures of these iridium complexes have been made clear by X-ray analysis.[8,9]

In Vaska iridium oxygen complex, $(IrClCO(PPh_3)_2O_2)$, the strong IR absorption spectrum at 856 cm^{-1} is ascribed to the peroxy-vibration,[1] but no definite assignment has been made. Hirota and his coworkers[10] studied the spectra of the peroxy-complexes, $Ni(Bu^tNC)_2O_2$ and $Pd(Bu^tNC)_2O_2$ and observed three bounds due to ^{16}O–^{16}O, ^{16}O–^{18}O and ^{18}O–^{18}O.[10]

In order to investigate the nature of chemical bonds of the iridium complexes, we have studied the IR and FIR (far infrared) spectra of Vaska oxygen complex containing heavy oxygen molecule.

The iridium oxygen complex containing heavy oxygen was prepared by the reaction of $IrClCO(PPh_3)_2$ complex and heavy oxygen (25.5% as $^{18}O_2$) at 170 mmHg for 45 hr. The IR spectrum of the complex in Nujol mulls is shown in Fig. 1. The IR band at 856 cm^{-1} splites into three strong absorption bands at 856, 832 and 808 cm^{-1}. Since the iridium oxygen complex contains three molecular species such as ^{16}O–^{16}O, ^{16}O–^{18}O and ^{18}O–^{18}O, the calculation on the assumption of free diatomic molecules gives wave numbers to be 856, 832 and 807 cm^{-1}. A good agreement between the observed wave numbers and those calculated shows that the band at 856 cm^{-1} which has been reported by Vaska[1] is clearly assignable to the stretching vibration of the O–O bond.

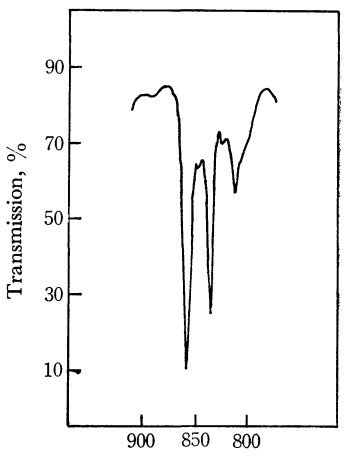

Fig. 1. Infrared spectrum of the iridium oxygen complex.

By measuring the relative intensity of the three bands at 856, 832 and 808 cm^{-1}, these bands are ascribed to such molecular species as ^{16}O–^{16}O, ^{16}O–^{18}O and ^{18}O–^{18}O, respectively. The shoulders at 843 cm^{-1} and 820 cm^{-1} are assignable to the stretching vibration of ^{16}O–^{17}O and ^{17}O–^{18}O, respectively, in comparison with the calculated.

The FIR spectra of Vaska complexes were reported already by Bennett *et al.*,[11] but those of Vaska oxygen complexes are not known and were measured accordingly.

The FIR spectrum of this oxygen adduct shown in Fig. 2 indicates that the very strong band assignable to the stretching vibration of Ir–Cl bond[11] shifts from 318 to 314 cm^{-1} and that a band at 184

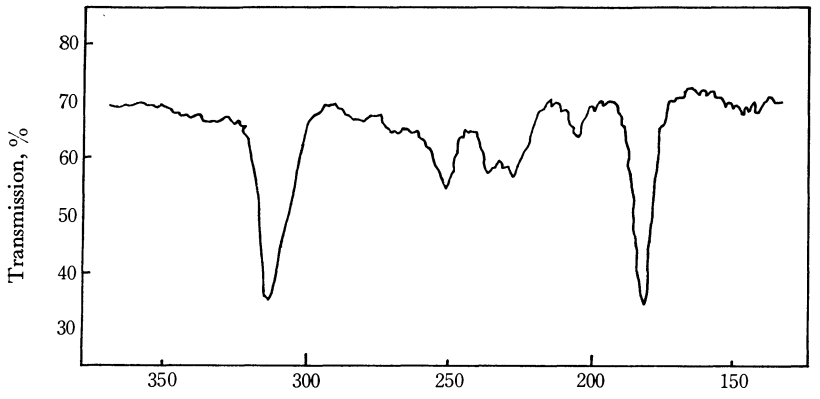

Fig. 2. Far infrared spectrum of the iridium oxygen complex.

cm^{-1} shifts to 182 cm^{-1} when heavy oxygen was used.

The stretching band of Ir–O bond which is expected in the region of 450—600 cm^{-1} can not be detected due to overlapping of the strong bands of triphenylphosphine ligand.

In addition, we have found that the oxygen complexes can easily cause the oxidation reaction of olefins under mild condition.[12]

Synthesis and Reactions of Sulfonium Diacylmethylide Having Active Hydrogen

Masaki TAKAKU and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received January 8, 1970)

Sulfonium diacylmethylides are easily prepared by acylating sulfonium monoacylmethylides[1] or by condensation of sulfoxides and 1,3-diketones.[2] Nevertheless few of their reactions are known with respect to the remarkable stability and inertness of these ylides.[3] We wish to report the reaction of sulfonium diacylmethylides having active hydrogens with a strong base.

Ylides Ia and Ib were prepared from the corresponding sulfonium phenacylides and phenylacetic anhydride in 71 and 72% yields, respectively, in the usual way. To a stirred solution of Ia in dimethyl sulfoxide (DMSO) under nitrogen was added equimolar sodium hydride in one portion. The reaction mixture was stirred for further 3 hr to produce a deep red solution. To this solution of IIa was added dropwise methyl iodide to give a new ylide IIIa (mp 132—133°C) in a 64% yield. Under the same conditions as above, Ib also yielded a red solution of IIb, which was treated with methyl iodide to give IIIb (mp 149—151°C) in a 70% yield. The

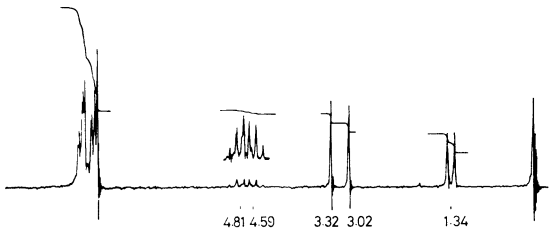

Fig. 2. NMR spectrum of methylphenylsulfonium benzoyl(α-phenylpropionyl)methylide (IIIb).

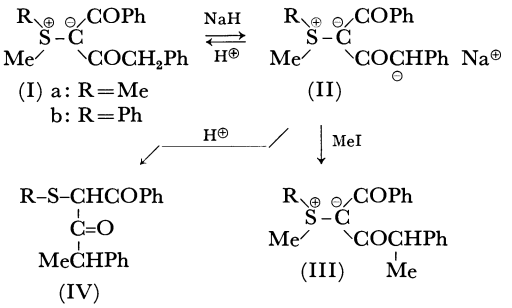
structures of IIIa and IIIb were determined on the basis of C, H analysis and spectral data. NMR spectrum of IIIa is given in Fig. 1, in which S-methyl signals were observed as two distinct singlets with chemical shift difference of 0.24 ppm. This shows that the S-methyl groups are diastereotopic to each other due to the pyramidal structure of sulfur atom and the presence of asymmetric carbon of α-phenethyl group. NMR spectrum of IIIb is given in Fig. 2. S-Methyl signals were observed as two singlets with chemical shift difference of 0.30 ppm as in IIIa. Methine protons appeared as two quartets (chemical shift difference: 0.22 ppm). The data indicate that IIIb is a *ca.* 1 : 1 mixture of two diastereomers due to two assymetric atoms (sulfur and α-phenethyl carbon), although it has a melting point 149—151°C and proved homogeneous on TLC. These diastereomers, however, have not been separated into components.



Treatment of a solution of IIa with acetic acid gave the starting ylide Ia in a 67% yield. In sharp contrast, however, treatment of IIb with acetic acid gave a rearranged product IVb (64%). The same rearrangement was also observed in DMF solvent. Simple treatment of Ib with acetic acid failed to induce the rearrangement.

Experimental

Preparation of Dimethylsulfonium Benzoyl(phenylacety)methylide (Ia). A solution of dimethylsulfonium phenacylide (3.6 g, 0.02 mol) and phenylacetic anhydride (5.1 g, 0.02 mol) in THF (100 m*l*) was stirred for 10 hr at room temperature. The reaction mixture was concentrated *in vacuo* and treated with chloroform. The chloroform solution was washed with aq. $NaHCO_3$, dried ($MgSO_4$) and concentrated. The residual solid was recrystallized from benzene to afford Ia (4.2 g, 70.5%), mp 108—110°C, IR (Nujol): 1591, 1565 and 1145 cm^{-1}, NMR: δ ($CDCl_3$) 2.86 (6H, s), 4.01 (2H, s), 7.2—7.5 (10H, m). (Found: C, 72.9; H, 6.1%. Calcd for $C_{18}H_{18}O_2S$: C, 72.5; H, 6.1%.)

Preparation of Methylphenylsulfonium Benzoyl(phenylacetyl)methylide (Ib). Treatment of methylphenylsulfonium phenacylide (4.8 g, 0.02 mol) with phenylacetic anhydride (5.1 g, 0.02 mol) in THF (100 m*l*) gave Ib (5.2 g, 72%), mp 130—132°C (from benzene), IR (KBr): 1596, 1570, 1350, 1118, 960, 735 and 710 cm^{-1}, NMR: δ ($CDCl_3$) 3.30 (3H, s), 4.09 (2H, s), 7.3—7.7 (15H, m). (Found: C, 76.8; H, 5.3%. Calcd for $C_{23}H_{20}O_2S$: C, 76.7; H, 5.6%.)

Reaction of Ia with Sodium Hydride Followed by Addition of Methyl Iodide. To a solution of Ia (3.0 g, 0.01 mol) in DMSO (50 m*l*) under nitrogen was added sodium hydride (1.0 g, 50% dispersion in mineral oil, 0.01 mol) in one portion at room temp. The reaction mixture was stirred for 3 hr to afford a red solution of IIa. To this solution of IIa was added dropwise a solution of methyl iodide (5.6 g, 0.04 mol) in DMSO (10 m*l*). After being stirred for an additional 1 hr, the reaction mixture was diluted with water and extracted with chloroform. The chloroform solution was dried ($MgSO_4$) and evaporated to afford a solid, which was recrystallized from benzene to yield IIIa (2.0 g, 64%), mp 132—133°C, IR (Nujol): 1590, 1580, 1565—1550 (broad), 1195, 1178, 1140, 1021 and 985 cm^{-1}. (Found: C, 72.8; H, 6.4%. Calcd for $C_{19}H_{20}O_2S$: C, 73.0; H, 6.5%.)

Reaction of Ib with Sodium Hydride Followed by Addition of Methyl Iodide. According to the same procedure as Ia, Ib (3.6 g, 0.01 mol) was treated with sodium hydride (1.0 g, 50% dispersion in mineral oil, 0.01 mol) followed by addition of methyl iodide (5.6 g, 0.04 mol) and gave IIIb (2.6 g, 70%), mp 149—151°C (from benzene-hexane), IR (KBr): 1580, 1570, 1295 and 1225 cm^{-1}. (Found: C, 76.6; H, 6.3%. Calcd for $C_{24}H_{22}O_2S$: C, 77.0; H, 5.9%.)

Treatment of IIa with Acetic Acid. To a solution of IIa (0.01 mol) in DMSO (50 m*l*) was added dropwise acetic acid (0.9 g, 0.015 mol) in DMSO (10 m*l*). The reaction mixture was diluted with aq. $NaHCO_3$ and extracted with chloroform. The chloroform solution was concentrated to afford Ia (2.0 g, 67%).

Treatment of IIb with Acetic Acid. A solution of IIb (0.01 mol) in DMSO (50 m*l*) was treated with acetic acid (0.9 g, 0.015 mol), diluted with water and extracted with chloroform. The chloroform solution was concentrated and ether was added to the residual oil to give a solid, which was recrystallized from ethanol to afford IVb (2.3 g, 64%), mp 90—93°C, IR (KBr): 1605, 1582, 1540 (broad), 1480 and 1380 cm^{-1}, NMR: δ ($CDCl_3$) 1.47 (3H, d, J=7.2 Hz), 4.11 (1H, s), 4.78 (1H, q, J=7.2 Hz), 7.0—7.8 (15H, m). (Found: C, 76.4; H, 5.5%. Calcd for $C_{23}H_{20}O_2S$: C, 76.7; H, 5.6%.)

The Estimation of Primary Radical Termination from Rate Data in Free Radical Polymerization

O. F. OLAJ

Institute for Physical Chemistry, University of Vienna, Austria

(Received January 20, 1970)

Recently an article has been published by Ito and Matsuda[1] in which a simple treatment of primary radical termination in free radical polymerization was proposed. Starting from the kinetic scheme for primary radical termination as it had been developed by Bamford and Jenkins,[2] however, omitting an eventual recombination of primary radicals outside the solvent cage, *viz.*,

$R_0=2(1-h)R_d$	rate of formation of primary radicals ($R_d=k_d[\mathrm{I}]$ = rate of initiator decomposition)
$R_i=k_i[\mathrm{R}][\mathrm{M}]$	rate of initiation (polymer radical formation)
$R_p=k_p[\mathrm{P}][\mathrm{M}]$	rate of chain propagation
$R_t=k_t[\mathrm{P}]^2$	rate of mutual termination between polymer radicals
$R_{ti}=k_{ti}[\mathrm{R}][\mathrm{P}]$	rate of termination of polymer radicals by primary radicals

[I], [M], [R], and [P] denoting the concentrations of initiator, monomer, primary radicals, and polymer radicals, respectively, $(1-h)$ being the fraction of primary radicals escaping the solvent cage, Ito and Matsuda simplified the cubic equation,

$$R_p^3 + (k_ik_p/k_{ti})[\mathrm{M}]^2R_p^2 + R_0(k_p^2/k_t)[\mathrm{M}]^2R_p - (k_ik_p/k_{ti})(k_p^2/k_t)R_0[\mathrm{M}]^4=0 \quad (1)$$

which is obtained after the usual stationary state treatment for primary and polymer radicals, by introducing several approximations finally arriving at an equation of the form

$$R_p/[\mathrm{M}][\mathrm{I}]^{0.5} = A - A^2B([\mathrm{I}]^{0.5}/[\mathrm{M}]) \quad (2)$$

where

$$A = k_p\{2(1-h)k_d/k_t\}^{0.5} \text{ and } B = k_{ti}/k_ik_p$$

which should allow an evaluation of the ratio $k_{ti}/k_ik_p(\equiv B)$ characteristic for the termination of the growing polymer radicals by the specific primary radicals by plotting $R_p/[\mathrm{M}][\mathrm{I}]^{0.5}$ *vs.* $[\mathrm{I}]^{0.5}/[\mathrm{M}]$ and dividing the (absolute value of the) slope by the squared intercept.

However, as had apparently escaped the notice of Ito and Matsuda, in 1965 an article had already appeared[3] in which the cubic equation (1) had been simplified on similar lines to yield another linear relationship

$$R_p/[\mathrm{M}][\mathrm{I}]^{0.5} = A - AB(R_p/[\mathrm{M}]^2) \quad (3)$$

A and B being defined identically as before. In this case which also does not require the knowledge of either k_p^2/k_t or $2(1-h)k_d$, the characteristic ratio $k_{ti}/k_ik_p(\equiv B)$ is easily calculated by dividing the absolute slope by the intercept after a plot of $R_p/[\mathrm{M}][\mathrm{I}]^{0.5}$ *vs.* $R_p/[\mathrm{M}]^2$ has been made. This method has been successfully applied to the polymerization of styrene initiated by 2,2′-azobisisobutyronitrile (AIBN) using results of Henrici-Olivé and Olivé[4] and Olaj[3] and later on also to the polymerization of styrene initiated by 1,1′-azobis-1-phenylethane and 1,1′-azobis-1-cyanocyclohexane[5] and the superiority of estimating k_{ti}/k_ik_p from rate measurements over all other methods existing at that time thoroughly discussed.[3] Although the rate of polymerization had been varied over a wide range, perfectly linear plots have been obtained within experimental accuracy.[3,5] This is in marked contrast to two of the three examples given by Ito and Matsuda[1] where strong deviations from linearity occur when experimental data are plotted according to their equation (Eq. (2)). The reason for this is that Eq. (3), which in the meantime also has been acknowledged and accepted by other workers,[6] is a clearly better approximation to the

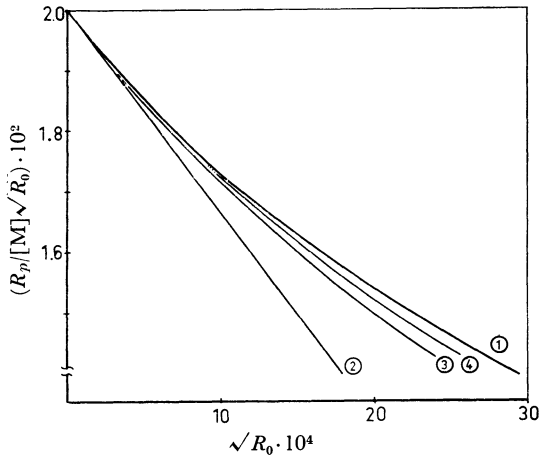

Fig. 1. $R_p/[M]R_0^{0.5}$ ($mol^{-1/2}\ l^{1/2}\ sec^{-1/2}$) calculated from given $R_0^{0.5}$ ($mol^{1/2}\ l^{-1/2}\ sec^{-1/2}$) values according to the (exact) Eq. (1) (curve 1, plot 1), Eq. (2) (curve 2), Eq. (3) (curve 3), and Eq. (4) (curve 4), plotted *vs.* $R_0^{0.5}$.
$k_ik_p/k_{ti}=1.4\times10^{-4}\ l\ mol^{-1}\cdot sec^{-1}$
$k_p^2/k_t=4.10^{-4}\ l\ mol^{-1}\cdot sec^{-1}$, $[M]=8.5\ mol\ l^{-1}$

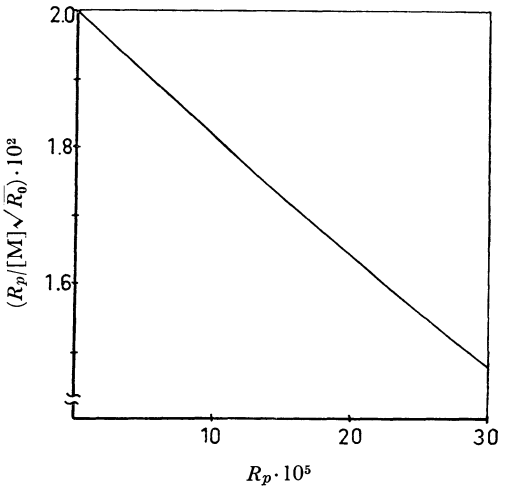

Fig. 2. $R_p/[M]R_0^{0.5}$ ($mol^{-1/2}\ l^{1/2}\ sec^{-1/2}$) calculated according to Eq. (1) and plotted *vs.* R_p ($mol\cdot l^{-1}\ sec^{-1}$) (plot 2).
(k_ik_t/k_{ti}, k_p^2/k_t, and [M] as in Fig. 1)

exact Eq. (1) than the Ito-Matsuda equation, Eq. (2). This will be shown in the following discussion.

In order to avoid ambiguity from experimental uncertainties let us assume a theoretical system with $k_p^2/k_t=4.10^{-4}\ l\ mol^{-1}\cdot sec^{-1}$, $k_ik_p/k_{ti}=1.4\times10^{-5} l\cdot mol^{-1}\cdot sec^{-1}$, and $[M]=8.5\ mol\ l^{-1}$ (for convenience a constant monomer concentration independent of the initiator concentration is used) which approximately corresponds to the system styrene - AIBN at 50°C. Let us further take a set of $R_p/[M]R_0^{0.5}-R_0^{0.5}$ pairs from the exact Eq. (1). On the other hand we use the same $R_0^{0.5}$ values and calculate the approximate $R_p/[M]R_0^{0.5}$ values according to Eqs. (2) and (3) (Table 1, columns 4 and 5). It can be easily seen from Fig. 1 that the latter (curve 3) deviate by far less from the exact values (curve 1) than Ito and Matsuda's values (curve 2). At a rate of initiation where $R_p/[M]R_0^{0.5}$ is reduced by 10% compared to its value at zero rate of initiation the deviation from the true values is *ca.* 0.45% for Olaj's equation while it amounts to *ca.* 1.65% for Eq. (2), at a 25% reduction of $R_p/[M]R_0^{0.5}$ the deviations are 3.2 and 18%, respectively.

The superiority of Eq. (3) over Eq. (2) can be demonstrated even more clearly in another way. Let us again take the true values from Table 1 and plot them according to the Eqs. (2) *vs.* $R_0^{0.5}$ (Fig. 1, curve 1) and (3) *vs.* R_p (Fig. 2). It appears from first sight that the latter plot (plot 2) is nearly linear, while Ito and Matsuda's plot (plot 1) shows a considerable curvature. Due to the small variation of $R_p/[M]R_0^{0.5}$ with R_p or $R_0^{0.5}$, respectively, the slope as the critical quantity will be comparatively sensitive to experimental error, and a least square treatment of the experimental data is often necessary. Such a treatment, however, will lead to erroneous results even from the theoretical point of view if the (theoretical) linearity of the plot is not warranted to a satisfying degree. On the other hand this difficulty is only partially circumvented if in the awareness of the limited theoretical linearity of the plot data only from low polymerization or initiation rates are used as the slope and therefore the value for k_{ti}/k_ik_p obtained in this way will be subject to considerable error due to the inevitable scatter of the experimental results. The difference between plot 1 and plot 2 becomes evident when the least square treatment is applied to the first six points in Table 1 to obtain the best slope and intercept: while plot 1 (Ito and Matsuda) gives a value of 5.04×10^4 (mol sec l^{-1}) for k_{ti}/k_ik_p which deviates by nearly 30% from the theoretical value (7.143×10^4) the value obtained from plot 2 (Olaj) is correct within 10% (6.44×10^4) which in most cases is less than the experimental uncertainty.

Mathematically the superiority of Eq. (3) over Eq. (2) can be explained as follows: When $R_p/A[M][I]^{0.5}(\equiv y)$ is expanded into a series of powers of $R_p\cdot B/[M]^2(\equiv x)$ the exact Eq. (1) will be written as

$$y = 1 - x + \frac{1}{2}x^2 - \frac{1}{2}x^3\cdots \qquad (1a)$$

Ito and Matsuda's Eq. (2) will take the form

$$y = 1 - x - x^2 - \frac{1}{2}x^3\cdots \qquad (2a)$$

while Eq. (3) will give the simple expression

$$y = 1 - x$$

Whereas the second term is represented correctly by both equations, the deviation from Eq. (1a) in the quadratic term is by far less in Eq. (3a) ($-\frac{1}{2}x^2$) than in Eq. (2a) ($-\frac{3}{2}x^2$). Furthermore Eq. (3a)

profits from a partial compensation of the deviations in the quadratic and the cubic term.

Following these considerations even further improvements in deriving a linear relationship as an approximation for Eq. (1) are possible,*1 *e. g.* adding $1/4x^2$ to the right hand side of Eq. (3a) and extracting the square root yields

$$y^{1/2} = 1 - \frac{1}{2}x$$

or as a full expression

$$(R_p/[\mathrm{M}][\mathrm{I}]^{0.5})^{0.5} = A^{0.5} - \frac{1}{2}A^{0.5}B(R_p/[\mathrm{M}]^2) \quad (4)$$

Therefore a plot of $(R_p/[\mathrm{M}][\mathrm{I}]^{0.5})^{0.5}$ *vs.* $R_p[\mathrm{M}]^2$ will give a nearly optimal linear representation of the experimental data provided they obey the kinetic scheme outlined above. From this plot B ($\equiv k_{ti}/k_i k_p$) will be available from a division of double the absolute value of the slope by the intercept, again the knowledge of k_p^2/k_t and $2(1-h)k_d$ being not necessary. $R_p/[\mathrm{M}][\mathrm{I}]^{0.5}$ values calculated according to Eq. (4) using the same kinetic parameters as before are summarized for comparison to the true values in the last column of Table 1 and plotted *vs.* $R_0^{0.5}$ (Fig. 1, curve 4). It can be seen that the deviations are reduced to 0.22 and 1.5% at a rate corresponding to an approximately 10 and 25% reduction of $R_p[\mathrm{M}][\mathrm{I}]^{0.5}$ compared to its value extrapolated to zero polymerization rate, respectively. From these examples it will appear that the fit to the theoretical curve is improved by one order of magnitude compared to the equation derived by Ito and Matsuda.[1] Using the same six $R_p-[\mathrm{I}]^{0.5}$ pairs as before the least square treatment yields a $k_{ti}/k_i k_p$ value which differs from the theoretical one by only 4.2%. This is better by a factor of 7 compared to the result obtained by application of Eq. (2) (plot 1).

After all, there will be no need to analyze primary radical termination using the method proposed by Ito and Matsuda[1] as there exist more accurate procedures which are at least as easily performed.

*1 A comprehensive survey on these improvements will be given in a separate paper.[7]

Pyrolysis of the Grignard Reaction Products of Benzenesulfonyl Azide*1

Suketaka Ito, Takashi Hirabayashi and Kiyoaki Matsumoto

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano

(Received January 20, 1970)

Several reports have appeared concerning the reactions of arenesulfonyl azides with carbanionic or organometallic reagents.[1-7] In a previous paper,[8] we ourselves reported the preparation of phenyl azide by the pyrolysis of the triazene salt obtained from benzenesulfonyl azide and phenylmagnesium bromide.[9]

This note will describe the formation of azides, diazo-compounds, and olefins by the reaction of benzenesulfonyl azide and aliphatic Grignard reagents, or by the pyrolysis of the triazene salts resulting from the reactions.

Results and Discussion

When benzylmagnesium chloride in ether was added to the ethereal solution of benzenesulfonyl azide at −20—−10°C, a triazene salt (white pre-

Table 1. The azides, the diazoalkanes, and the olefins obtained by the reaction of Grignard reagents with benzenesulfonyl azide

Grignard reagent	Azide (Yield, %)	Diazoalkane (Yield, %)	Olefin (Yield, %)
Benzylmagnesium chloride	Benzyl Azide (7.9)	Phenyldiazomethane (0.5)	——
Benzylmagnesium chloride*	Benzyl Azide (9.1)	Phenyldiazomethane (14.1)	——
Allylmagnesium chloride	Allyl Azide (13.1)	Vinyldiazomethane (—)**	——
Methylmagnesium iodide	Methyl Azide (—)	Diazomethane (1.5)	——
n-Hexylmagnesium bromide	*n*-Hexyl Azide (trace)	Diazo-*n*-hexane (trace)	1- plus 2-Hexene (11.2)
Cyclohexylmagnesium chloride	Cyclohexyl Azide (1.6)	Diazocyclohexane (0.9)	Cyclohexene (22.3)
t-Butylmagnesium chloride	*t*-Butyl Azide (2.7)	——	Isobutylene (3.1)

* Reaction in THF.

** Red-color development in the reaction of allylmagnesium chloride showed also the formation of vinyldiazomethane, though it could not be confirmed.

cipitates) and phenyldiazomethane (0.5%) were obtained in the ether solution. Benzyl azide (7.9%) was obtained in a cold trap by the vacuum pyrolysis of the triazene salt; the additional formation of a trace of *o*-tolyl azide was confirmed by gas-liquid chromatography.

When tetrahydrofuran (THF) was used as the solvent of sulfonyl azide in the reaction of benzylmagnesium chloride, no precipitates were formed and the yield of phenyldiazomethane was considerably increased (14.1%). In this case, white precipitates could be obtained after the removal of the greater part of the THF, followed by the addition of ether. Benzenesulfinic acid and benzenesulfonamide were isolated from the residue of the pyrolysis of the precipitates.

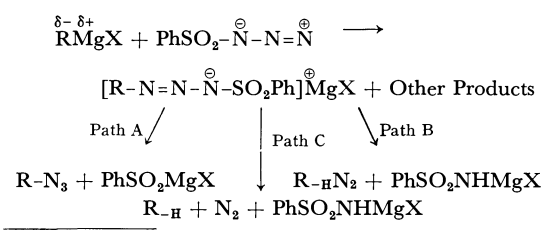
The major product of the pyrolysis of the triazene salt from cyclohexylmagnesium chloride was cyclohexene.

Upon the addition of *t*-butylmagnesium chloride to the ethereal solution of sulfonyl azide, *t*-butyl azide and isobutylene were generated in the solution almost immediately; the azide and the olefin could not be obtained by the pyrolysis of the solid part of the reaction mixture.

The reaction of vinylmagnesium bromide in THF with sulfonyl azide was also attempted, but it did not give any vinyl azide.[10]

The Grignard reagents, the azides, the diazoalkanes, and the olefins obtained are summarized in Table 1. The low yields of these products are probably due to their high volatility or law stability, and also to the complexity of the reaction.

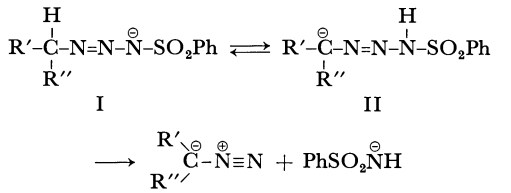
The reaction of aliphatic Grignard reagents with benzenesulfonyl azide can be illustrated as follows:



10) Nitrogen evolved and a certain polymer formed.

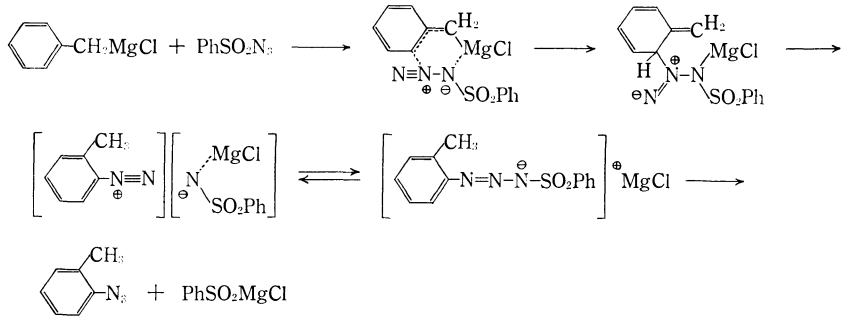
When the alkyl group of RMgX has no hydrogen atom in the α- and β-positions which can be eliminated, the reaction may proceed through Path A, which involves the α-elimination of the salt of sulfinic acid. On the other hand, when the alkyl group has such a hydrogen atom in the α-position, the reaction can proceed through both Paths A and B, the latter of which involves the elimination of the salt of sulfonamide.

In the reaction of benzylmagnesium chloride under the conditions of pyrolysis, no diazoalkane was obtained from the salt of triazene. However, when the triazene salt was not well dried, pyrolysis gave the benzyl azide, accompanied by a small amount of phenyldiazomethane. Furthermore, as has already been mentioned, the use of THF as the solvent in the Grignard reaction considerably increased the yield of phenyldiazomethane in the solution. Therefore, diazoalkane does not result directly from the triazene salt (I), but may be generated from a carbanion-type intermediate (II), which is itself derived from I in solution through proton transfer:



If the alkyl group has a structure in which the negative charge of the α-carbon is delocalizable by resonance, or if the R′ and/or R″ are electron-attractive groups, I can probably isomerize to II with ease, in which case the yield of the diazoalkane may increase.

The alkyl groups of cyclohexyl- and *n*-hexylmagnesium halide have eliminatable hydrogen atoms in the α- and β-positions respectively, so, in these cases, the reaction can proceed through Path A, B, or C. From the facts that 2-hexene and isobutylene were obtained, and that olefins are the major products in these types of reactions, the olefins must have been yielded through carbonium-ion



intermediates directly derived from the triazene salts.

The formation of *o*-tolyl azide can be explained by a mechanism similar to the cyclic six-membered transition state which was postulated in the reaction of benzylmagnesium chloride with formaldehyde to give 2-methylbenzyl alcohol.[11]

Experimental

Only the reaction of benzylmagnesium chloride will be described. The melting points are uncorrected. The yields of the final products are shown in percentages based on the benzenesulfonyl azide used.

The Reaction of Benzylmagnesium Chloride with Benzenesulfonyl Azide (BSA) in Diethyl Ether. Into a stirred solution of 9.2 g (0.05 mol) of BSA in 80 m*l* of dry ether, was added a solution of benzylmagnesium chloride (prepared from 7.6 g (0.06 mol) of benzyl chloride) in 70 m*l* of ether at −20—−10°C over a period of 45 min; whereupon white precipitates separated simultaneously, and the reaction mixture turned slightly red. The mixture was then separated by filtration into a reddish ether solution and a white solid (A), which was then washed with ether and dried in a vacuum desiccator. The yield of A was 16.5 g.

Upon the addition of a few drops of acetic acid, the red color of the combined filtrate and washings disappeared with an evolution of nitrogen. The ether solution, after being washed with a 5% sodium carbonate solution and then with water, and after being dried over anhydrous sodium sulfate, was concentrated to give 1.4 g of an oily residue.

By means of gas-liquid chromatography (GLC), benzyl acetate (0.5%) was found in the oily residue, which mainly consisted of unaltered BSA and benzyl chloride.

In a 200-m*l* round-bottomed flask, 16.5 g of the powdered solid (A) was placed; the flask was then connected to a series of traps and a vacuum system. The flask was heated to 40°C (oil bath temp.) (0.1 mmHg) to effect sufficient drying, and then to 120—130°C (oil bath temp.) (0.1—3.0 mmHg) in an oil bath for an hour. A colorless liquid (B) (1.57 g) was condensed at −70°C (trap temp.); from this liquid benzyl azide and *o*-tolyl azide were confirmed by means of GLC (7.9% and 0.1% respectively). The reaction of acetylenedicarboxylic acid with the colorless liquid (B) gave white granules with a mp of 183.0—184.0°C (lit,[12] 183°C for 1-benzyl-1,2,3-triazole-4,5-dicarboxylic acid). No depression of the melting point was observed on admixture with an authentic specimen of 1-benzyl-1,2,3-triazole-4,5-dicarboxylic acid.

The residue of the pyrolysis was treated with hydrochloric acid to give 3.5 g of benzenesulfinic acid, from which phenyl benzyl sulfone was then derived; mp 147.0—148.0°C (lit,[13] mp 148°C). No depression of the melting point was observed on admixture with an authentic sample.

The Reaction of Benzylmagnesium Chloride with BSA in THF. The Grignard reagent prepared from 7.6 g of benzyl chloride was allowed to react with 9.2 g of BSA in 80 m*l* of THF in the same manner as the reaction in ether. No precipitates were formed, and a homogeneous red solution was obtained.

After the greater part of the solvent had been removed from the reaction mixture *in vacuo* at 10°C, there were separated white precipitates upon the addition of each 60-m*l* portion of petroleum ether and diethyl ether. After being separated from the reaction mixture, the solid part (17.5 g) was pyrolyzed to give benzyl azide (9.1%) and *o*-tolyl azide (0.1%). From the ethereal-solution part of the reaction mixture, the amount of phenyldiazomethane (14.1%) was determined.

Benzenesulfinic acid (0.82 g, 11.6%) and benzenesulfonamide (3.1 g, 39.2%), mp 150.0—151.0°C (lit,[14] mp 153°C) were obtained from the residue of the pyrolysis of the solid part.

No depression of the melting point of the benzenesulfonamide thus obtained was observed on admixture with an authentic sample.

Studies of Hydrazine Derivatives. I. A Convenient Method of Preparing Chloroacetylhydrazones*1

Suketaka Ito and Toshiaki Narusawa*2

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano

(Received January 27, 1970)

Although chloroacetylhydrazones are expected to be useful for synthetic purposes, only those of benzaldehyde[1,2] and of *m*-nitro- and *o*-hydroxy-benzaldehyde[1] have been reported in the literature.

Talik and Plazek[1] prepared benzaldehyde chloroacetylhydrazone by the chloroacetylation of benzaldehyde hydrazone with chloroacetyl chloride; it was also obtained by Buyle[2] from benzaldehyde and chloroacetohydrazide hydrochloride, which had been prepared from hydrazine and *p*-nitrophenyl

Table 1. Yields and melting points of chloroctylhydrazones

Original carbonyl compound	Yield (%)	Solvent for recrystallization	Melting point (°C)[a]	Crystal form
Benzaldehyde	84	Methanol	165.5—166.5 (dec.)[b]	colorless fine needles
Acetophenone	81	Methanol	137.5—138.5	colorless long needles
Benzophenone	83	Methanol	105.5—106.5	colorless prisms
Furfural	77	Methanol	151.0—152.0 (dec.)	almost colorless columns
d-Camphor	60	Methanol	189.0—190.0	colorless needles
Cyclohexanone	69	Methanol	114.0—115.0	cololress plates
Cyclopentanone	62	Methanol	123.5—124.5	colorless prisms
Pinacolone	67	Methanol	94.5— 95.5	colorless needles
Ethyl methyl ketone	72	*n*-Hexane	76.0— 77.0	colorless prisms
Acetone	53	Benzene	96.0— 97.0	colorless prisms
Acetaldehyde	73	Benzene	109.0—110.0	colorless fine plates

a) All melting points were determined in capillary, and are uncorrected.
b) Reported mp: 164°C,[1] 166°C.[2]

Table 2. Analytical data of chloroacetylhydrazones

Original carbonyl compound	Molecular weight[a,c]	Elemental analysis[b,c]		
		C%	H%	N%
Benzaldehyde	197 (197)	55.15 (54.97)	4.67 (4.61)	14.31 (14.25)
Acetophenone	218 (211)	57.07 (57.02)	5.32 (5.26)	13.39 (13.30)
Benzophenone	283 (273)	65.77 (66.06)	4.81 (4.80)	10.18 (10.27)
Furfural	174 (187)	44.99 (45.06)	3.76 (3.78)	14.88 (15.01)
d-Camphor	241 (243)	60.53 (59.38)	8.06 (7.89)	11.67 (11.54)
Cyclohexanone	224 (189)	50.84 (50.93)	7.01 (6.95)	14.78 (14.85)
Cyclopentanone	178 (175)	48.43 (48.15)	6.43 (6.35)	16.05 (16.04)
Pinacolone	203 (191)	50.70 (50.39)	8.06 (7.93)	15.09 (14.69)
Ethyl methyl ketone	157 (163)	43.94 (44.32)	6.92 (6.82)	17.03 (17.23)
Acetone	165 (149)	40.62 (40.42)	6.19 (6.11)	19.01 (18.55)
Acetaldehyde	151 (135)	35.59 (35.70)	5.22 (5.24)	20.64 (20.82)

a) A Takara Twin-type Ebulliometer Model L4 was used for the molecular weight measurement.
b) A Perkin-Elmer Elemental Analyzer Model 240 was employed for the micro-analysis.
c) Figures in parentheses are calcd values.

chloroacetate. Kupcik and others[3] reported a method for the preparation of chloroacetohydrazide and its hydrochloride from hydrazine hydrate and methyl chloroacetate.

The method of Talik and Płażek[1] is not general, but is limited in its application to carbonyl compounds that can easily give hydrazones. Buyle's method,[2] though universally applicable, is complicated and expensive. The present authors attempted to prepare chloroacetohydrazide and its hydrochloride by the method of Kupcik and others,[3] but a considerable evolution of nitrogen was observed at the reported reaction temperature (25°C) and the expected hydrazide could not be obtained even at a low reaction temperature (−25°C).

An alternative method for the preparation of chloroacetylhydrazones was devised. It consists of the previous preparation of a chloroacetohydrazide solution by the reaction of ethyl or methyl chloroacetate with 80—90% hydrazine hydrate in methanol at −30——40°C and the addition of an equimolar amount of aldehyde or ketone to the solution, without any isolation of the chloroacetohydrazide. By this simple and convenient procedure, several chloroacetylhydrazones were obtained with a higher purity and in satisfactory yields (see Tables 1 and 2).

The IR spectra of these chloroacetylhydrazones show absorptions at 3260—3350 (γ_{NH}) and 1690—1700 cm^{-1} (γ_{CO}).

Each of the NMR spectra (1—2% in CCl_4 or $CDCl_3$) shows a singlet assigned to the methylene protons of the $ClCH_2CO$- group at about 5.5 ppm (τ value) and a proton signals of the –NH– group (broad singlet) at 0—1.5 ppm (τ value).

Chloroacetylhydrazones of acetophenone and benzophenone were also synthesized by Talik and Płażek's method[1] and confirmed to be identical with those prepared by the present method.

The study of the syn-anti isomerism and tautomerism of the chloroacetylhydrazones by means of NMR analysis is now in progress.

Experimental

General Procedure. Into a stirred solution of 0.5 mol of ethyl or methyl chloroacetate (61 or 54 g) in 75 ml[4] of methanol, was added 0.5 mol (30 g) of 85% hydrazine hydrate over a period of 20—30 min at −30——40°C. After the addition was completed, the temperature of the reaction mixture was allowed to rise slowly to 0—10°C while the mixture was being stirred for an additional hour.

To this solution, was then added 0.5 mol of a carbonyl compound[5] with external cooling at such a rate that the temperature of the reaction mixture did not rise over 10°C.[6] Crystalline precipitates appeared almost immediately or after a while, so it was necessary to continue the cooling. After the reaction was over, the precipitates were collected by filtration. Washing with methanol,[7] followed by drying under a vacuum, gave fairly-pure chloroacetylhydrazone.

Further purification of the product was achieved by recrystallization from an appropriate solvent.

3) F. Kupcik, M. Liska and M. Konupcik, *Czech.*, 101955 (1961); *Chem. Abstr.*, **60**, 1606a (1964).

4) As the chloroacetylhydrazones of aliphatic carbonyl compounds are fairly soluble in methanol, it was necessary to change the quantity of the solvent as follows:

Carbonyl compound	Quantity of methanol (m*l*)
Benzaldehyde, acetophenone, and furfural	125
Benzophenone and cyclohexanone	75
Cyclopentanone, *d*-camphor, and acetaldehyde	50
Pinacolone, ethyl methyl ketone, and acetone	35

5) When it was solid, it was dissolved in a small quantity of methanol.

6) In the reaction of benzaldehyde or furfural, it was necessary to cool the reaction mixture below −30°C.

7) For aliphatic carbonyl compounds, the procedure was modified as follows. After the addition of the carbonyl compound, the reaction mixture was kept at −20——30°C for 2—3 hr, and then filtered. The resulting solid were washed with a small amount of cold methanol diluted with water (−20——30°C, 50%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2259—2261 (1970)

Solution Equilibria between the Nickel(II) Ion and the Ethylenediaminetetrepropionate Ion and the Substitution Kinetics of the Nickel(II)-Ethylenediaminetetrapropionate Complex with Cyclohexane-1,2-*N*,*N*,*N*′,*N*′,-tetraacetic Acid (CyDTA)

Mutsuo KODAMA

Department of Chemistry, Ibaraki University, Bunkyo, Mito, Ibaraki

(Received January 21, 1970)

In the polarographic determination of solution equilibria between ethylenediaminetetrapropionic acid (EDTP) and the cadmium(II) ion,[1] we have previously mentioned that the cadmium(II) ion can form 1 : 1 as well as 1 : 2 complexes with EDTP. The nickel(II) ion in the EDTP solution gives an absorption curve with two maxima at around 375 and 600 mμ. With an increase in both the pH value and the EDTP concentration, the absorbance increases remarkably and the absorption maxima shift to shorter wavelengths. These facts can be interpreted as resulting from the formation of the 1 : 2 nickel(II)-EDTP complex. Furthermore, the nickel(II) ion in solutions containing an excess amount of EDTP has been found to react with CyDTA at a measurable rate. In this paper, the author will attempt to estimate the second successive formation constant of the nickel(II)-EDTP complex by determining the change in the absorbance with an increase in the pH, and to analyze polarographically the kinetics of the nucleophilic substitution reaction between the nickel(II)-EDTP complex and CyDTA. He hopes to show that, by analyzing the formation of the 1 : 2 nickel(II)-EDTP complex, we can understand the kinetic behavior of the nickel(II)-EDTP complex in a substitution reaction.

Experimental

Reagents. The preparation of a standard nickel(II) nitrate solution had been described in a previous paper.[2] The EDTP and CyDTA were recrystallized twice from their aqueous solutions by adding an appropriate amount of pure ethanol. The other chemicals were of analytical reagent grades and were used without further purification.[2,3]

Apparatus and Experimental Procedures. All the apparatus (the penrecording spectrophotometer and polarograph, and the dropping-mercury electrode(DME) and the experimental procedures used in this study have been described previously.[2,3] The rate of the substitution reaction was determined by measuring changgs over a period of time in the diffusion current due to the presence of uncomplexed CyDTA. In this study, all the measurements were carried out in solutions with an ionic strength of 0.30 ($NaClO_4$) at 25°C. Kinetic measurements were conducted in solutions containing excess amounts of complexed and uncomplexed EDTP over CyDTA in the pH range from 8.50 to 9.50. Therefore, no buffer reagent is needed to keep the pH constant, and the substitution reaction can be treated as a pseudo first-order reaction.

Results and Discussion

Spectrophotometric Determination of Solution Equilibria between the Nickel(II) Ion and the Ethylenediaminetetrapropionate Anion. From observing the magnitude of both the stability constant of a 1 : 1 nickel(II)-EDTP complex and the pK values of EDTP,[4] it can safely be concluded that the complexation reaction of the nickel(II) ion in 10 mM EDTP solutions with pH's higher than 5.0 proceeds completely. As has been reported previously,[5] the nickel(II) ion in the EDTP solution gives an absorption curve with two maxima, at 375 and 600 mμ. By increasing the solution's pH value and the concentration of the uncomplexed EDTP, the absorbance in the visible region was increased remarkably and both the maxima shifted to shorter wavelengths. This fact may be interpreted as resulting from the formation of the 1 : 2 nickel(II)-EDTP complex. As has been discussed in a previous paper,[6] if the nickel(II) ion forms 1 : 1 as well as 1 : 2 complexes with EDTP, the following relation can be applied to the present system:

$$\log \frac{K_2}{(\alpha_H)_X} = \log \frac{A - A_{NiX}}{A_{NiX_2} - A} \times \frac{1}{\left([X]_t - 2\cdot[Ni]_t + \dfrac{A_{NiX} - A}{\varepsilon_{NiX} - \varepsilon_{NiX_2}}\right)} \quad (1)$$

where:

K_2 = the second successive formation constant of the nickel(II)-EDTP complex

$$(\alpha_H)_X = 1 + \frac{[H^+]}{K_4} + \frac{[H^+]^2}{K_4 \cdot K_3} + \frac{[H^+]^3}{K_4 \cdot K_3 \cdot K_2} + \frac{[H^+]^4}{K_4 \cdot K_3 \cdot K_2 \cdot K_1},$$

K's = dissociation constants of EDTP,

$[X]_t$ = the total concentration of EDTP,

$[Ni]_t$ = the total concentration of the nickel(II) ion,

A_{NiX_2} = the absorbance for the solution where all the nickel(II) ions exist in the form of NiX_2^{6-},

A_{NiX} = the absorbance for the solution where all the nickel(II) ions exist in the form of NiX^{2-},

A = the absorbance of each of the solutions ($= \varepsilon_{NiX}[NiX^{2-}] + \varepsilon_{NiX_2}[NiX_2^{6-}]$),

ε's = the molar extinction coefficients.

The molar extinction coefficient for the 1 : 2 complex, ε_{NiX_2}, is much larger than that for the 1 : 1 complex, ε_{NiX}. This fact clearly shows that the EDTP anions in the 1 : 2 complex are coordinated to the nickel(II) ion through nitrogen. Equation (1) suggests that the plot of the right-hand side against log $(\alpha_H)_X$ will give a straight line with a slope of -1.0 and that the log $(\alpha_H)_X$ value at log $[(A-A_{NiX})/[(A_{NiX_2}-A)([X]_t-2[Ni]_t+(A_{NiX}-A)/(\varepsilon_{NiX_2}-\varepsilon_{NiX}))]]$ = zero can be equated with the log K_2 value. By means of this equation, the experimental data were analyzed successfully. The results are given in Fig. 1. From the intercept of the straight line, the log K_2 value was estimated to be 3.5_2.

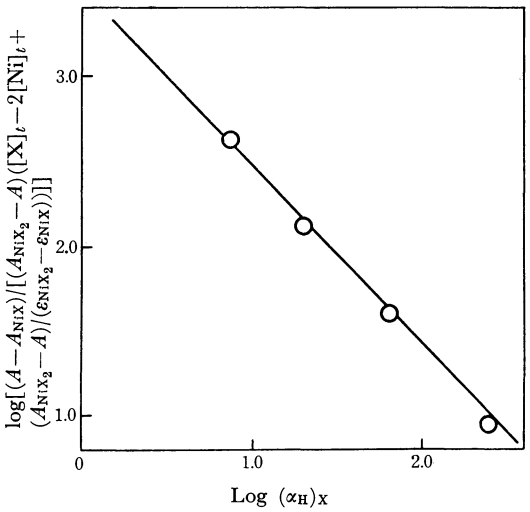

Fig. 1. The plot of $\log[(A-A_{NiX})/[(A_{NiX_2}-A)([X]_t-2[Ni]_t+(A_{NiX_2}-A)/(\varepsilon_{NiX_2}-\varepsilon_{NiX}))]]$ against log $(\alpha_H)_X$.

The Kinetic Study of the Substitution Reaction of the Nickel(II)-EDTP Complex with CyDTA. The CyDTA anion can displace the EDTP anion from its nickel(II) complex at a measurable rate. The present substitution reaction showed just the same kinetic behavior as that observed in the reaction of the nickel(II)-nitrilotriacetate complex with diethylenetriaminepentaacetic acid (DTPA).[2] The plot of log (i_0/i_t) against the time, t, invariably gave a straight line passing through the point of origin. Here, i_0 and i_t denote the wave heights of CyDTA at time $t=0$ and $t=t$ respectively. The slope of the above log-plot was independent of the initial concentration of CyDTA and was not influenced by the addition of the nickel(II)-CyDTA complex (the results are not shown). These facts clearly indicate that: (i) The rate of the backward reaction is negligibly small as compared with that of the forward reaction; (ii) the log-plot slope multiplied by 2.303 is equal to the apparent rate constant for the forward reaction, k_{ap}^+,[2] and (iii) the present reaction does not involve the dissociation of the nickel(II)-EDTP complex. In the solutions with constant pH's, the log-plot slope was exactly proportional to the concentration of the 1 : 1 complex, $[Ni]_t/(1+K_2\cdot[X]_f/(\alpha_H)_X)$ (Table 1). This means that the nickel(II) ion forms 1 : 1 as well as 1 : 2 complexes with an EDTP, and that the reaction proceeds exclusively through the 1 : 1 complex. Furthermore, provided that the other experimental conditions are kept constant, the product of the log-plot slope and $2.303\times(\alpha_H)_Z$

Table 1. The relation between the log-plot slope and the concentration of nickel(II)-DETP complex with a 1-to-1 composition
25°C, μ=0.30, pH=9.00
Initial cocentration of CyDTA=0.50 mM

Ni(II) ion concentration mM	EDTP concentration mM	Concentration of 1-to-1 ratio Ni(II)-EDTP complex, C_{NiX} mM	Log-plot slope, S sec^{-1}	S/C_{NiX}
5.00	35.0	1.87×10^{-1}	1.91×10^{-4}	1.02×10^{-3}
8.00	25.0	7.00×10^{-1}	7.00×10^{-4}	1.00×10^{-3}
10.00	40.0	4.38×10^{-1}	4.67×10^{-4}	1.07×10^{-3}
14.00	35.0	1.35	1.40×10^{-3}	1.04×10^{-3}

$(1+K_2\cdot[X]_f/(\alpha_H)_X)/[Ni]_t$ is a linear function of the hydrogen-ion concentration and can be given by:

$$\frac{k_{ap}^{+}\cdot(\alpha_H)_Z(1+K_2\cdot[X]_f/(\alpha_H)_X)}{[Ni]_t} = k_\alpha^{+} + k_\beta^{+}\cdot[H^+] \quad (2)$$

were $(\alpha_H)_Z$ is the (α_H) value of CyDTA. Therefore, the present reaction can be concluded to proceed through the following two simultaneous reaction pathways:

$$\text{i)}\quad NiX^{2-} + Z^{4-} \overset{k_1^+}{\rightleftharpoons} NiZ^{2-} + X^{4-}$$
$$\updownarrow \text{rapid}$$
$$NiX_2^{6-}$$

$$\text{ii)}\quad NiX^{2-} + HZ^{3-} \overset{k_2^+}{\rightleftharpoons} NiZ^{2-} + HX^{3-}$$
$$\updownarrow \text{rapid}$$
$$NiX_2^{6-}$$

where NiX_2^{6-} means the 1 : 2 nickel(II)-EDTP complex, and Z^{4-}, the completelydeprotonated CyDTA anion. Here, k_1^+ can be equated with k_α^+ and k_2^+, with the product of k_β^+ and the fourth dissociation constant of CyDTA, k_4. As was discussed with reference to the reaction of the nickel(II)-nitrilotriacetate complex with DTPA,[2] the k_1^+ and k_2^+ values in the above reaction mechanism can be determined from the intercept and the slope respectively of the straight line in Fig. 2. The k_1^+ and k_2^+ values obtained are listed in Table 2, together with the K_2 value determined spectrophotometrically. In the kinetic study of the substitution reactions of the nickel(II)-aspartate complex with CyDTA and DTPA,[7] we have previously mentioned that the six-membered ring in the nickel(II)-aspartate complex is much more substitutionlabile than the five-membered ring. Generally, the nickel(II)-oxygen bond rupture is much faster than the nickel(II)-nitrogen bond rupture. Therefore, in the substitution reaction of the nickel(II)-EDTP complex, a reaction intermediate (activated complex) having a propionate group bonded to the nickel(II) ion seems unlikely. If the present reaction proceeds through a reaction intermediate similar to that of the reaction of the nickel(II)-ethylenediamine complex with CyDTA,[6] a comparison of the rate constants for the two elementary reactions, i) and ii), with those of the reaction of the nickel(II)-ethylenediamine complex is possible. On the basis of the reaction intermediate having two nitrogen groups of EDTP or of ethylenediamine bonded to the nickel(II) ion, the k_1^+ and k_2^+ ratios between the reactions of EDTP and ethylenediamine complexes can be estimated to be $1/53._6$. When the additional stability of the reaction intermediate due to the electrostatic attraction between the nickel(II) ion and the propionate group is taken into consideration, the rate constant ratios should be larger than $1/53._6$. The observed ratios for the two elementary reactions, i) and ii), were $1/3.3\times10^2$ and $1/1.1\times10^4$ respectively. This disagreement may imply that the reaction of the nickel(II)-EDTP complex proceeds through a reaction intermediate quite different from that of the nickel(II)-ethylenediamine complex or that, although both reactions have the same reaction intermediate, the electrostatic repulsion between the nickel(II)-EDTP complex anion and the CyDTA anion makes the reaction more sluggish.

^{14}N Nuclear Quadrupole Resonances of 2,2′- and 4,4′-Dipyridyls

Hisao NEGITA, Masataka HAYASHI, Tadashi HIRAKAWA and Hiromu KUWATA*1

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received February 4, 1970)

^{14}N nuclear quadrupole resonances have been observed in a number of nitrogen heterocyclic compounds, such as diazines[1] and s-triazine,[2] since Guibé found the resonance of pyridine[3] in 1960. The electronic structures of these compounds have been studied by Lucken[4] recently.

In this connection, it seemed that it would be interesting to study the ^{14}N nuclear quadrupole resonances of 2,2′- and 4,4′-dipyridyls, which are considered to be as fundamentally important as pyridine, diazines and s-triazine. When 2,2′-dipyridyl is used as a chelate reagent, it attaches a cation, itself keeping the *cis*-form, whereas it is known to exist as the *trans*-form in the crystal.[5]

Experimental

Two kinds of dipyridyls obtained from commercial sources were purified by recrystallization in organic solvents; about 10-g portions of the samples were used in the experiment. 2,2′-Dipyridyl was examined in the powder state, while 4,4′-dipyridyl was examined after having once been melted.

A frequency-modulated spectrometer of the Pound-Watkins type was used to detect the resonance signals, because large asymmetry parameters were expected in both dipyridyls.[6] For the frequency modulation, the bidirectional square wave of 140 Hz was fed to an SD-111 diode, which was connected in parallel to the tank circuit of the main oscillator.

Results and Discussion

The resonance frequencies, ν, the quadrupole coupling constants, e^2Qq, and the asymmetry parameters, η, are given in Table 1.

Since ^{14}N has a nuclear spin of unity, one can usually observe a pair of resonance frequencies, ν_{I} and ν_{II}, due to a species of nitrogen atoms as follows:

$$\nu_{\mathrm{I}} = e^2Qq\,(3-\eta)/4$$
$$\nu_{\mathrm{II}} = e^2Qq\,(3+\eta)/4 \qquad (1)$$

The numbers of the resonance lines of 2,2′- and 4,4′-dipyridyls are two and six respectively. Since the six lines of the latter compound are grouped into two sets of three lines each, as is shown in Fig. 1, it seems that there are three kinds of nonequivalent nitrogen atoms, each slightly different from the others. This situation, however, gives rise to the problem on the pairing of the six lines. It can be seen from Fig. 1 that the three lines on the higher-frequency side have different intensities, while those on the lower-frequency side are so weak as to be undistinguishable. Accordingly, it is difficult to

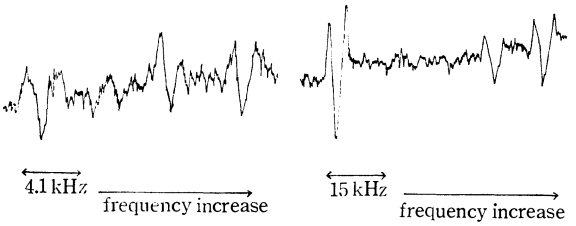

Fig. 1. ^{14}N nuclear quadrupole resonance absorption lines in 4,4′-dipyridyl.

determine which two are to be paired. The coupling constant and the asymmetry parameter of 4,4′-dipyridyl in Table 1 were derived from the two averaged values, $\nu_I(av)$ and $\nu_{II}(av)$, of three resonance frequencies grouped in the same sets.

The nitrogen atoms in dipyridyls are assumed to be in the sp^2-hybridized state and to have the maximum field gradient, q_Z, approximately in the direction of the bisector of the $\angle$CNC angle. The asymmetry parameter, η, is defined as $\eta=(q_x-q_y)/q_Z$ under the condition that $|q_y|>|q_x|$. In view of the ^{14}N nuclear quadrupole resonances of pyridine, hexamethylenetetramine, and γ-picoline,[7] it is preferable to choose the X- and Y-axes shown in Fig. 2.

From the bonding orbitals and the occupation numbers of these electrons, a, b_1, and b_2, at the nitrogen atom, the following expressions[4] are obtained:

$$U_p = [a+(b_1+b_2)/2]/2+[2-(b_1+b_2)/2]\cot^2\gamma - 2$$
$$\eta = -3[a-(b_1+b_2)/2]/(2U_p) \qquad (2)$$

7) E. A. C. Lucken, *Trans. Faraday Soc.*, **57**, 731 (1969).

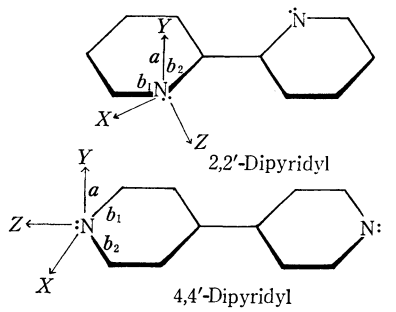

Fig. 2. Cartesian-coordinate systems at the nitrogen atoms of dipyridyls. a is the occupation number of π-orbital at the nitrogen atom, whereas b_1 and b_2 are those of σ-orbitals.

where $U_p=-e^2Qq_z/e^2Qq_p$. In Eq. (2) it is assumed that $2\gamma=\angle$CNC$=120°$ and that $e^2Qq_p=10$ MHz.

In 4,4′-dipyridyl, it is evident that $b_1=b_2=b$. Therefore, the values of a and b are calculated from e^2Qq and η. On the other hand, $b_1\neq b_2$ in 2,2′-dipyridyl; hence a, b_1, and b_2 cannot be calculated from Eq. (2). Therefore, the value of b in 2,2′-dipyridyl is obtained by averaging b_1 and b_2. As is shown in Table 1, the π- and σ- charge excesses in both dipyridyls are about 0.27 and 0.40 respectively, nearly equal to those of pyridine.

Simple LCAO MO calculations were carried out in order to compare the results with one another and also with those of NQR. The occupation numbers of the electrons calculated at the nitrogen atoms are almost all the same, as is to be expected from the experimental values, although calculated values are generally lower than experimental values. This discrepancy can be improved if a slightly smaller value than 10 MHz is adopted for e^2Qq_p.

Electrical Properties of the Platinum Anode in a Sodium Chloride Solution

Chiou-Chen Lu, Kazuo Fueki and Takashi Mukaibo

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received February 4, 1970)

In a previous paper[1] the present authors have shown that the anodic overpotential of chlorine evolution at the passivated platinum electrode is about 0.7 V higher than that of the activated electrode at the same current density. The purpose of the present investigation is to determine the electrical resistance, the double-layer capacitance, and the faradaic impedance of the platinum electrode in both active and passive states in a sodium chloride solution, in order to contribute to the elucidation of the passive state.

Experimental and Results

Electrolytic Cell. A platinum wire, 1 mm in diameter, was sealed in a glass tube and then cross-sectioned by grinding with emery paper. The smooth end of the platinum wire was used as the test electrode. The area of the test electrode was 0.008 cm^2. The reference electrode was a platinized platinum ring placed around the test electrode and worked as a reversible chlorine electrode. The counter electrode was a platinum plate of 8 cm^2. During the run, the solution was saturated with chlorine (1 atm).

TABLE 1. R_Ω, R_{soln} AND $R_{surface}$ ($\Omega \cdot cm^2$)

Temp. (°C)	R p	R a	R_{soln}	R p	R a
25	0.41	0.34	0.20	0.21	0.14
40	0.27	0.22	0.15	0.12	0.07
60	0.26	0.19	0.13	0.13	0.06
80	0.23	0.18	0.11	0.12	0.07

p : passivated electrode
a : activated electrode

The activation and passivation of the test electrode were carried out by polarizing it at −0.1 V (SCE) and 2.0 V (SCE) respectively.

Electrical Resistance. The galvanostatic transient method (current-interruptor method) was used for the measurements of the resistance and capacitance. A pulsed current was applied to the cell by means of an electrical switch. The rise time of the pulse was about 1 μs, and the potential decay from 2 to 6 μs after switching off was measured with a cathode-ray oscilloscope, the input impedance of which was 10^6 ohms. The steady-state potential before switching off was measured by means of a pen-recorder, the impedance of which was 10^6 ohms. The resistance polarization ($\eta_\Omega = \eta_{soln} + \eta_{surface}$) was determined by extrapolating the decay curves to $t=0$. An example of the plot of the resistance polarization *vs.* the current density

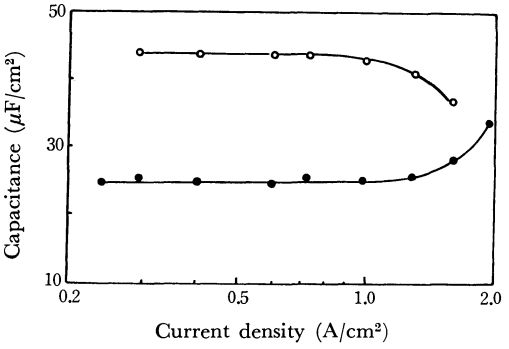

Fig. 2. Double layer capacitance of activated (○) and passivated (●) platinum electrode.
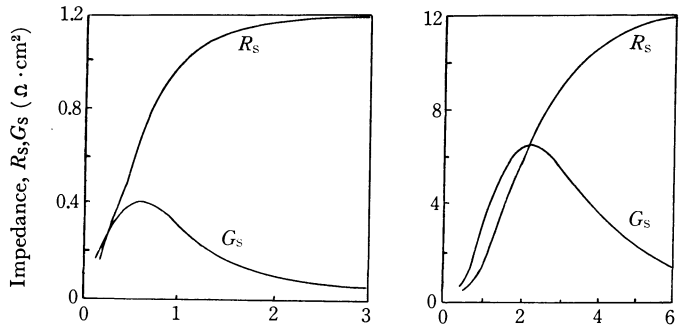
(NaCl 5M, pH 1, 25°C)



(a). Activated electrode (b). Passivated electrode

Fig. 3 (a), (b). Impedance of Pt electrode plotted against (frequency)$^{-1/2}$ in 5M solution, pH 1, 30°C.

is shown in Fig. 1. From the slope of the curves, the total resistance, R_Ω, was calculated.

For the determination of the $R_{surface}$, the test electrode was replaced by a platinized electrode of the same geometry and the R_{soln} was measured by means of an ac bridge. A preliminary experiment showed that the polarization and the resistance of the platinized platinum electrodes is negligibly small. From the values of R_Ω and R_{soln}, $R_{surface}$ was determined. The results are summarized in Table 1.

Double-layer Capacitance. The double-layer capacitance was estimated from the decay of the electrode potential by using the equation,

$$C = -I\mathrm{d}t/\mathrm{d}E$$

where I is the current density crossing the double layer during the decay period. In order to obtain the capacitance at $t=0$, the current density before switching off was taken as the value of I, $(\mathrm{d}t/\mathrm{d}E)_{t=0}$ was determined by extrapolating the values of $\mathrm{d}t/\mathrm{d}E$ at 2, 3, 4, 5, and 6 μs to $t=0$. The results are shown in Fig. 2. As may be seen from Fig. 2, the capacitance of the passivated electrode is about half that of the activated one.

Faradaic Impedance. The faradaic impedance was determined from Lissajous's figure on a cathode-ray oscilloscope. The input voltage was sine wave. Its amplitude was 3.5 mV, and its frequency was changed from 20 Hz to 30 kHz.

In Fig. 3, the ohmic component (R_s) and the capacitive component ($G_s = 1/\omega C_s$) of the electrode impedance (Z_f) are plotted against the frequency. From the shape of the curves, a surface reaction such as the recombination of chlorine atoms on the electrode is considered to be the rate-determining step.[2] The impedance of the passivated electrode was about ten times larger than that of the activated one.

Simultaneous Formation of Perylene Cation and Anion by Flash Excitation of Perylene in Solutions

Kiyoshi KAWAI, Naoto YAMAMOTO and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received February 12, 1970)

Formation of transient cations and anions from the electron donor-acceptor interactions in the excited states was confirmed by using the flash technique in polar solutions for the first time by Leonhardt and Weller[1] and recently by Koizumi and Yamashita[2] and by us.[3]

In this note, we report a simultaneous formation of positive and negative ions of perylene revealed by the flash technique.

An acetonitrile solution of perylene (8×10^{-5}M) was used as a sample solution. It was carefully de-aerated by the usual freeze-pump-thaw method, and placed in a quartz cylindrical cell, 1.5 cm in diameter and 20 cm in length. The instrument used for the flash illumination has been described elsewhere.[4] The electric energy of a flash was about 430 J. The profile of the flash is shown in Fig. 2. A concentrated aqueous solution of sodium nitrate was used as a filter solution, which absorbed the light in the region shorter than 340 mμ, so that the perylene was excited only in the region of its ^1L_a band.

Flash illumination of the sample through the filter solution gave a transient absorption spectrum consisting of two overlapping bands at 576 mμ and 538 mμ and two others near 490 mμ and 480 mμ

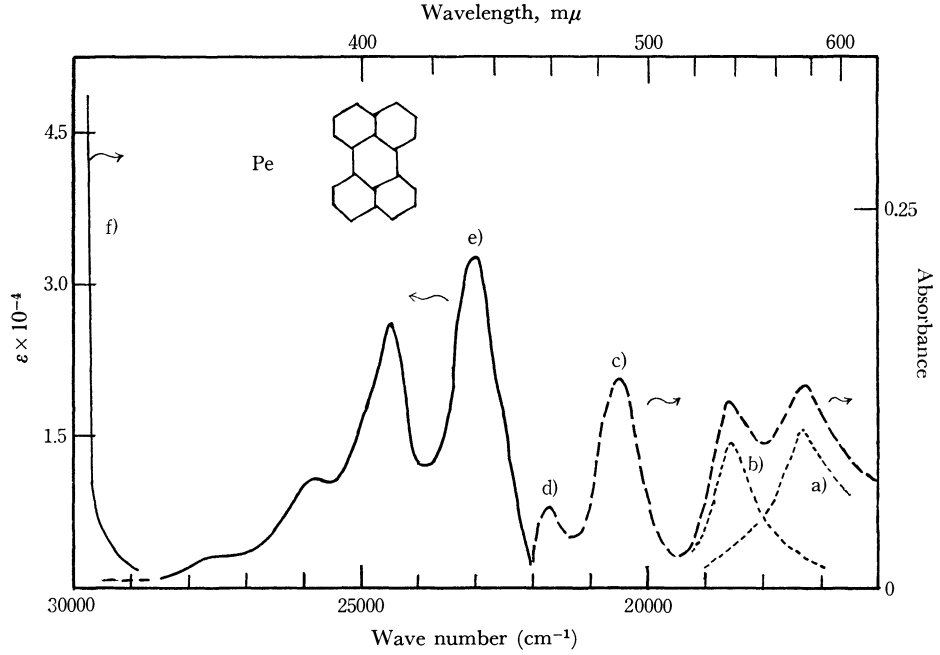

Fig. 1. Transient absorption spectrum caused by the flash illumination of perylene (8×10^{-5}M) in an acetonitrile solution. It was measured 10 μsec after illumination. Bands a) and b) correspond to perylene negative and positive ion respectively. Bands c) and d) indicate the T–T′ absorption of perylene. Spectrum e) indicates absorption of perylene in the ground state. Spectrum f) is that of the filter solution.

4) N. Yamamoto, Y. Nakato and H. Tsubomura, *ibid.*, **39**, 2603 (1966).

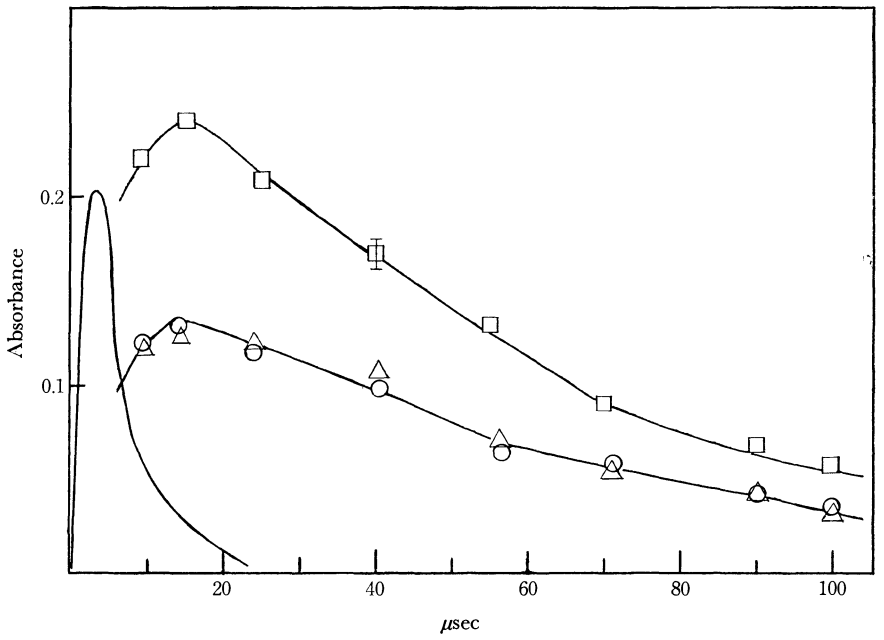

Fig. 2. The formation and decay curves of transient absorption spectra caused by flash illumination of acetonitrile solution of perylene.
-□-□- perylene in the triplet state.
-○-○- perylene anion
-△-△- perylene cation
——— flash profile.

(Fig. 1). Only two bands at 480 and 490 mμ appeared in the case where nonpolar solvents such as benzene or methylcyclohexane were used. When the acetonitrile solution of perylene was saturated with oxygen, the flash illumination of the solution resulted in the appearance of only the 538 mμ absorption band. From these results, it is highly probable that the 480—490 mμ bands are T−T′ absorption bands and the 576 mμ band is due to a negative ion.

The 576 mμ band may be ascribed to perylene mononegative ion, because it nearly agrees in position and shape with the spectrum of the perylene anion (λ_{max}: 581 mμ) formed by the action of sodium metal in a tetrahydrofuran solution.[5] The 538 mμ band is also attributed to the perylene cation, because it approximately agrees with the absorption peak at 543 mμ of perylene oxidized by antimony pentachloride in nitrobenzene.[6] The 490—480 mμ bands can be identified with the triplet-triplet absorption of perylene which Porter and Windsor found on flash illumination of perylene in solution.[7] The initial concentrations of perylene anion and cation formed at a flash energy of about 430 J was estimated to be about 2×10^{-7} M from the absorbances obtained and the molecular extinction coefficients, 4.3×10^{4} for the anion and 4.9×10^{4} for the cation.[5,6]

The absorbances of the transient species were followed in detail as the function of time. Some of the results obtained are given in Fig. 2. It was found that the ion concentrations increased during the flash illumination which continued for about 15 μsec. The decay of the ions nearly followed the second-order kinetics ($k=7\times10^{10}$ M^{-1} sec^{-1}). This result suggests that the decay of the ions is mainly due to recombination of the cations and anions and is a diffusion-controlled process.

Three mechanisms may be set up as possible routes for the simultaneous formation of perylene cation and anion:

1) *Auto-ionization* from perylene excimer.

$$^1Pe^* + Pe \longrightarrow (Pe \cdots Pe)^* \rightsquigarrow Pe^+_{solv.} + Pe^-_{solv.}$$

2) T-T annihilation.

$$^3Pe + {}^3Pe \rightsquigarrow Pe^+_{solv.} + Pe^-_{solv.}$$

3) Two-step (bi-photonic) excitation.

$$Pe + h\nu_1 \longrightarrow {}^1Pe^* \rightsquigarrow {}^3Pe$$

$$^3Pe + h\nu_2 \longrightarrow {}^3Pe' \rightsquigarrow Pe^+_{solv.} + e_{solv.}$$

$$e_{solv.} + Pe \longrightarrow Pe^-_{solv.}$$

The life time of perylene in the lowest singlet excited state (^{1}Pe) is 5×10^{-9} sec and, from this short life and low concentration of perylene in our experiment, it is unlikely that collisions of ^{1}Pe* and ground state perylene (Pe) occur to any appreciable degree. Therefore, mechanism (1) may be discarded. Also, the probability of formation of higher excited singlet state of perylene by the S—S′ absorption is very small.

The second mechanism, T–T annihilation, was assumed by Kawada and Jarnagin[8] for the explanation of photo-current of anthracene and phenanthrene in solutions. In such a process, ions need collisions of two triplet molecules. As the concentration of triplet perylene in our experimental condition is in the order of 10^{-6}M, the T–T annihilation process must be rather slow and the maximum of the ion concentration should appear at a time considerably later than that of the triplet molecules as seen in the case of Kawada and Jarnagin's work. Our experimental result shows that the concentrations of the ions increase almost in the same way as the triplet perylene and reach their maxima already at about 15 μsec after the start of the flash. Therefore, the second mechanism is also unlikely.

The third mechanism is consistent with the experimentally obtained rate of production of the ions. The ionization potential of perylene has been determined to be 7.15 eV[9] in the gas phase. Although the phosphorescence spectrum of perylene has not been observed, the lowest triplet state of perylene is estimated to be *ca.* 1.6 eV from MO calculations. As the filter solution used in the present experiment allows entrance of light having energy up to 3.6 eV, perylene can be excited to a level as high as *ca.* 5.2 eV by the T–T′ transition. This value seems to be a little too low for ionization of perylene even in a solution, based on our experience in the photo-ionization of aromatics in condensed environments.[10] In spite of this, mechanism (3) seems to be the most probable at the moment, as there is no other strong alternative. Stevens and Walker[11] have studied the photo-ionization of perylene in the rigid glass and conclude that the ionization potential of perylene is *ca.* 5.0 eV in liquid paraffine at 77°K. Photo-electron emission may then occur from the higher triplet states.

Once an electron is emitted from a highly excited perylene molecule, the electron can be captured by another perylene molecule leading to the formation of perylene anion.[10]

SHORT COMMUNICATIONS

The Photoinduced Rotational Isomerization of Benzil in a Mixture of Water and Ethanol

Hiroyasu INOUE and Toshiaki KUWAHARA*1

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Yokohama

(Received April 7, 1970)

The benzil molecule has been considered to take a nonplanar configuration in which the central carbonyl-carbonyl bond is strongly twisted.[1] Therefore, the two benzoyl parts are almost not in conjugation with each other and, consequently, benzil shows an electronic spectrum very similar to that of benzaldehyde.

Now, we wish to report on the photoinduced spectral changes of benzil in several liquid solutions. In a cyclohexane solution and in an ethanol solution the absorption spectra indicated only decompositions upon ultraviolet irradiation by means of a low-pressure mercury lamp. In a mixture of water and ethanol, however, benzil was found to show characteristic spectral changes with the irradiation. Obviously, water molecules play an essential role in this photoinduced change. As is shown in Fig. 1, the intensity of the 262 mμ band of the nonplanar species gradually decreases with the irradiation time, and at the same time an absorption band appears at 314 mμ. In this case, the isosbestic points were observed for the first several seconds of irradiation, but further irradiation shifted the absorption curves and caused them to deviate from the isosbestic points. The shift is probably due to the beginning of decomposition.

Moreover, in the initial stage of irradiation the photoproduced species absorbing at 314 mμ can be reversed to the original nonplanar benzil by heating at 83°C for 50 min in a dark room, as is indicated by curve IV in Fig. 1.

From the experimental results obtained above, the photoproduced species can be inferred to be a configurational isomer which possesses a nearly planar configuration, for the product shows a relatively longer wavelength band than that of the nonplanar species. As to the role of the water molecule, the hydrogen-bonding formation between two carbonyl groups and a water molecule can be considered plausible. The hydrogen-bonding energies may contribute to the stabilization of the nearly planar isomer of the benzil molecule, which is illustrated in Fig. 2. A detailed investigation is now in progress.

Ultraviolet Study for the Adsorption of Acetylacetone on D-Tartaric Acid Preadsorbed Nickel Film

Toshio NINOMIYA, Kosaku KISHI and Shigero Ikeda

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received April 2, 1970)

The ultraviolet spectra of β-diketones adsorbed on evaporated metals have been studied in order to clarify the chemical bonding of the chemisorbed species and the electronic properties of the metal surfaces.[1] The exposure of the metal films to acetylacetone vapor gives absorption peaks which can be assigned to the π–π^* transition of adsorbed acetylacetonate.

α-Amino and α-hydroxy acids function as chelating agents to metal ions. These acids are used as modifying reagents for hydrogenation catalysts, which then catalyze the asymmetric hydrogenation reaction of β-diketones.[2] The ultraviolet spectra of adsorbed β-diketones on the acid preadsorbed metal will, then, give important information shedding light on the mechanism of the modifications of catalysis and, in general, the corrosion mechanism of metal surfaces.

In the present communication, the adsorption of acetylacetone on evaporated nickel film pretreated with D-tartaric acid is studied.

The experimental apparatus shown in a previous paper[3] was improved for use here. The evaporation and other procedures have been described in the previous paper. After the nickel had been evaporated onto the quartz windows in a vacuum, a D-tartaric acid solution previously degassed was gently introduced into a quartz cell through a break-off seal broken by a glass-coated magnet. After treating the metal film with the acid solution for 30 min at 0°C, the solution was poured out from the quartz cell and the solvent water was completely removed by vacuum-distillation. Then acetylacetone was introduced, and the ultraviolet spectra of the adsorbed species were recorded on a Hitachi EPS-2 spectrophotometer.

The D-tartaric acid solutions had concentrations of 2% and were adjusted to various pH's, such as 2.0, 5.0, and 9.0, by a 1N NaOH aqueous solution.

The results are shown in Fig. 1.

In the treatment of the metal at pH 2.0, a weak, broad band was observed around 280 mμ after a 30 min adsorption of the acetylacetone. After 18 hr, the band maximum shifted to a longer wavelength.

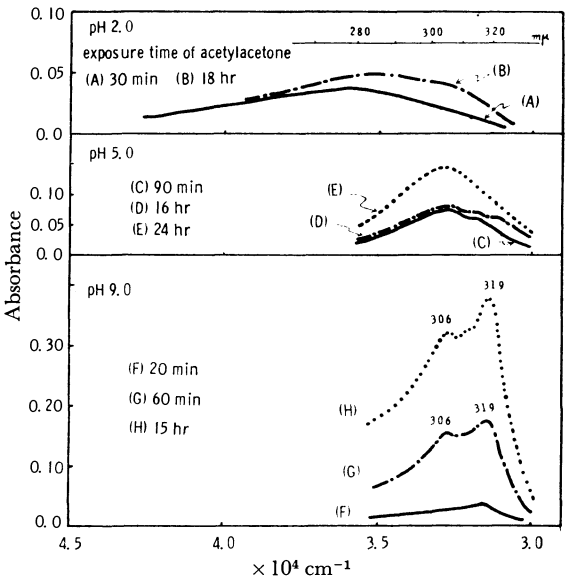

Fig. 1. Ultraviolet spectra of acetylacetone adsorbed on nickel film with preadsorbed D-tartaric acid at pH 2.0, 5.0 and 9.0.

In the case at pH 5.0, absorption peaks were obtained at 306, 316, and 322 mμ after 16 hr, and only one peak, at from 303 to 306 mμ, after 24 hr.

Figure 1 also shows the spectra obtained after the adsorption of acetylacetone on the metal film treated with the pH 9.0 solution. An absorption band was observed at 318 mμ after 20 min. After 15 hr, three intensive bands (about ten times that after 20 min) were obtained at 306, 313, and 319 mμ.

The adsorption of acetylacetone on nickel film without preadsorbed D-tartaric acid gives a band at 303 mμ which can be assigned to the π–π^* transition of adsorbed acetylacetonate.[1] In the cases with the preadsorbed acid, the absorption spectra of the adsorbed species are considerably different from that with no preadsorption procedure; furthermore, the spectra depend very significantly on the pH condition of the acid solution. By the way, the IR spectrum of D-tartaric acid adsorbed on the nickel film has been obtained, and the UV spectrum of adsorbed acetylacetonate on the nickel film treated with NaOH is different from the above spectra.

The elucidation of the relation between the spectral variation and the modification mechanism of the catalyst is now in progress.

α-Chlorination of Sulfoxides by Chlorine

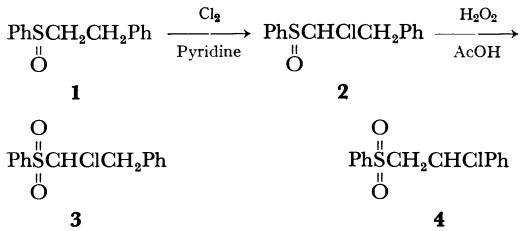
Gen-ichi TSUCHIHASHI and Shinobu IRIUCHIJIMA

Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa

(Received April 27, 1970)

Although α-halogenation of carbonyl compound is the well-established reaction in synthetic chemistry, a similar halogenation of sulfoxides was believed to be difficult until very recently.[1,2] It is now known that α-chlorination of sulfoxides can be achieved by using specific reagents such as *p*-toluenesulfonyl chloride,[1] nitrosyl chloride,[2] iodobenzene dichloride,[3] and *t*-butyl hypochlorite.[4] No research has been reported, however, on the halogenation of sulfoxides by molecular halogen. In this communication, we would like to report that sulfoxides can be easily α-chlorinated by chlorine and the reaction proceeds fairly stereo- and regioselectively.

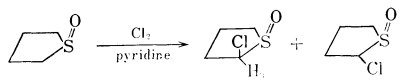
When sulfoxides were treated with chlorine, difficulty was encountered by the evolution of hydrogen chloride which causes Pummerer-type rearrangement of sulfoxides. This was overcome by the addition of an excess amount of pyridine. Chlorine gas (5.3 mmol) was bubbled with stirring into the methylene dichloride solution (30 m*l*) of 2-phenylethyl phenyl sulfoxide (**1**) (5.3 mmol) and dry pyridine (10.6 mmol) for one hour at 0°C. The usual work-up gave 1-chloro-2-phenylethyl phenyl sulfoxide (**2**)[5] in 92% yield, which proved to be homogeneous by NMR and TLC. **2**: mp 60°C; MS, M^+ 264; NMR, τ 7.55 (1H, q), 6.45 (1H, q), 5.44 (1H, q), 2.81 (5H, s), and 2.3—2.6 (5H, m).



The structure of **2** was confirmed by converting **2** to the corresponding sulfone (**3**, mp 67—67.5°C). 2-Chloro-2-phenylethyl phenyl sulfone (**4**, mp 88.5—89.5°C) was synthesized according to the method in literature,[6] and from the inspection of their spectral data, **3** was proved to be the positional isomer of **4**.

It is striking that the position alpha to sulfinyl is much more susceptible to chlorination than the benzyl position, and only one diastereomer was obtained although the reaction could produce two diastereomers of **2**.

A similar reaction of tetrahydrothiophene-1-oxide (**5**) afforded 2-chlorotetrahydrothiophene-1-oxide (**6**) in 65% yield: mp 42—43°C; MS, M^+ 138; NMR, τ 7.1—8.1 (5H, m), 6.65—6.95 (1H, m), and 4.85 (1H, q). The product consists of two diastereomers in a ratio of 8 : 2, and a study of the NMR solvent-induced shift of H_a proton[7] revealed that the major isomer is *cis*-**6**.

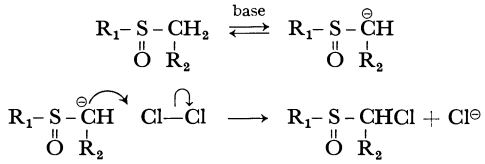


5 *cis*-**6** *trans*-**6**

In this case, the hydrogen atom *cis* to oxygen of sulfinyl group appears to be substituted preferentially.

Similarly, the reaction of methyl *p*-tolyl sulfoxide, ethyl phenyl sulfoxide, and dimethyl sulfoxide gave chloromethyl *p*-tolyl sulfoxide (mp 61.5—62°C), 1-chloroethyl phenyl sulfoxide (bp 83—84°C/1mmHg), and chloromethyl methyl sulfoxide (bp 63—68°C/0.2 mmHg, lit,[2] bp 65°/0.05 mmHg) in 70, 85, and 75% yields, respectively. Thus, this method of chlorination will provide a general route for synthesizing α-chlorosulfoxides.

The following scheme seems plausible for this reaction.



Sulfuryl chloride with pyridine can also be used as an α-chlorinating agent for sulfoxides, nearly equal to chlorine. Detailed studies on the mechanism of these chlorinations are in progress.

Reaction of Cobaltocene with Organic Compounds under an Oxygen Atmosphere: A new Route to π-Cyclopentadienyl-(1-*exo*-organylcyclopentadiene)cobalt

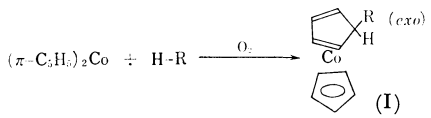
Hidetaka KOJIMA, Shigetoshi TAKAHASHI, Hiroshi YAMAZAKI*1 and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Yamada-Kami, Suita, Osaka

(Received April 30, 1970)

A number of π-cyclopentadienyl(1-*exo*-organylcyclopentadiene)cobalt complexes have been prepared by the reaction of organic halides with cobaltocene,[1] or organic alkali metals with cobalticenium perchlorate.[2]

We wish to report here a new reaction of cobaltocene with organic compounds having an active hydrogen atom under an oxygen atmosphere, which gives π-cyclopentadienyl(1-*exo*-organylcyclopentadiene)cobalt complexes in a high yield.



(I)

Oxygen was bubbled continuously through a dark red solution of cobaltocene in chloroform. After one hour, chloroform was removed from the resulting solution under reduced pressure to give orange red crystals of π-cyclopentadienyl(1-*exo*-trichloromethylcyclopentadiene)cobalt (Ia). The IR and NMR spectra and the melting point were identical with those of the authentic sample which was prepared by the reaction of cobaltocene with carbon tetrachloride.[3] Almost quantitative yield of Ia is a characteristic point of our method. In the case of the reaction of cobaltocene with carbon tetrachloride, the yield can not exceed 50% stoichiometrically, because half of the cobaltocene is consumed for the formation of cobalticenium chloride.

In the same way, cobaltocene reacted very smoothly with acetonitrile, propionitrile, phenylacetylene and acetone to form new complexes, $(\pi\text{-}C_5H_5)Co(C_5H_5\text{-}CH_2CN)$, $(\pi\text{-}C_5H_5)Co(C_5H_5\text{-}CH(CN)CH_3)$, $(\pi\text{-}C_5H_5)Co(C_5H_5\text{-}C{\equiv}CC_6H_5)$ and a new binuclear complex, $(\pi\text{-}C_5H_5)Co(C_5H_5\text{-}CH_2\text{-}COCH_2\text{-}C_5H_5)Co(\pi\text{-}C_5H_5)$. These complexes are summarized in Table 1.

Weiher *et al.*[4] reported smooth absorption of one mole of oxygen by four moles of cobaltocene at 0°C. They were unsuccessful in isolating and characterizing the oxygenated product. We observed that an orange solid was precipitated by the treatment of a solution of cobaltocene in ether with oxygen at −50°C. When chloroform was added to the orange solid suspended in ether under a nitrogen atmosphere, the solid was dissolved, the color of the solution turned to red, and the complex $(\pi\text{-}C_5H_5)Co(C_5H_5\text{-}CCl_3)$ was isolated in a 95% yield. This suggests that the oxygenated cobaltocene is an intermediate in the new reaction of cobaltocene. More detailed studies on the reaction mechanism are in progress.

TABLE 1. CYCLOPENTADIENYL(1-*exo*-ORGANYLCYCLOPENTADIENE)COBALT COMPLEXES*

Complex		H–R	Yield (%**)	Mp (°C)	Color
Ia	R=$-CCl_3$	$CHCl_3$	97	80—81	orange red
Ib	R=$-CH_2CN$	CH_3CN	87	58	red
Ic	R=$-CH(CN)CH_3$	CH_3CH_2CN	51	84—85	red
Id	R=$-C{\equiv}CC_6H_5$	$HC{\equiv}CC_6H_5$	56	130 (decomp.)	orange red
II***	R=$-CH_2COCH_2-$	CH_3COCH_3	70	100 (decomp.)	orange

* Satisfactory data of elemental analysis were obtained for all the new complexes.
** Based on cobaltocene. *** Binuclear complex.

C-Band Gas-Phase EPR Spectra of the Rotational Excited $J=3$ Level of SO in the $^1\Delta$ State

Hiromichi UEHARA and Yonezo MORINO

Sagami Chemical Research Center, Sagamihara-shi, Kanagawa

(Received May 6, 1970)

We report the gas-phase C-band electron paramagnetic resonance spectra of the rotational excited $J=3$ level of the electronically excited state $^1\Delta$ of SO. The EPR spectrum of SO in the $^1\Delta$ state was first observed by Carrington *et al.*[1] for the rotational ground state ($J=2$) by using X-band microwave frequencies (*ca.* 9 GHz). By lowering the microwave frequency from X- to C-band region we have succeeded in observing the spectrum in the next higher rotational level.

A Stark modulated cylindrical TE_{011} mode detection cavity resonated at about 4.46 GHz was used with the axis of the cylinder parallel to the dc magnetic field. The C-band spectrometer used was reported elsewhere.[2] Micowave discharged oxygen gas was introduced into the resonance cavity through a gas-inlet at a pressure of 0.3 Torr and carbonyl sulfide was introduced through another inlet at a pressure of 0.1 Torr and mixed the dischagre product immediately outside the detection cavity. A strong spectrum of SO ($^1\Delta$, $J=2$) was observed in a field of 4.7 kG at a signal-to-noise ratio of about 100. Five lines of the rotational excited $J=3$ state were observed in a field of 9.1 to 10 kG, as shown in Fig. 1. Although the spectrum of the $J=3$ level consists of a sextet according to the selection rule of $\Delta M=1$, the transition to be expected at the highest field was not observed because of the restriction of the magnetic field available to us (maximum field of 10000 G).

A preliminary calculation was made with the method presented by Carrington *et al.*[1] By using the matrix elements of $(J, \Lambda, M|\mathcal{H}|J, \Lambda\, M)$ and $(J, \Lambda, M|\mathcal{H}|J+1, \Lambda, M)$ of the Hamiltonian

$$\mathcal{H} = B_0(\boldsymbol{J}-\boldsymbol{L})^2 + g_l\beta\boldsymbol{L}\cdot\boldsymbol{H}, \qquad (1)$$

we set up a 4×4 matrix and diagonalized it. The molecular constants used were $B_0=0.709$ cm^{-1} [1] and $g_l=1.00000$. The main feature of the observed five transitions were well reproduced, although a fairly large discrepancy between the calculated and the observed was noted in the absolute (about 5 gauss) and relative (a few gauss) field positions of the resonance transitions. It is expected that the electronic g factor, l-uncoupling constants, and the rotational constant may be determined accurately by analyzing the spectra of the rotational excited state $J=3$, combined with those of the ground $J=2$ state.

Carrington *et al.*[1] presented the following three features for the identification of the lines for $^1\Delta$ SO: first, the spectrum consists of four lines of similar intensity, secondly, the center of the quartet pattern indicates a molecular g value very close to the expected value 2/3, and thirdly, analysis of the splitting between the lines leads to a value of the rotational constant B_0 which is very close to that known for the $^3\sum^-$ ground state. Similarly, the present observation of the spectral lines in the $J=3$ level close to the predicted positions with the relative intensities close to the expected ratios, 3 : 5 : 6 : 6 : 5, confirms the assignment of the spectra to the $^1\Delta$ of SO.

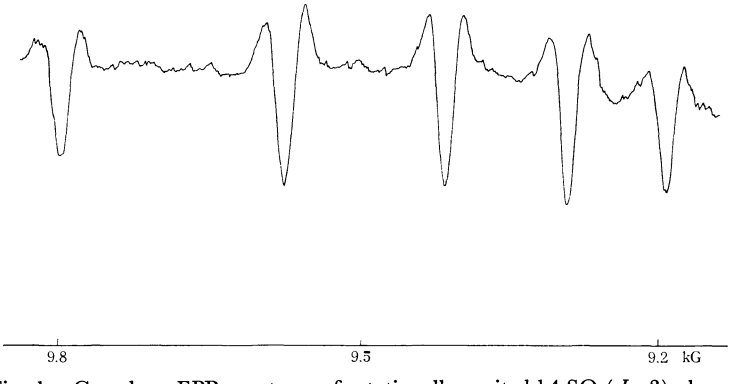

Fig. 1. Gas-phase EPR spectrum of rotationally excited $^1\Delta$ SO ($J=3$) observed with a microwave frequency of 4.46 GHz.

The Hydrogenation and Isomerization of Unsaturated Hydrocarbons over ZnO

Shuichi NAITO, Yuzo SAKURAI, Hazime SHIMIZU, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Tokyo

(Received May 6, 1970)

The catalytic reaction between unsaturated hydrocarbons and deuterium has been studied over several metal oxides, such as Cr_2O_3,[1] TiO_2[2] and ZnO,[3] and the main initial product in each case has been reported to be alkane-d_2. In this report, the reaction mechanism of propylene, butene, and 1,3-butadiene with deuterium was studied over ZnO. The adsorption during the course of the reaction was measured in order to study the working state of the surface. The mass and the microwave spectroscopic techniques were used to determine the deuterium content and distribution in the reactants and products.

The deuteration of propylene over ZnO proceeded readily at room temperature, and the catalytic exchange reaction between hydrogen atoms of propylene and deuterium took place simultaneously. The rate of the exchange reaction was considerably faster than that of the deuterium addition. The microwave spectroscopic measurements of propylene-d_1 demonstrated that, in the initial stage of the exchange reaction, propylene 3-d_1 predominated. As the reaction proceeded, three kinds of monodeuterio-propylene, 3-d_1, *cis*-1-d_1, and *trans*-1-d_1, were formed. However, propylene 2-d_1 was not observed during the reaction; this corresponds to the fact that the sixth hydrogen in propylene was not exchanged. These results suggest that the chemisorbed state of propylene is the π-allyl species.

The addition of deuterium to 1-butene over ZnO yielded only dideuterio-butane, and no exchange occurred in the hydrogen atoms of 1-butene in the initial stage of the reaction. During the course of the addition reaction, the isomerization of 1-butene proceeded simultaneously; this also occurred in the absence of deuterium, and the rate of isomerization was not affected by either the presence or absence of hydrogen in the ambient gas. The deuteration and isomerization of 1-butene seemingly proceed independently.

The deuteration of 1,3-butadiene over ZnO occurred easily at room temperature, and 1-butene was mainly produced (above 90%) until the 1,3-butadiene of the gas phase had been consumed; then butane started to be produced from 1-butene, accompanied by the isomerization described above. Only the dideuterio-1-butene was produced during the reaction; it was H_2DC–CHD–CH=CH_2 according to the microwave spectroscopy. On the other hand, hydrogen atoms of 1,3-butadiene did not exchange with deuterium molecules in the gas phase. When a mixed gas of 1,3-butadiene: H_2 : D_2=1 : 1 : 1 was introduced over ZnO, the main products were normal 1-butene and dideuterio-1-butene, while the amount of monodeuterio-1-butene was very small and was in proportion to the amount of HD in the gas phase.

The orders of the deuteration reaction of propylene, butene and 1,3-butadiene were all unity as to the partial pressure of deuterium and zero for the unsaturated hydrocarbons. The amounts of hydrocarbons and hydrogen chemisorbed during the hydrogenation were almost constant. In the case of 1-butene, the amounts of chemisorbed 1-butene and hydrogen were nearly half of their saturated amounts. The saturation value of the hydrogen chemisorption during the reaction between hydrogen and unsaturated hydrocarbons was in the following decreasing order: propylene, butene and butadiene, and the rates of the H_2–D_2 exchange reaction during the hydrogenation were retarded in the same order.

It can be seen from these experimental results that deuterium (or HD, H_2) participates in the addition process in a molecular form. To explain the experimental results, two alternative mechanisms may be considered. One of them is that dissociated deuterium atoms act in pairs on the surface, as if they were in a molecular form. In this case, the pair sites may be the zinc and oxygen ions on the surface, and the half-hydrogenated intermediate may be formed irreversibly. Secondly, the more probable mechanism is that deuteration proceeds by means of interaction between the chemisorbed hydrocarbons and the deuterium molecules in the ambient gas. The fact that the rate of deuteration is determined by the partial pressure of deuterium rather that by the amount of chemisorbed deuterium during the reaction favors the latter mechanism.

The Reduction of 1,2-Dihalo-3,4-bis(diphenylmethylene)cyclobutenes by Lithium Aluminum Hydride

Fumio Toda, Kunihiro Kumada and Katsuhiko Akagi

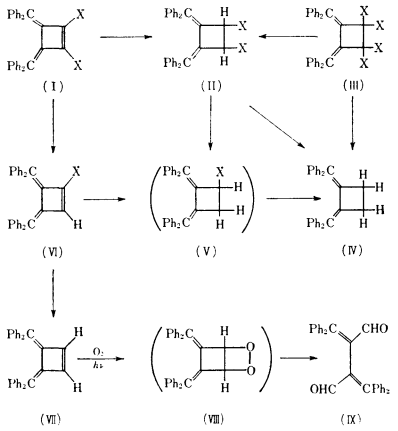
Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

(Received April 22, 1970)

Even though its calculated delocalization energy (1.21β) is comparable to that of cyclobutenedione (1.24β),[1,2] it has been established[3,4] on the basis of ultraviolet spectral data that dimethylenecyclobutene is better viewed as a cross conjugated diene rather than as a conjugated triene. Since this is probably because of the *endo*-double bond's causing ring strain, an anomalous reaction of the bond can be expected.

In the course of our studies of the title compounds (I),[5] we have found that the *endo*-double bond of I is easily reduced by lithium aluminum hydride (LAH) to afford 1,2-bis(diphenylmethylene)cyclobutane (IV).[6,7] Since no LAH reduction of carbon-carbon double bond has yet been reported, except where the double bond is conjugated with an electronegative group such as carbonyl, nitro, or cyano, the present results would seem to show an anomalous reactivity of the *endo*-double bond of I.

A mixture of Ia[5] and three equivalents of LAH in ether-tetrahydrofuran (3 : 2 ratio) was heated under reflux in a nitrogen atmosphere for 2 hr. After cooling, the reaction mixture was decomposed with water and hydrochloric acid, and then extracted with ether. The ether layer was washed with water and dried over sodium sulfate. Fractional recrystallization from the acetone of the crude product obtained by the evaporation of the solvent afforded IV and 3,4-bis(diphenylmethylene)butanedial (IX) in 33 and 8% yields respectively. The spectral data of IV (mp 180°C); $\lambda_{max}^{CHCl_3}$ 260 (23500), 357 nm (ε, 20900); NMR ($CDCl_3$) 2.89 (s, Ph, 10H), 3.30 (s, Ph, 10H), 7.16 τ (s, CH_2, 4H), and of IX (mp 208.5°C); $\lambda_{max}^{CHCl_3}$ 300 (16100), 335 sh, nm (ε, 11600); IR ($CHCl_3$) 2870 and 2750 (CHO), 1670 and



a: X=Br; b:X=Cl

1655 (CO), 1580 and 1555 cm^{-1} (C=C); NMR ($CDCl_3$) 0.45 (s, CHO, 2H), 2.90 τ (m, Ph, 20H), were identical with those of the corresponding authentic samples prepared according to the previously-reported method.[7]

Table 1. Yields (%) of the reduction products

Product	Reactant						
	Ia	Ib	VIa	VII	IIa	IIIa	IIIb
IV	33	41	30	—	78	71	67
IX	8	9	15	100	—	—	—

The yields of the reduction products, obtained by the same treatment as that employed for Ia, of 3,4-bis(diphenylmethylene)cyclobutenes (Ib,[5] VI[7] and VII[7]) and 3,4-bis(diphenylmethylene)-cyclobutanes (II[7] and III[8]) are summarized in Table 1.

The reduction of the cyclobutanes to afford IV may proceed by means of substitution processes. On the other hand, the reduction of the cyclobutenes into the two products can well be interpreted by two competing paths. One of them is the addition of hydride ion, followed by substitution, to afford IV finally. The other one is substitution to afford VII, which is photooxidized to IX, probably *via* VIII, during the course of isolation.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XV. Asymmetric Hydrogenation of Metal Chelate Compound

Tadashi TANABE, Toshio NINOMIYA and Yoshiharu IZUMI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received April 22, 1970)

The asymmetric hydrogenation catalysts prepared from Raney nickel catalysts by modifications with aqueous solutions of optically-active compounds have been studied in terms of the relationships between the modifying reagent and the substrate in this series.[1,2] In the asymmetric hydrogenation of carbonyl compounds, it was found that the asymmetric yield of the product was much affected by the structure of the substrate and that the best substrate for the catalyst modified with an optically-active 2-hydroxy or 2-amino acid was a β-ketocarbonyl compound, such as a β-ketoester or a β-diketone.[1]

At an early stage of the hydrogenation of acetylacetone using the unmodified catalyst or a catalyst modified with D-tartaric acid, nickel acetylacetonate was detected in the reaction mixture, but nickel acetylacetonate was not detected at the end of hydrogenation. Moreover, it has been reported how the spectrum of acetylacetone chelating with nickel metal was observed by the exposure of the evaporated nickel film in the acetylacetone vapor.[3,4]

In view of the above-mentioned facts, the chelations of β-ketocarbonyl compounds onto the nickel surface of the catalyst might contribute to their excellent asymmetric yields of the products. Moreover, it is very important in the elucidation of the asymmetric hydrogenation mechanism of carbonyl compounds to examine the asymmetric hydrogenation of the nickel chelates of β-ketocarbonyl compounds with nickel.

In this respect, the asymmetric hydrogenation of the nickel complexes of β-ketocarbonyl compounds as the substrate, nickel methyl acetoacetate and nickel acetoacetonate,[5] were tested.

The modified Raney nickel catalysts were prepared and the optical rotation of the product was measured in ways which have been reported in a previous paper.[2] D-Tartaric acid and L-glutamic acid were used as the modifying reagents; the results are shown in Table 1.

From the results in Table 1, the asymmetric hydrogenations of the nickel chelate compounds of β-carbonyl compound are found to occur in fairly lower asymmetric yields compared with those in the asymmetric hydrogenation of methyl acetoacetate or of acetylacetone itself. These lower asymmetric yields might be caused by the change in asymmetric centers caused by the nickel metal deposited on the catalyst surface in the hydrogenation of the chelate compounds or by the difference in the structures of the β-carbonyl compound adsorbed on the catalyst surface and on the nickel chelate compound, which is a trimer in crystal and in a benzene solution. This study will be discussed in detail in this Bulletin in the near future.

Table 1. Optical rotation of product

No.	Substrate*1 (g)	Amount of R-Ni (as alloy) (g)	Modifying reagent (mod. temp. and pH)	Product	Optical rotation $[\alpha]_D^{20}$
1	$Ni(MAA)_2 \cdot 2H_2O$*2 (3.0)	3	2%-D-Tartaric acid (0°C, 5.0)	Methyl 3-hydroxybutyrate	−0.04
2	$Ni(MAA)_2 \cdot 2H_2O$ (3.0)	3	2%-D-Glutamic acid (0°C, 5.0)	Methyl 3-hydroxybutyrate	+0.15
3	$Ni(AA)_2 \cdot H_2O$*3 (5.0)	3	2%-D-Tartaric acid (0°C, 5.0)	2,4-Pentanediol	−2.88
4	$Ni(AA)_2 \cdot H_2O$ (5.0)	3	2%-L-Glutamic acid (0°C, 5.1)	2,4-Pentanediol	−0.16
5	Acetylacetone (10.0)	1	2%-L-Glutamic acid (0°C, 5.0)	2,4-Pentanediol	−1.88

*1 50 ml of benzene was used as the solvent. *2 MAA: methyl acetoacetate. *3 AA: acetylacetone.

A Novel Synthesis for DL-Aspartic Acid and DL-Glutamic Acid*1

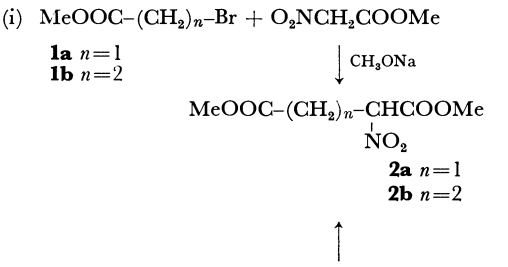
Shonosuke ZEN and Eisuke KAJI

Kitasato University, College of Pharmaceutical Sciences, Shirokane, Minato-ku, Tokyo

(Received April 27, 1970)

Our current interest in the synthesis of various amino acids[1] from α-nitroesters has led us to attempt to find an every method of synthesizing DL-aspartic acid and DL-glutamic acid.*2

The synthesis of α-nitrodicarboxylates by the *carbon-alkylation reaction* of methyl nitroacetate with the halo-ester of carboxylic acid consists of the following steps:



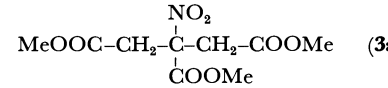
In the first method (i) sodium methylate is added to methyl nitroacetate and **1a** (or **1b**) to yield **2a** (or **2b**); the second method (ii) yields the same *C*-alkylated derivatives (**2a** and **2b**) by the reaction of sodium salt of methyl nitroacetate with **1a** (or **1b**).

Dimethyl nitrosuccinate[2] (**2a**): following Step i, an equimolecular reaction takes place between methyl nitroacetate and methyl bromoacetate (**1a**) in a dipolar aprotic solvent (such as dimethylacetamide or dimethylformamide) in the presence of sodium methylate (such as the 1N methanol solution) when it is stirred overnight at room temperature. The reaction product was extracted with benzene (from the water layer which resulted from adding water and benzene to the reaction mixture). The benzene was first distilled out; when the **2a** was further distilled under reduced pressure, its yield was 66%; bp. 70—72°C/0.05 mmHg, n_D^{20} 1.4452, IR (liquid film): 1745 (ester CO), 1565 and 1380 (C-NO_2) cm^{-1}, λ_{max}^{MeOH} 275 mμ (ε 290). Diethylammonium salt of **2a** recrystallized from ethanol - ether, melted at 103—104°C. Following Step ii, **2a** was synthesized in a 23% yield, and also the trimethyl ester of β-nitrotricarballic acid (**3a**) was obtained as colorless prismatic crystals in a 29% yield by recrystallization from an ether-isopropylether mixture; mp 88.5—89.5°C, IR (KBr): 1730 (ester CO), 1560 and 1370 (C-NO_2) cm^{-1}, λ_{max}^{MeOH} 283 mμ (ε 36).

The catalytic hydrogenation*3 of **2a** with Raney Nickel T-1[3] under 40 p.s.i.g. gave the corresponding ester of aspartic acid in a 90% yield. By the hydrolysis of the product with 6N hydrochloric acid, DL-aspartic acid was obtained in a 94% yield as HCl salt.

Dimethyl α-nitroglutarate[4] (**2b**): in a similar way, **2b** was given in an 88.5% yield by the reaction of the sodium salt of methyl nitroacetate with **1b**.

DL-Glutamic acid was then synthesized in a total yield of 83.2% from **2b** by hydrogenation and subsequent hydrolysis following the above-mentioned procedure.



(**3a**)

Investigations into the uses of this *C*-alkylation reaction using other halogeno-compounds with the nitro ester and into the mechanism of this reaction are now in progress.

Synthesis of a Heptacosapeptide Corresponding to the Human Corticotropin 1-27 Sequence

Hideo OTSUKA, Kunio WATANABE and Ken INOUYE

Biochemistry Division, Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received May 2, 1970)

In previous communications we described the syntheses and biological properties of corticotropin (ACTH)-octadecapeptides including [β-Ala[1]]-ACTH(1-18)-NH_2.[1-3] We wish now to report the synthesis of a peptide corresponding to the amino acid sequence 1-27 of human ACTH, *viz.*, H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-Val-Lys-Val-Tyr-Pro-Asp-Ala-Gly-OH, h-ACTH (1-27)-OH (I).[4]

Z-Val-Lys(Boc)-Val-Tyr-Pro-Asp(OBu^t)-Ala-Gly-OBu^t (II) ($[\alpha]_D^{25}$ $-69.2°$ (*c* 1, methanol). Found: C, 60.30; H, 7.84; N, 10.28. Calcd for $C_{60}H_{91}N_9O_{16}$: C, 60.34; H, 7.68; N, 10.55%) was synthesized stepwise starting from the Gly-OBu^t at *C*-terminal, in which Z-Ala, Z-Asp(OBu^t) and Z-Pro were incorporated with DCC and Z-Tyr(Z), Z-Vals and Z-Lys(Boc) by the *p*-nitrophenyl ester method in combination with the hydrogenolytic removal of the N^{α}-protecting group. Z-Arg(NO_2)-Arg(NO_2)-Pro-OMe (mp 115—120°C decomp, $[\alpha]_D^{27}$ -37.1 (*c* 1, AcOH), $-30.5°$ (*c* 1, DMF)) was treated with HBr/AcOH for removal of the Z-group, followed by acylation with Z-Lys(Boc)-OCOOEt to yield a tetrapeptide ester which was readily saponified to Z-Lys(Boc)-Arg(NO_2)-Arg(NO_2)-Pro-OH (III) ($[\alpha]_D^{23}$ $-36.7°$ (*c* 1, methanol)). Compound III and an octapeptide ester, derived from II by catalytic hydrogenolysis, were coupled by the *N*-hydroxysuccinimide-mediated DCC method[5] to give Z-Lys(Boc)-Arg(NO_2)-Arg(NO_2)-Pro-Val-Lys(Boc)-Val-Tyr-Pro-Asp(OBu^t)-Ala-Gly-OBu^t (IV) ($[\alpha]_D^{23}$ $-78.5°$ (*c* 1, methanol). Found: C, 54.14; H, 7.53; N, 15.88. Calcd for $C_{88}H_{140}N_{22}O_{26}\cdot H_2O$: C, 54.48; H, 7.38; N, 15.88%). Compound IV was submitted to hydrogenolysis and the product was coupled with Z-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-N_3[6] to give a heptadecapeptide, Z-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-Pro-Val-Lys(Boc)-Val-Tyr-Pro-Asp(OBu^t)-Ala-Gly-OBu^t, which was converted into the N^{α}-free peptide (V) ($[\alpha]_D^{23}$ $-74.2°$ (*c* 0.7, 50% AcOH)) by catalytic hydrogenolysis.

A decapeptide Z-Ser-Tyr-Ser-Met-Glu(OBzl)-His-Phe-Arg-Trp-Gly-OH (mp 205—210°C decomp, $[\alpha]_D^{22}$ $-13.0°$ (*c* 1, DMF)), which was synthesized from Z-Ser-Tyr-Ser-N_3[7] and H-Met-Glu(OBzl)-His-Phe-Arg-Trp-Gly-OH,[8] was esterified with *N*-hydroxysuccinimide by the DCC method[9] and the resulting active ester was allowed to react with V to afford a protected heptacosapeptide, which was treated with hydrogen fluoride[10] to liberate the free peptide (I). The crude product was purified by chromatography on a carboxymethyl cellulose column; $[\alpha]_D^{23}$ $-89.9°$ (*c* 0.5, 0.1N AcOH), $\lambda_{max}^{0.1N\ NaOH}$ $=282$ mμ ($E_{1cm}^{1\%}=25.3$), 288 mμ ($E_{1cm}^{1\%}=26.7$). Amino acid ratios in acid hydrolysate: Asp 1.07, Ser 1.72, Glu 1.02, Pro 3.17, Gly 3.15, Ala 1.03, Val 3.00, Met 0.98, Tyr 2.06, Phe 1.03, Lys 4.11, His 0.91, Arg 2.95. The Tyr/Trp ratio in intact I was 1.8 as determined spectrophotometrically. Peptide I was found to possess an adrenal-stimulating activity of 263 units/mg (3rd USP standard as standard) in the in vivo steroidogenesis.[11]

Hot-atom Chemistry of Tris-(acetylacetonato)-cobalt(III) in Benzene Solutions and Frozen Benzene Solutions

Takeshi TOMINAGA and Kitao FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received May 7, 1970)

We have initiated a systematic work to irradiate the organic solutions and frozen organic solutions of metal complexes with slow neutrons in order to elucidate the mechanism of hot-atom reactions in the systems. In the present paper we report our preliminary data on the ^{60}Co recoil reactions in benzene solutions and frozen benzene solutions of tris-(acetylacetonato)-cobalt(III) and the scavenger effect of ferric chloride added to the systems for the purpose of removing free acetylacetone.

Solid $Co(acac)_3$, 0.2M $Co(acac)_3$ benzene solutions and frozen 0.2 M $Co(acac)_3$ benzene solutions were irradiated with slow neutrons for 5 min in a TRIGA Mark II reactor (thermal neutron flux: 5×10^{11} n/cm^2·sec.). The solutions were irradiated at room temperature, the solid samples and the frozen solutions at dry-ice temperature. Various amounts of $FeCl_3\cdot6H_2O$ dissolved in small amounts of ethanol, or various amounts of anhydrous $FeCl_3$, were added to the benzene solutions and frozen benzene solutions (before freezing) before irradiation. An aliquot of the irradiated benzene solution (or frozen solution) was diluted to 5 m*l* with benzene and extracted with three 5-m*l* portions of 3% EDTA aqueous solution containing 0.8% sodium potassium tartrate and 10 mg of $CoSO_4\cdot7H_2O$ as carrier. Another aliquot of the irradiated benzene solution was stored overnight at room temperature and extracted the following day. All the ^{60}Co-labeled species exchangeable with Co^{2+} are extracted into the aqueous phase whereas $^{60}Co(acac)_3$ remains in the organic phase (as retention). The broken curves in Fig. 1 correspond to retentions obtained with the stored aliquots while the solid curves represent retentions in the aliquots extracted immediately. The irradiated solid samples (30—50 mg) were dissolved in 5 m*l* of benzene, ethanol, chloroform, or acetic acid, all with or without ferric chloride additive, and analyzed by means of solvent extraction or ion exchange.

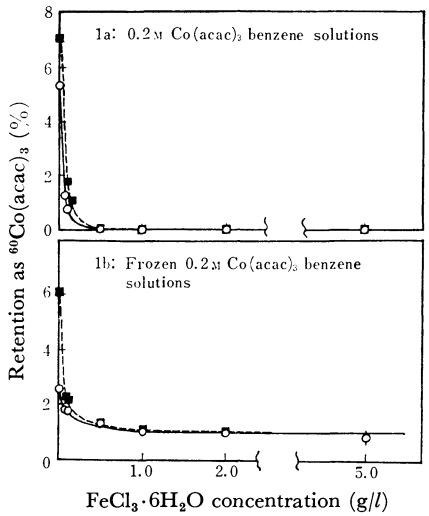

Fig. 1a-1b. Retention *vs.* ferric chloride concentration in irradiated $Co(acac)_3$ benzene solutions.

From the results we may draw the following conclusions:

1) As shown in Fig. 1a, the retention in $Co(acac)_3$ benzene solutions sharply decreases to 0% with the increase in the $FeCl_3\cdot6H_2O$ concentration. Although thermal reactions (recombination reactions) in the solutions during and after irradiation contribute appreciably to the apparent retention, their contribution can be eliminated effectively by the addition of $FeCl_3\cdot6H_2O$,*1 and the initial retention due to hot reactions alone can be estimated.

2) As seen in Fig. 1b, the retention in frozen 0.2M $Co(acac)_3$ benzene solutions decreases rapidly to a constant value (~1%) with increasing $FeCl_3\cdot6H_2O$*1 concentration. Since the most solute molecules (complex) should be precipitated as microcrystals in the frozen solutions at this concentration, it seems reasonable that the above retention value is fairly close to that observed with solid samples.

3) Retentions in solid samples fall within the range 1.3—1.5%, irrespective of solvents used, if they contain ferric chloride. Higher retentions 2.0—2.2% are obtained in the absence of ferric salts. The retention remains unchanged even after standing the solutions of the irradiated solid samples for several days if they contain ferric salts, whereas the retention increases appreciably after standing in solutions without ferric salts.

4) The effect of the ferric salt addition on the retention may be explained by assuming that ferric salts which can be easily complexed with acetylacetone work as good scavengers for free acetylacetone in solutions, and thus minimize the recombination of recoil species with acetylacetone through thermal reactions.

*1 Addition of anhydrous $FeCl_3$ is nearly as effective as $FeCl_3\cdot6H_2O$.

The Heat Capacity and the Phase Transition of the $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ Crystal

Akio KOSAKI, Yôichi IIDA,* Michio SORAI, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
**Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo*

(Received May 11, 1970)

The measurements of the temperature dependence of the magnetic susceptibility as well as the intensity of ESR spectra[1] of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ crystals have already revealed that there is some anomaly in their curves at around 40°C. The magnetic behavior has been explained in terms of a siglet - triplet transition based on the correlation between the electronic spins of each molecule, and the anomaly has been referred to a discontinuous change in the correlation energy at this temperature. The pressure dependence of the anomalous point has also been investigated by McConnell *et al.*[2] No consistent interpretation for the mechanism of this anomaly has, however, yet been given. The purpose of the present investigation is to measure the heat capacities of this radical salt precisely in order to clarify the mechanism of this anomaly.

This radical[3] was prepared by means of $(C_6H_5)_3P$ CH_3I and TCNQ (tetracyanoquinondimethan). The phosphonium salt and TCNQ were dissolved separately into acetonitrile and then mixed at about 70°C. This mixture was allowed to stand for about one day to produce black prism crystals as precipitates.

The heat capacities were measured with an adiabatic calorimeter[4] in the temperature region from 11 to 350°K.

As is shown in the following figure, the heat-capacity curve exhibited a phase transition at

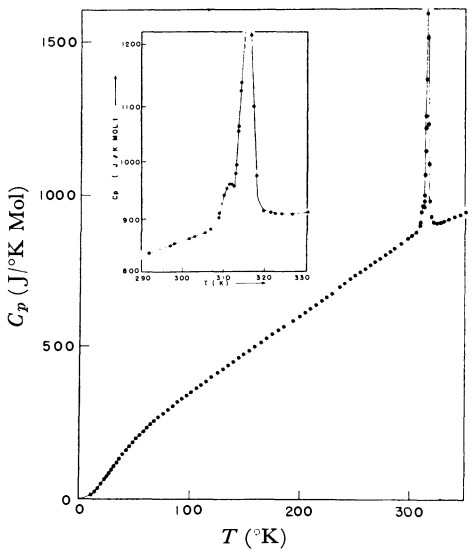

Fig. 1. Heat Capacity of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$.

315.7°K. The enthalpy and the entropy of transition were found to be 2030.0 J mol^{-1} and 7.1989 J°K^{-1} mol^{-1} respectively. This amount of entropy cannot be explained solely by the freedom of electronic spins, as would be expected from the magnetic measurements. It may be added here that this transition is accompanied by a small hump, as is shown on an enlarged scale in the figure. In order to clarify the origin of this small anomaly as well as the mechanism of the phase transition, we are hereafter going to measure the dilution effect on the heat capacity of this compound of the formation of a series of solid solutions: $[(C_6H_5)_3PCH_3]_{1-x}^+$-$[(C_6H_5)_3As\,CH_3]_x^+(TCNQ)_2^-$, as the pure $[(C_6H_5)_3$-$As\,CH_3]^+$ $(TCNQ)_2^-$ compound has no transition point. The detailed data on these compounds will be reported in due course.

The Formation of 6,8-Dihydroxypurine by the Oxidation of 7-Aminooxazolo[5,4-*d*]pyrimidine with Hydrogen Peroxide-Acetic Acid[1]

Yozo Ohtsuka and Kikuo Sugimoto

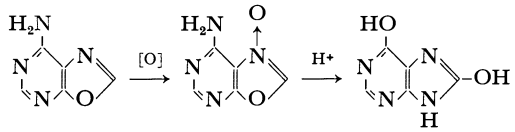
Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa

(Received May 14, 1970)

The direct oxidation of adenine with peracetic acid has been known to afford the 1-oxide,[2,3] while hypoxanthine is not convertible to the *N*-oxide by this method.[3,4] 7-Aminooxazolo[5,4-*d*]pyrimidine (I) can be considered as a compound having a structure intermediate between adenine and hypoxanthine; accordingly, its behavior when treated with a peracid is of interest. As an analogous compound, 7-aminothiazolo[5,4-*d*]pyrimidine has been reported to be oxidized to the *N*-oxide of the adenine type.[5]

We have found that the oxidation of 7-aminooxazolo[5,4-*d*]pyrimidine (I) with hydrogen peroxide and acetic acid afforded an unexpected product, 6,8-dihydroxypurine (III). Thus, one gram of I[6] was treated with 3.7 m*l* of a 30% aqueous solution of hydrogen peroxide and 10 m*l* of acetic acid at room temperature. After 2.5 days, light yellow precipitates (0.5 g, 48%) of a single compound were obtained. Recrystallization from water yielded colorless crystals, mp >340°C, which were identical with authentic 6,8-dihydroxypurine.[7]

As has been described in a previous paper,[8] 7-aminooxazolopyrimidines are easily converted into hypoxanthine. However, there is no possibility of the formation of III *via* hypoxanthine since hypoxanthine is inert under the conditions used here. Moreover, the oxidation of the pyrimidine moiety of I would not lead to such a product. Thus, the initial step of the oxidation probably occurs at the 1-*N* position of I,[9] giving 7-aminooxazolopyrimidine 1-oxide (II) as an intermediate. The conversion of II into III can be explained by analogy with the well-known rearrangement of aldonitrons into isomeric amides under acidic conditions:[10,11]



I II III

The difference in behavior towards oxidation between 7-aminooxazolo[5,4-*d*]pyrimidine and adenine or 7-aminothiazolo[5,4-*d*]pyrimidine may be attributed to the difference in the charge density on the ring-nitrogen atom, which is attacked preferentially by the electrophilic centre of the peracid. The present results may indicate that the electron-deficient character of the pyrimidine ring and the electron-excess character of the oxazole ring seem to be partly retained in the oxazolopyrimidine molecule,[12] while a more extensive donation of electrons from the five-membered ring to the pyrimidine ring takes place in purines[13] and even in thiazolopyrimidines. These factors account for the preferential oxidation on the oxazole ring in the oxazolopyrimidine.

9) Although the oxidation of azole compounds generally affords ring-opening products, the oxidation of 4-methylthiazole with hydrogen peroxide in acetic acid is known to yield the *N*-oxide [E. Ochiai and E. Hayashi, *Yakugaku Zasshi*, **67**, 34 (1947)].

10) W. Rundel, "Methoden der Organischen Chemie," ed. by E. Müller, Vol. 10/4, Georg Thieme Verlag, Stuttgart (1968), p. 428.

11) For example, pyridine *N*-oxide has been reported to afford 2-hydroxypyridine when treated with acetic anhydride [M. Katada, *Yakugaku Zasshi*, **67**, 51 (1947)]. An analogous rearrangement of pteridine derivatives [W. Hutzenlaub, G. B. Berlin and W. Pfleiderer, *Angew. Chem.*, **81**, 624 (1969)] or quinoxaline derivatives [Y. Ahmad, M S Habib, A Mohammady, B. Bakhtiari and S. A. Shamsi, *J. Org. Chem.*, **33**, 201 (1968)] seem to involve an acylation process, but we have no evidence for the involvement of acylation in the present reaction.

12) This was also suggested by the study of the spectroscopic properties of substituted 7-aminooxazolopyrimidines (see Ref. 6).

Solvent and Temperature Effects on the Electronic Spectra of Mixed Nickel(II) Chelates with *N,N,N',N'*-Tetramethylethylenediamine and Acetylacetone

Yutaka FUKUDA and Kozo SONE

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyoku, Tokyo

(Received May 8, 1970)

When equimolar quantities of $Ni(ClO_4)_2 \cdot 6H_2O$, *N, N, N', N'*-tetramethylethylenediamine(TMEN), acetylacetone(acaH) and sodium carbonate are mixed in ethanol, and the resulting mixture is concentrated under reduced pressure, blue crystals of the composition Ni TMEN aca $(ClO_4) \cdot 2H_2O$ separate out. This compound is stable in open air but is easily dehydrated in a P_2O_5 dessicator, and a red anhydrous compound is obtained which slowly reverts to the blue dihydrate in moist air.[1] The blue compound has a magnetic moment (μ_B) of 3.04 B.M. at 14°C, while the red one is only slightly paramagnetic ($\mu_B \sim 0.6$ B.M.).[2]

These values, and the spectral data shown below, indicate that they should be formulated as the mixed chelates, [Ni TMEN aca $(H_2O)_2$] (ClO_4) (octahedral) and [Ni TMEN aca] (ClO_4) (square-planar).

Both of these chelates are decomposed by water, but they are soluble in many organic solvents. Fig. 1 shows their spectra in some alcohols and acetone. It can be seen that in methanol both of the chelates exist as the blue octahedral species, [Ni TMEN aca $(X)_2$]$^+$ (X=H_2O or solvent); the spectra of these solutions (Curves A) are also very similar to the solid reflection spectrum of the blue chelate. On the other hand, the spectra in the other solvents show that they exist in part as blue species and in part as a red square-planar species, very probably [Ni TMEN aca]$^+$. The amount of this red species increases in the order MeOH$\ll$ EtOH$<$*n*-PrOH$<$Acetone$\ll$$CHCl_3$ or $C_2H_4Cl_2$, *i.e.* the order of decreasing coordination ability of the solvents. Corresponding to this spectral change, the color of the solution becomes gradually reddish from methanol to acetone, and the solutions in chloroform or 1,2-dichloroethane are quite red. In these two solvents, the red species clearly predominate (ν_{max}=20.5 kK; log ε=2.1—2.2).

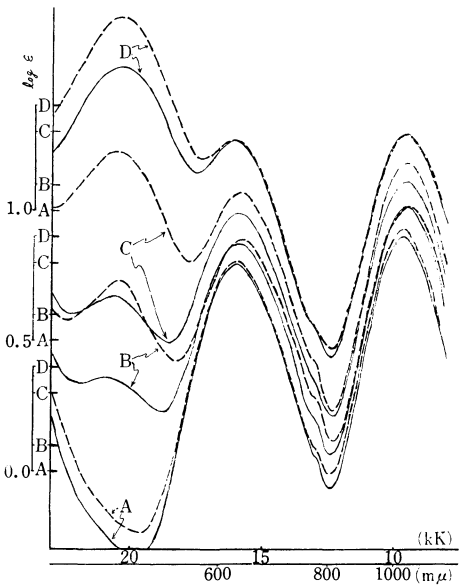

Fig. 1. Absorption spectra of the blue and red chelates at room temperature (18°C). Curves A,B,C and D refer respectively to the solutions in MeOH, EtOH, *n*-PrOH and acetone (0.8×10^{-1}—1.2×10^{-1}M); each curve is drawn in the same scale but displaced vertically (*cf.* the scale for log ε). The solid-line curves are those for the blue chelate, and the dotted-line curves for the red.

All the alcoholic and acetone solutions are thermochromic and become more reddish on heating. Spectral studies on the thermochromism show that the intensity of the band at 20.5 kK increases remarkably with the rise of temperature, showing that the equilibria [Ni TMEN aca $(X)_2$]$^+$ (octahedral)$\rightleftarrows$[Ni TMEN aca]$^+$ (square-planar)$+2X$ are shifted to the right hand side even by slight heating. It is interesting, however, to note that this type of reversible thermochromism is observed only in solvents of medium coordination ability (alcohols and acetone); the red solutions in poorly coordinating solvents($CHCl_3$ and $C_2H_4Cl_2$) as well as the blue ones in strongly coordinating solvents (DMSO and DMF) are not thermochromic, *i.e.* their colors do not changes by heating.

1) Elementary analyses of these compounds are as follows. Found for the blue compound: C, 32.40; H, 6.89; N, 6.88%. Calcd for [Ni TMEN aca $(H_2O)_2$](ClO_4): C, 32.26; H, 6.66; N, 6.84%. Found for the red compound: C, 34.65; H, 6.42; N, 7.42%. Calcd for [Ni TMEN aca](ClO_4): C, 35.37; H, 6.22; N, 7.50%.

2) The moments obtained with different samples of the red compound do not agree well with each other, and they all tend to increase slowly with time. It is therefore possible that this compound is in fact diamagnetic, and the observed moment is due to a small amount of the blue dihydrate which is readily formed in the sample. Work is now going on to confirm this view.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2283—2290 (1970)

Chemical Species Produced from Some Diazaazulene Derivatives in Aqueous Solutions of Various Acidities

Yoshie TANIZAKI and Hiroshi HIRATSUKA

Department of Chemitsry, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo

and Toshihiko HOSHI

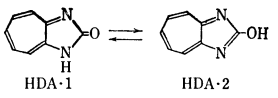
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Megurisawa, Setagaya-ku, Tokyo

(Received June 4, 1969)

Making use of the isosbestic points which appear in equilibrium between two chemical species, the chemical structures of various species produced from the diazaazulene derivatives have been investigated in aqueous solutions over a wide pH range. For 1-hydro-1,3-diazaazulene-2-one (abbreviation, HDA-1), for instance, four different species exist as stable species in the respective regions; (a) the pH region higher than 12, (b) around the neutral state, (c) the pH value of *ca.* 1.5, and (d) the strong acid state. In the (a) region, H^+ is taken off from the amino nitrogen of HDA-1 and the species becomes HDA-1^-; in (b) the species takes the HDA-1 structure, as its name indicates; in (c) it takes the H^+-HDA-1 structure protonated at the aza nitrogen, and in (d) it takes the H^+-HDA-1-H^+ structure, in which the position of the second protonation could not be clarified. In the case of 2-ethoxy-1,3-diazaazulene (EDA-2), the species corresponding to the second protonation (H^+-EDA-2-H^+) is hydrolyzed by acid catalysis and becomes H^+-HDA-1-H^+. In order to interpret the spectra of azaazulene compounds and the spectral change due to protonation, calculations by the LCAO–ASMO–SCF–CI method have been made for 1,3-diazaazulene and EDA-2. The characters of the first and the second transitions of the compounds have been satisfactorily explained by the diagrams of the AO coefficients of the LCAO-MO's representative of the transitions.

In the past two decades, a number of azaazulene compounds have been synthesized as tropolone derivatives. However, only a few physico-chemical studies have been reported, such as one on the dipole moment by Kurita and Kubo[1], and one on the electronic spectra by Nozoe and Murata.[2] As for the theoretical treatment, there seems to have been nothing except the study by Kon[3] using the simple molecular orbital method.

Nozoe *et al.*[4] have considered the product of the reaction of tropolone-methylether and guanidine hydrochloride to be a mixture of 2–amino-1, 3-diazaazulene and 1-hydro-2-imino-1,3-diazaazulene, which are tautomer with each other. Similarly, it is considered that a tautomerism exists between 2-hydroxy-1,3-diazaazulene (to be henceforth abbreviated as HDA-2) and 1-hydro-1,3-diazaazulene-2-one (HDA-1) as follows;



HDA·1 HDA·2 (1)

where the mole ratio of HDA-1 and HDA-2 in the methanolic solution is considered to be about 7:3.[5,6] If such an equilibrium as Eq. (1) exists, some spectral change may be expected to occur for the system when the temperature is changed. In order to determine the temperature dependence of the spectra, we measured the absorption spectra in ethanolic and aqueous solutions over the range from 25°C to 55°C. An appreciable change in spectra appeared, but the magnitude and the behavior of the spectral change were almost the same as those in the case of azulene in an ethanolic solution, in which no tautomerism like that of Eq. (1) is involved. For this reason, it is very doubtful that the above-mentioned system contains two chemical species as Eq. (1) indicates.

6) I. Murata, *Sci. Rep. Res. Inst., Tohoku Univ., Ser. A*, **12**, 271 (1963).

A tautomerism is also considered to exist between anthrone and anthranole; the ratio is said to be dependent on the amount of the alkaline substance (triethylamine) added to the system.[7] If this is true, the equilibrium between HDA-1 and HDA-2 of Eq. (1) should also be shifted by the variation in the nature of the solvent, for example, by the variation in the pH of the solution. In fact, the aqueous solutions of HDA-1 show a considerable change in spectra, while retaining definite isosbestic points, upon pH variation.

In the present investigation, the chemical structures of species produced from the azaazulene derivatives in the various pH regions will be clarified.

Azulene is well known as an isomer of naphthalene; it has been investigated in detail both theoretically[8] and experimentally.[9] Concerning the diazaazulene derivatives, however, there has been only one theoretical treatment, one by Kon[3] carried out by the Hückel method. Therefore, the electronic spectra of 1,3-diazaazulene and 2-ethoxy-1,3-diazaazulene will be calculated, and the results will be discussed with reference to those for azulene, which has previously been computed using the same approximation.[10]

Experimental

The 2-ethoxy-1,3-diazaazulene and 1-hydro-1,3-diazaazulene-2-one were provided by the Sankyo Company, Ltd. The 1-ethyl-1,3-diazaazulene-2-one was synthesized following Reference 11. The melting points were determined to be 101—102°C (lit, 101°C),[11] 243°C (245°C),[4] and 138°C (140°C)[12] respectively.

The concentrations of the samples used were of the order of 10^{-4} mol/*l*. The pH value of the solution was controlled by hydrochloric acid and sodium hydroxide, and was measured by means of a Toa Denpa pH meter, HM 5A. A strong acid or a strong alkaline solution of the sample was prepared by using concentrated sulfuric acid or sodium hydroxide respectively. The conditions of the solutions used are illustrated in the figures.

The measurement of the absorption spectra was carried out by a Shimadzu MPS-50A Recording Spectrophotometer over 220—400 mμ.

Results

Figure 1 shows the absorption spectra of 1-hydro-1,3-diazaazulene-2-one (abbreviation, HDA-1) in alkaline solutions with various pH values. The isosbestic points indicate the presence of two kinds of species in equilibrium. No further spectral change appeared upon an increase in the alkaline strength to more than pH=12.4 (by 0.5N of NaOH).

Figure 2 shows the absorption spectra of HDA-1 in the week acid region of pH=5.9—1.5. In this case, isosbestic points also appear, indicating an

equilibrium between two kinds of species. The spectrum for pH=5.9 of Fig. 2 coincides with that for pH=6.10 of Fig. 1, whereas the positions of the isosbestic points and the band shape of Fig. 2 (the acid solution) are different from those of Fig. 1 (the alkaline solution). This indicates, therefore, that the kinds of chemical species in the alkaline and the acid solution are different from each other.

With an increase in the acidity below pH=1.5, the spectral change appears again——that is, by increasing the concentration of sulfuric acid by at least from 9N to 27N, for instance, the spectrum is made to change with another set of isosbestic points. In this case, each absorption band for pH=1.50 of Fig. 2 behaves as follows. The 318 mμ band decreases in intensity, the 333 mμ band increases in intensity and shows a slight blue shift, and the 248 mμ band is only intensified, without any shift. According to the results for HDA-1, it is evident that four different kinds of species exist respectively as a stable one in four pH regions, including the strong acid and alkaline states (i.e., the extended

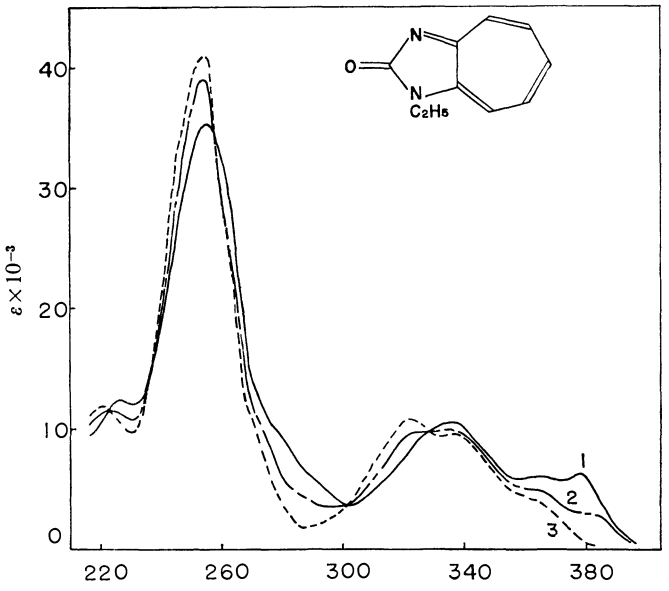

Fig. 3. Absorption spectra of (EDA-1) in aqueous acid solutions.
1. pH=5.85, 2. pH=4.01, 3. pH =1.85

pH region more than 12, the neutral state, at about the pH value of 1.5, and the strong acid state).

Figure 3 illustrates the absorption spectra of 1-ethyl-1,3-diazaazulene-2-one (abbreviated to EDA-1) in aqueous solutions from neutral to weak acid with various pH values. In addition, the spectrum of EDA-1 in an alkaline solution with a pH lower than 12.4 did not differ from that for pH=5.85 shown in Fig. 3. The behavior of the spectral change and the interval of acidity for the spectral change of EDA-1 correspond well with those in the case of HDA-1, though the absorption bands of the former are slightly longer in wavelength as a whole and are stronger in intensity than the corresponding bands of the latter. The correlation of the spectra of HDA-1 and EDA-1 in a strong acid solution is similar to that in a weak acid solution.

Consequently, in the case of EDA-1, there are a total of three kinds of species, each in one of three regions: neutral to alkaline, about pH=1.9, and strong acid.

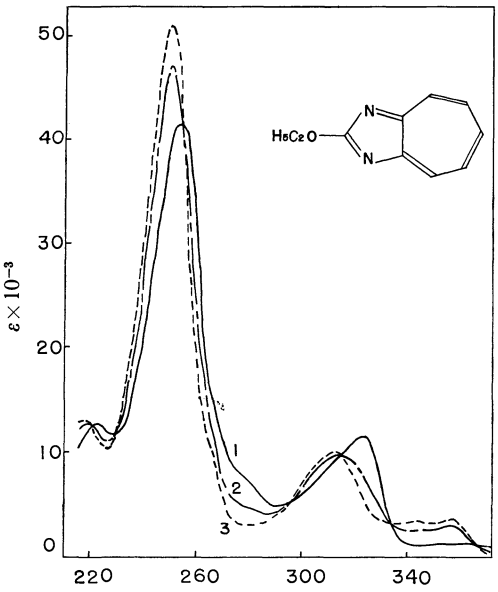

Fig. 4. Absorption spectra of (EDA-2) in aqueous acid solutions.
1. pH=5.62, 2. pH=3.30, 3. pH=1.88

Figure 4 represents the absorption spectra of 2-ethoxy-1,3-diazaazulene (abbreviation EDA-2) under conditions similar to those in Fig. 3. This sample did not show any appreciable change in spectra over the range from neutral to pH=11.9. In the strong acid solution, however, the sample showed a spectral change with the time dependence when the amount of added sulfuric acid was small, but the change was instantaneously completed when the amount was large. The resultant spectrum in either case coincided with that of HDA-1 in the strong acid solution. This suggests that EDA-2, which is stable in weak acid, is decomposed by strong acid and then becomes a species identical with that of HDA-1 in strong acid.

Accordingly, EDA-2 can exist as two independent species; one in the range from neutral to alkaline, and the other in the weak acid solution at about pH=1.90.

Calculation

The calculations were carried out by the semi-empirical method of LCAO-ASMO-SCF,[13] making use of the approximations by Pariser-Parr[14] and Nishimoto-Mataga [15] and the configuration interaction (CI). The geometry and the numbering of the atoms for 2-ethoxy-1,3-diazaazulene are shown in Fig. 5, in which the lengths of all C-C and C-N bonds are taken as 1.40Å. and in which that of C-O is taken as 1.41Å. The respective coordinates are listed in Table 1. For 1,3-diazaazulene, the same coordinates as above are taken, excluding the oxygen atom.

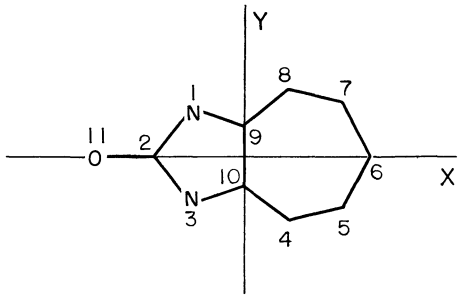

Fig. 5. Geometrical and numbering system for the 2-ethoxy-1,3-diazaazulene molecule.

For the Hückel MO calculation, the Coulomb integrals (α) and the resonance integrals (β) are used as follows:

$$\alpha_O = \alpha_C + 0.6\beta \qquad \beta_{CO} = 0.7\beta$$
$$\alpha_N = \alpha_C + 0.6\beta \qquad \beta_{CN} = 1.0\beta$$
$$\alpha_{C'} = \alpha_C + 0.1\beta$$

where α_C is the Coulomb integral of the carbon atom, where β is the resonance integral between the adjacent carbon atoms, where the subscript O or N indicates oxygen or nitrogen respectively, and where C′ indicates the carbon atom adjacent to oxygen or nitrogen.

The one-center integrals are evaluated by the Pariser-Parr's equation. The parameters employed here are summarized in Table 2. The SCF calculations were repeated ten times, and a satisfactory convergence was obtained for the respective AO

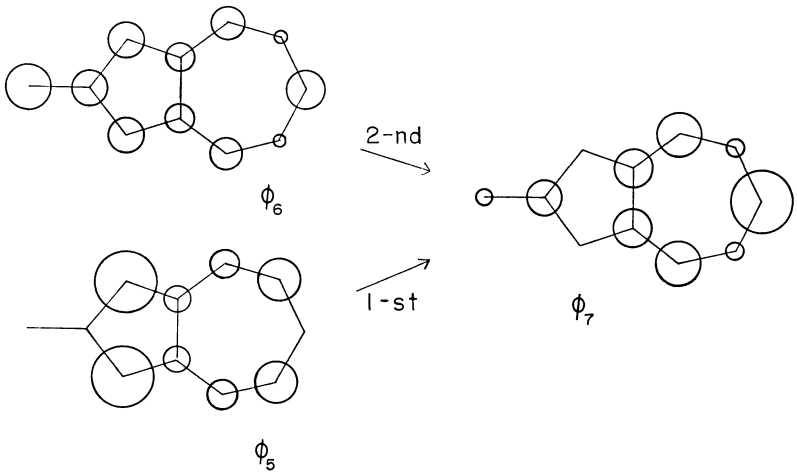

Fig. 7. $\Phi_5 \rightarrow \Phi_7$ and $\Phi_6 \rightarrow \Phi_7$ are representative of the first and second transitions of 2-ethoxy-1,3-diazaazulene (See, Fig. 6).

lene has larger wave numbers than that of azulene. This fact may be interpreted as follows. The magnitudes of the respective AO coefficients of the LCAO-MO's which are representative of the first and the second transitions, *i.e.*, $\Phi_5 \rightarrow \Phi_6$ and $\Phi_4 \rightarrow \Phi_6$ respectively, are shown diagrammatically in Fig. 6, where Φ_i represents the LCAO-MO and in which the subscript is the number in the order of increasing energy. According to Fig. 6, the change in the charge density at the positions 1 and 3 associated with the transitions $\Phi_5 \rightarrow \Phi_6$ is very large: that is to say, the large densities at 1 and 3 in Φ_5 and Φ_4 become exceedingly small in Φ_6, which is a representative MO of the excited states. Also, in the case of azulene, the corresponding transitions have the same character as above. However, the ionization potentials or the electron affinities at the positions 1 and 3 of azulene are small relative to those of 1,3-diazaazulene, because of the difference between carbon and nitrogen. Therefore, such a transition as $\Phi_5 \rightarrow \Phi_6$ or $\Phi_4 \rightarrow \Phi_6$ of 1,3-diazaazulene would need higher energies and appear at larger wave numbers than those of azulene. The same situations occur in connection with the other transitions.

2-Ethoxy-1,3-diazaazulene also possesses five electronic transitions in the range lower than 50000 cm^{-1} (above 200 mμ). The effect of the $-OC_2H_5$ substituent at the position 2 causes the first and the fifth transitions of 2-ethoxy-1,3-diazaazulene to shift to shorter wavelengths, and the rest to longer wavelengths relative to 1,3-diazaazulene. Moreover, the oscillator strengths of the second, the third, and the fourth transitions are increased, and the others are decreased, by the effect of $-OC_2H_5$. As above, the $-OC_2H_5$ substituent can cause some changes in the transition energies and oscillator strengths, but it cannot change the transition directions.

From a comparison of Figs. 6 and 7, it can be seen that the $-OC_2H_5$ group does not perturb the first and the second transitions. Especially, the character of the $\Phi_5 \rightarrow \Phi_7$ of 2-ethoxy-1,3-diazaazulene is almost the same as those representative of the first transitions of azulene and 1,3-diazaazulene.

Discussion

1. Chemical Structure. The three positions of protonation for HDA-1 or EDA-1 are considered to be aza nitrogen, amino nitrogen, and oxygen. Incidentally, a similar situation holds in the cases of the protonation of 1,6-dihydro-1-methyl-4-oxypyrimidine (expression (a), below) and 1,4-dihydro-1-methyl-4-oxypyrimidine (expression (b)).

(a) (b)

Brown *et al.*[16] have considered that a protonation occurs at the aza nitrogen atom, because the spectra of the protonated species of (a) and (b) are similar to each other.

The mechanism of the protonation to HDA-1 and EDA-1 may be different from the cases of (a) and (b). In the present case, however, let us assume that the order of the ability as the proton acceptor of the functional groups of HDA-1 and EDA-1 is similar to those of (a) and (b); that is to say, let us assume that the first protonation occurs at the aza nitrogen rather than at amino nitrogen or oxygen.

16) D. J. Brown, E. Hoerger and S. F. Mason, *J. Chem. Soc.*, **1953**, 331.

As has been shown in the "Experimental" section, all the absorption patterns over the range of 200 mμ to 300 mμ are similar to one another; no characteristic difference among them appears until above 300 mμ. For that reason, let us examine the absorption bands which appear above 300 mμ in comparing the spectra.

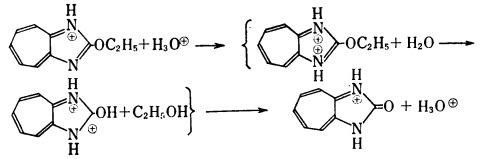
Murata[6] has considered that the system expressed by Eq. (1) contains HDA-1 as the main component, for the absorption pattern of the system is similar to that of EDA-1. It is natural that the electronic spectra associated with the π–π^* transitions of HDA-1 and EDA-1 are similar to each other, since they are isolectronic with respect to the π electron system. If some differences appear between the absorption patterns, it can be attributed to the difference in the substituents, –H and $-C_2H_5$. In fact, his consideration can be said to be reasonable, for the absorption spectra of HDA-1 (curve 1, Fig. 1) and EDA-1 (curve 1, Fig. 3) correspond to each other well.

We can now summarize our several results as follows. The temperature dependence of the spectrum of HDA-1 is as small as that of azulene, for which a tautomerism cannot be considered. HDA-1 and also EDA-1 can exist as independent species. HDA-1 in the neutral solution is not considered to be protonated, since no spectral change is observed in the range from neutral to pH=12. Taking these facts into account, it can safely be said that the hydrogen atom H of HDA-1 must be linked with the nitrogen atom at the position 1 of the diazaazulene skeleton in the same manner as C_2H_5 of EDA-1. If HDA-1 exists as a single species of another type (HDA-2 in Eq. (1)), then the spectrum should be correspondent to that of EDA-2. No such correspondencies, however, recognized between the curve 1 of Fig. 1 and the curve 1 of Fig. 4.

If an equilibrium such as Eq. (1) is supposed, the HDA-2 species may be found in the acid or the alkaline solutions. Let us compare the absorption spectra of HDA-1 and EDA-1 in the acid solution and that of EDA-2 in the neutral solution. In the case of EDA-1, the proton addition upon an increase in the acidity is expected to take place at the aza nitrogen atom and to produce H^+-EDA-1, as has been mentioned at the beginning of this section. The spectrum of HDA-1 in the acid state (curve 3, Fig. 2) closely resembles that of H^+-EDA-1 (curve 3, Fig. 3) rather than that of EDA-2 in the neutral state (curve 1, Fig. 4). This indicates that HDA-1 is not isomerized to HDA-2, as in Eq. (1), but is protonated and becomes H^+-HDA-1, as in the case of H^+-EDA-1.

Next, let us discuss the chemical species in the alkaline solution. As has been pointed out, EDA-1 and EDA-2 exist as a single species in the range from the neutral to the alkaline state, while HDA-1 in the alkaline state takes a spectral species different from that in the neutral state. The spectra of the chemical species may be compared as follows. The spectrum of the species of HDA-1 in the alkaline solution (curve 3, Fig. 1) does not resemble either the curve 1 of Fig. 4 in the neutral solution of EDA-2 or the curve 1 of Fig. 3, which is identical with that of EDA-1 in the alkaline solution. It is especially remarkably different from the former. This indicates that the species of HDA-1 in the alkaline state does not take the structure corresponding to EDA-2; that is, no isomerism such as Eq. (1) takes place. Moreover, the spectrum of HDA-1 in the alkaline state is not similar to that of EDA-1. Taking into consideration the possibility that a dissociation in the reverse process of the protonation occurs because of the variation from neutral to alkaline, it is reasonable that H is taken off as a proton from the amino nitrogen of HDA-1 during the variation, in some way such as $HDA\text{-}1+OH^-\rightarrow HDA\text{-}1^-+H_2O$.

When HDA-1 is protonated and becomes H^+-HDA-1, the proton will go to aza nitrogen. This theory is strongly supported by the following facts. As has been pointed out in the "Experimental" section, in the process of the first protonation of EDA-2 a proton must go to either of two aza nitrogens, and H^+-EDA-2 is produced. If the second protonation occurred, the place to be attacked by a proton would be another aza nitrogen. In order to confirm this expectation, we carefully determined the second change in spectra upon the addition of sulfuric acid. The spectrum of the doubly-protonated species (H^+-EDA-2-H^+) gradually varied and became a spectrum coincident with that of H^+-HDA-1 in the weak acid solution. Upon the further addition of concentrated sulfuric acid, the spectrum of H^+-EDA-2-H^+ completely coincided with that of H^+-HDA-1-H^+ in the strong acid solution. The above results for the second protonation of H^+-EDA-2 include two important facts — that the resultant species loses the ethyl group and that it possesses amino nitrogen. In this case, the fact that the ethyl group is separated from H^+-EDA-2 in a strong acid state can be explained by the usual mechanism of hydrolysis by acid catalysis:

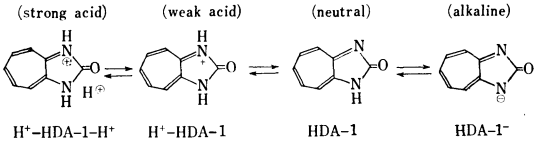


(2)

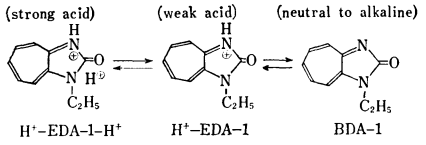
The mechanism shows that the product possesses amino nitrogen and is H^+-HDA-1 itself. Since the product shows an absorption pattern identical with that of H^+-HDA-1-H^+, the hydronium ion in the last expression of Eq. (2) may be attached as a proton to H^+-HDA-1 somewhere, but the exact position is not evident at the present stage. The

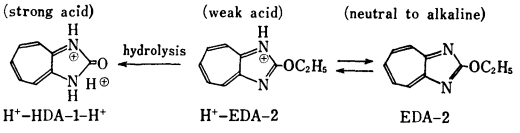
mechanism also establishes that, in the first protonation-process for HDA-1, a proton must make an attack on the aza nitrogen atom at the position 3.

Conclusively, as for HDA-1 the chemical species which can exist over the whole region from strong acid to alkaline may be summarized as follows:



Also, the respective species considered with respect to EDA-1 and EDA-2 are;





2. Interpretation of the Spectra. The absorption spectrum of EDA-2 is shown in Fig. 8, as are, for the sake of comparison, the computed results. The correlation between the observed and the computed absorption bands with respect to number, location and intensity are satisfactory. The theoretical assignments of the bands are listed in Table 3. The transition energies of azulene and 1,3-diazaazulene in Table 3 have been computed taking larger values of the ionization energy and the electron affinity at the positions 1 and 3 for the latter than for the former. The resultant transition energies of 1,3-diazaazulene are always larger (at shorter wavelengths) than the corresponding ones of azulene.

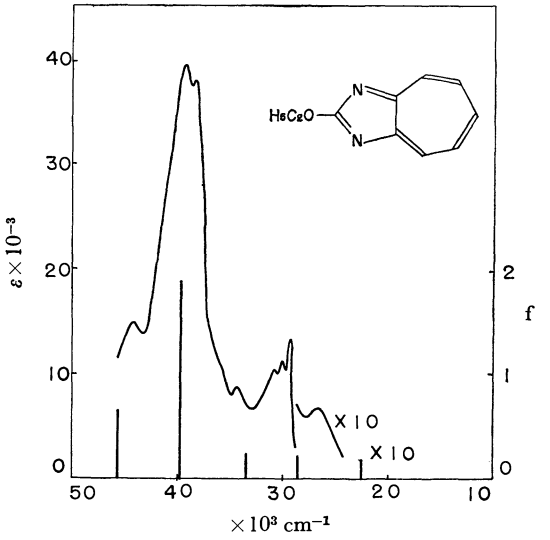


Fig. 8. Comparison of the calculated and observed (in cyclohexane) absorption bands of 2-ethoxy-1,3-diazaazulene, EDA-2.

In the case of protonation, the color bands of azobenzenes (*e.g.*, methyl-orange), for example, can remarkably shift to longer wavelengths.[17] On the contrary, in the present case, the protonation makes the π–π^* band shift to a shorter wavelength. When EDA-2 is protonated at the aza nitrogen atom and becomes H⁺-EDA-2 the apparent increase in the ionization potential and the electron affinity of the nitrogen atom results. Therefore, if we take the larger ionization potential and electron affinity at either the 1 or 3 position for H⁺-EDA-2, the resultant transition energies will become larger than those for EDA-2. Thus, the absorption bands of H⁺-EDA-2 are at shorter wavelengths than the corresponding ones of EDA-2.

The absorption bands of H⁺-HDA-1 and H⁺-EDA-1 are located at shorter wavelengths, or at least not at longer ones, than the corresponding bands of HDA-1 and EDA-1 respectively. This can be explained in the same way as above. It should be noted here that an extra band peak appears at about 330 mμ, as illustrated in Fig. 2; at the present stage, however, we cannot assign that absorption. According to the dichroism analysis,[18] however, both of the 330 mμ peaks must belong to the second electronic transition, and so they are attributed to the fine structure. The first band of H⁺-HDA-1 corresponding to the 370 mμ band of HDA-1 is the weak shoulder at about 360 mμ (curve 3, Fig. 2).

The authors are greatly indebted to Dr. H. Negoro, Dr. G. Sunagawa, Dr. N. Soma and Dr. H. Nakao of the Sankyo Company, Ltd., for providing the samples and for their helpful advice on the synthesis of the compounds. The authors are also deeply indebted to Miss K. Taniyama and Miss M. Watanabe of the Computer Center of Aoyama Gakuin University for their considerable assistance with the computer programs. This work was supported in part by a Scientific Research Grant of the Ministry of Education, to which the authors' thanks are due.

Studies of the Aggregation of Dyes. The Scope of Application of the Maximum-slope Method

Mitsuhiko HIDA and Teruko SANUKI

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received September 18, 1969)

The maximum-slope method, previously suggested by one of the authors has proved to be more advantageously applied to the determination of the aggregation constant (K_n) and the degree of aggregation (n) in a dye solution than is Zanker's method. Changes in the spectra of the aqueous or ethanolic solutions of Rhodamine 6G, 3,6-diaminoacridine and thionine were studied as their concentration increased by means of both the maximum-slope method and Zanker's method. The aggregation characteristics obtained by these two methods were then compared with each other and discussed.

Recently the aggregation of molecules in solutions has been drawing much attention from men in various fields because it has a wide application.

Spectroscopic measurement has been employed in determining the aggregation constant and the degree of aggregation because of its accuracy and its simplicity.

It is, however, rather difficult to make a reliable estimation of the aggregation parameters, even for a simple equilibrium system between a monomer and a polymer of one definite degree of aggregation, by means of the graphic analysis of the spectroscopic data. The reason for this is that there are more unknown parameters than the number of given equations.

A way to overcome this difficulty has already been developed. Zanker derived the following equation (Eq. (1))[1]:

$$\log C_0(\varepsilon_1-\varepsilon) = n\log C_0(\varepsilon-\varepsilon_n/n) + \log K_n n(\varepsilon_1-\varepsilon_n/n)^{1-n} \quad (1)$$

were ε is the apparent absorptivity at a difinite wave length, where ε_1 and ε_n are the absorptivities of the monomer and the aggregate respectively, at the same wavelength, and where C_0 is the total concentration. He assumed suitable values for ε_1 and ε_n/n, and plotted $\log C_0(\varepsilon_1-\varepsilon)$ against $\log C_0(\varepsilon-\varepsilon_n/n)$. The degree of aggregation, n, was given by the slope of this plotted straight line, and the equilibrium constant (K_n) was calculated from the intercept.

This method has been recognized as the simplest and most convenient, bus it cannot be advantageously applied to the cases where the value of either ε_1 or ε_n/n has not been determined accurately.

Another graphic method has been developed by one of the present authors (M.H.). The method, which is called "the maximum-slope method"[2], estimates the ε_1 value by extrapolating the ε-$\log C_0$ curve to an infinite dilution, while the maximum slope (m_0) is determined by the tangent of the curve. The values of n, ε_n/n, and K_n are selected in such a way that they give the best agreement with the experimental curve.

In this paper, the maximum-slope method will be compared with Zanker's method and the advantages and applicability of the former will be discussed.

Results and Discussion

1. Analysis of the Computed Aggregation System. By taking suitable values for ε_1, ε_n/n, and $\log K_n$, the apparent absorptivities were computed over a range of concentrations between 10^{-6} and 10^{-3} mol/l, and the ε-$\log C_0$ curve was analyzed graphically by both the maximum-slope method and Zanker's method. A single equilibrium system between the monomer and the dimer was postulated for the sake of simplicity. The apparent absorptivities (ε) of this system were calculated by means of following equation:

$$\varepsilon = \varepsilon_2/2 + \frac{(\varepsilon_1-\varepsilon_2/2)}{4K_2}\left(-1+\sqrt{1+8K_2C_0}\right) \quad (2)$$

Assuming ε_1 and $\varepsilon_2/2$ to be 1×10^5 and 0.0 respectively, the apparent absorptivities were computed for $\log K_2=2,3,4$ and 5. Curve (1) in Fig. 1 suggests that the dimerization of $\log K_2=5$ commences even in a very dilute range (below 10^{-5} mol/l); consequently, ε_1 cannot be accurately determined. If

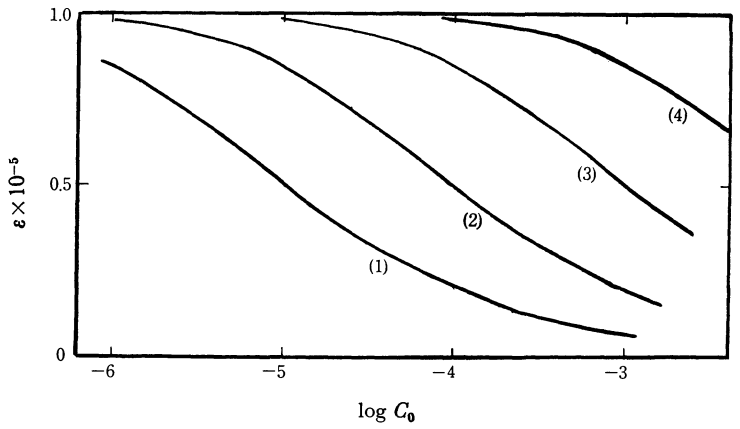

Fig. 1. Computed absorptivity *vs.* log C_0.
(1); log K_2=5.0, (2); log K_2=4.0, (3); log K_2=3.0, (4); log K_2=2.0

ε_1 is estimated by extrapolation at 0.95×10^5, $\varepsilon_2/2$ and logK_2 will be found to be -0.06×10^5 and 4.81 respectively by the use of the maximum slope method. These smaller values may be caused by the underestimation of the value of ε_1. If the errors made in estimating ε_1 and in drawing the maximum slope (m_0) are designated as $\delta\varepsilon_1$ and δm_0, the errors in the values of ε_n/n and logK_n obtained by the maximum-slope method are given by Eqs. (3) and (4):

$$\delta(\varepsilon_n/n) = \delta\varepsilon_1 - (\varepsilon_1-\varepsilon_n/n)_t(\delta m_0/m_0) \quad (3)$$

$$\delta(\log K_n) = (n-1)\delta\varepsilon_1/m_0 + n\log(\overline{1-r}/r\sqrt{n}) + (n-1)\log(1+\delta m_0/m_0) \quad (4)$$

where $r=(m/m_0)/(1+\sqrt{n})$ and where the subscript t denotes the true value.

By substituting the numerical values listed below for $\delta\varepsilon_1$, δm_0, r, and m_0 in Eqs. (3) and (4), $\delta(\varepsilon_2/2)$ and $\delta(\log K_2)$ are obtained as -0.06×10^5 and -0.114 respectively.

TABLE 1. COMPARISON OF THE TRUE AND OBTAINED VALUES OF THE AGGREGATION PARAMETERS

No.	True values		
	$\varepsilon_1\times10^{-5}$	$\bar{\varepsilon}_2\times10^{-5}$	log K_2
1	1.0	0.0	5.0
2	1.0	0.0	4.0
3	1.0	0.0	3.0
4	1.0	0.0	2.0

$$\delta\varepsilon_1 = -0.05\times10^5,$$
$$\delta m_0/m_0 = -0.01,$$
$$r = (1-0.01)/(1+\sqrt{2}) = 0.411,$$
$$m_0 = 0.396\times10^5$$

Therefore, the values of $\varepsilon_2/2$ and logK_2 obtained by the maximum-slope method would be -0.06×10^5 and 4.886 (*cf.* Table 1).

The maximum-slope method can derive correct values of $\varepsilon_2/2$ and logK_2 for the dimerization of logK_2=4 and 3, because the values of ε_1 and the maximum slope can be determined accurately. On the other hand, Curve (4) (logK_2=2) in Fig. 1 shows that the amount of the aggregate is not sufficient to determine the accurate maximum slope. If the slope at log$C_0=-3.5$, which is eight-tenths of the maximum value, is taken as the maximum slope, we obtain:

$$\delta m_0/m_0 = -0.20.$$

Consequently, $r=(1-0.20)/(1+\sqrt{2})=0.331$. The absorptivity of the monomer (ε_1) can be determined precisely by means of curve (4); that is:

$$\delta\varepsilon_1=0.$$

By substituting the numerical values for these quantities in Eqs. (3) and (4), the deviations of the values of $\varepsilon_2/2$ and logK_2 were found to be 0.2×10^5 and 0.213 respectively. Therefore, the values of $\varepsilon_2/2$ and logK_2 obtained by the maximum-slope method are 0.2×10^5 and 2.21 respectively. These

Table 2. Aggregation parameters of rhodamine 6G in aqueous solution

Method	Without KCl				With KCl			
	n	$\varepsilon_1\times10^{-4}$	$\varepsilon_2\times10^{-4}$	$\log K_2$	n	$\varepsilon_1\times10^{-4}$	$\varepsilon_2\times10^{-4}$	$\log K_2$
Max. slope	2	8.50	1.50	3.41	2	8.55	0.67	3.57
Zanker	2	8.50	0.39	3.35	2	8.55	0.0	3.51

values agree well with the values shown in Table 1. Table 1 may suggest that the maximum-slope method can more reasonably be applied, if the maximum slope and either ε_1 or $\varepsilon_2/2$ are determined, than Zanker's method, which is confined within narrower limits of $\log K_2$, because the values of both ε_1 and $\varepsilon_2/2$ should be determined.

2. Aggregation of Rhodamine 6G in an Aqueous Solution. The changes in the spectrum of the solution with the dye concentration were analyzed by both methods. The results are compared in Table 2.

Baranova and Levshin reported that Rhodamine 6G aggregates in the dimerization stage at concentrations below 2×10^{-3} mol/l, but higher aggregates are formed at higher concentrations.[3] The plotting of ε against $\log C_0$ (Fig. 2) also shows that this dye appears to exist in an equilibrium between the monomer and the dimer in the concentration range below $10^{-3.5}$ mol/l, but, since there was some discrepancy between the measured value and the calculated curve ($n=2$) in the concentration range above about $10^{-3.5}$ mol/l, Rhodamine 6G is likely to exist in equilibria between the monomer and higher aggregates ($n\geq3$) in a higher concentration range.

Table 2 also shows no influence of the added potassium chloride (0.2 mol/l) on the aggregation, while Glowacki and his co-workers observed some effect of added salts (>0.24 mol/l) on the aggregation and interpreted the effect on the basis of the structural change in the aqueous solution and the salt effect. Therefore, it seems that the formation of the ion pair does play little part in the aggregation of Rhodamine 6G in a solution which has no added salt.

Figure 3 shows the spectra of the monomer and dimer, computed from those of Rhodamine 6G at different concentrations by means of the least-squares method. The spectrum of the monomer has two absorption bands in the visible region; their maximum wavelengths are 525 and about 490 mμ, while the absorption band of the dimer is at 490 mμ. This hypsochromic shift may be interpreted in terms of the weak coupling theory suggested by DeVoe.[4]

According to the weak coupling theory, the dimer absorptivity of the band M at the wave number σ is expressed by Eq. (5):

$$\varepsilon_M(\sigma) = 2\varepsilon_M^0(\sigma)[1-2(F_{MM}(\sigma)\alpha_M(\sigma)+F_{MN}(\sigma)\alpha_N(\sigma))] \quad (5)$$

where $\varepsilon_M(\sigma)$ and $\varepsilon_M^0(\sigma)$ denote the monomer and dimer absorptivities respectively, where α_M is the partial group polarizability of the band M of the

monomer, and where F_{MN} is a group interaction factor between the monomer bands M and N. The value of F_{MN} in (erg D^{-2}) can be calculated by means of Eq. (6):

$$F_{MN} = (10^{-36}/2)\sum_i \sum_{j \neq i} (R_{ij})^{-3} \times [\mathbf{e}_{iM}\mathbf{e}_{jN} - 3(\mathbf{e}_{iM}\cdot\mathbf{e}_{ij})(\mathbf{e}_{jN}\cdot\mathbf{e}_{ij})] \times (\mathbf{e}_{iM}\cdot\mathbf{e}_{jN}) \quad (6)$$

where R_{ij} is the distance (cm) between the molecules i and j, where $\mathbf{e}_{iM}$ and $\mathbf{e}_{jN}$ are the unit vectors of the transition moments, and where $\mathbf{e}_{ij}$ is a unit vector along the line connecting the molecules.

The partial group polarizability of the band M (α_M) is given by:

$$\alpha_M(\sigma) = 0.923 \times 10^{14} \int \frac{\varepsilon_M^0(S)}{S^2 - \sigma^2} dS$$

The value of $\alpha_M(\sigma)$ is positive for wave numbers shorter than σ_0, where a nearly maximum absorption is obtained,[5] and negative for wave numbers larger than σ_0.

If the transition moments of the two monomer bands (A and B) are perpendicular to each other, and if the molecular plane is perpendicular to a common axis,[6] the dimer spectrum may be predicted to be as follows: (1) When neighbouring moments, μ_{1A} and μ_{2A} (μ_{1B} and μ_{2B}), are parallel to each other in the dimer,

$$F_{AA} > 0,\ F_{BB} > 0, \text{ and } F_{AB} = 0;$$

namely, there is self-interaction between the monomer bands, A and B, but no mutual interaction between them.[7] In this case, both monomer bands (A and B) can be predicted to shift hypsochromically and hyperchromically. (2) On the other hand, when the monomer bands, A and B, interact with each other without self-interaction, that is, when $F_{AB} > 0$ and $F_{AA} = F_{BB} = 0$ (this is possible if the neighbouring moments, μ_{1A} and μ_{2A} (μ_{1B} and μ_{2B}), are perpendicular to each other,[8]) the absorptivity of the band with the longer λ_{max} may decrease, while that with the shorter λ_{max} may increase.

Thus, the dimer spectra observed may be understood in terms of the weak coupling mechanism, in which monomer bands interact with one another

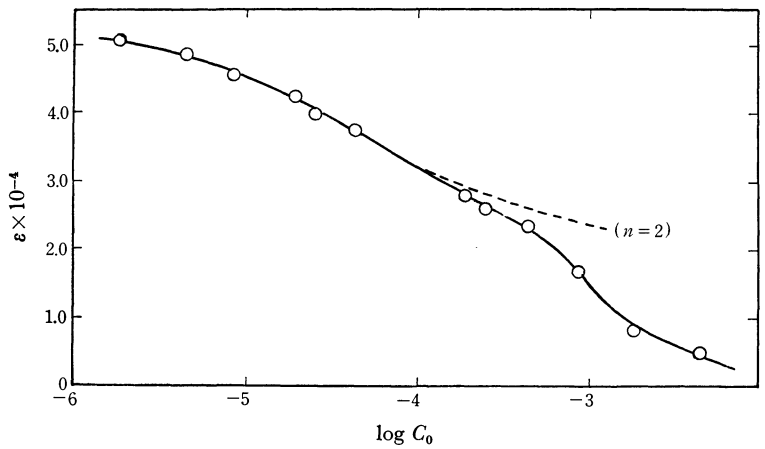

Fig. 4. Apparent absorptivity *vs.* log C_0 of 3,6-diaminoacridine in ethanolic solution.

5) The partial group polarizability is not always zero at the wave number of maximum absorption. When the monomer absorptivity ($\varepsilon_M{}^0(\sigma)$) is symmetrical about the wave number of maximum absorption, the wave number, where α_M is zero, is very near to that of the maximum absorption.

6) The spectra of dimer with another geometry will be discussed elsewhere.

7) Self-interaction means vibronic interaction of monomer band with the other wave number regions of the same band.

8) Therefore, μ_{1A} and μ_{2B} (μ_{1B} and μ_{2A}) are parallel to one another.

with or without self-interaction. However, much more work has to be done in this connection.

3. 3,6-Diaminoacridine in Aqueous and Ethanolic Solutions. Since the change in the spectrum of an aqueous solution of 3,6-diaminoacridine with the increase in the concentration was not very large, reliable results could not be obtained. Assuming that $\varepsilon_n/n=0$, Mataga determined the degree of aggregation and $\log K_n$ as 2 and 3.43 respectively by means of Zanker's method.[9]

The maximum-slope method suggested that the monomer-dimer system agrees better with the experimental data than any other system, as is shown in Table 3. If the aggregation parameters are corrected by the minimum deviation method and have a minimized mean relative deviation,[10] the monomer-trimer system seems to agree better with the experimental data. However, the two mean relative deviations (Δ) calculated by taking $n=2$ and 3 are sufficiently smaller than the experimental error (about 2%). Thus, we were not able to conclude which model was preferable.

Figure 4 shows that 3,6-diaminoacridine aggregates in two steps in an ethanolic solution. In the concentration range below 10^{-4} mol/l, 3,6-diaminoacridine seems to exist in a monomer-dimer equilibrium system, but higher aggregations proceed above 10^{-4} mol/l as:

$$nD_2 \rightleftarrows D_{2n}.$$

A specific value of n was not determined in the experiment because of a lack of sufficient reliable experimental data.

The aggregation parameters obtained by different methods are compared in Table 3.

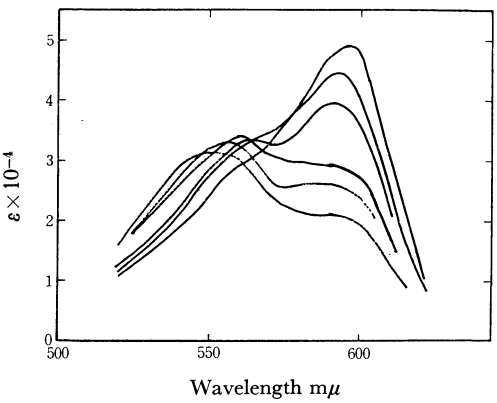

Fig. 5. Spectral change of thionine with increase of concentration.

4. Thionine (T^+Cl^-) in Aqueous Solution. Since no isosbestic point is observed, as is shown in Fig. 5, it seems that there are more than three species of thionine in its aqueous solution. The following species may be considered:

(i) several aggregates with different degrees of aggregation: $(T^+)_n$,
(ii) acid-base reaction products: TH^{2+} or TOH,
(iii) their aggregate(s), and
(iv) the ion pair and its aggregate(s): TCl and $(TCl)_n$.

In order to examine whether or not acid-base reaction products take part in the aggregation of thionine, it is necessary to determine the pK_a and pK_b values of thionine. The apparent absorptivity (ε) of the system of the protonation reaction (Eq. (7)) is given by Eq. (8):

$$T^+ + nH^+ \rightleftarrows (TH_n)^{(n+1)+} \quad (7)$$

$$\varepsilon = (\varepsilon_T[T^+]+\varepsilon_{TH_n}[TH_n])/([T^+]+[TH_n]) \quad (8)$$

By combining Eq. (8) with the law of mass action (Eq. (9)), Eq. (10) is obtained:

$$K = [TH_n]/[T^+][H^+]^n \quad (9)$$

$$\log(\varepsilon-\varepsilon_{TH_n})-\log(\varepsilon_T-\varepsilon) = n\mathrm{pH} + pK_b \quad (10)$$

If the values of both ε_T and ε_{THn} are determined, the slope and the intercept of the straight line made by plotting $\log(\varepsilon-\varepsilon_{THn})/(\varepsilon_T-\varepsilon)$ against the pH give the degree of protonation and the pK_b of thionine.[11] On the other hand, when either ε_{THn} or ε_T cannot be determined, the values of n and pK_b are obtained by a procedure similar to the maximum-slope method, because the maximum slope (m_0) of the tangent of the ε-pH curve is given by Eq. (11):

$$m_0 = \left(\frac{d\varepsilon}{d\mathrm{pH}}\right)_{max} = \frac{n}{4}(\varepsilon_T-\varepsilon_{TH_n}) \quad (11)$$

The n and pK_a values of the hydroxylation reaction can be similarly determined by analyzing the chages in the spectrum of the alkaline solution. The pK_a and pK_b values of thionine, as determined by the method described above, are shown in Table 4.

Table 4. The vlaues of pK_a and pK_b of thionine

Wavelength (mμ)	$\varepsilon_T\times10^{-4}$	$\varepsilon_{TH_n}\times10^{-4}$	n	pK_b
597	4.90	1.56	1	0.72
670	0.0	4.00	1	0.86
		mean	1	0.79
Wavelength (mμ)	$\varepsilon_{T^+}\times10^{-4}$	$\varepsilon_{TOH}\times10^{-4}$	n	pK_a
597	4.90	1.00	1	8.8

9) N. Mataga, This Bulletin, **30**, 375 (1957).

10) Adjustment of the parameters by trial and error method is repeated until the minimum value of deviation is attained and the final values of the aggregation parameters are regarded as the best ones (Ref. 2). But it can be shown that the final values obtained somewhat depend on definition of deviation. This subject will be discussed further elsewhere.

11) In very high acid concentration H_0-function should be used in site of pH.

TABLE 5. AGGREGATION PARAMETERS OF THIONININE IN AQUEOUS SOLUTION

n	$\varepsilon_1 \times 10^{-4}$	$\bar{\varepsilon}_2 \times 10^{-4}$	$\bar{\varepsilon}_3 \times 10^{-4}$	$\log K_2$	$\log K_3$	Δ	Method
2	5.25	0.0	—	2.90	—	0.0237	max. slope
3	5.25	—	1.39	—	6.52	0.0511	max. slope
2+3	5.03	2.38	0.93	2.90	6.52	0.0049	min. dev.

These results indicate that the amounts of TOH and TH^{2+} are negligibly small in the pH range between 1 and 8. Hence, the existence of acid-base reaction products and thir aggregates can be disregarded.

In addition, the ion pair and its aggregate(s), TCl and $(TCl)_n$, can also be neglected because no change was observed in the spectrum upon the addition of potassium chloride in the concentration range between 2×10^{-3} and 2 mol/l. Therefore, the absence of an isosbestic point in the change in the thionine spectrum implies that several aggregates are equilibrated; the aggregation system may, then, be in a multistage equilibrium. Although the maximum-slope method cannot be advantageously employed for the analysis of the system which includes several species with different degrees of aggregation, the change in absorptivity at 597 mμ (wavelength where the maximum absorption of the monomer is observed) was analyzed by this method, assuming that the aggregation system could be approximated by a single equilibrium system. The results (shown in Table 5) indicate that thionine may aggregate in the dimer and the trimer in an aqueous solution.

In order to minimize the mean relative deviation, the molar absorptivities of the monomer and the aggregates and the formation constants of the aggregates were adjusted by the minimum deviation method. These corrected values are also given in Table 5. Thus, thionine seems to aggregate in the monomer-dimer-trimer system. The wavelengths of the maximum absorptions of the spectra of the monomer, the dimer, and the trimer, obtained by means of least-squares calculations, are shown in Table 6. A hypsochromic shift in the spectrum of thionine was observed just as in the case of Rhodamine 6G.

Experimental

The prepared dye solutions were left at 25°C until no further spectral changes were observed. This took about 12 hr in the cases of Rhodamine 6G and 3,6-diaminoacridine, but 24 hr for the thionine solution.

Commercial Rhodamine 6G was purified by repeated recrystallizations from water and was then dried at 110°C in a vacuum. Pure 3,6-diaminoacridine was obtained by treating purified proflavine sulfate with aqueous ammonia. The purification of proflavine sulfate was carried out by repeated recrystallizations from an aqueous alcoholic solution. Commercial thionine was also purified by repeated recrystallizations from an aqueous ethanolic solution. The purities of the dyes were confirmed by means of paper chromatography, elementary analysis, and a study of their absorption spectra.

(Received September 25, 1969)

The thermal decomposition of lead carbonate tablets was kinetically studied in a nitrogen gas stream at temperatures of 240, 320, and 360°C. The tablets used in this work were prepared by compressing lead carbonate particles in a steel mold under pressures of 2—15 ton/cm^2. The decomposition reaction for the tablet was represented in two ways. Rate expressions were developed from the unreacted-core shrinking model applied to the individual particles (for the first of the two decomposition processes) and to the whole tablet (for the second). The effect of the pressure applied in preparing the tablet on the decomposition rate was attributed to the deviation in the pressure profile for carbon dioxide in a tablet (for the first process) or to the variation in the effective diffusivity and bulk density of the tablet (for the second).

Publications have appeared on the non-isothermal decomposition of lead carbonate, reporting the existence of such intermediate phases as $PbO \cdot 2PbCO_3$, $PbO \cdot PbCO_3$, and $2PbO \cdot PbCO_3$ in a carbon dioxide atmosphere at 1 atm.[1-3] In 1964 Crisafe and White[4] examined the thermal decomposition of lead carbonate by equilibrium methods and found the presence of $3PbO \cdot 4PbCO_3$, which is stable under very high P-T conditions. It was recently shown, from isothermal decomposition studies[5,6] in a nitrogen-gas flow or under reduced pressure, that a mass of lead carbonate particles decomposed to form two intermediate phases, $PbO \cdot PbCO_3$ at high partial pressures of carbon dioxide and $2PbO \cdot PbCO_3$ at low partial pressures. One of the basic lead carbonates, $PbO \cdot 2PbCO_3$, is formed only in the decomposition of lead carbonate hydroxide, $2PbCO_3 \cdot Pb(OH)_2$.[7]

Few studies had been published on the rate of the decomposition of lead carbonates; therefore, kinetic studies of the thermal decomposition of these samples were previously made by the present authors,[5-7] showing that the unreacted-core shrinking model provided a good explanation for the decomposition of the samples. The thermal decomposition of a packed mass of lead carbonate particles in a small glass tube[8] was also investigated in a nitrogen-gas stream and was found to be:

$$2PbCO_3(s) \longrightarrow PbO \cdot PbCO_3(s) + CO_2(g) \quad (1)$$

$$PbO \cdot PbCO_3(s) \longrightarrow 2PbO(s, \text{litharge}) + CO_2(g) \quad (2)$$

We will refer to these processes, for convenience, as the first and second processes respectively. It was shown previously that the over-all rate of the decomposition of each process was influenced by the dissociation pressure of the reactant(s)-product(s)-product(g) system, and that it was also influenced to some extent by the carbon dioxide pressure at the gas-solid interface.[8]

In the present study, lead carbonate tablets prepared by compacting lead carbonate particles under different pressures were decomposed isothermally, and a kinetic study of the decomposition of these tablets was made in order to evaluate the effect of the compacting pressure.

Experimental

The disk-shaped tablets used in this work (11.3 mm in diameter, *ca.* 2 mm thick, and *ca.* 1 g in weight) were prepared by compressing lead carbonate particles

uniformly in a steel mold which consisted of a cylindrical die with two punches, lower and upper. The lead carbonate particles used (3—4 μ in diameter, as determined under an electron microscope) were prepared from cold aqueous solutions of lead acetate and ammonium carbonate, and were then compressed under pressures of 2—15 ton/cm^2 for 5 min by a hydraulic press. The lead carbonate tablets thus prepared were porous and had different porosity values as Fig. 1 shows. The porosity of the tablet was calculated from its bulk density and the theoretical net density of the sample. Some of the porosities of the tablets before decomposition, ε_0, were smaller than 0.2595, the minimum value of the theoretical porosities corresponding to that of the closest packing of equal-sized rigid spheres. This may be attributed to the fact that not all the lead carbonate particles in these tablets were exactly spherical or the same size. No change in the X-ray diffraction pattern was observed between two different lead carbonate samples, compressed and uncompressed. This fact suggests the absence of any appreciable effect of the applied pressure on the crystal structure.

The thermogravimetric apparatus used was an ordinary one consisting of a helical quartz spring and a 38-mm-i.d. $\times$ *ca.* 1-m-long quartz tube whose lower half was enclosed in an electrically-heated furnace. Preheated nitrogen-gas flows of 0.03—0.80 *l*/min were led, at 1 atm, into the vertical quartz tube at the bottom in order to sweep off the product gas or the carbon dioxide gas evolved during the decomposition runs. The tablet was supported on a stainless-steel wire sample-holder and was so suspended in the apparatus that the base of the tablet was parallel to the axis of the vertical tube. The extension of the spring was measured with a cathetometer during the decomposition reaction. The sample was also weighed exactly both before and after the run. The temperature of the sweeping gas was assumed to be close to the sample temperature and was measured with a chromel-alumel thermocouple. The decomposition runs were carried out at the constant temperatures of 240°C (for the first process) and 320 and 360°C (for the second process).

An X-ray diffractometer was also used to identify the decomposition products and to ascertain whether or not a decomposition reaction occurred.

Results and Discussion

Preliminary runs showed that the thermal decomposition of lead carbonate tablets proceeded according to Eqs. (1) and (2); this finding was in agreement with the results of the decomposition studies of the powdered mass packed tightly into a glass tube.[8] In this paper the two processes represented by Eqs. (1) and (2) are designated as the first process and the second process respectively.

For the thermal decomposition of the powdered mass, two simple, idealized models can be considered. One of them is chosen for the case where all the particles in the powdered mass decompose at all times. The other is applicable when only some particles in the outer shell of the powdered mass decompose at first, and then the decomposition zone (in which some particles are decomposing) moves inwards, leaving a completely decomposed solid behind.

In slicing and examining the inside of the partly-decomposed tablets, as will be described below, the thermal decomposition of lead carbonate (the first process) was found to occur at every individual particle within the tablet. Thus, the thermal decomposition study of the first process was made by selecting the former model, or by simultaneously applying the unreacted-core shrinking model to the individual particles within the tablet. However, the second process was found to occur at the particles localized in the outer shell of the tablet. The kinetic study of this process was made by employing the latter model.

A number of decomposition studies of solid materials have been made assuming a profile of a uniform temperature throughout the powdered mass.[8-12] This assumption is acceptable when a small amount of the sample is used and when its rate of decomposition is small, as in the present case. The theoretical expression for the effective thermal conductivity within a powdered mass[13] indicates that the effective thermal conductivity decreases with an increase in the porosity. Consequently, the rate of the heat transfer may be more rapid with the tablet compressed at the pressure of 15 ton/cm^2 than with that compressed at 2 ton/cm^2. On the other hand, experimental runs showed that the over-all rate of decomposition for the former tablet was much slower than that for the latter.

These facts suggest that the step of heat transfer played no appreciable role in determining the rate of the decomposition reaction in our experiment. In addition, the following facts suggest the important role of the carbon dioxide pressure: during the thermal decomposition of the lead carbonate mass in a glass tube, as has been reported previously,[8] no decomposition reaction of the second process occurred at the lateral face of the cylindrical pellet, this face being surrounded by glass through which the product gas (carbon dioxide) could not be removed but through which heat could be transported. Moreover, no decomposition reaction occurred at elevated pressures of carbon dioxide. For these reasons, the temperatures within a tablet were presumed to be uniform throughout the tablet during the decomposition reaction and not practically affect the over-all rate of the decomposition. The temperature profile in each particle was also presumed to be uniform, since the expression for heat-transfer control did not fit the experimental data satisfactorily. In view of the above considerations, only the pressure profile for carbon dioxide was considered in the treatment to be described below.

Nitrogen flow rates in the range studied were found to influence the rate of the decomposition. It is obvious that the partial pressure, P_i, of carbon dioxide at the tablet surface decreases as the rate of nitrogen-gas flow increases. Therefore, the effect of carbon dioxide pressure on the decomposition rate was evaluated in this paper on the basis of the partial pressure, P_i, which was determined by means of equations to be described below.

The rate of the decomposition reaction of the lead carbonate tablet was very small; therefore, in the present work we can assume that the sample temperature is almost equal to that of the gas stream.[14]

No significant reduction in the size of the tablet during decomposition was observed, while L was constant throughout the decomposition run.

The First Process. The thermal decomposition of some solid materials occurs at an interface advancing from the outside of the particle toward the interior. The unreacted-core shrinking model proposed earlier by Yagi and Kunii[15] provides a good representation of this phenomenon. When the over-all rate of the thermal decomposition is virtually independent of the mass-transfer rates of gases through the porous solid layer, as well as across the gas-film surrounding the particle, but is controlled solely by the inherent chemical reactivity of the solid reactant, the following equation for the single particle can be developed from the model:

$$1-(1-F)^{1/3}=kt \tag{3}$$

where k is a constant which is a function of the temperature, the particle size, the specific properties of the reactant, and so on. This expression is also applicable to the powdered mass in applying the model simultaneously to all the individual particles in the powdered mass, whose constituents are practically equal in size and in the same conditions. When the decomposition of each particle in the mass is controlled by the surface phenomenon and only the partial pressure of carbon dioxide outside the particles changes, an expression of the type of Eq. (3) is still useful for the decomposition of the particles.

If the pressure profile for carbon dioxide is uniform throughout the tablet, all the individual particles in the tablet should be under essentially the same conditions. Therefore, the relationship between the conversion of the whole tablet and the decomposition time for the first process should be:

$$1-(1-F_1)^{1/3}=k_1t_1 \tag{4}$$

where the constant, k_1, comprises a decomposition rate constant which is proportional to the difference between the equilibrium partial pressure of carbon dioxide and the partial pressure of carbon dioxide within the tablet; k_1 can then be expressed as follows:

$$k_1=k_1'P_{e1}(1-P/P_{e1}) \tag{5}$$

These two expressions, (4) and (5), are useful for the decomposition study of the lead carbonate tablet with a uniform internal-pressure profile.[8]

When the pressure profile for carbon dioxide within the tablet is not uniform, consider the pressure, P, of carbon dioxide within an arbitrary volume element in the tablet ($\Delta r\cdot r\Delta\theta\cdot\Delta l$ in cylindrical coordinates) and take an average value throughout the whole tablet; then:

$$k_1=k_1'P_{e1}\frac{1}{2R^2\pi L}\int_0^R\int_0^{2\pi}\int_{-L}^{L}(1-P/P_{e1})r\,dr\,d\theta\,dl \tag{6}$$

This expression is simple and is useful for an engineer in developing approximate rate expressions without undue complexities; nevertheless, it is not strictly accurate from the mathematical standpoint.

A partly-decomposed tablet was sliced off and examined by exposing the cross-sectional surface to X-rays. In the tablet compressed at the pressure of 2 ton/cm^2, little difference was detected between the heights of the corresponding peaks of the two X-ray diffraction patterns[4,5] for the particles located in the center and near the surface, each X-ray diffraction pattern showing the existence of only two phases, $PbCO_3$ and $PbO\cdot PbCO_3$. On the contrary, a great difference between the corresponding peak heights was observed in the tablet compacted at the pressure of 15 ton/cm^2. Further experiments were made by roasting the central part of the partly-decomposed tablet and by deter-

TABLE 1. FRACTIONAL DECOMPOSITIONS FOR THE WHOLE TABLET AND FOR ITS CENTRAL PART

Applied pressure, (ton/cm²)	2	2	5	10	15
Weight of the whole tablet undecomposed, U_u (g)	1057.4	949.4	1075.9	1071.2	1042.2
Weight of the whole tablet decomposed partly, U_p (g)[a]	1016.5	909.0	1033.4	1032.1	1002.9
Time for decomposition, t_1 (min)	16	17	20	21	25
Fractional decomposition for the whole tablet, F_1 (dimensionless)[b]	0.470	0.517	0.480	0.443	0.458
Weight of the sample: the central part of the partly decomposed tablet, U_p' (g)	143.4	123.7	127.9	82.8	134.2
Weight of the sample at the completion of decomposition, U_c (g)[c]	124.6	107.8	110.9	71.3	115.5
Fractional decomposition for the central part of the partly decomposed tablet, F_1' (dimensionless)[d]	0.470	0.504	0.445	0.364	0.358
Ratio of F_1' to F_1 at about $F_1=0.5$, F_1'/F_1 (dimensionless)	1.000	0.975	0.928	0.821	0.781

a) The decomposition runs were carried out at the temperature of 240°C in the nitrogen-gas flow of 0.40 *l*/min.

b) $F_1 = 2\times\left(\frac{U_u-U_p}{44.01}\right)\Big/\left(\frac{U_u}{267.2}\right)$

c) The samples were decomposed at 400°C in the nitrogen-gas stream for 70 min.

d) $F_1' = 2\times\left\{1-\left(\frac{U_p'-U_c}{44.01}\right)\Big/\left(\frac{U_c}{223.2}\right)\right\}$

mining its fractional decomposition. The results obtained from these experiments (see Table 1) as well as the observation of the X-ray diffraction patterns showed that the difference between the degrees of decomposition of particles at the two locations became greater with an increase in the compacting pressure (*viz.*, with a decrease in the porosity of the tablet). This fact suggests that the carbon dioxide pressure profile within a tablet becomes less uniform with a decrease in the porosity of the tablet.

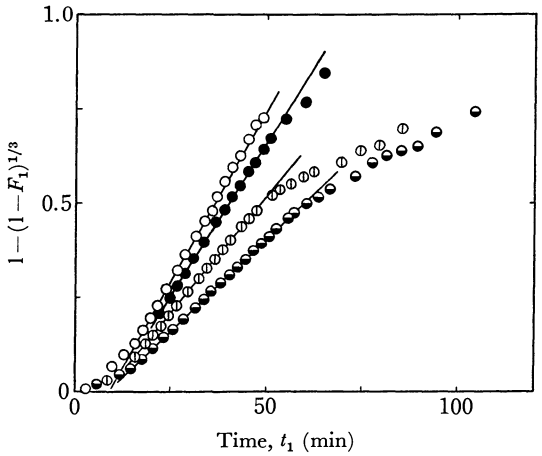

Fig. 2. Plots of $1-(1-F_1)^{1/3}$ *vs.* decomposition time for the first process at 240°C.
○: P=2 ton/cm², $G\times10^4$=2.09 g/(cm²)(sec)
●: P=2 ton/cm², $G\times10^4$=0.74 g/(cm²)(sec)
ⓘ: P=15 ton/cm², $G\times10^4$=4.01 g/(cm²)(sec)
◒: P=15 ton/cm², $G\times10^4$=2.51 g/(cm²)(sec)

Figure 2 shows some typical results obtained from the two series of experiments for the tablets prepared under two different compacting pressures. Similar plots, illustrated in Fig. 2, were obtained in the other runs, and in all cases, good, straight lines were obtained. It is evident from the linearity of the relationship in Fig. 2 that the approximate expression of Eq. (4) is applicable to the major period of the decomposition run. The slight deviations of the experimental plots from the linearity in the beginning of the decomposition reaction may be attributed to the formation and the growth of the nuclei of $PbO\cdot PbCO_3$; this initial period is usually termed an induction period. Deviations of the plots were also observed at the end of the decomposition of the tablets compressed at higher pressures, partially because of a lack of mathematical accuracy in deriving Eqs. (4) and (6). However, for the sake of simplicity, the approximate expressions of Eqs. (4) and (6) were used successfully in this work by being applied only to the experimental data in the major period.

It is now necessary to determine the partial pressure, P_i, of carbon dioxide at the external surface of the tablet. The values of P_i under the different experimental conditions were determined by calculating the following equations concerning a dimensionless factor of j_d:[16]

$$j_d = \alpha\left(\frac{\sqrt{a_p}\cdot G}{\mu}\right)^{-\beta} \qquad (7)$$

in which:

16) K. H. Yang and O. A. Hougen, *Chem. Eng. Prog.*, **46**, 146 (1950).

$$N_{Re} = \sqrt{a_p}\cdot G/\mu > 620;\ \alpha=1.25,\ \beta=0.41$$

$$N_{Re} < 620;\ \alpha=2.44,\ \beta=0.51$$

$$j_d = \left(\frac{k_f\cdot M_m\cdot P_f}{G}\right)\left(\frac{\mu}{\rho_N\cdot D}\right)^{2/3} \quad (8)$$

The rate of mass transfer in a boundary film, N', which is presumed to be equal to the apparent rate of the thermal decomposition, can be expressed as:

$$N' = k_f\cdot a_m(P_i - P_g) = r_a \quad (9)$$

Equations (7), (8), and (9) are combined to give an appropriate expression for the partial pressure:

$$P_i - P_g = \frac{1}{\alpha}\left(\frac{r_a\cdot\sqrt{a_p}\cdot M_m\cdot P_f}{\mu\cdot a_m}\right)\left(\frac{\mu}{\rho_N\cdot D}\right)^{2/3}\left(\frac{\sqrt{a_p}\cdot G}{\mu}\right)^{\beta-1} \quad (10)$$

The specific values of M_m, G, μ, and ρ_N in this equation are represented by those of nitrogen-gas at the temperature of 240°C, since the partial pressure of carbon dioxide in the bulk-gas phase was so low as to be negligible compared with that of nitrogen. The partial pressure of carbon dioxide in the main stream, P_g, was successfully regarded as zero. Let the film pressure factor, P_f, be equal to 1 atm because of the small value of P_i compared with the partial pressure of nitrogen at the solid-gas interface. The binary molecular diffusivity of interest was predicted by means of the appropriate method.[17] In this procedure, an empirical value of D, estimated at 0.6050 cm²/sec at 600°K by Walker and Westenberg,[18] was also used for the prediction. The overall rate, r_a, was empirically determined at the major period corresponding to F_1 of 0.4—0.7. The value of P_i in each run was then obtained by the substitution of the appropriate properties and empirically-determined variables into Eq. (10).

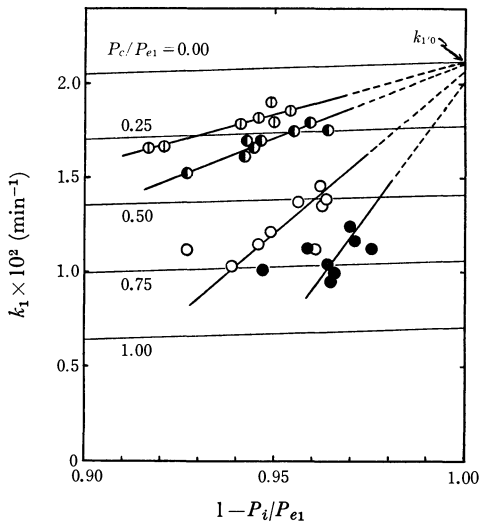

Fig. 3. Correlation between k_1 and $(1-P_i/P_{e1})$ for the first process at 240°C.
◯: P=2 ton/cm²: ◐: P=5 ton/cm²
○: P=10 ton/cm²: ●: P=15 ton/cm²

Figure 3 shows the relationship between k_1, the slope of each line illustrated in Fig. 2, and $(1-P_i/P_{e1})$, the dimensionless pressure term at the solid-gas interface as evaluated from the empirically-determined value of P_i. In estimating the $(1-P_i/P_{e1})$ quantity, the dissociation pressure of lead carbonate was determined from the experimental data by Peretti.[1] Good, straight lines were obtained in the two series of decomposition runs carried out with the tablets compacted at the pressures of 2 and 5 ton/cm². However, the empirical plots obtained from the tablets compacted at the pressures of 10 and 15 ton/cm² were scattered to some extent. This may be attributed to the large deviations of the tablet porosities. Figure 3 also shows that the rate of the decomposition, which was represented by k_1, apparently increased with the $(1-P_i/P_{e1})$ term, the function of the partial pressure at the solid-gas interface. Furthermore, it is shown that the pressure term $(1-P_i/P_{e1})$ apparently had a more significant effect on the rate of the decomposition when the compacting pressure was high (*viz.*, the porosity of the tablet was small).

It is obvious that the mean value of $(1-P/P_{e1})$, averaged through the whole tablet, necessarily exerts an influence upon the overall rate of decomposition. Since it comprises the decomposition rate constant, the k_1 constant should be affected by the averaged term of $(1-P/P_{e1})$, as is to be expected from Eq. (6). Therefore, the empirical value of k_1 gives useful information about the pressure profile within a tablet.

The dimensionless-pressure profile for carbon di-

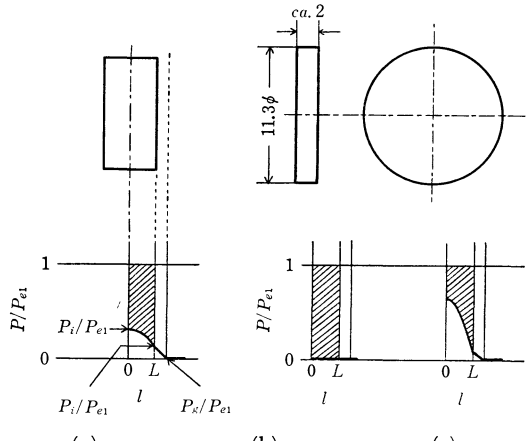

Fig. 4. Sketch of the tablet and pressure profiles for carbon dioxide.

17) E. N. Fuller, P. D. Schettler and J. C. Giddings, *Ind. Eng. Chem.*, **58**(5), 19 (1966).
18) R. E. Walker and A. A. Westenberg, *J. Chem. Phys.*, **29**, 1139 (1958).

oxide in the l-direction (the axial direction of the tablet) for the first process may be shown analogously as Profile (a) in Fig. 4, since the local pressure of carbon dioxide may be higher at the center than at the surface. It can reasonably be considered that, in estimating the rate of the decomposition of the lead carbonate tablet, the transfer of carbon dioxide in the l-direction is more important than in the r-direction (the radial direction of the tablet) because of the very small length-to-diameter ratio (L/R) of the tablet used in this work. These considerations and the symmetrical pressure distribution in the θ coordinate lead to the conclusion that Eq. (6) can be rewritten as a function of only one coordinate direction. Hence:

$$k_1 = \frac{k_1' \cdot P_{e1}}{2L}\int_{-L}^{L}(1-P/P_{e1})\mathrm{d}l \qquad (11)$$

In Fig. 3 the straight line for the tablets compacted at the pressure of 2 ton/cm^2 is extrapolated to the point $(1-P_i/P_{e1})=1$; thereby, $k_{1,0}$ is estimated at 2.12×10^{-2} min^{-1}. This constant, $k_{1,0}$, is assumed to be identical with the k_1 at $P=0$ in Eq. (11), which corresponds to that of the carbon dioxide-pressure profile (b) in Fig. 4. This assumption is reasonable because there was little difference, as has already been mentioned, between the local pressures of carbon dioxide with the tablet compressed at the pressure of 2 ton/cm^2 and because the partial pressure of carbon dioxide at the center of this tablet is, thereby, negligibly low when the partial pressure at the surface approaches zero. The integration of Eq. (11) at $P=0$ and the application of this assumption give the following equation:

$$k_{1,0} = k_1' \cdot P_{e1} \qquad (12)$$

The ratio of k_1 to $k_{1,0}$ can then be expressed as follows:

$$\frac{k_1}{k_{1,0}} = \frac{1}{L}\int_{0}^{L}(1-P/P_{e1})\mathrm{d}l \qquad (13)$$

in which the integral from zero to L with respect to l is satisfactorily used because of the symmetrical pressure profile. The integral term in Eq. (13) gives the shaded area illustrated in Profile (a) in Fig. 4 as a typical example, while the denominator, L, which is given by the integration from zero to L of the $(1-P/P_{e1})=1$ quantity, shows the area of the rectangle indicated as Profile (b) in Fig. 4. Therefore, the expression of Eq. (13) indicates that the ratio of k_1 to $k_{1,0}$ is equal to the ratio of one area to the other, each area corresponding to the overall pressure-driving force to decomposition.

It was impossible to determine the real pressure profile within a tablet because of the experimental difficulties. However, it is obvious that the partial pressure, P, of carbon dioxide at an arbitrary situation, l, varies with l; this is expressed as a continuous function of l $(-L\leqq l\leqq L)$. On introducing a dimensionless coordinate, $z=l/L$, the pressure profile within a tablet is given as $P(z)$. Noting that $P(z)=P(-z)$, the expression for $P(z)$ at $0\leqq|z|\leqq1$ can be represented by a "power series" of the type:

$$P(z) = a_0 + a_2z^2 + a_4z^4 + \cdots + a_{2n}z^{2n} + \cdots \qquad (14)$$

where:

$$\frac{a_{2n}}{a_{2n+2}z^2} > \frac{P_c}{P_c-P_i} > 1$$

for all n's greater than or equal to m.

The absolute value of the nth term in this infinite series approaches zero as $n\to\infty$. The terms with a large n value are, then, negligibly small and the approximate expression for $P(z)$ can be written with the first several terms in Eq. (14). Many of the terms should be employed for the very close approximation to $P(z)$, especially when $|z|$ approaches unity, while the value of $P(z)$ at $z=1$ is determined from the experimental data. However, in the absence of full information about the profile, the approximate expression for $P(z)$ was assumed to be given by the first two terms on the right-hand side of Eq. (14); in addition, the integral term in Eq. (13) was also assumed to give the following area in place of the real area corresponding to the overall pressure-driving force: the area being surrounded by a curved line (defined by Eq. (15)) and three straight lines ($z=l/L=0$, $z=1$, and $P/P_{e1}=1$). On the basis of these assumptions, the pressure profile in a tablet can be outlined without deviating too greatly from reality.

From the above considerations, the approximate expression presumed for the pressure profile at $0\leqq|z|\leqq1$ is:

$$P(z) = a_0 + a_2z^2 \qquad (15)$$

The boundary conditions employed are:

$$\left.\frac{\mathrm{d}P}{\mathrm{d}z}\right|_{z=0} = 0$$

$$P(0) = P_c$$

$$P(1) = P(-1) = P_i$$

The solution to Eq. (15) with these conditions is:

$$P(z) = P_c + (P_i-P_c)z^2 \qquad (16)$$

so that Eq. (13) becomes:

$$\frac{k_1}{k_{1,0}} = \frac{(1-P_i/P_{e1}) + 2(1-P_c/P_{e1})}{3} \qquad (17)$$

Since the value of $(1-P_i/P_{e1})$ in each run had already been calculated from Eq. (10), the value of $(1-P_c/P_{e1})$ in each run could be determined from the approximate expression of Eq. (17). The results for the dimensionless pressure, P_c/P_{e1}, as well as the experimental values of $k_1/k_{1,0}$ at $(1-P_i/P_{e1})=0.97$, are illustrated in Fig. 5 against the porosity, ε_1.

It is shown in Fig. 5 that the partial pressure of carbon dioxide at the center of the tablet rises with a decrease in the porosity, as was suggested earlier by the diffractmetrical and the thermogravimetrical analyses, in spite of these being the same pressure at the solid-gas interface (*viz.*, $P_i/P_{e1}=0.03$).

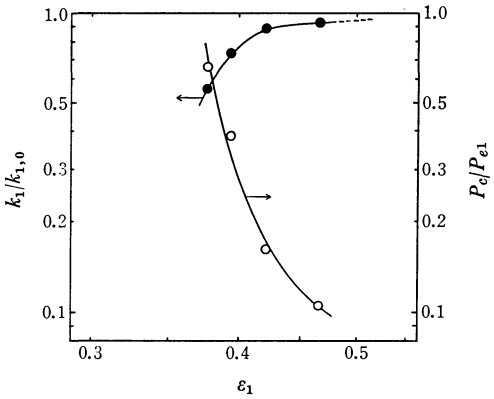

Fig. 5. Effect of porosity ε_1 on dimensionless ratios, $k_1/k_{1,0}$ (●) and P_c/P_{e1} (○).

Equation (17) with a given parameter of P_c/P_{e1} is, then, plotted in Fig. 3. The series of lines thus obtained shows how high the P_c/P_{e1} ratio was in each run. It is apparent from Fig. 3 that the carbon dioxide pressure at the center becomes higher, on the whole, with an increase in the compacting pressure; therefore, the pressure profile for carbon dioxide during the decomposition reaction is less uniform for the tablets of a lesser porosity.

The empirical plots of k_1 against $(1-P_i/P_{e1})$ for the tablets compacted at the pressure of 15 ton/cm^2 (*cf.* Fig. 3) show that the averaged value of P_c/P_{e1} can be estimated to be approximately 0.7. This fact shows that the carbon dioxide-pressure profile of this tablet might be represented analogously as Profile (c) in Fig. 4. No attempt has been made to demonstrate this simplified pressure profile, whereas these considerations are supported by the fact that the plots of $1-(1-F_1)^{1/3}$ against t_1, which give a straight line in the case of a uniform pressure profile, deviated to some extent with the tablets compacted at higher pressures. It was also considered that the simple expressions of Eqs. (4) and (11) were useful for the first process of the thermal decomposition of only the lead carbonate tablets with a greater porosity. However, these expressions proved applicable also to tablets compressed at the pressure of 15 ton/cm^2.

The Second Process. The thermal decomposition study of a mass of basic lead carbonate ($PbO \cdot PbCO_3$) particles[5] showed that the decomposition reaction of the materials occurred only at low partial pressures of carbon dioxide, and the rate of the decomposition for every single particle was found, at small nitrogen-flow rates, to be controlled by the step of the mass transfer of carbon dioxide through the atmosphere within the mass of particles. It was, then, reasonably considered that the decomposition rate of a tightly-compacted mass of the basic lead carbonate particles was controlled by the diffusional step through the powdered mass. Visual observation and the X-ray diffraction data showed that the decomposition product, PbO (litharge), formed a shell of a reddish brown color sharply separated from the grey-colored reactant, $PbO \cdot PbCO_3$, inside the shell, and that the decomposition front advanced from the outside of the lump, or of the whole tablet, to the interior. Hence, the diffusional step through the product layer (the porosity of which is given as ε_2) proves to have a significant connection with the rate of the decomposition. When the decomposition of one particle is subject to the gas-film-diffusion controlling step, the specific rate of the decomposition of this particle is constant at any given time during the decomposition run, irrespective of the size of the undecomposed-core in the particle. It can, then, be concluded that all the rates of decomposition for the particles of any conversion under the same conditions are equal during the decomposition. Therefore, the thermal decomposition of the whole tablet was reasonably considered, from a macroscopic point of view, to occur at the interface between decomposed and undecomposed materials. It is also reasonable to suppose that the decomposition interface moved inward only in the direction normal to the base of the tablet since the decomposition front, curved slightly like a lens, was taken to be almost parallel to the base of a tablet because of its small height-to-diameter ratio. Therefore, only the l component of the mass transport will be considered in this paper.

The moler flux with respect to a stationary coordinate, N_p in g-mol/(cm^2)(sec), of carbon dioxide diffusing through the porous layer of the decomposition product is expressed by the following expression, which is called Fick's first law of diffusion:

$$N_p = y_p(N_p + N_N) - c\bar{D}_e(\mathrm{d}y_p/\mathrm{d}l) \qquad (18)$$

There may be a net motion of carbon dioxide away from the decomposition interface during the decomposition run, and nitrogen-gas is stationary in a pseudo-steady-state condition; these things were assumed successfully by previous workers[19-21] and were also applicable to the present study. The molar flux of nitrogen was, thereby, taken to be zero. Then, by substituting $N_N=0$ in Eq. (18) and solving for N_p, we obtain:

$$N_p = -\frac{c\bar{D}_e}{1-y_p}\cdot\frac{\mathrm{d}y_p}{\mathrm{d}l} \qquad (19)$$

With the pseudo-steady-state approximation valid for the solid-gas system, the rate of the decomposition at any instant is, in the present case, given by the rate of diffusion of the product gas away from the decomposition interface through the product layer; therefore:

21) C. Y. Wen, *Ind. Eng. Chem.*, **60**(**9**), 34 (1968).

$$-\frac{dW_r}{dt}=\frac{dW_p}{dt}=2SN_p=\text{constant} \quad (20)$$

The amount of the reactant present in a tablet is expressed as the product of the molar bulk density and the volume of the undecomposed mass. The disappearance of a small amount of the solid reactant is accompanied by the decrease in its volume; thus:

$$-dW_r=dW_p=-2S\rho_a dl \quad (21)$$

Noting that the decomposition interface was taken to advance only in the l-direction, the fractional conversion for the second process can be written as follows:

$$F_2=\frac{L-l}{L} \quad (22)$$

By substituting Eqs. (19) and (21) into Eq. (20), solving with the pseudo steady-state approximation, and using the appropriate expression for F_2 we obtain the conversion-time expression for the second process of the decomposition of the tablet, or:

$$(F_2)^2=k_2t_2 \quad (23)$$

where:

$$k_2=\frac{2\bar{D}_eP_{e2}P_t}{RT\rho_aL^2(P_N)_{ln}}(1-P_i/P_{e2}) \quad (24)$$

The $(P_N)_{ln}$ term in this expression is the logarithmic mean of the partial pressures of nitrogen-gas at the solid-gas interface and at the decomposition interface, defined by the following equation:

$$(P_N)_{ln}=\frac{P_{N,t}-P_{N,l}}{\ln(P_{N,i}/P_{N,l})}=\frac{(1-P_t)-(1-P_{e2})}{\ln\dfrac{1-P_i}{1-P_{e2}}} \quad (25)$$

in which the subscripts i and l refer to the solid-gas interface and the decomposition interface respectively.

Some typical correlations between $(F_2)^2$ and t_2 for the decomposition of a lead carbonate tablet are shown in Fig. 6. These plots, as well as the similar plots from the other runs, indicate that the experimental data gave a linear relationship in almost all regions of the decomposition run, showing that Eq. (23) is valid under the present experimental conditions and can be used for the second process of the decomposition of a lead carbonate tablet. Each slope of the straight lines in Fig. 6 gives the experimental value of k_2.

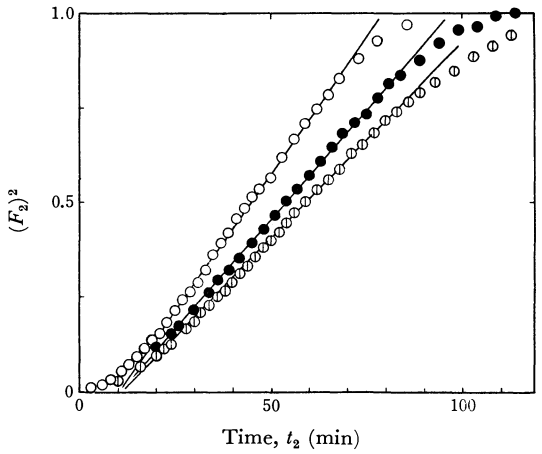

Fig. 6. Plots of $(F_2)^2$ *vs.* decomposition time for the second process at 320°C.
applied pressure P=5 ton/cm²;
○: $G\times10^4$=7.71 g/(cm²)(sec)
●: $G\times10^4$=2.67 g/(cm²)(sec)
ⓘ: G=10^4=2.01 g/(cm²)(sec)

It is now necessary to examine the effect of the compacting pressure on the decomposition rate. All the variables in Eq. (24), except for $\bar{D}_e$ and ρ_a, are naturally independent of the compacting pressure. Some variables, such as L, $(P_N)_{ln}$, and P_i, are expected to have different values varying in every run, while the rest of the variables give constant values in a series of runs carried out with tablets of the same compacting pressure. All the numerical values of $(P_N)_{ln}$ were, however, found to be almost equal in every run with the tablets of the same

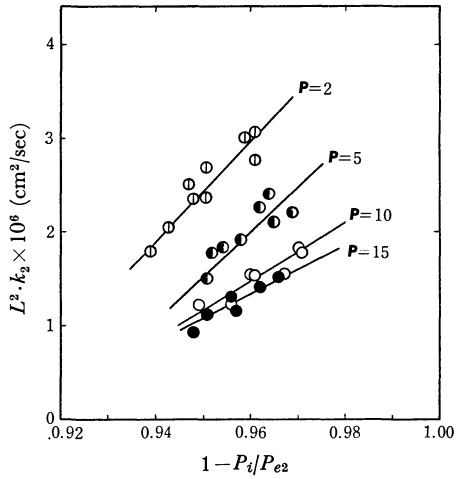

Fig. 7. Correlation between $L^2\cdot k_2$ and $(1-P_i/P_{e2})$ for the second process at 320°C.

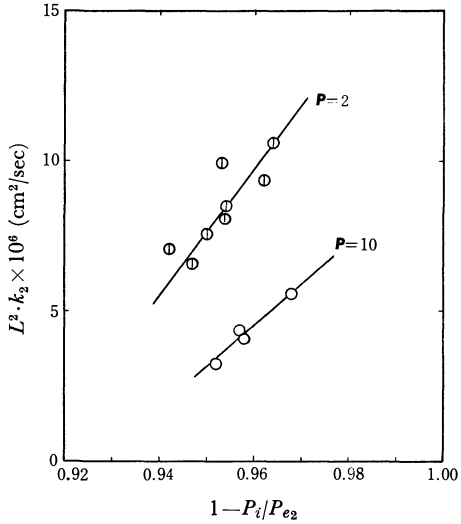

Fig. 8. Correlation between $L^2\cdot k_2$ and $(1-P_i/P_{e2})$ for the second process at 360°C.

compacting pressure (an error to within 0.2%). Consequently, a constant value of $(P_N)_{ln}$ was used for each series of runs. The plots of $L^2 \cdot k_2$ against $(1-P_i/P_{e2})$ are, then, illustrated in Fig. 7, where each experimental value of P_i was obtained from the calculation of Eq. (10). Figure 8 also shows the experimental correlation between the $L^2 \cdot k_2$ and $(1-P_i/P_{e2})$ values obtained from the other two series of experimental runs done at 360°C. Each value of the slopes in Figs. 7 and 8 was incorporated into Eq. (24); the subsequent substitution of appropriate values in the equation gave the numerical values of the mean effective diffusivity, which were subject to the influence of the compacting pressure used in the preparation of the tablet. These values of $\bar{D}_e$ are plotted against ε_2 in Fig. 9. It is apparent from Fig. 9 that the decrease in ε_2 (attributed to the increase in applied pressure) corresponds to the decrease in $\bar{D}_e$.

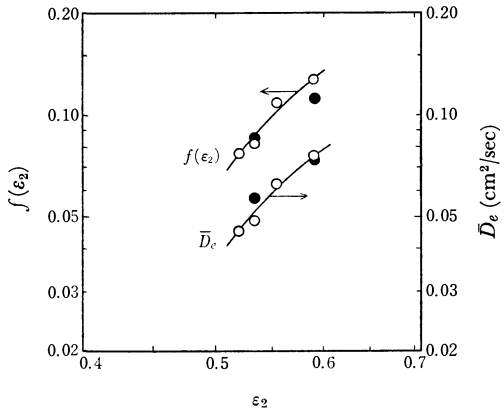

Fig. 9. Effect of Porosity ε_2 on $\bar{D}_e$ and $f(\varepsilon_2)$ at 320°C (○) and 360°C (●).

It can reasonably be concluded, on the basis of the previous considerations, that the effect of the applied pressure on the decomposition rate is reduced to that on the term $\bar{D}_e/\rho_a$ in Eq. (24). The values of $\bar{D}_e/\rho_a$ calculated from the slopes in Figs. 7 and 8 were not identical; this indicates that $\bar{D}_e$ and ρ_a were affected to different degrees by the applied pressure. Many investigations have been made of the correlation between the applied pressure and the bulk density or porosity of the powdered mass compacted. These investigations are summarized comprehensively in several papers.[22,23]

An expression between the applied pressure and the porosity, ε_0, applicable to the present work was as follows:

$$-\frac{d\varepsilon_0}{dP} = C(1-\varepsilon_0)P^{-0.9} \quad (26)$$

This expression is Nutting's Equation as modified by Kawakita and Tsutsumi.[22] The exponent, -0.9, was derived from the text.[24] Equation (26) can be easily integrated, or:

$$\ln(1-\varepsilon_0) = C_1 \cdot P^{0.1} + C_2 \quad (27)$$

The relationship between P and ρ_a can be analogously derived from Eq. (26) by noting that:

$$\varepsilon_0 = 1 - \rho_a/\rho_r \quad (28)$$

thus:

$$\ln \rho_a = C_3 \cdot P^{0.1} + C_4 \quad (29)$$

The good fits of Eqs. (27) and (29) are illustrated in Fig. 10.

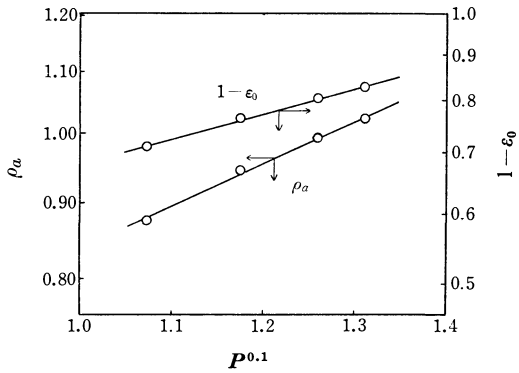

Fig. 10. Plots of log ρ_a and log $(1-\varepsilon_0)$ against $P^{0.1}$.

The mean effective diffusivity, $\bar{D}_e$, on the other hand, is a function of several variables, such as ε_2, the molecular diffusivity, the Knudsen diffusivity, and the surface diffusivity, among which ε_2 is influenced by the applied pressure, as is shown in Fig. 1. A useful study of the surface diffusion in a porous solid was made by Sakashita, Arai, and Kobayashi,[25] who concluded that the amount of carbon dioxide transported by the surface diffusion increases as the pressure of carbon dioxide rises. They also reported that, for the diffusion of carbon dioxide through a sintered mass of glass beads (ε= 0.40), the ratio of the surface diffusivity to the total effective diffusivity could be estimated to be 0.11 for CO_2–H_2 system at 1 atm. It may be analogously considered in the present case that the surface diffusion through a porous layer is almost negligible in comparison with the molecular diffusion because of the very low pressures of carbon dioxide. The empirically-determined value of $\bar{D}_e$ in the present work might include some errors due to some assumptions and errors included in Eqs. (10) or (20). For this reason and because of a lack of information about the Knudsen and surface diffusions, no explicit expression for $\bar{D}_e$ could be proposed. However, the large porosity (ε_2) values of the samples suggest that the diffusion of carbon dioxide through the product layer is predominantly

influenced by the molecular-diffusional step within a macropore produced after the decomposition reaction. The plots of $f(\varepsilon_2)$ against ε_2 are shown in Fig. 9, where $f(\varepsilon_2)$, a function of ε_2, was determined from the conventional expression for the effective diffusivity, or:

$$\bar{D}_e = f(\varepsilon_2) \cdot D \qquad (30)$$

The numerical values of $f(\varepsilon_2)$ are in good agreement with the data on some other porous materials of the same porosity.[25,26]

Further information about $f(\varepsilon_2)$ or $\bar{D}_e$ should be derived from another appropriate experiment for $\bar{D}_e$. However, the approximate value of $\bar{D}_e$, varying with ε_2, was proved in the present work to be useful as a criterion by which the influence of the compacting pressure on the decomposition rate could be investigated.

Conclusions

Experiments on the rate of the thermal decomposition of a lead carbonate tablet have shown that it is possible to make kinetic studies taking into account the partial pressure distribution of carbon dioxide only in the axial direction of the tablet. It has been shown that the rate of the decomposition of the whole tablet for the first process is represented by two approximate equations, (4) and (11), which were derived from the unreacted-core shrinking model applied to the individual particles in a tablet. Consequently, the effect of the applied pressure on the decomposition rate was evaluated from the integral term in Eq. (11). The partial pressure of carbon dioxide at any location within a tablet, but outside the fine particles, was influenced by the pressure used in compressing lead carbonate particles into a tablet.

It has also been shown that the overall rate of the decomposition of the tablet for the second process is controlled by diffusion of carbon dioxide through the product layer. The rate of the decomposition for the second process was, then, expressed by two appropriate equations, (23) and (24), which were developed for the whole tablet without regard to the individual particles. The effective diffusivity and the bulk density of the tablet in Eq. (24) were affected by the applied pressure.

Notation

a, a_2, a_4, $\cdots$, a_{2n}, $\cdots$=coefficient in Eq. (14), atm
a_m=interfacial surface area per unit mass of the tablet undecomposed, cm^2/g
a_p=exterior surface area of the tablet, cm^2

Dielectric Relaxation and Molecular Structure. I. Dielectric Relaxation in Substituted Anilines

K. K. SRIVASTAVA and J. K. VIJ*1

Department of Physics, Panjab University, Chandigarh, India

(Received December 10, 1969)

Measurements of static dielectric constant at 1 Mc, refractive index (for sodium D-line) and complex dielectric constant at 9.44 GHz (X-band) have been made to determine the relaxation times and dipole moments of *N,N'*-dimethylaniline (A), *N,N'*-diethylaniline (B), *o*-chloroaniline (C), *m*-chloroaniline (D) and *p*-chloroaniline (E) in dilute solutions of non-polar solvents. Substances A, B, C and D have been studied in *n*-heptane, benzene decalin and Nujol. The measurements for A and B have also been extended to cyclohexane, whereas E has only been studied in benzene. The values of relaxation time, calculated by Higasi's equations in terms of a_0, a', a'' and a_∞, and those of α, calculated from Cole-Cole's equation in terms of the same parameters, showed an evidence for the existence of more than one relaxation mechanism. This has been interpreted in terms of the intramolecular rotations of the amino (or the substituted amino) group occurring simultaneously with the overall molecular orientation.

A study of dipole moment and dielectric relaxation time has provided an evidence for the existence of internal or intramolecular rotations in several organic molecules.[1-3] The present work extends this study to several substituted anilines. Garg and Smyth[4] have studied liquid aniline and *N,N'*-dimethylaniline. They have analyzed their data with the help of Roberti and Smyth's[5] equation in terms of τ_1 and τ_2 which are 22.0 ps (1 ps$=10^{-12}$ sec) and 0.9 ps for aniline and 28.0 ps and 1.5 ps for dimethylaniline. The values of τ_1 and τ_2 refer to the molecular and intramolecular rotations, respectively. Smyth[6] has postulated that unusually small values of τ_2, obtained for aniline, and a small change in the value of τ_2 from aniline to dimethylaniline, can only be explained by an inversion mechanism for an amino or substituted amino group. In order to confirm his viewpoint, a systematic study of some substituted anilines has been undertaken in various solvents of different viscosity. Chitoku and Higasi[7] have recently studied a few substituted anilines in dilute solutions of benzene and dioxane. They have reported relaxation times in the main dispersion region and have predicted another dispersion region in the mm wave range.

Experimental

Purification of Materials. *Benzene* was purified by the process already described.[8]

n-Heptane (E. Merck quality) was fractionally distilled and the middle fraction was collected. It was then dried over sodium and subsequently distilled (bp 98.0°C).

Cyclohexane (L.R., B.D.H.) was treated like *n*-heptane and the final sample was collected for use (bp 80.0°C).

Decalin (Reidel, Pure grade) was used without purification.

Nujol (B. P. Grade, meant for medicinal purposes) was passed through oil-free sodium wire and was subsequently subjected to vacuum for several hours.

p-Chloroaniline (Fluka A. G., A. R. grade) was used without purification. The following chemicals were imported from Dr. Theodor Schuchardt, West Germany.

N,N'-Dimethylaniline. Analytical reagent, free from monomethylaniline.

N,N'-Diethylaniline. Pure grade.

o-Chloroaniline. Analytical reagent.

m-Chloroaniline. Analytical reagent.

Since the measured values of their physical constants tallied well with literature values, further purification was not deemed necessary.

Table 1 gives a comparative statement of the measured and literature values of physical constants which indicates

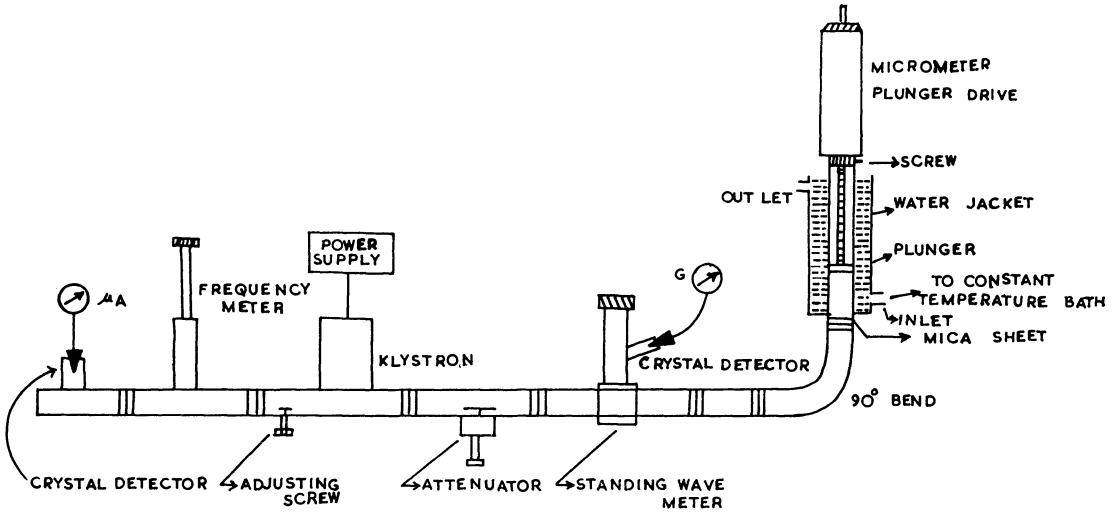
the extent of their purity. The melting point of *p*-chloroaniline (70°C) agreed well with the literature value (70—71°C).

Apparatus and Theory of Measurements. Dielectric constants and losses have been measured at two frequencies (1 Mc and 9.44 GHz). The measurements at 1 Mc are based on the principle of heterodyne beat method using a dielectrometer.[9] The accuracy in dielectric constant measurements is estimated to be ±0.05%. Refractive index measurements were made by means of an Abbey Refractometer (Hilger) having an accuracy upto the fourth decimal place. Viscosities were measured by means of a Ubbelohde[10] viscometer (accuracy ±0.5%). The final value was computed by applying kinetic energy corrections. Density was measured with an Oswald pycnometer (bulb capacity≈23 cc) having an accuracy of $\pm 5\times10^{-5}$ in 1. The temperature of the thermostatic bath was kept constant by means of a Thermomix within ±0.03°C.

Figure 1 shows the block diagram of the 9.44 GHz apparatus imported from Microwave Instruments, England. The measurement technique is based on the standing wave method, developed by Heston, Franklin and Smyth.[11]



Set-up in X-band

With the standing wave detector (SWD) at any fixed position the plunger is turned away from the mica window in the upward direction. The output of the SWD (probe position fixed) is noted at successive minima positions. The distance between the successive minima is equal to $\lambda_2/2$. The positions of at least five minima were noted and their mean value is taken as $\lambda_2/2$. In the majority of the cases, various distances between successive minima do not differ by a factor greater than the least count of the micrometer (0.001 cm). For low-loss materials the dielectric constant is given by

$$\varepsilon' \approx (\lambda_0/\lambda_c)^2 + (\lambda_0/\lambda_2)^2 \quad (1)$$

where λ_c is the cut-off wavelength, λ_0 is the free space wavelength and λ_2 is the wavelength in the dielectric filled guide of the cell.

The dielectric loss is determined by bringing the plunger down to the mica window so that the liquid length is zero. The plunger is then kept at different positions in steps of $\lambda_2/2$ and the standing wave pattern is recorded. The width at "twice minimum power points" is determined in each case and the values of the inverse voltage standing wave ratio ρ are calculated. These values of ρ are then plotted against 'n', *i. e.* the number of half wavelengths from the mica window, and the slope $(d\rho_{measured}/dn)$ is determined for each solution. The dielectric loss factor is approximated by

$$\varepsilon'' \approx (2/\pi)(\lambda_0/\lambda_2)^2(\lambda_g/\lambda_2)(d\rho_{measured}/dn)$$

where λ_g is the empty guide wavelength. The overall estimated accuracy of measurements is 0.5 to 1% for ε' and 2 to 4% for ε''.

For dilute solutions in non-polar solvents, ε, ε', ε'' and ε_∞ can be expressed as linear functions of concentration[12-14] in the following manner:

$$\left.\begin{aligned} \varepsilon &= \varepsilon_1 + a_0 w_2 \\ \varepsilon' &= \varepsilon_1' + a' w_2 \\ \varepsilon'' &= a'' w_2 \\ \varepsilon_\infty &= \varepsilon_{1\infty} + a_\infty w_2 \end{aligned}\right| \quad (3)$$

Subscript 1 refers to the pure solvent, 2 to the solute and subscript ∞ refers to the values at infinite frequency, w_2 may be taken as the weight fraction of the solute. The values of the so called slopes, *i. e.*, a_0, a', a'' and a_∞ for all the systems are given in Table 2. Most of the solutes were studied upto 0.10 weight fraction and the variable parameters were found to vary linearly with concentration. Higasi[14] showed that the Cole-Cole[15] equation can be represented in terms of the slopes a_0, a', a'' and a_∞ which would take the form

$$a' - ja'' = a_\infty + \frac{a_0 - a_\infty}{(1+j\omega\tau)^{1-\alpha}} \quad (4)$$

τ in this equation is the most probable relaxation time and α is the distribution parameter. For a system with a single relaxation time, α is zero and Eq. (4)

Table 2. Values of a_0 (slope of ε *vs.* concn. curve), a' (slope of ε' *vs.* concn. curve), a'' (slopn of ε'' *vs.* concn. curve) and a_D (slope of n_D^2 *vs.* concn. curve)

becomes Debye's equation in terms of a', a'', *etc.*, *i. e.*

$$a' - ja'' = a_\infty + \frac{a_0 - a_\infty}{1 + j\omega\tau}$$

This equation leads to the following four relations.

$$\frac{a' - a_\infty}{a_0 - a_\infty} = \frac{1}{1 + \omega^2\tau^2} \quad (5)$$

$$\frac{a''}{a_0 - a_\infty} = \frac{\omega\tau}{1 + \omega^2\tau^2} \quad (6)$$

$$a' = a_\infty + \frac{1}{\tau}(a''/\omega) \quad (7)$$

and

$$a' = a_0 - \tau(\omega a'') \quad (8)$$

If the Debye equation for a single relaxation time is valid for the system under consideration and if the measurements are conducted with sufficient accuracy, determination of the correct value of the relaxation time could be made by means of any of the equations mentioned above. Higasi and Kiyohara,[16] in their investigation of Smyth's experimental data, compared the τ values obtained by this method and those by the

usual method of Cole-Cole[15] for three different cases. The important conclusion drawn was the dependence of relaxation time upon the choice of a_∞.

In case the system has a distribution of relaxation times, values of τ and α can be calculated from the measurement of a' and a'' at a single frequency[14,17] by using the equations.

$$\tau = \frac{1}{\omega}\left(\frac{A^2 + B^2}{C^2}\right)^{1/2(1-\alpha)} \tag{9}$$

and

$$1 - \alpha = \left(\frac{2}{\pi}\right)\tan^{-1}\frac{A}{B} \tag{10}$$

where

$$\left.\begin{aligned} A &= a''\,(a_0 - a_\infty) \\ B &= (a_0 - a')(a' - a_\infty) - a''^2 \\ C &= (a' - a_\infty)^2 + a''^2 \end{aligned}\right| \tag{11}$$

Though this method has not been used by many workers yet the authors feel that it can provide more information, particularly for non-rigid molecules, in the absence of data at various frequencies. This method can, at least, determine the degree of distribution of various relaxation processes.

Method Adopted for the Calculation of Relaxation Time. If a system possesses a single relaxation time, then the values of τ calculated by using either of the four equations ((5) to (8)), should be the same within experimental errors, because all these relations are basically derived from a single equation. In the absence of an exact knowledge of a_∞, values of τ should preferably be calculated by using Eq. (8). Knowing τ for such a system, the value of a_∞ can subsequently be computed by the use of Eq. (7). This value of a_∞ should be slightly higher than the corresponding a_D value of the system, because a_∞ term involves some contribution from atomic polarization as well.

Even if the system possesses two relaxation times sufficiently far apart, values of τ can be calculated by using Eq. (8) and consequently the values of a_∞ can be estimated. Then the difference $(a_\infty - a_D)$ would give us an idea about the dispersion range to which the τ value belongs. With this picture in mind, the values of τ have been calculated for all the molecules in different solvents and these values are presented in Table 3 which also contains a_∞ values. The experimentally determined values of a_D have also been inserted in this table with a view to estimate the magnitude of $(a_\infty - a_D)$.

Discussion

A perusal of Table 3 reveals that there is a regular increase in the relaxation times of all the molecules as the solvent viscosity increases. Another noteworthy feature is the unusually high values of $(a_\infty - a_D)$ which should be negligibly small if the

17) G. L. Clark, *J. Chem. Phys.*, **25**, 125 (1956).

system has a single relaxation time. The large difference suggests that apart from relaxation in the main dispersion region, another relaxation mechanism seems to occur in the mm range which is due to the relaxation of the amino (or the substituted amino) group. One would therefore conclude that the relaxation process in anilines involves the molecular rotation as well as the intramolecular rotational mechanism. Also, it is interesting to note that the a_∞ values for all the anilines (except *m*-chloroaniline) are either less than the a_D values or negative in *n*-heptane. The values of relaxation time are also found to be relatively less in this solvent. This indicates that in *n*-heptane (having the lowest viscosity coefficient), there is a little disparity between the values of relaxation time for both processes which jointly contribute to the observed loss by competing with each other. The intramolecular process may possibly dominate.

We conclude that these relaxation times correspond to the ones in the main dispersion region.

Grubb and Smyth[18] have studied pure dimethylaniline and predicted, with reservation, two relaxation mechanisms with slightly hindered rotations of $N(CH_3)_2$ group. One of us (K.K.S.) also made a dielectric relaxation study[19] of liquid *N,N'*-dimethylaniline and *N,N'*-diethylaniline using two microwave frequencies (9.72 GHz) and 31.82 GHz), and analyzed the data with the help of "Cole-Cole plots" by taking ε_∞ as the square of refractive index. The findings show that the most probable relaxation time (τ) in both cases is frequency-dependent. The values obtained for the molecular relaxation time at 9.72 GHz are 38.2 ps for dimethylaniline and 290.3 ps for diethylaniline, whereas for 31.82 GHz, these values are 84.7 ps and 167.1 ps respectively. Furthermore, K.K.S. also found high values of distribution parameter (α), *i.e.*, 0.59 for dimethylaniline and 0.52 for diethylaniline. All these reported values correspond to the measurements at 30°C.

These observations and an examination of ($a_\infty - a_D$) values (given in Table 3) provide evidence of two relaxation mechanisms in anilines. One involves the rotation of the molecule as a whole and the other involves intramolecular or the group rotation. This suggests that the dipole in anilines is inclined at a particular angle to the C–N bond, thus making the molecule nonplaner. This possibly leads to the conclusion that the conjugation energy is insufficient to make the molecule planer. The conclusion supports the one already drawn by Tiganik[20] from the dipole moment studies. The amino group together with the benzene ring perhaps retains its pyramidal shape similar to that of an ammonia molecule even when one of its hydrogen atoms has been replaced.

Distribution Parameter (α) and Dipole Moment. In the absence of experimental data for a wide range of frequencies, the Cole-Cole[16] equation has been used in the form of relations (10—11) for the calculations of the distribution parameter (α) with the assumption that $a_\infty \approx a_D$. This will at least provide us with qualitative information about the existence of more than one relaxation mechanism. The values of relaxation time have purposely not been calculated by this method as it will give values in agreement with the values given in Table 3 only for the cases having $\alpha \approx 0$.

These values of distribution parameter are listed in Table 3 which also contains the dipole moments calculated by using the modified Higasi's equation.[8]

Study of Relaxation Time, Distribution Parameter and Dipole Moment Values. *a) N,N'-Dimethylaniline and N,N'-Diethylaniline.* Table 3 shows that for both these substances, relaxation time values increase with the increasing viscosity of the medium. Their reported[7] values in benzene are 14.5 ps and 33.2 ps at 20°C, whereas the authors found them to be 13.4 ps and 32.9 ps at 25°C. Obviously, the agreement between the two is good. Again the value of τ for dimethylaniline in benzne, determined by Kramer,[21] is 13.7 ps again in good agreement with the present value.

The reported[7] values of distribution parameter for dimethylaniline and diethylaniline in benzene, obtained by "Cole-Cole Plots", are 0.06 and 0.0 respectively as against 0.11 and 0.15 obtained by the authors. Certainly, the disparity is due to a different method adopted for calculations. The present method provides, at least qualitatively, a direct evidence of the existence of more than one relaxation mechanism, because the α values show a systematic increase with the increase in viscosity of the medium and are, in general, unusually high. Such large values cannot merely be due to the distribution of activation energies. It certainly indicates that there is more than one relaxation mechanism and that the disparity between the values of relaxation time increases with viscosity. However in *n*-heptane, α values for both these substances are slightly less than zero which perhaps indicates the predominance of intramolecular relaxation process in this solvent. These predictions are in agreement with those already drawn from the negative values of ($a_\infty - a_D$).

Small variations in the dipole moment values for different solvents are possibly due to the solvent effect.

b) o-, m-, and p-Chloroanilines. Liquid *o-* and *m*-chloroanilines have also been studied by Bhattacharyya[22] at a wavelength of 3.18 cm. His

values of relaxation time, calculated by Debye's equation, are 12.28 ps and 12.49 ps respectively. From the existence of a loss-maxima at 30°C in both cases, he inferred that the amino group is free to rotate and the presence of a chlorine group does not hinder its rotations in any way. It was thought therefore, that the study of the relaxation time in various solvents would give more information about the nature of intramolecular process.

Table 3 again shows a regular increase in relaxation time of these anilines with the increasing viscosity of the solvent. Of course, the variation is not as large as should be expected from Debye's equation[23,24] for a rotating sphere in a continuous fluid of viscosity η. On examining α values, one finds a systematic increase as was the case for dimethyl and diethyl anilines. The increase in values with the increasing viscosity of the medium is interpreted in terms of the disparity in the two relaxation mechanisms involved in the relaxation process. The almost regular rise in α further implies that the molecular relaxation time regularly increases with viscosity, whereas the intramolecular mechanism does not seem to increase very much with the viscosity of the medium. However, one does not expect such behaviour if the amino group (or the substituted one) rotates around the (C–N) bond, because it has some effective volume and this volume goes on increasing with the substitution of the radicals: CH_3 and C_2H_5, *etc.* Amino (or the substituted amino) group possibly relaxes with an inversion mechanism similar to the ammonia molecule, as postulated by Smyth.[6] However, a detailed and systematic study of the substances with a corresponding analysis of the data in terms of τ_1 and τ_2 is required before confirming this possibility. This is not possible with the measurements at two frequencies.

The values of relaxation time for *o*-, *m*- and *p*-isomers measured in benzene at 30°C are 6.5 ps, 13.0 ps and 20.6 ps respectively. These values increase with the shift of chlorine group from *o*- to *m*-, and finally to *p*-position with respect to the amino group. A regular variation in τ values may either be due to the change in the molecular volume or due to a change in the effective length of the dipole involved in the orientation process. The molecular volume (M/d) in all the three cases is approximately the same, *i.e.*, 106 cc. It, therefore, seems that the effective change in length of the dipole is actually responsible for the observed rise in relaxation times of these substituted anilines. Another interesting feature is that the values of α for these anilines in a particular solvent, in general, increase from *o*- to *m*- to *p*-isomers. This indicates, as is expected, that the hindrance for intramolecular rotation of NH_2 group is greater in *o*-chloroaniline, less in *m*-chloroaniline and still less in *p*-chloroaniline.

The authors are grateful to Professor H. S. Hans, Head, Department of Physics, and Professor V. B. Bhanot for their interest in the work and for providing the facilities.

Dielectric Relaxation and Molecular Structure. II Dielectric Relaxation in Dibutyl Ether, Diphenyl Ether and Benzophenone in Various Nonpolar Solvents

J. T. VIJ*1 and K. K. SRIVASTAVA

Department of Physics, Panjab University, Chandigarh-14, India

(Received December 10, 1969)

Measurements of dielectric constant and loss have been made at 1 Mc and 9.44 GHz for dibutyl ether and benzophenone in various solvents, *e.g.*, *n*-heptane, benzene, cyclohexane, carbon tetrachloride, decalin and Nujol. Whereas, diphenyl ether has only been studied in benzene and cyclohexane. The values of relaxation time and distribution parameter have been determined by using Cole-Cole's equation in terms of the so-called slopes, a_0, a', a'' and a_∞. The relaxation time values show a regular increase with the increase in viscosity of the medium both for dibutyl ether and benzophenone. The observations seem to suggest that dibutyl ether relaxes both by molecular and intramolecular mechanisms. The dipole moments in various solvents have also been calculated.

Several workers[1-6] have reported their findings about relaxation times for diphenyl ether and benzophenone and much has been said particularly about the anomalous behavior of the former.[7-10] However, no such data on relaxation study seems to be available for dibutyl ether. A study of this molecule may provide some information about the relaxation mechanism of aliphatic ethers in contrast to aromatic ones.

Experimental

Dibutyl ether, diphenyl ether and benzophenone (all of pure grade specifications) were imported from Dr. Theodor Schuchardt, West Germany, and were used without purification. The values of density, viscosity and refractive index for dibutyl and diphenyl ethers tallied[11] with their literature values. Melting point of benzophenone (48.0°C) agreed well with its literature value (48.1°C). All the solvents were purified by the processes described in our previous communication[12] which gives the measured values of their physical constants along with their literature values.

The dielectric constant, loss (at 1 Mc and 9.44 GHz) and refractive index measurements were made as per method already discussed.[12] All the measurements were made at 25°C. The accuracy in dielectric constant (at 1 Mc) is ±0.5%, in ε' and ε'' (at 9.44 GHz) 0.5 to 1% and 2 to 4%, respectively. The values of ε, ε', ε'' and n_D^2 were found to be linearly dependent upon weight fraction (w_2) for all the systems. The values of "the so-called slopes" a_0, a', a'' and a_D were determined and are presented in Table 1.

Method of Calculations. It has been shown by Higasi[13] that Cole-Cole[14] equation can be represented in terms of a_0, a', a'' and a_∞ which would take the form

$$a' - ja'' = a_\infty + \frac{a_0 - a_\infty}{1 + (j\omega\tau)^{1-\alpha}} \tag{1}$$

where τ is the most probable relaxation time and α is the distribution parameter. τ and α can be calculated from the measurements of a' and a'' at a single frequency[13,15] and their values are obtained from Eq. (1) in the manner given below:

$$\tau = \frac{1}{\omega}\left(\frac{A^2 + B^2}{C^2}\right)^{1/2(1-\alpha)} \tag{2}$$

and

$$1 - \alpha = \frac{2}{\pi}\tan^{-1}\frac{A}{B} \tag{3}$$

5	Nujol	5.62	0.78	0.85	0.270

where

$$A = a''(a_0 - a_\infty)$$
$$B = (a_0 - a')(a' - a_\infty) - a''^2$$
$$C = (a' - a_\infty)^2 + a''^2$$

The values of a_∞ are assumed to be approximately equal to a_D. This will not introduce much error in view of the inaccuracies involved in the measurements of a_0, a' and a''. Though this method has not been used by many workers, yet the authors feel that it would give reasonably accurate values of relaxation time for rigid molecules and the average values for molecular and intramolecular rotations in non-rigid molecules, depending upon their relative contributions to the overall relaxation process. The values of τ and α thus calculated are given in Table 2 along with the values of the dipole moment calculated by the method described earlier.[16]

Nujol	14.2	0.40	1.25

Discussion

a) Diphenyl Ether. Values of relaxation time for diphenyl ether are 3.4 ps and 4.4 ps in benzene and cyclohexane respectively. The former compares favourably well with the literature values of 4.1[1] ps at 25°C and 4.0[3] ps at 20°C. The relaxation time for liquid diphenyl ether is 5.0 ps/30°C,[11] again in fair agreement with the value 5.1 ps/30°C as reported by Calderwood and Smyth.[17] Values of distribution parameter in both the solvents are nearly equal to zero which indicates one type of relaxation mechanism to be predominant.

The reason for a lesser value of τ for diphenyl ether as compared to a similar molecule (benzophenone) has been attributed to the internal rotations of the phenyl groups.[8] The possible mechanism responsible for giving lesser value of relaxation time is the mesomeric shift of charge due to changes in the interaction between the π-electrons in the phenyl rings and the unshared pairs on the oxygen as a function of ring twisting with respect to the C–O–C plane. However, Nelson and Smyth,[18] in a study of molecules similar in structure to diphenyl ether, seem to support Fong's[9] hypothesis that "double or coupled internal rotations, resembling a rowing motion with one oar feathered are

responsible for the rapid relaxation mechanism". In the latter hypothesis, a fixed volume is always swept in rotation and it becomes difficult, on the basis of Debye's[19] concept of a rotating sphere in the viscous fluid characterized by its ordinary viscosity, to explain why the ratio of the rotating volume of diphenyl ether to benzophenone becomes only 2% in Nujol in comparison to 22% in benzene.[20] Indeed, some sort of internal rotation is definitely responsible for the rapid relaxation mechanism.

b) Benzophenone. Relaxation times for benzophenone along with the literature values (if available) are given in Table 3.

The value of 20.1 ps in benzene agrees fairly well with that of 20.4 ps/25°C determined by Chitoku and Higasi[6] from their study at low frequencies. However, a great disagreement appears in the case of Nujol. We found the τ value to be 135.0 ps as against 238.0 ps/25°C reported by Chitoku and Higasi.[6] and 295.0 ps/19°C reported by Jackson and Powels.[21] The reason for the large difference between the present and the literature values is perhaps due to the wide difference in frequencies at which the measurements have been carried out. Chitoku and Higasi determined the value from a study at low frequencies (~few Mc.) in which internal rotations may not have been taken into account.[6] The present value corresponds to the microwave frequency which accounts for both rotations, *i.e.*, molecular as well as intramolecular. The lesser value therefore indicates that the contributing factor of the rapid relaxation mechanism becomes predominant to the observed complex dielectric constant in the microwave range, which is obviously expected. This is further indicated by a comparatively higher value of distribution parameter (0.23) obtained in this solvent. Moreover, the existence of both processes is clearly established from the study of liquid benzophenone by Vaughan and Smyth[4,5] and from a recent study by Farmer and Walker[22] in cyclohexane. The values of τ_1 and τ_2 determined by the latter workers are also inserted in Table 3. It is interesting to note that the values of 3.0 ps[4,5] for liquid benzophenone and 3.5 ps for benzophenone in cyclohexane are nearly the same irrespective of the differences in the values of viscosity coefficients of the two media. The viscosity coefficent for liquid benzophenone is

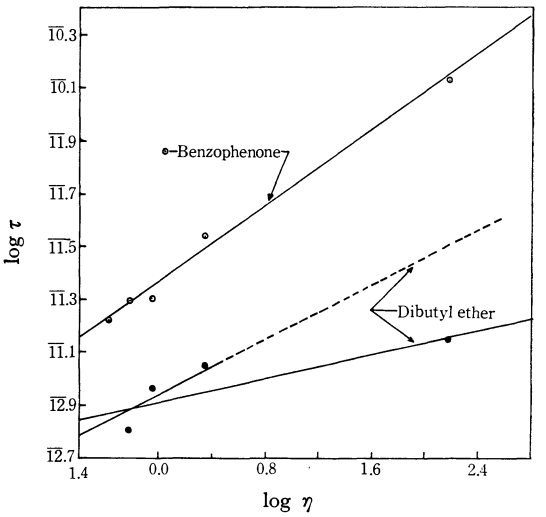

Fig. 1. Dependence of log τ upon log η.

19) P. Debye, *Trans. Faraday Soc.*, **30**, 679 (1934).
20) Ref. 10, p. 22.
21) W. Jackson and J. G. Powels, *Trans. Faraday Soc.*, **42a**, 101 (1946).
22) D. Farmer and S. Walker, *Tetrahedron*, **22**, 111 (1966).

4.19 c.p. whereas that of cyclohexane is 0.88 c.p. This suggests that the nature of rapid relaxation mechanism in this molecule is essentially the same as that of diphenyl ether. However, its contribution to the overall rotation is only about 6% in comparison to 74% for the diphenyl ether.[4,5]

The plot of log τ *vs.* log η gives a fairly reasonable linear curve and the value of x compares well with the value 0.46.[6] This confirms the viewpoint that semi-empirical equation[6] ($\tau=A\eta^x$) may replace Debye's formula[19] for a rigid sphere in a viscous fluid in which the coefficient of internal friction was taken to be the macroscopic measurable viscosity η. A systematic study of the coefficients A and X may provide a better insight into (i) the relaxation mechanism and (ii) internal rotations *vs.* overall rotations.

c) Dibutyl Ether. The relaxation time in benzene has been found to be 6.5 ps, whereas, for liquid dibutyl ether, the value (molecular relaxation time) is 5.0 ps/30°C as found by Srivastava.[11] Viscosity of dibutyl ether at 30°C is 0.58 c.p. which is almost the same as that of benzene (0.569 c.p.) A small difference between relaxation times hardly indicates any observable difference involved between the two systems.

Values of τ for this molecule, in solvents of low viscosity, show a usual trend. Ratio of relaxation times in carbon tetrachloride and cyclohexane is 1.23 as against their viscosity ratio of 1.03. This trend, possibly, is due to sticky nature[23,24] of carbon tetrachloride. Relaxation time in Nujol (having the largest viscosity coefficient) does not seem to be in accordance with its viscosity, if the molecules were considered to be of rigid structure. High value of α (0.40) in Nujol is interesting. Also a plot of log τ *vs.* log η hardly shows any trend towards linearity (see Fig. 1). This suggests intramolecular relaxation mechanism in dibutyl ether. The presence of internal rotation in the alkyl chains can also decrease the dependence of the relaxation time on the viscosity.

Considering the molecular volumes of dibutyl ether and benzophenone, one finds that these have similar values of 170.9 and 170.0 cc, but the relaxation times of these molecules in benzene are 6.5 ps and 20.1 ps respectively. This is possibly due to the reason that aliphatic groups (in comparison to phenyl groups) sweep lesser area of the solvent molecules while relaxing. This is further clear when we compare the relaxation time of this molecule with that of dipropyl ketone which has a similar molecular structure and nearly the same molecular volume (140 cc). The latter has the value of τ 5.4 ps in benzene at room temperature which compares well with that of dibutyl ether.[25]

The authors are grateful to Professor H. S. Hans, Head, Department of Physics and Professor V. B. Bhanot for their interest in the work and for providing the facilities.

A New Crystal with Kalsilite-type Structure on the $CaAl_2O_4$-SiO_2 Join

Takashi YOSHIOKA

Nihon Cement Co., Ltd. Research Laboratory, Kiyosumi, Koto-ku, Tokyo

(Received December 19, 1969)

A new crystal phase with a kalsilite-type structure has been found in devitrified glass with compositions close to $CaAl_2O_4$ on the $CaAl_2O_4$-SiO_2 join. The crystal can be synthesized as a nearly pure phase by heating the glass for 5 to 20 min at 1000°C. After prolonged heating, the crystal easily decomposes into an assemblage of the stable compounds, $CaAl_2O_4$, $CaAl_4O_7$, and $Ca_2Al_2SiO_7$(gehlenite). Most of the X-ray powder diffraction lines of the kalsilite-type phase can be indexed on the basis of a hexagonal unit cell with $a=5.0$ Å and $c=8.1$ Å. In addition to these reflections, some weak ones which cannot be indexed on the basis of this unit cell are also present. The kalsilite-type phase reacts with water, resulting in heat liberation and hardening.

In the course of an experimental investigation of a nepheline-type solid solution,[1] two kinds of new crystals were found along the $CaAl_2O_4$-SiO_2 join. One was a kalsilite-type phase formed in compositions closer to $CaAl_2O_4$ than the nepheline-type solid solution, while the other was formed closer to $CaAl_2Si_2O_8$(anorthite). The latter has not yet been investigated in detail. These phases are crystallized from glass at relatively low subsolidus temperatures around 1000°C in the air and gradually disappear at the same temperatures.

In the present report, the mode of formation and some of the physical properties of the kalsilite-type phase will be described.

Experimental

Homogeneous glass with compositions close to $CaAl_2O_4$ on the $CaAl_2O_4$-SiO_2 join was prepared by melting mixtures of chemicals above 1700°C in an electric furnace. Crushed glass was heated and devitrified under various conditions. The products were identified by means of a polarizing microscope and X-ray powder diffraction. The powder patterns of the kalsilite-type phase were indexed.

The rate of the heat liberation of the kalsilite-type phase in a hydration reaction was observed with a conduction calorimeter,[2] CM-502 type, of the Oyo Denki Kenkyusho Co., Ltd. Two kinds of kalsilite-type phases were synthesized by heating glass No. 1 and glass No. 2 (Table 1) for 20 min at 1000°C. They were then pulverized, and grains 4 to 16 microns in

diameter were used for the hydration examination. Ten milliliters of water were added to 10g of the specimen. The measurement of the rate of heat liberation was performed at 20°C.

Results

Mode of Formation. The kalsilite-type phase was produced when the glass was heated for a short time at approximately 1000°C (Table 1). The crystallized products of glass No. 1 and glass No. 2 after 10 mins' heating at 1000°C were composed mostly of this phase, plus a trace of the nepheline-type solid solution or residual glass. After prolonged heating, this phase easily decomposed into an assemblage of compounds, $CaAl_2O_4$, $CaAl_4O_7$, and $Ca_2Al_2SiO_7$, as shown in the table. The crystallized product of glass No. 3, obtained by 20 mins' heating at 1000°C, was composed of both the kalsilite-type phase and the nepheline-type solid solution with residual glass. Further heating at 1000°C resulted in the formation of the nepheline-type solid solution with a concomitant disappearance of the kalsilite-type phase.

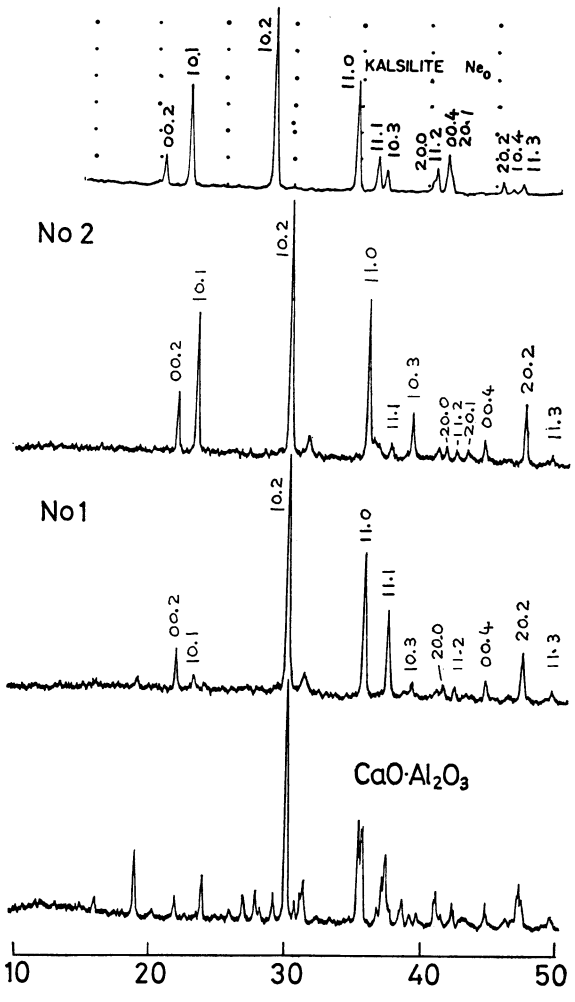

Fig. 1. X-ray powder patterns of the kalsilite-type phase.
Numbers correspond to those in Table 1. The pattern of kalsilite according to J. V. Smith and O. F. Tuttle is reproduced from Fig. 1 in p. 284 of Amer. Journ. Sci., Vol. 255 (1957). Indices are added for convenience by the present writer.

X-Ray Diffraction Pattern. In Fig. 1 powder diffraction patterns of the kalsilite-type phase obtained as a nearly pure phase (no trace of the nepheline-type solid solution was observed in the powder patterns) from glass No. 1 and glass No. 2 by 10 mins' heating at 980°C are shown, along with those of synthetic kalsilite[3] and $CaAl_2O_4$. Indexed powder data are also given in Table 2.

A close resemblance is observed between the kalsilite-type phase from glass No. 2 and the synthetic kalsilite. The diffraction pattern of the phase from glass No. 1 differs from that of the kalsilite. However, it resembles $CaAl_2O_4$ as a whole (Fig. 1). Almost all the diffraction lines of the kalsilite-type phases can be indexed on the basis of a hexagonal unit cell with $a=5.0$ Å and $c=8.1$ Å (ordinary kalsilite $KAlSiO_4$ has a hexagonal unit cell with $a=5.2$ Å and $c=8.7$ Å[3]). In addition to these reflections, some weak ones are also present, although these also are believed to be due to this phase. However, these lines cannot be indexed on the basis of the ordinary kalsilite unit cell;

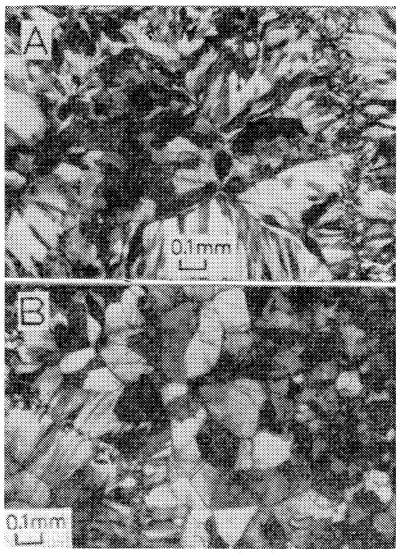

Fig. 2. Photomicrographs of the kalsilite-type phase crystallized from glass No. 2. Crossed nicols.
A) Feather-like form.
B) Granular form. Class was prepared by oxygen-acetylene flames.

3) J. V. Smith and O. F. Tuttle, *Amer. J. Sci.*, **255**, 282 (1957).

some of them can, however, be indexed by making the a parameter three or four times larger than that of the ordinary kalsilite, like that of tri-kalsilite[4] or tetra-kalsilite.[3] Also, some of them can be accounted for by the unit cell in which the a parameter is made $\sqrt{3}$ times larger than that of the ordinary cell, as in the case of ordered kalsilite.[5] However, none of these three unit cells can explain the weak reflections completely. One diffraction line remained unindexed in the pattern of the kalsilite-type phase from glass No. 1. It appears at the angle, about 19°(2θ) Cu$K\alpha$, which coincides with one of the reflections of $CaAl_2O_4$.

Optical Properties. After having been heated at 1000°C for 5 to 30 min, the glass appeared to be translucent; however, under a microscope it was observed as almost fully crystallized with a polycrystalline feature. Most of the crystals of the kalsilite-type phase appeared in a featherlike form, but they varied in their crystal habit according to the way the original glass had been prepared. They appeared in granular form when they were crystallized form the glass prepared by an oxygen-acetylene flame (Fig. 2). No difference was observed between the two forms in chemical composition, X-ray powder pattern, or refractive index. The kalsilite-type phase are uniaxially negative. The refractive indices of the one crystallized from No. 2 glass are ω 1.640 and ε 1.629, and those of the one crystallized from No. 1 glass are ω 1.646 and ε 1.636.

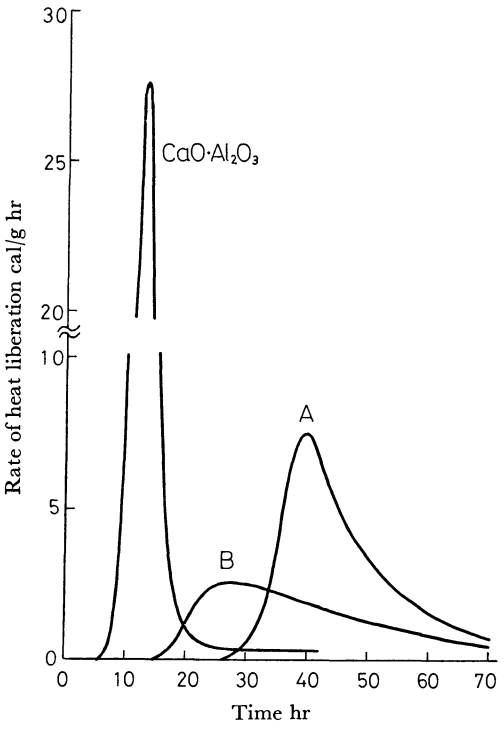

Fig. 3. Rate of heat liberation of the kalsilite-type phase.
A kalsilite-type phase cristallized from glass No. 1.
B kalsilite-type phase cristallized from glass No. 2.

Hydraulic Properties. Since the kalsilite-type phase appears in the compositions close to $CaAl_2O_4$ and has structural similarity to $CaAl_2O_4$, this phase was expected to have a hydraulic property. Generally, the cement-clinker compounds show features characteristic of heat liberation when they react with water. In the present study, therefore, the rates of the heat libetraion of the specimens of the kalsilite-type phase were examined, and they were compared with that of $CaAl_2O_4$, the grain size of which was 10—16 microns in diameter, as is illustrated in Fig. 3. Two kinds of kalsilite-type phases reacted with water, resulting in heat liberation and hardening. The rate of the heat liberation of these specimens was much smaller than that of $CaAl_2O_4$. The hydration products of the phases three days after the addition of water were composed mostly of $CaAl_2O_4 \cdot 10H_2O$, plus a small amount of $Ca_2Al_2O_5 \cdot 8H_2O$. Also, a small amount of the kalsilite-type phase remained unreacted in the No. 1 product, and much, in the No. 2 product.

Consideration

In the previous report[1] the nepheline-type solid solution on the $CaAl_2O_4$–$CaAl_2Si_2O_8$ join was expressed as:
$Ca_{8-(1/2)x}\square_{(1/2)x}Al_{16-x}Si_xO_{32}$. It takes an x value of about from 2 to 5.3. When x became less than 2, the kalsilite-type phase appeared. Kalsilite is the stable form of $KAlSiO_4$ below 850°C,[6] and its structure is based on that of the ideal, high-temperature tridymite. The kalsilite-type phases of this study can be expressed ss follows:
$Ca_{1.82}\square_{0.18}(Al_{3.64}Si_{0.36})O_8$ for the compound crystallized from glass No. 2, and $Ca_{1.85}\square_{0.15}(Al_{3.69}Si_{0.31})O_8$ for the compound crystallized from glass No. 1.

It is interesting to note that some of the weak reflections of the phases can be indexed on the basis of a unit cell similar to those of trikalsilite or tetra-kalsilite; these latter phases are regarded as metastable phases and appear only in compositions near the boundary between the stability ranges for nepheline and for kalsilite.[4,6] That the X-ray powder pattern of the No. 1 phase resembles, in general, that of $CaAl_2O_4$ more closely than that of kalsilite suggests that it is in a transitional stage

to the monoclinic $CaAl_2O_4$ structure.

Rankin and Merwin[7] and Carstens[8] have reported the existence of uniaxial $CaAl_2O_4$. Recently Nurse *et al.*[9] described, in their study of the CaO–Al_2O_3 system, that the uniaxial $CaAl_2O_4$ was a spherulitic quench-growth of a melt of the composition close to $CaAl_2O_4$. It can be expected that the uniaxial $CaAl_2O_4$ in high aluminous cements will correspond to the kalsilite-type phase because high aluminous cements have compositions close to $CaAl_2O_4$ and usually contain a certain percentage of SiO_2; in addition, they are usually produced by melting.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2321—2325 (1970)

Magnetic Circular Dichroism of $[Fe(CN)_6]^{3-}$

Hiroshi KOBAYASHI, Masayuki SHIMIZU and Youkoh KAIZU

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 25, 1969)

Magnetic circular dichroism (MCD) of $[Fe(CN)_6]^{3-}$ was measured in aqueous solution and in a polyvinylalcohol film. The use of the polyvinylalcohol (PVA) film made it possible to measure the MCD and the absorption spectrum of an electrolyte such as $K_3[Fe(CN)_6]$ at dry ice - methanol and liquid nitrogen temperatures, since the film was still optically transparent at lower temperatures. From a comparison between the observations at 300°K, 195°K and 77°K, the magnitude of an angular momentum due to the orbital motion of a hole in the ground state $^2T_{2g}$ (t_{2g}^5) was calculated to be 0.04—0.07 Bohr magneton (β). The observed reduction of the angular momentum was interpreted to be due to partial quenching of the orbital motion by the Jahn-Teller distortion, and also to the delocalization effect between the iron $d\pi$ orbital and the antibonding π molecular orbitals of the coordinating CN^- ions. The B term in $[Fe(CN)_6]^{3-}$, which had been ignored, was predicted to be non-zero and was estimated as -2.4×10^{-3} β/cm^{-1} at the band I and 0.97×10^{-3} β/cm^{-1} at the band II.

The majority of magnetic circular dichroism (MCD) measurements have been carried out with liquid solutions. However the use of the technique at low temperature makes it possible to get much more information about the electronic structure of an open-shell species such as inorganic complexes, free radicals, solvated electrons, or organic negative or positive ions. We present in this paper an MCD measurement of $[Fe(CN)_6]^{3-}$ ion which was carried out at dry ice - methanol and liquid nitrogen temperatures with a film of polyvinylalcohol (PVA) dispersing $[Fe(CN)_6]^{3-}$.

$[Fe(CN)_6]^{3-}$ has an iron(III) ion with a low spin d^5 system. A hole exists in a π molecular orbital which is delocalized over the iron $d\pi$ orbital and the antibonding orbitals of the coordinating CN^- ions. The angular momentum produced by an orbital motion of the hole in the ground state plays an important role in the temperature dependent magnetic circular dichroism. According to Buckingham and Stephens, and Schatz *et al.*,[1,2] the magnitude of molar circular dichroism observed at a transition $a\rightarrow j$ is given by

$$[\theta(a\rightarrow j)]_M = -\frac{24N}{\hbar c}\{f_1A + f_2(B+C/kT)\} \quad (1)$$

where the term C/kT is only a temperature-dependent term,

$$A = \frac{3}{d_a}\sum[\langle j|\hat{\mu}_z|j\rangle - \langle a|\hat{\mu}_z|a\rangle]\cdot \boldsymbol{I}_m[\langle a|\hat{m}_x|j\rangle\langle j|\hat{m}_y|a\rangle] \quad (2)$$

1) A. D. Buckingham and P. J. Stephens, *Ann. Rev. Phys. Chem.*, **17**, 399 (1966).

2) P. N. Schatz, A. J. McCaffery, W. Suëtaka, G. N. Henning, A. B. Ritchie and P. J. Stephens, *J. Chem. Phys.*, **45**, 722 (1966).

$$B = \frac{3}{d_a}\sum \boldsymbol{I}_m\left\{\sum_{k\neq a}\frac{\langle k|\hat{\mu}_z|a\rangle}{W_k - W_a}[\langle a|\hat{m}_x|j\rangle\langle j|\hat{m}_y|k\rangle - \langle a|\hat{m}_y|j\rangle\langle j|\hat{m}_x|k\rangle] + \sum_{k\neq j}\frac{\langle j|\hat{\mu}_z|k\rangle}{W_k - W_j}[\langle a|\hat{m}_x|j\rangle\langle k|\hat{m}_y|a\rangle - \langle a|\hat{m}_y|j\rangle\langle k|\hat{m}_x|a\rangle]\right\} \quad (3)$$

$$C = \frac{3}{d_a}\sum\langle a|\hat{\mu}_z|a\rangle \boldsymbol{I}_m[\langle a|\hat{m}_x|j\rangle\langle j|\hat{m}_y|a\rangle] \quad (4)$$

d_a is the degeneracy of the state a, and $\hat{m}$ and $\hat{\mu}$ are the electric and magnetic dipole operators, respectively. The summations are over all transitions degenerate with $a \rightarrow j$, and the state a and j are diagonal in $\hat{\mu}_z$. W_a is the energy of the state a. A correction for condensed medium effects has been avoided by expressing $[\theta(a\rightarrow j)]_M$ in terms of ratios of A, B, or C to D, the dipole strength ($D \equiv 3\sum|\langle a|\hat{m}_x|j\rangle|^2/d_a$) obtained from the observed absorption intensity.

Recently McCaffery, *et al.*[3] observed a temperature-dependent MCD of $[IrCl_6]^{2-}$ doped in a crystalline $(CH_3NH_3)_2SnCl_6$. The temperature-dependence was assumed to arise primarily from the term $C/\boldsymbol{k}T$. The term $C/\boldsymbol{k}T$ is ascribed to the orientation effect of a temperature-independent magnetic moment of the ground state in a magnetic field. However, another possibility is a temperature-dependent magnetic moment,[4] which arises from a population of the higher sublevels ($J=3/2$) other than the lowest sublevels ($J=1/2$) of the ground state $^2T_{2g}$. Since the spin-orbit coupling in $[IrCl_6]^{2-}$ is so strong that a sufficient gap exists between the sublevels $J=1/2$ and $J=3/2$, the higher sublevels are not populated.[4d] In the case of $[Fe(CN)_6]^{3-}$, however has been observed a temperature-dependent orbital contribution to the magnetic susceptibility due to a population of the higher sublevels.[4c] In this paper, a temperature-dependent MCD of $[Fe(CN)_6]^{3-}$ in a PVA matrix will be presented.

Experimental

The aqueous solution of polyvinylalcohol was added with an aqueous solution of $K_3[Fe(CN)_6]$ and the mixture was allowed to evaporate to dryness on a glass plate. When it was dried, it gave a yellow transparent film.*1 The concentrations and their mixing ratio of the solutions were adjusted to give a film with an optical density of 1.0—2.0.

Our measurement techniques of magnetic circular dichroism will be described elsewhere.[5] All measurements were carried out by a JASCO model ORD/UV-5 instrument with a drastically modified optical path for an electromagnet which produced a magnetic field up to 12000 gauss. When the current in the magnet is reversed, the signal coming out is also reversed. The deviation between two curves thus obtained (Figs. 1—3) gives an effective signal corresponding to that observed in a magnetic field of twofold strength.

The instrument was also furnished with a special Dewar system for the low temperature measurement.

Results and Discussion

The magnetic circular dichroism (MCD) and the absorption spectrum of $[Fe(CN)_6]^{3-}$ were measured with an aqueous solution and a polyvinylalcohol (PVA) matrix at room temperature. They are shown in Figs. 1 and 2. There seems to be only a little solvent effect. The magnitude of MCD was given in molar ellipticity per unit external magnetic field $[\theta]_M$. Since the concentration of $[Fe(CN)_6]^{3-}$ in PVA was unknown, the MCD was given in experimentally observed ellipticity per unit external magnetic field θ_M. The film was actually 0.25 mm thick and had an optical density corresponding to that observed for 0.82×10^{-3} mol/l aqueous solution of $[Fe(CN)_6]^{3-}$ in a 1 cm path. If it is necessary, $[\theta]_M=\theta_M/C\cdot l$, where C is the concentration, l is the path length and the product $C\cdot l$, is given by optical density measurement as 0.82×10^{-3} mol l^{-1} cm.

The observed $[\theta]_M$ of $[Fe(CN)_6]^{3-}$ arises predominantly from the term $(B+C/\boldsymbol{k}T)$, since the MCD spectrum shows its maximum at the position of an absorption maximum. If the A term plays an important role, however, the observed MCD should give a sigmoid dispersion curve at the position of the absorption maximum. The function f_1 in (1) is approximately given by a function such as

$$\{\pi^{1/2}\tilde{\nu}(\tilde{\nu}_{ja}-\tilde{\nu})\exp[-(\tilde{\nu}-\tilde{\nu}_{ja})^2/\Delta^2_{ja}]\}/\boldsymbol{h}\Delta^3_{ja}$$

which shows a sigmoid dispersion curve at the position of the absorption maximum ($\tilde{\nu}_{ja}$) and the area obtained by integration of $f_1/\tilde{\nu}$ over whole range of an absorption band should be zero. The function f_2 is approximately given by a function such as Gaussian

$$\{\pi^{1/2}\tilde{\nu}\exp[-(\tilde{\nu}-\tilde{\nu}_{ja})^2/\Delta^2_{ja}]\}/2\Delta_{ja}$$

which shows a maximum at the position of the absorption maximum ($\tilde{\nu}_{ja}$) and the area obtained by integration of $f_2/\tilde{\nu}$ over whole range of an absorption band should be $\pi/2$. The A term makes no contribution to the integrated MCD and

$$\int\frac{[\theta(a\rightarrow j)]_M}{\tilde{\nu}}d\tilde{\nu}=-\frac{24\boldsymbol{N}}{\hbar c}\frac{\pi}{2}(B+C/\boldsymbol{k}T). \quad (5)$$

We avoided troublesome correction for condensed medium effect by expressing our results in terms of a ratio of $\int[\theta]_M/\tilde{\nu}d\tilde{\nu}$ to the dipole strength D. Assuming the best fit Gaussian $\varepsilon(\tilde{\nu})$ to the molar

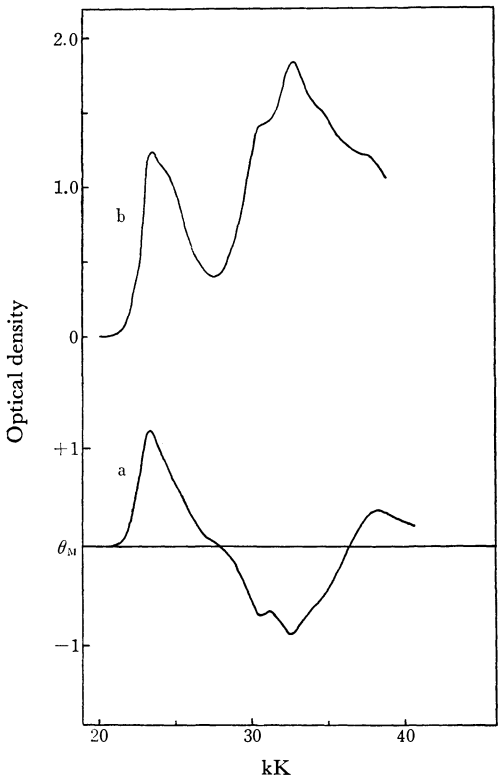

Fig. 4. (a) Ellipticity per unit magnetic field of $[Fe(CN)_6]^{3-}$ in PVA at dry ice-methanol temperature (195°K).
(b) Absorption spectrum of $[Fe(CN)_6]^{3-}$ in PVA at dry ice-methanol temperature (195°K).

absorption curve, the dipole strength D was evaluated from the area obtained by the integration of $\varepsilon(\bar{\nu})/\bar{\nu}$ over whole range of an absorption band. The value of $\int[\theta]_M/\bar{\nu}d\bar{\nu}$ was also obtained by the integration of a Gaussian which best reproduced the observed magnetic molar ellipticity curve. B and $C/\boldsymbol{k}T$ were given in units of square Debye·Bohr magneton per cm^{-1}. Our observation at room temperature and the value of C obtained by an assumption that the B term is negligibly small, are given in Fig. 1 and Table 1, respectively, and are in good agreement with the data published by Schatz, *et al.*[2] Measurements of MCD at various temperatures are expected to give a criterion to the validity of the assumption.

TABLE 1. PARAMETER VALUES FOR $[Fe(CN)_6]^{3-}$ IN AQUEOUS SOLUTION AT ROOM TEMPERATURE (300°K)

	$C(D^2\cdot\beta)$	$D(D^2)$	$C/D(\beta)$
Band I	−0.824	1.34	−0.615
Band II	0.961	3.03	0.317
Band III	−0.153	1.35	−0.113

D: Debye unit; β: Bohr magneton.

Three bands of moderate intensity (ε_{max} ~1000—2000) at 24000, 33000 and 38500 cm^{-1} have been observed.[6] These bands have been assigned to the allowed "ligand to metal" charge transfer transitions. Of these, two are $^2T_{2g}\rightarrow{}^2T_{1u}$ and one is $^2T_{2g}\rightarrow{}^2T_{2u}$. After some different assignments had been given,[7,8] the first band was assigned to $^2T_{2g}\rightarrow{}^2T_{1u}$ transition and the second to $^2T_{2g}\rightarrow{}^2T_{2u}$ transition based on magneto-optical rotatory dispersion (MORD) measurements[9] which had been carried out by Shashoua[10] and Briat.[11] Since C/D is a measure of the angular momentum of an orbital motion in the ground state, the magnitude of $|C/D|$ should not be changed from one band to another and the sign of C/D should be opposite that for the transitions to T_{1u} and T_{2u} states. Actually the MCD observed at the second band shows an opposite sign to the MCD observed at the first band and at the third band. From existing MCD data[2] including a semiquantitative measurement by Foss and McCarville[12] and also MORD data, it follows that the first band and the third band corresponding to $^2T_{1u}$ excited states show a negative C, and the second band corresponds to $^2T_{2u}$ excited state and shows a positive C.

The PVA film was optically transparent even at liquid nitrogen temperature (77°K). An optically transparent PVA film dispersing $[Fe(CN)_6]^{3-}$ was measured for MCD at various temperatures. The results are shown in Figs. 2—4. The PVA film technique made it possible to observe the MCD and the absorption spectrum of an electrolyte such as $K_3[Fe(CN)_6]$ at dry ice-methanol temperature and at liquid nitrogen temperature. When the measurements of the MCD and the absorption were carried out with exactly the same sample, the ratio of the observed value of the integrated MCD to the observed value of the integrated absorption is independent of the actual concentration of $[Fe(CN)_6]^{3-}$ in the film and gives the value of $(B+C/\boldsymbol{k}T)/D$.

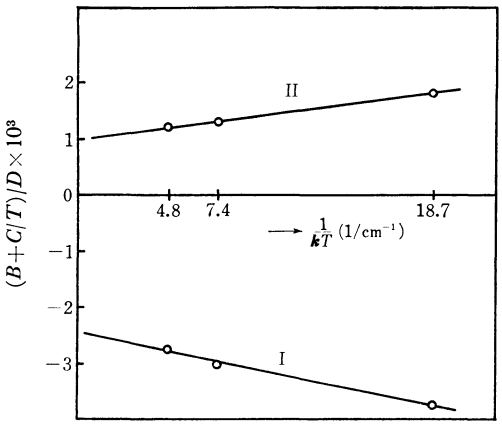

Fig. 5. Temperature dependence of $(B+C/kT)/D$.

Table 2 shows our observed values of $(B+C/kT)/D$.

As shown in Fig. 5, a plot of the observed values of $(B+C/kT)/D$ *versus* $1/kT$ gave a straight line. It gave non-zero B/D from its intercept and fairly small C/D from its slope. The value of B/D was found to be -2.44×10^{-3} β/cm^{-1} for the first band, while the value was obtained to be 0.97×10^{-3} β/cm^{-1} for the second band. The ignored angular momentum induced by magnetic field is not zero. A difference of the magnitudes of B/D between the two bands seems to be appreciable. The value of C/D was -0.070 β for the first band and $+0.044$ β for the second band. These values of C/D in the absolute value are fairly smaller than 0.5 β theoretically expected for an orbital motion of a hole at the central iron.[2] Delocalization of the hole over whole complex will reduce the absolute value of C/D. However, another important mechanism expected to reduce the value is a quenching of the orbital motion by trapping the hole in the lowest component of t_{2g} molecular orbitals split by a dynamical or static Jahn-Teller distortion of the open shell $d\pi^5$ system. As far as the MCD measurements are concerned, a population of the higher sublevels ($J=3/2$) in $[Fe(CN)_6]^{3-}$ does not seem to change the values of B and C since the plot shown in Fig. 5 gives a nice straight line. However, a theoretical approach to the problem is required. Theoretical interpretations including molecular orbital calculation will be given elsewhere.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2326—2331 (1970)

ζ-Potentials of Natural and Synthetic Fibers in SDS Solutions and the Viscosity of SDS Solutions above the Critical Micelle Concentration*1,*2

Yoshio IWADARE and Toshiro SUZAWA

Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received December 31, 1969)

In order to investigate the adsorption behavior of an anionic surfactant on fibers, the ζ-potentials of natural and synthetic fibers in aqueous solutions of sodium dodecyl sulfate (SDS), mainly above the critical micelle concentration (CMC), were measured. Further, the change in the structure of the SDS micelle in aqueous solutions was studied by means of the viscosity method. At first the reduced viscosity for the SDS micelle, η_{spm}/c_m (c_m: the micellar concentration), increased rapidly with the c_m as long as the c_m was small; thereafter, after a break, it approximated the saturated values as a whole. The results calculated from the experimental data using Jones and Dole's equation showed two distinct breaks. The first break corresponded to the 1st CMC, and the second, nearly to the break in the η_{spm}/c_m *vs.* c_m curve. In addition, the intrinsic viscosity for the SDS micelle, $[\eta]_M$, and the effective specific volume, V, were obtained. From these results, it can be assumed that the structure of the SDS micelle is variable at the break in the η_{spm}/c_m *vs.* c_m curve. The ζ-potentials of fibers in aqueous SDS solutions changed rapidly with an increase in the concentration of SDS, but they remained approximately constant in the vicinity of the CMC. At much higher concentrations above the CMC (in the vicinity of the SDS concentration of 2×10^{-2} mol/l), the ζ values again gradually changed; thereafter, after a break, they became nearly constant again. The change in the ζ-potentials corresponds approximately to the break in the η_{spm}/c_m *vs.* c_m curve. Therefore, it may be suggested that it is connected with the change in the structure of the SDS micelle.

The adsorption of an anionic surface active agent on the fiber-solution interfaces is considered to be an important factor in problems of detergency. It is generally known that the washing power of a surfactant increases up to a certain concentration of surfactant; beyond this point, however, the further addition of the surfactant has little effect.[1-3]

On the other hand, in the case of the adsorption of a surfactant on solid materials, the appearance of maxima in adsorption isotherms has been observed by many authors.[4-11] It seems that the maxima in adsorption isotherms correspond to the critical washing concentration (CWC) in detergency. However, several investigators[12-17] did not clearly observe such maxima in isotherms.

Previous papers[18] have described the relationship

between the ζ-potentials of synthetic fibers in aqueous solutions of a surfactant and the surface-adsorption properties of its agent on the fibers below the critical micelle concentration (CMC). It was suggested that the adsorption of an anionic surfactant on fibers in an aqueous neutral solution takes place mainly by means of van der Waals' force. Further, the amount of anionic surfactant adosorbed per unit of the area of the fiber surface increased with an increase in the concentration of its agent; the increase was the greater, the smaller the degree of swelling of the fiber and the more hydrophobic the fiber. These facts indicate that the interaction between the hydrocarbon chain of an anionic surfactant and the hydrophobic part of a fiber is important for the adsorption of its agent on the fiber.

At present, in order to contribute to the study of the adsorption behavior of an anionic surfactant on the fibers in the vicinity of the CMC and above of its agent, the ζ-potentials of natural and synthetic fibers in aqueous solutions of sodium dodecyl sulfate (SDS) were measured. On the other hand, the viscosity of an aqueous SDS solution was determined in order to investigate the relationship between the structure of the micelle and the concentration of the surfactant. In this paper, the relationship between the ζ-potentials of fibers in aqueous solutions of SDS and the change in the structure of the SDS micelle will be primarily reported on.

Experimental

Apparatus and Procedures. *ζ-Potential.* The ζ-potential was measured by the method of the streaming potential described in a previous paper.[19] The streaming potential was measured by using a Transistorized Dynamic-Condenser Electrometer, Model UFE 26301 H

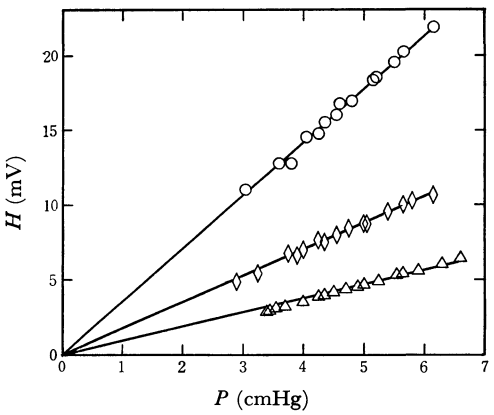

Fig. 1. Relation of streaming potential (H) to pressure (P) for Nylon 6 fiber.
SDS concentration (mol/l):
(○) 4×10^{-3}; (◇) 10×10^{-3}; (△) 26×10^{-3}

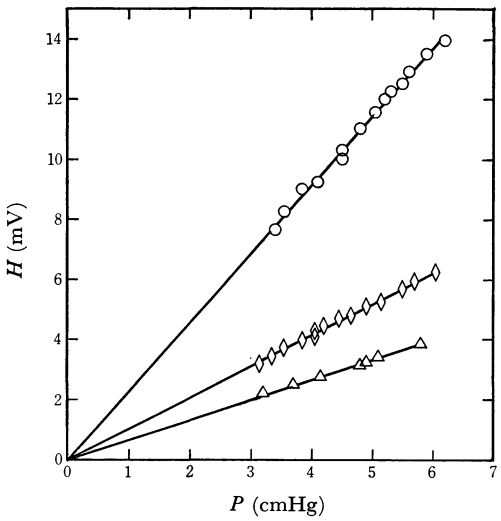

Fig. 2. Relation of streaming potential (H) to pressure (P) for Cashimilon fiber.
SDS concentration (mol/l):
(○) 4×10^{-3}; (◇) 10×10^{-3}; (△) 26×10^{-3}

(Tokyo Shibaura Electric Co., Ltd.). The relation between the streaming potential, H (mV), and the pressure, P (cmHg), is shown in Figs. 1 and 2, the figures corresponding, respectively, to Nylon 6 and Cashimilon fibers. On the basis of these results, the streaming potential can be said to be accurately proportional to the pressure (*i. e.*, to the velocity of streaming) between mercury pressures of 3 and 6 cm above the CMC as well as below it.

Actually, the streaming potential measurements were always carried out at a mercury pressure of 5 cm and at a temperature of 25 ± 0.02°C. The solutions examined all contained 10^{-4} mol/l of sodium chloride.

Critical Micelle Concentration (CMC). The critical micelle concentration was determined by measuring the surface tension, the conductance, and the viscosity of aqueous solutions of the surfactant in the presence of 10^{-4} mol/l sodium chloride and at 25 ± 0.02°C.

Surface Tension: A drop method was used for measuring the surface tension of solutions. The surface-tension values were corrected by the method of Harkins and Brown.[20]

Conductance: The conductance values were obtained by means of a Yanagimoto Conductivity Outfit, Model MY-7 (Yanagimoto MFG. Co., Ltd.).

Viscosity: The viscosities of the solutions were measured with an Ostwald viscometer prepared by reference to the British Standard,[21] so the surface tension correction was small.[22] The capillary of this viscometer was 12.5 cm long, and its average radius was 0.028 cm. Reynolds number was about 30. The kinetic correction amounted to less than 1 part in 1000 over the whole concentration range studied.[22]

20) W. D. Harkins and F. E. Brown, *J. Amer. Chem. Soc.*, **38**, 288 (1916); *ibid.*, **41**, 499 (1919).

21) A. E. Alexander and P. Johnson, "Colloid Science," Appendix IV (1949).

22) Y. Iwadare and T. Suzawa, *Nippon Kagaku Zasshi*, **90**, 1106 (1969).

The viscometer was cleaned immediately before each filling with a warm sulfuric acid-dichromate solution, rinsed numerous times in order to remove all traces of the acid, and dried with air. The flow time for water was 663.9 sec. From three to five flow-time measurements were made on each solution.

Materials. *Fibers.* Polyamide Nylon 6 (manufactured by the Toray Co., Ltd.; draw ratio, 1; denier, unknown; 30 filaments), polyvinylalcohol Vinylon (Kurashiki Rayon Co., Ltd.; 1.4 denier; monofilament; degree of formylation, 0.34), polyacrylonitrile Cashimilon (Asahi Chemical Industry Co., Ltd.; 52 counts; monofilament) and polypropylene Pylen (Toray Co., Ltd.; 100 denier; 24 filaments) were first extracted with ethanol for about 24 hr at room temperature; then they were extracted with deionized water and finally dried in air. Cotton fiber (Kanegafuchi Spinning Co., Ltd.; 30 counts; yarn) was extracted with deionized water, with ethanol, and with an ethanol-benzene mixed solvent (volume ratio 1: 1) for 24 hr at room temperature; finally it was extracted with deionized water.

Glass capillaries were used instead of glass fiber. Hario glass tubes (JIS K-250) sold by the Shibata Chemical Apparatus Mfg. Co., Ltd., were used for the capillaries. These capillaries were 23 mm long, and their average inner and outer diameters were 0.2 and 0.4 mm respectively. They were cleaned with a warm sulfuric acid - dichromate solution and rinsed numerous times with conductivity water in order to remove all traces of acid by means of suction with a aspirator.

Surface Active Agent. The sodium dodecyl sulfate (SDS) was provided by the Nippon Oils & Fats Co., Ltd. The surface tension *vs.* the log concentration curve showed no minimum. The CMC values obtained are given in Table 1.

Table 1. The CMC values of SDS in aqueous solution (NaCl: 10^{-4} mol/*l*, 25°C)

Method	CMC (mol/*l*) $\times 10^3$
Surface tension	7.1
Conductivity	7.6
Viscosimetry	7.0

Results and Discussion

Viscosity of SDS Solution and Change in the Structure of SDS Micelles. *Viscosity of Aqueous SDS Solution.* The results of the viscosity measurement for an aqueous SDS solution in the presence of 10^{-4} mol/*l* sodium chloride are shown in Fig. 3. The SDS solution was studied over the concentration range $(4—255) \times 10^{-3}$ mol/*l*.

The variation in the relative viscosity, η_r, with the SDS concentration, c_s (mol/*l*), is shown by curve I. The gentle upward curvature of the curve seems to be a result of mutual interference between the colloidal particles in motion during flow.[23]

The relation between the reduced viscosity, η_{sp}/c_s, and c_s, as is shown by curve II, reaches a minimum at the SDS concentration of 7×10^{-3} mol/*l*. This minimum point is believed to correspond to the CMC, $c_{c(1)}$, it agrees well with the CMC value obtained by surface-tension measurements (*cf.* Table 1).

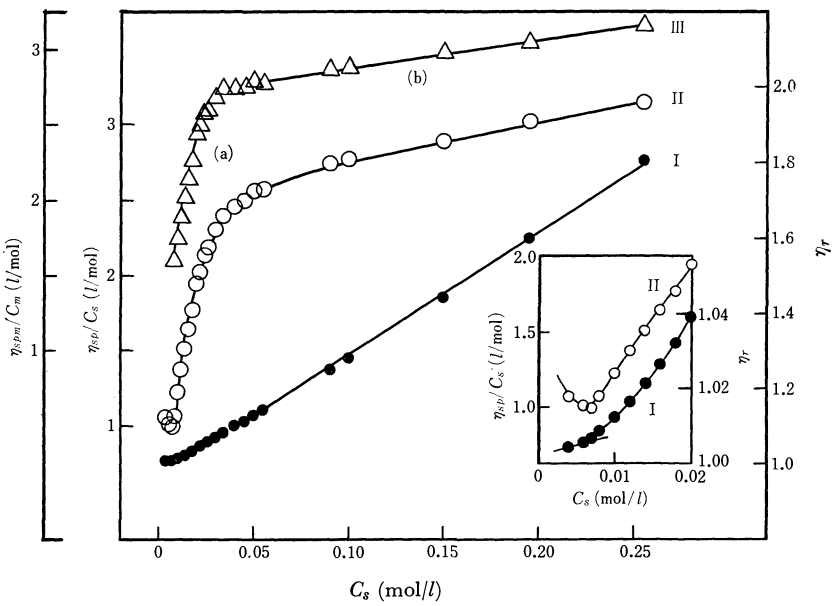

Fig. 3. Viscosity of aqueous SDS solution.
curve I: η_r *vs.* c_s; curve II: η_{sp}/c_s *vs.* c_s; curve III: η_{spm}/c_m *vs.* c_m

23) R. J. Vetter, *J. Phys. & Colloid Chem.*, **51**, 262 (1947).

Sata and Tyuzyo[24] presumed that above the 1st CMC, the concentration of a surfactant monomer in a solution which is in equilibrium with the micelle is almost constant and remains unchanged. Accordingly, the following operations were performed:

$$c_m = c_s - c_{c(1)}$$

$$\eta_{spm}/c_m = \{(\eta_r/\eta_{rc(1)}) - 1\}/(c_s - c_{c(1)}) \quad (1)$$

where;

η_{spm}/c_m: reduced viscosity for the micelle.
$\eta_{rc(1)}$: relative viscosity at the 1st CMC, $c_{c(1)}$.

Therefore, the recuced viscosity for SDS micelles, η_{spm}/c_m, is shown by curve III.

From this figure, it can be seen that the η_{spm}/c_m increases linearly with the c_m as long as the c_m is small; thereafter, after a break observed in the concentration range $(20—25)\times 10^{-3}$ mol/l, it approximates the saturated value as a whole. The second, sharper break did not appear in the concentration range studied.

Intrinsic Viscosity and Hydration of SDS Micelles. Shinoda[25] has suggested that the shape and the size of micelle depend on the concentration, the temperature, the molecular structure of the respective surface active agent, the kind of intermolecular force, and the kinds of additives. Grindley and Bury[23,26] have indicated that the micelle size increases to a maximum over a short transition concentration range. At present, while the evidence that amphipathic molecules associate to form aggregates of micelles is overwhelming, the size and shape of these micelles are still disputed.[27]

Mukerjee[28] has estimated the hydrations of micelles of SDS and dodecyl and tetradecyl trimethyl ammonium chlorides from the viscosity data in the following manner. That is, the hydration, h, in weight percentage is obtained, assuming that the micelles are spherical, from an extension of Einstein's equation:

$$[\eta]_M = 2.5(\bar{V}_s' + h) \quad (2)$$

where $[\eta]_M$ is the corrected intrinsic viscosity for the charged micelle, and where $\bar{V}_s'$ is the partial specific volume of the micelle. Consequently, it was concluded that the formation of ice-like hydration sheaths on hydrocarbon surfaces and the thickening of the shear layer on highly-charged surfaces because of the viscoelectric effect are probably unimportant.

Table 2. Intrinsic viscosities and hydration of SDS micelles

	$[\eta]_M$ (ml/g)	Hydration in weight per cent		Hydrodynamic volume	Hydration in volume per cent
		Author	Mukerjee[28]		
Portion (a)	3.3	43	39±4	1.32	24
Portion (b)	7.5	211		3.00	67

On the basis of Eq. (2), the hydration of SDS micelles obtained from the curve III are shown in Table 2. Further, in the table the hydrodynamic volumes[23] and hydrations in volume percentage, calculated from hydrodynamic volumes, are also shown. The electroviscous effect, included as part of the intrinsic viscosity, was corrected for by using the data of Parker and Wasik.[29] The partial specific volume of SDS micelles, $\bar{V}_s'$, is 0.889 ml/g.[30]

At all events, on the basis of Table 2 it seems likely that the degree of hydration and, hence, the size of SDS micelles increase to some extent with an increase in the concentration on the portion (a). As the solution becomes more concentrated, the counter-ion concentration steadily increases, with a resulting decrease in the degree of ionization of the micelles; the stability is thereby enhanced.[31] The reduced viscosity for SDS micelles, η_{spm}/c_m, linearly increases little by little with an increase in the concentration on the portion (b). This fact suggests that the micellar properties remain constant over a relatively wide range of concentration, indicating that the dimensions and the form of the micelles remain constant.[32,33]

Effective Specific Volume of SDS. Use was made of Guth and Simha's equation,[32,34,35] which is a form of Einstein's equation extended for application to more concentrated solutions:

$$\eta_r = 1 + 2.5\phi + 14.1\phi^2 \quad (3)$$

where ϕ is the volume fraction occupied by the spherical particles. The effective specific volume of 1 g of a surfactant including hydrated water, V, is expressed as follows[32,35]:

$$V = \phi/c \quad (4)$$

where c is the concentration of the solution in g/ml.

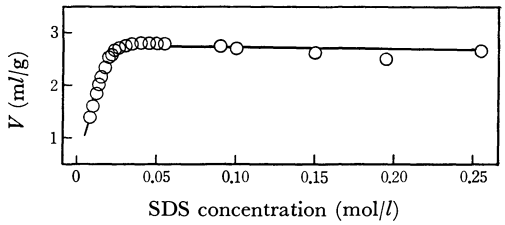

Fig. 4. Effective specific volume (V) with SDS concentration.

The values of V thus calculated are shown in Fig. 4. The effective specific volume of the dispersed colloidal particles of SDS increases with the concentration as long as the SDS concentration is small; thereafter, after a break, it remains approximately constant in the range of high concentration. This break roughly corresponds to that of curve III in Fig. 3. The constancy of the effective specific volumes is also indicative of a spherical micelle.[32,35] Therefore, the shape and size of these micelles must remain constant in the range of concentration beyond the break, but they are not constant in the smaller range.

The Change in the Structure of SDS Micelle Observed from Jones and Dole's Equation. The relative viscosity of an electrolyte solution with a molar concentration, m, is given by Jones and Dole's equation[28,36,37]:

$$\eta_r = 1 + A\sqrt{m} + Bm \qquad (5)$$

where A and B are constants. It is believed that the B coefficient for a particle in water is a positive quantity indicating a structure-forming tendency. On the other hand, if the electrolyte particle tended to destroy the structure of water and produce disorder, then the B coefficient would be a negative quantity.[37]

It is suggested that the formation of micelles is attended by a change in the structure of the solvent, that is, by an interaction between micelles and solvent.[23] If the change in the structure of the micelle were attended by a change in the structure of water, the B coefficient would be variable.

The results calculated from the experimental data are shown in Fig. 5. From this figure, it can be seen that there are two distinct breaks, at points a and b. The point a nearly corresponds to the 1st CMC, and the point b, roughly to the break of curve III in Fig. 3 and to that of the V *vs.* concentration curve in Fig. 4.

Nakagaki and Ninomiya[38] have shown the viscosity data that the 2nd CMC of SDS is 0.02

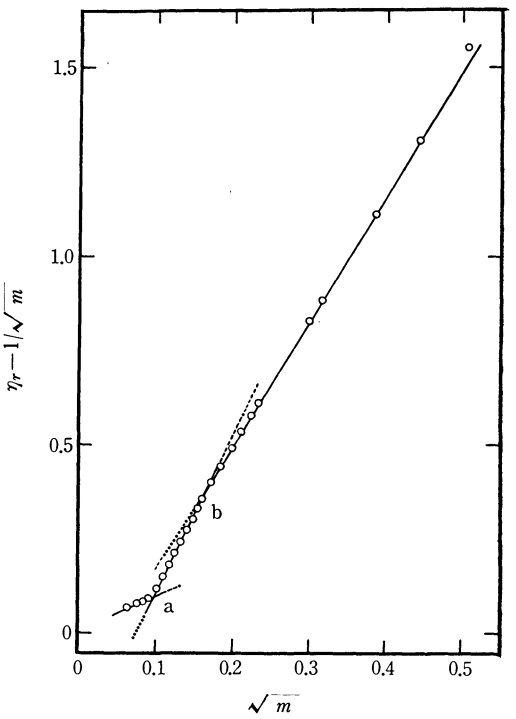

Fig. 5. Behaviour in viscosity of aqueous SDS solution observed by Jones and Dole's equation.

mol/l (40°C). This concentration nearly corresponds to that of the point b in the curve. On the basis of these results, it can be assumed that the structure of the SDS micelle is variable at the point b in Fig. 5.

ζ-Potential of Fibers in Aqueous SDS Solutions. *ζ-Potential below the CMC.* The ζ-potential was measured over the SDS concentration range $(0—30)\times10^{-3}$ mol/l in the presence of 10^{-4} mol/l sodium chloride, and every hour on the hour. The results obtained are shown in Fig. 6. These are the equilibrium values which were approximated after four hours of immersion.

The ζ-potential for the Nylon 6 fiber is negative and rapidly increases with an increase in the SDS concentration. This fact suggests that, in spite of the negative charge of Nylon 6 in an aqueous solution, the amount of SDS adsorbed on the surface of the fiber rapidly increases with an increase in the agent concentration. It can also be suggested that the Nylon 6 fiber combines mainly with SDS by means of van der Waals' force, as has been described in a previous paper.[18b]

The ζ *vs.* SDS concentration curve for the Pylen fiber resembles that for Nylon 6 very closely in its behavior, but the negative ζ values for the former are larger than those for the latter over the concentration range studied. This fact suggests that surface-surfactant adsorption for the Pylen fiber is appreciably larger than that for the Nylon 6 fiber.[18b]

37) M. Abu-Hamdiyyah, *J. Phys. Chem.*, **69**, 2720 (1965).
38) M. Nakagaki and Y. Ninomiya, This Bulletin, **37**, 817 (1964).

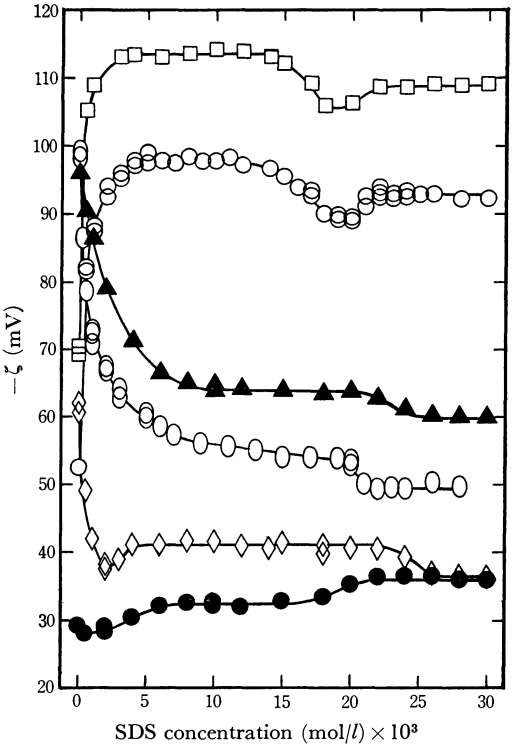

Fig. 6. ζ-potentials for fibers with SDS concentration.
(□) Pylen; (○) Nylon 6; (▲) Cashimilon; (0) glass; (◇) Vinylon; (●) cotton

On the other hand, the ζ-potentials for the glass and Cashimilon rapidly decrease with an increase in the SDS concentration. It can be suggested that the decrease in ζ values with an increase in the concentration may be due to a decrease in the thickness of the double layer, because the total ionic strength in solutions increases with an increase in the concentration. Furthermore, it may be due to a small adsorption of SDS on the surfaces of these samples, because of the large electrostatic repulsion between the surfaces of fibers and SDS anions.

A similar behavior for the ζ *vs.* SDS concen tration curve of Vinylon is also observed, except that this curve passes through a minimum at the 2×10^{-3} mol/*l* concentration. It is not at all clear why the ζ-potential of Vinylon shows its minimum at this concentration.

The negative ζ-potential for cotton increases from about 29 mV at the SDS concentration of zero to about 32 mV at the CMC. This change in the ζ-potential is small; therefore, it can be presumed that the surface-surfactant adsorption for cotton is small, in spite of the small electrostatic repulsion between the surfaces of the fiber and the SDS anions.

ζ-Potential in the Vicinity of the CMC. The ζ-potentials of all the fibers investigated remain nearly constant in the vicinity of the CMC. This constancy is also kept to some distance above the CMC. On the basis of these results, it can be presumed that the surface adsorption of SDS on fibers remains nearly constant in this concentration range.

Relationship between the Change in ζ-Potentials of Fibers and That in the Structure of the SDS Micelle. As the solution becomes more concentrated, the ζ-potentials for fibers change again; thereafter, after a minimum or a break, they again remain constant. It is rather interesting that the ranges of SDS concentration in which the apparent changes of the ζ-potentials of fibers are observed correspond approximately to the concentration for the break in curve III in Fig. 3, to that for the break in the curve in Fig. 4, and to that for the point b in Fig. 5.

From these facts, it can be presumed that, if the structure of the micelle changed at the concentration for the break in the η_{spm}/c_m *vs.* c_m curve, as has been mentioned above, there would be a change in the structure of the diffuse double layer and that, consequently, the ζ-potentials of the fibers would change.

In more concentrated solutions, the degree of ionization of the micelle must be more decreased and the stability thereby enhanced.[31] As is shown by the viscosity data (*cf.* Table 2 and Figs. 3—5), the micellar properties remain constant over a relatively wide range of concentrations, indicating that the size and the shape of micelle remain approximately constant.[32,33] Consequently, the structure of the double layer should again be kept stable. It is, therefore, understandable that the ζ-potentials for fibers are again kept constant in much higher concentration ranges, that is, in $(22—30)\times10^{-3}$ mol/*l* for Pylen, Nylon 6, and cotton, in $(25—30)\times10^{-3}$ mol/*l* for Cashimilon and Vinylon, and in $(21—28)\times10^{-3}$ mol/*l* for glass.

Studies of Photochemical Reactions Using Organic Photosensitizers. I. Benzene-Photosensitized Decomposition of Nitrous Oxide

Shigeru YAMASHITA, Kin-ichi ADACHI and Teruo HAYAKAWA

Department of Chemistry, Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Mozu-umemachi, Sakai, Osaka

(Received January 12, 1970)

Benzene-photosensitized decomposition of nitrous oxide has been studied in a mercury-free reaction system. 2537 Å line of low-pressure mercury lamp was absorbed by benzene and the excitation energy of benzene was transferred to nitrous oxide by triplet-triplet energy transfer mechanism. Only N–O bond rupture of nitrous oxide has been observed, which is reasonable from energetic view point. The decomposition yield of the excited triplet state of nitrous oxide was estimated to be 15% and the triplet state seems to be less than 84 kcal/mol above the ground state.

In recent years a large number of works on photochemical reactions using organic photosensitizers have been reported. Most of the work, however, has been carried out on the reactions of organic compounds in liquid phase. Since the pioneer work of Dubois and Noyes[1] only a few studies have been reported about gas phase photochemical reactions involving chemical bond splitting caused by organic photosensitizers,[2,3] although a number of gas phase photochemical reactions have been studied by mercury-photosensitization and a review of these studies has been presented.[4]

It is easy to choose organic sensitizers of various triplet state energies. However, only a few sensitizers such as Hg and Cd are available as inorganic photosensitizers. Hammond *et al.* studied the energy dependecne of *cis-trans* isomerization reactions of olefins using various organic photosensitizers.[5]

In the present work, the photochemical decomposition of nitrous oxide was studied using benzene vapor as a sensitizer. Benzene is one of the most well-studied photosensitizer in photochemical reactions,[1,6,7] and the lowest triplet energy level is known to be 84 kcal/mol.[8]

Bond energies of nitrous oxide have been studied by electron impact method[9,10] and the linear structure of nitrous oxide has been given by infrared spectroscopy.[11]

Although nitrous oxide is a simple triatomic molecule, the cross section of nitrous oxide in quenching of the excited mercury atom (Hg 6^3P_1) is relatively high compared with other simple molecules.[4] Nitrous oxide was used as a quencher competing with ketene in the mercury-photosensitized reaction for the determination of the quenching cross section of ketene.[12]

From the study of thermal decomposition of nitrous oxide, N–O bond splitting seems to occur through a triplet state about 60 kcal/mol[13,14] above the ground state.

Since the absorption band of nitrous oxide lies in vacuum-ultraviolet region,[15,16] photosensitized decomposition of nitrous oxide would be observed by some organic sensitizers as well as by excited mercury atoms[17,18] if the excited triplet state of the organic sensitizers is higher than 60 kcal/mol.

Experimental

For the study of benzene-photosensitized reaction, 2537 Å line of Toshiba FI-3S type low-pressure mercury lamp was used. The contribution from 1849 Å line was removed by Toshiba UVD-25 filter. In order to exclude the contribution from mercury-photosensitized decomposition of nitrous oxide, the reaction was carried out in a newly constructed, completely mercury-free reaction system and the pressure of the reaction system was measured by all-glass Bourdon pressure gauge. The reactor is a cylindrical quartz tube, 4 cm in diameter and 10 cm in length, and connected to the analyzing system. The reaction products were fractionated by cold traps and analyzed by Hitachi gas chromatograph Model K-53 and Hitachi RMU-5 mass spectrometer.

The sample of nitrous oxide used in the present work was 99.9% purity standard gas obtained from Takachiho Trading Co. The light intensity of the incident light into the reactor was measured by a ferrioxalate chemical actinometer.[19]

Results and Discussion

The decomposition of nitrous oxide was observed in the experiments of benzene-photosensitization of nitrous oxide. The reaction products which were not condensable in liquid nitrogen trap mainly consisted of nitrogen and carbon monoxide. The minor components in the noncondensable products were methane, hydrogen and sometimes a trace of oxygen.

Because of the difficulties in the identification of non-volatile species in the reaction products, material balance of the reaction was not measured.

Table 1 shows the N_2 and CO production under various benzene pressures for the same initial pressure of N_2O. The increase of N_2 formation with increase of the benzene pressure in the reaction system is seen in Fig. 1. This means that the amount of N_2 production corresponds to the number of photons absorbed by the sensitizer benzene.

Table 1. Benzene-photosensitized decomposition of nitrous oxide

Nitrous oxide pressure: 40.0 mmHg
Irradiation: 2537 Å, 60 min

C_6H_6 pressure (mmHg)	Product		N_2/CO	Quantum yield for N_2 formation
	N_2 (cc)	CO (cc)		
0	0.11×10^{-1}	—	—	—
5.2	0.44×10^{-1}	0.10×10^{-1}	4.4	2.60×10^{-2}
11.0	0.52×10^{-1}	0.10×10^{-1}	5.2	1.76×10^{-2}
13.0	0.62×10^{-1}	0.10×10^{-1}	6.2	1.75×10^{-2}
17.0	0.75×10^{-1}	0.15×10^{-1}	5.0	1.79×10^{-2}

34.0	1.20×10^{-1}	0.36×10^{-1}	3.3	1.99×10^{-2}
35.0	1.12×10^{-1}	0.32×10^{-1}	3.7	1.84×10^{-2}
38.5	1.50×10^{-1}	0.45×10^{-1}	3.3	2.81×10^{-2}

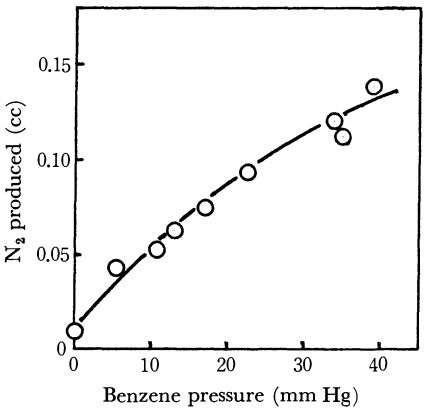

Fig. 1. The effect of benzene pressure on the amount of nitrogen formation.

Table 2 shows the N_2 and CO production with various N_2O initial pressure for the same benzene pressure. Here the apparent quantum yield presented in the table is the ratio of the mole number N_2 produced from N_2O to the number of photons absorbed by benzene.

The dissociation energies of N–N bond of nitrous oxide is 115 kcal/mol and N–O bond is 40 kcal/mol respectively,[9,10,20] and the excited triplet state energy of benzene is 84 kcal/mol.[8] It is quite reasonable, therefore, to expect that only N–O bond is split in the benzene-photosensitized decomposition of nitrous oxide. Nitric oxide was not produced and N_2 was the only nitrogen-containing product found in the reaction mixture after irradiation, which result is in agreement with the prediction of decomposition products of nitrous oxide.

While N_2 was produced by the decomposition of nitrous oxide in the present work, O_2 was not observed in almost any of the runs. Cvetanović observed that molecular oxygen was not formed when hydrocarbon was present in the reaction system of mercury-photosensitized decomposition of nitrous oxide.[17] It seems reasonable to suppose that oxygen atom, which was produced by N–O bond splitting in the benzene-photosensitized reaction of nitrous oxide, reacts rapidly with benzene before O_2 is formed by the recombination of oxygen atoms.[21] Carbon monoxide seems to be formed by the reaction of the oxygen atom from N_2O with benzene sensitizer. As seen in Tables 1 and 2, the ratio N_2/CO is larger than the stoichiometric value

20) V. I. Vedeneyev, L. V. Gurvich, V. N. Kondratyev, V. A. Medvedev and Ye. L. Frankevich, "Bond Energies, Ionization Potentials and Electron Affinities (English edition)," St. Martin's Press, New York (1966).

21) G. Boocock and R. J. Cvetanović, *Can. J. Chem.*, **39**, 2436 (1961).

1/1. This means that some of the oxygen atoms from N_2O molecules must have been missed in the analysis of the reaction products because of some non-volatile oxygen-containing products formed by the reaction of the oxygen atoms with benzene.[21]

The reaction scheme of the benzene-photosensitized decomposition of nitrous oxide may be presented as follows:

$$C_6H_6 + h\nu\ (2537\ \text{Å}) \longrightarrow C_6H_6^* \quad (1)$$

$$C_6H_6^* \longrightarrow C_6H_6 + h\nu' \quad (2)$$

$$C_6H_6^* \longrightarrow C_6H_6^{**} \quad (3)$$

$$C_6H_6^* + C_6H_6 \longrightarrow 2C_6H_6 \quad (4)$$

$$C_6H_6^{**} \longrightarrow C_6H_6 \quad (5)$$

$$C_6H_6^{**} + C_6H_6 \longrightarrow 2C_6H_6 \quad (6)$$

$$C_6H_6^{**} + N_2O \longrightarrow N_2O^{**} + C_6H_6 \quad (7)$$

$$N_2O^{**} \longrightarrow N_2 + O(^3P) \quad (8a)$$

$$N_2O^{**} \longrightarrow N_2O \quad (8b)$$

* and ** denote the excited state of molecule in singlet and triplet state, respectively. It is assumed that the reaction between the excited benzene and the reactant nitrous oxide can be neglected as in the case of previous workers.[1,2,6,7] The decomposition yield of nitrous oxide in the triplet state N_2O^{**} produced by the energy-transfer process (7) is expressed by $[k_{8a}/(k_{8a}+k_{8b})](N_2O^{**})$. When $k_{8a}/(k_{8a}+k_{8b})$ is replaced by n_t, the rate of N_2 formation is expressed as follows:

$$\begin{aligned} d(N_2)/dt &= n_t \cdot d(N_2O^{**})/dt \\ &= n_t k_7 (C_6H_6^{**})(N_2O) \\ &= \frac{n_t k_7 k_3 I(C_6H_6)(N_2O)}{(k_5+k_6(C_6H_6)+k_7(N_2O))(k_2+k_3+k_4(C_6H_6))} \end{aligned}$$

where, $I(C_6H_6)$ is the number of photons absorbed by benzene per unit time and k is the appropriate individual rate constant. Since the apparent quantum yield for N_2 formation Φ_t is expressed by $d(N_2)/dt \,/\, I(C_6H_6)$, we obtain

$$\begin{aligned} \frac{1}{\Phi_t} &= \frac{1}{[d(N_2)/dt]/I(C_6H_6)} \\ &= \frac{1}{n_t}\left(1+\frac{k_2+k_4(C_6H_6)}{k_3}\right)\left(1+\frac{k_5+k_6(C_6H_6)}{k_7(N_2O)}\right) \end{aligned}$$

According to the results of the previous workers,

$$k_2/k_3 = 1/4^{7,22,23)}$$

$$k_2 + k_3 = 1.7\times10^6/\text{sec}^{24)}$$

and

$$k_4 = 4.6\times10^{-13}\ \text{cm}^3/\text{molecule sec}^{7)}$$

Table 2. Benzene-photosensitized decomposition of nitrous oxide

Benzene pressure: 35.0 mmHg

Irradiation: 2537 Å, 60 min

N_2O Pressure (mmHg)	Product N_2 (cc)	Product CO (cc)	N_2/CO	Quantum yield for N_2 formation
14.0	0.22×10^{-1}	—		0.36×10^{-2}
22.0	0.40×10^{-1}	0.08×10^{-1}	4.3	0.65×10^{-2}
25.0	0.64×10^{-1}	0.13×10^{-1}	4.9	1.05×10^{-2}
29.0	0.81×10^{-1}	0.21×10^{-1}	3.9	1.33×10^{-2}
35.0	0.91×10^{-1}	0.18×10^{-1}	5.0	1.47×10^{-2}
44.0	1.12×10^{-1}	0.32×10^{-1}	3.5	1.84×10^{-2}
53.0	1.47×10^{-1}	0.38×10^{-1}	3.9	2.41×10^{-2}
55.0	1.20×10^{-1}	0.36×10^{-1}	3.3	1.99×10^{-2}
65.0	1.57×10^{-1}	0.43×10^{-1}	4.3	2.57×10^{-2}

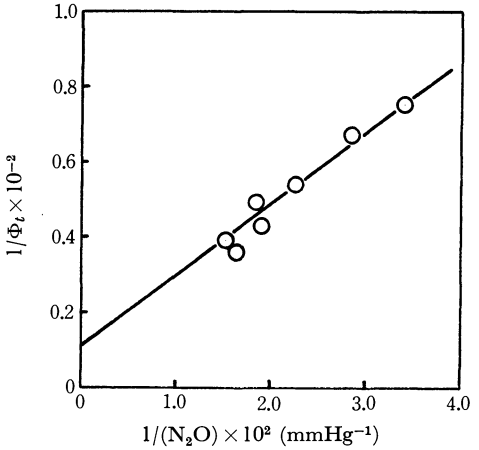

Fig. 2. Linear relation between $1/(N_2O)$ and reciprocal of apparent quantum yield for N_2 formation.

In the present work sensitizer benzene pressure was kept constant at 35.0 mmHg in every run listed in Table 2, thus

$$\frac{1}{\Phi_t} = \frac{c}{n_t}\left(1+\frac{k_5+k_6(C_6H_6)}{k_7(N_2O)}\right)$$

where the constant c denotes $\left(1+\frac{k_2+k_4(C_6H_6)}{k_3}\right)$ which was calculated using the numerical values of k_2, k_3, k_4 and (C_6H_6) mentioned above. The above equation shows the linear relation between $1/\Phi_t$ and $1/(N_2O)$. This is shown in Fig. 2 obtained from the experimental results in Table 2. From the intercept in Fig. 2, we obtain

$$c/n_t = 1.1\times10^1$$

Since the constant c is calculated to be 1.67, $n_t = k_{8a}/(k_{8a}+k_{8b})$ is evaluated to be

$$n_t = 0.15$$

We might propose that the decomposition yield of N_2O^{**} is 15%, since the material balance was not

obtained from the analysis of the reaction products as mentioned before.

Since the excited singlet state of nitrous oxide lies in a vacuum-ultraviolet region shorter than 2537 Å, which is the wavelength of the light source for exciting benzene sensitizer in the present work, the energy transfer process (7) seems to be exclusive for exciting nitrous oxide under the present experimental conditions.

It has been pointed out that, in mercury-photosensitized reactions of the reactant molecule species having large quenching cross sections to excited mercury atoms, triplet-triplet energy transfer process is preferable to the direct attack mechanism.[25] Nitrous oxide has a large quenching cross section compared with other simple inorganic compounds and saturated hydrocarbons.[4,26] Considering the similarity of benzene-photosensitization with mercury-photosensitization, energy transfer process (7) for N_2O excitation is more plausible than the direct attack of excited benzene molecule on the nitrous oxide molecule.

Since N–O bond splitting has been observed by the benzene-photosensitized reaction of nitrous oxide in the present work, the excited triplet state of nitrous oxide in process (7) should be located less than 84 kcal/mol above the ground state, which is consistent with the results obtained in the thermal decomposition studies of nitrous oxide by previous workers[13,14] and also with those of the biacetyl-photosensitized reaction of nitrous oxide in which N_2 formation was observed by the present authors.[27] For more elaborate discussions about the triplet excited state of nitrous oxide assumed in the present work, however, reliable experimental evidence such as emission studies would be necessary.

Magnetic Circular Dichroism of Iron Tetraphenylporphins

Hiroshi KOBAYASHI, Masayuki SHIMIZU and Ichiro FUJITA

Department of Chemistry, Tokyo Institute of Technology Ookayama, Meguro-ku, Tokyo

(Received January 12, 1970)

The magnetic circular dichroism of iron tetraphenylporphins was measured. Since the ground state of the open-shell iron porphin is degenerate and several charge-transfer excited states exist near the ^1Q and ^1B states, the A term as well as the B and C terms are very important for describing the MCD of the iron porphin, whereas the MCD at the ^1Q and ^1B bands, which arise from the pure degenerate (π,π^*) excitations in D_{4h} porphin assumed for zinc tetraphenylporphin, is ascribed to the A term. The MCD of carboxyhemoglobin, oxyhemoglobin and also deoxyhemologin was observed and compared with that of the synthesized iron porphins.

Iron porphyrin plays an essential rôle in the biological processes of hemoprotein. Current interest leans to the studies of biological processes by means of physical measurement and theoretical calculations based on molecular physics. Magnetic optical rotatory dispersion (MORD) and magnetic circular dichroism (MCD) measurements are physical techniques recently developed to obtain information on the electronic behavior in a molecule.[1] MORD measurements of myoglobin,[2] hemoglobin[3] and cytochromes,[4] which are hemoproteins

containing Fe(II)- or Fe(III)porphyrins, have been carried. Schooley *et al.* also reported the MCD measurements of some biologically important molecules including oxyhemoglobin, cytochrome-*c* and chlorophylls.[5]

In a magnetic field parallel to the incident light beam, the complex refractive indices of a substance for left- and right- handed circularly polarized lights, $\hat{n}_l$ and $\hat{n}_r$, respectively, are generally different because of the Zeeman splitting of the levels of orbital angular motion. The complex refractive index is given by $\hat{n}=n-ik$, where n is refractive index and k is absorption coefficient. Magnetic optical rotation arises from a magnetically induced deviation of the refractive indices for left- and right-handed circularly polarized lights, (n_l-n_r). In the region of optical absorption, a deviation in the absorption coefficients for left- and right- handed circularly polarized lights, (k_l-k_r) is observed in a magnetic field. Magnetic circular dichroism is ascribed to the difference between k_l and k_r induced by a magnetic field.

A theoretical study of the MORD observed in the region of the (π, π^*) transitions of porphyrins and phthalocyanines, first measured by Shashoua,[6] has been carried out by Stephens *et al.*[7] Since the electronic excitations corresponding to the absorption bands of iron porphyrin, however, should be interpreted in terms of a configuration-interaction admixture of the charge transfer excitations and the (π, π^*) transitions, a treatment such as employed by Stephens *et al.* can not be applied to the analysis of the MORD and the MCD of the iron porphyrins. The measurements of the MCD of the iron porphyrins have been required for further theoretical analysis of the electronic structure. In this paper, we should like to present the result of the MCD measurements of the iron tetraphenylporphins recently synthesized in this laboratory.[8]

Experimental

Materials. The free base of tetraphenylporphin (abbreviated to TPP) and Zn(II) tetraphenylporphin (TPPZn) were prepared and purified by the method given in the literature.[9] Iron tetraphenylporphins have been synthesized in this laboratory. The synthesis will be given elsewhere.[8] Samples of TPPFe(III)Cl, TPPFe(III)OCH_3, TPPFe(II)2Py, TPPFe(II)·2THF and TPPFe(II) identified by elemental analysis were used without further purification. In the formula, Py denotes the coordinating pyridine and THF the coordinating tetrahydrofuran.

Horse hemoglobin also was prepared and purified by the method in the literature.[10] Deoxyhemoglobin was prepared by adding a small amount of sodium dithionite to the buffer solution (pH 6) of freshly prepared hemoglobin. Carboxyhemoglobin was prepared by bubbling carbon monoxide into the solution of hemoglobin until the intensity of the characteristic absorption of the carboxyhemoglobin attained the highest value. The observed absorption spectra of the deoxyhemoglobin and the carboxyhemoglobin were in good agreement with those given in the literature.[10]

Preparation of the Solutions for Measurement. As solvents, tetrahydrofuran (THF) was used for TPP and TPPZn(II), benzene for TPPFe(III)Cl and TPPFe(III)OCH_3, and buffer solution (pH 6) for hemoglobins. Since ferrous tetraphenylporphins are readily autoxidized in the presence of oxygen and/or moisture in the air, the solution was prepared under inert atmosphere in a vacuum system using the solvents previously dried, distilled and degassed. The solution was transferred into a branch joined to an optical cell and the branch was then sealed off. As solvents, pyridine free from oxygen and moisture was used for TPPFe(II)·2Py, tetrahydrofuran for TPPFe(II)·2THF and benzene for TPPFe(II).

The concentration of the porphyrin in the solutions was adjusted to 10^{-4} mol/*l* for the measurement in the visible region and to 10^{-5} mol/*l* for the measurement in the near ultraviolet region.

Measurements. In a preliminary stage of this work, a permanent magnet with an 8 mm axial hole and a 13 mm pole gap was placed in the sample compartment of a JASCO automatic recording spectropolarimeter model ORD/UV-5. The external magnetic field was 3600 gauss. After a preliminary study, the light path of the spectropolarimeter was drastically modified and an electromagnet with a 15 mm pole gap was placed in the sample compartment of the spectropolarimeter. The electromagnet gave a magnetic field up to 12000 gauss. For the present work, the external magnetic field was set as 10000 gauss. When the current in the electromagnet was reversed, the reading of the out-put was completely reversed in sign over the whole range of wavenumber. A deviation between two symmetrical curves obtained for the reversed currents in the magnet, as shown in Fig. 6, gave an effective signal corresponding to one that could be obtained in a magnetic field of 20000 gauss. This technique was used for determination of the magnetic circular dichroism (MCD). The MCD of a solution was actually measured in optical density units by a deviation from the base line obtained by the first running with a pure solvent. The magnitude of MCD was given in molar ellipticity per unit external

magnetic field $[\theta]_M$.[7,11] The molar ellipticity is given by the molar circular dichroism $(\varepsilon_l - \varepsilon_r)_M$ measured in a cell with 1 cm light path in a magnetic field of 10000 gauss as follows.

$$[\theta]_M = 3300\,(\varepsilon_l - \varepsilon_r)_M/10000$$

In the case of hemoglobin, even in the non-magnetic condition, it shows a circular dichroism which is ascribed to its helical structures in the counterpart of the iron porphyrin. The MCD of hemoglobin was derived from the difference between the circular dichroisms observed in the magnetic and non-magnetic conditions assuming an additivity between CD and MCD.

Results and Discussion

The structure of the coordination spheres in TPPFe(II)·2Py and TPPFe(II)·2THF is a distorted octahedron, while that of TPPFe(III)OCH_3 and TPPFe(III)Cl is a square pyramid, where the central iron might be slightly out of the porphin plane.[12,13] The structure of the coordination sphere in deoxyhemoglobin is a square pyramid[14] and that of carboxyhemoglobin is a distorted octahedron. The structure of TPPFe(II), TPP-Zn(II) and also TPP is almost planar, as shown in Fig. 1. This particular porphin has much less tendency to aggregate in solution because of the four phenyl groups perpendicular to the porphin plane.[12,15,16,] Table 1 summarizes the spin states of the iron complexes of TPP and the hemoglobins. The magnetic susceptibility measurements of the iron tetraphenylporphins have been carried out at room temperature by the Gouy method. Ferrous tetraphenylporphins were unstable in the air, so the MCD, absorption spectra and the magnetic moments were measured *in vacuo* without exposing the sample to the air.

Table 1.

	μ_{eff} (Bohr magneton)	S
TPP Fe(III) Cl	5.88	5/2
TPP Fe(III) OCH_3	1.84	1/2
TPP Fe(II)·2Py	0	0
TPP Fe(II)·2THF	2.75	1
TPP Fe(II)	4.75	2

	S
Carboxyhemoglobin	0
Oxyhemoglobin	0
Deoxyhemoglobin	2

The MCD and absorption spectra are shown in Figs. 2—6. Though TPPFe(II)·2THF and TPP-Fe(II) were of considerable interest from the electronic structure point of view, the observed MCD both in the visible and near ultraviolet regions was so low that no reliable value could be obtained in a magnetic field up to 10000 gauss. However, the magnitude of the MCD of TPPFe(II)·2Py was fairly large.

The magnitude of magnetic molar circular dichroism observed at a transition $a \rightarrow j$ is given[1,7,11] by

$$[\theta]_M = -\frac{24N}{\hbar c}\{f_1 A + f_2(B + C/rT)\} \quad (1)$$

where

$$A = \frac{3}{d_a}\sum[\langle j|\hat{\mu}_z|j\rangle - \langle a|\hat{\mu}_z|a\rangle]\cdot Im[\langle a|\hat{m}_x|j\rangle\langle j|\hat{m}_y|a\rangle] \quad (2)$$

MCD spectra are given for a normal magnetic field (———) and a reversed magnetic field (·····). The sense of the normal magnetic field was set to that of the light beam propagation.

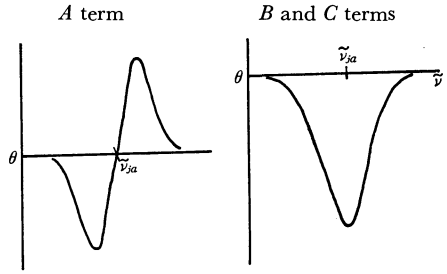

Fig. 7. The band shapes of MCD and absorption spectra.

$$B=-\frac{3}{d_a}\sum I_m\left\{\sum_{k\neq a}\frac{\langle k|\hat{\mu}_z|a\rangle}{W_k-W_a}\left[\langle a|\hat{m}_x|j\rangle\langle j|\hat{m}_y|k\rangle-\langle a|\hat{m}_y|j\rangle\langle j|\hat{m}_x|k\rangle\right]+\sum_{k\neq j}\frac{\langle j|\hat{\mu}_z|k\rangle}{W_k-W_j}\left[\langle a|\hat{m}_x|j\rangle\langle k|\hat{m}_y|a\rangle-\langle a|\hat{m}_y|j\rangle\langle k|\hat{m}_x|a\rangle\right]\right\} \quad (3)$$

$$C=-\frac{3}{d_a}\sum\langle a|\hat{\mu}_z|a\rangle I_m[\langle a|\hat{m}_x|j\rangle\langle j|\hat{m}_y|a\rangle] \quad (4)$$

W_a, W_k and W_j are the energy of the respective states, d_a is the degeneracy of the state a, and $\hat{m}$ and $\hat{\mu}$ are the electric and magnetic dipole operators, respectively.

f_1 is a function which shows a dispersion at the absorption maximum, while f_2 is a function which shows a maximum or a minimum at the absorption maximum. If term A is predominant, $[\theta]_M$ shows an anomalous dispersion at the absorption maximum, while if term B or C is predominant, $[\theta]_M$ shows an extreme value as shown in Fig. 7. Term A depends upon the absorption intensity and also the difference of angular momenta between the ground state and the excited state involved in the absorption. If the ground state is not degenerate, term A depends on the angular momentum only of the excited state. Term C depends upon the angular momentum of the ground state. Term B is ascribed to the angular momenta induced by the external magnetic field. As seen in Fig. 5 the MCD spectrum of TPPZn(II) is predominantly described by term A. As has been shown by the molecular orbital calculations,[17] the lowest (π,π^*) excited state (^1Q state) of porphin is of E_u symmetry and has an angular momentum of ± 9 in the sense of a circular box model, while the second one (^1B state) which gives rise to the Soret band, is also of E_u symmetry and has an angular momentum of ± 1. While in the case of the metal free base, the degenerate excited states of D_{4h} porphin assumed for the metalloporphins such as TPPZn(II) are split by the localization of the central two protons to the nitrogen atoms at opposite positions.[16,18] The splitting of the lowest degenerate transition in the visible region is fairly large, while that of the second one in the near-ultraviolet is usually too small to be observed. Therefore, as seen in Fig. 6 the MCD spectrum in the visible region of the metal free base should show a contribution of term B, mainly arises from the magnetically induced mixing between the split components of the degenerate excited states. The MCD observed in the near-ultraviolet region can be ascribed to term A. The ground state of TPPZn(II) and also of the metal free base can be described by a closed shell configuration, term C being vanished.

In the case of ferric porphin, the absorption spectra in the visible- and near-ultraviolet region can not be described in terms of (π,π^*) transitions, because of appreciable configuration mixings due to the charge-transfer excited states of exactly the same symmetry, E_u. The charge-transfer excited state arises from the charge-transfer from one of the top filled π molecular orbitals of porphin to one of the vacant degenerate $d\pi$ orbitals. There seem to be several excited states in the visible- and near-ultraviolet region other than the ^1Q and ^1B states which are ascribed to the (π,π^*) excitations. Thus the contribution of term B due to the magnetically induced mixings between the closely existing states is expected for the MCD of these complexes. Furthermore TPPFe(III)OCH_3 is expected to have an

18) J. Weigl, *J. Mol. Spectrosc.*, **1**, 133 (1957); B. G. Anex and R. S. Umans, *J. Amer. Chem. Soc.*, **86**, 5026 (1964).

angular momentum due to the orbital motion of a hole in the $d\pi$ orbitals in the ground state, while TPPFe(III)Cl lacks such an angular momentum. Although further experimental work under various temperatures is required to see how it depends on each of terms B and C, the MCD observed for the high-spin TPPFe(III)Cl and the low-spin TPP-Fe(III)OCH_3, as shown in Figs. 2 and 3, can be ascribed to a contribution of the terms B, C as well as A.

In the case of diamagnetic ferrous porphin, TPP-Fe(II)·2Py, the absorption spectrum in the visible- and near-ultraviolet region was very close to that of TPPZn(II). However, the MCD were quite different. A predominant contribution of term B to the MCD was observed at the Soret band and also at the 21000 cm^{-1} band. The latter can be assigned to a charge-transfer transition of a $d\pi$ electron of the iron to a vacant pyridine molecular orbital, since the piperidine adduct of TPPFe(II) does not show the 21000 cm^{-1} band.[8] Similarly near the Soret band there exist charge-transfer excited states which produce a hole in the closed $d\pi$ orbitals. These charge-transfer excited states are mixed to the Soret band by the external magnetic field. In oxyhemoglobin and carboxyhemoglobin, the iron porphyrin exists in a diamagnetic state. Their MCD and absorption spectra are given in Figs. 8 and 9. The absorption intensity of the iron porphyrin in these proteins was slightly weaker than that of TPPFe(II)·2Py, while the MCD of the iron

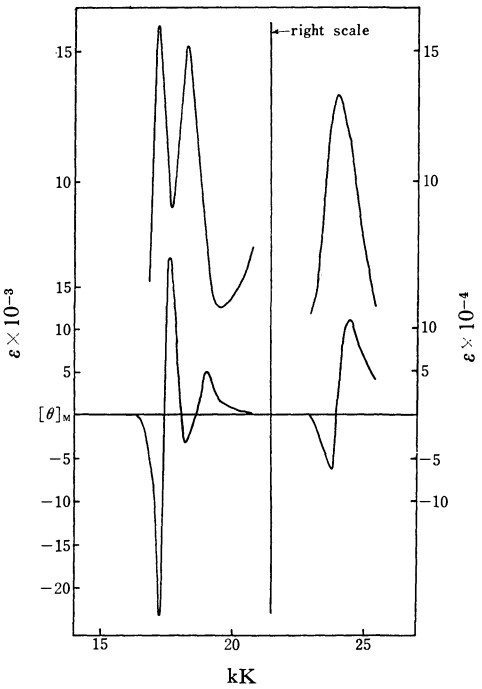

Fig. 9. MCD and absorption spectra of oxy-hemoglobin.

- - - -: MCD observed in a normal magnetic field (The sense of the magnetic field is that of the light beam propagation).
·····: MCD observed in a reversed magnetic field.

porphyrin in these proteins was much stronger. In these naturally occurring proteins, there exists a circular dichroism due to the helical structure of the counterpart of the iron porphyrin. Assuming an additivity between MCD and CD, the difference between observed CD values for the magnetic and non-magnetic conditions was assigned to the MCD of these proteins. The iron(II) porphyrin in these proteins seems to be quite free from the contribution of term *B* to the MCD at the Soret band. This indicates the charge-transfer excited states, which show an angular momentum due to a hole produced in the closed $d\pi$ shell, are fairly higher than that of TPPFe(II)·2Py.

The MCD and absorption spectra of deoxyhemoglobin are shown in Figs. 10 and 11. When the current in the electromagnet was reversed, the deviation between the circular dichroisms in the near-ultraviolet region for the magnetic and non-magnetic conditions was not symmetrically reversed in this particular case (Fig. 11). There might be a non-linear interaction between MCD and CD. The MCD of deoxyhemoglobin remarkably shows a contribution of terms *B* and *C*.

The authors wish to thank Dr. T. Samejima, Aoyama Gakuin University for kindly permitting them to use his instrument at a preliminary stage of this work. One of the authors (H.K.) is grateful to Professor S. Nagakura, The University of Tokyo for his interest in the work. Grateful acknowledgment is also made to Dr. M. Shigehisa of Japan Spectroscopic Co. Ltd. for helpful technical advice. This research was supported by a grant from the Ministry of Education.

Mössbauer Spectra of Iron Tetraphenylporphins

Hiroshi KOBAYASHI,* Yutaka MAEDA** and Yasuo YANAGAWA*

* *Department of Chemistry, Tokyo Institute of Technology Ookayama, Meguro-ku, Tokyo*
** *Research Reactor Institute, Kyoto University, Kumatori-cho, Osaka*

(Received January 23, 1970)

Mössbauer spectra were measured for a series of the central iron in Fe(II)- and Fe(III) complexes of tetraphenylporphin. The electronic structure of the central iron in the complex was modified by the axial ligand field. The Mössbauer spectra assigned the most probable electronic configurations to various iron states in the iron porphins.

Mössbauer spectroscopy provides valuable information on the electronic structure of iron complexes, complementary to those from the measurements of magnetic susceptibility and from paramagnetic resonance spectroscopy. Recently this technique has been applied to the study of some biologically important substances containing iron atom. Mössbauer effect has been observed with heme proteins such as hemoglobin, myoglobin, cytochromes, catalase, peroxidase and others.[1,2] However, a systematic investigation of the Mössbauer spectra has never been carried out with synthetic iron porphyrin complexes other than those obtained from the naturally occurring heme proteins.[3] Some studies have been performed on the adducts of nitrogeneous ligands and synthetic iron porphyrins.[4,5] Another study on the iron phthalocyanines has also been published.[6] Recently a series of the Fe(II)- and Fe(III) complexes of tetraphenylporphin (TPP) have been synthesized in our laboratory.[7] We present Mössbauer spectra observed for a series of the central iron in the tetraphenylporphin complexes.

Experimental

The Mössbauer spectra were obtained with a scanned velocity spectrometer operating in the time mode. The instrument consisting of an electromagnetic velocity transducer, a gamma-ray counting system and a Dewar has been described.[2] The radiation source was ^{57}Co diffused into metallic Pd. The absorber could be maintained at room temperature, dry ice acetone temperature (195°K) or liquid nitrogen temperature (77°K).

Since our radiation source was strong enough, it was not necessary to enrich ^{57}Fe for the measurements of Mössbauer spectra of our synthetic iron porphins. The measurements were carried out with the powder samples of TPPFe(III)Cl ($S=5/2$), TPPFe(III)OCH_3 ($S=1/2$), TPPFe(II) ($S=2$), TPPFe(II)·2THF ($S=1$) and TPPFe(II)·2Py ($S=0$), where THF denotes tetrahydrofuran and Py, pyridine. All samples had been synthesized in our laboratory and identified by elementary analysis. Their spin states determined by magnetic susceptibility measurements are given above in the brackets. The Fe(III) complexes were fairly stable even in the atmospheric circumstance, while the Fe(II) complexes were very sensitive to oxygen and moisture in the air. In a dried nitrogen atmosphere, the Fe(II) porphin was homogeneously packed and sealed in a planar capsule made of polyacrylic resin.

The velocity scale was calibrated absolutely from an independent Mössbauer run using a thin metallic iron absorber and the center of symmetry of the spectrum was taken as zero velocity. The velocity was determined to an accuracy of ± 0.06 mm/sec for the Fe(III) complexes, and ± 0.04 mm/sec for the Fe(II) complexes.

(S=1)	77	0.64	0.33
TPPFe(II)·2Py	300	1.22	0.36
(S=0)	77	1.15	0.41

Results and Discussion

The observed spectra are shown in Figs. 1—5. The isomer shift, δ, and the quadrupole splitting, ΔE_Q, obtained from the spectra are summarized in Table 1.

(1) Isomer Shift. The isomer shift arises from the electrostatic shift of nuclear levels by an interaction between the charge distribution at the nucleus of definite dimension and the electronic charge distribution surrounding the nucleus.[8,9] The isomer shift is decreased when the s electron density at the nucleus is increased or the s orbitals are contracted, which depends upon the number of non-bonding d electrons and the charge distributions of σ-and π coordination bonds.

For ionic complexes, ferrous ion $(3d)^6$ usually shows a larger shift than ferric ion $(3d)^5$. For covalent complexes, strong σ donation by the ligands gives rise to two competitive effects to the isomer shift. The σ donation enhances the charge density in $4s$ orbital and also in $3d$ orbitals and $4p$ orbitals. An increase in the charge density in $4s$ orbital decreases the isomer shift, whereas an increase in the charge densities in $3d$ and $4p$ orbitals gives rise to an expansion of inner s orbitals and therefore an increase in the isomer shift. Another factor to be considered is an effect due to the π electron delocalization between $d\pi$ orbitals and the π molecular orbitals of the ligand.

TPPFe(III)Cl (S=5/2) shows the lowest isomer shift. In the ferric porphins, the central iron behaves like a σ and π acceptor. Since the low spin iron in TPPFe(III)OCH_3 (S=1/2) is a much stronger electron acceptor than the iron in TPPFe(III)Cl, the increase of isomer shift observed for TPPFe(III)OCH_3 can be explained by a predominant contribution from the expansion of the inner s orbitals due to an enhancement of shielding by the donated electrons. For an adduct of TPPFe(III)Cl and imidazole, of which an effective moment of S=1/2 has been observed, the value of isomer shift is still very close to that of the high spin iron in TPPFe(III)Cl.[4] Similar phenomena have been observed for the Fe(III) hemoglobins in the low spin state and in the highest spin state.[1e] In these cases, both the two competitive effects seem to be of equivalent importance.

In the case of ferrous porphin, the central iron behaves like a σ acceptor but a π donor. The iron with intermediate spin shows the lowest isomer shift. The iron has relatively higher π donating power. If there exists a significant migration of $d\pi$ electron to the ligands, a decrease in the isomer is expected. However, the iron is coordinated by relatively weak axial ligands with no electron acceptable π molecular orbital. Some migration of the $d\pi$ electron into the porphin ring is possible. The low value of isomer shift may arise from a higher population in $4s$ orbital due to the σ donations by the axial ligands and by the porphin. The iron in the highest spin state (S=2) shows the highest value of isomer shift. The iron has no axial ligand. Since it is less σ-acceptable and less π-donating, its high value of

8) See for example, A. Abragam, "L'Effet Mössbauer," Gordon and Breach Science Publishers, New York (1964).

9) G. K. Wertheim, "Mössbauer Effect," Academic Press, New York (1964).

isomer shift may readily be expected.

The diamagnetic iron(II) porphin shows an intermediate value of isomer shift. The iron is a strong σ acceptor and π-donor. Although the strong σ donation by the axial ligands and the porphin should appreciably affect the isomer shift, the migration of $d\pi$ electron seems to take an important part in this particular case. The isomer shift, however, shows almost the same values for an adduct of TPPFe(II) and pyridine and that of piperidine.[4] Pyridine has electron acceptable π molecular orbitals, whereas piperidine lacks such orbitals. Therefore the $d\pi$ electron migration to the axial ligands does not seem to be of crucial importance for the isomer shift.

(2) Quadrupole Splitting. The second nonzero term of the electrostatic interaction of a nucleus with its surrounding electrons is the electric quadrupole interaction. For the nucleus ^{57}Fe, the nuclear spins of the ground state and the excited state are 1/2 and 3/2, respectively, and the Mössbauer spectrum shows two resonance peaks. The separation between these peaks, ΔE_Q, is given by

$$\Delta E_Q = (e^2Q/2)q(1 + \tfrac{1}{3}\eta^2)^{1/2} = (e^2Q/2)X \qquad (1)$$

where Q is the quadrupole moment of the nucleus; $eq=V_{zz}$, $\eta=(V_{xx}-V_{yy})/V_{zz}$ and V_{xx}, V_{yy} and V_{zz} are the principal components of an electric-field gradient due to the electronic distribution.[8,9] For metalloporphyrin, as has been done by Weissbluth and Maling,[10] q and $(q\eta)$ are given by

$$\begin{aligned} q &= (1-R)_d q_d + (1-R)_p q_p + (1-\gamma_\infty)q_l, \\ (q\eta) &= (1-R)_d(q\eta)_d + (1-R)_p(q\eta)_p + (1-\gamma_\infty)(q\eta)_l, \end{aligned} \qquad (2)$$

in which q_d and q_p are contributions to q from the electrons occupying $3d$ and $4p$ orbitals, respectively; $(q\eta)_p$ and $(q\eta)_p$ have analogous definitions; q_l and $(q\eta)_l$ are contributions from the ligands and $(1-R)$ and $(1-\gamma_\infty)$ are Sternheimer factors.

Weissbluth and Maling have estimated the contributions to q and $(q\eta)$ from $3d$ and $4p$ orbitals and also from the ligand orbitals based on the molecular orbital calculations by Zerner, Gouterman and Kobayashi.[11] According to their estimation, the quadurpole splitting in hemoglobins predominantly arises from a charge distribution of the electrons occupying $3d$ orbitals. Therefore q and $(q\eta)$ are approximately given in terms of the contributions from the electrons occupying the molecular orbitals with equal symmetry of $3d$ orbitals.

$$\begin{aligned} q &= \sum\langle V_{zz}/e\rangle = \langle 1/r^3\rangle\sum_i A_i f_i \\ (q\eta) &= \sum\langle (V_{xx}-V_{yy})/e\rangle = \langle 1/r^3\rangle\sum_i B_i f_i \\ A_i &= -\langle 3\cos^2\theta - 1\rangle_i \\ B_i &= -\langle 3\sin^2\theta\cos 2\varphi\rangle_i \end{aligned} \qquad (3)$$

where f_i is orbital occupation number; A_i and B_i are readily calculated from the angular part of d orbital[12] and $\langle 1/r^3\rangle$ is also calculated from the radial part of d orbital, however, it can be regarded as a parameter for the intercomparison. As has been shown for the spin-orbit coupling constant in the complexes, the value of the integral $\langle 1/r^3\rangle$ should be adjusted for the molecular orbital formation.[13]

For the ferrous low spin state $(xy)^2(yz)^2(zx)^2$ and the ferric high spin state $(xy)(yz)(zx)(z^2)(x^2-y^2)$, the electronic charge distributions are approximately of spherical symmetry and therefore there are no electric field gradients. However, other electronic configurations should show electric field gradients. The values of X in (1) which actually determine the magnitude of quadrupole splittings

are obtained for the most probable configurations in the iron porphyrins with various spin states. The results are summarized in Table 2. For the ferric low spin state and also the ferrous intermediate spin state, two alternative configurations are possible. If an anisotropy is introduced in the porphin plane by a Jahn-Teller distortion of bi-axial ligand fields, the anisotropic contribution of B term is expected. However, as Table 2 shows, the ratios between the observed quadrupole splittings and the values of X obtained from the isotropic contributions (underlined in Table 2) are fairly constant except for the diamagnetic ferrous porphin.

In TPPFe(II)·2THF, the iron is in the intermediate spin state. As was shown by electronic absorption spectroscopy,[7] the observed intermediate spin value is not ascribed to a mixture of the state $S=2$ and the state $S=0$ but a single state $S=1$. Mössbauer spectrum also shows a spectrum characteristic of the intermediate spin iron(II) complex, which is quite different from a spectrum expected for a mixture of the high spin porphin $S=2$ and the diamagnetic one $S=0$.

The diamagnetic ferrous complex, TPPFe(II)·2Py shows a relatively higher quadrupole splitting despite its closed shell structure. Similar values have been found for carboxyhemoglobin, oxyhemoglobin[1e] and nitrogeneous base adducts of iron-porphyrins and[3e,4,5] phthalocyanine, all of which are diamagnetic. The delocalization of $d\pi$ electron to the porphin ring and also to the axial ligands produces some vacancy in the $d\pi$ orbital of the central iron. If a hole is produced in each of the degenerate yz and zx orbitals or a hole is produced in either split yz or zx orbital, the value of X (underlined in Table 2) can explain the observed quadrupole splitting. There might be anisotropy due to the coplanarity of the axial two pyridines. If this is the case, the production of an effective hole in the $d\pi$ orbital is sufficient.

A linear relationship was found between the quadrupole splitting and the isomer shift in these particular iron porphins except for the low spin ferric and also diamagnetic ferrous porphin (Fig. 6). Because of higher $d\pi$ electron affinity of the former, some of π electron charge of porphin ring can migrate into the iron and annihilates the hole existing in yz and/or zx orbital, while in the diamagnetic ferrous one, the charge migration of $d\pi$ electron over whole complex becomes significant and produces some vacancy in the $d\pi$ orbital.

(3) Temperature Dependence. The existence

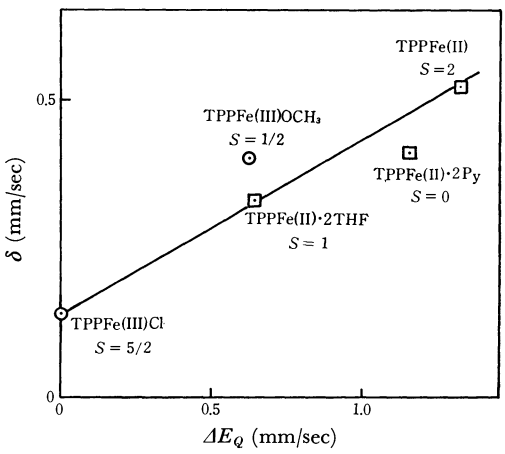

Fig. 6. The isomer shifts plotted *vs.* the quadrupole splittings.
The values were obtained at 77°K.

of low-lying excited states is theoretically and experimentally identified. Temperature dependence of Mössbauer spectrum arises from a population of higher sublevels. Remarkable temperature dependence of the spectrum had been observed for the high spin ferric porphins,[1,3] while relatively small temperature dependence was observed for the isomer shift of TPPFe(III)Cl. Asymmetric spectrum observed for TPPFe(III)OCH_3 showed a temperature dependence, which was however, less remarkable than that observed for other iron porphins of naturally occurring source. In the case of TPPFe(II), no remarkable quadrupole splitting was observed at room temperature, the splitting being observed at 77°K. Between two intense bands, there seems to exist some bands which might be assigned to the lower sublevels, although a possible contamination of the impurity formed by partial oxidation can not be eliminated.

Generally speaking, an increase in the isomer shift seems to be parallel to an increase in the quadrupole splitting observed at low temperature. An increase in the isomer shift of TPPFe(II)·2Py is observed at low temperature, while the quadrupole splitting is decreased. Similar phenomena have been observed for the diamagnetic hemoglobins[1e] and bis(pyridine)phthalocyanine iron(II).[5]

The Crystal Structure of Bis-(2-hydroxyacetophenone)-trimethylenediiminocopper(II)

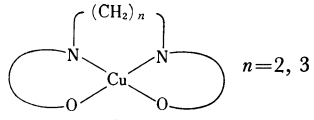
Kiyoto IIDA, Isao OONISHI, Akitsugu NAKAHARA*1 and Yoshimichi KOMIYAMA*2

Department of Applied Chemistry, Faculty of Engineering, Yamanashi University, Kofu, Yamanashi

(Received January 21, 1970)

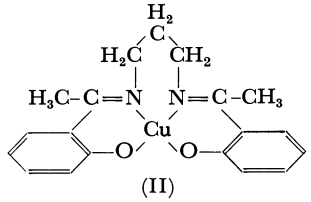
The crystal structure of bis-(2-hydroxyacetophenone)trimethylenediiminocopper(II), [Cu-(hapt)], has been determined on the basis of the X-ray diffraction data. The crystals are monoclinic. The cell dimensions are: $a=17.746$, $b=9.467$, $c=10.646$ Å, and $\beta=114.06°$. The space group is *Cc*, with four formula units in the unit cell. The structure has been refined from three-dimensional data by the least-squares method with anisotropic temperature factors to an *R*-value of 0.093. The copper atom is four-covalent, with the two planar 2-hydroxyacetophenone groups oriented so as to give a flattened tetrahedral co-ordination geometry. The six-membered copper-trimethylenediamine ring takes a "twisted boat" configuration. The Cu–O bonds are 1.88 and 1.89 Å in length, while the Cu–N bonds are 1.94 and 1.97 Å. The angle between the mean planes of the 2-hydroxyacetophenone moieties is 46.2°.

An extensive study has recently been made of the copper(II) complexes with tetradentate Schiff bases derived from several aldehydes or ketones and diamines by Nakahara and his collaborators.[1] These complexes possess three chelate rings, and their structures can be represented as follows:



(I)

An investigation of the relative stabilities of the complexes has revealed that those complexes which have a five-membered central chelate ring ($n=2$) are generally more stable than those with a six-membered central chelate ring ($n=3$). It seemed that it would be of interest to clarify this point by determining the structure of a complex with a six-membered central chelate ring. For this purpose crystals of bis-(2-hydroxyacetophenone)trimethylenediiminocopper(II) were chosen. The complex has a 6-6-6*3 fused chelate ring structure, (II). The molecular structures of the complexes with a 6-5-6 (*N,N'*-disalicylidene-ethylenediaminecopper) and a 6-7-6 (*N,N'*-(2,2'-biphenyl)bis(salicylaldiminato)copper(II)) fused chelate ring structure have already been determined by Waters and his collaborators.[2,3] The former has a pyramidal-square coordination, while the latter has a distorted flattened-tetrahedral coordination, around the copper atom.



(II)

[Cu(hapt)]

The crystal and molecular structure of the complex, [Cu(hapt)], will be reported in this paper.

Experimental

The crystals of [Cu(hapt)] were prepared according to the method described by Tsumaki *et al.*[4] They are dark green in color and very stable in the air. The unit-cell dimensions were determined from higher-order reflections recorded on Weissenberg photographs (Cu$K\alpha$, $\lambda=1.5418$ Å). The possible space group was found to be $C2/c$ or Cc from the following systematic absences: hkl when $h+k$ is odd and $h0l$ when l is odd. Cc was shown to be consistent with the structure.

The specimens with dimensions of $0.05\times0.20\times0.80$ mm were used for the collection of the intensity data around the *c*-axis. Equi-inclination Weissenberg photographs were taken around the *c*-axis up to the eighth

layer, while the zero layer photograph was taken around the b-axis with Cu$K\alpha$ radiation. A multiple film technique was used. Of the 1454 independent reflections within the effective copper sphere ($\sin\theta \leqq 0.98$), 1220 non-zero reflections were observed. The intensities were estimated visually with a standard film strip. The usual Lorentz, polarization, and spot-shape corrections were applied, but the absorption correction was neglected. The crystal data are shown in Table 1.

Structure Analysis

The positions of the copper atom and the four-coordinating atoms around the copper atom could be easily deduced from the three-dimensional Patterson maps. The structure factors were calculated from the parameter values of these atoms. The discrepancy factor, R (defined as $\sum||F_o|-|F_c||/\sum|F_o|$), was 0.32. Preliminary Fourier projections of the electron density upon (010) and (001) were then synthesized, using phases determined by the parameters of these five atoms. The approximate orientation of two 2-hydroxyacetophenone moieties could be deduced from these projections, but the trimethylenediamine ring could not be fixed. The atomic parameters of the trimethylenediamine ring were, therefore, assigned by constructing a scale model of the molecule. Considerable improvement was achieved in the agreement between the observed and calculated structure factors. The structure thus obtained was refined by the three-dimensional difference synthesis to $R=0.20$, and later by a block-diagonal least-squares method using a HBLS-4 program written by T. Ashida. After six cycles of this refinement, anisotropic temperature factors were introduced. The weighting scheme for the least-squares procedure was:

$$w=0.2, \quad \text{if } F_o \leqq F_{\min} \ (4.0)$$
$$w=1.0, \quad \text{if } F_{\min} < F_o < F_{\max} \ (25.0)$$
$$w=F_{\max}/F_o, \quad \text{if } F_o \geqq F_{\max}.$$

The effect of secondary extinction was corrected for five reflections which showed a marked extinction effect ($F_o > 45$). The final R-value became

0.093 for all the observed reflections. The atomic scattering factors were taken from the "International Tables for X-ray Crystallography".[5] The final atomic parameters and their estimated standard deviations are listed in Table 2. The observed and calculated structure factors are compared in Table 3.

Discussion

A perspective drawing of the [Cu(hapt)] molecule is shown in Fig. 1. The bond lengths and angles in the molecule are listed in Table 4, together with their e.s.d.'s, they are also shown in Fig. 2.

The bis-(2-hydroxyacetophenone)trimethylenediimine group is coordinated to the copper atom as a tetradentate ligand through two phenolic oxygen atoms and two nitrogen atoms of the Schiff-base linkage. The coordination around the copper atom is a distorted tetrahedron. The Cu–O distances are 1.88 and 1.89 Å, and the Cu–N distances are 1.94 and 1.97 Å. These values agree well with those found in the related complexes.[6–8] The angle between the two planes defined by Cu, O(1), and N (1) and by Cu, O(2), and N(2) is 34.4°, being equal neither to 90°, a value expected for a regular tetrahedral environment, nor to 0° for a square-planar configuration. The distorted tetrahedral configu-

rations are found in some *N*-substituted bis-salicylaldimine complexes of copper.[3,9-11] These authors claim that the substituent is sufficiently bulky to prevent the normal square-planar complex from being sterically feasible in the case of *N*-*t*-butyl[9] and *N*-isopropyl[10] complexes, and that the distortion in the *N*-ethyl[11] complex is due to packing forces in the crystal.[12] In the present compound, the two planar 2-hydroxyacetophenoneimine groups are joined by three methylene groups. Consequently, the central chelate ring is six-membered. The presence of this six-membered ring appears to give rise to the distortion of the square-planar coordination around the central copper atom. In fact, the related ethylenediamine analogue, *N*,*N*′-disalicylidene-ethylenediaminecopper,[2] exhibits a square-planar coordination. The conformation of the Cu(II)-trimethylenediamine ring is a twisted boat form, as is illustrated in Fig. 3. The six-membered chelate ring has approximately a twofold axis of rotation through the central copper atom and the central carbon atom C(10) of the ligand. The carbon atoms, C(9) and C(11), are 0.81 and 0.80 Å respectively apart from the plane defined by Cu, N(1), and N(2). It should be noted here that all the isolated metal-trimethylenediamine chelate rings

*4 The crystal structures of *trans*-$[Co(NO_2)_2(tn)_2]NO_2$ and *cis*-$[Co(NCS)_2(tn)_2]NCS$ were presented at the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1969.

to be planar.

The twofold symmetry of the fused central chelate ring is also observed in such related complexes as *N,N'*-disalicylidene-ethylenediaminecopper with a 6-5-6 fused chelate ring structure and *N,N'*-(2,2'-biphenyl)bis(salicylaldiminato)copper(II) with a 6-7-6 structure.[2,3] In Table 5, the shape and size of the central ring in the 6-*X*-6 fused chelate-ring structures are compared ($X=5$, 6, and 7). Obviously, the N–Cu–N' angle increases with the increase in X. The dihedral angles between the two coordination planes show the same tendency: 0° for $X=5$, 34.4° for $X=6$, and 37.0° for $X=7$. It seems likely that the extent of the distortion of square-planar coordination is related to the number of atoms in the central chelate ring.

Such a distorted-tetrahedral coordination around the central copper atom as is described above will certainly decrease the stability of the complex.[1]

The bond distances and angles within 2-hydroxyacetophenone moieties do not differ significantly from those reported for similar molecules.[6-8]

Equations for several least-squares planes are listed in Table 6, while the deviations from those planes are shown in Table 7. The two 2-hydroxyacetophenone moieties are approximately planar, and the deviations of the copper atom from these planes are 0.35 and 0.34 Å respectively. The angle between the two planes is 46.2°.

A projection of the structure along the a-axis is shown in Fig. 4. The molecules are alternately stacked with 2–hydroxyacetophenone groups parallel, but with Cu-C(10) directions opposite along the *c*-axis, thus forming columns. The short contacts in the columns occur between C(7) and O(2), (3.19 Å), and between C(12) and O(1), (3.19 Å). These columns of molecules are packed laterally with the usual van der waals contacts.

The numerical calculations were carried out on the HITAC 5020E at the Computer Centre of the University of Tokyo.

The authors are grateful to Professor Y. Saito for his keen interest and valuable suggestions throughout this work. Part of the cost of this work has been defrayed by a Scientific Research Grant of the Ministry of Education, to which the authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2354—2359 (1970)

Application of the Continuous Variation Method to the Conductometric Determination of Formation Constants—Hexamminecobalt(III) Chloride - Sodium Sulfate and Tris(ethylenediamine)cobalt(III) Chloride - Sodium Sulfate Systems

Shunzo KATAYAMA and Reita TAMAMUSHI

The Institute of Physical and Chemical Research, Yamato-machi, Kita-adachi-gun, Saitama

(Received January 29, 1970)

The conductance behavior of mixtures was investigated with the following systems in aqueous solutions of various ionic strengths at 25°C; NaCl - KCl, NaCl - $NaClO_4$, NaCl - Na_2SO_4, $[CO(NH_3)_6]Cl_3$ - Na_2SO_4 and $[CO(en)_3]Cl_3$ - Na_2SO_4. Appreciable deviations of the measured conductivities from additivity were observed in the last two systems involving the cobalt(III) complexes. The deviation was attributed to the ion-pair formation of the complex cations with sulfate ions; the ion-pair formation constants at various ionic strengths were determined by means of computer analysis of the deviation without relying on the Onsager conductance equation. The thermodynamic ion-pair formation constants at 25°C were as follows: $\log K = 3.5_3$ for $[CO(NH_3)_6]^{3+} \cdot SO_4^{2-}$ and $\log K = 3.6_0$ for $[CO(en)_3]^{3+} \cdot SO_4^{2-}$. The analysis of conductance behavior of mixtures was proved to be a useful method of studying ion-pair formation particularly at relatively high ionic strengths.

The method of continuous variations is a useful technique for determining both stoichiometric compositions and equilibrium constants of complexes in solutions. The application of this method to the conductometric determination of formation constants appears to have the advantage that the measured quantities can be analysed, in principle, without relying on the quantitative validity of the Onsager conductance equation; this advantage is particularly important when the method is applied

to the systems of relatively high ionic strengths.[1] This approach, however, when applied rather loosely, often gives results which are inconsistent with those obtained by other methods, and the utility of the method has been subjected to critical discussions.[2,3] The complication involved in the application of continuous variation method to the study of the conductance behavior of mixtures lies in the fact that the deviation of the observed conductance from additivity may be caused not only by specific ionic interactions but also by the effect of the added ions on the mobility of the ions.[3,4]

This paper deals with the application of continuous variation method to the conductometric determination of ion-pair formation constants of hexamminecobalt(III) and tris(ethylenediamine)-coblt(III) ions with sulfate ions at some varying ionic strengths. The additivity rule was also examined with some mixtures of simple electrolytes, in which no specific individual effects is expected.

Experimental

Procedure and Apparatus. The electric conductivities of mixtures were measured by mixing the solutions of the same ionic strength at various volume fractions. A precision a.c. bridge (HBS-5M, Ando Electric Co., Ltd.), operated at 1000 Hz, was used for conductivity measurements; the balance of the bridge was detected by a tuned null-detector of high sensitivity. The resistance readings of the bridge were calibrated by the substitution method with a precision decade resistance box (Dekastat RS-624, Electro Scientific Industries; accuracy, $\pm 0.005\%$). The resolution of the apparatus was about one part per million, and the reproducibility of conductivity measurements was better than 0.1%. Two dipping-type cells similar to that described in previous papers[5,6] were used; the cell constants were 0.1945 and 0.7704 cm^{-1}, respectively, as determined with standard potassium chloride solutions. All measurements were carried out in a water-thermostat of 25.000 ± 0.005°C.

Hexamminecobalt(III) chloride and tris(ethylenediamine)cobalt(III) chloride were prepared according to the procedure described in literature;[7] these samples were purified by three recrystallizations from their aqueous solutions containing a few drops of acetic acid. The conventional chemical analysis and conductivity measurement showed that the samples obtained were of very high purity. Sodium sulfate of analytical reagent grade was dried at 120°C until it reached constant weight. All other chemicals were of analytical reagent grade. Each solution was carefully prepared by using the conductivity water of low specific conductance ($<2 \times 10^{-7}$ ohm^{-1} cm^{-1}) in an atmosphere of purified nitrogen gas.

Results

Mixtures of Simple Electrolytes. The conductance behavior of sodium chloride - potassium chloride and sodium chloride - sodium perchlorate mixtures showed no appreciable deviation from additivity at ionic strength, I, of 0.01 as shown in Fig. 1 (curves (1) and (2)). Sodium chloride - sodium sulfate mixtures of $I=0.01$ and 0.1, however, gave slightly smaller conductivities than those expected from additivity; the deviation reached the maximum value of about 0.5% at the volume fraction, x, of 0.5—0.6 (Fig. 1, curve (3)).

$[Co(NH_3)_6]Cl_3$ - Na_2SO_4 and $[Co(en)_3]Cl_3$ - Na_2SO_4 Mixtures. In hexamminecobalt(III) chloride-sodium sulfate and tris(ethylenediamine) cobalt(III) chloride - sodium sulfate mixtures a large departure of the measured conductance from additivity was observed at each ionic strength: the deviation, $\Delta\kappa$, between the measured and calculated conductivities is shown in Figs. 2 (a—e) as a function of the volume fraction, x, of the complex. The conductivities of the mixtures were always smaller

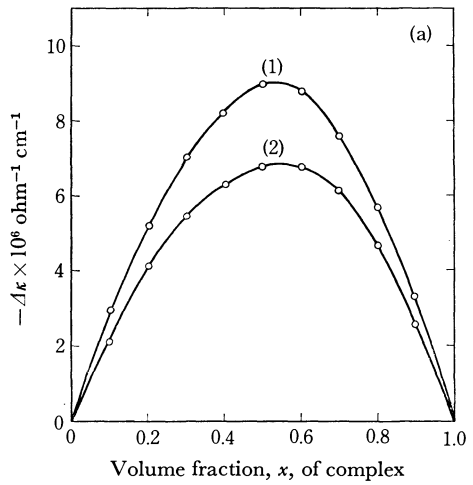
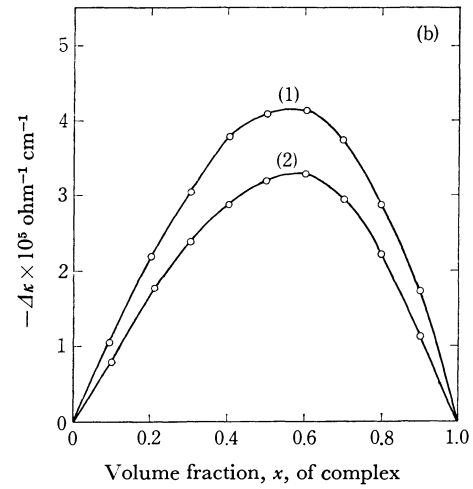
than those expected from additivity and showed an extreme at $x=0.5$—0.7 in each system.

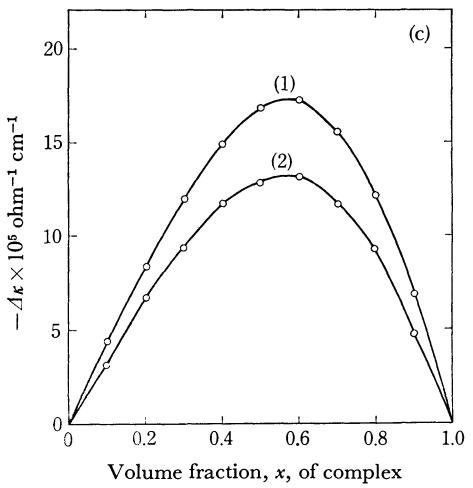
Discussion

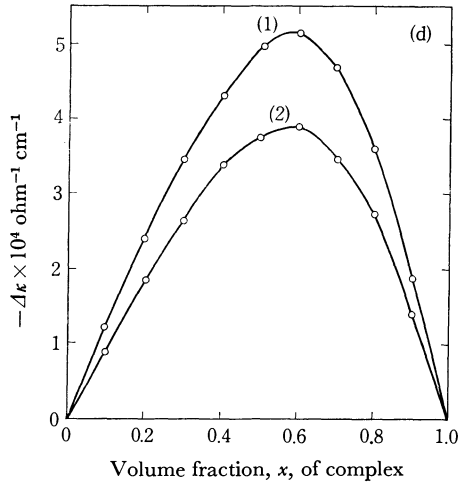
The conductivity of electrolyte mixtures is never strictly additive because of the effect of added ions on the time of relaxation;[4] in our present systems, however, this effect is shown to be negligibly small in comparison with the specific individual effects as seen from Figs. 1 and 2. Therefore, the deviation of the observed conductivities of the cobalt(III) complex - sodium sulfate mixtures from additivity may be attributed entirely to the ion-pair formation of the complex cation with sulfate ions.

Let us consider the conductance of the solution prepared by mixing xV cc of a C_1 molar solution of $M^{z_M}_{\nu_M}A^{z_A}_{\nu_A}$ and $(1-x)V$ cc of a C_2 molar solution of









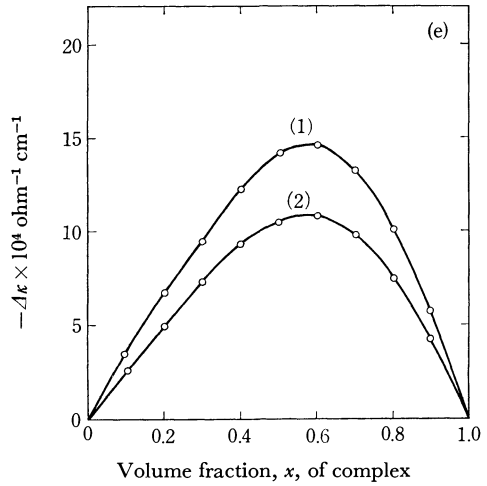


Fig. 2. Deviation of the observed conductivity from additivity, $\Delta\kappa$, as a function of the volume fraction, x, of the complex (1000 Hz, 25°C).

$N_{\nu_N}^{z_N}B_{\nu_B}^{z_B}$ to give the solution of total volume V; the concentrations, C_1 and C_2, are adjusted so that the apparent ionic strength of the mixtures is independent of x. In the following presentation of ions and ion-pairs, the ionic charge for each species will be omitted for the sake of simplicity. If the following ion-pair formations are assumed in the mixture,

$$M + B \rightleftharpoons MB,$$
$$M + A \rightleftharpoons MA,$$
$$N + B \rightleftharpoons NB,$$

the specific conductivity, κ, of the mixture is given by

$$1000\kappa = C_1 x \Lambda_m (M_{\nu_M}^{z_M} A_{\nu_A}^{z_A}) + C_2 (1-x)\Lambda_m (N_{\nu_N}^{z_N} B_{\nu_B}^{z_B}) + \alpha[MB] + \delta \quad (1)$$
$$\alpha = z_{MB}\lambda_{MB} - z_M\lambda_M - z_B\lambda_B$$

where z_i and λ_i are the ionic valence and the ionic equivalent conductance of species i, respectively, Λ_m is the molar conductance, and δ represents the contribution of ion-pairs MA and NB to the specific conductivity.

The deviation of the observed conductivity from additivity is then given by

$$\Delta\kappa' \equiv 1000\Delta\kappa = 1000\kappa - C_1 x \Lambda_m (M_{\nu_M}^{z_M} A_{\nu_A}^{z_A}) - C_2(1-x)\Lambda_m (N_{\nu_N}^{z_N} B_{\nu_B}^{z_B}) \quad (2)$$
$$= \alpha[MB] + \delta$$

Calculating [MB] by Eq. (2) and estimating the concentrations of MA and NB from their formation constants, we can determine the concentration formation constant, K_c, of MB according to the following relation.

$$K_c = \frac{[MB]}{[M][B]} = \frac{\frac{\Delta\kappa'-\delta}{\alpha}}{\left(\nu_M C_1 x - [MA] - \frac{\Delta\kappa'-\delta}{\alpha}\right)\left(\nu_B C_2(1-x) - [NB] - \frac{\Delta\kappa'-\delta}{\alpha}\right)} \quad (3)$$

In the cobalt(III) complex ($z_M=3$) - sodium sulfate mixtures, the contribution of [MA], [NB] and δ in Eq. (3) can be neglected without introducing serious errors in the determination of K_c, because the formation constants of MA and NB should be very much smaller than that of MB. Equation (3) is then simplified as

$$K_c = \frac{\frac{\Delta\kappa'}{\alpha}}{\left(\nu_M C_1 x - \frac{\Delta\kappa'}{\alpha}\right)\left(\nu_B C_2(1-x) - \frac{\Delta\kappa'}{\alpha}\right)} \quad (4)$$

Small amounts of higher order ion-pairs other than the one-to-one type may be formed between the complex cations and sulfate ions; a preliminary calculation, however, showed that the contribution of such higher order ion-pairs, if any, could be ignored in the present systems.

The determination of K_c according to Eq. (4) requires the knowledge of parameter α; the estimation of α at a given ionic strength involves some arbitrariness. In the present study, we estimated the values of α according to the following procedure: $\lambda([Co(NH_3)_6]^{3+})$ and $\lambda(SO_4^{2-})$ were obtained from the equivalent conductivities[8,9] $\Lambda([Co(NH_3)_6]Cl_3)$, $\Lambda(Na_2SO_4)$ and the corresponding transport numbers[8,10] $t([Co(NH_3)_6]^{3+})$ and $t(SO_4^{2-})$; $\lambda(Cl^-)$ from $\Lambda([Co(NH_3)_6Cl_3)$ and $t([Co(NH_3)_6]^{3+})$; $\lambda([Co(en)_3]^{3+})$ from $\Lambda([Co(en)_3]Cl_3)$ and $\lambda(Cl^-)$; and the λ-values of ion-pair MB were assumed to be equal to $\lambda(M)/3$. A slight change in the actual ionic strength is expected with varying ratio of mixing at a given nominal ionic strength; its effects, however, was ignored in the present calculation. The concentration formation constants thus determined at each nominal ionic strength are given in Tables 1 and 2.

The arbitrariness arising from the difficulty in the estimation of parameter α can be removed, when the least square method of curve fitting with the aid of a computer is applied to the analysis of the

a) determined by means of computer calculation
b) determined dy estimating parameter α

where

$$a = C_1x, \quad b = C_2(1-x)$$

By this method of computer calculation, a set of K_c and α for the best fit between the observed and calculated $\Delta\kappa'$ values can be definitely determined at each ionic strength; the K_c values obtained are given in the bottom lines of Tables 1 and 2.

These two methods of calculation resulted in the K_c-values which are in relatively good agreement. The computer method, however, is expected to give more reliable results particularly at higher ionic strengths, because the analysis can be made without assuming a quantitative expression for the

conductance behavior of the component ions.

The thermodynamic formation constants were then determined by the extrapolation of the $\log K_c$ *vs.* $\sqrt{I}$ plots as shown in Figs. 3(a, b). The results are presented in Table 3, in which the K values determined by other methods are summarized for comparison. The good agreement of our results with those of Jenkins and Monk[11] suggests that the conductance measurement of mixtures is a useful method for determining formation constants if the method is properly applied. A great advantage of the method is expected when it is applied to the systems of relatively high concentrations where the theoretical equations of conductance behavior lose their validity.

We wish to thank Mrs. K. Takahashi for her kind collaboration in programming the computer calculation.

Photochemical Reactions of Uranyl Ions with Organic Compounds. II. The Mechanism of the Photo-Oxidation of Alcohols by Uranyl Ions

Shukichi SAKURABA and Ryoka MATSUSHIMA

Faculty of Engineering, Shizuoka University, Hamamatsu

(Received February 2, 1970)

Quantum yields were measured under various conditions for the photo-oxidation of aliphatic alcohols by uranyl ions in aqueous solutions and kinetic treatments were made. The measurements of uranyl fluorescence quenching by the alcohols showed that a complex formation between uranyl ions and alcohol molecules prior to the photolysis is not likely to be involved. The temperature effect on the quantum yield is strong evidence for a collisional energy transfer from the excited uranyl ions to the alcohol molecules. The relative rates of the photolysis of four isomeric butyl alcohols, and the isotope effect on the photo-reactivity by using alcohols labeled with deuterium, showed that the alcohol molecules are attacked on the α-hydrogen atom as a primary photochemical act.

There have been few studies of the mechanisms of the photo-reactions of uranyl ions with alcohols in aqueous solutions, and many basic problems remain unsolved. Kinetic studies have been made of the reaction mechanisms of uranyl ions with carbohydrates[1] and with alcohols,[2-4] but these experimental data are not enough to discuss the mechanism, as has been pointed out by Rabinowitch and Belford.[5] For example, a complex of an uranyl-organic substrate has been assumed to be a photosensitive cluster:

$$UO_2^{2+} + S(\text{substrate}) \rightleftharpoons UO_2S^{2+},$$

and it has been assumed to undergo an intramolecular photo-redox reaction:

$$UO_2S^{2+} + h\nu \rightarrow (UO_2S^{2+})^* \rightarrow\rightarrow U(IV) + \text{Products}.$$

However, the linear relation between the reciprocal quantum yield of the U(IV) formation, ϕ^{-1}, and the reciprocal concentration of the substrate, $[S]^{-1}$, which is inferred from the above assumed mechanism dose not support the above assumption, since the linearity can be inferred both from the mechanism assuming such a complex formation and from the alternative mechanism, in which a collisional energy transfer from the excited uranyl ions to the substrate molecules is involved.

Recently several piecies of evidence for collisional-excitation energy transfer between rare earth metal ions and α-diketones in solution have been reported.[6-8] The present investigation was undertaken

in order to elucidate in some detail the mechanism of the photo-oxidation of alcohols with uranyl ions.

Experimental

Doubly-distilled water and guaranteed reagents (Koso Chemical) were used. The solutions to be tested were de-aerated by the passage through of oxygen-free nitrogen, placed into a cylindrically-shaped, sealed pyrex cell with flat windows (5 m*l* volume), and then exposed to light of the desired wavelength by using an interference filter or by a combination of glass filters. The absorbance at every wavelength, or the rate of light absorption, I_a, of the uranyl - alcohol system was independent of the alcohol concentration. The quantum yields were measured by the usual method[9,10] by using a ferric oxalate solution. The time of exposure was so regulated that the reaction was not more than 5% completed, in order to avoid the complications which might arise from the subsequent reactions of the products or from the inner filter effect of the uranium(IV) ions. The temperature was usually 20±0.1°C. The light sources were a 500-W or 100-W high-pressure Hg lamp. The amounts of uranium(IV) formed were measured colorimetrically by the use of arsenazo III.[11] The aldehydes or ketones formed were determined by means of 2,4-dinitrophenylhydrazine. The spectrophotometric measurements and fluorescence measurements were carried out with a Hitachi 124 spectrophotometer and with a Hitachi fluorescence spectrophotometer respectively. The acidities of the solutions were regulated by using a Toa Denpa pH-meter.

Results and Discussion

Effect of Light Intensity on the Rate. Figure 1 shows that the rate of uranium(IV) formation is directly proportional to the absorbed light intensity (I_a), *i.e.*, the quantum yield is independent of I_a.

Effect of Alcohol Concentration on the Rate. The quantum yields of uranium(IV) formation were measured at various initial concentrations. The plot of $1/\phi$ *vs.* $1/C$ gave a straight line with an intercept $\fallingdotseq 2$, as is shown in Fig. 2. This result is similar to that obtained with the uranyl-carbohydrates system by Heidt and Moon.[1] The question as to whether a photo-activated uranyl ion reacts with a substrate molecule by encounter collisions or whether a certain complex between UO_2^{2+} and substrate is activated to produce the reaction cannot be decided on the basis of this result, since the linear relation, $1/\phi$ *vs.* $1/C$, is inferred both from the mechanism proposed by Heidt[1] assuming a complex as to be a photosensitive cluster and from the alternative mechanism assuming a collisional energy transfer.

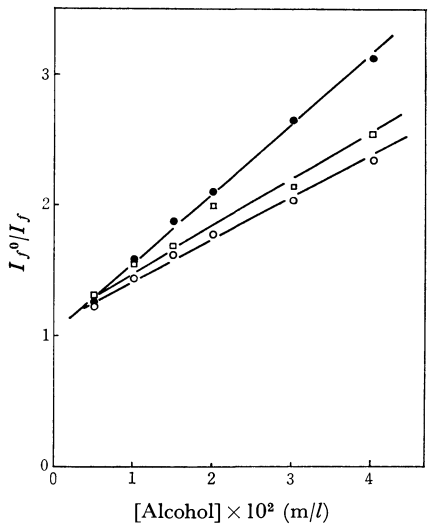

Fig. 3. Reciprocal relative fluorescence intensity of uranyl ions as a function of alcohol concentration. Excited at 4358 Å. Measured at 5090 Å. $UO_2(NO_3)_2$=0.02M.
○: Ethyl alcohol, pH=1.5, □: Ethyl alcohol, pH=3.5, ●: Isopropyl alcohol, pH=1.5, I_f^0 and I_f are the fluorescence intensities in the absence and in the presence of alcohol, respectively.

Fluorescence Intensities at Various Concentrations of Alcohol. The results shown in Fig. 3 can be expressed by the Stern-Volmer equation:

$$\frac{I_f^0}{I_f} = 1 + K_q[Q],$$

where I_f^0 and I_f are the fluoresence intensities in the absence and in the presence of a quencher respectively. K_q is the quenching constant, and [Q] is the concentration of a quencher. It can be seen that the slope, K_q, varied with the nature of the alcohol and not with the acidity of the solution.

Correlation between the Photo-Reactivity and Fluorescence Quenching. The K_q's for

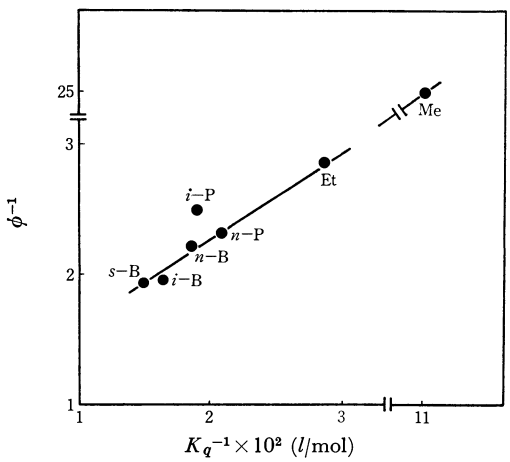

Fig. 4. Photoreactivity and fluorescence quenching constants in the system of aqueous uranyl-alcohols. ϕ_r: quantum yield of uranium(IV) formation at 3650—3606 Å, $[UO_2^{2+}]$=0.02M, [alcohol]=0.02M. pH=1.5 λ(emission)=5090 Å, λ(excitation)=4360 Å.

aliphatic alcohols were measured. Figure 4 shows the correlation between the photo-reactivity, ϕ_r, and the fluorescence quenching constant, K_q. Neither the quenching efficiency nor the photochemical reactivity of alcohols seems to be related to the stability of the uranyl-alcohol complexes assumed, on the supposition that the steric factor

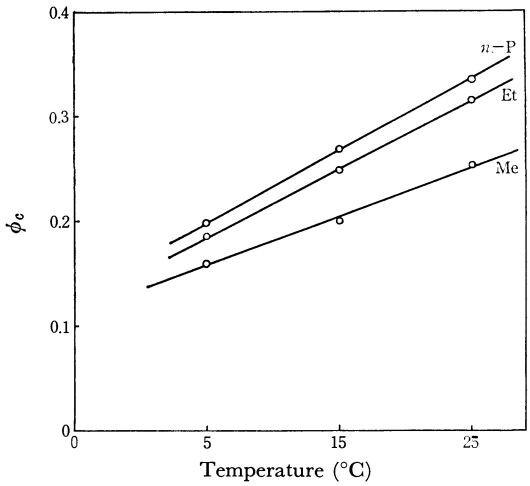

Fig. 5. Temperature effect on the rate of uranium-(IV) formation. $[UO_2^{2+}]$=0.02M. [alcohol]=0.2M. pH=1.5 λ=3650—3660 Å. The quantum yields were corrected for the self-quenching; $(UO_2^{2+})^* + UO_2^{2+} \rightarrow 2UO_2^{2+}$, on the assumption that the temperature dependence of the self-quenching is mainly due to that of the viscosity of the medium.[12]

Apparent activation energy, $\Delta E^{\ddagger}$, obtained was 8.5 kcal/mol for both ethyl alcohol and *n*-propyl alcohol.

dominates the stability of the complex; rather, it seems likely that the photo-sensitivity is related to the bond strength between the α-hydrogen atom and the carbon atom adjacent to the hydroxy group, on the assumption that the increasing order of the bond-dissociation energies in solution is approximately the same as that in the gaseous phase.

The close correlation between the quenching efficiency, K_q, and the chemical reactivity, ϕ_r, suggests that chemical quenching is predominant in the radiationless deactivation of the excited uranyl ions by alcohol molecules, while physical quenching is less important.

Temperature Effect on the Reaction Rate. The quantum yield increases with an increase in the temperature, as is shown in Fig. 5; this suggests that the reaction mechanism involves a collisional transfer from the excited uranyl ions to alcohol molecules. The values of the quantum yield in Fig. 5 were corrected for the self-quenching of uranyl ions.[12]

Relative Rates of Butyl Alcohols and the Isotope Effect on the Rate. The relative rates of *n*-butyl, isobutyl, *s*-butyl, and *t*-butyl alcohol (the last one has no α-hydrogen) were measured in order to decide which of two alternatives is the primary process. The results are listed in Table 3.

Table 3. Relative reactivity of butyl alcohols
k and k_n are relative rate constants for uranium (IV) formation with butyl alcohol isomer and with *n*-butyl alcohol, respectively.

Butyl alcohol	k/k_n
n-Butyl	1.00
Isobutyl	1.14
s-Butyl	1.05
t-Butyl	0.11

Further, the rate constants of the uranium(IV)-formation with deuteriated alcohols were compared to those with non-deuteriated alcohols in an ordinary water solution. The ratios obtained were $k_{(CH_3CH_2OH)}/k_{(CD_3CD_2OD)}=2.33$ and $k_{(CH_3CH_2OH)}/k_{(CH_3CH_2OD)}=1.02$. These results indicate that the path:

$$R_1R_2CHOH + U(VI)^* \rightarrow R_1R_2\dot{C}OH + U(V) + H^+,$$

is predominant in the primary act, while the alternative path:

$$R_1R_2CHOH + U(VI)^* \rightarrow R_1R_2CHO\cdot + U(V) + H^+,$$

is less important.

Effect of Cupric Ions. As is shown in Table 4,

Table 4. Interfering effect of cupric ions
$[CH_3CH_2OH]=0.2$M, $[UO_2(NO_3)_2]=0.02$M, $\lambda=4047$, 4358 Å
The fraction of light absorbed by cupric ions was negligible under the experimental conditions.

$[CuSO_4]$ added $\times 10^3$M	$[U(IV)]$ formed $\times 10^3$M	$[CH_3CHO]$ formed $\times 10^3$M
0.0	6.7	6.6
5.0	0.1	6.4

the formation of uranium(IV) is nearly completely interfered with by the addition of a small quantity of cupric ions, while acetaldehyde-formation is not affected.

Since cupric ions do not quench the excited uranyl ions,[13] the interfering effect must be due to the reaction between cupric ions and the intermediates, U(V); *i.e.*;

$$U(VI)^* + R_1R_2CHOH \rightarrow U(V) + R_1R_2\dot{C}OH + H^+,$$
$$U(V) + Cu(II) \rightarrow U(VI) + Cu(I),$$
$$2Cu(I) \rightarrow Cu^0 + Cu(II).$$

The selective interfering effect by cupric ions indicates that the secondary process of uranium(IV)-formation is:

$$U(V) + U(V) \rightarrow U(VI) + U(IV)$$

and not the alternative process:

$$U(V) + R_1R_2\dot{C}OH \rightarrow U(IV) + R_1R_2CO.$$

The radical intermediate, $R_1R_2\dot{C}OH$, would seem to be rapidly oxidized by the ground-state uranyl ions; *i.e.*:

$$R_1R_2\dot{C}OH + U(VI) \rightarrow R_1R_2CO + U(V) + H^+,$$

before the disproportionation reaction of the radical:

$$2R_1R_2\dot{C}OH \rightarrow R_1R_2CO + R_1R_2CHOH,$$

since the concentration of uranyl ions is much higher than that of the radical, $R_1R_2\dot{C}OH$. However, the selective inhibitory effect by maleic acid, as is shown in Table 5, indicates that the latter path (the disproportionation of the radical) is predominant.

Table 5. Effect of maleic acid
$[UO_2(NO_3)_2]=0.02$M, $[CH_3CH_2CH_2OH]=0.2$M
$\lambda=4047$, 4358 Å, Irradiation time=30 min

$[(CHCOOH)_2]$ added $\times 10^2$M	$[U(IV)]$ formed $\times 10^3$M	$[CH_3CH_2CHO]$ formed $\times 10^3$M
0.0	4.1	4.0
2.0	3.2	0.4

13) Y. Volmar and Mathis, *Bull. Soc. Chim. Fr.*, **53**, 385 (1933).

A slight decrease in the amount of U(IV) upon the addition of maleic acid in Table 5 may be attributed to a weak masking effect of maleic acid or to a reaction between U(V) and maleic acid.

On the basis of the above data, the following mechanism may be proposed:

$$U(VI) + h\nu \xrightarrow{I_a} U(VI)^*, \text{ (absorption)} \quad (1)$$

$$U(VI)^* \xrightarrow{k_1} U(VI) + h\nu', \text{ (fluorescence emission)} \quad (2)$$

$$U(VI)^* \xrightarrow{k_2} U(VI) + \text{heat}, \text{ (radiationless deactivation)} \quad (3)$$

$$U(VI)^* + U(VI) \xrightarrow{k_3} 2U(VI), \text{ (self-quenching)} \quad (4)$$

$$U(VI) + R_1R_2CHOH \xrightarrow{k_4} U(VI) + R_1R_2CHOH, \text{ (physical quenching)} \quad (5)$$

$$U(VI)^* + R_1R_2CHOH \xrightarrow{k_5} U(V) + R_1R_2\dot{C}OH + H^+, \text{ (chemical quenching)} \quad (6)$$

$$2R_1R_2\dot{C}OH \xrightarrow{k_6} R_1R_2CO + R_1R_2CHOH, \text{ (disproportionation)} \quad (7)$$

$$2U(V) \xrightarrow{k_7, H^+} U(VI) + U(IV). \text{ (disproportionation)} \quad (8)$$

Here I_a is the rate of light absorption in einsteins$\cdot$mol$^{-1}\cdot$min^{-1}.

The steady-state assumption for U(VI),* U(V), and $R_1R_2\dot{C}OH$ leads to:

$$\phi_U = \phi_C = k_5[R_1R_2CHOH]/2\{k_1+k_2+k_3[U(VI)] + (k_4+k_5)[R_1R_2CHOH]\}, \quad (9)$$

where ϕ_U and ϕ_C are the quantum yields for the formations of U(IV) and R_1R_2CO respectively. The reciprocal expression is:

$$1/\phi_U = 1/\phi_C = 2 + 2k_4/k_5 + 2(k_1+k_2+k_3[U(VI)]/k_5[R_1R_2CHOH]. \quad (10)$$

The relative intensity of uranyl fluorescence becomes:

$$I_f^0/I_f = 1 + K_q[R_1R_2CHOH], \quad (11)$$

where:

$$K_q = (k_4+k_5)/(k_1+k_2+k_3)[U(VI)]. \quad (12)$$

The comparison of Eq. (10) with the experimental results in Fig. 2 leads to:

$$k_4/k_5 = 0 \quad (13)$$

i.e., the physical quenching is much less important than the chemical quenching. This is in agreement with the conclusion from the results shown in Fig. 4. The low probability of electronic-vibration energy transfer without a chemical reaction seems plausible.[14]

From Eqs. (10),(12) and (13), we obtain:

$$1/\phi = 2 + 2/K_q[R_1R_2CHOH]. \quad (14)$$

The plot of $1/\phi$ *vs.* $1/K_q$ should be a straight line with an intercept of 2 and a slope of $2/[R_1R_2CHOH]$. The slope in Fig. 4 is 70, roughly in agreement with the theoretical value from Eq. (14), $2/[R_1R_2CHOH]=100$. The discrepancy between Eq. (14) and the experimental results in Fig. 4 may be partly due to the inaccuracy in the value of K_q.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2364—2366 (1970)

Spreadability of Ovalbumin Monolayers at Air-water Interface

Toshio Ishii*1 and Mitsuo Muramatsu

Department of Chemistry, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received February 4, 1970)

The spreading processes of ovalbumin have been studied quantitatively at air-water interface with either no additive or a small amount of hydrochloric acid for controlling subphase pH. Limiting area which is obtained by extrapolating force(F)-area(A) curve to $F=0$, increases with time, t, which has elapsed after the application of protein solution at the surface of subphase. Near the isoelectric point, the spreading processes are completed instantaneously to give the equilibrated value of limiting area which is found to be 0.83 m^2/mg. The processes are much slower at both sides of the point, but the limiting area in equilibrium is found to be the same as in the case of isoelectric pH. It has also been shown that the processes are expressed in terms of two first-order reactions.

Work has been done by many investigators[1-3] on the nature of protein monolayers at air-water interfaces, in relation to the mechanism of their denaturation processes. In many cases, however, the experiments were carried out under the tacit assumption that the protein films were in the equilibrated state in which surface-chemical processes could be considered to reflect thermodynamical properties, though the assumption could hardly be verified. It is practically difficult to confirm the equilibrium state of protein monolayer at the air-water interface. In many cases, therefore, it has been assumed that the equilibrated state is attained if a monolayer gives no time effects upon the quality to be studied. This was indeed the case in determining the thermodynamical properties of monolayers of various proteins to be compared.

On the other hand, the denaturation processes are considered to take place during the course of monolayer formation by applying a protein solution to the surface of subphase water. The course is conveniently defined[4-6] to involve (1) dissolution of protein molecules into the bulk of subphase and their return to the surface by diffusion, (2) their spreading at the surface and (3) their uncoiling to form the structures of denatured protein. Thus the denaturation processes seem to be studied conveniently by elucidating the course of monolayer formation with elimination of processes (1) and (2) as much as possible. This has been achieved to some extent by the addition of a large amount of salt into subphase,[1] or of surface active, volatile solvent to spreading solution.[7] The former involves the difficulty to eliminate surface-chemical impurities from subphase,[8] while the latter gives little effects on eliminating the process (1). None of these methods always reflects the true nature of surface denaturation of protein molecules, because process (3) may be much affected by the addition of salt or solvent. Any additives should be avoided for quantitative studies on the spontaneous processes of protein denaturation. It has been pointed out[4] that the decreased contribution of processes (1) and (2) to the whole spreading course can be expected by applying dilute protein solution without additives on the top of the glass rod standing in the trough which contains water alone.[9] This has proven to be effective for decreasing the conditions of (1) and (2), making it easy to understand the surface denaturation of protein molecules in terms of unfolding processes of their polypeptide chains.[4-6] The technique has been extended in the present investigation to elucidate the kinetic processes of protein denaturation at air-water interface.

Experimental

A sample of ovalbumin was recrystallized seven times from aqueous ammonium sulfate and its purity was confirmed by paper electrophoresis and by microscopic observation of crystalline shape. Its aqueous solution was treated with Sephadex-G25 to remove inorganic materials and made the desired concentration (0.0859 mg/ml) which was confirmed spectrometrically. The water both for the spreading solution and for the subphase was distilled twice from alkaline permanganate in Hysil glass ware. Hydrochloric acid for controlling pH was distilled at its azeotropic point.

A glass tray, 48 cm × 15 cm in area and 0.5 cm in depth, had a well for a glass plate to be dipped for measuring surface pressure, F (dyn/cm). The plate, 2.4 cm × 3.2 cm × 0.015 cm, was cleaned by soaking it into a hot chromic acid mixture or alkali-alcohol solution prior to each measurement. The displacement of the plate was magnified by a lamp and scale system to give the surface pressure with an accuracy of 0.05 dyn/cm. The whole apparatus was thermostated at 20± 0.5°C.

The protein solution was applied onto the glass rod (0.5 cm dia. × 10 cm above the water level), which stood vertically in the subphase with pH 2.0—8.2 at such a dropping rate as to permit less than 0.1% of protein molecules to get into the subphase, the figure being based on the theoretical calculation by Trurnit.[9] Surface contamination was low enough to give $F<5$ dyn/cm when the aqueous surface was kept standing for 24 hr and then compressed to 1/20 its area.

The surface pressure was measured as a function of area, A (m²/mg), at given time, t, which had elapsed from the application of spreading solution to the surface of subphase. The limiting area, A^0, obtained by extrapolating the straight part of F-A curve was taken as a measure of the extent of the denaturation processes at given time, t.

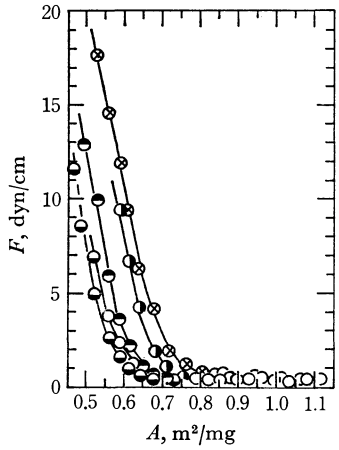

Fig. 1. Time dependence of F-A curves of ovalbumin monolayer spread on subphase of pH 5.2—6.0; —◒—, t=15 min; —○—, 1 hr; —◓—, 4 hr; —◑—, 24 hr; —⊗—, 42 hr

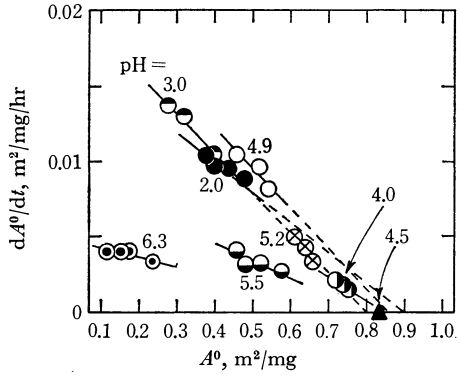

Fig. 2. The relationship of dA^0/dt and A^0 for ovalbumin nomolayers on subphases of various pH.

Results and Discussions

Figure 1 gives the F-A curves as a function of t obtained with monomolecular film of ovalbumin spread on the subphase of pH 5.2. It was inevitable to find a gradual change of pH during the elapsed time, giving the final pH of 6.0 at t=42 hr. It can be seen that the F-A curve is shifted to the right, showing an increase of limiting area with increasing time. The shift suggests an asymptotic tendency to reach the definite A^0 value at $t=\infty$. This is indeed the case of the linear relationship of log A^0 with t, suggesting the validity of the equation

$$dA^0/dt = k_2(A_\infty{}^0 - A^0), \qquad (1)$$

where $A_\infty{}^0$ is A^0 at $t=\infty$ and k_2 the constant. The relationship holds throughout the long period of t >2—3 hr.

In Fig. 2 is shown the dA^0/dt as a function of A^0 for the monolayers on subphases varying in pH values. The slope of the linear part gives the rate constant, k_2, of the first order denaturation process of ovalbumin approaching the equilibrated state, in which the monomolecular film consists of completely unfolded molecules of protein. If k_2 is plotted against pH of subphase, one finds the maximum value, as seen in Fig. 3, near the isoelectric point of protein. In both sides from the isoelectric point, k_2 decreases with increasing departure from the point. It is thus concluded that the spreading processes in the period sufficiently long after the initial spreading are expressed by

$$(A_\infty{}^0 - A^0) = (A_\infty{}^0 - A_2{}^0)\exp(-k_2 t) \qquad (2)$$

where $A_2{}^0$ is A^0 value at $t=0$.

Rigorously speaking, however, Eq. (2) does not hold in the small t region, namely, shortly after the spreading, as can be seen in Fig. 4, which gives considerable deviation of the empirical values from the calculated slope (solid lines) based on Eq. (2). If, however, we plot the deviation against t on the same figure, we have the dotted lines which show fairly linear relationships. Therefore, the whole processes could better be expressed by

$$(A_\infty{}^0 - A^0) = (A_\infty{}^0 - A_2{}^0)\exp(-k_2 t) + (A_2{}^0 - A_1{}^0)\exp(-k_1 t) \qquad (3)$$

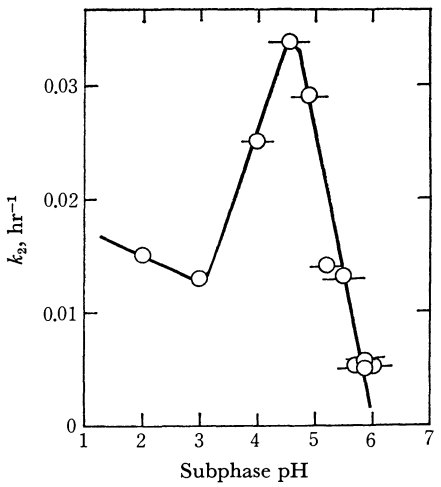

Fig. 3. k_2 as a function of subphase pH. The circles are given for the average pH from the initial and final values, which are shown as the horizontal bars.

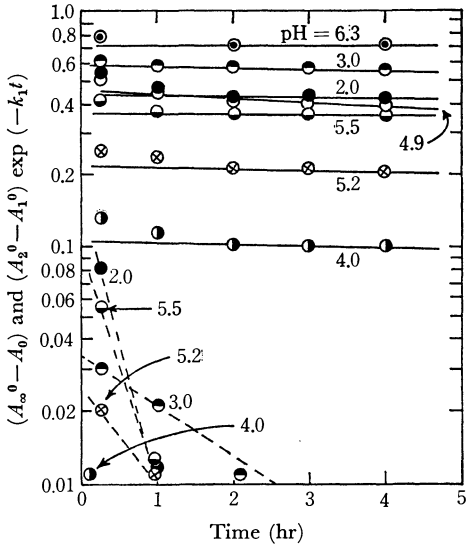

Fig. 4. Time dependences of $A_\infty^0 - A^0$ (solid lines) and $(A_2^0 - A_1^0)\exp(-k_1 t)$ (dotted).

where A_1^0 is the extrapolated value of the dotted lines to $t=0$ and k_1 the rate constant for the process shown as the dotted lines in Fig. 4. Equation (3) suggests that the spreading processes are expressed as the sum of two independent processes, one is fast and the other slow, and that, if we assume the first order reaction for one of them, the other should give the same order in its mode.

The above results suggest that the uncoiling of protein molecules at air-water interface involves the two processes; the fast process starts from A_1^0, while the slow process covers the range A_2^0 to A_∞^0. These values are plotted in Fig. 5 against the pH of subphase on which the protein is spread.

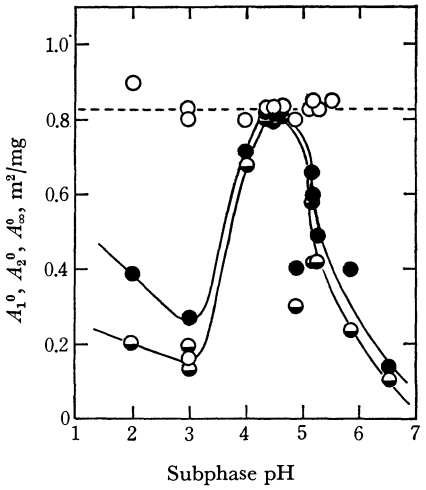

Fig. 5. A_1^0 (semiclosed), A_2^0 (closed) and A_∞^0 (open) as a function of subphase pH.

It is clear from Fig. 5 that the A^0 value (0.83 m^2/mg) is independent of pH, as mentioned previously, while A_1^0 and A_2^0 give almost the same tendency to each other, giving the maximum value near the isoelectric point, where the spreading is completed instantaneously. It should be noted that the two solid curves in the figure resemble in shape the pH dependences of limiting area reported by many investigators[1-3] who paid little attention to the time-dependent nature of protein monolayers. This means that, when subphase pH is at the isoelectric point, the spreading of protein molecules at air-water interface and the unfolding of their polypeptide chains are completed immediately after their arrival at the interface, and that, at any other pH, the protein molecules shrink to give smaller A_1^0 and A_2^0 values and then gradually uncoil to reach finally the same A_∞^0 value. This process is characterized by the slower rate of uncoiling for the more deviated pH value from the isoelectric point, as can be seen in Fig. 3.

It has been claimed by many investigators[1-3] that the limiting area of protein molecules gives the maximum value when they are spread on subphase of isoelectric pH value. It seems to be more reasonable to treat the spreading of protein at air-water interface as a reflection of kinetic processes to be characterized by the unfolding of protein molecules concerned. The subphase pH does not influence the limiting area, A_∞^0, in the equilibrium state, but affects markedly the kinetic processes with which the protein molecules uncoil to approach the equilibrated state.

In conclusion, the authors wish to express their thanks to Professor T. Sasaki for his suggestion and advice. This reseach has been supported by the Scientific Research Grant of the Ministry of Education.

The Interaction of Polymer Ions with Counterions. II. Polymethacrylates

Kunio TAMAKI and Teruo HORIUCHI

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama

(Received February 4, 1970)

The equivalent conductivities and the electrophoretic mobilities of sodium, tetramethyl-, tetraethyl-, and tetrabutyl- ammonium salts of polymethacrylic acid (PMA) in 0.05 M solutions of the simple salts of the corresponding cations are measured at 25°C, and the results obtained are interpreted in terms of the counterion binding. The calculated values of the apparent degree of ionization for sodium, tetramethyl-, and tetraethylammonium salts of PMA are found to be larger than those of the corresponding salts of polyacrylic acid (PAA), indicating that the methyl groups in PMA generally hinder the binding of counterions with polyions. With tetrabutylammonium salt of PMA, the apparent degree of ionization is nearly equal to that of the tetrabutylammonium salt of PAA. This fact suggests hydrophobic interaction between the methyl groups in PMA and tetrabutylammonium ions.

The role of the nonpolar side chains of polyelectrolytes in the water phase is of great interest in connection with hydrophobic interaction in grobular proteins. Polymethacrylic acid contains extra methyl groups in the main chain compared with polyacrylic acid. In the previous paper,[1] the conductivities and electrophoretic mobilities of polystyrenesulfonates, polyethylenesulfonates, and polyacrylates, measured in 0.05M solutions of the simple salt of the corresponding cations at 25°C, were discussed on the basis of the apparent degree of ionization of the polyelectrolytes. The object of the present paper is to compare the additional data on polymethacrylate with those of polyacrylates.

Experimental

Polymethacrylic acid (PMA) was prepared by the polymerization of methacrylic acid in water, in the presence of hydrogen peroxide as an initiator, according to the method described by Leyte and Mandel.[2] A commercial sample of methacrylic acid was distilled under reduced pressure before polymerization. The polymer was dissolved in methanol and fractionally precipitated by the gradual addition of ether to give different molecular weights. The fraction used in this experiment had a molecular weight of 1.11×10^6, determined from the viscosity measurement of the polymer solution in methanol using the equation proposed by Wiederhorn and Brown.[3] Sodium, tetramethylammonium (Me_4N), tetraethylammonium (Et_4N), and tetrabutylammonium (Bu_4N) salts of PMA were prepared by the neutralization of PMA with the corresponding hydroxides. The sodium hydroxide solution was preapred by diluting its saturated aqueous solution. Tetraalkylammonium hydroxides were prepared by the reaction of the respective bromide salts in aqueous solutions with silver oxide. The tetraalkylammonium bromides were purchased from the Tokyo Kasei Kogyo Co. and were recrystallized from suitable solvents: an ethanol-water mixture for Me_4NBr_4, ethanol for Et_4NBr, and ethyl acetate for Bu_4NBr. Sodium chloride was a reagent-grade sample. Water was obtained by redistillation from an alkaline permanganate solution.

The detailed procedure for measuring the equivalent conductivities and electrophoretic mobilities of polyelectrolytes in 0.05M solutions of the simple salts of the corresponding cations at 25°C was described in the previous paper.[1] As simple salts, sodium chloride was used for Na-PMA and tetraalkylammonium bromides were used for respective tetraalkylammonium salts of PMA.

The electrical conductivities were measured with a Yokogawa BVZ-13A auto-frequency bridge, using a frequency of 1000 Hz. The electrophoretic mobilities were measured with a Hitachi HTB-2 Tiselius electrophoresis apparatus, varying the electric currents from 1 to 2 mA. A polyelectrolyte solution was dialysed in a cellophane tube against a large volume of a 0.05M solution of a simple salt for 2 days. From the boundaries recorded on a photographic plate at a different time, the electrophoretic mobility was then calculated.

Results

The equivalent conductivity of polyelectrolyte in a simple salt solution, Λ_p, may be expressed;[4]

$$\Lambda_p = 10^3(K_{ps}-K_s)/N_p$$

where K_{ps} and K_s are the specific conductivities of the salt solution with and without an added polyelectrolyte, and N_p is the polyelectrolyte concentration, expressed in terms of equiv./l. Although K_s in a salt solution containing polyelectrolyte is not generally equal to that of the same concentration of a simple salt solution without an added polyelectrolyte, in this study K_s may be considered to be equal to the value of a 0.05M solution of a simple salt; this means that the 0.05M solution of a simple salt is taken to be serving as the solvent. The values of Λ_p calculated in this manner are given as a function of the polyelectrolyte concentration in Fig. 1. Λ_p shows no noticeable trend with the variation in the polyelectrolyte concentration.[4,5] Therefore, the values of Λ_p, taken as the intrinsic equivalent conductivities, are listed in Table 1, in which the values of polyacrylates under the same conditions are also included.

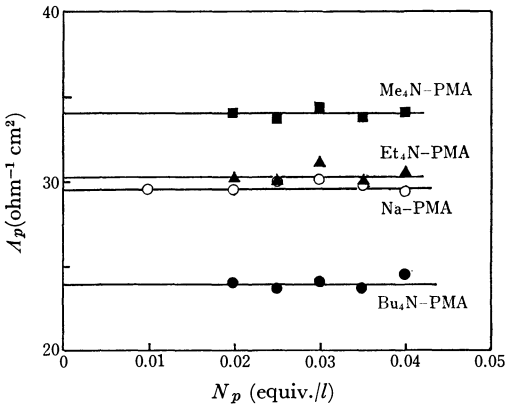

Fig. 1. Equivalent conductance in 0.05M simple salt solution as a function of the polymer concentration.

The observed electrophoretic mobility varied generally with the polyelectrolyte concentration, and it was found that the descending boudary became diffuse with the time. Thus, the mobilities of the ascending boudary as a function of the polyelectrolyte concentration are shown in Fig. 2. By extrapolation to an infinite dilution, the intrinsic mobilities of polyelectrolytes in 0.05M solutions of simple salts are obtained. The values are listed in Table 1.

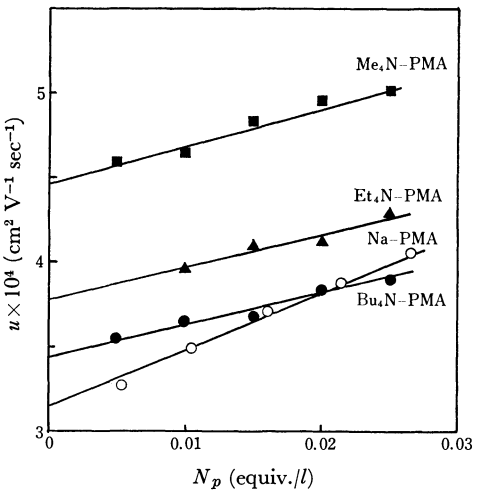

Fig. 2. Electrophoretic mobility in 0.05M simple salt solution as a function of the polymer concentration.

Discussion

As may be seen in Table 1, the electrical transport properties of the salts of PMA vary with the kinds of their counterions, indicating the difference in the strength of the interaction of this polymer with counterions. As an quantitative analysis of the data is not possible at present, the counterion-binding theory[6] is adopted as in the previous work.[1] This theory implies that part of the counterions, associated with the region of the polyion, does not contribute to the conductivity, whereas the other part of counterions remains free and behaves as in a corresponding solution of simple salt. The equivalent conductivity of polyelectrolyte can thus be written:[4]

$$\Lambda_p = i\,(\boldsymbol{F}u + l_c)$$

where i is the apparent degree of ionization, $\boldsymbol{F}$ is the faraday, and l_c is the equivalent ionic conduc-

TABLE 1

tivity of the counterion in the solution of a simple salt. In this case, l_c can be taken as the value of the ionic conductivity of counterions in a 0.05M concentration of a simple 1-1 electrolyte.[1] Therefore, we can regard the apparent degree of ionization, i, or the apparent degree of binding, $1-i$, as a means of interpreting the strength of the interaction of the polyion with the counterion. The calculated values of i for polymethacylates are listed in Table 1; the values of polyacrylates are also shown in the table for purpose of comparison. With sodium salts, the values of i are larger in PMA than in PAA; that is, the methyl groups in PMA tend to hinder the binding of counterions with polyions. This is consistent with the finding of Crescenzi *et al.*[7] and Strauss and Leung.[8] With tetramethyl- and tetraethylammonium salts, the values of i are also about 1.2—1.3 times larger in PMA than in PAA; in fact, the binding of counterions with polycarboxylic acids is mainly determined by the size of the counterions.[1,9,10]

The value of i for Bu_4N-PMA does not increase so much as that of Et_4N-PMA, being rather equal to that of Bu_4N-PAA. From the size effect of the counterions, the values of i for Bu_4N-PMA should be much larger; however, in this case the methyl groups in PMA may play an additional part in the interaction with counterions, although the effect of the methyl groups is not so remarkable as to reverse the sequence of Et_4N and Bu_4N ions in the apparent degree of binding.

Many investigators[2,11,12] have reported the pH-induced transition of the molecular configuration of PMA in relation to the intramolecular hydrophobic or van der Waals interactions due to the methyl groups at low degrees of neutralization. However, as for the interaction of methyl groups in PMA with counterions at the full degree of neutralization, as in this study, it may be concluded that the hydrophobic effect is apparent with a strongly hydrophobic ion such as Bu_4N ion.

Magnetic and Optical Properties of Ionic Electron-Donor-Acceptor Complexes

Yoichiro SATO,[*1] Minoru KINOSHITA, Mizuka SANO[*2] and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received February 14, 1970)

The magnetic susceptibilities and optical absorption spectra of a number of ionic electron-donor-acceptor complexes have been studied in a solid state. The complexes of *N,N,N'N'*-tetramethyl-*p*-phenylenediamine with *o*-chloranil and *o*-bromanil were found to have a composition of 2 : 3 and their paramagnetic susceptibilities followed the Curie-Weiss law with the Weiss constant of 0 ± 5°K in the temperature range between 77°K and room temperature. It was noted that in these complexes paramagnetism is dominated by the monopositive ion radical of the amine and not by the quinone part. In contrast to this, the complexes formed by combinations of *p*-phenylenediamine and tetramethyl-*p*-phenylenediamine with *p*-chloranil and *p*-bromanil had a composition of 1 : 1 and showed paramagnetic susceptibilities which varied with temperature according to the thermal equilibrium between magnetic and non-magnetic states. The thermal equilibrium is characterized by the activation energy determined by the interaction between the monopositive and the mononegative ion radicals of the components. The absorption spectra of 1 : 1 complexes showed a charge-transfer band in the near-infrared region, while those of 2 : 3 complexes did not. The activation energy obtained magnetically is discussed in relation to the appearance of the charge-transfer absorption band. The temperature dependence of the activation energy is also discussed.

In the previous papers,[1,2] we suggested the importance of the charge-transfer interaction between ion radicals for understanding the observed magnetic susceptibilities of the crystals made of radicals. There is a correlation between the magnetic susceptibility and the appearance of a charge-transfer band in the absorption spectrum of a radical crystal. A radical crystal which shows an intense charge-transfer band is apparently diamagnetic or at most weakly paramagnetic at room temperature. The exchange coupling constant (J) for the crystal was found to be as large as 0.05 eV or more. A crystalline radical with the exchange coupling constant $J\leq0.02$ eV exhibits a fairly weak charge-transfer band. A charge-transfer band is usually undetectable for a solid with $J<10^{-3}$ eV. We have studied a similar relationship between the magnetic and optical properties for the ionic electron-donor-acceptor complexes, which may be designated as D^+A^--type complexes. In this case, the interactions between unlike molecules are of primary importance, in contrast to the systems, previously studied, of ion radical salts where interactions between like molecules are important.

We have prepared the stable solid complexes by the combination of *p*-phenylenediamines which are strong electron donors (D) with halogenated benzoquinones which are strong electron acceptors (A). In these solid complexes, an electron transfers completely from a donor molecule to an acceptor molecule, resulting in the $|D^+A^-\rangle$ ground state and $|DA\rangle$ charge-transfer excited state, when expressed in terms of a DA pair. The situation is thus reversed when compared to usual charge-transfer complexes.

Experimental

Preparation. Ionic complexes were formed between electron donors; *p*-phenylenediamine (PD), *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) and electron acceptors; chloranil (*p*-CA), *o*-chloranil (*o*-CA), bromanil (*p*-BA) and *o*-bromanil (*o*-BA), according to the method described by Kainer *et al.*[3-6] The complexes were precipitated by mixing the benzene solutions of amine

and quinone. The composition was found to be 1 : 1 for *p*-quinone complexes. The complex formed from TMPD and *o*-BA was found to have the composition $TMPD_2 \cdot o\text{-}BA_3$. The composition of the complex formed from TMPD and *o*-CA was not determined. It was tentatively assigned, however, to be $TMPD_2 \cdot o\text{-}CA_3$, because of the close resemblance of the magnetic and optical behavior to that of $TMPD_2 \cdot o\text{-}BA_3$.

$TMPD_2 \cdot o\text{-}BA_3$ (Found: C, 28.59; H, 2.17; N, 3.19%. Calcd: C, 28.53; H, 2.07; N, 3.50%).

Measurements. The static susceptibilities of the complexes were measured as a function of temperature with a Faraday-type magnetic balance[7] in the range from 77°K to room temperature or a somewhat higher temperature according to the stability of a compound. The absorption spectra were measured in the range from 340 to 2400 mμ for a powder sample suspended in liquid paraffin.

Results

Magnetic Susceptibilities. The susceptibilities of $TMPD_2 \cdot o\text{-}CA_3$ and $TMPD_2 \cdot o\text{-}BA_3$ were found to be strongly paramagnetic at room temperature and increased with decreasing temperature, while the susceptibilities of the other complexes were diamagnetic and their temperature variations were relatively small.

For the purpose of evaluating diamagnetic contribution, the susceptibilities of the neutral component molecules were measured. The results are given in Table 1. The susceptibilities of the *o*-quinones are seen to be somewhat less diamagnetic than those of the corresponding *p*-quinones.

Table 1. Magnetic susceptibilities of the amines and the quinones

Compound	Molar susceptibility $\chi_M \times 10^6$(emu/mol)

Bromanil	−148
o-Bromanil	−139

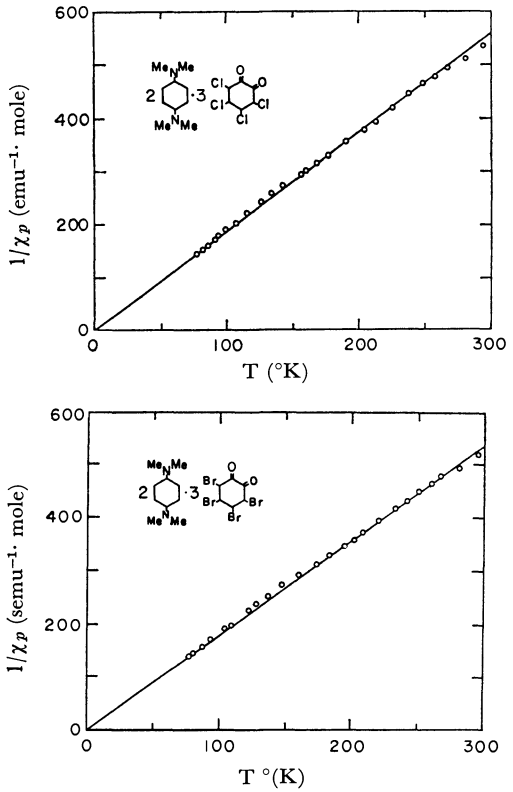

Fig. 1. Inverse paramagnetic susceptibilities of $TMPD_2 \cdot o\text{-}CA_3$ and $TMPD_2 \cdot o\text{-}BA_3$ versus temperature.

For $TMPD_2 \cdot o\text{-}CA_3$ and $TMPD_2 \cdot o\text{-}BA_3$, the sum of the susceptibilities of the neutral components was taken to be their diamagnetic susceptibility. When the inverse paramagnetic susceptibility $1/\chi_p$ was plotted against temperature, straight lines were obtained as shown in Fig. 1. The values of the Curie constant C and the Weiss constant θ were obtained from the slope of the line and its intersection on the temperature axis, respectively. The results are given in Table 2.

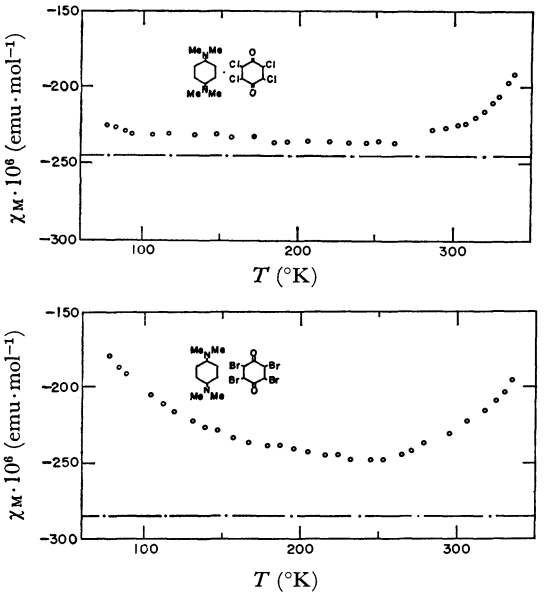

Fig. 2. Magnetic susceptibilities of TMPD·p-CA and TMPD·p-BA versus temperature.
—·—·— χ_{dia}.

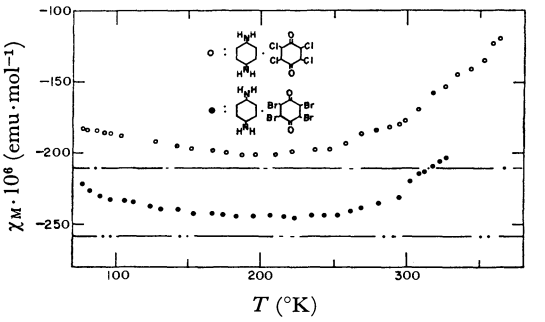

Fig. 3. Magnetic susceptibilities of PD·p-CA and PD·p-BA versus temperature.
—·—·—·—·— χ_{dia}.

The susceptibilities of TMPD·p-CA, TMPD·p-BA, PD·p-CA and PD·p-BA are plotted as a function of temperature in Figs. 2 and 3. The general feature of temperature dependence resembles each other. In a higher temperature region the susceptibility decreased with decreasing temperature, but it increased through a minimum in a lower temperature region. The diamagnetic contribution was evaluated by assuming that the susceptibility change in the lower temperature region was dominated by the paramagnetic susceptibility of an impurity which followed the Curie law.*3 The diamagnetic susceptibilities thus obtained are given in Table 3, which are in reasonable agreement with the sum of the values for neutral components. The intrinsic paramagnetic susceptibilities, after corrections for the diamagnetic and impurity parts were made, are plotted as a function of temperature in Figs. 4 and 5.

*3 The assumption seems to be plausible for the reasons mentioned in the following paragraph. It has, in fact, been supported for TMPD·p-CA by ESR experiments (Ref. 6).

Table 3. Diamagnetic parts of the complexes

Compound	χ_d(obs) $\times 10^6$ (emu/mol)	χ_d(calc) $\times 10^6$* (emu/mol)
TMPD·p-CA	−245	−238

PD·p-BA	(−259)	−221

* The sum of the values found for the neutral components given in Table 1.

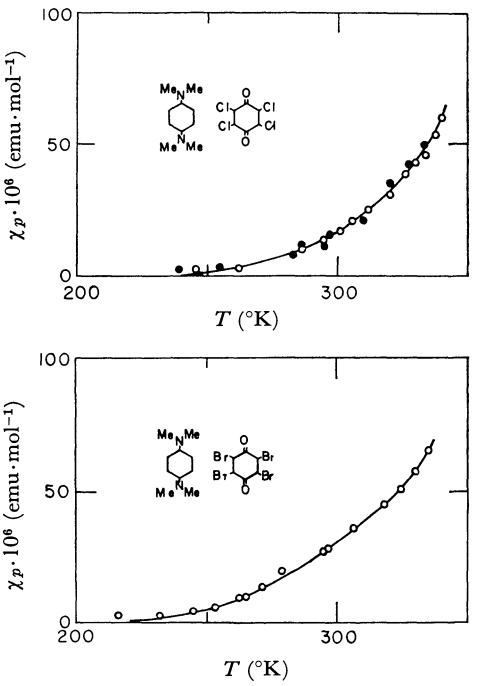

Fig. 4. Intrinsic paramagnetic susceptibilities of TMPD complexes.

The observed susceptibilities of a given complex exhibited slightly different values among the samples which had been prepared independently. The difference, however, was considered to be caused by a variation in the impurity content, since the difference in susceptibility was found to be proportional to $1/T$ within experimental errors. The intrinsic susceptibility determined after the above-mentioned corrections gave the same value for the different samples.

Electrton Spin Resonance. In order to obtain information on the origin of unpaired electrons, g-values were determined for powder samples by

ESR measurements at room temperature. The values are given in Table 4. A single exchange-narrowed absorption line was observed for the complexes; TMPD·*p*-CA, TMPD·*p*-BA, $TMPD_2 \cdot o\text{-}CA_3$ and $TMPD_2 \cdot o\text{-}BA_3$. An axially symmetric *g*-factor was observed with the *p*-phenylenediamine complexes, which is in agreement with the result obtained by Ottenberg, *et al.*[8] and Hughes and Soos.[9] The principal *g*-values were determined to be: $g_{\parallel}=2.0023$, $g_{\perp}=2.0056$ for PD·*p*-CA and $g_{\parallel}=2.0020$, $g_{\perp}=2.0087$ for PD·*p*-BA. The average value, $g_{av}=(g_{\parallel}+2g_{\perp})/3$, is given in Table 4*[4]

8) A. Ottenberg, C. J. Hoffman and J. Osiecki, *J. Chem. Phys.*, **38**, 1898 (1963); M. E. Browne, A. Ottenberg and R. L. Brandon, *ibid.*, **41**, 3265 (1964).

9) R. C. Hughes and Z. G. Soos, *J. Chem. Phys.*, **48**, 1066 (1968).

*[4] Static susceptibility data showed that the impurity paramagnetism contributed appreciably to the observed paramagnetic susceptibilities of TMPD·*p*-CA, TMPD·*p*-BA, PD·*p*-CA and PD·*p*-BA, but no separate ESR signal was observed at room temperature.

The *g*-values of the *p*-quinone complexes were found to be intermediate between the values of the components, while those of $TMPD_2 \cdot o\text{-}CA_3$ and $TMPD_2 \cdot o\text{-}BA_3$ were close to the *g*-value of Würster's blue ion ($TMPD^+$).

Absorption Spectra. The solid *p*-quinone complexes showed broad absorption bands as shown in Figs. 6 and 7. It was noted that the spectra of TMPD·*p*-CA and TMPD·*p*-BA resembled each other and also those of PD·*p*-CA and PD·*p*-BA.

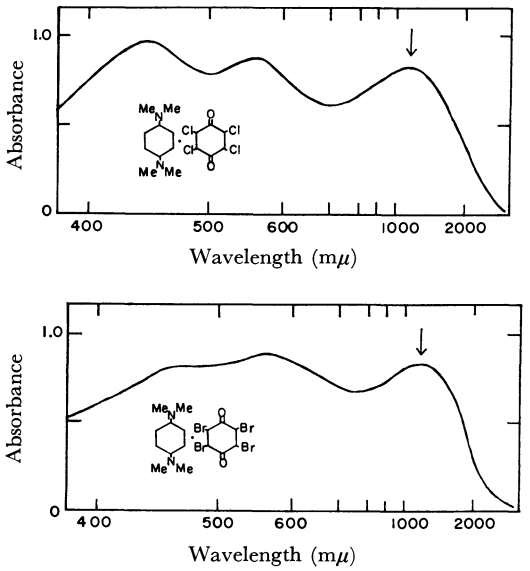

Fig. 6. Absorption spectra of solid TMPD·*p*-CA and TMPD·*p*-BA. Arrows indicate the charge-transfer bands.

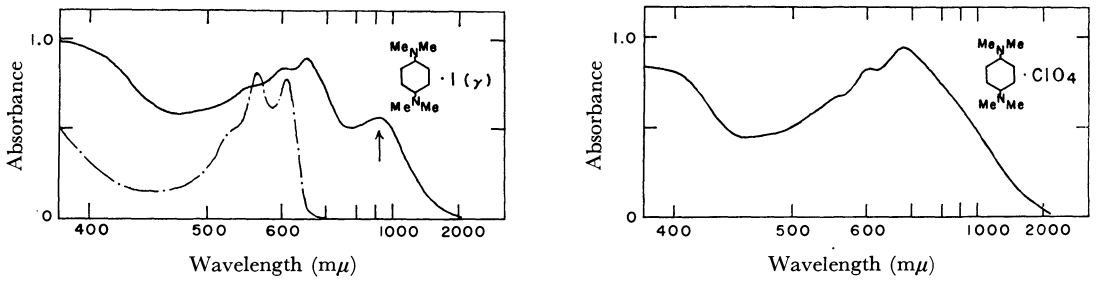

Fig. 9. Absorption spectra of TMPD·I (γ-form) and $TMPD \cdot ClO_4$.
——— Solid spectra, —·—·— $TMPD^+$ in CH_2Cl_2 solution

In contrast to the broad structureless bands of these complexes, $TMPD_2 \cdot o\text{-}CA_3$ and $TMPD_2 \cdot o\text{-}BA_3$ showed spectra in which the band around 600 mμ had a well-defined structure as seen in Fig. 8. In the observed region, the two spectra were identical as far as position and general features were concerned. For the purpose of comparison, the solid spectra of Würster's blue perchlorate ($TMPD \cdot ClO_4$) and Würster's blue iodide (TMPD·I, γ-form) are shown in Fig. 9. The spectrum of $TMPD \cdot ClO_4$ is in agreement with those observed by other investigators.[10–12] The positions of the absorption peaks are given in Table 5.

Discussion

$TMPD_2 \cdot o\text{-}TMPD_2 \cdot o\text{-}CA_3$. As evidenced by the strong paramagnetism, these complexes are considered to be fundamentally ionic, though they are expected to include a neutral quinone per formula unit. The observed value of the Curie constant indicates that there are only two free spins in a formula unit instead of four spins expected from the simple consideration that there are two monopositive $(TMPD)^+$ and two mononegative (o-CA^- or o-BA^-) ion radicals and a neutral quinone molecule per formula unit.

Table 5. Approximate positions of the absorption peaks of the solid spectra

	(mμ)
TMPD·p-CA	440, 550, 1200
TMPD·p-BA	460, 550, 1200
PD·p-CA	400, 445, 900
PD·p-BA	415, 445, 950
$TMPD_2 \cdot o\text{-}CA_3$	540, 595, 650
$TMPD_2 \cdot o\text{-}BA_3$	540, 595, 650
$TMPD \cdot ClO_4$	550, 600, 670
TMPD·I (γ-form)	550, 595, 650, 940

It is noted that the g-value of $TMPD_2 \cdot o\text{-}CA_3$ coincides with that of the monopositive ion of TMPD in $TMPD \cdot ClO_4$, and that of $TMPD_2 \cdot o\text{-}BA_3$ is close to this value. Moreover, the band structure around 600 mμ shows close resemblance with those found for $TMPD \cdot ClO_4$ and TMPD·I as compared in Figs. 8 and 9 and also in Table 5. It seems certain that the peaks are due to Würster's blue ion. Thus, it is concluded that the strong paramagnetism of these complexes is almost entirely due to $TMPD^+$ ion radicals. Since the neutrality condition requires the existence of negative ions, the question remains why the paramagnetic contribution from the quinone anion radicals is undetectable. Although no further attempts have been made to elucidate the question,*5 the following explanation is possible: 1) The cations and anions form separate column in the crystal. The cations are nearly free, while the anions are strongly coupled with each other due to the different manner of stacking in the columns. As a result, the cations contribute to paramagnetism strongly, while the

10) G. R. Anderson, *J. Chem. Phys.*, **47**, 3853 (1967).

*5 No detailed information on the quinone part was obtained from the absorption spectra of Fig. 8.

anions only slightly. 2) The anions exist in certain diamagnetic form, *e. g.*, as dinegative ions or as diamagnetic anions produced by chemical reaction. It is noted that the interaction between Würster's blue ions in these complexes is quite small, in fact the smallest among those observed for other Würster's blue ion radical salts.

Kainer and Überle[4] reported that the complexes formed from TMPD and *o*-quinones were 1:1 complexes. Although the absorption spectra were not explicitly shown, they described the same observations mentioned above, *i. e.*, the appearance of a band with structure in the visible region and the absence of absorption in the near-infrared region in contrast to the case of *p*-quinone complexes. Moreover, they observed strong paramagnetism which corresponded to only one spin per formula unit contrary to their expectation of two spins.[4,6] The highest radical concentration of 0.80 spins per unit of TMPD·*o*-BA in their report corresponds to 2.0 spins per unit of $TMPD_2$·o-BA_3. Therefore, their complexes also seem to have the composition 2 : 3 rather than 1 : 1.

TMPD·*p*-CA; TMPD·*p*-BA. Magnetic and optical data are in agreement with those reported by Kainer and Überle[4] and Pott and Kommandeur.[13] The absorption bands in the visible region are reasonably assigned to the intramolecular transitions of the ionized component molecules but not those of neutral components. For TMPD·*p*-CA, the bands at 550 and 440 mμ may be ascribed to $TMPD^+$ and p-CA^-, respectively, and for TMPD·*p*-BA, the bands at 550 and 460 mμ may be due to $TMPD^+$ and p-BA^-, respectively.*6 These complexes are therefore considered to consist of the amine monopositive and the quinone mononegative ions. The band at approximately 1200 mμ in each spectrum is assigned to the charge-transfer band as pointed out previously on the basis of the polarization spectrum.[14] de Boer and Vos[15] have revealed the alternant face-to-face stacking of $TMPD^+$ and p-CA^- molecules in the crystal. The interaction between D^+ and A^- is therefore thought to be important and the charge-transfer absorption should be ascribed to the transition of the type $|\cdots D^+A^-D^+A^-D^+A^-\cdots\rangle \rightarrow |\cdots D^+A^-D^0A^0D^+A^-\cdots\rangle$. The molecular stacking in TMPD·*p*-BA seems to be similar in view of the close resemblance of the magnetic and optical behavior.

The interpretation of the absorption spectra is consistent with the result from ESR measurements. The fact that the *g*-values of these complexes are close to the average *g*-values of the component ions indicates an equal contribution of the cation and anion radicals to the paramagnetism.[16] As will be discussed below, the static susceptibility data show that the spins in these complexes are coupled by rather strong antiferrromagnetic interaction of about 0.08 eV.

PD·*p*-CA; PD·*p*-BA. The absorption bands of these complexes in the visible region are also assigned to the intramolecular transitions of the amine monopositive and the quinone mononegative ions. The band in the near-infrared region in each spectrum may also be due to the charge-transfer interaction between D^+ and A^- ions.[14] The *g*-values of these complexes also indicate that the cations and anions contribute equally to paramagnetism.

Thus, the magnetic and optical properties of the complexes studied here are explained on the basis of the completely ionized component molecules in the ground state and strong antiferromagnetic interaction between D^+ and A^- ions. Moreover, it is noted that the charge-transfer bands of these complexes are strong. As a result, it is concluded that the correlation between the exchange coupling constant and the intensity of the charge-transfer band is also present in ionic donor-accepter complexes, in which the interaction between unlike molecules, D^+ and A^-, is important. This implies that the nature of the exchange interaction in D^+A^--type complexes is essentially the same as that in the previously studied D^+D^+-type or A^-A^--type complexes. It also suggests the importance of the charge-transfer stabilization of the singlet ground state in the determination of the observed values of exchange coupling constant. The same argument may also hold for the molecular complexes of diaminodurene-chloranil[17] and TMPD-tetracyano-*p*-quinodimethane.[18]

Temperature Variation of Exchange Coupling Constant

The values of exchange coupling constant (J) can be evaluated by comparison of the intrinsic paramagnetic susceptibilities with a theoretical model; the singlet-triplet model or the linear Ising model. For $TMPD_2$·o-BA_3 and $TMPD_2$·o-CA_3, the exchange coupling constants were fairly small, being estimated to be $J \leq 4\times10^{-4}$ eV from the observed Weiss constant of 0 ± 5°K. For the complexes containing *p*-quinones, the values of J were evaluated by two methods. The apparent activation energy E, expressed in the formula

$$\chi_p = (C/T)\exp(-E/kT) \qquad (1)$$

was obtained by plotting $\log(\chi_p T)$ against $1/T$. In

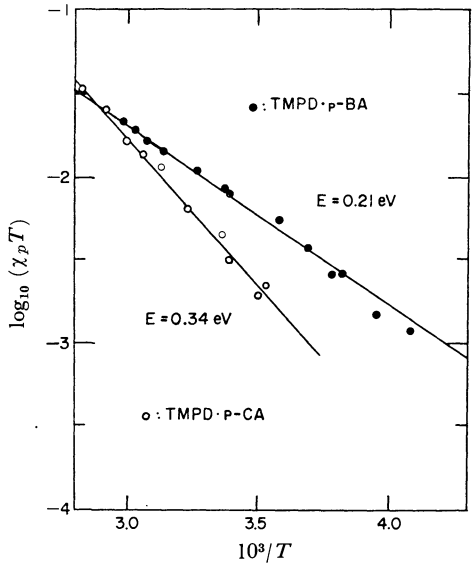

Fig. 10. Plots of log $\chi_p T$ against $1/T$ for TMPD·p-CA and TMPD·p-BA.

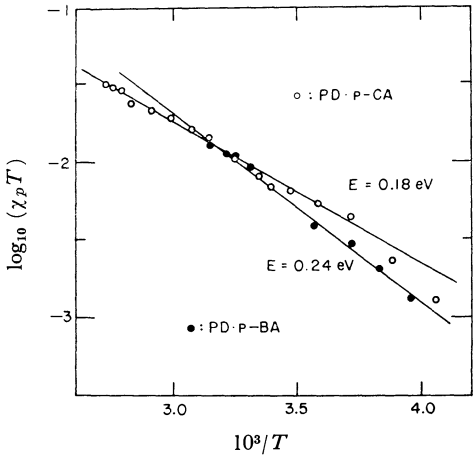

Fig. 11. Plots of log $\chi_p T$ against $1/T$ for PD·p-CA and PD·p-BA.

the case of the singlet-triplet model, E corresponds to the energy separation $\delta(=2J)$ between the singlet ground state and the thermally accessible triplet state ($E=\delta$), and in the case of the linear Ising model it corresponds to J ($E=J$). The plots of $\log(\chi_p T)$ against $1/T$ are shown in Figs. 10 and 11. Direct comparison of experimental data with theoretical curves, by finding the best fit, also gives the value of J. The singlet-triplet model with $\delta=0.15$ eV accounted for the experimental plots for TMPD·p-BA and PD·p-CA fairly well. The susceptibility rise for TMPD·p-CA and PD·p-BA, however, was so steep that neither of the models could explain the result. For a closer study, we calculated the values of J at several points of temperature by comparing the experimental susceptibilities with the theoretical ones. The results

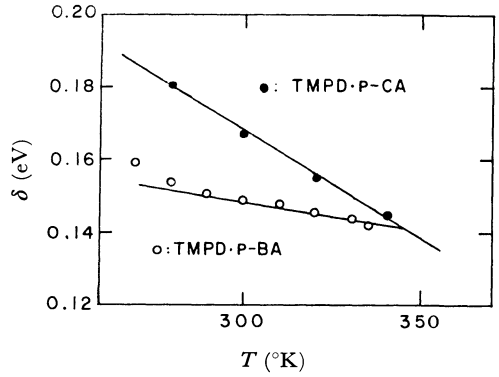

Fig. 12. Temperature variations of the singlet-triplet separation δ ($=2J$) for TMPD·p-CA and TMPD·p-BA.

Table 6. Temperature variations of exchange coupling constants

	δ_0 ($=E$) (ev)	δ(eV) at 300°K	α(ev/°K)	$\delta_0+\alpha T$ at 300°K	J(eV) at 300°K
TMPD·p-CA	0.34	0.17	-6.0×10^{-4}	0.16	0.09
TMPD·p-BA	0.21	0.15	-1.8×10^{-4}	0.16	0.08
PD·p-CA	0.18	0.15	-0.8×10^{-4}	0.16	0.08
PD·p-BA	0.24	0.15	-4.4×10^{-4}	0.11	0.08

obtained with the singlet-triplet model are shown in Figs. 12 and 13. It appears that δ is a linear function of temperature and that the temperature variation is small for TMPD·p-BA and PD·p-CA, and quite large for TMPD·p-CA and PD·p-BA. The values of δ obtained by the above procedures are given in Table 6. The largest difference between E and δ is noted for TMPD·p-CA, *i. e.*, $E=0.34$ eV and $\delta=0.17$ eV at 300°K.

If δ is a linear function of temperature, we may write

$$\delta = \delta_0 + \alpha T \qquad (2)$$

where δ_0 and α are constants. The slope of the

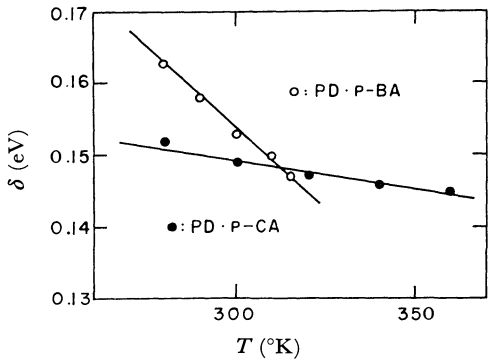

Fig. 13. Temperature variations of the singlet-triplet separation δ ($=2J$) for PD·p-CA and PD·p-BA

plot of $\log(\chi_p T)$ against $1/T$ gives δ_0 rather than δ itself. Therefore, we put $E=\delta_0$ and see if the large discrepancy between E and δ may be explained by relation (2). The values of α are obtained from the slopes of the straight lines shown in Figs. 12 and 13. The agreement between δ and $\delta_0+\alpha T$ is good as seen from Table 6, which indicates that δ decreases linearly with temperature. It would be appropriate therefore to employ the values of $J(=\delta/2)$ given in the last column of Table 6, *i. e.*, approximately 0.08 eV for all these complexes. If the linear Ising model is employed, a larger value of about 0.11 eV is obtained. It seems that the large effective change in the exchange coupling constant found for TMPD·*p*-CA and PD·*p* BA suggests the temperature variation of intermolecular interactions associated with variation in intermolecular distance. For TMPD·*p*-CA it may be related to the gradual phase transition suggested by Pott and Kommanduer.[13]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2377—2380 (1970)

Electron Spin Resonance of Oxidized ZnO at −195°C

Morio SETAKA, Shigeaki FUJIEDA and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received February 14, 1970)

An asymmetric ESR spectrum of ZnO at the g value of 1.96 was found to split into $g=1.957$ and 1.963 components at −195°C provided that ZnO was pretreated with oxygen. Temperature dependence of these two signals as well as the effect of doping Al^{3+} or Li^{+} on their intensities were investigated to qualify these signals. It was suggested that the $g=1.957$ signal is correlated with conduction electrons while the $g=1.963$ signal is ascribable to electrons trapped at interstitial zinc ions. The ZnO sample also gave rise to another signal at $g=2.013$ at −195°C. The signal was attributed to holes in the bulk.

As has been recognized by numerous workers, a highly outgassed ZnO sample produces a broad and asymmetric ESR spectrum around the g value of 1.96 at room temperature.[1] While this signal has been interpreted as due to electrons in the bulk, some detailed arguments were previously made concerning the origin of the electrons.[2] Recently, Codell *et al.*[3] reported that the signal splits into two components ($g=1.961$ and 1.965), when ZnO is pretreated with tertiary butyl hydroperoxide vapors and subjected to ESR mesurements at −195°C. During the course of our work,[4] we have also recognized that the $g \sim 1.96$ signal is replaced by a doublet at −195°C in accordance with the report of Codell *et al.* with respect to a ZnO sample pretreated with O_2. A similar phenomenon was reported more recently by Iyengar *et al.*[5] who pretreated ZnO with N_2O, NO or Cl_2 at 25°C.

In view of these results, it was felt necessary to further investigate the nature of the two component signals and to elucidate the relationship between the $g \sim 1.96$ signal and the two components. Since doping of ZnO with Al^{3+} or Li^{+} is expected to control the concentration of electrons or interstitial zinc in the bulk, it should be interesting to investigate ESR spectra of the doped ZnO samples and to see how the $g \sim 1.96$ signal is modified at −195°C. On the other hand, we have already noted that another signal appears at $g=2.013$ which is distinguishable from that due to adsorbed O_2^- ($g=2.002$, 2.008, 2.051)[4] when an oxidized ZnO is subjected to ESR measurement at −195°C. Undoubtedly, there still remains a question of interest on the ESR spectra of ZnO especially at low temperatures. In the present paper the results of such ESR investigations are reported using Al^{3+} or Li^{+} doped ZnO and undoped one, respectively.

Experimental

ZnO of high purity (Pb: 0.003%, Fe: 0.0001%, other metal: 0.01%) supplied by Sakai Chemical Co., was used for experiments. ZnO samples doped with Al^{3+} or Li^{+} were prepared as follows. A powdered ZnO was slurried with dilute aqueous solution of $Al(NO_3)_3 \cdot 9H_2O$ (Guaranteed, Kanto Chemical Co.) and $LiNO_3$ (Guaranteed, Koso Chemical Co.) respectively and dried at 100°C. It was then calcined in air at 500°C for two hours and at 700°C for another hour. The degree of doping was so adjusted that 1.5 mol percent Li_2O or Al_2O_3 is incorporated. Li_2CO_3 was also used instead of $LiNO_3$ to investigate the effect of anion. No difference was found, however, between the two anions.

ESR measurements were made at room temperature and −195°C respectively using a JEOL-P-10 type spectrometer (X-band, 100 kcps field modulation). ZnO samples were placed in a quartz tube (4 cm long, 4 mm id), at the center of which a sealed capillary containing MgO : Mn^{2+} was inserted as a means of measuring relative ESR sensitivity. The spin concentrations of ESR signals were determined by the first moment of the derivative absorption curve, normalized with the intensity of Mn^{2+} signal which was calibrated at room temperature and −195°C with a solution of DPPH (5×10^{-5}M) in benzene substituted for the ZnO sample.

Results and Discussion

Pretreatment of vacuum outgassed ZnO with a small amount of oxygen at room temperature usually results in a decrease in the ESR spectral intensity of the $g \sim 1.96$ signal without perceptible change in its signal shape.[4] Such a spectrum observed at room temperature is illustrated in Fig. 1-a. It was found, however, that the signal is replaced by two *components* ($g = 1.963 \pm 0.001$ and 1.957 ± 0.001) as shown in Fig. 1-b when measured at −195°C. Further pretreatment of the ZnO with 30 Torr O_2 at 200°C for 30 min, followed by evacuation at room temperature, gave a spectrum of Fig. 1-c at −195°C. It is apparent from Figs. 1-b and 1-c that the spin concentrations of the $g = 1.963$ component markedly decrease with the oxygen pretreatment or oxidation of the ZnO sample, while the $g = 1.957$ signal remains nearly constant.

We shall start with a raw ZnO sample (no pretreatment) and investigate how the spin concentrations of the two signals vary with successive oxygen pretreatments of the sample. The untreated ZnO sample showed only the $g = 1.957$ signal when measured at −195°C in a vacuum (stage 1) which we have called so far the $g \sim 1.96$ signal. The ZnO sample was then outgassed at 500°C in a high vacuum for 30 min and then allowed to contact with 30 Torr O_2 at room temperature. The sample was then evacuated for residual oxygen at room temperature and subjected to ESR measurements at −195°C (stage 2). It was found that the original $g = 1.957$ signal is accompanied by the $g = 1.963$

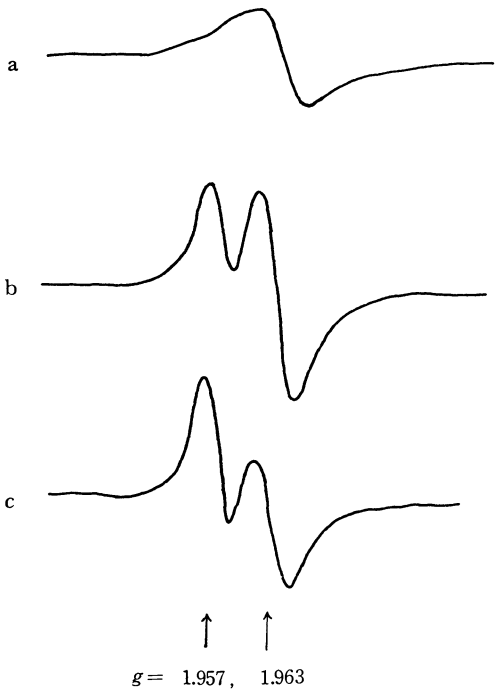

Fig. 1. ESR spectra of ZnO pretreated with oxygen measured at room temperature (a) and −195°C (b, c).

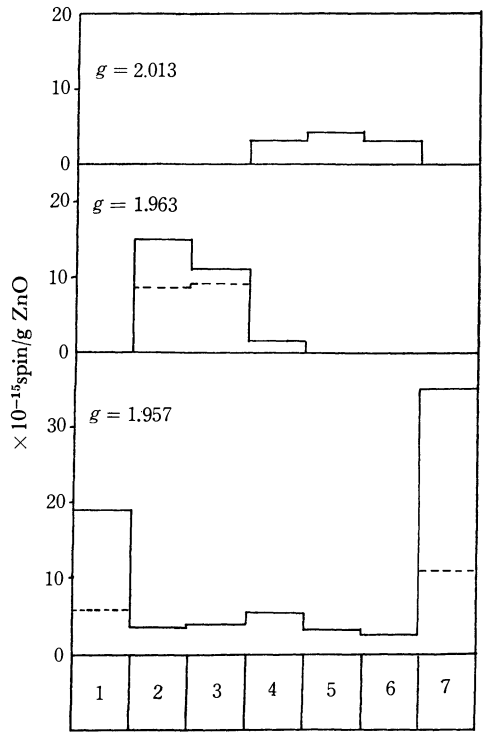

Fig. 2. Effect of successive pretreatments of ZnO on ESR signals. Dashed line indicates spin concentrations at room temperature.

signal; the $g \sim 1.96$ signal was now replaced by the $g=1.957$ and 1.963 signals as already shown in Fig. 1-b.

Changes in the spin concentrations of the two signals were further investigated by treating the ZnO sample at higher temperatures under 30 Torr oxygen (200, 350 and 500°C for stage 3, 4 and 5 respectively). It was found in this way that the $g=1.963$ signal entirely disappears by heat treatment above 350°C whereas the $g=1.957$ remains quite stable up to 500°C. The ZnO sample at stage 5 was kept at room temperature for 5 days (stage 6) where little change was observed in signal intensity. The growth or decay of the two signals with heat treatment in ambient oxygen is illustrated in Fig. 2, where annexed figures 1—6 indicate successive stages for pretreatment. It is apparent from Fig. 2 that the $g=1.957$ and 1.963 species are energetically different.

In stage 7, the ZnO sample was allowed to contact with water vapor. As a result, the 1.957 signal increased to a remarkable extent while the 1.963 signal remained unaffected. As the electric conductivity of ZnO increases on adsorbing water vapor[6] and dereases on adsorbing oxygen, the growth or decay of the 1.957 signal, as demonstrated in Fig. 2, should be correlated with the change of the concentration of conduction electrons in the bulk of ZnO.

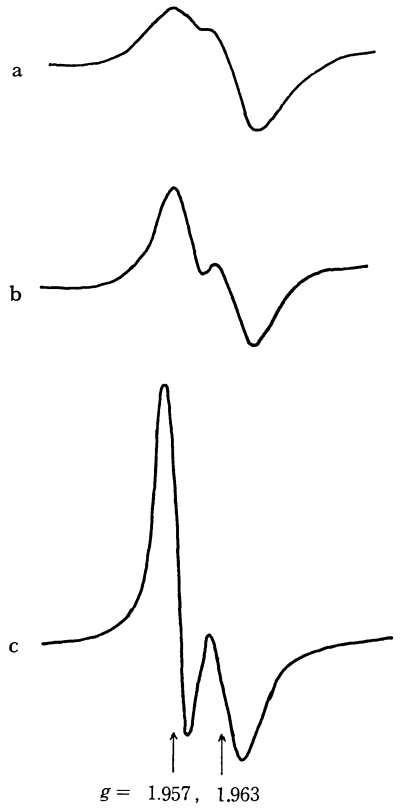

Fig. 3. ESR spectra of ZnO pretreated with oxygen measured at −100°C (a), −150°C (b) and −195°C (c).

Figure 3 indicates the temperature dependence of the $g=1.957$ and $g=1.963$ signals for the ZnO pretreated with 30 Torr O_2 at 200°C for 30 min. ESR measurements were carried out at −100°C (a), −150°C (b) and −195°C (c) respectively. According to Fig. 3, the $g=1.957$ species seems to be more temperature dependent than the $g=1.963$ species. This suggests that the $g=1.957$ species is originated from lower energy levels.

It is generally accepted[7] that Al^{3+} doped ZnO contains more electrons than an undoped one:

$$\text{ZnO crystal} + Al_2O_3 \rightleftarrows 2Al^{3+} + 2\ominus + 2ZnO + 1/2O_2$$

Conversely, Li^+ doped ZnO contains less electrons:

$$\text{ZnO crystal} + LiO_2 \rightleftarrows 2Li^+ - 2\ominus + 2ZnO - 1/2O_2$$

Attempts were made, therefore, to investigate the behavior of the $g=1.957$ signal with Al^{3+} and Li^+ doped ZnO samples respectively. The doped ZnO samples with or without oxygen pretreatment were subjected to ESR measurements at −195°C. It was found, as shown in Table 1, that the $g=1.957$ signal increases with Al^{3+} doped ZnO while it vanishes completely with Li^+ doped ZnO irrespective of pretreatment. The result is qualitatively in accord with the above equations, *viz*, the $g=1.957$ signal could be attributable to electrons whose behavior is largely in parallel with that of conduction electrons.

Table 1. Spin concentrations ($\times 10^{-15}$ spin/g) of the $g=1.957$ and 2.013 signals

Sample	Pretreatment	$g=1.957$	$g=2.013$
Al-ZnO	A	270	0
	B	120	0
Li-ZnO	A	0	7
	B	0	6

A: Sample evacuated at room temperature.
B: Sample heated at 500°C under 100 Torr of oxygen for 30 min.

Generally speaking, ZnO may contain cation and anion vacancies and many other defects which act as acceptors or donors. Electrons in the bulk of ZnO are expected to be either in the conduction band or localized in donor states, *e.g.*, interstitial Zn_i^+ ion, or trapped at oxygen ion vacancies. Oxygen ion vacancies are considered to be stable

6) H. Hasebe and A. Inoue, *Nippon Kagaku Zasshi*, **87**, 332 (1966).

7) G. Heiland, E. Mollwo and F. Stockmann, "Solid State Physics," Vol. 8, Academic Press, Inc., New York (1959), p. 191.

below the Tamman temperature of ZnO[8] (900°C) and may capture electrons produced upon Al^{3+} doping. Thus the electrons trapped at the oxygen ion vacancies could also contribute to the signal $g=1.957$. Interstitial Zn_i^+ ions are known[9] to be rather labile and may disappear completely upon heating at 550°C for a few minutes in air. It appears, therefore, that electrons responsible for $g=1.957$ may not correspond to the interstitial zinc ions. The thermal behaviour of the $g=1.963$ signal, on the other hand, seems to be consistent with that of Zn_i^+ ions; electrons responsible for the $g=1.963$ signal could be localized at these defects. However, another possibility that the $g=1.963$ signal is due to electrons trapped at the oxygen vacancies near surface[8] may not be excluded. The trapping site near the surface would be distorted to a greater extent as compared with that in the bulk, leading to a slight shift in their g values.

During the course of the above measurements the ESR spectra were accompanied with another signal at the g value of 2.013 ± 0.001. The signal does not seem to be due to contaminated impurities such as Fe^{3+} in ZnO[10] ($g=2.0056$, 2.0041) but due to intrinsic defects in ZnO. In Fig. 2, changes in the spin densities of the 2.013 signal in the successive stages were also illustrated. As shown in stage 7, the $g=2.013$ signal completely disappeared when water vapor was adsorbed on ZnO. It should be noted that the direction of change is opposite to that of the $g=1.957$ signal. This fact may suggest that the $g=2.013$ signal originates from holes in acceptor levels. The supposition is consistent with the experimental result obtained with doped ZnO samples; as shown in Table 1, Li^+ doped ZnO, that is expected to contain *holes*, definitely gave rise to the $g=2.013$ signal while it was absent with Al^{3+} doped ZnO. The $g=2.013$ signal showed no dipolar broadening at high pressures of oxygen, suggesting that it is a bulk species. It would be interesting to investigate whether or not the $g=2.013$ species are correlated with the zinc ion vacancies as suggested by Matsushita and Nakata[11] from their studies on the infrared absorption spectroscopy of a ZnO sample.

The authors gratefully acknowledge the informative discussion with Dr. Y. Fujita of this Laboratory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2381—2385 (1970)

Electrical and Optical Behaviour of Tetrathionaphthacene at High Pressures

Ichimin SHIROTANI, Kaoru KAWADA and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received February 14, 1970)

The temperature dependence of the electrical resistance and the absorption spectra for tetrathionaphthacene (T.T.N.) have been studied at high pressure. It has been found that the intrinsic conduction level, which does not correspond to the observed optical transition, is located about 2 eV above the valence band. The red shift of absorption peaks with the pressure was much smaller than the contraction of the intrinsic band gap. The existence of the intrinsic conduction level is supported by the fact that the minimum of the photoemission yield arising from electron-pair production is located about 2 eV above the threshold point. The band gap of 0.4—0.62 eV previously observed seems to correspond to an acceptor level formed by chemical impurities.

Certain types of impurities and imperfections drastically affect the electrical properties of organic semiconductors. Adsorbed oxygen, as one kind of impurity, is known to modify strongly the semi- and photo-conduction of organic crystals.[1,2] For example, the semiconduction of the quaterrylene*1 film is especially sensitive to oxygen.[1] Under atmospheric circumstances, this compound is a p-type semiconductor due to an oxygen impurity level which lies 0.6 eV above the valence band. The intrinsic energy gap, observed under a high vacuum or at a high temperature, is 1.7 eV. The effect of the pressure on these energy gaps has already been studied.[3]

Tetrathionaphthacene (T.T.N.) has a low electrical resistivity, 10^4 Ωcm at room temperature. This observed value is very low when compared with others in the group of polycyclic aromatic semiconductors. Matsunaga has suggested that this anomalously low value is due to the presence of a small quantity of positive tetrathionaphthacene ions formed by oxidation with air.[4] However, no abrupt change in the electrical properties of this compound occurred when oxygen was adimitted to a sample stored in a high vacuum of 10^{-8} mmHg. Therefore, the effect of oxidation with air on the electrical resistivity may be disregard.[5] Though the activation energy and the electrical resistance of the microcrystals decrease with an increase in the pressure, these properties are not very sensitive to pres-

sure.[6] The anomalous electrical behaviour may arise from the chemical impurities. We have studied the temperature dependence of the electrical resistance of tetrathionaphthacene (T.T.N) at high pressures and have found the intrinsic energy gap, near 2 eV. In this report, the intrinsic conduction level of tetrathionaphthacene will be discussed.

Experimental

A tetrahedral anvil-type high-pressure apparatus similar to those described by Hall was used for this study. The present apparatus consisted of four 250-mm hydraulic rams, with 20-mm triangular tungsten carbide anvils, which were driven together simultaneously on a pyrophyllite-tetrahedron sample assembly with an edge length of 25 mm. Figures 1 (a) and 1(b) illustrate the sample assembly used for the electrical-resistance measurements. The temperature was measured with a chromel-alumel thermocouple. A tublar graphite furnace was placed nearly at the centre of gravity of the pyrophyllite-tetrahedron and was used for heating the sample. The electric power was supplied to the graphite furnace through molybdenum tabs which made contact with the faces of a pair of anvils. The sharp changes in the electrical resistances of Bi(I—II, 26 kbar),*2 Tl(II—III, 37 kbar), and Ba(I—II, 55 kbar) at their phase transitions were used to calibrate the pressure applied to the pyrophyllite-tetrahydron. The details of the high-pressure technique have already been reported.[7]

Tetrathionaphthacene ($C_{18}H_8S_4$) was provied by Matsunaga. This sulphur compound was purified by recrystallisation from trichlorobenzene and also by fractional sublimations (three times). The sample was studied as a powder which was fused into flat platelets by applied pressure.

The absorption spectra were measured by using a Shimazu SV-50A spectrophotometer. The thin tetrathionaphthacene film was grown on a glass plate by sublimation in a vacuum. The high-pressure optical cell has been described elsewhere.[3] A hydrostatic pressure up to 7 kbar was applied by means of a pressure-transmitting medium through a pressure-intensifier. The pressure was determined by a Harwood manganine resistance gauge and a Heise Bourdon tube gauge.

Results

Figure 2 shows the relation between the logaithm of the electrical resistance and the reciprocal temperature for the compressed tetrathionaphthacene at 30 kbar. For temperatures less than 340°C the impurity conduction was dominant. The temperature range of 340—400°C was the intrinsic conduction region. The sample seems to melt about 410°C. Above 430°C the electrical resistance of the compound increased slowly with an increase in the temperature; the chemical reaction must, then, occur. The behaviour of the curve was reproducible for temperatures below 400°C at high pressures.

Under 30 kbar the energy gap calculated from the temperature dependence of the conductivity over the temperature range of 300—613°K was 0.61 eV. This is assumed to be an extrinsic energy gap and is denoted as E_a. On the other hand, the energy gap from the temperature-conductivity relation, shown in Fig. 2, at 613—673°K was 1.62 eV at the same pressure. This energy gap, E_g, is considered of to be the intrinsic one. Figure 3 shows the plots of E_g and E_a as functions of the pressure. E_g decreased remarkably with an increase in the pressure. However, E_a was less affected by the pressure. If the relation between the energy gap and the applied pressure is assumed to be linear,*3 the extrapolated value of intrinsic gap at atmospheric pressure is about 2 eV. Table 1 shows the values of E_g and E_a at high pressures. From Fig. 3, we can find that the values of E_a and E_g decrease with an increase in the pressure at the rates of:

$$\left(\frac{dE_g}{dp}\right)_T \cong -15\times10^{-3} \quad \text{eV/kbar} \qquad (1)$$

and:

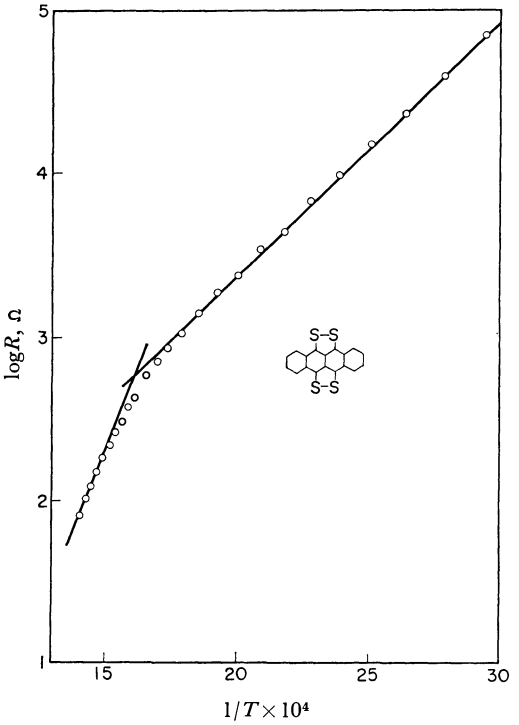

Fig. 2. The electrical resistance of tetrathionaphthacene as a function of temperature at 30 kbar.

6) I. Shirotani, H. Inokuchi and S. Minomura, *ibid.*, **39**, 386 (1966).

*2 The phase transition from Bi(I) to Bi(II) occurres at 26 kbar.

7) S. Akimoto and H. Fujisawa, *J. Geophys. Res.*, **70**, 443, 1969 (1965).

*3 For quaterrylene, E_g and E_a are proportional to the pressure, at least up to 50 kbar.

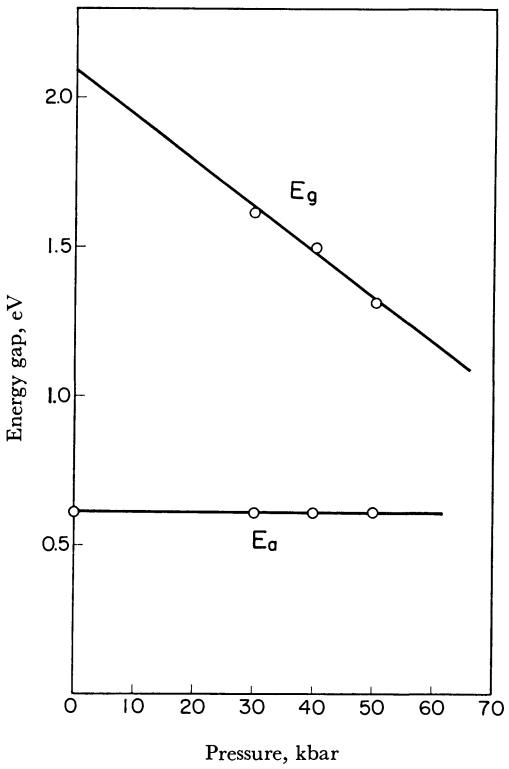

Fig. 3. The pressure dependence of the energy gaps.

$$\left(\frac{dE_a}{dp}\right)_T \cong 0 \qquad \text{eV/kbar} \qquad (2)$$

It is interesting to note that the pressure dependence of E_g is larger than that of E_a. Similar behaviour has already been found in the quaterrylene crystal.[3]

Figure 4 shows the pressure dependence of the electrical resistance at room temperature and at 360°C. The electrical resistance in the extrinsic region was insensitive to pressure, but the intrinsic resistance rapidly decreased with an increase in the pressure. These phenomena, as is shown in Fig. 3, are due to the pressure depencence of the energy gaps. Since the mobility of the charge carrier in the crystal is not so sensitive to applied pressure, the large increase in the conductivity at high pressures is mostly due to the great increment in the concentration of the charge carriers.[6]

Table 1. The pressure dependence of the thermal energy gaps of tetrathionaphthacene

Pressure (bar)	E_g (eV)	E_a (eV)

TABLE 2. THE RED SHIFT OF THE OPTICAL ABSORPTION PEAK FOR TETRATHIONAPHTHACENE AND NAPHTHACENE

Compound	Absorption peak mμ	Shift per unit of pressure 10^{-3} eV/kbar
Tetrathionapthacene	476	− 2.2
	680	− 2.6
	763	− 4
Naphthacene	471	− 9.4
	521	−13.4

an increase in the pressure. Table 2 illustrates the average rate of the red shift of the absorption spectra for T.T.N. and naphthacene. The values of the pressure shift for T.T.N. were much smaller than that of ordinary aromatic hydrocarbons.[8] The energy shift was approximately proportional to the applied pressure. The small red shift of T.T.N. should be noted.

Discussion

The pressure coefficient for the optical-energy gaps of such inorganic semiconductors as silicon and germanium agrees with the value determined by measuring the intrinsic resistivity as a function of the pressure.[9] In the case of the molecular crystal, similar behaviour has been observed in the absorption spectra of quaterrylene ($C_{40}H_{20}$); the rate of the red shift of the peak at 760 mμ which corresponds to the absorption peak in the solution-state spectrum, agrees approximately with that of the contraction of the thermal-energy gap. This behaviour may be useful in analyzing the mechanism of the carrier generation in quaterrylene crystal.[3]

The absorption peaks in the 575—700 mμ region observed in the benzene solution spectrum may be due to the lowest-singlet excitation of the tetrathionaphthacene molecule. The crystalline spectrum of T.T.N. corresponds to the spectrum of the free molecule, though a spectral red shift and broadening were observed. The 630, 680, and 760 mμ peaks in the film spectrum may form an exciton band arising from this lowest molecular excitation. As has been stated earlier, it was found, from the temperature dependence of the electrical resistance that the intrinsic energy gap was about 2 eV. This thermal-energy gap did not correspond with the absorption band of the T.T.N. evaporated film. As is shown in Eq. (1) and in Table 2, the red shift of the absorption peaks was very small compared with the contraction of the thermal-band gap. This suggests that the absorption band observed on evaporated film is the singlet-exciton state.

The photoconductance of anthracene crystals in the ultraviolet region (250—400 mμ) has also been investigated.[10,11] Castro and Hornig observed a peak in the photocurrent at 280 mμ which does not correspond to any known optical transition.[10] The magnitude of the 280 mμ electron photocurrent was relatively insensitive to the condition of the crystal surface. Therefore, they pointed out that the intrinsic conduction band is located in anthracene at about 4.4 eV. In the case of the tetrathionaphthacene crystal, the study of the photocurrent spectral-response curve was very difficult because of the large dark conductivity.[12] However, if the photocurrent curve can be investigated, the peak of the photoconductivity may be located near 2 eV.

The photoemission from polycyclic aromatic crystals in the vacuum ultraviolet region has also been studied.[13] Figure 6 shows the spectral distri-

bution of the photoemission yield for T.T.N. The decrease in the yield has a minimum around 2 eV above the threshold of 4.55 eV. Kochi *et al.* have suggested[14] that this decrease in the photoemission yield arises from pair-production scattering*4 and that the threshold near 2 eV for the pair production for T.T.N. corresponds to the intrinsic-band gap. This experimental result supports the idea that the energy gap obtained from conductivity measurements under high pressure, above 2 eV, is an intrinsic one.

The inner heat of the sublimation of T.T.N. is about 36 kcal/mol. As is shown in Table 3, the sublimation energy for T.T.N. ($C_{18}S_4H_8$) and four aromatic hydrocarbons of 22 carbons is of the same order.[15] These results show that the cohesive energy of the sulphur compound is not much larger than that of aromatic hydrocarbons. The spectral red shift of the crystalline T.T.N. relative to the solution spectrum was quite small; further, the energy shift was not so sensitive to the pressure. In view of these points, the molecular interaction between T.T.N. seems to be weak. However, the electrical resistivity of this compound is quite low under atmospheric pressure. The anomalous electrical behaviour arises from the chemical impurities. Judging the photoemission data,[13] the band gap of 0.4—0.62 eV previously observed[4,5] seems to correspond to an acceptor level formed by the impurity.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2386—2389 (1970)

Surface Properties of the System SiO_2-Al_2O_3 prepared by the Hydrolysis of Metal Alkoxides

Hiroyoshi MURAYAMA and Kenjiro MEGURO

Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received February 16, 1970)

The mixtures of aluminum *s*-butoxide and silicon ethoxide in different molar ratio were hydrolyzed in aqueous alcohol. The precipitates were dried, and the growth and transformation of the crystals at calcination were estimated by X-ray diffractometry. The surface properties of the oxide powder were studied by means of the heats of immersion and the adsorption of nitrogen, water vapor and ammonia. The samples calcined at 500°C have surface areas 260—600 m^2/g. Heats of immersion and surface hydrophilicity with respect to the composition, from pure silica gel to pure alumina, have a fairly good resemblance to each other, but this is not found between the heats of immersion and surface acidity.

In the preceding paper,[1] we reported surface properties of the system Al_2O_3-TiO_2 prepared by the co-hydrolysis of metal alkoxides under ion-free conditions. The study of surface properties of silica-aluminas is extremely important and interesting from a catalytic point of view.[2-5] However, few investigations have been reported on the surface properties of amorphous silica-aluminas[6-8] obtained from metal alkoxides.

In the present paper, an investigation of the surface properties of silica-aluminas produced by hydrolysis of silicon ethoxide and aluminum *s*-butoxide under ion-free conditions is reported.

Experimental

Materials. The products of hydrolysis of metal alkoxides are usually free from ionic impurities.[9-12] It is therefore advantageous to use the co-hydrolysis of aluminium *s*-butoxide and silicon ethoxide, purified by distillation, to obtain ion-free silica-aluminas. Excess aqueous ethanol was poured, with vigorous stirring, into the various mixtures of these alkoxides in *n*-butanol. Stirring was continued for 15 hr at a temperature near boiling point. The precipitate was separated by centrifuging, thoroughly washed with alcohol (by decantation) to remove undecomposed alkoxides, finely ground, and then dried at 100°C until the residual pressure of gas was less than 10^{-5} Torr. Hydrolysis of these alkoxides was confirmed by infrared analysis. The dried products were calcined for 2 hr at temperatures 100—1000°C, and the resulting samples were kept in a desiccator. The compositions of the samples determined by means of X-ray fluorescence were 0, 35.0, 64.0, 80.5, 89.6, and 100 in weight percent ratio $Al_2O_3/(Al_2O_3+SiO_2)$, respectively.

Apparatus and Procedure. The compositions of all the samples were determined by means of X-ray fluorometry with a Rigaku Denki X-ray vacuum spectrograph.[6] The analyser crystal was ethylenediamine ditartrate. The Cr-target was adjusted at 45 kV, 22 mA (for Al) and 45 kV, 12 mA (for Si). The X-ray radiation was detected by a proportional counter (90% Ar+10% CH_4) and discriminated as follows: for Al, base line 35/1000, channel width 100/100; for Si, base line 70/1000, channel width 100/100.

The differential thermal analysis curves were obtained with an automatically recording instrument, and the rate of heating was 10°C per minute. X-Ray diffraction patterns were obtained with a Geigerflex X-ray diffractometer of Rigaku Denki Co. The setting of the instrument was 35 kV, 15 mA for radiation on the target Cu$K\alpha$.

measurement and the experimental techniques used were the same as previously described.[13] The calorimeter was the isoperibol type equipped with a thermistor temperature sensing element. All measurements were carried out at 25±0.1°C in water with samples evacuated at 100°C for 1 hr at 10^{-5} Torr before immersion.

Adsorption isotherms were determined at −195°C, 25°C and 260°C for nitrogen, water vapor, and ammonia, respectively, by using a conventional volumetric gas adsorption apparatus. For the water vapor adsorption the apparatus was maintained at 25±0.5°C in air thermostat. Each sample for water vapor adsorption was outgassed at 100°C for 1 hr at 10^{-5} Torr to remove physically adsorbed water and cooled to 25°C prior to the adsorption studies.

Results and Discussion

(i) Bulk Properties. The typical experimental results of X-ray analysis on the samples treated at different temperatures and the differential thermal analysis curve of the 0% ($Al_2O_3/Al_2O_3+SiO_2$) sample, that is pure silica gel, are illustrated in Fig. 1. The pure alumina, 100% ($Al_2O_3/Al_2O_3+SiO_2$) sample, is the same sample used in the previous study.[1] X-ray diffraction patterns of the 100% Al_2O_3 sample heated at 500°C for 2 hr possess only very few faint lines of γ-Al_2O_3. On the other hand, all other samples calcined for 2 hr at 500, 600, 700, and 800°C are amorphous to X-ray, as can be seen from the results given in Fig. 1.

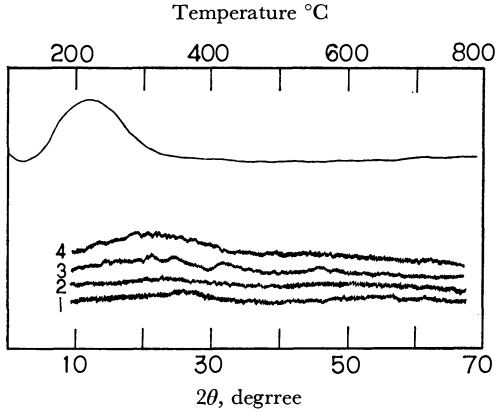

Fig. 1. X-Ray diffraction patterns at different temperatures (1: 100°C, 2: 500°C, 3: 800°C, 4: 1000°C) and differential thermal analysis curve of 0% ($Al_2O_3/Al_2O_3+SiO_2$) sample, that is pure silica gel.

Pure silica gel, 0% ($Al_2O_3/Al_2O_3+SiO_2$) sample, gives a differential thermal analysis curve which is characterized by the presence of a broad exothermic peak between 150—300°C, and a small endothermic peak at 120°C (Fig. 1). The first peak results from the loss of physically adsorbed water, and the last exothermic peak is attributed to the oxidation of chemically adsorbed butanol. The differential thermal analysis curves of other silica-alumina samples studied shows analogous features.

Changes of the surface properties of the system Al_2O_3-SiO_2 with composition were confirmed on these samples calcined at 500°C for 2 hr. Samples calcined below 500°C retain residues of butanol

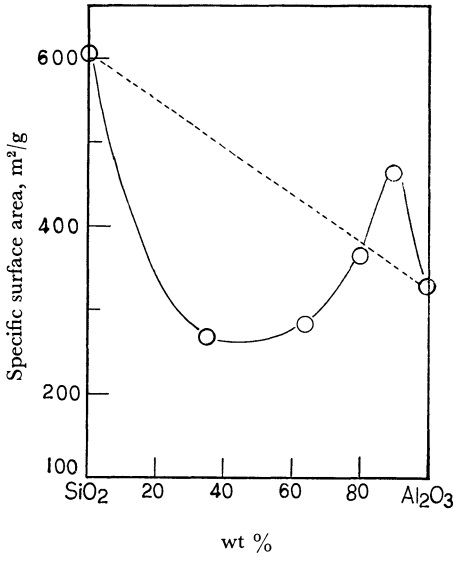

Fig. 2. Variation of specific surface areas of the system Al_2O_3-SiO_2 calcined at 500°C with composition. Dotted line is theoretical one under the assumption of additivity.

Table 1. Surface properties of the system Al_2O_3-SiO_2 prepared from alkoxides followed by heating at 500°C for 2 hr

Sample composition, % ($Al_2O_3/Al_2O_3+SiO_2$)	X-Ray analysis	S_{N_2} m²/g	S_{H_2O} m²/g	$S_{H_2O}/S_{N_2}\times 100$	ΔH_i ergs/cm²	Amounts of NH_3 adsorbed cc/m²
100	broad γ-Al_2O_3	324	140	43	423	0.0185
89.6	amorphous	464	207	45	454	0.0259

and water, and it is only above 500°C that the structures begin to show their crystalline nature.

(ii) Specific Surface Area. Specific surface areas have been determined by standard B.E.T. procedure, using 10.8 and 16.2 Å² for the molecular cross-sectional areas of water vapor and nitrogen, respectively.[14] Specific surface areas estimated from nitrogen and water vapor adsorption are given in Table 1. The variation of the specific surface area of the system Al_2O_3-SiO_2 with composition is represented in Fig. 2, in which the surface area is plotted as a function of Al_2O_3 contents (wt%) determined by X-ray fluorometry. The dotted line in Fig. 2 shows the theoretical specific surface areas of mixtures calculated under the assumption of additivity of surface area. The surface areas observed deviate from this theoretical line. The rise of Al_2O_3 contents decreases the specific surface area to a broad minimum of about 263 m²/g obtained in the case of the 35.0% ($Al_2O_3/Al_2O_3+SiO_2$) sample, above which a slow increase in area occurs with further rise of Al_2O_3 content. The maximum in the specific surface area of silica-alumina is obtained in the case of 89.6% ($Al_2O_3/Al_2O_3+SiO_2$) sample.

Inspection of columns 3 and 4 of Table 1 reveals that the surface areas calculated from nitrogen adsorption are considerably higher than those calculated from the water vapor isotherms.

(iii) Surface Hydrophilicity and Heat of Immersion. Water vapor adsorption data were plotted as isotherms from which the monolayer capacity, V_m, was calculated by the B.E.T. method. The surface area, S_{H_2O} (m²/g), was calculated from V_m, taking the molecular area of water vapor at 25°C as 10.8 Å². The results are given in column 4 of Table 1.

Healey *et al.*[15,16] have shown that surface hydrophilicity is represented as the ratio of total surface area to hydrophilic surface area. Thus it follows that

$$\text{Surface hydrophility}(\%) = S_{H_2O}/S_{N_2} \times 100,$$

where S_{H_2O} and S_{N_2} denote the specific surface areas as based on water vapor and nitrogen adsorption, respectively. The variation of the surface hydrophilicities of the system of Al_2O_3-SiO_2 with composition is listed in Table 1 and illustrated in Fig. 3, in which the hydrophilicities are plotted as a function of Al_2O_3 contents (wt%).

The data of heats of immersion of the system SiO_2-Al_2O_3 are shown in column 6 of Table 1. The variation in heats of immersion is represented in Fig. 3, in which the heats are plotted as a function of Al_2O_3 contents (wt%).

The dotted line in Fig. 3 shows the theoretical heats calculated under the assumption of additivity. The heats observed deviate from this theoretical line, and the rise of Al_2O_3 contents increase the heats to a maximum of about 500 erg/cm² obtained in the case of the 80.5% ($Al_2O_3/Al_2O_3+SiO_2$) sample.

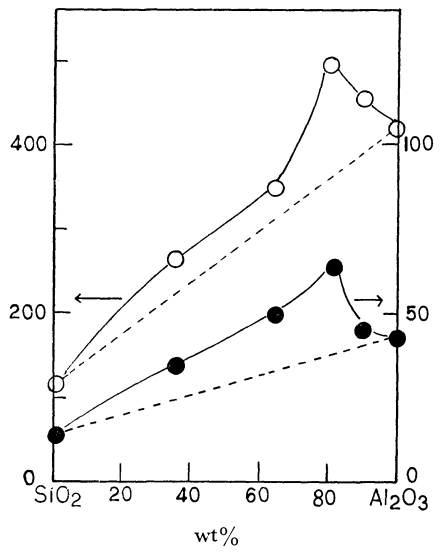

Fig. 3. Variation of surface hydrophilicities and heats of immersion of the system Al_2O_3-SiO_2 with composition.
●----Surface hydrophilicity (S_{H_2O}/S_{N_2} X 100, percent).
○----Heat of immersion (erg per square centimeter).
Dotted lines are theoretical ones under the assumption of additivity.

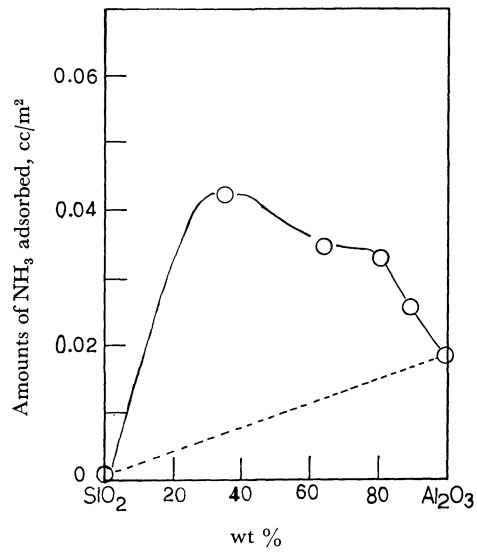

Fig. 4. Variation of amounts of ammonia adsorbed of the system Al_2O_3-SiO_2 calcined at 500°C with composition.
Dotted line is theoretical one under the assumption of additivity.

15) F. H. Healey, Y. F. Yu and J. J. Chessick, *J. Phys. Chem.*, **59**, 399 (1955).
16) A. C. Zettlemoyer, *Official Dig.*, **29**, 1238 (1957).

It is interesting to note that this tendency of the surface hydrophilicity coincides with that of heats of immersion. This strongly suggests a relationship between the magnitude of the heats of immersion and the concentration of hydroxyl sites on the surface, as pointed out by Young and Bursh,[17] and Zettlemoyer *et al.*[18]

(iv) Surface Acidity. The surface acidtiy of the system Al_2O_3-SiO_2 was determined by the chemisorption of basic gas (ammonia) at high temperature and low pressure. Ammonia adsorption isotherms at 260°C, where the highest equilibrium pressure was about 15 Torr, were determined[1] on all the samples studied after outgassing at 260°C for 1 hr at 10^{-5} Torr. The shape of the isotherms of all the samples studied is Langmuir's type. The amounts adsorbed at saturation per unit surface area calculated by the Langmuir equation are listed in Table 1 and illustrated in Fig. 4, in which the amounts of ammonia adsorbed are plotted as a function of Al_2O_3 contents. The rise of Al_2O_3 contents increases the amount of ammonia adsorbed to a maximum of about 0.04 cc/m² obtained in the case of the 35.0% ($Al_2O_3/Al_2O_3+SiO_2$) sample, above which a decrease in the amount of ammonia adsorbed occurs with further rise of Al_2O_3 contents.

From the fact[19] that silica gel does not behave as an acid-catalyst in the catalytic reaction such as propylene polymerization, it is reasonable to consider that its acidity is zero. The experiment on the ammonia adsorption at 260°C in the case of the 0% ($Al_2O_3/Al_2O_3+SiO_2$) sample gives near zero value (0.0009 cc, at S.T.P./m²) for its acidity, as indicated in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2389—2394 (1970)

The Reactions of Propylene-1,3,3,3-d_4 Photosenitized by $Hg(^3P_1)$, $Cd(^3P_1)$, and Benzene-h_6 and -d_6

Shun-ichi HIROKAMI and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 19, 1970)

A comparative study has been made of the reactions of *cis*- and *trans*-propylene-1,3,3,3-d_4 photosensitized by benzene-h_6 and -d_6 and by $Hg(^3P_1)$ at room temperature and by $Cd(^3P_1)$ at 275°C. The main reaction observed in every photosensitization was a *cis-trans* isomerization; no isomerization to propylene-2,3,3,3-d_4 was observed under the conditions employed. This is in marked contrast to the isomerization of ethylene-d_2. The ratio of *cis*- to *trans*-propylene-1,3,3,3-d_4 after prolonged irradiation was unity. The decomposition observed in the mercury photosensitization was also studied in detail; its quantum yield was less than one-tenth that of the *cis-trans* isomerization. The material balance between the decrease in the reactant and the amount of the products was well preserved, but the energy balance between the absorbed photons and the quantum yield of products was not preserved at pressures below 150 Torr. A possible mechanism is discussed.

cis- or *trans*-Dideuteroethylene, when photosensitized by benzene or $Cd(^3P_1)$, undergoes two types of reactions: (i) *cis-trans* isomerization, and (ii) hydrogen-atom scrambling, *i. e.*, the formation of 1,1-dideuteroethylene.[1-3] Since the π electronic structure of propylene is similar to that of ethylene, it seemed interesting to study whether or not propylene undergoes reactions similar to those of ethylene.

On the other hand, in the study of the reaction of 2-butene photosensitized by $Hg(^3P_1)$ we have found that the balance between the absorbed quanta and the sum of the quantum yields of products is not preserved at pressures below 150 Torr.[4] In

2) S. Hirokami and S. Sato, *ibid.*, **45**, 3181 (1967).

3) S. Tsunashima, S. Hirokami and S. Sato, *ibid.*, **46**, 995 (1968).

4) S. Tsunashima and S. Sato, This Bulletin, **41**, 284 (1968).

other words, a part of the energy absorbed by mercury atoms does not seem to contribute to the chemical reactions occurring in the system over a wide range of pressure. We tentatively explained this observation in terms of the formation of vibrationally-excited states of the reactant.

With these prospects in mind, a study of the reactions of partially-deuterated propylene-1,3,3,3-d_4, was made by using mercury and cadmium atoms and benzene-h_6 and -d_6 as the photosensitizers.

Experimental

trans- and *cis*-Propylene-1,3,3,3-d_4 were synthesized from methylacetylene-d_4 by a method previously described.[5] Methylacetylene-d_4 was obtained by means of a reaction between magnesium carbide and heavy water.[6] Methylacetylene was separated from other compounds by gas chromatography using a column packed with dimethylsulforane-on-celite. The mass-spectrometric analysis showed the isotopic impurities in the synthesized methylacetylene-d_4 to amount of less than 5%. Research-grade *cis*-2-butene and propylene-h_6 supplied by the Takachiho Trading Co. were used after bulb-to-bulb distillations. According to the gas-chromatographic analysis, the impurities in *cis*-2-butene amounted to less than 0.5%, and those in propylene, to less than 0.1%. Benzene-h_6 and -d_6 were both of a spectrograde; they were supplied by the Merck Co. The mass-spectrometric analysis of benzene-d_6 showed that the isotopic impurities amounted to less than 2%.

The light sources and the apparatus used were similar to those reported on in previous papers. The reaction vessels used for the mercury photosensitization had volumes of 52.3 m*l* (a), 25.4 m*l* (b), and 9.4 m*l* (c).

The isomerization products were analyzed with a Perkin-Elmer 125 double-beam grating infrared spectrometer. The absorption peak at 983 cm^{-1} was assigned to *trans*-, the peak at 785 cm^{-1}, to *cis*-propylene-1,3,3,3-d_4, and the peak at 912 cm^{-1}, to propylene-2,3,3,3-d_4.*1

In the mercury photosensitization, various products were obtained. They were analyzed as follows. After each run, the reaction products were transferred into a trap at the temperature of liquid nitrogen and non-condensables were collected in a gas buret by means of a Toepler pump. After the amount had been measured, the gas was analyzed by means of a mass-spectrometer. For the condensed part, a cold trap at −120°C was used to separate the reaction products from the reactant, propylene. The amount of propylene remaining was measured volumetrically, and the products condensed at −120°C were identified and measured with a gas chromatograph equipped with dimethylsulpholane (10 m long), dioctylphthalate columns (2 m long), and a flame-ionization detector.

The light intensity absorbed by benzene-h_6 and -d_6 was estimated by using the benzene-h_6 or -d_6-photosensitized *cis-trans* isomerization of *cis*-2-butene.[7] In the mercury photosensitization, the light intensity of the 2537 Å resonance line used for the reaction was estimated from the amount of hydrogen produced in the mercury-photosensitized decomposition of ethylene at 45 Torr, assuming the quantum yield to be 0.203.[8] The absorbed light intensity of the cadmium-resonance line at 3261 Å was estimated by using the cadmium-photosensitized *cis-trans* isomerization of *cis*-2-butene.[4]

Results

Photosensitizations by Benzene-h_6 and -d_6. By the photosensitization of benzene-h_6 or -d_6, the *cis-trans* isomerization of propylene-1,3,3,3-d_4 was observed to occur, but neither decomposition nor isomerization to propylene-2,3,3,3-d_4 was observed. Table 1 summarizes the results. After prolonged irradiation, a 1 : 1 ratio of *cis*- to *trans*-propylene-1,3,3,3-d_4 was obtained, but not even a trace of

propylene-2,3,3,3-d_4 was observed. The quantum yield of the formation of propylene-2,3,3,3-d_4 must be less than one-thousandth at the pressures employed, if it occurs at all.

Cadmium Photosensitization. The products obtained in the reaction of propylene-1,3,3,3-d_4 photosensitized by cadmium were *cis-trans* isomers, plus small amounts of propane and probably C_6-hydrocarbons, whose elution times on a gas chromatograph were almost equal to those of C_6 hydrocarbons. After prolonged irradiation (72 μEinstein, the pressure of the reactant being 23 Torr), equal amounts of *cis-* and *trans*-propylenes were obtained, but propylene-2,3,3,3-d_4 was again not observed.

Mercury Photosensitization. Mercury-photosentitized reactions were studied with *cis*-propylene-1,3,3,3-d_4 and propylene-h_6. Even in the mercury photosensitization, the formation of propylene-2,3,3,3-d_4 could not be observed. Table 2 summarizes the mol% of *trans-* and *cis*-propylene-d_4 observed after the mercury-photosensitized reaction.

In this photosensitization, the decomposition process cannot be ignored. Table 3 shows the pressure dependence of the quantum yields of the decomposition products observed when propylene-h_6 and *cis*-propylene-d_4 were used as the reactants. Obviously, at pressures above 20 Torr the decomposition products consist mainly of C_6-hydrocarbons. In order to check the material balance, the amount of propylene-h_6 consumed in the mercury photosensitization was measured over a wide range of pressures. The results are shown in Fig. 1, which also includes the plots of the quantum yields of the C_6-hydrocarbons and non-condensable gas formed. Obviously, the quantum yield of the consumption of propylene is about twice that of the formation of C_6-hydrocarbons.

action of *cis*-propylene-d_4 were also measure. The results are listed in Table 4. The pressure dependence of the quantum yield is very similar to that obtained with propylene-h_6 in Fig. 1. However, the absolute value is about a quarter that obtained with propylene-h_6. This is probably due to the isotope effect in the initial process of the mercury-photosensitized reaction.

Discussion

Isomerization of Propylene-1,3,3,3-d_4. The *cis-trans* isomerization of *cis*-propylene-d_4 may be visualized as follows:

$$cis\text{-}CD_3CH{=}CDH + S^* \longrightarrow P^* + S$$
$$P^* + M \longrightarrow 1/2\ trans + 1/2\ cis + M$$

Here, S and S* represent the ground state and the excited triplet state of a photosensitizer respectively. P* is an excited state of propylene, probably the lowest triplet. M is the third body for the stabilization. In the case of *cis*-ethylene-d_2, the state corresponding to P* further isomerizes to the second excited state, which is a precursor of 1,1-dideuteroethylene, but in the present case this process is ignored because the formation of propylene-2,3,3,3-d_4 was not observed in any photosensitized reaction performed. To estimate the initial quantum yield of the isomerization, the following equation has to be applied to the data because the reverse reaction from *trans*- to *cis*-isomer is always included in a finite conversion:

$$\phi_{iso} = \frac{[C]+[T]}{2It} \ln \frac{[C]+[T]}{[C]-[T]} \qquad (I)$$

The derivation of this equation has already been shown in a previous paper.[9] Here, ϕ_{iso} is the initial quantum yield of isomerization. It is the light quanta absorbed by a photosensitizer, and the brackets show the concentrations of *cis*- and *trans*-isomers after the reaction. Thus, the relative quantum yields of isomerizations photosensitized by benzene-h_6 and -d_6 are calculated to be as is shown in Fig. 2. Although the data are scattered,

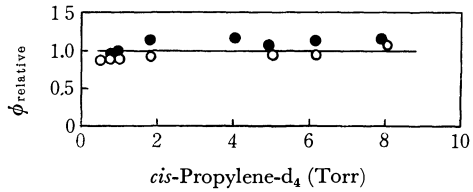

Fig. 2. Relative quantum yield of *cis-trans* isomerization of propylene-1,3,3,3-d_4 photosensitized by benzene-h_6 (○) and benzene-d_6 (●).

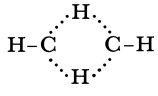
it may be said that the quantum yield of the *cis-trans* isomerization of *cis*-propylene-d_4 is independent of the pressure of the reactant above a few Torr. This trend has previously been observed in the isomerization of 2-butenes.[10]

As has been stated in the previous section, the formation of propylene-2,3,3,3-d_4 was not observed in any photosensitization, while this type of isomerization is important in the reaction of ethylene-d_2. The reason for this discrepancy is not clear, but a speculation may be offered. If the hydrogen-atom scrambling observed in the reaction of ethylene occurs through the formation of a structurally-symmetric intermediate such as



,

9) S. Tsunashima and S. Sato, This Bulletin, **42**, 329 (1969).

10) M. Tanaka, K. Kato and S. Sato, *ibid.*, **39**, 1423 (1966).

then the substitution of a methyl radical for a hydrogen atom may disturb the formation of this type of intermediate. This structure for the hydrogen-atom scrambling state was suggested by Whalley years ago,[11] but it obviously needs more deliberate theoretical consideration.

Decomposition of Propylene. An appreciable decomposition of propylene was observed only in the mercury photosensitization. The reaction mechanism has already been discussed by many investigators.[12–15] When propylene-1,3,3,3-d_4 is the reactant, the mechanism may be described as follows:

$$CD_3CH{=}CDH^* \longrightarrow D + \dot{C}D_2CH{=}CDH \quad (1)$$

$$\searrow \dot{C}D_3 + \dot{C}H{=}CDH \quad (2)$$

$$CD_3CH{=}CDH^* + M \longrightarrow 1/2\ trans + 1/2\ cis \quad (3)$$

Here, $CD_3CH{=}CDH^*$ is the excited state of the propylene produced by the mercury photosensitization. This is probably the lowest triplet state. Reference to Tables 2 and 3 makes it obvious that the process (3) is the most important at pressures higher than 10 Torr and that the process (1) is preferable the process (2), since many more C_3 and C_6 hydrocarbons than C_1, C_2 and C_4 hydrocarbons are produced. In order to estimate the quantum yields of the decomposition processes, the material balance between the consumed reactant and the observed products has to be checked. This calculation has been made regarding carbon atoms. The results are included in Table 3. Obviously, the material balance obtained is not too bad in any of the runs examined.

The formation of C_6 hydrocarbons may be described as follows (here, propylene-h_6 is used as the reactant to avoid complexity):

$$C_3H_6^* \longrightarrow H + C_3H_5 \quad (1)$$

$$H + C_3H_6 \longrightarrow C_3H_7\ (\text{mainly } CH_3\dot{C}HCH_3) \quad (4)$$

$$2C_3H_7 \longrightarrow \text{2,3-dimethyl butane} \quad (5)$$

$$\searrow C_3H_8 + C_3H_6 \quad (6)$$

$$C_3H_7 + C_3H_5 \longrightarrow \text{4-methyl pentene-1} \quad (7)$$

$$\searrow 2C_3H_6 \quad (8)$$

$$2C_3H_5 \longrightarrow \text{1,5-hexadiene} \quad (9)$$

A small amount of 1-hexene may be formed in the reaction between C_3H_5 and $CH_3CH_2CH_2$. The formation of this radical is in competition with that of the isopropyl radical in the reaction (4). The formation of 1-butene may result from the reaction of C_3H_5 with the CH_3 produced in the reaction (2). If the mechanism is correct so far, the quantum yield of the reaction (1) may be calculated by the following relations:

$$\phi_{C\text{-}H} = (C_3H_5) = \phi(C_6H_{12}) + 2\phi(C_6H_{10}) + \phi(C_4H_8) \quad (II)$$

$$\phi_{C\text{-}H} = (C_3H_7) = \phi(C_6H_{12}) + 2\phi(C_6H_{14}) + 2\phi(C_3H_8) \quad (III)$$

Here, the contribution of the reaction (8) is ignored. The quantum yield of this reaction may be comparable to that of the reaction (7). The values calculated by the relations (II) and (III), therefore, are meaningful only in their order. The calculated values are summarized in Table 5, which obviously shows a strong isotope effect on the rupture of the C–H bond. The estimation of the quantum yield of the reaction (2) may be similar but the calculation was not carried out because a large experimental error was expected.

Table 5. Estimation of the quantum yield of carbon-hydrogen bond rupture

Reactant pressure (Torr)	Propylene-h_6			Propylene-d_4	
	21.0	53.0	80.2	19.3	82.0
$\phi_{C\text{-}H}$ or $\phi_{C\text{-}D}$ (II)*	0.18	0.12	0.07	0.03	0.015
(III)*	0.18	0.11	0.07	0.03	0.015

* Calculated by Eqs. (II) and (III).

Energy Balance in the Mercury Photosensitization. It was found in the mercury-photosensitized decomposition of propylene-h_6 that the amount of the reactant consumed was almost consistent with that of the products observed, and that a large part of the products were C_6-hydrocarbons. In the case of *cis*-propylene-1,3,3,3-d_4, we could not measure the amount of the reactant consumed because the amount of the reactant itself was small

and we had to avoid a high conversion in order to estimate the quantum yield of isomerization. However, judging from the results obtained with propylene-h_6, the C_6-hydrocarbons obtained with *cis*-propylene-d_4 may form the main part of the decomposition products. Figure 3 shows the quantum yields of the *cis-trans* isomerization and of the formation of C_6-hydrocarbons in the reaction of *cis*-propylene-1,3,3,3-d_4 photosensitized by mercury. The quantum yield of the *cis-trans* isomerization was calculated by applying Eq. (I) to the data in Table 2. If all the photons absorbed by mercury atoms contribute to the reaction of the *cis-trans* isomerization or decomposition, the sum of the two quantum yields in Fig. 3 should be nearly equal to unity at any reactant pressure. Obviously, the sum deviates from unity with a decrease in the pressure of the reactant and approaches 0.5 at the pressure of 10 Torr. This trend has already been observed in the reaction of 2-butene photosensitized by mercury, where the quantum yield of decomposition was estimated from the formation of hydrogen.[4]

To explain this observation, we tentatively propose a mechanism including the formation of a vibrationally-excited state of olefins. The mechanism may be described as follows:

$$\mathrm{Hg^*} + \textit{cis}\text{-P} \longrightarrow \mathrm{HgP^*} \quad (10)$$

$$\mathrm{HgP^*} \longrightarrow \mathrm{Hg} + \mathrm{P^*} \quad (11)$$

$$\mathrm{HgP^*} \longrightarrow \mathrm{Hg} + \mathrm{P'} \quad (12)$$

$$\mathrm{HgP^*} \longrightarrow \mathrm{Hg} + \text{Decomposition} \quad (13)$$

$$\mathrm{HgP^*} + \mathrm{P} \xrightarrow{(\mathrm{HgP_2^*})} \mathrm{Hg} + \mathrm{P^*} + \mathrm{P} \quad (14)$$

Here, P* is the triplet state which is subject to the *cis-trans* isomerization and P′ is the vibrationally-excited state which does not isomerize. If the quantum yield of the process (12) is represented by ϕ_X, its value may be approximated by the following relation:

$$\phi_X = 1 - (2\phi_{iso} + \phi_{C_4})$$

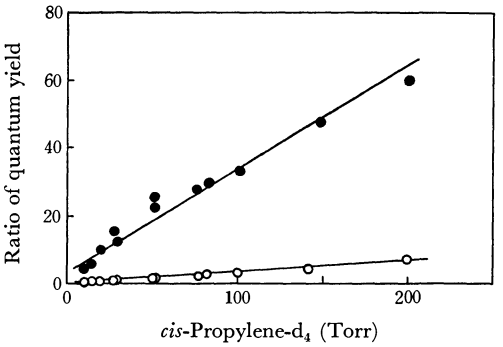

Fig. 4. Pressure dependences of the ratios, ϕ_{iso}/ϕ_X (○) and ϕ_{iso}/ϕ_{C_6} (●).

Figure 4 shows the pressure dependences of the ratios among these three quantum yields. Although the plots are scattered, it may be concluded that ϕ_{iso}/ϕ_X and ϕ_{iso}/ϕ_{C_6} are linearly dependent on the pressure. If so, and if the mechanism proposed above is correct, the contribution of the process (11) to the *cis-trans* isomerization should be small compared with that of the the process(14), because the linear relations for ϕ_{iso}/ϕ_X and ϕ_{iso}/ϕ_{C_6} have small intercepts at zero pressure. In other words, the main quenching process should occur through the formation of an unstable intermediate, HgP_2^*, in the reaction of propylene photosensitized by mercury at pressures higher than 10 Torr. Obviously, further experiments and different approaches are needed to confirm this speculation.

The authors are grateful to Dr. S. Maeda for the infrared analyses.

The Crystal and Molecular Structure of Bis(acetylacetonato)manganese(II) Dihydrate

Shigeki ONUMA and Shuzo SHIBATA

Department of Chemistry, Shizuoka University, Shizuoka

(Received February 21, 1970)

The crystal and molecular structure of bis(acetylacetonato)manganese(II) dihydrate, $Mn(C_5H_7O_2)_2 \cdot 2H_2O$, has been determined from three-dimentional X-ray diffraction data. The compound has a center of symmetry. The octahedral arrangement of the ligand atoms about the central manganese atom is distorted; the Mn–O(1) and Mn–O(2) distances are 2.129 and 2.150 Å, respectively, the Mn–O(H_2O) distance is 2.267 Å. The metal atom lies 0.561 Å out of the least-squares plane of the chelate ring. The chelate is isostructural with the cobalt, nickel, and magnesium analogues.

The molecular structures of the acetylacetonato complexes of some bivalent first transition metals were studied by gaseous electron-diffraction method by one of us (S. S.).[1] The complexes take the coordination number four in a gaseous state, but usually six in a solid state because of polymerization of the chelate or addition of solvent molecules. The purpose of the present study is to find the difference between the molecular structures in the two phases.

The crystal structure of $Mn(C_5H_7O_2)_2 \cdot 2H_2O$ has been reported recently by Montgomery and Lingafelter.[2] However, we were not aware of this when we started this work. Montgomery and Lingafelter determined the structure using 588 independent reflections recorded on Weissenberg photographs which were taken with Fe$K\alpha$ radiation and intensities of which were measured with the aid of a photometer. Comparison of their results with ours showed a good agreement between the two independent determinations.

Experimental

The crystals of bis(acetylacetonato)manganese(II) dihydrate were prepared by standard procedure.[3] The unit cell dimensions and the space group were determined from Weissenberg and rotation photographs using Cu$K\alpha$ radiation ($\lambda=1.5418$ Å). It is monoclinic with two molecules in a unit cell of the dimensions, $a=11.17$, $b=5.42$, $c=11.32$ Å and $\beta=106.2°$, and the space group is $P2_1/c$ (No. 14) which is required from the systematic absence for $0k0$ when k is odd and for $h0l$ when l is odd. The calculated density is 1.46 g cm^{-3}. A needle-shaped crystal selected carefully was used for intensity measurements. Three-dimensional intensity data were recorded on equi-inclination Weissenberg photographs taken with Cu$K\alpha$ radiation by means of the multiple film technique at room temperature. The intensities of 1202 independent reflections from $h0l$ to $h4l$ were measured visually by the use of a scale consisting of spots obtained from a selected reflection with different exposure times. All intensities were used in a least-squares calculation. Corrections for Lorentz and polarization factors were made in the usual way, while those for absorption and extinction were neglected.

Structure Determination

Since the compound $Mn(C_5H_7O_2)_2 \cdot 2H_2O$ has a center of symmetry, the manganese atom was placed at the origin of the unit cell. The two-dimensional coordinates of the five carbon and three oxygen atoms were obtained approximately from the sharpened ($B=4.0$ Å^2) Patterson projection, $P(u,w)$. Successive Fourier syntheses refined the positional parameters of the light atoms on the same plane and gave the orientation of the molecular framework. At this stage, calculated structure factors gave a discrepancy factor, $R_1=\sum||F_o|-|F_c||/\sum|F_o|$, of 0.218 for $h0l$ reflection, assuming an isotropic temperature parameter of 3.0 Å^2 for all atoms.

The three-dimensional structure which was used as the input for a least-squares calculation was assumed as follows: The acetylacetone ring takes a planar form, and the bond lengths and bond angles are equal to the average values which were estimated by Lingafelter[4] from the structures of many other acetylacetonate complexes.

The positional and the isotropic thermal para-

meters were refined by a least-squares procedure with block-diagonal matrix approximation. Computations were carried out by means of a HITAC 5020E computor using a program by T. Ashida.

In the refinement procedure, the function to be minimized was $\sum w(|F_o|-|F_c|)^2$ and the weights, w, were unity for $F_o \geqq 0.5$ and zero for $F_o < 0.5$. All of the observed data including zero reflections were used in the calculation. The atomic scattering factors of manganese, oxygen and carbon atoms were taken from International Tables for X-ray Crystallography.[5] Correction for anomalous scattering of manganese atom was neglected.

Five iterations of the refinement gave a discrepancy factor R_1 of 0.139 and the isotropic temperature factors were obtained for each atom. It was noticeable that the isotropic temperature factors for the two methyl carbon atoms, C(1) and C(5), and the oxygen atom of water, O(3), are considerably large.

Refinement with a consideration of anisotropic temperature factors was carried out five cycles with the use of the same program and gave a smaller discrepancy factor R_1 of 0.093 for non-zero reflections. Anisotropic temperature factors were expressed as

$$\exp\left[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{23}kl+B_{13}hl)\right]$$

The final atomic coordinates with their estimated standard deviations and the anisotropic temperature factors are listed in Tables 1 and 2, respectively. The observed and the calculated structure factors are tabulated in Table 3.*1

Discussion

According to preliminary results from an electron-diffraction experiment,[1] gaseous bis(acetylacetonato)manganese(II) takes planar form and the distance between manganese and oxygen atoms is 2.28 Å. However, the present study showed that the chelate in a crystal takes distorted octahedron and the average length of the corresponding bond is 2.14 Å. A comparison between them will be made when a conclusive result of electron-diffraction is obtained.

are occupied by the water molecules. The average distance of the Mn–O($C_5H_7O_2$) is much shorter than that of Mn–O(H_2O), 2.267 Å, by 0.130 Å. However, in the crystal structure of $Zn(C_5H_7O_2)_2 \cdot H_2O$,[6] there is no considerable difference between the Zn–O($C_5H_7O_2$) distance and the Zn–O(H_2O); the average distance is 2.02 ± 0.02 Å.

The O–O separation in an acetylacetonate ring is 2.926 Å. Lingafelter[4] pointed out that the O–O distance of the acetylacetonate chelate ring decreases with the increase in an oxidation number of a metal, and the above result seems to be an additional proof to this rule.

The structure of $Mn(C_5H_7O_2)_2 \cdot 2H_2O$ is essentially the same as the structures of the corresponding cobalt,[7] nickel[8] and magnesium analogues.[9] Morosin found that in these metal acetylacetonates the metal is displaced out of the least-squares plane formed by the chelate ring OCCCO. In the present work a similar displacement was observed. The sum of the interior angles of the ring was 539.9°, although 540° must be required for planarity. Therefore the chelate ring is planar within experimental errors, and the least-squares plane has the equation $-0.2845X+0.6796Y+0.7287Z= -0.5611$ (referred to the monoclinic coordinates). The distance from the manganese atom to this ligand plane was 0.561 Å, in contrast to the corresponding distance in $Mn(C_5H_7O_2)_3$, 0.12 Å.[10] The decrement may be due to steric hindrance among the chelate frames which are considerably flexible. Deviations of the light atoms from the least-squares plane are as follows:

O(1)	0.027	O(2)	−0.019	C(1)	−0.151
C(2)	−0.039	C(3)	0.017	C(4)	0.014
C(5)	0.092	O(3)	2.655 Å

C(1)	C(2)	C(3)	120.0
O(2)	C(4)	C(5)	116.3

* Average error is 1°.

Both of the methyl groups exist significantly out of the chelate plane. The chelate ring is folded by 21° about the O(1)–O(2) axis. The intramolecular bond lengths and angles are listed in Table 4.

The intermolecular distance between O(3) (x,y,z) and O(2) $(x, 0.5-y, 0.5+z)$ and between O(2) $(-x, -y, -z)$ and O(3)$(-x, -0.5+y, 0.5-z)$ are 2.867 Å. The lengths may indicate the presence of the intermolecular hydrogen bonds between neighbouring oxygen atoms related by the twofold screw axis. Other intermolecular distances can be explained reasonably by the assumption that they are in van der Waals contact.

Structural Studies of Antimony Tribromide and Its Molecular Complex with Benzene by Means of the ^{81}Br Nuclear Quadrupole Resonance

Tsutomu OKUDA, Hiromitsu TERAO, Osamu EGE and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received February 25, 1970)

The structures of α-antimony tribromide and its molecular complex with benzene $2SbBr_3 \cdot C_6H_6$ were investigated by studying the Zeeman effect on the nuclear quadrupole resonance (NQR) due to ^{81}Br at room temperature. The bond angles, ∠Br–Sb–Br, of α-antimony tribromide in its solid state were found to be 94°14′±4′, 94°31′±8′, and 98°27′±7′. The polar angles specifing the directions of the Sb–Br bonds with respect to the orthorhombic crystal axes are (60°0′±9′, 62°13′±7′), (59°10′±7′, −54°35′±8′), and (57°39′±17′, 180°0′±3′). These values are consistent with those of the X-ray analysis by Cushen *et al.* within about 1°. The asymmetry parameters at the three bromine atoms were 0.068±0.002, 0.049±0.002, and 0.080±0.004. On the other hand, the bond angles, ∠Br–Sb–Br, of the $SbBr_3$ molecule in the complex $2SbBr_3 \cdot C_6H_6$ were found to be 92°24′±11′, 97°7′±14′, and 97°40′±6′. The crystal has a monoclinic symmetry, and the three Sb–Br bonds have directions making angles of 29°4′±21′, 76°26′±9′ and 63°33′±11′ relative to the *b*-axis. The asymmetry parameters at the three bromine atoms in the complex were 0.169±0.001, 0.063±0.002, and 0.094±0.002. The largest value of the asymmetry parameters seems to be the result mostly of the intermolecular bonding. From the coupling constants, the Sb–Br bond characteristics in antimony tribromide and its molecular complex, $2SbBr_3 \cdot C_6H_6$, are considered to be almost the same.

It has long been known that antimony tribromide has two distinct crystal "habits," acicular and bipyramidal. When a warm carbon disulfide solution of antimony tribromide is cooled, needle-like crystals of α-antimony tribromide are obtained, contaminated with a few crystals of the β-form. The α-form is gradually transformed into the β-form at room temperature. When the β-form is melted, it can be reversed to the α-form.

Studies of the nuclear quadrupole resonance on antimony tribromide have been made by several authors.[1-3] All of them, however, used polycrystalline samples. The X-ray analyses of the α- and β-forms were carried out by Cushen[4] and Hulme[5] respectively. The α-form is orthorhombic, with the *c*-axis as the needle axis, and it has four molecules in the unit cell. The space group is $P2_12_12_1$. The β-form is orthorhombic, with the *a*-axis as the bipyramidal axis, and it has four molecules in the unit cell. The space group is *Pbnm*. The molecule in the gaseous state has been found to have a trigonal pyramidal form by the electron diffraction method. According to the latest report by Swingle[6] it has a bond angle of 97°±2° for ∠Br–Sb–Br and a bond distance of 2.51±0.02 Å for Sb–Br.

On the other hand, it is well known that antimony tribromide forms 1 : 1 and 2 : 1 molecular complexes with aromatic compounds. Studies of the nuclear quadrupole resonances for the powder of these complexes have already been reported,[1,3] but neither a Zeeman analysis of the resonances nor X-ray analysis has been done, so far as we know. Therefore we carried out a Zeeman analysis of the single crystals of α-antimony tribromide and its molecular complex with benzene, $2SbBr_3 \cdot C_6H_6$, in order to identify the ^{81}Br resonance lines and clarify the nature of the Sb–Br bonds as well as the shape of the $SbBr_3$ molecule.

Experimental

Antimony tribromide (mp 96°C) was synthesized by the reaction of bromine and antimony powder suspended in carbon disulfide; it was then refined by distillation. A 2 : 1 molecular complex of antimony tribromide with benzene was prepared by mixing molten antimony tribromide and a small excess of benzene. It was filtered

and dried in a vacuum desiccator. The melting point of the product was 93°C, whereas the literature value[1] is 92.5°C. The single crystals of these substances were obtained by a melting method. They were 15 mm in diameter and 40 mm in length. The single crystal obtained for antimony tribromide was the α-form, because a melting method was used.

An externally-quenched super-regenerative spectrometer with Lecher wires was used for the detection of the resonance absorption lines, which were displayed on an oscilloscope. The resonance frequency was measured by a frequency meter, TS-175 C/U. The single crystal was set on a goniometer equipped with a Helmholtz electro-magnet, and the magnetic field was applied on the sample from all directions in order to obtain the zero-splitting patterns. Several kinds of Zeeman fields ranging from 150 to 300 gauss were used in order to avoid misreading of the spurious signal. The crystal could be rotated about a fixed axis of the crystal, and its angle, Φ, could be measured to within 0.1°. On the other hand, the magnetic field could be rotated on a horizontal plane, and its angle, Θ, could be measured to within 1′. All of the measurements were carried out at about 20°C.

Results and Discussion

In a previous paper[3] we reported the ^{81}Br nuclear quadrupole resonance frequencies of antimony tribromide and its complexes. The ^{81}Br quadrupole resonance lines of α-antimony tribromide have been observed at 135.11, 135.32, and 140.35 MHz, with an intensity ratio of 1 : 1 : 1, at room temperature (19.5°C), as may be seen in Fig. 1 (a). In the case

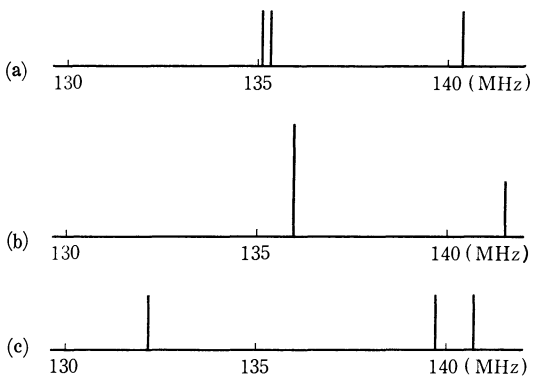

Fig. 1. Resonance spectra of antimony tribromide and its complex with benzene.
(a) α-$SbBr_3$, (b) β-$SbBr_3$, (c) $2SbBr_3 \cdot C_6H_6$

of β-antimony tribromide, the resonance lines have been observed at 135.96 and 141.49 MHz, with an an intensity ratio of 2 : 1, at room temperature (20.5°C), as may be seen in Fig. 1 (b). The resonance frequencies of α- and β-antimony tribromides are slightly different from one another. This fact reflects the delicate difference in the crystal fields surrounding the resonant nuclei in these modifications.

The quadrupole resonances of two modifications of antimony tribromide were reported by Ogawa.[2] Her synthesized antimony tribromide (1) corresponds to α-antimony tribromide, but her purchased antimony tribromide (2) is different from β-antimony tribromide. We could not obtain a sample like her second one.

As for the ^{81}Br resonance lines of $2SbBr_3 \cdot C_6H_6$, we have reported two resonance lines in a previous paper.[3] Through reexamination, however, we found a new resonance line, at about 8 MHz, below these two lines. Finally, then, three resonance lines with the same intensity have been observed; the frequencies are 132.14, 139.70, and 140.69 MHz at room temperature (21.5°C), as may be seen in Fig. 1 (c). The resonance lines in the complex are more widely spread than those of antimony tribromide, and two of them are closely spaced on the higher-frequency side. The grouping of the resonance lines is reversed from those of α- and β-antimony tribromides. We may say, however, that all resonance lines of the three samples are in nearly the same frequency regions. Thus, it can be assumed that there is no essential difference in the nature of the Sb–Br bonds, and that the shape of $SbBr_3$ molecule in its own crystal is retained in the complex.

The results of the Zeeman analyses of ^{81}Br resonance lines of α-antimony tribromide and its molecular complex with benzene $2SbBr_3 \cdot C_6H_6$ will be described below.

(a) α-Antimony Tribromide. Let us label the three resonance lines of ^{81}Br as ν_1, ν_2, and ν_3 from the lower to the higher. Then, from the number and their intensity ratio, these lines can be ascribed to three kinds of bromine atoms, Br_1, Br_2, and Br_3, in one molecule. The zero-splitting patterns of the Zeeman effect on the resonance lines are shown in Fig. 2. For the resonance lines, ν_1, ν_2, and ν_3, four, four, and two loci were obtained respectively. These loci are contributed by the Br_{1A}, Br_{1B}, Br_{1C}, and Br_{1D} atoms, the Br_{2A}, Br_{2B}, Br_{2C}, and Br_{2D} atoms, and the Br_{3A} and Br_{3B} atoms respectively. The direction of the principal z-axis of the field gradient on the bromine atom can be obtained from the zero-splitting pattern. The z-axis is usually parallel to the direction of the Sb–Br bond; the angle between any two Sb–Br bonds can thus be deduced. These angles are listed in Table 1, where the angle in parenthesis is the supplementary angle of the other. Since the gas molecule of $SbBr_3$ has been found to be a trigonal pyramid, one may expect that this molecule is nearly a trigonal pyramid in the solid state.

Taking the molecular shape and the bond angle, 97°, in the gaseous state into consideration, we find from Table 1 that each of the groups—Br_{1A}, Br_{2A}, Br_{3A}; Br_{1B}, Br_{2B}, Br_{3B}; Br_{1C}, Br_{2C}, Br_{3A}, and Br_{1D}, Br_{2D}, Br_{3B}, belongs to the same molecule. The directions of the symmetry axes of the crystal, a, b,

* The value in parenthesis is supplementary angle.

and c, can easily be found from the symmetry distributions of the z-axes. These directions are shown in Fig. 2.

The values of the asymmetry parameters can be determined from the distortion of the zero-splitting loci by the following equation:[7]

$$\eta = 3(\sin^2\theta_{max} - \sin^2\theta_{min})/(\sin^2\theta_{max} + \sin^2\theta_{min}) \quad (1)$$

where θ_{max} and θ_{min} are the maximum and minimum zero-splitting angles, corresponding to $\phi = 0°$ and 90° respectively. Consequently, the quadrupole coupling constant can be calculated by substituting the value of η in the following relation:

$$\nu = (eQq_{zz}/2)(1+\eta^2/3)^{1/2} \quad (2)$$

7) C. Dean, *Phys. Rev.*, **96**, 1053 (1954).

The values of η and eQq_{zz} derived in this way are listed in Table 2.

All of the asymmetry parameters are relatively small. In the antimony trichloride, which has the same crystal structure as β-antimony tribromide and

TABLE 2. RESONANCE FREQUENCIES (ν), ASYMMETRY PARAMETERS (η) AND QUADRUPOLE COUPLING CONSTANTS (eQq_{zz}) OF ^{81}Br ATOMS IN α-$SbBr_3$ AT 19.5°C

Bond	$Sb–Br_1$	$Sb–Br_2$	$Sb–Br_3$
NQR	(60°0′±9′, 62°13′±7′)	(59°10′±7′, −54°35′±8′)	(57°39′±17′, 180°0′±3′)
X-Ray	(59°28′, 62°16′)	(57°52′, −55°4′)	(58°49′, 181°18′)

which exhibits a similar pattern of NQR lines, the value of η is 15.3%[8] for the chlorine atom corresponding to the lower line, which has an intensity twice as strong as the higher. This large asymmetry parameter has been ascribed by Peterson[9] to the intermolecular bonding between the chlorine and antimony atoms.

On the basis of X-ray data, let us ascertain whether or not there are unbound Sb–Br distances which are smaller than the sum of the van der Waals radii, 4.15 Å, as preparation for discussing the effect of the intermolecular bonding in antimony tribromide. In β-antimony tribromide there are short unbound Sb–Br distances, 3.66 and 3.85 Å, for the bromine atom, which contributes to the lower NQR line. The value of 3.66 Å seems evidently to be ascribable to the intermolecular bonding, and it is thought that the bromine atom corresponding to the lower NQR line has an asymmetry parameter as large as 15.3% in antimony trichloride. On the other hand, in α-antimony tribromide there are short unbound Sb–Br distances, 3.81 and 3.84, 3.75 and 4.10, and 3.78 Å for Br_1, Br_2, and Br_3 atoms respectively. These values are, however, larger than that of 3.66 Å in β-antimony tribromide. Therefore, we consider that the intermolecular bonding in α-antimony tribromide is less considerable than in antimony trichloride and β-antimony tribromide.

Gordy[10] proposed, on the basis of an extensive study using the equation of Schomaker-Stevenson,[11] that the tendency to form a double bond by using d orbitals falls off rapidly in descending rows in the periodic table, essentially vanishing for such fifth-row elements as Sn and Sb. In the case of $SbBr_3$, the bond length, Sb–Br, calculated by means of the Shomaker-Stevenson equation is in good agreement with the experimental value calculated by means of the electron diffraction. Therefore the possibility of double-bond formation is thought to be negligibly small, so that the ionicity of the Sb–Br bond, i, may be obtained from the following equation:

$$U_p = (1-i)(1-s) \qquad (3)$$

where s is the s electron character and where U_p is the number of unbalanced p electrons. Usually s is assumed to be 0.15,[12] and U_p is evaluated from the observed quadrupole coupling constant:

$$U_p = (eQq_{zz})_{obs}/(eQq_{zz})_{atom} \qquad (4)$$

where $(eQq_{zz})_{atom}$ is 643.0 MHz.[13] From the mean value of $(eQq_{zz})_{obs}$, 273.65 MHz, one obtains the values of U_p=42.5% and i=50.0%.

The values of (Θ', Φ') specifying the direction of the Sb–Br bonds with respect to the crystal axes are listed in Table 3, together with those values obtained from X-ray analysis. In this table, the direction of $\Theta'=0°$ is chosen to be along the c-axis, and the plane of $\Theta'=0°$ is taken as the bc plane. The bond angles obtained from the Zeeman and X-ray analyses[4] are listed in Table 4, together with

Table 4. The bond angles ∠Br–Sb–Br in α-and β-$SbBr_3$

α-$SbBr_3$	$\angle Br_1$–Sb–Br_2	$\angle Br_2$–Sb–Br_3	$\angle Br_3$–Sb–Br_1
NQR	94°31′±8′	98°27′±7′	94°14′±4′
X-ray	93°38′	97°23′	95°28′
β-$SbBr_3$	$\angle Br_1$–Sb–Br_2	$\angle Br_2$–Sb–Br_3	$\angle Br_3$–Sb–Br_1
X-ray	92°48′	97°37′	97°37′

the bond angles of the β-form obtained from X-ray analysis.[5] Our values are consistent with those obtained from X-ray analysis to within about 1°. The direction of the Sb–Br_3 bond obtained from the Zeeman analysis lies on the bc plane, whereas that from X-ray analysis deviates from the bc plane by about 1°. According to the X-ray analysis, there must be four nonequivalent directions of Sb–Br_3 bonds, in each of which two directions are situated close together. However, for the Br_3 atom, which is responsible for the ν_3 line, we could observe only two loci and could not resolve either of them into two closely situated loci, even when a field of 350 gauss was used. At this stage we can not determine whether the present result and/or those obtained by the X-ray analysis are correct.

(b) The Molecular Complex $2SbBr_3 \cdot C_6H_6$. Let us label the three resonance lines of ^{81}Br as before. Again, from the number and the intensity ratio of the resonance lines, these lines can be ascribed to the three kinds of bromine atoms, Br_1,

Br_{3A}	87°26′ (**92°34′**)	144°56′ (35° 4′)	**97°21′** (82°39′)	85° 1′ (94°59′)	
Br_{3B}	34°41′ (145°19′)	**92°13′** (87°47′)	85°13′ (94°47′)	**96°53′** (83° 7′)	52°55′ (127° 5′)

* The value in parenthesis is the supplementary angle.

Considering that the antimony tribromide molecule may retain a trigonal pyramid and take the value of the bond angle near to 97°, we find from Table 5 that each of the groups, Br_{1A}, Br_{2A}, and Br_{3A}, and Br_{1B}, Br_{2B}, and Br_{3B}, belongs to the same molecule.

Because each line has two nonequivalent z-axes (zero-splitting loci), we conclude that this complex crystal has a monoclinic symmetry.[14] However, it is impossible to distinguish between C_s, C_2, and C_{2h} on the basis of the Zeeman analysis, which always introduces the center of symmetry to the crystal. The relative orientations of the Sb–Br_1, Sb–Br_2, and Sb–Br_3 bonds with respect to the b-axis are 29°4′±21′, 76°26′±9′, and 63°33′±11′ respectively. The bond angles obtained from Table 5 are listed in Table 6. The shape of the $SbBr_3$ molecule in the complex is similar to that of β-antimony tribromide as established by X-ray analysis.

TABLE 6. THE BOND ANGLES ∠Br–Sb–Br IN THE COMPLEX $2\,SbBr_3 \cdot C_6H_6$

Bond angle	∠Br_1–Sb–Br_2	∠Br_2–Sb–Br_3	∠Br_3–Sb–Br_1
NQR	97°40′±6′	97°7′±14′	92°24′±11′

The values of the asymmetry parameter obtained from the zero-splitting loci using Eqs. (1) and the values of eQq_{zz} calculated from Eqs. (2) are listed in Table 7. The value of η at the Br_1 atom, 16.9%, is considerably larger than the remaining ones and those in α-$SbBr_3$; it is almost the same as the largest value in $SbCl_3$, which amounts to 15.3%. As we excluded the possibility of a double bond, this large value of η must be ascribed to the intermolecular bonding. Two cases of intermolecular bonding

TABLE 7. RESONANCE FREQUENCIES (ν), ASYMMETRY PARAMETERS (η) AND QUADRUPOLE COUPLING CONSTANTS (eQq_{zz}) OF ^{81}Br ATOMS IN THE COMPLEX $2\,SbBr_3 \cdot C_6H_6$ AT 21.5°C

Complex	ν,	MHz	η, %	eQq_{zz}, MHz

	ν_2	139.70	6.3±0.2	279.23
	ν_3	140.69	9.4±0.2	280.98

14) K. Shimomura, *J. Phys. Soc. Jap.*, **12**, 652 (1957).

may be thought of. One is the bonding between the Br atom and the benzene ring, this bonding being formed by charge transfer. The other is the intermolecular Sb–Br bonding among neighboring $SbBr_3$ molecules. Since the bonding by charge transfer is weak,[15] the former is not likely to be responsible for the large value of η. On the contrary, the latter case seems reasonable.

The lowest line in the complex is lower by about 3 MHz than the lowest line of antimony tribromide itself. It has been thought that the charge transfer from the benzene to the bromine atom may cause the lowering of the resonance frequency. It has been found, however, that this lowering is very small.[15,16] Thus, the relatively large frequency lowering in the complex can be considered to be caused primarily by the intermolecular Sb–Br bonding. On the other hand, the spacing of the resonance lines of this complex, as may be seen in Fig. 1 (c), resembles that of aluminum tribromide. One of the three lines is situated apart from the two closely-spaced lines on the higher-frequency side. This appearance is characteristic of the halides of the third-group elements which form the dimer.[17] The lowest line is attributed to the bridging Br atom; it is lower by about 15 MHz than those of the upper pair in aluminum tribromide.[18] The corresponding lowering in the present molecular complex is about 8 MHz.

Therefore, we consider that there exist predominantly interacting partner molecules of $SbBr_3$ in the complex crystal, and that the Br_1 atom in one molecule is bound to the Sb atom in a partner molecule to some extent. It must, however, be remembered that a slight deviation of the direction of the z-axis of the field gradient from the bond axis occurs because of moderate intermolecular covalent bonding.

At this stage, it is not evident whether the benzene ring is bound to the Br or the Sb atom in the complex. Meanwhile, Hulme and Szymański[19] have proposed, on the basis of their X-ray analysis of the complex $2SbCl_3 \cdot C_{10}H_8$ that the aromatic ring is bound to the Sb atom; they based their proposal on the distance between the Sb atom and the aromatic ring

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2404—2409 (1970)

Effect of Halogenation on Intramolecular Energy Transfer in Rare Earth Chelates

Makoto MORITA*1 and Shigeo SHIONOYA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received February 27, 1970)

Using tris-dibenzoylmethanates of terbium(III) and other rare earths(III) we investigated the effect of halogenation of the central hydrogen of a 1,3-diketonate ligand on the luminescence properties of these chelates in rigid media. As a result of halogenation, all chelates display blue shift of the ligand phosphorescence, the intensity of the rare earth emission I_{RE} relative to that of the phosphorescence I_{ph} is markedly decreased in the order of H→Cl→Br, and the lifetime of the phosphorescence τ_{ph} decreases in the same order. These facts provide the evidence that the intramolecular energy transfer takes place *via* the triplet state of the ligand. In halogenated and nonhalogenated terbium chelates the ratio of the probability of energy transfer P_t estimated from the quantity $I_{RE}/I_{ph}\tau_{ph}$ to the overlap integral S between the phosphorescence spectrum and the terbium absorption spectrum is found to be roughly constant. These results lead us to the conclusion that intramolecular energy transfer is governed by the resonance mechanism due to exchange interaction.

For the intramolecular energy transfer from the ligand to the central metal ion in rare earth chelates, Crosby's proposal[1,2] has been generally accepted. This states that excitation energy is transferred from the triplet state of the ligand to the resonance level of the rare earth ion. In our previous paper,[3] we reported perturbation effects on the triplet states, such as oxygen effect and external heavy atom effect usually known in organic molecules, and gave some facts which strongly suggest Crosby's mechanism. Some other investigators[4-6] used the technique of triplet quencher to study this problem and presented some useful information.

Recently we have studied[7] this energy transfer process under the excitation of the triplet state of europium chelates by utilizing intermolecular triplet-triplet energy transfer from lanthanum chelates, and have presented evidence for Crosby's proposal. Further, we have investigated[8] the correlation between the energy transfer probability and the stretching vibration frequency of the chelate bond as obtained from infrared absorption measurements, and have concluded, according to an approximated treatment of Dexter's theory,[9] that the energy transfer process is dominated by the exchange interaction of the π electron system of the ligand triplet state with the f electron system of the central rare earth ion.

In parallel with these studies, we have continued the study of heavy atom effect on this intramolecular energy transfer with the purpose of investigating the transfer mechanism. Substitution of a halogen atom for 2-hydrogen of 1,3-β-diketonate as the ligand is expected to give an internal heavy atom effect, because this should change the probability of the transition from the triplet state to the ground singlet state and consequently influence the luminescence process of chelates. One may expect that this internal heavy atom effect is much more strongly observed than the external heavy atom effect. In the present paper, the luminescence properties of various halogenated tris-dibenzoylmethanates are reported. Exchange interaction has

been further confirmed to dominate the intramolecular energy transfer process.

Experimental

1) Samples. Tris-dibenzoylmethanates of rare earth ions were prepared by the usual procedures.[2] Halogenated chelates were obtained by the direct substitution method similar to that used by Collman *et al.*[10] for transition metal chelates. Chlorinated chelates were also prepared by the indirect method, *i. e.* by treating rare earth nitrates or acetates with 3-chloro-3-dibenzoylmethane prepared by the method reported by Kochetkov *et al.*[11] The two different methods were found to give the same chlorinated products. However, the former method was mostly employed to obtain halogenated compounds in this paper. We have synthesized various samples of $Ln[(C_6H_5CO)_2CX]_3 \cdot H_2O$ in which Ln stands for Eu, Sm, Tb, Dy, Gd and La, and X is H, Cl or Br (abbreviated hereafter as LnD, LnDCl or LnDBr). Chemical analysis of rare earth content as well as measurement of infrared absorption spectra were carried out in order to identify the obtained products.

2) Spectroscopic Measurements. Infrared absorption spectra were measured by means of the KBr disk method with a Hitachi EPI-2 infrared spectrophotometer attached with an NaCl or KBr prism (for NaCl or KBr region, respectively). Ultraviolet and visible absorption spectra were obtained at room temperature using a Cary model 14 spectrophotometer for both alcohol and chloroform solutions with chelate concentrations 5×10^{-5} mol/*l*.

Measurement of emission spectra was made at liquid nitrogen temperature by using a Kipp and Zonen prism double monochromator for ether-toluene (4 : 1) solutions with chelate concentration 5×10^{-4} mol/*l*. For the reference, powder samples of chelates were also measured. The 254 nm line obtained from the combination of a 100 W high pressure mercury lamp and an appropriate set of filters were used as the exciting source, and the response of an EMI 9558QB photomultiplier was fed to a millivolt recorder.

In the measurements of time-resolved emission spectra and emission lifetime, an Edgerton xenon flash lamp of type FX-3 attached with ultraviolet pass filters was used as the exciting light source. Chelate solutions of ether-toluene (4 : 1) with the concentration 5×10^{-3} mol/*l* were irradiated at liquid nitrogen temperature by pulse light from the flash lamp having a half-width of 2 μsec and frequency of 25 Hz. The response of an RCA 931A photomultiplier gated for 1 μsec was recorded with delay times ranging from zero to 100 μsec. Lifetime was obtained directly from the decay characteristics of the time-resolved emission spectra.

Results and Discussion

Infrared absorption spectra of halogenated rare earth chelates were found not to involve the absorption of 1200 cm^{-1} region which is due to the C–H in-plane bending mode. The carbonyl stretching bands in 1500 and 1600 cm^{-1} region are simplified in the halogenated products and the absorption band due to the M–O bond stretching does not change appreciably upon halogenation. These facts are considered to give structural evidence for the halogenation as was done for chromium

chelates.[12]

The ultraviolet absorption spectra of LnD involve two broad bands at about 250 nm and 350 nm, respectively.[1] As a result of halogenation the 250 nm band strongly increases its absorbance and slightly shifts to longer wavelengths, while the 350 nm band almost disappears. We therefore used the mercury line of 254 nm as the exciting source in this study.

The emission spectra of ether-toluene solutions of GdD, GdDCl and GdDBr under steady excitation at 77°K are shown in Fig. 1. These spectra demonstrate how the ligand emission changes as a result of halogenation. If these spectra under steady excitation are compared with time-resolved emission spectra with a delay time of about 60 μsec, it turns out that in the GdD spectrum the weak band at about 430 nm is that of fluorescence while the strong band ranging from 480 to 600 nm is that of phosphorescence, and

that in the case of GdDCl and GdDBr the spectra observed under steady excitation are only those of phosphorescence. It is noted that as a result of halogenation the phosphorescence spectrum is markedly blue-shifted, but the shape and peak position of the spectrum are nearly the same among the halogenated chelates.

The results of the emission spectrum measurements for a series of LaD, EuD, TbD, SmD and DyD and their halogenated derivatives are as follows. Lanthanum chelates show broad band emission of the ligand which is analogous to gadolinium chelates. Other chelates show sharp line emissions due to central rare earth ions in addition to the ligand emission. As examples, the emission spectra of europium chelates and terbium chelates are given in Figs. 2 and 3, respectively. It was found that in all cases the ligand emission spectra are quite similar to those of gadolinium chelates.

However, it should be noted, as is observed from these figures, that the intensity of the ligand emission relative to that of rare earth emission strongly increases as a result of halogenation. For example, although EuD shows hardly any ligand emission, EuDCl and EuDBr exhibit pronounced ligand phosphorescence. In the case of EuDCl the emission lines due to $^5D_0 \rightarrow {}^7F_J$ transition of Eu^{3+} ion are found only weakly at the tail of the strong ligand phosphorescence without the detectable change in the positions of the lines. In the case of EuDBr, the emission lines of Eu^{3+} ion are much more weakened. They are scarcely observed in glassy solutions as shown in this figure, although they are clearly found in a powder sample in which phosphorescence is completely quenched.

As in the case of europium chelates, terbium chelates have similar features of the halogenation effect. The variations of the emission intensity of rare earth ion as well as of the ligand are more clearly found in terbium chelates than in europium chelates. The emission spectra of samarium chelates, although not shown here, are also characterized by the halogenation effect. SmD has emissions of both ligand and rare earth ion with nearly equal intensities. However, in SmDCl and SmDBr the emission of ligand appears strongly and the emission of Sm^{3+} ion is almost quenched just as in the case of europium chelates. In the case of dysprosium chelates, the effect of halogenation is somewhat different. Namely, although DyD does not show Dy^{3+} emission, it becomes observable at around 500 nm in powder samples of DyDCl and DyDBr. This is interpreted as a result of the increase of the matching between the energies of the triplet state and the Dy^{3+} resonance levels caused by the blue shift of phosphorescence.

The decay time was obtained from time-resolved emission spectra. It was found that phosphorescence lifetime of GdD is 610 μsec while that of GdDCl and GdDBr decreases to 5.6 μsec and 4.1 μsec, respectively.

The results of the spectral measurements are summarized as follows. 1) The phosphorescence spectra of halogenated chelates are apparently blue-shifted in comparison with non-halogenated chelates, and chlorinated and brominated chelates have similar spectral features. 2) As a result of halogenation, the intensity of the ligand emission increases markedly, and instead the intensity of the rare earth emission lines decreases in the order H→Cl→Br. 3) The phosphorescence lifetime of gadolinium chelates decreases in the same order H→Cl→Br.

From these facts, one is led to the conclusion that the substitution of halogen atoms for hydrogen, *i.e.* the internal halogen effect, gives influences quite similar to the case of the external heavy atom effect.[3]

Let us next consider this substitution effect. In the case of naphthalene and its halogenated derivatives, relative decrease of the phosphorescence lifetime is H(1.0)→Cl(0.126)→Br(0.0078) against the relative increase of molecular weight of H(1.0)→Cl(1.27)→Br(1.62).[13] The internal heavy atom effect is known to depend predominantly on the weight of heavy atoms. Therefore, if we assume that for the phosphorescence lifetime of rare earth chelates the change of the same order of magnitude with halogenation as in the case of naphthalene and its derivatives is obtained, the lifetime of halogenated gadolinium chelates is estimated to fall into an order of magnitude of 10 μ to 100 μsec. The observed lifetime is comparable in magnitude with this value. However, since the peak position and shape of phosphorescence spectra change as a result of halogenation in rare earth chelates, it is inferred that the substitution effect in rare earth chelates is a pseudo-internal heavy atom effect. Hence, this substitution effect is considered to give the same conclusion as derived from the external heavy atom effect.[3] This then presents further evidence for Crosby's proposal that the intramolecular energy transfer takes place *via* the triplet states.[1,2]

Let us discuss the precise mechanism of the intramolecular energy transfer from the results obtained above. The theory of intermolecular energy transfer due to the resonance mechanism in condensed systems developed by Dexter[9] could be considered to be applicable to our present case of rare earth chelates.[5,6,8] Since intramolecular energy transfer takes place *via* the triplet state, the probability of the transfer P_t is given by the emission efficientcy of rare earth ion η divided by the lifetime of the ligand phosphorescence τ_{ph} as

$$P_t = \eta/\tau_{ph} \quad (1)$$

Here η is expressed by the intensity ratio of the rare earth emission to the ligand phosphorescence I_{RE}/I_{ph}. We have to estimate the overlapping of the

13) V. L. Ermolaev, *Opt. Spectry.*, **11**, 266 (1961).

phosphorescence spectrum of the ligand with the absorption spectrum of the rare earth ion. The overlap integral S is given by

$$S = \int I_{ph}(E)A(E)\mathrm{d}E, \qquad (2)$$

where $I_{ph}(E)$ represents the phosphorescence spectrum and $A(E)$ the absorption spectrum of rare earth ion, both being normalized to unit area.

In order to obtain the values of P_t with Eq. (1), those rare earth chelates which display appreciably both ligand phosphorescence and rare earth ion emission when halogenated must be used. Although we have examined various rare earth chelates as mentioned above, only terbium chelates were found to be appropriate for this purpose. In the case of europium and samarium chelates, the rare earth emission are almost quenched in brominated chelates in rigid media. We have further investigated the use of chelates with different ligands, but it was found that chelates with many other ligands commercially available are not so easily halogenated according to the direct substitution method. Therefore, we have to confine our discussion to terbium-(III) tris-dibenzoylmethanate and its chlorinated and brominated ones in this paper.

Let us discuss the mechanism of intramolecular energy transfer in terbium chelates. The quantities of P_t, S, η and τ_{ph} are estimated as shown in Table 1. In obtaining S, the absorption spectra of rare earth ion were substituted by those of terbium-(III) chloride in aqueous solution, because the absorption in chelate solutions is too weak to be measured. Since the ligand emission of TbD is very weak, the lifetime τ_{ph} could not be measured. Then, the relative τ_{ph} values for terbium chelates were substituted by those observed for gadolinium chelates. This substitution is allowed because only the relative value of the lifetime is important in our present analysis.

The transfer probability P_t due to exchange interaction is approximately given by[9]

$$P_t(\mathrm{exch}) = \mathrm{const.}\ S \exp(-2R/L), \qquad (3)$$

where R is, in the case of rare earth chelates, the bond distance between the metal ion and the ligand, and L is the effective Bohr radius for the excited and unexcited states of energy donor and acceptor.

On the other hand, the transfer probability P_t due to electric multipole interaction is given by

$$P_t(\mathrm{multipole}) = \mathrm{const.}\ S/R^s\tau_{ph}\tau_{RE} \qquad (4)$$

Here, s is 6, 8 or 10 corresponding to dipole-dipole, dipole-quadrupole or quadrupole-quadrupole interaction, respectively.

The magnitude of the spacial overlap of the wavefunctions of the rare earth ion and the oxygen atom of the ligand, expressed by $\exp(-2R/L)$ in Eq. (3), is nearly independent of halogenation, because the frequency of the metal-oxygen vibration as obtained by infrared absorption measurement remains nearly unchanged as a result of halogenation so that the value of R is regarded as not changing. Therfore, if the energy transfer in rare earth chelates under discussion is dominated by exchange interaction, the P_t/S values must be constant among chelates in the table. In the case of multipole interaction, since the lifetime of rare earth ion τ_{RE} is not usually affected by the kinds of ligands, the value of $P_t\tau_{ph}/S$ in Eq. (4), which is equal to η/S, must be constant. Therefore, the values of P_t/S and η/S were calculated and are shown in the table to examine which of these mechanisms is responsible.

It is noted that the values of η/S change in two orders of magnitude while those of P_t/S are in the same order. By taking account of the experimental error in estimating the shape of phsphorescence spectrum in TbD, we might be allowed to conclude that P_t/S is kept nearly constant among three compounds, although η/S changes appreciably.

Although only poor data are available for the moment, we may conclude that the intramolecular energy transfer in rare earth chelates is governed by the resonance mechanism due to exchange interaction, but not to electric multipole interaction, between the ligand triplet state and central rare earth ion. In fact, this conclusion is in agreement

TABLE 1. RELATIVE VALUES OF THE QUANTITIES CONCERNING ENERGY TRANSFER PROCESS FOR HALOGENATED TERBIUM CHELATES IN ETHER-TOLUENE SOLUTIONS AT 77°K

with that obtained by our previous investigation[8] in which the measurement of the infrared absorption spectra was used as the tool.

Conclusion

The substitution of chlorine and bromine atoms for the central hydrogen of the ligand has been performed in a number of dibenzoylmethanates of rare earth ions such as Eu, Tb, Sm, Dy, Gd and La. The changes of luminescence properties due to halogenation have been found to be remarkable. The intensity of the rare earth ion emission decreases in the order H→Cl→Br, while the phosphorescence spectra are blue-shifted and the intensity is strongly enhanced accompanied by the decrease of the lifetime. This is understood as being due to a pseudo-internal heavy atom effect, and provides evidence that intramolecular energy transfer takes place *via* the triplet state of the ligand. Luminescence features were examined further according to the theory of resonance energy transfer. In the case of terbium chelates, the ratio of the transfer probability to the overlap integral between the phosphorescence spectra and the rare earth absorption spectra has been found to remain nearly unchanged under halogenation. These facts lead us to the conclusion that the intramolecular energy transfer is caused by the resonance mechanism due to exchange interaction.

The authors would like to thank Dr. Y. Matsuda for his discussion. They are also indebted to Mr. S. Tamura and Miss F. Miyazawa of this Institute for the analysis of rare earth chelates.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2409—2413 (1970)

An Electron Spin Resonance Study of 1,1′- and 2,2′-Biazulenyl Anion Radicals

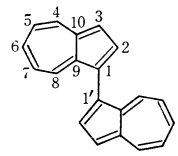
Yusaku IKEGAMI and Shuichi SETO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2-chome, Sendai

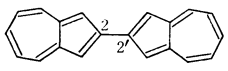
(Received March 2, 1970)

The electron spin resonance (ESR) spectra of the anion radicals of 1,1′- and 2,2′-biazulenyls have been examined. The ESR spectrum of the latter shows that the unpaired spin is distributed equally between both azulene rings of the molecule. Theoretical calculation of the spin densities by the McLachlan procedure gave satisfactory agreement with the experimentally estimated densities. The ESR spectrum of the anion radical of 1,1′-biazulenyl, which could only be generated by an electrolytic technique, is explained by the fact that the spin exchange between the two halves of the molecule is slow. However, the ESR spectrum of the anion radical of the 3,3′-dicarbethoxy derivative of 1,1′-isomer showed rapid spin exchange through 1,1′-bond.

Recent success in the synthesis of 1,1′- (I) and 2,2′-biazulenyls (II) by Morita and Takase[1] revealed that there is a wide difference in the physical properties of the two isomers. Difference of their absorption spectra, for example, is distinct at around 400 mμ region: the absorption maximum of I is at 382 mμ ($\varepsilon=13200$) while II has two peaks at 406 (25600) and 432 mμ (45300) in dimethoxyethane (DME). A similar tendency for the positions of the absorption maxima is noted in the spectra of 3,3′- and 2,2′-biguaiazulenyls which have been reported by Hagen, Heilbronner and Straub.[2] It is presumed that a conformational problem between two planar azulene rings of biazulenyls might be closely related to the essential features of their electronic spectra.



I



II

Several investigators[3] have studied the electron spin resonance (ESR) spectra of the anion radicals

1) T. Morita and K. Takase presented at the 20th Annual Meeting of the Chemical Society of Japan in Tokyo, 1967.

2) R. Hagen, E. Heilbronner and P. A. Straub, *Helv. Chim. Acta*, **51**, 45 (1968).

3) P. H. Rieger and G. K. Fraenkel, *J. Chem. Phys.*, **37**, 2795 (1962); **39**, 609 (1963); K. Ishizu, This Bulletin, **37**, 1093 (1964); M. Hirayama, *ibid.*, **40**, 2530 (1967).

formed by the reduction of biphenyl derivatives and have discussed the planarity of the two aromatic rings. ESR studies of azulene anion radical, a particularly interesting compound as a non-alternant hydrocarbon, have been made by some investigators,[4-6] and the π-electron densities estimated theoretically and experimentally have been discussed in detail.[4] It should be possible to obtain considerable information on the spin density contribution in the biazulenyls, as well as their molecular structures, by ESR study of their anion radicals. The ESR spectra and the calculated spin densities for the biazulenyl anion radicals are reported in this paper.

Experimental

The materials, 1,1′-biazulenyl, mp 104°C, 2,2′-biazulenyl, mp 200°C, and 3,3′-dicarbethoxy-1,1′-biazulenyl, mp 212°C, were purified by recrystallization. All solvents were degassed by at least five freezing-pumping cycles after being purified. 1,2-Dimethoxyethane (DME) and tetrahydrofuran (THF) were preserved in each flask, connected with a high vacuum apparatus as solutions of sodium anthracenide. *N,N*-Dimethylformamide (DMF) was distilled on to a molecular sieve (4A, small pellet) which had been flame dried in a vacuum. The solvents were distilled into the reaction vessels connected with the sample tube for measurement.

Reduction with alkali metal was performed by the usual method using lithium, sodium and potassium metals as reducing agents. The technique employed in the electrolytic generation of free radicals is similar to that used by Hirayama.[7] Electrolytic reduction was performed using DMF as a solvent and tetra-*n*-propylammonium perchlorate as the supporting electrolyte.

The ESR spectra were measured at room temperature with a Hitachi X-band ESR spectrometer, Model MPU-3B, using a field modulation of 100 kcps. Analysis of the spectra was confirmed by simulation for which a JEOL spectrum computer, JRA-5, was used.*1 Numerical calculation was carried out on the NEAC 2230 at the Computation Center, Tohoku University.

The absorption spectra were measured in the degassed solvent at room temperature by using a Cary Model 14 spectrophotometer.

Results and Discussion

2,2′-Biazulenyl Anion Radical. Treatment of 2,2′-biazulenyl (II) with lithium, sodium or potassium metal in degassed DME or THF caused an immediate change in color to deep blue. The

colored solution is quite stable for a long period and shows a strong ESR signal. The absorption spectrum of the solution generated by the treatment of II with a lithium metal for a few days at room temperature is shown in Fig. 1, and compared with the spectrum of the neutral compound. Further treatment of the colored solution with the metal for a a week resulted in a loss of both the blue color and the ESR signal. This might be due to the formation of the diamagnetic dianion of II by the further reduction of the anion radical.

The ESR spectrum of the blue solution in Fig. 2 was measured at room temperature. Similar spectra were obtained by the reduction of II with sodium or potassium metal in DME or THF and by the electrolytic reduction of II in DMF using tetra-*n*-propylammonium perchlorate as the supporting electrolyte. Hyperfine structure of the spectrum was analyzed with four splitting constants (a_i^H), as expected for the symmetrical structure of II. It is thus recognized that the unpaired electron in the anion radical is distributed equally between both azulene rings. No metal coupling has been observed in all the spectra. The line widths for the spectra are between 75 and 140 milligauss. The observed splitting constants and their assignments are given in Table 1. The assignments were made reasonably by comparison with the calculated spin densities.

Calculations of unpaired spin densities (ρ_i) for the anion radical were carried out by employing both the Hückel LCAO molecular orbital theory and the approximate configuration interaction treatment proposed by McLachlan.[8] The resonance integral parameters (β_{ij}) for the 2,2′- and 9,10- (9′,10′-) bonds were varied over the following ranges:

$$0.6\beta \leqq \beta_{2,2'} \leqq 1.2\beta,$$

$$0.9\beta \leqq \beta_{9,10} = \beta_{9',10'} \leqq 1.0\beta.$$

All other bond length variations were neglected and the λ parameter in the McLachlan procedure was fixed at the value, $\lambda = 1.2\beta$, in our calculation. The $|Q_{CH}^H|$ values obtained by the relation, $a_i^H = Q_{CH}^H \cdot \rho_i$, using the observed splitting constants and the calculated spin densities, are compared with the resonance integral parameters. As easily expected from the fact that the total extent of the spectrum, 33.4—34.1 gauss, suggests the presence of negative spin densities, the McLachlan procedure showed better values than by Hückel molecular orbital calculation.

Variations of the $|Q_{CH}^H|$ values versus the parameter, $\beta_{2,2'}$, are shown in Figs. 3a and 3b for the cases in which $\beta_{9,10}$ are 0.9β and 1.0β. We see that the parameter $\beta_{2,2'}$ mostly affects the Q_{CH}^H values at the 1- and 3-(1′- and 3′-)positions. As far as the above parameters are concerned, each of the McLachlan spin densities at the positions from 4 through 8 (also

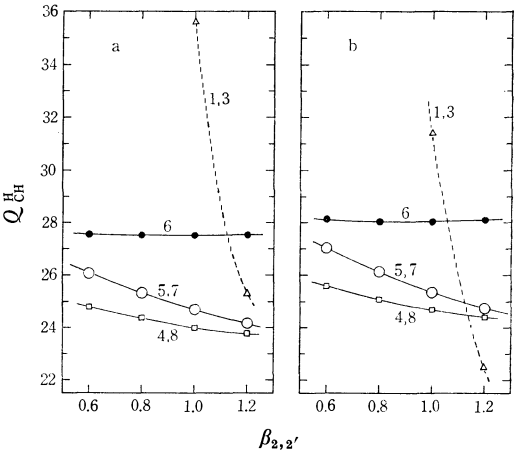

Fig. 3. Q_{CH}^H values in the relation, a_i^H(obsvd.) = $Q_{CH}^H \rho_i$ (calcd.), as a function of the resonance integral parameter for the 2,2′-bond ($\beta_{2,2'}$) of 2,2′-biazulenyl anion radical.

4′ through 8′) in the seven membered rings differs by less than 12%. Assuming the tendency of the variation of Q_{CH}^H with bond angle in the azulene anion radical, estimated by Bernal *et al.*[4] a good agreement with the experimental splitting constants is recognized by the McLachlan method when both the parameters, $\beta_{9,10}$ and $\beta_{2,2'}$, were close to 1.0β. Using 0.9β[4] as the $\beta_{9,10}$, a good result was also obtained when $\beta_{2,2'}$ was close to 1.0β; the re-

sults are listed in Table 2. Thus, the π-electrons of the two halves in II conjugate freely through the central 2,2′-bond, and it is clear that the two azulene rings are co-planar in the anion radical. Bernal *et al.*[4] estimated theoretically the Q^H_{CH} value for a regular seven-membered aromatic ring to be −15.2 gauss. However, the $\lvert Q^H_{CH}\rvert$ value does not seem to be far from 23—28 gauss as seen from Table 2. Similar values are also seen for the cases of 2-methoxyazulene anion radical,[9] tropone anion radical,[10] cycloheptatrienyl radical[11] and cycloheptatrienyl dianion radical.[12]

1,1′-Biazulenyl Anion Radical. The anion radical of 1,1′-biazulenyl (I) is not so stable as that of its 2,2′-isomer. For example, the solution of I in degassed DME or 2-methyltetrahydrofuran reacted readily with an alkali metal losing its green color. However, no ESR signals were observed during the course of reaction at room temperature. Electrolysis of the green solution of I in DMF at *ca.* 2.3 V, however, resulted in a pale greenish yellow solution which exhibited a stable ESR spectrum of the anion radical. The spectrum is shown in Fig. 4. No decay of the intensity of the spectrum was observed during the course of a few hours.

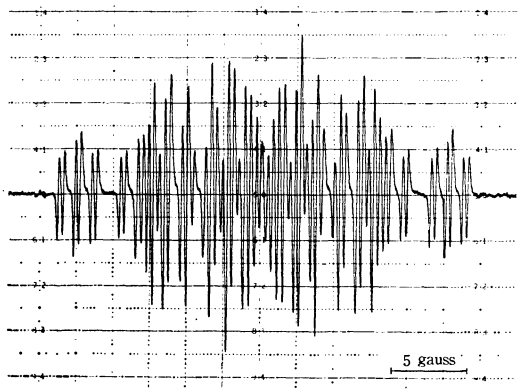

Fig. 4. ESR spectrum of 1,1′-biazulenyl anion radical generated by the electrolytic reduction in DMF.

Interesting facts seen from the spectrum are that it does not have a central strong line and that the hyperfine structure consists of five splitting constants, listed in Table 3, each of which is close to that of the azulene anion radical.[4-6] Thus, the spectrum resembles that of the azulene anion radical except that the smallest splitting is shown by doublets of relative intensities 1 : 1 as in Fig. 4. The simplest explanation of the spectrum is that spin exchange between the two halves of the molecule is slow, and the hyperfine structure originates from the seven protons on one half of the molecule. The assignment for the splitting constants is made by comparison with that for the azulene anion radical,[4] as indicated in Table 3. It might be necessary to see if the rate of intramolecular electron transfer of the anion of I can be increased by measuring its spectrum at elevated temperatures. However, measurement has not been successful because of the instability of the anion radical.

The slow spin exchange in the anion of I is analogous to the situation existing in the anion radical of

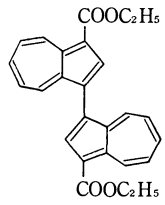
bis(*p*-nitrophenyl)ether.[13] In the anion radical of I, the localization of the unpaired electron should be attributed to the inability of the π-electrons in both azulene rings to overlap at the position of the 1,1′-bond. Moreover, the equivalence of both protons at 4- and 8-positions (and also 5- and 7-positions), shown by their splitting constants, indicates that the electronical interaction through the 1,1′-bond between the five-membered rings is small. The steric repulsion between ring protons at 2- and 8′- (2′- and 8-)positions probably makes it impossible for the two azulene rings to be co-planar. This difficulty might also be assisted by the electronical repulsion between the five-membered rings which are usually known to be negatively charged in azulene structure.[14] Such a slow spin exchange was not observed in the ESR spectrum of 1,1′-binaphthyl anion radical, prepared by the reduction of 1,1′-binaphthyl with sodium metal in DME, in which at least 135 hyperfine splitting lines with a central strong line were observed within the total extent of 22 gauss of the spectrum.[15]

The Anion Radical of 3,3′-Dicarbethoxy-1,1′-biazulenyl. In contrast to the case of I, the dicarbethoxy derivative (III) of I exhibits rapid spin exchange through 1,1′-bond.



III

The anion radical of III generated by reduction with sodium metal in DME showed an ESR spectrum which is analyzed with four hyperfine splitting constants. The spectrum and the splitting constants are shown in Fig. 5 and Table 4, respectively. Each of the constants represents coupling with two equivalent protons giving triplets of relative intensities 1 : 2 : 1. A similar spectrum was obtained by the electrochemical reduction of III in DMF. The splitting constants are included in Table 4. Measurement of the spectrum at −50°C did not show any signs of slow spin exchange as in the spectrum of the anion radical of compound I.

Total extent of the spectrum (14.3 gauss) in Fig. 5 suggests that a considerable amount of spin density might be expected to be on the two carbethoxy groups in the molecule. However, an explanation of this suggestion by the calculation of the McLachlan spin densities, using some parameters related to the carbethoxy group[7,16] and resonance integral parameters for the 1,1′-bond, can not be given yet, although the two splitting constants, 2.923 and 0.640 gauss, could be easily assigned to the protons at 6- and 2- (6′- and 2′-)positions, respectively. ESR measurements of the anion radicals of other carbethoxy derivatives of azulene may provide some information on the effect of the substituents in the anion of III. However, our experiments for the cases of 1-carbethoxyazulene[17] and 1,3-dicarbethoxyazulene[18] did not show any ESR signals by standard techniques. Further attempts are being made.

Electronic Absorption Spectra and Electronic Structures of Some Würster's Blue Salts

Tadayoshi SAKATA and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received March 4, 1970)

Electronic absorption spectra were measured at various temperatures for Würster's blue iodide, bromide, and chloride. The charge-transfer bands were found to be strongly dependent upon temperature. Concerning the iodide, the temperature dependency can be explained quantitatively, or at least semiquantitatively, by the aid of the linear Ising model in relation to the local ordering of the electron spins of Würster's blue cation radicals. This model gives the exchange energy of 99 ± 23 cm^{-1} for the iodide. For the bromide and the chloride, the dimer model was successfully applied to the analysis of the temperature dependence of the charge-transfer bands, giving singlet-triplet energy separations of 248 ± 30 cm^{-1} and 255 ± 30 cm^{-1} for the bromide and the chloride, respectively. The electronic structure and the intermolecular interaction were discussed for these radical salts, their electronic absorption spectra being compared with one another.

The Würster's blue radical salts are interesting research subjects because of their peculiar physicochemical properties.[1-12] For example, Würster's blue perchlorate (WBP) exhibits an unusual temperature dependency in the intensity of its electronic absorption spectrum. In previous papers[11,12] we studied this phenomenon, paying special attention to the phase transition mechanism and concluded that the dimerization mechanism of the phase transition is appropriate to solid WBP and that the disproportionation mechanism proposed by Kommandeur *et al.*[7-10] may be disregarded.

In the present paper, the temperature dependence of electronic absorption spectra was measured for the other Würster's blue salts: Würster's blue iodide (WBI), Würster's blue bromide (WBB), and Würster's blue chloride (WBC). The X-ray crystal analysis study of WBI was performed by de Boer *et al.*[13] According to their result, WBI takes a crystal structure in which the Würster's blue cations pack face-to-face to form regular columns parallel to the *b*-axis. The magnetic susceptibility of WBI was found to be well explained in the temperature range of 77—300°K by the aid of the linear Ising model.[14,15] From this it is revealed that the phase transition observed for WBP may not occur WBI in this temperature range. In view of this, we have undertaken to measure the temperature dependence of the electronic absorption spectra of WBI, WBB, and WBC and to compare the results with those for WBP.

Experimental

WBI and WBB were prepared by the method described in the literature.[16] WBC was prepared by oxidizing *N,N,N',N'*-tetramethyl-*p*-phenylenediamine in methanol with chlorine gas.

A Cary recording spectrophotometer model 14 M was used for the measurement of the electronic absorption spectra of solid samples. Solid, thin films used for the

absorption measurements were prepared by coating powdered samples on quartz plates by a stainless steel spatula.[11]

Absorption measurements at low temperatures were made by using glass Dewar vessels containing liquid helium or liquid nitrogen as a refrigerant, the temperature being measured by a thermocouple of (Au–Co) and Cu.

Results and Discussion

The Temperature Dependence of the Charge-Transfer Band of WBI. According to the X-ray crystal analysis data, WBI takes the crystal structure in which WB cations are located face-to-face forming one-dimensional columns.[13] Since the overlap between the π-electron orbitals of the neighboring cations is expected to be largest in the direction parallel to the columns, the one-dimensional model is applicable to the study of the charge-transfer (abbreviated hereafter to CT) interaction in solid WBI.

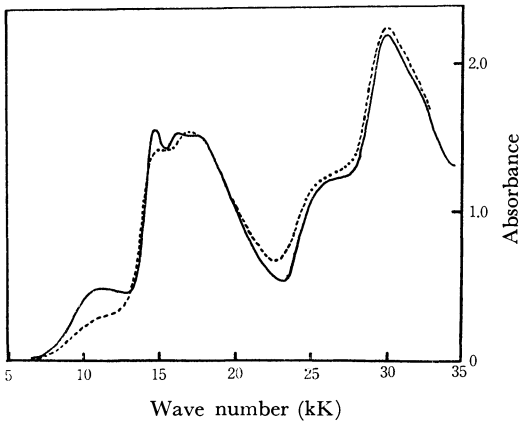

Fig. 1. The electronic absorption spectrum of the solid WBI.
---- at 260°K, ——— at 40°K

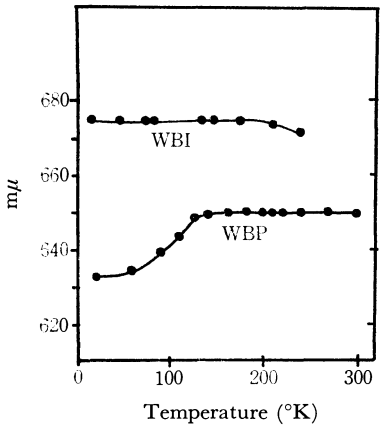

Fig. 2. Temperature dependence of the peak position of the first vibronic band for WBI and WBP.

The electronic absorption spectra of WBI measured at 260°K and at 40°K are shown in Fig. 1. First, let us consider the 600 mμ band due to the $^2B_{1u} \leftarrow {}^2B_{3g}$ transition of the WB cation. The peak position of this band is almost independent of temperature, though the vibrational structure becomes sharp with the decreasing temperature. The temperature dependence of the first vibronic band position observed for WBI is shown in Fig. 2, together with that for WBP. The peak position is almost constant for WBI in the temperature range of 40—260°K, while it varies greatly for WBP below the phase transition point. This suggests that the phase transition does not occur for WBI in this temperature range.

The 900 mμ band observed for solid WBI can safely be regarded as the CT band due to electron transfer between the half-occupied orbitals of the WB cation radicals. Its intensity greatly depends on temperature and increases with the decreasing temperature, as seen in Fig. 3. Since WBI shows no phase transition as mentioned above, it is not probable that solid WBI takes the dimer model which can be successfully applied to WBP. Therefore, we have undertaken to interpret the temperature dependency of the CT band of WBI by the aid of the one-dimensional Ising model, taking only the two neighboring WB cations in a chain.

The CT transition corresponding to the electron

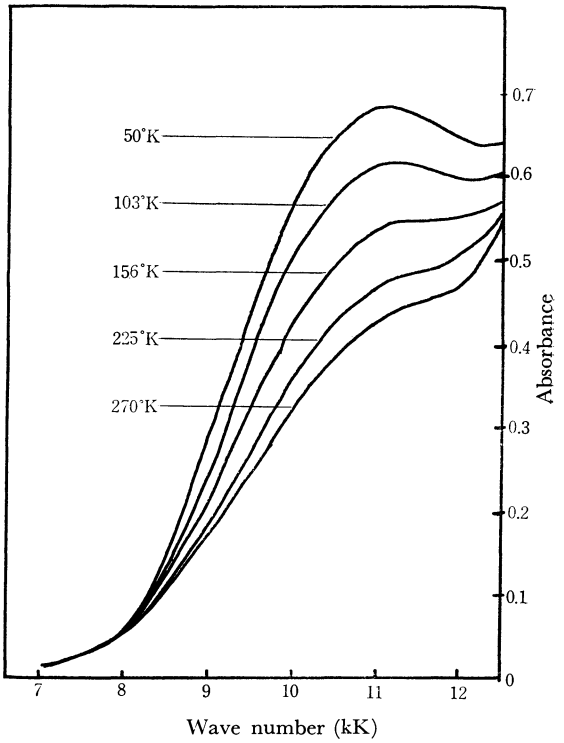

Fig. 3. The temperature dependence of the CT band of solid WBI.

transfer between the half-occupied orbitals of the two WB cation radicals is allowed, when the unpaired electron spins on these two orbitals are antiparallel with each other in the ground state ($S_1^zS_2^z=-1/4$). When they are parallel ($S_1^zS_2^z=1/4$), however, the transition is forbidden. This rule comes from the facts that the two spins must be antiparallel in the CT state from Pauli's principle and that the electron does not change its spin in the optical transition. We define the normalized intensity of the CT band, I_{CT}, in such a way as it takes 1 and 0 for the allowed and forbidden transitions, respectively; it is expressed with regard to the spin of the ground state as follows:

$$I_{CT} = -2S_1^zS_2^z + \frac{1}{2} \tag{1}$$

The above consideration can be generalized for a regular linear chain as follows:

$$I_{CT} = -2\langle S_i^zS_{i+1}^z\rangle + \frac{1}{2} \tag{2}$$

where $\langle\ \rangle$ represents the statistical average for the system. Now let us write the Ising Hamiltonian of the system by the aid of the exchange energy, J, as follows:[17]

$$\boldsymbol{H} = 2J\sum_i S_i^zS_{i+1}^z \tag{3}$$

The solution of this Hamiltonian is well known, and $\langle S_i^zS_{i+1}^z\rangle$ is given as follows:

$$\langle S_i^zS_{i+1}^z\rangle = -\frac{1}{4}\tanh\frac{J}{2kT} \tag{4}$$

Accordingly, the following equation can be obtained from Eqs. (2) and (4):

$$I_{CT} = \frac{1}{2}\left(\tanh\frac{J}{2kT} + 1\right) \tag{5}$$

Figure 4 shows the temperature dependence of the normalized intensity of the CT band.*1

We can obtain J from the temperature, T_1, at which I_{CT} equals 3/4, namely, $\tanh J/2kT_1=1/2$. From Fig. 4, T_1 may be taken to be 130 ± 30°K; J is evaluated to be 99 ± 23 cm^{-1}. The theoretical curve for $J=99$ cm^{-1} is also shown in Fig. 4 for the purpose of comparison. The discrepancy between the theoretical and observed curves becomes predominant at higher temperatures. There may be two reasons for this discrepancy: 1) the J value and the transition probability may be dependent upon the temperature through the intermolecular distance, and 2) the Ising model may be applied inadequately. At any rate, it may be said that the calculated I_{CT} values are at least semiquantitatively

17) R. Kubo, H. Ichimura, T. Usui and N. Hashizume, "Statistical Mechanics," North-Holland Publishing Company, Amsterdam (1965), p. 348.

*1 The CT band intensity was obtained by integrating the area below the respective absorption curve over the frequency region lower than 11300 cm^{-1}. Since, in our experiment, the lowest temperature was 50°K, the intensity at 0°K was estimated approximately by extrapolation.

Table 1. The peak positions (cm^{-1}) of the absorption bands of various Würster's blue salts

		CT	lst LE	3 rd LE
Solution	WBP monomer	—	17000	30700
	WBP dimer	12900	19800	32300
Solid	WBP (high temp.)	11700	16500	30000
	WBP (low temp.)		17000	30800
	WBI (77°K)	11300	17000	30000
	WBB (77°K)	11200	19600	31600
	WBC (77°K)	11100	20500	31900

coincident with the observed values at lower temperatures. The J value obtained by this method agrees with that obtained from the magnetic susceptibility (83 cm^{-1}) measurements within the expermental error.[14] This seems to mean that our explanation on the temperature dependence of the CT band intensity is essentially correct for solid WBI.

The Absorption Spectra of Solid WBB and WBC. The absorption spectra of solid WBB and WBC were measured at ~77°K; the results are shown in Fig. 5(a). In Fig. 5(b) the absorption spectra of solid WBP and the free WB cation in solution are shown for the purpose of comparison. As is clearly seen in Fig. 5, the absorption spectra of solid WBB, WBC, and WBP are different from one another in their peak positions and in their shapes.

In Table 1, the peak positions in the absorption spectra of the solid Würster's blue salts under consideration are shown, together with those for WBP in solution. In this table, the first and third locally excited (LE) bands correspond, respectively, to the ~600 mμ and ~330 mμ ones of the WB cation radical monomer. Approximate values are taken for the peak positions of the first local excitation bands of WBP and WBI, since it is difficult to obtain their values definitely because of the vibrational structure. As is seen in Table 1, the first LE band shifts to higher frequencies in the order of WBP (high-temperature form)<WBI<WBP (low-temperature form)<WBB<WBC. The same tendency was observed for the third LE band. Furthermore, the ratio of the intensity of the CT band to that of the first or the third LE band also increases in the above order. This means that the ~600 mμ and ~330 mμ bands of the monomer are increasingly perturbed by the intermolecular interaction in the above order. That is to say, the strong interaction between the WB cation radicals is not only the source of the CT band but also has an influence on the intramolecular excitation band. In this connection, it may be noticed that the vibrational structures characteristic of the first absorption band of the WB cation radical disappear in solid WBB and WBC and that their band shapes resemble the spectra of the dimer in solution as seen in Fig. 5.

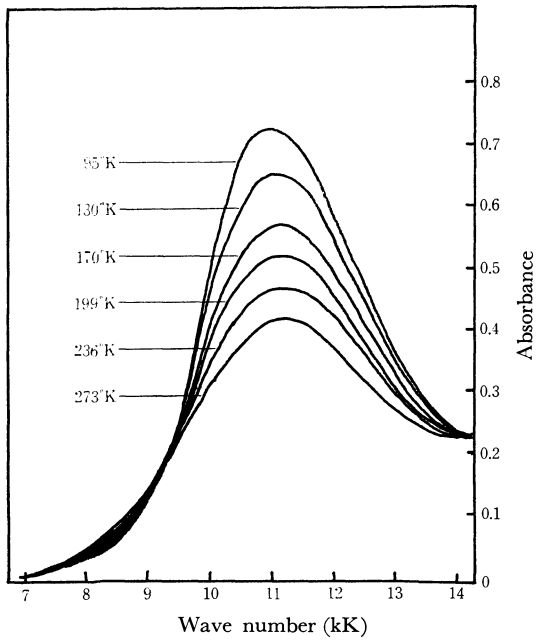

Fig. 6(a). The temperature dependence of the CT band of solid WBC.

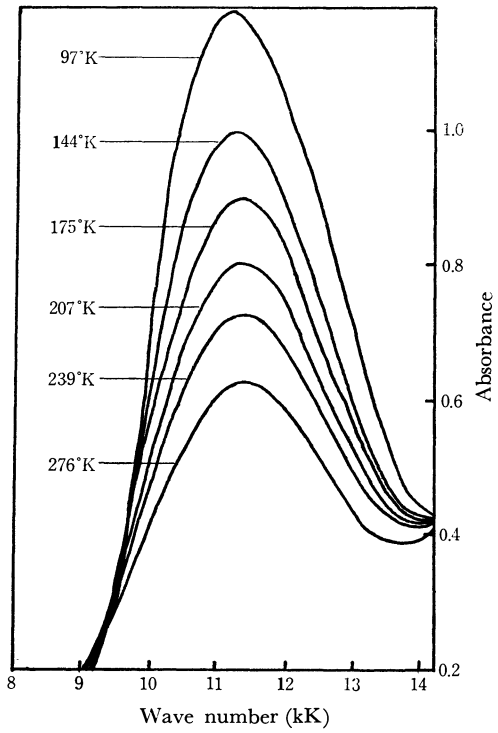

Fig. 6(b). The temperature dependence of the CT band of solid WBB.

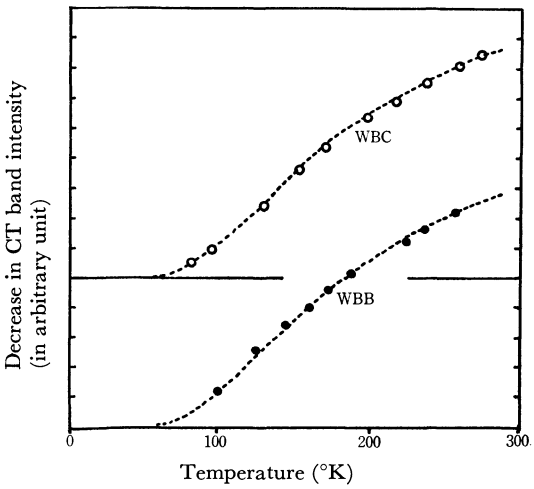

Fig. 7. Temperature dependence of the CT band intensity for WBC and WBB. The circles represent the observed values and the broken lines the theoretical ones.

The temperature dependence of the CT band was measured for WBB and WBC; we found an increase in its intensity with the decreasing temperature. Since this tendency observed for WBB and WBC is similar to that for WBP in the low-temperature phase, it may be expected that the temperature dependence of the CT band observed for the former salts can be explained by the dimer model which was successfully applied to the latter.[11] According to this model, the decrease in the CT band intensity turns out to be proportional to the population on the thermally accessible triplet exciton state caused by the exchange interaction between the two radical monomers. Actually, we applied the analytical method described in a previous paper[11] to the experimental data given in Fig. 6 and evaluated the singlet-triplet separation, J', as 248 ± 30 cm^{-1} and 255 ± 30 cm^{-1} for WBB and WBC, respectively. The theoretically expected temperature dependence of the CT band, calculated by the aid of the evaluated singlet-triplet separation, is shown in Fig. 7 for WBC and WBB. In this figure the observed values are also plotted for the purpose of comparison. We can find good agreement between the theoretical and experimental values for both WBC and WBB.

The authors should like to express their deep thanks to Dr. Akio Sakurai of this Institute for his helpful discussion.

Studies of Helical Aggregates of Molecules. II. The Sense of Twist in the Fibrous Aggregates from the Alkali Metal Soaps of Optically Active 12-Hydroxystearic Acid

Taro TACHIBANA, Shyoko KITAZAWA and Hideko TAKENO

Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo

(Received March 12, 1970)

Under an electron microscope, it was observed that the alkali metal soaps of 12-D(or L)-hydroxystearic acid separated out twisted fibers from various solutions. A symmetrical relationship regarding the sense of the twist was found between the soap fibers of the D-enantiomer and those of the L-enantiomer. In the case of the soap fibers of the D-enantiomer, the sense of twist was right-handed for the Li soap and left-handed for the Rb and Cs soaps. The Na- and the K- soap fibers produced both right-handed and left-handed fibers. A solvent effect with respect to the sense of twist was found for the fibers of the free acid and its Li soap. The cause of the twisting was discussed in connection with the structure and the growth process of the soap crystal.

In the preceding paper[1] we reported that optically active 12-hydroxystearic acid and its lithium soap produced twisted fibers when allowed to crystallize out from appropriate solvent and that the sense of twist is related to the optical isomerism of this hydroxy acid. Studies have since been extended to other univalent metal soaps, as has been described in part in a preliminary report.[2]

The sense of twist has been found to be associated with the cation size. This paper will describe the results obtained mainly with a series of the alkali metal soaps; the solvent effect on the sense of twist is also included.

Experimental

The purification of D-12-hydroxystearic acid from the commercial product and the preparation of L-12-hydroxystearic acid have been described previously.[1] The alkali metal soaps were prepared by neutralizing the acid with the desired metal hydroxide in anhydrous ethanol or in aqueous ethanol, by then recrystallizing several times from ethanol, and finally by drying over P_2O_5 *in vacuo*. The purity of these soaps was checked by elementary analysis, infrared absorption spectroscopy, and differential thermal analysis. The infrared spectra of these samples showed no peak at about 1700 cm^{-1} (the C=O stretching vibration for carboxylic acid) or at from 1600 to 1650 cm^{-1} (the deformation vibration for water). The absence of water was also confirmed by the use of differential thermographs. These results show that these soaps were reasonably pure and in an anhydrous form. The sample of the Rb soap was mixed with the K soap, since it was prepared by using RbOH, which had been found by fluorescent X-ray analysis to contain K in a Rb/K ratio of 80/20.

The sample of the NH_4 soap was a gift of Dr. Yoshiro Tsutsui, who prepared it by reacting the D-acid with liquid ammonia under 59 atm at 110°C for 24 hr in an autoclave.

The Ag soap was prepared by the metathesis of the Na soap in aqueous ethanol in a dark room.

The Tl(I) soap was prepared by neutralizing the D-acid in ethanol with an aqueous solution of thallous hydroxide.

The soap fibers are formed in the grease or the gel, which is made by dissolving the soap in a solvent at a high temperature and by then cooling the hot solution to room temperature. Since it was considered that the free acid may have been formed by the thermal decomposition of the soap during the preparation of the grease, the soap samples recovered from the grease were subjected to infrared analysis. It was confirmed that these samples contain no free acid.

The procedure of observing the fibers by means of an electron microscope was described in the preceding paper.[1]

Results

a) The Alkali Metal Soaps. Under the electron microscope, the grease or gel from the soaps was observed to consist of twisted fibers with a certain thickness, the thickness being dependent on the procedure used in making the grease. Figure 1 shows typical micrographs of the fibers of the alkali metal soaps.

As has been stated previously,[1] the Li soap produced twisted fibrils about 0.03 μ in width from ethanol, while helical ribbons of from 0.03 to 0.3 μ in width were produced from mineral oil and from Nujol. The Na and K soaps formed twisted fibers and ribbons from 0.02 to 0.3 μ in width, depending on the conditions used in the grease preparation. The Rb and Cs soaps produced ribbons of the form characteristic of these soaps, in addition to the fibers of a form such as was observed in the other alkali metal soaps.

The sense of twist was characteristic of the respective soaps. It is represented, together with the results for the free acid, in Table 1; it is found that

Table 1. The sense of twist in the fibers from both enantiomers of 12-hydroxystearic acid and their alkali metal soaps

Enantiomer	The sense* of twist					
		Alkali metal soap				
	Acid	Li	Na	K	Rb	Cs
D	l	r	r&l	r&l	l	l
L	r	l	r&l	r&l	r	r

* r: right-handed twist, l: left-handed twist

there is an enantiomorphic relationship between the D-enantiomer and the L-enantiomer for the alkali metal soaps as well as for the free acid. From this table, it can be seen also that the sense of twist for the soaps of the D-acid changes from right to left with an increase in the cation radius; it is right-handed for the Li soap of the D-acid, while it is left-handed for the Rb and Cs soaps of the D-acid.

The Na and K soaps, which occupy the intermediate positions, did not always give reproducible results. Usually, but not always, they were inclined to exhibit both right-handed fibers and left-handed fibers from the same sample. In detail, the same sample of the Na soap or the K soap produced either of these fibers alone on one occasion, and both right-handed and left-handed fibers at the same time on another occasion. In the latter case, the right-handed and the left-handed fibers appeared as separated groups, either group being predominant. These results led us to draw a hasty conclusion in a previous communication[3] that the sense of twist was always right-handed for the Na and K soaps.

Since the non-reproducible results were considered to be due to the slight difference in the soap samples, a further investigation was made with the samples of the Na and K soaps, which had been prepared by the reaction of the D-acid in its ethanol solution, (1) with an NaOH (or KOH) aqueous solution, (2) with an NaOH (or KOH) ethanol solution, and (3) with Na (or K)-alcoholate. The samples thus obtained showed identical infrared absorption spectra, X-ray diffraction patterns, and differential thermographs, indicating that they

belong to the same crystalline phase. Moreover, it was confirmed from these measurements that these samples are samples of the neutral soap, but not so-called acid soaps. The greases were prepared from these samples under the same conditions as far as was possible; consequently, all of the greases gave the same results. These Na-(or K-) soap samples produced both right-handed fibers and left-handed fibers from mineral oil or Nujol as well as from ethanol. Each fiber appeared as a separated group from the same sample; for the Na-soap fibers from mineral oil or Nujol, one group consisted of uniformely-thin fibrils with a right-handed twist, and another, of wide ribbons with a left-handed or right-handed twist. One may consider the possibility that the left-handed fibers consist of the free D-acid produced by the thermal decomposition of the Na soap during the preparation of the grease. However, the infrared analysis showed no free acid in the sample of the Na soap recovered from the grease. Therefore, the fact that both fibers were produced from these samples of the Na soap is to be ascribed to a property of this metal soap. Almost the same result was also obtained in the case of the K soap. Probably, the fibers twist in either the right-hand or the left-hand direction as a result of some slight difference in the conditions under which the fibers are formed. It can thus be suggested that the energy difference which determines whether the Na(or K)-soap fibers twist to the right or to the left is very slight, so that the effect of the asymmetric molecule is obscured. On the other hand, the Li-soap fibers twist stably to the right, and the Rb- and the Cs-soap fibers do so to the left. On the basis of these results, a specific effect of the alkali-metal cations can clearly be seen on the sense of twist.

b) The Other Soaps. The NH_4, Ag, and Tl(I) soaps of the D-acid were also investigated. Figure 2 shows typical micrographs of the fibers of these soaps. Since the NH_4 soap is readily decomposed with a rise in the temperature, the crystallization was done in a refrigerator after the saturated solution in ethanol had been prepared at room temperature. The precipitate thus obtained was found to contain more or less the free D-acid by infrared analysis; it was found to consist of fibers of the left-handed twist alone. These results strongly suggest that the NH_4-soap fibers exhibit a left-handed twist.

The Ag soap produced left-handed fibers from its ethanol solution.

The Tl(I) soap produced left-handed fibers from its ethanol, *n*-butanol, or *n*-octanol solution, although sometimes right-handed fibers were included. From these results, it can be roughly concluded that the fibers from the univalent metal soaps of the D-acid having a cation of a comparatively large size are inclined to twist to the left.

c) The Solvent Effect. An investigation was made into the effect of various solvents on the sense of twist in the fibers from the free D-acid and from its soaps. When the solvents used for the preparation of the grease were mineral oil, Nujol, ethanol, carbon bisulfide, nitrobenzene, and dimethyl formamide, it was found that these solvents greatly affect the form of the twisted fibers produced, but they had no influence on the sense of twist.

When a series of *n*-aliphatic alcohols were used as the solvents, a notable effect on the sense of twist was found only for the free D-acid and its Li soap, the cation sizes of which are comparatively small. The results are shown in Table 2. The free D-acid and its Li soap produced both left-handed fibers and right-handed fibers from the solution in an alcohol of from C_6 to C_{10}, while from the shorter-chain (C_2 to C_4) alcohols the D-acid fibers exhibited only a left-handed twist, and the Li-soap fibers, a right-handed twist alone. No solvent effect on the sense of twist was found for the fibers from the Na, K, Rb, and Cs soaps.

TABLE 2. THE EFFECT OF *n*-ALIPHATIC ALCOHOLS AS THE SOLVENT ON THE SENSE OF TWIST IN THE FIBERS OF D-12-HYDROXYSTEARIC ACID AND ITS ALKALI METAL SOAPS

Sample	Carbon number of *n*-aliphatic alcohols as the solvent								
	C_2	C_3	C_4	C_5	C_6	C_7	C_8	C_9	C_{10}
Free acid	l	l	l	r&l	r&l	r&l	r&l	r&l	r&l
Li soap	r	r	r	r	r&l	r&l	r&l	r&l	r&l
Na soap	r&l	r&l	r&l	r&l	r&l	r&l	r&l	r&l	r&l
K soap	r&l	r&l	r&l	r&l	r&l	r&l	r&l	r&l	r&l
Rb soap	l	l	l	l	l	l	l	l	l
Cs soap	l	l	l	l	l	l	l	l	l

r: right-handed twist, l: left-handed twist

The crystalline aggregates of the D-acid or its Li soap recovered from *n*-heptanol solution showed a melting point, an X-ray diffraction pattern, and an infrared spectrum identical to those of the samples from ethanol solution. This indicates that the observed effect is not due to the difference in the crystalline phase of the fibers produced. Probably, in any stage of the growth of the fibrous crystal the solvent molecules may act so as to obscure the asymmetrical effect of the enantiomer molecule through the solvation. Here it is interesting to note that the molecules of these alcohols approximate a fragment of 12-hydroxystearic acid molecules.

In this connection, it may be mentioned that cyclohexanol, which is a cyclic alcohol, did not exhibit this abnormal behavior, but functioned much like the normal C_2- to C_4-alcohols.

An attempt was made to investigate the effect of an optically-active solvent. The D-acid, the L-acid, and the respective soaps produced twisted fibers from solutions in optically active amyl alcohol (L-form). The results regarding the sense of twist

were quite identical with those with the solution in *n*-amyl alcohol. Accordingly, no effect of the optically-active solvent was observed.

Discussion

Twisted crystal shapes are not unique to soap fibers, but they have been observed for quartz and various whiskers. Wilman[4] explained such structures as the results of the rotational slip of crystal layers parallel to the cleavage plane. McClellan[5] explained the shape of soap fibers in terms of an equation derived by Eshelby,[6] who showed that a whisker containing an axial-screw dislocation must be uniformly twisted by an amount equal to the Burger vector of the dislocation divided by the crosssectional area of the whisker. However, the explanation that the twisting is a result of the dislocation seems doubtful in the case of the soap fibers, because it is difficult to explain why the Li soap of 12-D(or L)-hydroxystearic acid forms twisted fibers, whereas the racemic soap always forms non-twisted fibers.
