The effects of the temperature on the tautomeric equilibria are summarized in Table 1. There are five derivatives for which the temperature dependence of the electronic spectra could not be detected. Such cases may occur when the azo and hydrazone tautomers have nearly the same energy or when the energy difference between the two tautomers is so large that the amount of the minor one is too small to affect the spectrum. In the present system, the former situation seems to be likely. If the magnitude of the energy difference is in the order of thermal energy, the electronic spectrum may be modified by the temperature change. The direction of the movement of the equilibrium upon an elevation of the temperature should be towards the minor tautomer. Thus, more than 50% of the molecules in the o-Me, p-Me, o-OH, o-MeO, m-NO_2, and p-NO_2

Table 1. The movement of the equilibrium by elevating temperature; towards the azo tautomer (+) or the hydrazone tautomer (−)
The number in parenthesis is Hammett substituent constant.

Substituent	Position		
	ortho	meta	para
None		not detectable (0.00)	
Methyl	+	not detectable (−0.07)	+ (−0.17)
Chloro	not detectable	not detectable (0.37)	− (0.23)
Hydroxy	++	− (0.12)	− (−0.37)
Methoxy	+	not detectable (0.12)	− (−0.27)
Nitro	−−	+ (0.71)	++ (0.78)

derivatives are expected to exist as hydrazone tautomers in the present two-component system. On the other hand, the situation must be reversed in the *p*-Cl, *m*-OH, *p*-OH, *p*-MeO, and *o*-NO_2 derivatives. This conclusion is in serious conflict with the estimations made by Bansho *et al.* On the basis of this disagreement, we have to conclude that the relative intensities of the bands of the tautomers are not independent of the kind and position of the substituents. Although the distribution of the substituents in the above-discussed three groups reveals the general tendency for the hydrazone tautomer to be favored in the derivatives carrying substituents with large Hammett constants, no simple correlation can be established in the present system.

The electronic and vibrational spectra examined as potassium bromide discs have been considered like those of solid samples.[3-5] However, our observation that the spectra depend greatly upon the degree of dilution casts some suspicion on the technique. As has been mentioned earlier, the spectral changes caused by dilution may be attributed not only to a decreasing deviation from the Kubelka-Munk theory, but also, at least in part, to the movement of the equilibrium towards the hydrazone tautomer. As a matter of fact, Rau has considered his spectrum of 1-phenylazo-2-naphthol, measured at a concentration of 0.01%, as that of the species adsorbed on the diluent.[6] These pieces of evidence suggest that the spectra obtained by the potassium-bromide-disc method are also not free from the influence of the diluent. It has been pointed out by Burawoy *et al.* that the relative stability of the hydrazone tautomer increases in this order of the solvents: hexane< ethanol<chloroform<water.[2] The observed trend of the movement of the equilibrium upon dilution with sodium chloride seems reasonable, since more and more molecules of 1-arylazo-2-naphthol are dispersed and adsorbed on the highly polar surface of the alkali halide. As has been discussed earlier, measurements at higher concentrations may provide the spectra of true solids, but they will be very much distorted. At a maximum concentration of 1% or higher, the reflectance spectra are expected to be flattened because of an increasing regular reflection.

The authors wish to express their thanks to Mr. Nobuhiko Miyajima for his collaboration throughout the course of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3410—3414 (1970)

Catalytic Activity and Reactivity of Aromatic Nitrile and Alkali Metal Ion Radical Salt. I. Homogeneous and Heterogeneous Catalysis of Benzonitrile-Cesium Ion Radical Salt

Motoyuki TSUDA*1 and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received June 13, 1970)

Homogeneous and heterogeneous mechanisms of parahydrogen conversion and hydrogen-deuterium exchange reactions were investigated in the presence of benzonitrile–cesium ion radical salt. Studies of their activation energies and rate constants showed that the heterogeneous reaction on the solid-ion radical salt occurs mainly through the "chemisorption mechanism" and the "exchange mechanism", but the homogeneous reaction over the salt solution in benzonitrile takes place only through the "physical mechanism." According to these results, it was concluded that the catalytic activity and reactivity of the ion-radical salt must be due to the nature of its solid phase, not to that of its aromatic anion or free-ion radical pair.

Since tetracyanopyrene-cesium ion radical salt was found to catalyze the hydrogen-deuterium exchange reaction,[1] the catalytic activities for various aromatic–alkali metal ion radical salts[2–7] and charge-transfer complexes[8,9] have been studied. The results of these works may be summarized as follows: (1) the aromatic–aromatic charge-transfer complexes have only a weak catalytic activity for para-orthohydrogen conversion through the physical mechanism[8,10] (see Appendix 1); (2) the aromatic-halogen charge-transfer complexes, for instance, the violanthrene-iodine complex, catalyze the isomerization of 1-butene⇌2-butene, but no H_2-D_2 equilibration takes place over the complexes,[9] and (3) aromatic-alkali metal ion radical salts catalyze the hydrogen-deuterium equilibration. Further, over these ion radical salts it is found that deuterium exchanges with the hydrogen of the bulk aromatic anion.[1–7]

Recently, some assumptions about the catalytic mechanism on these ion salts were proposed, mainly on the basis of the electronic properties of the acceptor aromatic molecule, that is, the electron affinity,[7] the charge density of the lowest unoccupied orbitals,[4,7] the valency,[5] the reduction potential, and the effect of substitution on the aromatic skeleton,[4] but not on the basis of the properties of the bulk complex. Accordingly, no findings have been reported on whether the nature of isolated molecules or that of molecular aggregates is decisive in the catalytic activity.

In this paper, we will present the results of our study of homogeneous and heterogeneous catalyses over benzonitrile*2-alkali metal ion salts. Because the melting point of benzonitrile is fairly low (−13°C), the homogeneous reaction*3 on the ion salts dissolved in a benzonitrile solution with hydrogen was observed satisfactorily.

*2 The electronic spectra and also the ESR spectra show that only the mononegative anion (benzonitrile$^-$) in the ion salt is stable, though other aromatic anions have multivalencies.

*3 We demonstrated a homogeneous catalysis for para-orthohydrogen conversion in the presence of a gaseous anthracene-*syn*-trinitrobenzene charge-transfer complex under illumination.[8] However, no ion-radical salts in the gaseous phase could be obtained.

nitrile was refluxed with diphosphorus pentoxide in a sealed glass vessel to eliminate a trace of water and was subsequently degassed by alternate boiling under a vacuum and repeated distillations. The cesium metal was prepared by reduction between its chloride and calcium metal, that is, $2CsCl+Ca=CaCl_2+2Cs$; it was distilled several times *in vacuo* in order to purify it.

Preparation of the Benzonitrile-Alkali Metal Ion Radical Salts. The benzonitrile-cesium ion radical salt used in this study was prepared as follows. A known amount of benzonitrile was placed in a glass vessel cooled with a dry ice-ethanol mixture, on which a measured volume of purified cesium metal had previously been evaporated. The vessel was then sealed off and heated at 60°C for 40 hr in order to complete the formation of the complex; a deep red-coloured ion radical salt solution was thus obtained. To separate the solid-phase salt aggregates from the solution, if any existed, the solution was passed through a fine glass filter. The solution was then submitted to a homogeneous catalytic reaction. The excess benzonitrile in the solution was completely evaporated at 60°C *in vacuo* in order to obtain the solid specimen.

Experimental Procedure. For the investigation of the homogeneous catalysis of the hydrogen conversion in the ion-radical salt solution, a cylindrical, thermostated glass vessel containing the solution was agitated with a magnetic stirrer arrangement, as is shown in shown in Fig. 1. A known amount of the salt solution was placed in the vessel and sealed off at the point indicated by the arrow ↓ in Fig. 1. Para-rich-hydrogen (80% p-H_2) was admitted into the vessel under a pressure of 100 Torr (at room temperature), and the system was sealed off by a greaseless stopcock. The temperature of the reaction system (surrounded by a broken line in Fig. 1) was controlled at temperatures between 33—90°C.

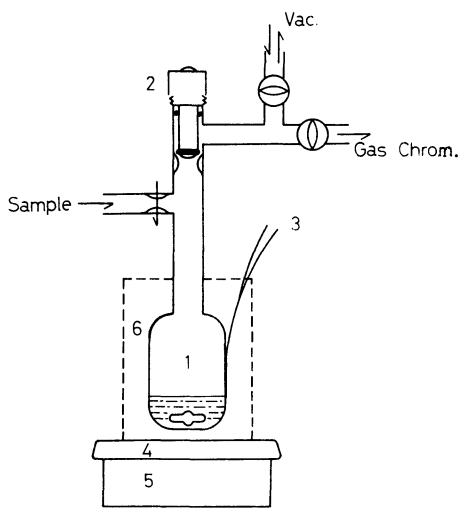

Fig. 1. The schematic diagram of the reaction system.
1. reaction vessel containing a piece of magnet, 2. greaseless stopcock, 3. chromel-alumel thermocouple, 4. electrical heater controlled at appropriated temperature, 5. magnetic stirrer and 6. air bath.

In order to keep the condition of the homogeneous catalytic reaction constant, after finishing each procedure the ion-salt solution was degassed in order to remove the converted hydrogen by alternate boiling under a vacuum.

In the heterogeneous reaction, the exchange of gaseous deterium with the hydrogen of the aromatic anion occurred. Therefore, after measuring the hydrogen–deuterium equilibration on the solid specimen, the hydrogen gas was admitted into the vessel to replace the deuterium in the aromatic ring of the anion and/or the chemisorbed deuterium of the salt at 70°C. This procedure was repeated until no D_2 (or HD) was detected in the gas phase. By this method, the solid specimen could be reproduced repeatedly.

The compositions of the various orthohydrogen–parahydrogen or hydrogen-deuterium mixtures were measured successfully by means of gaschromatography. A mixture was separated quantitatively by passing it through a heat-treated alumina column at the temperature of liquid nitrogen.[11,12] The electronic spectrum of the benzonitrile-cesium ion radical salt in a benzonitrile solution and that of the solid-ion salt film were measured with a Cary recording spectrophotometer, Model 14. The preparation of the radical anion and the measurement of the electronic absorption spectra were made in a vacuum system, as is shown in Fig. 2.

Results

The kinetics of the heterogeneous and homogeneous reactions of the benzonitrile-cesium ion radical salt were investigated as a function of the hydrogen pressure and of the temperature. The experimental results on the heterogeneous reaction will first be shown, while those of the homogeneous reaction will be described later.

Heterogeneous Reaction. *Pressure Dependency.* The para-orthohydrogen conversion on

11) W. R. Moore and H. W. Ward, *J. Amer. Chem. Soc.*, **80**, 2909 (1958).

12) S. Ohkoshi, Y. Fujita and T. Kwan, This Bulletin, **31**, 771 (1958).

the solid-ion radical salt was investigated as a function of the partial pressure of parahydrogen under a constant pressure (110 Torr) and at a constant temperature (87°C). Figure 3 shows the results, in which the rate was found to be a first-order reaction concerning the partial pressure of parahydrogen. Hence, the experimental rate constant, k_e^H, was derived from the following equation:

$$k_e^H = \frac{1}{t} \ln \frac{C_p(t) - C_p(\infty)}{C_p(0) - C_p(\infty)} \quad (1)$$

where $C_p(0)$, $C_p(\infty)$, and $C_p(t)$ are the concentration of parahydrogen at the initial point, in equilibrium, and after t min respectively.

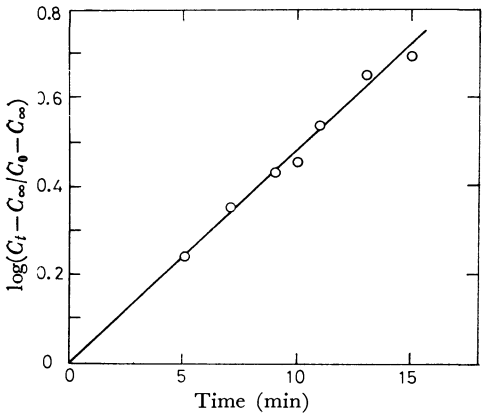

Fig. 3. The reaction velocity of ortho-parahydrogen conversion under constant pressure for determining the order of rate constant.

Temperature Dependency. The kinetics of the hydrogen conversion were studied over the temperature range between 0°C and 100°C under a constant pressure of hydrogen. The experimental rate constant was also given by Eq. (1); the progression of the para-orthohydrogen conversion is plotted against the reaction time in Fig. 4.

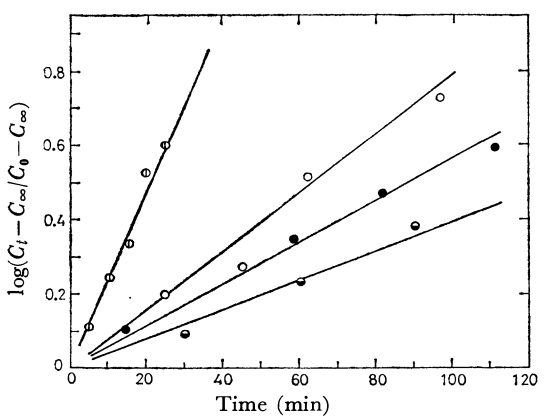

Fig. 4. The progression of the para-orthohydrogen conversion on the solid of the benzonitrile-cesium ion radical salt.
—◑— at 80°C, —○— at 41°C,
—●— at 20°C, and —◒— at 0°C.

On the other hand, when deuterium gas was placed in contact with the benzonitrile-cesium solid film, it was found that exchange took place between the admitted deuterium and the hydrogen of the aromatic anion. In the reaction, denoted as the exchange mechanism, the decay of the concentration of deuterium in the gas phase obeyed the first-order law.*4 The rate constant, k_e^D is:

$$k_e^D = -\frac{1}{t} \ln \frac{D(t)}{D(0)} \quad (2)$$

where $D(0)$ and $D(t)$ represent, respectively, the concentrations of deuterium in the gas phase at the initial point and t min later. The experimentally-determined rate constants, k_e^H and k_e^D, are shown in Fig. 5 as functions of the temperature. On the basis of the temperature dependence of the rate constant, we could determine an apparent activation energy, E^D or E^H, for these two reactions:

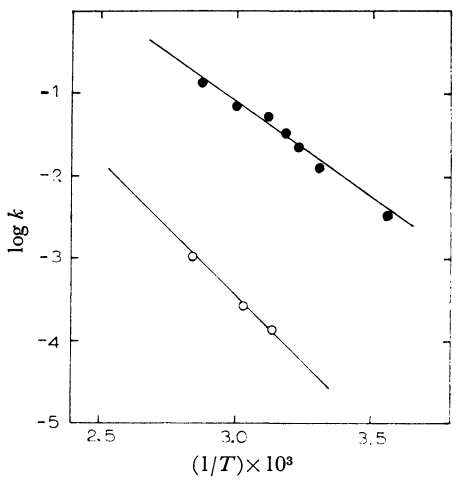

Fig. 5. The rate of the conversion at various temperatures for the solid of the benzonitrile-cesium ion radical salt.
-●- the rate of the para-othohydrogen conversion, -○- the rate of $D_2 + \phi H \rightleftarrows HD + \phi D$ reaction.

$$k_e^H = S^H A^H \exp(-E^H/\boldsymbol{k}T) \quad (3a)$$

$$k_e^D = S^D A^D \exp(-E^D/\boldsymbol{k}T) \quad (3b)$$

where S^H and S^D are the areas of the catalyst and where A^H and A^D are the factors which depend hardly at all upon the temperature. Experimentally, we obtained $E^H = 10.2$ kcal/mol, and the value of E^D was 14.3 kcal/mol.

Homogeneous Reaction. The catalytic activity and the reactivity of benzonitrile-cesium ion salt dissolved in benzonitrile were also investigated by means of the para-orthohydrogen con-

*4 This reaction rate will be analyzed in Part II.

version and the hydrogen-deuterium exchange reaction. As was shown in the previous section, the solid film of the ion radical salt has a good catalytic activity. On the contrary, the hydrogen conversion with the salt solution occurred very slowly. Further, we could not detect any H_2-D_2 exchange reaction even after a long time, 1320 hr.*5 These facts suggest that the hydrogen conversion in the homogeneous system is caused by the paramagnetic mechanism,[13] but not by the chemical mechanism.

The rate constant, $[k_e^H]_L$, which was found to be first order, as given by Eq. (1) for the solid system, was investigated at a series of temperatures between 33—90°C under a constant pressure of hydrogen (100 Torr).

The concentration of parahydrogen is plotted against the reaction time in Fig. 6. From these

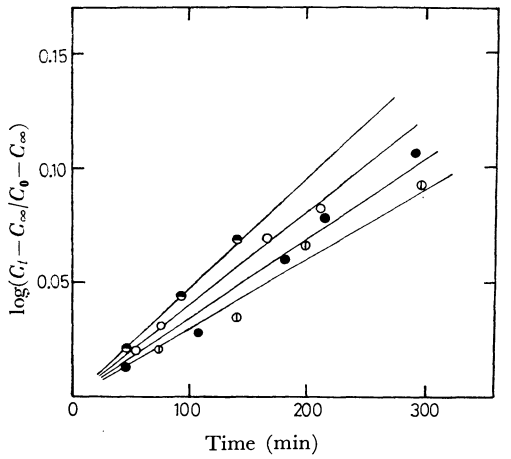

Fig. 6. The progression of the para-orthohydrogen conversion in the presence of the benzonitrile-cesium ion radical salt solution.
-◒- at 90°C, -○- at 70°C,
-●- at 40°C, and -◑- at 33°C.

results, it seems that the apparent rate constant, $[k_e^H]_L$, is enhanced with the increase in the temperature. To obtain the intrinsic rate constant, k_L, however, we must eliminate the term of the temperature dependency of the solubility of hydrogen in the solution, as is described in the following equation:[14]

$$[k_e^H]_L = \frac{a(T)V_L}{V_G + a(T)V_L} k_L \qquad (4)$$

where $a(T)$ is the solubility*6 and where V_G and V_L are the volumes of the gas and the solution in the reaction vessel. Figure 7 shows an Arrhenius plot for the k_L and $[k_e^H]_L$. The intrinsic activation energy, $[E^H]_L$, was found to be 0.1 kcal/mol though the apparent activation energy was 1.0 kcal/mol. When we compare these values with the value of $E^H = 10.2$ kcal/mol for the solid film, the mechanism of hydrogen conversion for these two systems may be assumed to be different.

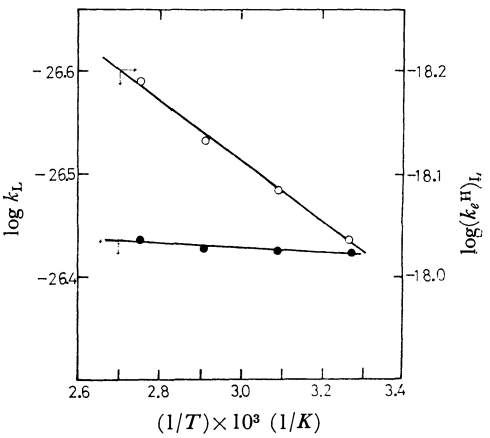

Fig. 7. The rate of the conversion at various temperatures for the benzonitrile-cesium ion radical solution.
-○- apparent rate, -●- intrinsic rate.

Discussion

In the last five years, the mechanism of the hydrogen conversion of the aromatic-alkali metal ion radical salt and the reaction of deuterium with the hydrogen of the aromatic anion have been investigated extensively, and some assumptions have been proposed based on the electronic structure of the aromatic *molecule* or the aromatic *anion*. However, the compounds used in those studies were in a solid state. Accordingly, the question was still left whether the nature of the isolated molecule or that of solid state is decisive in the catalytic activity.

The essential point is the fact that the isolated ion and/or ion pair shows no catalytic activity caused by the chemical mechanism; rather, a slow para-orthohydrogen conversion occurs in the presence of the ion and/or ion pair through the

*5 No apparent change in the activity for para-orthohydrogen conversion with the solution was found between before and after the long reaction; that is, the ion-radical salt solution was stable under these conditions.

*6 Because of various experimental difficulties, the solubility, $a(T)$, of hydrogen in benzonitrile has not yet been measured, but the solubilities of hydrogen in benzene ($a = 5.8\times10^{-2} + 5\times10^{-4}$T) and in chlorobenzene ($a = 5.5\times10^{-2} + 3.5\times10^{-4}$T) have been observed.[15] For the present system, the solubility of hydrogen is assumed to be of the same order as that of benzene or chlorobenzene.

physical mechanism. This conclusion is supported by the following two reasons.

First, the ratio of the rate constant of the hydrogen conversion to that of the deuterium exchange reaction is very different in the cases of the solid film and the liquid phase at the same temperature. The empirically-determined rate constant of each case at 90°C is given as: $k_e^H = 2.6 \times 10^{-1}$/min and $k_e^D = 2.1 \times 10^{-3}$/min for the solid phase and $[k_e^H]_L = 1.8 \times 10^{-5}$/min and $[k_e^D]_L \simeq 0$ for the liquid phase. Assuming that the catalytic mechanism for hydrogen is the same for both states and that the large difference in the absolute value of k_e^H and $[k_e^H]_L$ originates only from the difference in collision efficiency in the two states, the following relation must be satisfied:

$$\frac{k_e^H}{k_e^D} = \frac{[k_e^H]_L}{[k_e^D]_L} \tag{5}$$

Equation (5) requires the value of 2.22×10^{-3}/min for $[k_e^D]_L$ instead of nearly zero, in view of the experimental results for k_e^H, k_e^D and $[k_e^H]_L$; for instance, 4.8% of HD must be detected for a hydrogen-deuterium exchage reaction at 90°C after 1320 hr. However, we could not find any trace of HD content during that long period, as has been menitoned above.

Second, the catalytic mechanism is recognized from the activation energies of the para-ortho-hydrogen conversion for the two states. Figure 5 shows $E^H = 10.2$ kcal/mol; the hydrogen conversion on solid film occurs with the chemical mechanism. In the case of the molecular state, however, the activation energy is $[E^H]_L \simeq 0$; this means that the hydrogen conversion occurs through the physical process.[13]

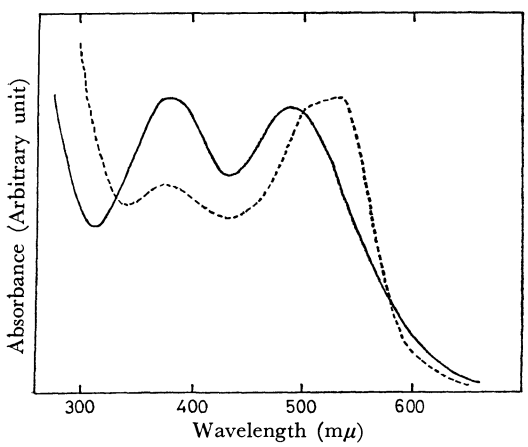

Fig. 8. The electronic spectra of the benzonitrile-cesium ion radical salt.
—— solid film, ---- solution.

The mechanism of the chemisorption of hydrogen on the aromatic-alkali metal ion radical salt is not clear at present. However, we may conclude that the mechanism can not be explained only in terms of the electronic structure of the isolated aromatic anion.

The electronic absorption spectra of the solid and liquid phases are both similar to the spectrum of the benzonitrile mononegative anion,[16] as is shown in Fig. 8. However, the wavelengths of the peaks are shifted from 375 mμ and 510 mμ in the solution to 380 mμ and 488 mμ in the solid, and the ratio of the extinction coefficients, ε, varies from $\varepsilon_{488m\mu}/\varepsilon_{380m\mu} = 1.06$ in the solution to $\varepsilon_{510m\mu}/\varepsilon_{375m\mu} = 2.01$ in the solid. These changes suggest that the benzonitrile anion in the solid-ion radical salt is strongly perturbed by the neighbouring cesium cations and the other benzonitrile anions. Therefore, in order to analyze the chemical mechanism of the hydrogen conversion on the ion salts, the structure of aromatic anion-alkali metal cation pairs perturbed strongly by neighbouring ions must be considered.

The authors wish to thank Drs. N. Wakayama and Y. Mori for their helpful discussion. One of us (M.T) also wishes to express his thanks to Professor S. Okamoto and Professor H. Suzuki of Waseda University for helpful discussion and for continuous encouragement. Thanks are due to Kawakami Foundation for financial support.

Appendix 1

The catalytic activity of a number of aromatic-aromatic charge transfer complexes, mentioned below, has been examined by means of the hydrogen-deuterium exchange reaction by us. (T. Kondow, N. Wakayama, Y. Mori, Y. Matsunaga and the authors) However, no exchange reaction occurred over these complexes.

Catalytic Activity and Reactivity of Aromatic Nitrile and Alkali Metal Ion Radical Salt. II. Hydrogen Exchange on Benzonitrile Ion Salt as a Function of Alkali Metals

Motoyuki TSUDA*1

The Institute for Solid State Physics, the University of Tokyo, Roppongi, Tokyo
and Department of Physics, School of Science and Engineering, Waseda University, Tokyo

(Received June 13, 1970)

The para-orthohydrogen conversion (rate constant k_e^H and the deuterium exchange reaction (rate constant k_e^D) over the benzonitrile-alkali metal ion radical salt were investigated as functions of the donor component—alkali metal. The sort of alkali metals in the ion radical salts greatly affected the catalytic activity and the reactivity. The activation energies obtained from the temperature dependence of k_e^H and k_e^D, E^H and E^D, and the value of α(depending on the ratio of k_e^H to k_e^D monotonously decreased as Na→K→Rb, but those values showed an irregular trend for the Cs-complex. The results suggest that the catalytic activity cannot be understood only in terms of the nature of the components; must also be considered the structural nature of the solid phase of the ion radical salt.

In a previous paper,[1] we reported that the benzonitrile-cesium ion radical salt has a strong catalytic activity in the solid phase, but that the salt solution in a benzonitrile solvent does not possess any catalytic activity for hydrogen-deuterium equilibration. Thus, we concluded that the catalytic activity on the ion radical salts can be explained not by the electronic structure of the isolated aromatic anion, but by the structure of the solid ion radical salt which is perturbed strongly by neighbouring ions.

In this report, we wish to discuss mainly the catalytic activity on benzonitrile-alkali metal ion radical salts as a function of their donor metals in order to clarify the role of the metallic cations in the ion salt with regard to the catalytic activity. Further, we will discuss the mechanism of hydrogen-deuterium equilibration on the ion radical salt.

Experimental

The preparation of the benzonitrile-alkali metal ion radical salts has already been reported.[1] In this work, four sorts of alkali metals—Na, K, Rb and Cs— were used as electron-donor components. Their preparations and purifications were carried out carefully.*2 The purified alkali metal was first evaporated onto the surface of a glass reaction vessel *in vacuo* and then the purified benzonitrile was introduced. A dark red-coloured ion radical salt solution was obtained immediately. The excess benzonitrile was completely evaporated from the salt solution by heating *in vacuo* about 8 hr, since no catalytic activity was found for the ion radical salt solution or the wet ion salt.

The hydrogen mixtures (p-H_2+o-H_2 and H_2+HD+D_2) were analyzed by gaschromatography using a heat-treated alumina column at the temperature of liquid nitrogen, as has been described in a previous paper.[2]

The electronic spectra of benzonitrile-alkali metal ion radical salt in a benzonitrile solvent and the solid film of the salt were observed with a Cary recording spectrophotometer, Model 14.

Results

As has been mentioned in the previous papers,[1-4] the aromatic-alkali metal ion radical salts show two chemical reactivities for hydrogen molecules; one is the "chemisorption mechanism", and the other is the "exchange mechanism."*3 To make clear the mechanisms of these two reactions, the

*3 The chemisorption mechanism and exchange mechanism proceed by way of a hydrogen-deuterium equilibration over the catalyst and by way of an exchange reaction between gaseous deuterium and the hydrogen atom of the aromatic anion respectively.

para-orthohydrogen conversion (p-$H_2 \rightleftarrows o$-H_2) and the deuterium-exchange reaction ($D_2+H\text{-}\phi \rightleftarrows HD+D\text{-}\phi$) were employed.

Hydrogen Conversion and Deuterium-Exchange Reaction. The kinetic analysis of these two reactions was done over the temperature range from 0°C to 80°C under a constant pressure of hydrogen (100 Torr). The rate constant, k_e^H, for the hydrogen conversion was found to obey a first-order law, as has been shown in Part I. The rate constant for the deuterium exchange reaction, k_e^D, obeys a first-order law for a fresh sample (curve a in Fig. 1), but the value of k_e^D for the salt washed with hydrogen seems to deviate a first-order law (curve b in Fig. 1). In the Fig. 1, where the progression of the decay of deuterium on the ion radical salt is plotted against the reaction time, a sharp kink is found at the initial stage (region I of curve b) of the reaction. This behaviour suggests that both the two different mechanisms for hydrogen exchange occur on the hydrogen-exposed ion radical salt.*4

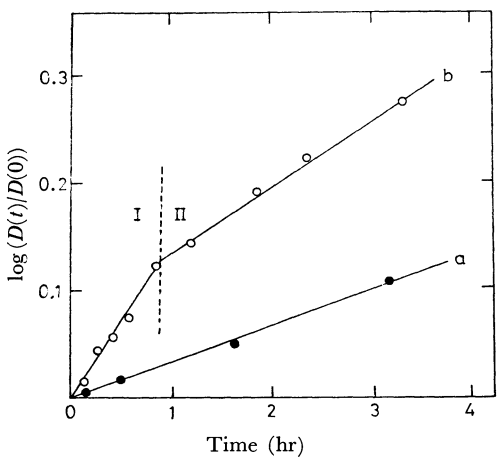

Fig. 1. The progression of deuterium exchange reaction with the benzonitrile-cesium ion radical salt.
—●— for fresh film
—○— for hydrogen exposed film

The progression of the reaction on the fresh salt was similar to that of the later stage (region II of curve b) of the reaction on hydrogen-exposed film. Therefore, the rate constant for the deuterium exchange reaction was obtained from the analysis of the reaction of region II of curve b at various temperatures, as is shown in Fig. 2 (see "Discussion").

*4 Whenever the deuterium-exchange reaction was carried out over the salt, the species were washed with hydrogen gas completely in advance in order to eliminate the exchanged and/or chemisorbed deuterium of the proceeding reaction from the salt, and the hydrogen was evacuated for about 3 hr.

----- Cesium salt

From the temperature dependency (0°C—80°C) of k_e^H and k_e^D for the benzonitrile-alkali metal ion

radical salts under a constant pressure (100 Torr), the activation energies for four alkali metal ion radical salts were obtained; they are summarized in Table 1.

Spectroscopic Survey. The results presented in the previous section show that the catalytic activity of the salt is greatly affected by a variation in the component—alkali metal. These findings suggest that the electronic state of the ion radical salt is influenced by the change in the donor metals. Figure 3 shows the electronic spectra of the benzo-

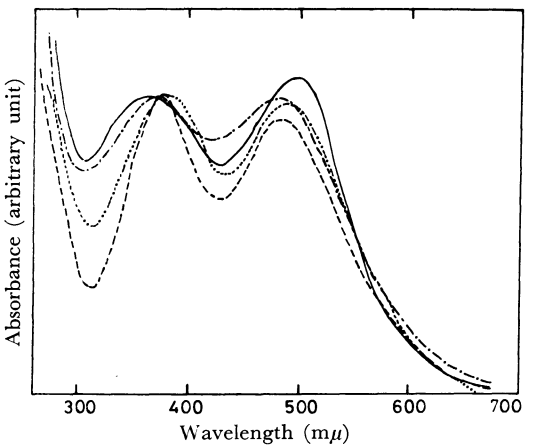

Fig. 4. Electronic spectra of solid film of benzonitrile-alkali metal ion radical salt as sorts of donor metals.

- ----- Cesium salt

nitrile solutions of the above four ion radical salts while Fig. 4 illustrates the patterns for their solid films. The spectral responses of the salt solutions resembled those of the benzonitrile mononegative ion reported by Ishitani and Nagakura.[5] The sort of donor metals in the salt solution did not strongly affect the response curve. For the solid films, however, the positions of the absorption peaks and also their extinction coefficients changed as a function of the donor metals. As the atomic weight of the alkali metals increased, the 380 mμ absorption peak shifted to the longer-wavelength side and the 480 mμ absorption peak shifted to the shorter-wavelength side. Moreover, the ratio of the extinction coefficient of the 380 mμ-peak to that of the 480 mμ-peak decreased.

Discussion

In the studies of the catalytic behaviour of the ion radical salts, the mechanism has often been interpreted in terms of the nature of the acceptor molecules[6,7]—aromatics. Among the various types of aromatic complexes,[8,9] however, only the aromatic-alkali metal (or alkali earth metal) ion radicals show catalytic activity in relation to hydrogen-deuterium equilibration. This suggests that the donor metal plays an important role in the reactivity of the ion radical salt. Therefore, we will discuss the relation between the catalytic activity and the sort of alkali metal in the salt.

First, the mechanism of the deuterium-exchange reaction on the hydrogen-exposed film will be discussed. Then, the role of the donor metal in the catalytic activity of the salt will be investigated. Finally, the electronic state of the salt is surveyed by means of the spectroscopical method.

Deuterium-Exchange Reaction. As has been mentioned in the section on "Results," two different mechanisms for deuterium exchange occur on the hydrogen-exposed ion radical salt. These mechanisms may be supposed to be as follows. One is that deuterium gas (D_2) exchanges with chemisorbed hydrogen ($\overset{*}{H}$) [Mechanism A]. The other is that deuterium gas chemisorbs on the salt surface ($D_2+2*\rightarrow 2\overset{*}{D}$), and that the chemisorbed deuterium ($\overset{*}{D}$) exchanges with the hydrogen of the aromatic anion (H-ϕ) and that the chemisorbed hydrogen thus produced reacts with D_2 ($\overset{*}{D}+$ H-$\phi\rightarrow\overset{*}{H}+$D-$\phi$; $D_2+\overset{*}{H}\rightarrow HD+\overset{*}{D}$) [Mechanism B].

The procedures are illustrated as:

$$D_2 + \overset{*}{H} \rightarrow HD + \overset{*}{D} \qquad \text{[Mechanism A]*5}$$

$$\left.\begin{aligned} &D_2 + 2* \rightarrow 2\overset{*}{D} \\ &\overset{*}{D} + H\text{-}\phi \rightarrow \overset{*}{H} + D\text{-}\phi \\ &D_2 + \overset{*}{H} \rightarrow HD + \overset{*}{D} \end{aligned}\right\} \qquad \text{[Mechanism B]*5}$$

It is assumed that the rate-determining process for the initial stage (region I of curve b in Fig. 1) of the exchange reaction is "Mechanism A," and that for the later stage (region II of curve b in Fig. 1) is the chemisorption of deuterium on the complex salt ($D_2+2*\rightarrow 2\overset{*}{D}$) of "Mechanism B." The above assumptions require that the deuterium exchange on the fresh sample occur through Mechanism B (curve a in Fig. 1). The fact that the region II of curve b (Fig. 1) has a similar inclination to that of curve a for the fresh sample supports this assumption. Therefore, in order to obtain

*5 Here, * indicates a site of salt for chemisorption.

the rate constant for deuterium exchange with the hydrogen of the aromatic anion over the hydrogen-exposed salt film, the behaviour in the region II must be adopted.

The Role of the Donor Metal in the Catalytic Activity. As has been described in previous papers,[1-4] there are two processes which occur over the complexes: the chemisorption mechanism and the exchange mechanism. The para-ortho-hydrogen conversion (its rate constant: k_e^H) takes place through both these mechanisms,*6 but the deuterium-exchange reaction (the rate constant: k_e^D) takes place only through the exchange mechanism. The ratio k_e^H/k_e^D,*7 therefore, indicates the quantity of the contribution of the chemisorption mechanism to the hydrogen conversion. When we introduce the value of $\alpha(k_e^H/k_e^D=\alpha I_{HD}$, where I_{HD} is as described in the Appendix), we can eliminate the hydrogen-deuterium isotope effect on the exchange reaction. Accordingly, the value of α is unity when the hydrogen conversion takes place through only the exchange mechanism, and the increasing value of α shows the increasing contribution of the chemisorption mechanism to the hydrogen conversion. The experimentally-determined values were about 1—10[2]. The α-values are plotted against the reciprocal of the temperature for each alkali metal ion radical salt in Fig. 5. This behaviour shows that the contribution of the chemisorption mechanism to the hydrogen conversion increases as the temperature decreases.

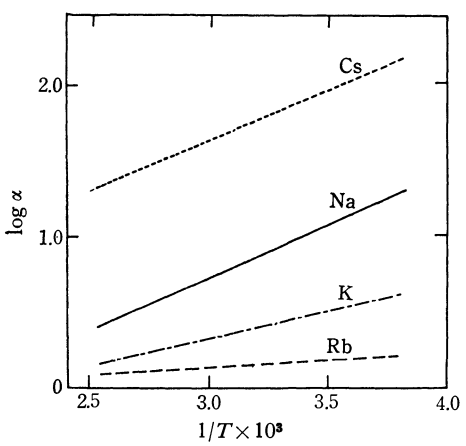

Fig. 5. log α is ploted as a function of temperature.

----- for benzonitrile-Cs

From Table 1 and Fig. 5, two parameters for the reactivity of the salt—the activation energy, E^H and E^D, and the α-value—seem to be influenced by the sort of donor metal in the salt. In this section, therefore, the catalytic activity (E and α) of the ion radical salt will be discussed as a function of alkali metals—Na, K, Rb and Cs. The nature of the alkali metals—the ionization potential, the electron affinity, the ion radius and so on—changes monotonously with their atomic numbers. Among these characteristics, the cation radius of the alkali metal is adopted as a parameter for the reactivity for two reasons. An ESR study of the ion radical salt has shown that the cation radius correlates with the magnitude of the alkali metal splittings and with that of the spin density at the carbon of the aromatic anion.[10] Further, the location of the metal cation in the salt crystal or the interionic separation depends on the metal ion radius.

The activation energies, E^H and E^D, are first compared with the cation radius. Figure 6 shows the values of E^H and E^D plotted as functions of the cation radius. There is a regular trend for the E^H and E^D values to decrease with an increase in the size of the metal cations with the exception of cesium-benzonitrile ion radical salt. Similar phenomena are observed in the relation between the value of α and the ion radius, as is illustrated in Fig. 7. The value of α decreases in this order: Na→K→Rb, but for the Cs salt the value shows an irregular tendency.

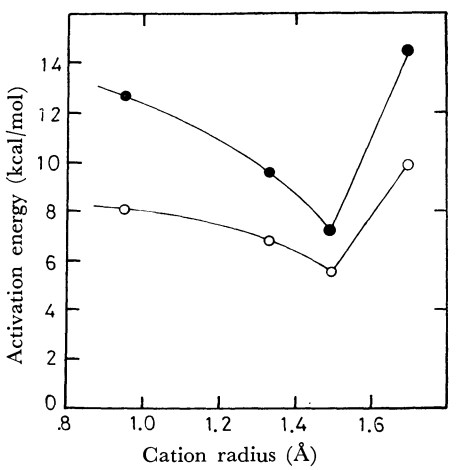

Fig. 6. Activation energies E^H for para-ortho-hydrogen conversion and E^D for deuterium exchange reaction plotted against the size of ion radius of donor metals.
—○— for E^H
—●— for E^D

*6 The contribution of the paramegnetic mechanism to the ortho-parahydrogen conversion is negligible.

*7 As the rate constants, k_e^H and k_e^D, are studied with relation to the same specimen, the two surface areas, S^H and S^D, may be assumed to be equivalent (see Eq. (3a) and (3b) in Part I). Therefore, the ratio (k_e^H/k_e^D) includes only A (enthropy factor) and E (activation energy) belongs to the nature of the catalyst.

Mori *et al.*[11] proposed that the reactivity of the ion radical salt could be understood from the ionization potential of the donor metals. The present result does not, however, support their assumption.

As the activation energy and the α-value show a monotonous tendency to change in the orders: Na→K→Rb, the reactivity of the ion radical salt seems to be influenced by the metal-cation field. However, the irregularity in the cesium ion radical salt suggests that the reactivity of the salt can not be understood only in terms of the nature of the donor metals; also, the nature of the salt in the solid phase must be taken into consideration. To analyze the nature of the salt in the solid phase, the crystal structure must be considered, but the structure of the benzonitrile-alkali metal ion radical salt has not yet been reported.

Sometimes, the crystal structure of ion radical salts changes with the kind of their donor metal; for instance, the structure of *p*-chloranil-alkali metal salt shows a difference between the Li (or Na)-salt and the K (or Rb)-salt.[12] Accordingly, the crystal structure of the benzonitrile ion radical salt must be studied in order to ascertain the mechanism of the catalytic reaction.

Spectroscopical Analysis

Figure 3 illustrates that the patterns of the spectral response of the ion radical salt solutions scarcely change at all with the kind of metal cation. In the solution, the salt is stable as a free-anion or a loose-ion pair, as has been established by Carrington and Todd.[13] Therefore, the spectra of the ion radical salt in a solution is almost the same as that of a free anion. On the other hand, the spectral response curves of the solid film (illustrated as Fig. 4) vary with the kind of alkali metal. The interionic separation in the solid ion radical salt would be smaller than that in solution, and the perturbation of the neighbouring ionic field seems to affect the electronic state of the aromatic anion strongly. Figure 6 shows that the metal dependency of the parturbation increases monotonously in this order: Na<K<Rb, and the Cs salt seems to be tremendously perturbed compared with the other three metal salts. As a tentative explanation for these irregularities, it is assumed that the Cs-benzonitrile ion radical salt has a unique structure, because the cesium ion, Cs^+, has an enormously large ion radius as comparison with those of the other alkali metal cations.

The author wishes to express his thanks to Professor H. Inokuchi for his valuable advice, his many stimulating discussion, and his reading of the manuscript. He also wishes to express his thanks to Dr. N. Wakayama and Dr. Y. Mori for their helpful discussion.

Appendix

As shown in Part I, the rate constant, k_e^H, for the hydrogen conversion and that, k_e^D, for the deuterium-exchange reaction are expressed as:

$$k_e^H = S^H A^H \exp(-E^H/\boldsymbol{k}T) \quad \text{(A1)}$$

$$k_e^D = S^D A^D \exp(-E^D/\boldsymbol{k}T) \quad \text{(A2)}$$

The ratio between k_e^H and k_e^D can be described as:

$$\frac{k_e^H}{k_e^D} = \alpha I_{HD} \quad \text{(A3)}$$

where I_{HD} is the kinetic isotope effect in the activated complex and is given as a function of the temperature:

$$I_{HD} = I_0 \exp(-\varepsilon/\boldsymbol{k}T) \quad \text{(A4)}$$

I_0 and ε have the following values:[14,15] Theoretically $I_0=1.15$ and $\varepsilon=1.08$ kcal/mol, and experimentally $I_0=1.10$ and $\varepsilon=1.3$ kcal/mol. From Eqs. (A1)—(A4), α is given as;

$$\alpha = \frac{1}{I_0}\frac{A^H}{A^D}\exp\left(-\frac{E^H-E^D-\varepsilon}{\boldsymbol{k}T}\right), \quad \text{(A5)}$$

assuming that the surface areas, S^H and S^D, are equivalent. Thus, the value of α of Eq. (A5) can be estimated experimentally.

Determination of Ion Activity Coefficients from the Measurement of Membrane Concentration Potentials—Activity Behavior of Alkali-metal Cations in Aqueous Solutions at 25°C

Reita TAMAMUSHI

The Institute of Physical and Chemical Research, Yamato-machi, Kita-adachi-gun, Saitama

and Shojiro GOTO*

Department of Physics and Chemistry, Gakushuin University, Tokyo

(Received July 2, 1970)

The membrane concentration potentials across a permselective sulfonated polystyrene collodion-base membrane were measured with aqueous solutions of alkali-metal salts at 25.0°C. By assuming the ideal behavior of the membrane, the activity coefficients of the critical cations were determined from the membrane concentration potentials at ionic strengths higher than 0.01. The ion activity coefficients of alkali-metal cations were found to follow the order $Li^+ > Na^+ > K^+$ for the chlorides, nitrates, perchlorates, and sulfates. The order of activity coefficients of Na^+ in different halide solutions was bromide > chloride > fluoride. Considerable differences were observed between the individual and mean activity coefficients at ionic strengths higher than 0.01. The individual ion activity coefficients determined from the experimental data were analysed by means of the extended Debye-Hückel equation.

The application of permselective membranes, *i.e.*, membranes of highest ionic selectivity and high permeability, to the determination of ion activities has been suggested and demonstrated by Sollner and his collaborators.[1-3] Among various ion-selective membranes, some of them being available on market, Sollner's permselective collodion-base membranes seem to be the best for theoretical activity studies because of their ideal characteristics over a considerable range of concentration.

This study deals with the measurement of membrane concentration potentials with aqueous solutions of some alkali-metal salts across a permselective sulfonated polystyrene collodion-base membrane, and shows the applicability of the method to the study of ion activity behavior. The individual activity coefficients of the critical cations determined from the membrane concentration potentials will be discussed on the basis of theoretical activity equations.

Experimental

Permselective Sulfonated Polystyrene Collodion-base Membrane. Test-tube-shaped sulfonated polystyrene collodion-base membranes were prepared by the method proposed by Sollner and Neihof,[4,5] and a membrane of the best quality was employed throughout this study. The ohmic resistance of the membrane, being measured in a 0.1 M potassium chloride solution at 1000 Hz, was 50 ohms cm^2. The ionic selectivity of the membrane was examined by measuring the rates of exchange of critical and non-critical ions across the membrane.[5,6] The anion leak after five hours was found to be less than 0.5% of actual cation movement in a 0.5 M KNO_3/membrane/0.5 M NH_4Cl system whose bi-ionic potential was about 5.2 mV.

Solutions. All solutions were made from analytical reagent grade chemicals and redistilled water.

Measurement of Membrane Concentration Potentials. For the determination of membrane concentration potentials, the electromotive force of a cell,

SCE(I)/sat. KCl-agar bridge/soln. (c)/membrane/
soln. (c')/salt. KCl-agar bridge/SCE(I') (1)

was measured by a precision potentiometer (Model P-1, Yokogawa Electric Works). The concentration ratio $c : c' = 2 : 1$ was used. In each experimental run, the solutions were renewed after 20 min from the

construction of the cell, and then several readings of the electromotive force were made at a 10 min-interval. Stable electromotive forces were established within 10 min with the membrane which had been saturated with the critical ions by prior ion exchange. The reproducibility of the individual measurements was better than ± 0.05 mV, except at the ionic strengths lower than 0.01. All measurements were carried out in a a water thermostat of 25.0 ± 0.1°C.

Results and Discussion

The electromotive force, E, of the concentration cell represented by (1) is given by

$$E = E_M + \Delta E_{SCE} + E_L \qquad (2)$$

where E_M is the membrane concentration potential, ΔE_{SCE}, the asymmetry of electrode potentials of the two saturated calomel electrodes, and E_L, the sum of liquid junction potentials at sat. KCl-agar bridge/soln. (c) and soln. (c')/sat. KCl-agar bridge. In order to obtain the membrane concentration potential from the raw experimental data, the electromotive force of the cell should be corrected for ΔE_{SCE} and E_L.[3] The value of ΔE_{SCE} was determined directly from the electromotive force measurement of a cell, SCE (I)/sat. KCl-agar bridge/sat. KCl/sat. KCl-agar bridge/SCE (I'), while the liquid junction potentials were calculated by using Henderson's equation[7] and ionic mobility data. The accuracy of E_M thus obtained is considered to be of the order of ± 0.1 mV because of the uncertainty in estimating liquid junction potentials. Table 1 presents the membrane concentration potentials with aqueous solutions of alkali-metal salts at various concentrations.

The following analysis of the membrane concentration potentials is based upon the assumption of virtually ideal selectivity of the membrane. The extremely small leak of anions across the membrane provides a strong evidence to support the fulfilment of this assumption in the present systems.

Theoretically, the membrane concentration potential of a concentration chain, soln. (c)/membrane/soln. (c'), with an ideal negative membrane is given by a Nernst-type equation,

$$E_M = \frac{RT}{z_+F} \ln \frac{a_+}{a_+'} = \frac{RT}{z_+F}\left(\ln \frac{c_+}{c_+'} + \ln \frac{y_+}{y_+'}\right) \qquad (3)$$

where z_+, a_+, c_+ and y_+ are the valency, activity, molar concentration, and activity coefficient on the molarity basis, respectively, of the critical cation. Thus the ratio of activity coefficients of the critical cation at two different concentrations, c and c', can be determined from the membrane concentration potential:

$$\ln \frac{y_+}{y_+'} = \frac{z_+F}{RT} E_M - \ln \frac{c_+}{c_+'} \qquad (4)$$

Figures 1—5 show the experimental relationship between log (y_+/y_+^{st}) and $I^{1/2}$, where I is the ionic strength on the molarity scale, y^+, the ion activity coefficient at a given value of I, and y_+^{st}, the ion activity coefficient at the ionic strength I^{st} chosen for standard; in the present study, I^{st} being equal to 0.01 for 1 : 1 electrolytes and 0.015 for 1 : 2 electrolytes, respectively. The behavior of mean ionic activity coefficients, $y_\pm$, of the salts[8] is also

From these figures the following remarks can be made about the behavior of the individual ion activity coefficients with changing ionic strength.

(i) The individual activity coefficient curves of the cations follow the order of $Li^+>Na^+>K^+$ for the chlorides, nitrates, perchlorates, and sulfates. The order of the curves for Na^+ of different halides is bromide>chloride>fluoride. These sequences are consistent with those observed for the mean ionic activity coefficients of alkali-metal salts.[9]

(ii) Considerable differences between the individual and mean activity coefficients arise at ionic strengths higher than 0.01, which indicates the specific effect of individual ions on their activity behavior.

The determination of individual ion activity coefficients requires the introduction of a non-thermodynamic assumption. The activity coefficients of the critical cations at relatively low ionic strengths ($I\lesssim 0.01$) can be given with reasonable accuracy by the Debye-Hückel equation (5),

$$\log y_+ = \frac{-z_+^2 A\sqrt{I}}{(1+Ba_+^\circ\sqrt{I})} \tag{5}$$

where A and B are the Debye-Hückel constants, and a_+° is the ion-size parameter. Estimating y_+^{st} by Eq. (5) with suitable values of a_+°, we can determine the individual activity coefficients of the critical cations at higher ionic strengths from the experimental data according to the following relation,

$$\log y_+ = \log\frac{y_+}{y_+^{st}} - \frac{z_+^2 A\sqrt{I^{st}}}{(1+Ba_+^\circ\sqrt{I^{st}})} \tag{6}$$

The numerical values used in the calculation are as follows: $A=0.5116$ and $B=0.3292\times 10^8$ on the molarity basis at 25°C; $a_+^\circ=6$, 4.5 and 3 (10^{-8} cm) for Li^+, Na^+ and K^+, respectively.[10] The individual ion activity coefficients, y_+, of Li^+, Na^+ and K^+ thus obtained for various salts are summarized in Table 2. The uncertainty in the y_+-values is estimated to be ±1%.

In most cases the deviation of the experimentally determined activity coefficients, y_+, from the Debye-Hückel values, $(y_+)_{DH}$, calculated by Eq. (5) increases with increasing ionic strength as shown in Fig. 6. It is expected that the experimental

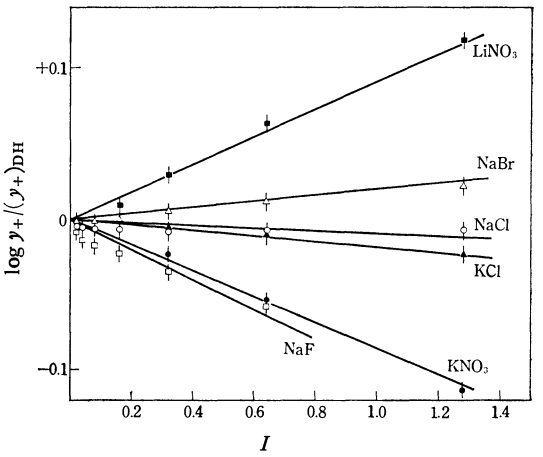

Fig. 6. Deviation of the experimentally determined activity coefficients, y_+, from the Debye-Hückel values, $(y_+)_{DH}$, as a function of ionic strength: —□— (NaF), —○— (NaCl), —△— (NaBr), —▲— (KCl), —●— (KNO_3), —■— ($LiNO_3$).

results at higher ionic strengths can be reproduced with smaller deviations by using the extended Debye-Hückel equation (7) with a linear term,

$$\log y_+ = \frac{-z_+^2 A\sqrt{I}}{(1+Ba_+^\circ\sqrt{I})} + b_+ I \tag{7}$$

*** The $[\log y_+ - \log(y_+)_{DH}]$ *vs.* I plot was not linear.
**** Not determined because of a narrow range of I.

where b_+ is another adjustable parameter. Rough estimates of parameters b_+ for each cation of given salts were obtained from the slope of the plot of $[\log y_+ - \log (y_+)_{DH}]$ against I (Fig. 6), and are presented in Table 3.

The individual ion activity coefficients calculated by Eq. (7) with $a_+°$- and b_+-parameters given in Table 3 are presented in parentheses in Table 2. The agreement between the experimental and calculated values is reasonable except for the LiCl-system in which an appreciable deviation of the $[\log y_+ - \log (y_+)_{DH}]$ *vs.* I plot from linearity was observed. A better fit may be expected by adjusting both parameters, $a_+°$ and b_+; such a trial, however, will be meaningless unless more accurate data are available for analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3425—3434 (1970)

Chemi-ionization of Cs*($8^2P_{1/2}$) with Cs and Foreign Gases

Yoko ONO, Inosuke KOYANO, Yuji MORI and Ikuzo TANAKA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received July 2, 1970)

Chemi-ionization has been studied by the collision of the excited atom of cesium ($8^2P_{1/2}$), whose energy is lower by 0.7 eV than its ionization energy, with cesium, rare gases or simple molecules. The mechanisms for the chemi-ionization, and quenching processes occurring simultaneously were set up and the cross sections of the processes have been determined. Since the pressure effects of added gases to the absorption coefficient of Cs at 3888 Å from the He lamp could not be neglected, suitalbe corrections were made.

It has long been known that the vapor of cesium or rubidium[1] can be photoionized by the light in the discrete region of its atomic spectrum. This ionization has been known[2,3] to take place by absorption of the light at the principal series of cesium (6S→*n*P). Their observation suggested that the mechanism of the ionization processes was

$$Cs + h\nu \rightarrow Cs^*(nP) \qquad n \geq 8 \qquad (1)$$

$$Cs^* \rightarrow Cs + h\nu \qquad (2)$$

$$Cs^* + Cs \rightarrow Cs_2^+ + e \qquad (3)$$

From the measurement of the mobility of the ions Lee and Mahan[4] showed that another process

$$Cs^* + Cs \rightarrow Cs^+ + Cs^- \qquad (4)$$

can not be excluded for the state above 12P. On the basis of the energetic relation the old[2,5] and recent[4,6] data have indicated that the one-electron bond in such ions as Cs_2^+ is stronger than the two-electron bond in Cs_2. Another paper[7] of Mohler and Boeker showed the effects of the foreign gases on the photoionization of cesium at line absorption. They obtained the value of σ (collision radius) between 1.4 and 4×10^{-8} cm for foreign gases, N_2, H_2, He, and Ar, while the value for Cs-Cs collision was about ten times larger. Recent work[8] by Williams has shown the effect of Cs using a Kingdom Cage or space-charge ion collector. The addition of ammonia has altered the photoionization at the principal series lines of cesium by attenuating the wavelength peaks longer than 3440 Å and intensifying the shorter wavelength peaks. They suggested the two processes, one is quenching and the other is ionization.

$$Cs^* + NH_3 \rightarrow Cs + NH_3 \qquad (5)$$

$$Cs^* + NH_3 \rightarrow Cs(NH_3)^+ + e \qquad (6)$$

The latter is similar to the molecular ion formation by collisions between Cs* and normal Cs. The present authors have reported the mass spectrometric identification of Cs_2^+ ion produced by line absorption at 3888 Å.[9] In this paper we report detailed measurements for the chemi-ionization of Cs at 3888 Å and the effects of foregin gas atoms on the chemi-ionization.

Experimental

Reaction System. In the static system, the cesium vapor was irradiated with the 3888 Å light from a microwave discharge He lamp. Figure 1 illustrates the reaction system used in this work. The quartz cell contained platinum parallel-plate electodes of 1.5×4 cm dimension separated by 2 cm. The cell with a window for light irradiation, a small tube for cesium supply and a side-arm to a vacuum system through two grease-free valves was placed in a constant temperature oven. Another small oven around the Cs tube was heated independently in order to control the Cs vapor pressure. Light from the He lamp passed through a chopper, a filter, a collimating lens, a slit, and the photoionization cell. Care was was taken to prevent scattered light or photoexcited atoms from striking the electrodes. The helium discharge lamp emitted the two intense lines at 3888 and 3188 Å in the region between 3000 and 4000 Å. The longer wavelength lines than 4000 Å could not be absorbed by Cs and the shorter ones than 3000 Å could not be through a pyrex window. The 3188 Å line was re-

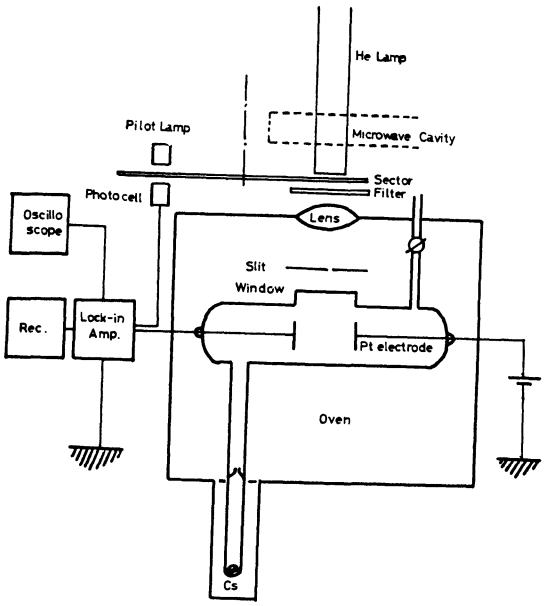

Fig. 1. Schematic diagram of reaction system.

moved by a filter and the essentially monochromatic 3888 Å light was then modulated by a chopper to form the 20 Hz square-wave. The total ions arriving to the cathode were detected by a lock-in amplifier tuned to 20 Hz. Dc voltage from mercury dry cells was applied between the electrodes.

Materials. An ampule of Cs metal from Merck Ltd. was opened in an evacuated tube and the metal was distilled into the tube with a break-off seal and the tube was sealed off. The rare gases such as He, Ne, Ar, Kr, and Xe, inorganic gases such as NH_3, H_2 and N_2, saturated hydrocarbons such as CH_4, C_2H_6, C_3H_8 and n-C_4H_{10} and unsaturated hydrocarbons such as C_2H_4, C_3H_6, *cis*-2-butene, and 2-pentene were supplied from Takachiho Co., Ltd.

Procedure. Before the experiment, the reaction cell was heated at 400°C and evacuated to less than 10^{-6} Torr for at least a few days. The metal vapor was introduced into the cell through the break seal from the Cs tube, and the foreign gas was introduced through a tube containing Cs getter to remove a trace of impurities in the gas after the gas pressure was measured by an oil manometer. During the experiments the vapor pressure of Cs was controlled by the temperature of the Cs supply tube. The temperature of the reaction cell was maintained about 350°C in order to avoid the condensation of Cs in the reaction cell.

Since the electrodes were always covered by adsorbed Cs metal, a current due to surface ionization followed by detachment from the surface by electric field was detected. In a new cell this ion current was 10^{-9} amp/cm² at 350°C with 1.3 V collecting potential and became larger as the cell aged. Since this ion current was always much larger than the expected photoionization current, the latter could only be detected by chopping the incident light beam and using a lock-in amplifier. By using this technique the limit of detection for photoionization current was 10^{-13} A, and 10^{-14} A with a narrow-band preamplifier. In most runs the collecting voltage was fixed at 1.3 V dc for the reason which will be described later. The sector was so designed that the light was irradiated during 1/120 sec by a hysteresis motor of 10 Hz.

At first the photoionization for Cs vapor without foreign gases was measured, and then the variation of the ion current by the addition of foreign gases was measured. The pressure of foreign gas introduced was measured by an oil manometer through a tube of getter of Cs to remove a trace of impurities. Since the pressure effect of the absorption lines of Cs atoms due to foreign gases can not be ignored, a correction was made as described in the appendix.

Results

i) Collecting Efficiency of Chemi-ionization Current. In order to confirm the saturation of the ion collecting efficiency by the electrodes the ion current was examined by changing the collecting voltage. The plots of the ion current *versus* the voltage were shown in Fig. 2. Curve 1 shows the variation of the ion current for Cs vapor only, curve 2 that for the addition of N_2 gas at 4 Torr, and curve 3 that for the addition of Xe gas at 6 Torr. All curves indicated that the collecting voltage of about 1.3 V was suitable for measuring the ion current. The output of the lock-in amplifier used depends on the input signal form, therefore the values of ion currents measured by the lock-in amplifier must be corrected by a suitable method. In our experiments this correction was made by the use of dc amplifier.

ii) Chemi-ionization of Cs*($8\,^2P_{1/2}$) with Cesium Atom. The vapor pressure of cesium was calculated from the relation given by Langmuir and Kingdon.[10] In order to interpret these experimental results, the reaction mechanisms can be assumed as follows:

$$Cs(6S) + h\nu(3888\,Å) \rightarrow Cs^*(8^2P_{1/2}) \quad (7)\ I_{abs}$$

$$Cs^*(8^2P_{1/2}) \rightarrow Cs'(7S, 6S, etc.) + h\nu' \quad (8)\ 1/\tau$$

$$Cs^*(8^2P_{1/2}) + Cs(6S) \rightarrow Cs_2^+ + e \quad (9)\ k_i$$

$$Cs^*(8^2P_{1/2}) + Cs(6S) \rightarrow Cs_2 \text{ or } Cs + Cs \quad (10)\ k_g$$

where I_{abs}, the light intensity absorbed by Cs(6S), is nearly equal to $\varepsilon l I_0[Cs]$, ε is the absorption coefficient of Cs at 3888 Å He line which was determined to be 1.4×10^{-19} cm²/molecule as described in the appendix, l is the absorption path length, 15 mm, I_0 is the intensity of the incident light which was measured to be 1×10^{15} photons/sec, τ is the radiative life time of Cs*($8\,^2P_{1/2}$), k_i and k_q are the rate constants of the collisional ionization with Cs and of the quenching process by Cs, respectively. The possibility of the ion pair formation was neglected because the electron affinity of Cs is about 0.19 eV[4] whose energy is insufficient to produce Cs^+ ion and also the ion except Cs_2^+ was not detec-

curve (1): ● Cs vapor (10^{-2} Torr)
curve (2): ◐ Cs vapor (10^{-2} Torr) + N_2(4 Torr)
curve (3): ○ Cs vapor (10^{-2} Torr) + Xe(6 Torr)

ted by the mass spectrometer as has been described in the previous paper.[9] The rate equation for the concentration of Cs*($8\ ^2P_{1/2}$) is

$$\frac{d[Cs^*]}{dt} = \varepsilon l I_0[Cs] - \frac{1}{\tau}[Cs^*] - (k_i + k_q)[Cs^*][Cs] \tag{11}$$

Since the apparent life time of Cs* is much shorter than the duration of irradiation pulse, *i.e.*, 1/120 sec, the stationary concentration would be maintained during the irradiation. In this case the concentration of Cs* is obtained as follows:

$$[Cs^*] = \frac{\varepsilon l I_0[Cs]}{1/\tau + (k_i + k_q)[Cs]} \tag{12}$$

Now the equation for the ion current of Cs_2^+ ion is

$$I = k_i[Cs][Cs^*] \tag{13}$$

Substituting Eq. (12) into Eq. (13) we obtain

$$I = \frac{\varepsilon l I_0 k_i[Cs]^2}{1/\tau + (k_i + k_q)[Cs]} \tag{14}$$

and

$$\frac{[Cs]}{I} = \frac{1}{\varepsilon l I_0}\left\{\frac{1}{\tau k_i} \cdot \frac{1}{[Cs]} + \frac{k_i + k_q}{k_i}\right\} \tag{15}$$

The values of P/I were plotted against $1/P$ and then a straight line was obtained as shown in Fig. 3. These experimental results indicated that the reaction mechanisms (7)—(10) were reasonable, and the values of τk_i and τk_q were determined from the intercept and the slope of these linear plots. τk_i was calculated to be 1.3×10^{-15} mol^{-1} cm^3 and τk_q was 1.6×10^{-15} mol^{-1} cm^3. Using the following relation between the reaction rate k and

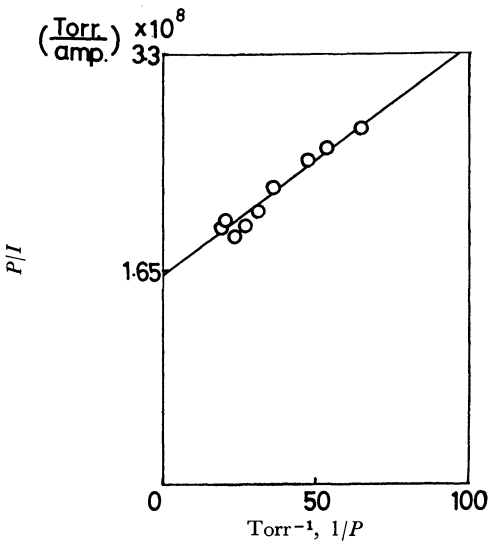

Fig. 3. Plot of the ratio of the pressure of Cs to the chemi-ionization current against the reciprocal value of the pressure according to Eq. (15) for cesium.

the cross section σ^2, $k=\sigma^2(8\pi RT/\mu)^{1/2}$, the products of the life-time τ of Cs* and the cross sections for photo-ionization σ_i^2, and quenching, σ_q^2, have been calculated to be

$$\tau\sigma_i^2 = 9.5\times10^{-21}\ \text{cm}^2\cdot\text{sec}$$

and

$$\tau\sigma_q^2 = 1.17\times10^{-20}\ \text{cm}^2\cdot\text{sec}$$

respectively.

iii) Chemi-ionization of Cs*($8^2P_{1/2}$) with Foreign Gas. The gases used were a) rare gases such as He, Ne, Ar, Kr, and Xe, b) simple inorganic gases NH_3, H_2, and N_2, c) saturated hydrocarbons CH_4, C_2H_6, C_3H_8, and *n*-C_4H_{10} and d) unsaturated hydrocarbons C_2H_4, C_3H_6, *cis*-2-butene, and 2-pentene. The results were described qualitatively as follows. The addition of rare gas except He increased the ion current, while the He gas decreased it. The H_2, NH_3, and N_2 gases decreased the ion current. The saturated hydrocarbon increased the ion current but the unsaturated hydrocarbons C_2H_4, C_3H_6, and 2-pentene except *cis*-2-butene decreased it.

From these qualitative results, the following processes should be added to the previous four processes (7)—(10).

$$Cs^*(8^2P_{1/2}) + M \rightarrow CsM^+ + e \qquad (16)\ k_i'$$

$$Cs^*(8^2P_{1/2}) + M \rightarrow Cs + M \qquad (17)\ k_q'$$

where k_i' and k_q' are the rate constants of the collisional ionization between Cs* and a foreign gas M, and of the collisional quenching process by M, respectively. Since the electron affinities of atoms and molecules used in this experiment are considered to be less than 0.7 eV, the ion pair formation ($Cs^*+M \rightarrow Cs^+ + M^-$) seems to be impossible so that the ion pair formation can be excluded. Therefore the rate equation for the excited Cs* atom is

$$d[Cs^*]/dt = \varepsilon l I_0[Cs] - (1/\tau)[Cs^*] - (k_i + k_q)[Cs^*][Cs] - (k_i' + k_q')[Cs^*][M] \qquad (18)$$

The stationary state treatment leads to the following equation for the concentration of the Cs*,

$$[Cs^*] = \frac{\varepsilon l I_0[Cs]}{1/\tau + (k_i + k_q)[Cs] + (k_i' + k_q')[M]} \qquad (19)$$

The ion current for the total ionic species is

$$I' = k_i[Cs^*][Cs] + k_i'[Cs^*][M] \qquad (20)$$

Substituting Eq. (19) into Eq. (20), the following equation is derived,

$$I' = \frac{\varepsilon l I_0\{k_i[Cs] + k_i'[M]\}[Cs]}{1/\tau + (k_i + k_q)[Cs] + (k_i' + k_q')[M]} \qquad (21)$$

The ratio of the ion current in the presence of a foreign gas to that in the absence of foreign gas is

$$\frac{I'}{I} = \frac{k_i[Cs] + k_i'[M]}{1/\tau + (k_i + k_q)[Cs] + (k_i' + k_q')[M]} \cdot \frac{1/\tau + (k_i + k_q)[Cs]}{k_i[Cs]} \qquad (22)$$

Changing this equation to the suitable form to analyse the data, the following equation can be derived,

$$\frac{[M]}{Y-1} = \frac{(k_i' + k_q')[M]}{k_i'(\beta-\alpha) - k_q'\alpha} + \frac{\alpha\beta}{\{k_i'(\beta-\alpha) - k_q'\alpha\}\tau} \qquad (23)$$

where $Y = I'/I$,

$\alpha = \tau k_i[Cs]$,

and

$\beta = \tau(k_i + k_q)[Cs] + 1$.

Since for a series of measurements the vapor pressure of cesium was kept constant, α and β have the constant values. The plots of $[M]/(Y-1)$ *versus* [M] gave straight lines as shown in Figs. 4—7. These results suggested that the mechanisms considered for chemi-ionization and quenching of cesium with M should be reasonable. From the slopes and the intercepts of these lines the values of $\tau k_i'$ and $\tau k_q'$ could be determined. Utilizing the values of $\tau k_i'$ and $\tau k_q'$, the values of $\tau\sigma'_i{}^2$ and $\tau\sigma'_q{}^2$ could be obtained. The values of $\tau\sigma'_t{}^2 = \tau(\sigma'_i{}^2 + \sigma'_q{}^2)$, $\tau\sigma'_i{}^2$ and $\tau\sigma'_q{}^2$ were summarized in Table 1. The value of collisional cross

section was nearly equal to $2.2\times10^{-20}/\tau$ cm²/sec obtained by Mohler using the space charge method. This coincidence is surprising, considering the two quite different experimental techniques. If the life time of Cs*($8^2P_{1/2}$) is assumed to be the order of 10^{-6} sec, the value of collisional radius is estimated to be $1-3\times10^{-7}$ cm for Cs–Cs collision. This value remarkably large compared with the kinetic radius obtained from the viscosity data. The collisional cross sections for excited cesium with foreign gases, are reduced by two or three orders. The radii for collisions with foreign gases agree in magnitude with the kinetic radii. For the Cs–Cs collision, the ionization and the quenching cross sections are almost equal.

Discussion

Figure 8 shows the schematic potential energy curves for Cs–M system relevent to the ionization quenching processes from the system Cs*($8^2P_{1/2}$)+M. It is to be seen in Fig. 8 that $Cs^+ + M^-$ and $Cs^+ + M + e$ curves both interact with the curve for the Cs*($8^2P_{1/2}$)+M, and also the repulsive curves (Π state) of the lower excited states of Cs with M (for example, Cs**($7^2P_{1/2}$)+M) cross the curve of Cs*+M in the $\sum$ state. The quenching of Cs*($8^2P_{1/2}$) by M can be interpreted by cross over from Cs*+M to Cs**+M. The chemi-ionization of Cs*($8^2P_{1/2}$) with M can be interpreted by transfer from the Cs*+M curve to the $CsM^+ + e$ curve.

As predicted in the theories of inelastic collisions[11] between alkali and rare gas atoms concerning the spin-orbit relaxation of alkali atoms, cross section should depend on the attractive force between the atoms, and increase monotonically with the polarizabilities of rare gas atoms from helium to xenon. The total cross section equal to the sum of the quenching and ionization cross sections should follow exactly the predicted sequence. The plots of $\tau\sigma_t^2/r_0^2$ *versus* $\alpha\mu^{1/2}$ gave a straight

line as shown in Fig. 9, where r_0 is the kinetic collision diameter between the Cs atom and the rare gas atoms, α is the polarizability of each rare gas atom, and μ is the reduced mass of cesium and each rare gas atom. This relation indicated that the total cross section ($\sigma_t'^2$) divided by kinetic cross section (πr_0^2) corresponding to the easiness of making collision complex should be related with the $\alpha\mu^{1/2}$ which means the effective intermolecular attractive force. H_2, N_2 and NH_3 have larger cross sections than rare gases, and H_2 has the largest one. In the case of hydrocarbons, the cross section decreases from CH_4 to C_2H_6 and then shows a rather steep rise to n-C_4H_{10}. The cross sections of unsaturated hydrocarbons have smaller values than those of rare gases and those of corresponding saturated hydrocarbons. This tendency seems to be reverse to that for the physical quenching cross sections of Na*(3^2P) by hydrocarbons.[12] This difference may be caused by the different processes from excited states of atoms.

Since we can exclude the ion pair formation in the reaction of Cs*($8^2P_{1/2}$) with the foreign gases as described before, the increase of ion current by the foreign gases should be explained by the occurrence of chemi-ionization reaction

$$Cs^* + M \rightarrow CsM^+ + e$$

Herman and Cermak[13] confirmed the presence of ions $CsAr^+$ and $CsKr^+$ in the reactions

$$Ar^* + Cs \rightarrow ArCs^+ + e$$

and

$$Kr^* + Cs \rightarrow KrCs^+ + e$$

A recent work by Williams and Naiditch[8] suggested the molecular ion $Cs(NH_3)^+$, from the reaction

$$Cs(nP) + NH_3 \rightarrow CsNH_3^+ + e \quad (n \geq 12)$$

On the energetic basis for the possibility of the chemi-ionization reaction between Cs*($8^2P_{1/2}$) and M, the value of bond energy of molecular ion CsM^+ should be greater than 0.7 eV. The bond energy of CsM^+ strongly depends on the polarizability and/or ionization potential of foreign gases. If the ionization potential of M is lower, the energy of the molecular ion becomes lower. It is expected that the ionization cross section with M may be correlated with the ionization of M. This correlation is found in the series of foreign gases such as rare gases and saturated hydrocarbons

except for Xe and CH_4 as shown in Fig. 10. Compared with the ionization cross section, $\tau\sigma_i^2$, it is interesting to note that the plots of $\log \tau\sigma_t^2$ *versus* the ionization potential give three straight lines for three groups of foreign gases; rare gases, saturated hydrocarbons, and unsaturated hydrocarbons as shown in Fig. 11.

In Fig. 12 the quenching cross sections listed in Table 1 are plotted against atomic weight in cesium-rare gas system. The plots show a minimum at argon. Similar behavior of the cross sections was observed in the cases of the collisional spin-orbit relaxation of $Cs(6^2P_{1/2} \rightarrow 6^2P_{3/2})$ by rare gases.[11] It was demonstrated that there was a good correlation between the spin-orbit relaxation cross sections for $Cs(6^2P_{1/2})$-rare gas collisions and the elastic scattering cross sections of electrons by the rare gases with the electron velocity assumed as equal to that of the valence electron of cesium. However the complete theoretical interpretation of this behavior of rare gases has not been given.

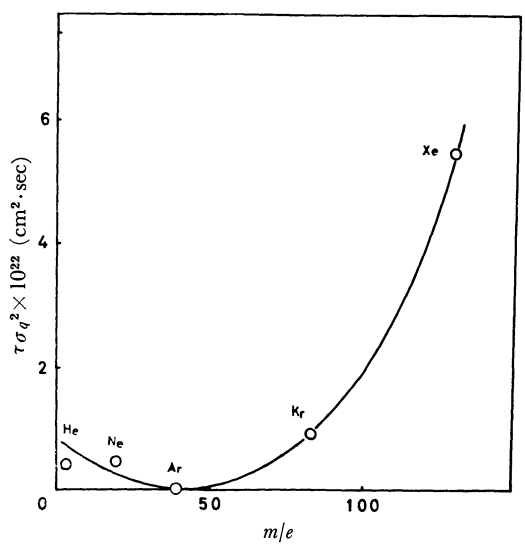

Fig. 12. Correlation $\tau\sigma_q^2$ *versus* atomic weight.

Figure 13 shows that the plots of $\eta(\sigma_i^2/\sigma_t^2 = \sigma_i^2/(\sigma_i^2+\sigma_q^2))$, relative ionization efficiency, *versus* the mass weight gave the same configuration for each group of gases. For rare gases they have a maximum at arogn, and the saturated hydrocarbons at C_3H_8 and the unsaturated at C_4H_8. The increases in η from He to Ar, CH_4 to C_3H_8 and C_2H_4 to C_4H_8, can then be ascribed to the increase in the ionization probability owing to the decrease in ionization potential of M which lowers the $CsM^+ + e$ curve. The decrease from Ar to Xe for rare gases can be interpreted by the rapid increase in the quenching probability owing to the increasing spin-orbit interaction which will be evidenced from the experimental results shown in Fig. 12. However, for the saturated and unsaturated hydrocarbons, the increase in the number of potential curves which cross the CsM* curve to dissipate the electronic energy to various vibrational energies may play an important role for the decreases in η from C_3H_8 to n-C_4H_{10} and from

C_4H_8 to C_5H_{10}.

Appendix

Effects of Foreign Gases on the Line Absorption of Cs. The modification of the spectral lines of emitting or absorbing atom due to collisions with other atoms and molecules is exhibited by broadening, shift and symmetry of lines and the occasional appearance of a certain diffuse band. The emission line 3888 Å from the He lamp used is substantially broader than the absorption line of cesium, and also the peak of He line does not coincide with that of cesium line. Since the added gas pressure was varied up to about 10 Torr in this experiment, the pressure effect on the absorption of the light at 3888 Å could not be neglected for the quantitative discussion.

The absorption cell consists of 150 cm length and 1.5 cm diameter pyrex tube with pyrex windows at both ends, a small tube for supply of Cs vapor and a tube connected with a gas inlet system through the two grease-free valves. The cell was mounted in a constant temperature oven. Before measurement the cell was evacuated to less than 10^{-6} Torr by heating at 400°C for a few days, and kept at 350°C during the measurement. In the experiment the slit width of the monochrometer 0.1 mm was enough to cover the whole emission line at 3888 Å line. After the absorption of the light by Cs vapor only was measured, a foreign gas purified by a getter was introduced into the cell and the variation of the intensity by adding a foreign gas was measured.

The Apparent Absorption Coefficient. The logarithmic plots of the transmitted light intensity, I, *versus* the cesium pressure can give the apparent absorption coefficient. The value of the apparent absorption coefficient calculated from Fig. 14 was 1.4×10^{-19} cm²/molecule.

Pressure effects of foreign gases on the absorption line of Cs. Relative measurements of the

effects of rare gas atoms in the pressure region, 0 to 10 Torr were shown in Fig. 15. The results for simple inorganic gases such as H_2, N_2, and NH_3 were shown in Fig. 16, the results for CH_4, C_2H_4, C_2H_6, and cyclo-C_3H_6, for C_3H_6, C_3H_8, and n-C_4H_{10}, and for C_5H_{10} are shown in Fig. 17, 18, and 19, respectively. For each foreign gas plots of the relative absorption *versus* the pressure of gas yield almost a straight line. In order to evaluate the pressure effect of the foreign gas on the chemi-ionization of Cs, the ion current of chemi-ionization is corrected by multiplying the factor I_{t_0}/I_t at each foreign gas pressure, where I_t and I_{t_0} are the transmitted light intensities with and without foreign gases, respectively.

Reactive States of Acridine for the Photoreduction in Tetrahydrofuran

Yoshikatsu MIYASHITA, Shigeya NIIZUMA, Hiroshi KOKUBUN and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received July 6, 1970)

The photoreduction of acridine in tetrahydrofuran (THF) has been investigated by the steady light experiment and also by the flash technique. The quantum yields in the aerated and deaerated solution were 0.12 and 0.36 respectively. The former value is referred to molecular mechanism while the difference of the two, 0.24, to radical mechanism. It was established that the sensitized reaction occurs with biacetyl ($T(n\text{-}\pi^*)$, 19700 cm^{-1}) as a triplet energy donor. The probability factor β with which the produced $T(\pi\text{-}\pi^*)$ of acridine (15840 cm^{-1}) reacts with THF was found to be $\gtrsim 0.6$. Anthracene ($T(\pi\text{-}\pi^*)$, 14700 cm^{-1}) was found to act as a triplet energy acceptor and to reduce the photoreduction. From the decrease of the quantum yield caused by the addition of anthracene, the quantum yield *via* the lowest $T(\pi\text{-}\pi^*)$ of acridine was evaluated as 0.06. By combining this value with the above β-value, the apparent φ_{ST} has proved to be $\lesssim 0.1$. This very small value compared with the φ_{ST} values presented for other solvents (benzene $\gtrsim 0.25$, water $\gtrsim 0.24$, ethanol $\gtrsim 0.29$) leads to the conclusion that in THF, $T(n\text{-}\pi^*)$ is also a reactive state for the photoreduction. Further, an interesting aspect of the radical mechanism was elucidated from the comparison of Φ_R (quantum yield due to radical mechanism) and Φ_{O_2} (quantum yield of oxygen consumption).

There is at present some disagreement as to the reactive state of acridine for the photoreduction in alcohols. In 1965, Kellmann and Dubois[1] reported that in methanol, the $T(n\text{-}\pi^*)$ state in addition to the singlet excited state may participate in the reaction but the lowest $T(\pi\text{-}\pi^*)$ does not. On the other hand, Vander Donkt and Porter[2] concluded that in isopropanol, only the singlet excited state is reactive. That this discrepancy in methanol and in isopropanol really exists was verified by our group[3] using biacetyl as a T-energy acceptor. This was further reconfirmed from the study on the pH dependence of the photoreduction quantum yield.[4] But a little later, Wilkinson and Dubois[5] proposed that only $^1L_a(\pi\text{-}\pi^*)$ is a reactive state in ethanol on the basis of the experiments involving external heavy atom effects.

Recently Zanker and Prell asserted that for the photoreduction of 9-methylacridine in ethanol, the singlet ($n\text{-}\pi^*$) instead of $^1L_a(\pi\text{-}\pi^*)$, is a reactive state.[6] According to our results, the quantum yields of photoreduction *via* $T(n\text{-}\pi^*)$ in methanol, ethanol, *n*-propanol and isopropanol are 0.063, 0.019, 0.022 and 0.00 respectively. These results may perhaps be interpreted in terms of the number of α-H atoms and of the steric factors in the reaction. Some workers however seem to have the opinion that the higher T states of short duration are unable to participate in the reaction. One purpose of the present paper is to show another example opposite to such a view.

The second point which we would like to stress is that although all the above workers agree in the point that the lowest $T(\pi\text{-}\pi^*)$ is not reactive in the photoreduction in alcohols, this can not be true in general. For instance, Koizumi *et al.*[7] established that the photoreaction between acridine and acridan in benzene occurs *via* the lowest $T(\pi\text{-}\pi^*)$ of the former. It is expected therefore, that such a possibility exists also in the photoreduction of acridine in some suitable solvents. The second object of the present paper is to demonstrate such an example. We found that the photoreduction of acridine in tetrahydrofuran (THF) occurs with a high quantum yield and now the lowest $T(\pi\text{-}\pi^*)$ has been established to be reactive in this solvent, and most likely, the higher

$T(n\text{-}\pi^*)$ takes part in the photoreduction.

In addition, an interesting feature of the radical process has been elucidated from the review of all our data so far obtained on the quantum yields for photoreduction and for oxygen consumption.

Experimental

Apparatus for the flash photolysis and the steady light experiment, procedures and samples are all essentially similar as in our previous papers. All the steady light experiments were carried out at 25°C. The light intensity for the steady light experiment was usually $2\text{—}3\times10^{-9}$ mol cm^{-2} sec^{-1}. As an exciting light, 365 nm was used for the direct photoreduction and 435.8 nm for the sensitized reaction by biacetyl. The reaction was followed by measuring the change in optical density at 365 nm ($\varepsilon=3.75\times10^3$). A Hitachi MPF-2 spectrofluorometer was used for the measurement of the emission spectra. The concentration of oxygen in THF was decided by the manometric method using Bunsen absorption coefficient. The solubility of oxygen in THF, being not found in literature, was measured with an apparatus specially constructed for the present purpose. See Appendix.

Results and Discussion

Broadly speaking, the photoreduction of acridine in THF occurs in the similar way as in alcohol. Thus as shown in Fig. 1, the absorption maximum at 357 nm declines upon irradiation with 365 nm, and a new peak rises at 285 nm with an isosbestic point at 324 nm. Since the absorption maximum of acridan lies at 290 nm, the photoproducts may contain some acridan derivatives and possibly diacridan in addition to acridan. It was established further, that as in alcohols, the photoreduction occurs even in the aerated solution. The quantum yields in the aerated and in the deaerated solutions were respectively 0.12 and 0.36.

The Effect of Oxygen Concentration on the Quantum Yield. Figure 2 shows the plots of $\ln(e^{2.303D}-1)$ against time (D, the optical density at 365 nm) for various concentrations of oxygen up to 2×10^{-3} M. It is seen that the runs for low concentrations of oxygen consist of two linear portions, the earlier portion with almost the same slope as that in the aerated solution and the later one with the slope approaching that in the deaerated solution. These results are similar to those in alcohols,[8] and can be interpreted as follows.

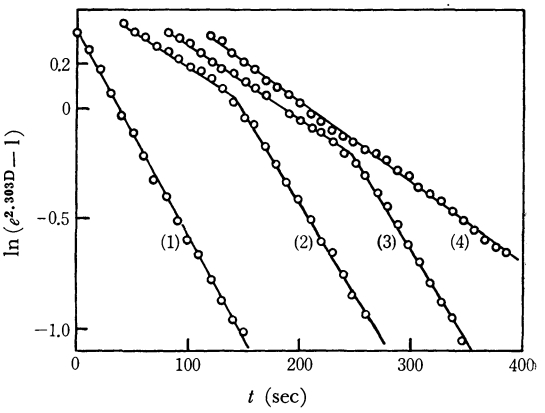

Fig. 2. Plots of $\ln(e^{2.303D}-1)$ *vs.* time for acridine.
[A] $=1\times10^{-4}$ M
(1) Deaerated soln.
(2) [O_2] $=3.4\times10^{-4}$ M
(3) [O_2] $=5.8\times10^{-4}$ M
(4) Aerated soln.

Firstly, the reaction proceeds in proportion to the absorption of light. Secondly, the first linear portion corresponds to the period during which the reaction proceeds *via* molecular mechanism, *i.e.*, proceeds as an elementary process or the like, and not *via* semiquinone which, as has already been fully established, is oxidized by oxygen. A sharp breaking point on each run corresponds to the time point where oxygen has been almost exhausted. After the breaking point, the reaction proceeds essentially in the same way as in the deaerated solution, where the molecular and radical mechanisms (the mechanism *via* semiquinone) occur. As shown in Fig. 3, the decrease in acridine concentration during the first period, $-\Delta$[A] is proportional to the initial oxygen concentration. This implies that as long as the oxygen concentration is above a certain critical value which is very small, only the molecular mechanism occurs

8) S. Niizuma and M. Koizumi, This Bulletin, **36**, 1629 (1963).

Table 1. Quantum yields for the photoreduction of acridine in THF

$[O_2]\times10^4$ (M)	Φ_{air}	mean	Φ	mean
20	0.12_1			
20	0.11_5	0.12		
20	0.12_3			
0			0.34_3	
0			0.36_4	0.36
0			0.36_4	

$[O_2]\times10^4$ (M)	Φ_1	Φ_2	$-\Delta[A]\times10^5$ M
1.02	—	0.36_2	—
1.83	0.13_1	0.34_5	0.8_8
3.37	0.11_8	0.30_5	2.2_2
3.95	0.12_4	0.33_1	2.3_3
5.84	0.12_7	0.29_7	3.6_9
6.25	0.12_4	0.29_2	3.9_4
7.91	0.10_0	0.17_5	5.2_9
8.98	0.10_0	0.17_3	5.0_8
9.04	0.09_8	0.19_9	6.5_5
11.3	0.10_0	—	—

and accordingly, $-\Delta[A]$ is the decrease of acridine due to this mechanism during the first stage. The critical value lies in the region, 1.02—1.83$\times10^{-4}$ M. Table 1 gives the values of $-\Delta[A]$, the quantum yields for the aerated (Φ_{air}) and deaerated solution (Φ) and those for the various concentrations of oxygen. In the latter cases, the quantum yields for the early stage Φ_1 and for the later stage Φ_2 are tabulated separately.

The quantum yields of oxygen consumption, Φ_{O_2} can be evaluated simply from the following relation,

$$\frac{-d[O_2]}{dt}\Big/\frac{-d[A]}{dt}=\frac{\Phi_{O_2}}{\Phi_1}=\frac{-\Delta[O_2]}{-\Delta[A]} \qquad (3)$$

where $-\Delta[O_2]$ can be equated to the initial concentration of oxygen. From the plot of Fig. 3 the value of Φ_{O_2}/Φ_1 was evaluated as 16 and accordingly Φ_{O_2}, as $\sim$2.0. This value suggests the occurrence of chain mechanism for the disappearance reaction of oxygen.

Reaction Sensitized by Biacetyl. In order to know whether the lowest $T(\pi\text{-}\pi^*)$ can participate in the reaction, the photosensitized reaction by triplet energy transfer using biacetyl as a donor was attempted at first. The T-levels of biacetyl $T(n\text{-}\pi^*)$ and acridine $T(\pi\text{-}\pi^*)$ are respectively 19700 cm^{-1} [9] and 15840 cm^{-1}.[10] The lifetime of biacetyl $T(n\text{-}\pi^*)$ in methanol is 0.2×10^{-3} sec[3b] and the diffusion controlled rate constant in THF estimated from the Stokes-Einstein relation is 1.4×10^{10} $M^{-1}sec^{-1}$. Therefore, it is expected that 10^{-4} M of acridine is enough for the complete energy transfer to occur from biacetyl to acridine. This was really verified by the complete quenching of biacetyl phosphorescence in the solution containing 10^{-4} M of acridine. This is shown in Fig. 4.

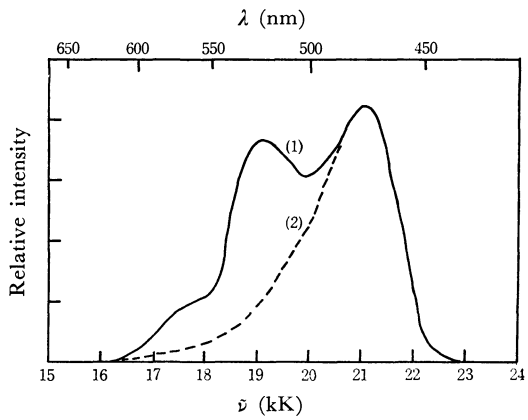

Fig. 4. Emission spectra of biacetyl in the deaerated THF solution (exciting light, 420 nm).
(1) [B]$=1\times10^{-1}$ M
(2) [B]$=1\times10^{-2}$ M, [A]$=1\times10^{-4}$ M

Hence the photosensitized reaction was investigated with the THF solutions containing 10^{-2} M biacetyl and 1×10^{-4} M acridine. The exciting light was chosen at 435.8 nm where there is no absorption of acridine. It is to be noted however, that biacetyl undergoes some unknown reaction in THF gradually when kept in dark for a long time. Hence the sample solution was always prepared immediately before each measurement.

In the aerated solution, the reaction did not occur at all. This is natural since the triplet biacetyl is expected to be quenched completely by $\sim2\times10^{-3}$ M of oxygen.

10) D. F. Evans, *J. Chem. Soc.*, **1957**, 1351.

In the deaerated solution the reaction occurred as shown in Fig. 5. In Fig. 6, the relation between the decrease of acridine, $-\Delta$[A] as measured by the optical density at 357 nm and the increase of

○ Sensitized reaction

photoproducts, Δ[P] measured by the optical density at 285 nm in the present sensitized reaction, is compared with that for the direct reaction. The agreement between the two cases supports that the similar reaction is occurring in the two cases. If one assumes the following scheme,

$$B + h\nu \longrightarrow {}^1B^* \qquad I_{abs}$$
$${}^1B^* \longrightarrow {}^3B \qquad \varphi_{ST}^B I_{abs}$$
$${}^1B^* \xrightarrow{k_1} B + h\nu_f$$
$${}^3B \xrightarrow{k_2} B + h\nu_p$$
$${}^3B \xrightarrow{k_3} B$$
$${}^3B + A \xrightarrow{k_4} B + {}^3A$$
$${}^3A + RH_2 \xrightarrow{k_5} Prod$$
$${}^3A \xrightarrow{k_6} A$$

where $^1B^*$, ^3B and ^3A are respectively the singlet excited state of biacetyl, the n–π^* triplet of biacetyl and the π–π^* triplet of acridine. RH_2 stands for THF which acts as a reducing agent. The steady state method gives the following equation,

$$-d[A]/dt = \varphi_{ST}\cdot\chi\cdot\beta\cdot I_{abs} \qquad (4)$$
$$\chi = k_4[A]/(k_2+k_3+k_4[A])$$
$$\beta = k_5[RH_2]/(k_5[RH_2] + k_6)$$

Putting $\varphi_{ST}^B \simeq 1$[9] and $\chi = 1$, the following zeroth order rate formula is expected to hold, which enables us to evaluate the value of β.

$$[A] = [A]_0 - \beta I_{abs} t \qquad (5)$$

In reality however, this does not hold satisfactorily as shown in Fig. 7. Perhaps it may be due to the occurrence of some side reactions involving biacetyl. Thus the exact value of β could not be decided and only its lower limit was estimated as $\beta \gtrsim 0.6$.

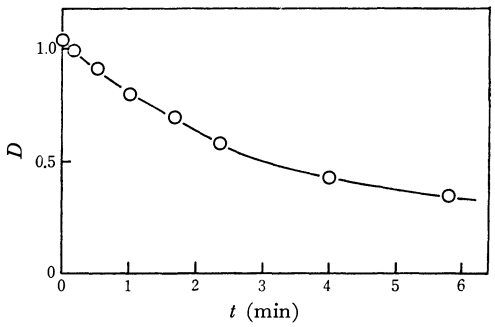

Fig. 7. Plot of D at 357 nm *vs.* time for the biacetyl sensitized reaction.

The Effect of the Addition of Anthracene as a *T*-Energy Acceptor. Although the above results support the occurrence of photoreduction at the lowest $T(\pi$–$\pi^*)$ of acridine, there still remains some suspicion that the reaction is not due to *T–T* energy transfer but due to some other type of sensitization, for instance, a reaction involving half-reduced biacetyl.[2] To get further evidence, the effect of the addition of a triplet energy acceptor on the photoreduction was examined. As such a substance, anthracene $T(\pi$–$\pi^*)$ of which is located at 14700 cm^{-1} [11] was employed. Anthracene has

11) J. Nag-Chaudhuri, L. Stoessell and S. P. McGlynn, *J. Chem. Phys.*, **38**, 2027 (1963).

however, the absorption in the region common to acridine, and care should be paid on its inner filter effect.

Generally, the information on the energy transfer can be obtained directly by the flash technique. But before doing this, the feature of the transient species produced by the flash illumination in THF solutions of acridine alone, anthracene alone and of the two, were examined preliminarily. The transient spectra of acridine, 1×10^{-4} M in THF, resemble those obtained in ethanol[12] and in benzene[7b] very well, and the peaks at 440 nm and at 520 nm are safely assigned to the T–T absorption and to semiquinone. The first order decay constant of the former could not be measured very accurately but was estimated about $\sim1\times10^{4}$ sec^{-1}. The second order decay constant of semiquinone measured at 520 nm was $\sim4\times10^{5}$ ε M^{-1} sec^{-1}. The transient absorption for anthracene alone 1×10^{-5} M and for the mixture of anthracene 1×10^{-5} M and acridine 1×10^{-4} M were compared. The former agrees very well with T–T absorption in literature,[13] and its decay is of the second order in agreement with Linschitz *et al.*[14] The decay constant was measured at 425 nm and was decided as 8.1×10^{4} ε M^{-1} sec^{-1}. The agreement of the main peak position in the two solutions suggested the almost complete energy transfer from acridine to anthracene.

Quantitative Investigation on the Energy Transfer. The energy transfer from acridine $T(\pi\text{–}\pi^*)$ to anthracene was investigated quantitatively under various conditions using the flash technique involving the emission measurement.[15] For this purpose, the yields of triplet anthracene $[^3An]_0$ were investigated at a fixed acridine concentration, $[A]=1\times10^{-4}$ M and at various anthracene concentrations up to 2×10^{-5} M. Under such a condition, the inner filter effect of anthracene may be neglected to a first approximation. The yield of triplet anthracene $[^3An]_0$ for which conventionally the quantity 50 μsec after flashing was taken,[15] consists in general of the two portions, the one due to the direct excitation of anthracene, $[^3An]_d$ and the other due to energy transfer from acridine, $[^3An]_e$. Thus,

$$[^3An]_0 = [^3An]_d + [^3An]_e \qquad (6)$$

Under the above assumption the efficiency of energy transfer can be studied from the effect of anthracene concentration on $[^3An]_e$, and to do this it is necessary to know the magnitude of $[^3An]_d$. This was performed as follows. $[^3An]_d$ which is equated to $\varphi_{ST}^{An}\int I_{abs}^{An}dt$, is proportional to the integrated fluorescence intensity during a flash because of the following relation,

$$\int I_F\,dt \propto \phi_F \int I_{abs}^{An}\,dt$$

in which ϕ_F is the fluorescence quantum yield. The fluorescence of anthracene was measured at 405 nm where there is no absorption of acridine and of anthracene. Figure 8 gives the relationship between $\int I_F\,dt$ (at 405 nm) and D_0 (at 425 nm) measured at various flash intensities for the solution of anthracene alone. It is obvious that the relation

$$D_0 = \gamma\int I_F\,dt \qquad (7)$$

holds satisfactorily and that the parameter γ can be evaluated correctly from the plot. This relation can be used to know the quantity of $[^3An]_d$ for the mixed solution of acridine and anthracene, because acridine is nonfluorescent in THF.

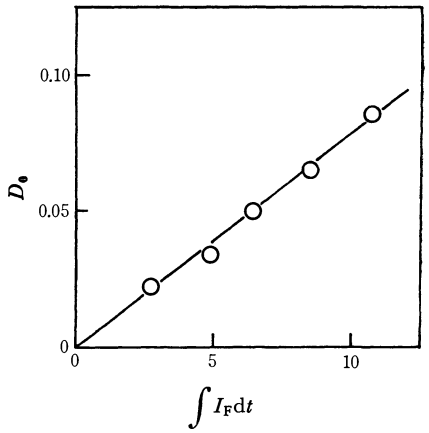

Fig. 8. Plot of D_0 at 425 nm *vs.* $\int I_F dt$ at 405 nm for the THF solution of anthracene.

Now in practice, it is more convenient to make argument in terms of the optical densities, and for this purpose equation (6) is to be rewritten as follows using eq. (7).

$$D_0 = D_0^A + D_{0e}^{An} + \gamma\int I_F\,dt \qquad (8)$$

where D_0, D_{0e}^{An} and D_0^A are respectively the entire optical density at 425 nm, that due to anthracene produced by energy transfer and that due to acridine. The values of $D_0^A+D_{0e}^{An}$ thus obtained are in general written as follows,

$$D_0^A + D_{0e}^{An} = \{\varepsilon_{^3A}[^3A]_0 + \varepsilon_{^3An}[^3An]_e\}d \qquad (9)$$

12) A. Kira, S. Kato and M. Koizumi, This Bulletin, **39**, 1221 (1966).

14) H. Linschitz, C. Steel and J. A. Bell, *J. Phys. Chem.*, **66**, 2574 (1962).

15) K. Kikuchi, H. Kokubun and M. Koizumi, This Bulletin, **49**, 1545 (1968).

In the special case that [An]=0,

$$D_{00}^{A} = \varepsilon_{^3A}[^3A]_{00}d \tag{10}$$

From these two equations and using the relation $[^3A]_{00}=[^3A]_0+[^3An]_0$, one gets

$$\Delta D_{0e} = D_0^A + D_{0e}^{An} - D_{00}^A = \{(\varepsilon_{^3An}-\varepsilon_{^3A})[^3An]_e\}d \tag{11}$$

which shows that ΔD_{0e} is a measure of $[^3An]_e$.

Figure 9 gives the plot of ΔD_{0e} *vs.* [An]. It can be concluded from Fig. 9 that the energy transfer occurs completely above 5×10^{-6} M of anthracene. It is to be added that the decay of triplet anthracene in the mixed solution is $\sim0.8\times10^4$ sec^{-1} and is very much larger than that in the solution of anthracene alone. This may suggest the attack of some intermediates originating from acridine upon triplet anthracene, but this does not invalidate the above treatment.

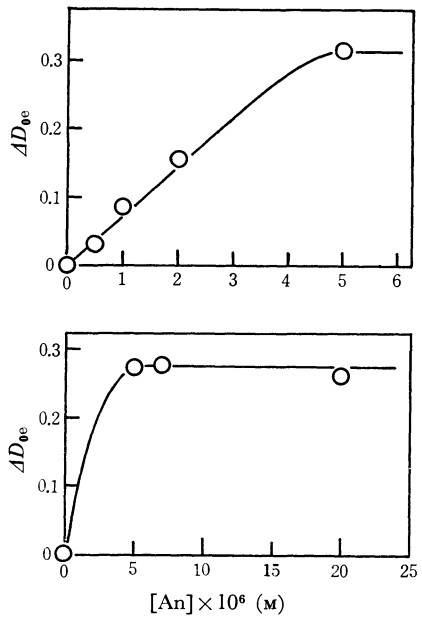

Fig. 9. Plots of ΔD_{0e} *vs.* [An].

lower: higher concentration region

Dependence of the Quantum Yield on the Anthracene Concentration. This was investigated by varying the concentration of anthracene from 5×10^{-7} to 1.4×10^{-4} M and by fixing the concentration of acridine at 1×10^{-4} M. It was found that the solution of anthracene alone undergoes the photoreaction but the quantum yield is less than 10^{-2} and can be neglected in the present case. The inner filter effect was corrected on the basis of the following equation,

$$\ln(e^{2.303D_0}-1) - \ln(e^{2.303D}-1) = \Phi I_0\alpha\left(t-\int_0^t \frac{D_{An}}{D}dt\right)\times10^3 \tag{12}$$

where α is the molar absorption coefficient of acridine at 365 nm, where D and D_0 are the optical densities at t and $t=0$ and where D_{An} is the optical density of anthracene. The other notations are the usual ones. Thus the correct value of Φ can be obtained only by changing the time axis by $-\int_0^t D_{An}/D\cdot dt$. It was checked that this correction was very satisfactory. The quantum yields at various anthracene concentrations are given in Table 2.

TABLE 2. QUANTUM YIELDS AT VARIOUS ANTHRACENE CONCENTRATIONS

[An] (M)	Φ	$-\Delta\Phi$
0	0.36	—
5×10^{-7}	0.35_7	0.00_3
1×10^{-6}	0.33_0	0.03_0
2×10^{-6}	0.31_4	0.04_6
5×10^{-6}	0.29_8	0.06_2
5×10^{-6}	0.31_2	0.04_8
7×10^{-6}	0.30_6	0.05_4
1×10^{-5}	0.32_1	0.03_9
2×10^{-5}	0.30_2	0.05_8
2.5×10^{-5}	0.29_3	0.06_7
5×10^{-5}	0.28_5	0.07_5
9×10^{-5}	0.26_8	0.09_2
1.4×10^{-4}	0.25_1	0.10_9

It is obvious that the addition of anthracene causes a decrease in the quantum yield. Assuming that this decrease is due to the energy trnasfer from acridine $T(\pi\text{-}\pi^*)$ to anthracene, the analysis can be made on the following scheme,

$$A + h\nu \longrightarrow A^* \qquad I_{abs}$$
$$A^* + RH_2 \longrightarrow Prod \qquad \Phi^* I_{abs}$$
$$A^* \longrightarrow {}^3A \qquad \varphi_{ST} I_{abs}$$
$${}^3A \xrightarrow{k_1} A$$
$${}^3A + RH_2 \xrightarrow{k_2} Prod$$
$${}^3A + An \xrightarrow{k_3} A + {}^3An$$
$${}^3An \xrightarrow{k_4} An$$

where ^3A is the lowest $T(\pi\text{-}\pi^*)$ of acridine and A* stands conventionally for the other reactive states (singlet excited state and $T(n\text{-}\pi^*)$) and where ^3An is the anthracene triplet state. The total quantum yield consists of two parts, one due to A^* (Φ^*) and the other due to ^3A (Φ_T). In the absence of anthracene,

$$\Phi_0 = \Phi^* + \Phi_T^0$$

and in the presence of anthracene (assuming that anthracene quenches only $T(\pi\text{-}\pi^*)$),

$$\Phi = \Phi^* + \Phi_T$$

Then,

$$-\Delta\Phi = \Phi_0 - \Phi = \Phi_T^0 \frac{k_3[\mathrm{An}]}{k_1+k_2[\mathrm{RH_2}]+k_3[\mathrm{An}]} \quad (13)$$

and

$$1/-\Delta\Phi = 1/\Phi_T^0(1+1/(k_3[\mathrm{An}]\tau)) \quad (14)$$
$$(1/\tau = k_1+k_2[\mathrm{RH_2}])$$

Since the flash experiment has already demonstrated that the energy transfer is complete above 5×10^{-6} M of anthracene, it is desirable to apply the above equation at lower concentrations. But in such a region the effect was so small that the reliable data could not be obtained. In fact, Table 2 shows that the values of $-\Delta\Phi$ in the region 5×10^{-6}—2.5×10^{-5} M of anthracene, are almost constant and are 0.06. The further decrease in the higher concentration of anthracene might be due to the quenching of $T(n\text{-}\pi^*)$. Figure 10 gives the plot of $1/\Phi$ *vs.* log [An] and the plot of $1/-\Delta\Phi$ *vs.* [An] which was drawn under the assumption that Φ_T^0 is equal to 0.06. The value of $k_3\tau$ obtained from the latter plot is 3.5×10^6 M^{-1} and by putting $k_3=1.4\times10^{10}$ M^{-1} sec^{-1}, one gets $\tau=2.5\times10^{-4}$ sec. Although these values are not very reliable, the latter value is compared with the result obtained by the flash experiment.

Conclusion

The present work has established that the quantum yields of the photoreduction of acridine in the aerated and in the deaerated THF solution are respectively 0.12 and 0.36. The former occurs by molecular mechanism, and the latter by radical mechanism in addition to molecular one. The contribution of radical mechanism is thus 0.24. We have not yet succeeded in deciding the contribution of different excited states to the above two processes. But it has been demonstrated that a certain portion is due to the reaction involving $T(\pi\text{-}\pi^*)$. Thus firstly, the sensitized reaction has been found to occur by using biacetyl as a sensitizer, of which the triplet level is lower than acridine $T(n\text{-}\pi^*)$ but higher than its $T(\pi\text{-}\pi^*)$. Furthermore, it has been shown by the flash technique that anthracene above 5×10^{-6} M, deactivates $T(\pi\text{-}\pi^*)$ of acridine completely and that the quantum yield of photoreduction of acridine decreases by about 0.06 ($=\Phi_T$) by the addition of anthracene of the same concentration. Combining the value of Φ_T with the probability factor $\beta\gtrsim0.6$ with which the $T(\pi\text{-}\pi^*)$ state reacts with THF, it can be concluded that the φ_{ST} value in the present system appears to be $\lesssim0.1$.

On the basis of this value, further conclusion

Table 3. Quantum yields in various solvents

	Φ_{total}	Φ_M (%)	Φ_R (%)	$\Phi_{T(\pi-\pi^*)}$ (%)	Φ_{O_2}
THF	0.36	0.12 (33)	0.24 (67)	0.06 (17)	2
Methanol	0.128	0.033 (25) (S 0.027, T 0.006)	0.096 (75) (S 0.039, T 0.057)	0	0.096
Ethanol	0.129	0.043 (30) (S only)	0.086 (70) (S 0.067, T 0.019)	0	0.086
n-Propanol	0.088	0.030 (35) (S only)	0.058 (65) (S 0.036, T 0.022)	0	—
Isopropanol	0.089	0.031 (35) (S only)	0.058 (65) (S only)	0	0.16

S: Singlet excited state, T: $T(n\text{-}\pi^*)$ state.

can be made on the reactive states in the present system. Table 3 lists the present result with those obtained by our group in the past. From the results in alcohols, one may say that molecular mechanism occurs mainly at singlet excited state. This may perhaps be true for THF. Then the Φ_R value of 0.24 includes 0.06 of $\Phi_{T(\pi-\pi^*)}$ and the remaining part 0.18 may be due to the reaction at both singlet excited and $T(n-\pi^*)$ states. It is highly unlikely that this is due only to singlet excited state in view of the φ_{ST} values estimated from the previous work. Thus the value of φ_{ST} in benzene and in water was estimated respectively as $\gtrsim 0.25$[7a] and $\gtrsim 0.24$.[16] Furthermore it has been decided recently by Kikuchi that the φ_{ST} value in ethanol is 0.27.[17] This value, however, is concerned with the $T(\pi-\pi^*)$ state which is produced under the condition that the reaction *via* $T(n-\pi^*)$ is occurring as shown in the above table. Thus the true φ_{ST} value in ethanol is $\gtrsim 0.27+0.019=0.29$. At any rate, it seems that the φ_{ST} value does not vary so much according to solvents, and it lies in the range 0.25—0.3. Hence, it is very unlikely that the true φ_{ST} value in THF is so small as $\lesssim 0.1$. It may be concluded that this low value is due to the participation of $T(n-\pi^*)$ in the reaction to some considerable extent. Further decrease in the quantum yield by the addition of anthracene $> 2\times 10^{-5}$ M, is also consistent with this conclusion. Determination of the reliable φ_{ST} values of acridine in various solvents are now in progress.

At the end, some consideration will be added on the quantum yields of the oxygen consumption, Φ_{O_2}. In table 3 are added the Φ_{O_2} values in THF and in alcohols, the values in alcohols being recalculated from the old data.[8] It is remarkable that the values of Φ_{O_2} in methanol and ethanol do agree exactly with the Φ_R values. This is interpreted very satisfactorily as follows. Acridine semiquinone AH and the solvent radical RH produced by radical mechanism in these solvents mainly undergo disproportionation reaction separately, as has been substantiated to some extent in the previous paper.[12] Oxygen when existent, is considered to be consumed mainly by the following processes,

$$AH + (O_2) \longrightarrow A + HO_2,\quad 2HO_2 \longrightarrow H_2O_2 + O_2$$

where (O_2) denotes the oxygen involved in the oxidative species.

Then for each two semiquinone molecules, one acridan molecule is produced in the absence of oxygen while in the presence of oxygen, one oxygen molecule is exhausted. Thus the material balance is in excellent agreement with the above data. On the other hand, for isopropanol and especially for THF, the Φ_{O_2} values are much larger than those of Φ_R. It is suggested that in these solvents, the following reactions may occur as proposed by Stockhausen *et al.*,[18] in the presence of oxygen.

$$RH + O_2 \longrightarrow RHO_2 \quad (1)$$

$$RHO_2 + RH_2 \longrightarrow RHO_2H + RH \quad (2)$$

$$RHO_2 + RHO_2 \longrightarrow \text{Prod} \quad (3)$$

If process (2) predominates over process (3) then the chain type-reaction will become possible. In fact, it really occurs in THF, as has been clearly demonstrated by the Φ_{O_2} value larger than unity.

THF are found in literature, the measurement was made with an apparatus constructed according to the direction recommended by Morrison and Billet,[19] which in principle is based on the saturation method.

Result. The measurement was made at 25°C. The analysis was made by plotting the volume of dissolved gas against that of solvent. Some examples are shown in Fig. 11. From the slope of the plot, the solubility, L was evaluated and Bunsen coefficient was obtained from the following relation.

$$\alpha = L\frac{273}{273+t}$$

As a check Bunsen coefficients of oxygen in methanol and benzene were measured. The results are given in Table 4, together with the data in literature.

Electronic Structures of Aromatic Ketyl Radicals and Related Hydrocarbon Radicals

Nobuaki KANAMARU*1 and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July 7, 1970)

The π-electron structures of neutral aromatic ketyl radicals and their related hydrocarbon radicals were studied theoretically by combining the open-shell SCF MO method with the configuration-interaction calculation. The observed absorption bands of these radicals were well explained by the present theoretical study. From a comparison of the calculated transition energies and intensities with the observed values, it was concluded that the longest and second longest wavelength bands of the benzyl radical and the second longest wavelength band of the diphenylmethyl radical shift to shorter wavelengths upon hydroxy substitution. This may be regarded as characteristic of the substituent effect upon the absorption bands of aromatic radicals. The calculated spin densities were found to be consistent with the reactivity of the ketyl radicals in the formation of pinacols.

Neutral aromatic ketyl radicals and related hydrocarbon radicals are known to be prepared by the photo-reduction of the parent aromatic carbonyl compounds[1-4] and by the photo-decomosition of the parent hydrocarbons,[5,6] respectively. Their electronic spectra have been studied experimentally by several authors and the absorption bands pertinent to each radical have been observed. However, there have been rather few theoretical studies of the electronic structures of the ketyl radicals.

We are interested in the correlation in electronic absorption bands between hydrocarbon radicals and the corresponding ketyl radicals. This is because the latter can be regarded as the hydroxy derivatives of the former and therefore the comparison of their absorption bands may give some information on the substituent effect upon the electronic absorption spectra of radicals. On this line, we have undertaken to study theoretically the electronic absorption spectra of some ketyl radicals and the corresponding hydrocarbon radicals.

Theoretical

The π-electron structures of aromatic ketyl radicals and related hydrocarbon radicals were studied by the method combining the open-shell SCF MO procedure of Longuet-Higgins and

Pople[7] with the configuration-interaction (abbreviated hereafter to CI) calculation. The CI calculation was made by taking at most 50 configurations of lower energies constructed by putting $2m+1$ π electrons into the lower molecular orbitals represented by the linear combination of atomic orbitals. They include the ground configuration and also the singly and doubly-excited configurations.

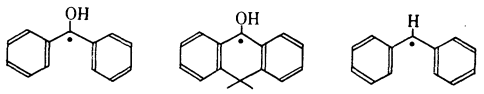
The Coulomb repulsion integrals of the type of (pp|qq) were calculated according to the Pariser-Parr approximation,[8] the radii of the electron clouds being evaluated with the aid of the effective nuclear charge determined by the Slater rule, and the ionization potentials (I) and electron affinities (A) of the appropriate valence states being taken from Pilcher and Skinner's Table.[9] The I_C, A_C, I_{O^+} and A_{O^+} values are 11.22 eV, 0.62 eV, 34.43 eV and 14.97 eV, respectively. The core Coulomb integral, α_p, was evaluated as the sum of the ionization potential of the π electron on the p-th atom and the Coulomb attraction terms due to the other atomic cores. The penetration integrals were disregarded.

A planar structure was assumed for the radicals under consideration, all the C-C bond lengths and all the bond angles being taken to be equal to 1.39 Å and 120°, respectively. The C-O bond length was taken to be equal to that of 1,4-dimethoxybenzene, 1.36 Å.[10] The core resonance integral, β_{CC}, for the neighbouring carbon atoms was taken to be -2.39 eV, the value for benzene. The core resonance integral, β_{CO}, for the neighbouring carbon and oxygen atoms was taken to be -3.42 eV on the basis of its proportionality to the overlap integrals taken from the table of Mulliken *et al.*[11]

The actual calculation was carried out by an electronic computer HITAC 5020E located at the Computer Centre, The University of Tokyo.*2 The energies and wave functions of the ground and excited states, the spin densities in the ground state, and also the transition moments (in Å) were evaluated for the benzyl, diphenylmethyl and ketyl radicals.

Results and Discussion

Concerning the π-electron structures, the benzophenone (a) and anthrone (b) ketyl radicals may be regarded as equal to each other and as the hydroxy derivative of the diphenyl-methyl radical (c). The situation is same for the benzaldehyde and acetophenone ketyl radicals, the hyperconjugation effect of the methyl group being disregarded.



(a) (b) (c)

Hydrocarbon Radicals. The energies of the ground and lower excited states are shown in Table 1. This table also shows the percentages of the configurations mainly contributing to each state. The effect of CI upon the energy levels is shown in Fig. 1. An inspection of Table 1 and Fig. 1 shows that the CI procedure has a great effect upon the energy values and wave functions and is indispensable for this kind of calculation. The excitation energies, the oscillator strengths, and the directions of the transition moments obtained theoretically for the benzyl and diphenylmethyl radicals are shown in Table 2, together with the observed excitation energies and molar extinction coefficients.

From the consideration of the transition energies and oscillator strengths given in Table 2a), the 453 mμ and 318 mμ bands observed for the benzyl radical[5] are assigned to the $E_1{}^B \leftarrow G^B$ and $E_3{}^B \leftarrow G^B$ transitions, respectively. The band corresponding to the $E_2{}^B \leftarrow G^B$ transition may be too weak to be observed and may be covered by the $E_1{}^B \leftarrow G^B$ transition band.

Longuet-Higgins and Pople[7] made a calculation on the benzyl radical, taking only the first-order CI among five configurations. According to their result, the lower excited states corresponding to $E_1{}^B$ and $E_3{}^B$ in our calculation can be represented as follows:

	State function	Excitation energy (eV)
$E_1{}^{B'}$	$\frac{1}{2}(\psi_{3-4}+\psi_{4-5})$	3.46
$E_3{}^{B'}$	$\frac{1}{2}(\psi_{3-4}-\psi_{4-5})$	4.18

The present calculation greatly improves the agreement between the observed and theoretical transition energies compared with the Longuet-Higgins and Pople calculation.

A similar consideration was made of the diphenylmetyl radical, with the results given in Table

* The values in the parentheses are concerned with the benzaldehyde or anthrone ketyl radical.
** X is the symmetry axis of the benzophenone (anthrone) ketyl radical.

2b). A weak band was observed by Shida[12] at 460 mμ in addition to the strong band at 335 mμ. The absorbance ratio of the former to the latter is about 1:150. From the comparison of the calculated transition energies and intensities with those obtained experimentally, the observed bands at 460 mμ and at 335 mμ can be assigned to the $E_1^D \leftarrow G^D$ and $E_7^D \leftarrow G^D$ transitions, respectively. The $E_5^D \leftarrow G^D$ and $E_6^D \leftarrow G^D$ transitions also contribute to the 335 mμ band. The weak bands due to the $E_2^D \leftarrow G^D$, $E_3^D \leftarrow G^D$ and $E_4^D \leftarrow G^D$ transitions may be covered by the two bands.

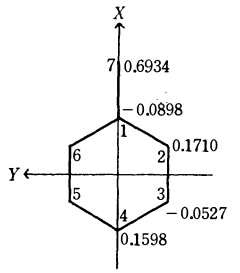
Ketyl Radicals. The energies of the ground and lower excited states calculated for the ketyl radicals are shown in Table 1. This table also gives the percentages of the configurations mainly contributing to each state. The effects of CI upon the energy levels are shown in Fig. 2. The calculated transition energies and oscillator strengths are given in Table 3, together with the observed values.

From the comparison of the observed and calculated transition energies given in Table 3a), the 415 and 277 mμ bands of the acetophenone ketyl radical may be assigned to the $E_2^{Ak} \leftarrow G^{Ak}$ transition overlapped by the weak $E_1^{Ak} \leftarrow G^{Ak}$ transition and to the $E_5^{Ak} \leftarrow G^{Ak}$ transition overlapped by the $E_3^{Ak} \leftarrow G^{Ak}$ and $E_4^{Ak} \leftarrow G^{Ak}$ transitions, respectively.

An inspection of Table 3b) shows that the longer and shorter wavelength bands of the benzophenone ketyl radical can be ascribed to the $E_1^{Bk} \leftarrow G^{Bk}$ and $E_7^{Bk} \leftarrow G^{Bk}$ transitions, respectively. The latter band may be overlapped by the $E_6^{Bk} \leftarrow G^{Bk}$ and $E_5^{Bk} \leftarrow G^{Bk}$ transition bands, and the weak bands corresponding to the $E_2^{Bk} \leftarrow G^{Bk}$, $E_3^{Bk} \leftarrow G^{Bk}$ and $E_4^{Bk} \leftarrow G^{Bk}$ transitions may be covered by the two bands.

Substituent Effects upon the Absorption Bands of Hydrocarbon Radicals. First let us compare the absorption bands of the benzophenone ketyl radical with those of the diphenylmethyl radical. The observed longer wavelength band of the former shifts to longer wavelengths upon hydroxy substitution, as is usually observed with substituted aromatic hydrocarbons. On the other hand, the shorter wavelength band shows the reverse tendency. That is to say, the band corresponding to the 335 mμ band of the diphenylmethyl radical appears at 330 mμ for the benzophenone ketyl radical. The calculated transition energies given in Tables 2b) and 3b) can well explain the above-mentioned substituent effect on the two bands.

Concerning the benzyl and acetophenone radicals, either the longer or the shorter wavelength band was observed to shift to shorter wavelengths upon hydroxy substitution. This tendency is the opposite of the ordinary substituent effect observed for absorption bands of aromatic molecules like benzene and its derivatives; it may be regarded as characteristic of the aromatic radicals. According to the present calculation, the energies for the $E_5^{Ak} \leftarrow G^{Ak}$ and $E_2^{Ak} \leftarrow G^{Ak}$ transitions corresponding to the 277 mμ and 415 mμ bands of the acetophenone ketyl radical are greater than those



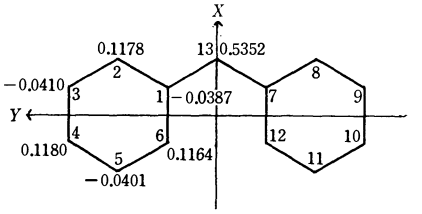


Fig. 3. Spin densities calculated for the benzyl and diphenylmethyl radicals.

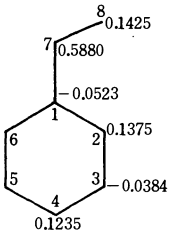

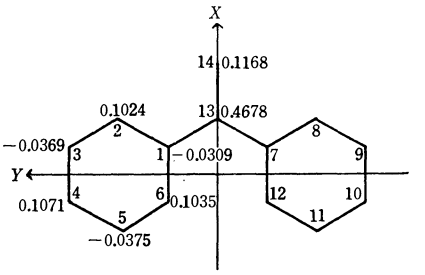

Fig. 4. Spin densities calculated for the acetophenone (benzaldehyde) and benzophenone (anthrone) ketyl radicals.

12) Private communication from Dr. Tadamasa Shida, The Institute of Physical and Chemical Research.

for the $E_3^{B}\leftarrow G^{B}$ and $E_1^{B}\leftarrow G^{B}$ transitions corresponding to the 318 mμ and 453 mμ bands of the benzyl radical, respectively. Therefore, the substituent effect upon the longest and second longest wavelength bands of the benzyl radical can be explained by the present theory.

Since the characters of the wave functions of the E_1^{B} and E_2^{Ak} states are similar to each other, the 415 mμ band of the acetophenone ketyl radical may be regarded as a shifted band of the 453 mμ band of the benzyl radical. This is the real blue shift phenomenon due to the hydroxy substitution. On the other hand, the E_3^{B} state does not correspond to the E_5^{Ak} state, but to the E_3^{Ak} state. Therefore, the 277 mμ band of the acetophenone ketyl radical can not be regarded as a shifted band of the 318 mμ band of the benzyl radical. In this sense, this band may be interpreted as apparently exhibiting the blue shift.*3

Spin Densities. The electron spin densities of the radicals under consideration were calculated with the results shown in Figs. 3 and 4. According to the results, the electron spin densities of the acetophenone and benzophenone ketyl radicals are greatest at the 7 th and 13 th positions, respectively. This is consistent with the fact that the formation of pinacol occurs at the above positions. A similar tendency holds for the hydrocarbon radicals.

The authors are greatly indebted to Dr. Tadamasa Shida, The Institute of Physical and Chemical Research, for his kindness in informing them of his unpublished results on the absorption spectrum of the diphenylmethyl radical.

*3 According to the present calculation, the transition energy for the $E_3^{Ak}\leftarrow G^{Ak}$ is greater than for the $E_3^{B}\leftarrow G^{B}$. This means that the 318 mμ band of the benzyl radical shows the real blue shift upon the substitution of the hydroxy group. In view of this, it may be interesting to carry out detailed experimental studies of the 277 mμ band of the acetophenone ketyl radical, if possible, and to separate it into the three components due to the $E_3^{Ak}\leftarrow G^{Ak}$, $E_4^{Ak}\leftarrow G^{Ak}$ and $E_5^{Ak}\leftarrow G^{Ak}$ transitions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3449—3452 (1970)

The Chemical Behavior of Low Valence Sulfur Compounds. VI. Decomposition of Tetrasulfur Tetranitride in Aqueous Ammonia Solution

Mu-Chang SHIEH, Kenichi KATABE and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

(Received April 10, 1970)

The decomposition of tetrasulfur tetranitride in an aqueous ammonia solution has been investigated. Ammonolysis of tetrasulfur tetranitride gives thiosulfate, sulfite, sulfate and sulfamate through the intermediate compound of trithionate. An increase in the concentration of ammonia raises the yield of sulfamate and lowers that of sulfate, but gives no remarkable change in the yield of thiosulfate. Besides this, in a concentration of ammonia higher than 15 N at 100°C an explosive reaction takes place. Addition of copper ion improves the yield of sulfamate, and the sulfite ion reacts with tetrasulfur tetranitride in an ammonia aqueous solution to form sulfate and sulfamate ion quantitatively.

In a previous paper[1] describing the reaction of low valence sulfur compounds, such as elemental sulfur, thiosulfate, sulfide, tetrathionate and trithionate in aqueous ammonia solution, it was shown that sulfate and sulfamate were finally formed in the oxidation of sulfur under oxygen pressure through polythionates as intermediate compounds, when the concentration of ammonia was restricted to about 16 N. On the other hand, it was reported[2] that the reaction of sulfur in an anhydrous ammonia gives tetrasulfur tetranitride:

$$10S + 4NH_3 = S_4N_4 + 6\,H_2S^{*1} \quad (1)$$

In this reaction, if a highly concentrated solu-

1) M. C. Shieh, H. Otsube and T. Okabe, This Bulletin, **38**, 1596 (1965).

2) F. W. Bergstrom, *J. Amer. Chem. Soc.*, **48**, 2319 (1926).

*1 The reaction is reversible, and the following reaction can take place according to the molar ratio of ammonia to sulfur.

$$H_2S + 2NH_3 = (NH_4)_2S$$
$$S_4N_4 + 2NH_3 = 2\,S(NH)_2 + S_2(NH)_2$$
$$(NH_4)_2S + xS = (NH_4)_2S_{x+1}$$
$$(NH_4)_2S_{x+1} = (NH_4)_2S_x + S$$

tion of ammonia is used for sulfur oxidation, tetrasulfur tetranitride can be regarded as an important intermediate compound. Thus we studied the decomposition of tetrasulfur tetranitride in aqueous ammonia solution in order to clarify the behavior of tetrasulfur tetranitride in the solution.

The decomposition of tetrasulfur tetranitride in aqueous sodium hydroxide solution has been studied by Meuwsen,[3] Goehring,[4] and Nair,[5] and it was revealed that the reactions depend on the alkalinity of solution as follows.

In a weak alkaline solution:

$$2S_4N_4 + 6OH^- + 9H_2O = S_2O_3^{2-} + 8NH_3 + 2S_3O_6^{2-} \quad (2)$$

In a strong alkaline solution:

$$S_4N_4 + 6OH^- + 3H_2O = S_2O_3^{2-} + 4NH_3 + 2SO_3^{2-} \quad (3)$$

Thiosulfate, trithionate and ammonia were formed in the former, and thiosulfate and ammonia in the latter. When the reaction, however, was carried out in aqueous ammonia, sulfite, sulfate, thiosulfate and sulfamate were produced through trithionate.

Experimental

Materials. Tetrasulfur tetranitride was prepared by the reaction of ammonia with sulfur chloride as described by Meuwsen.[3]

$$6S_2Cl_2 + 16NH_3 = S_4N_4 + 8S + 12NH_4Cl \quad (4)$$

The crude product was recrystallized from benzene, washed with carbon disulfide and dried over silica gel. The final product has a 99.5% purity and is free from sulfur.

Procedure. Known weights of finely ground tetrasulfur tetranitride and ammonium hydroxide were put into a 100 m*l* flask at 50°C or in a 30 m*l* pressure glass tube at 100°C. The flask or tube was kept in a heated glycerol bath regulated within ±0.5°C, withdrawn at regular intervals and the contents were analyzed in the same manner as described previously. Since the solubility of tetrasulfur tetranitride in the aqueous ammonia solution is low and the rate of reaction is determined merely by the dissolution of tetrasulfur tetranitride, no kinetic research was undertaken.

Results

When aqueous ammonia is added to finely ground tetrasulfur tetranitride, the solution gradually becomes slightly yellowish brown. Colora-

tion is caused by a slight dissolution of tetrasulfur tetranitride and fades away to a colourless state in less than 10 min, producing a large amount of thiosulfate. The results of the decomposition of tetrasulfur tetranitride at 50°C and 100°C are presented in Tables 1 and 2, respectively. The products of the reaction are thiosulfate, sulfite, sulfate and sulfamate and the conversions of sulfur in tetrasulfur tetranitride are $S_2O_3^{2-}$ 50—80 mol%, $SO_3NH_2^-$ 2—19 mol%, SO_4^{2-} 20—5 mol%, and SO_3^{2-} 1—4%.

Figs. 1 and 2 show the effect of ammonia concentration on the yield. An increase in the concentration of ammonia raises the yield of sulfamate and lowers that of sulfate, but gives no remarkable effect on the yield of thiosulfate.

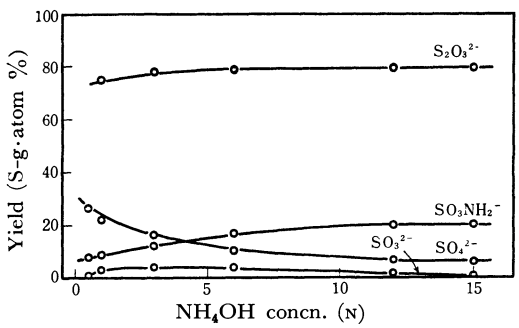

Fig. 1. Effect of ammonia concentration on the yeild of products.
React. temp.: 15°C React. time: 17 hr

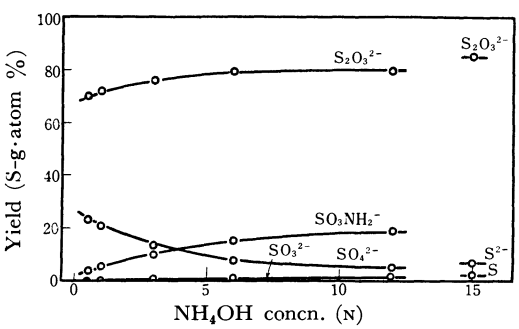

Fig. 2. Effect of ammonia concentration on the yield of products.
React. temp.: 100°C React. time: 3 hr

The effect of reaction temperature on the yield of products is slight as is shown in Fig. 3 and Fig. 4. When the concentration of ammonia is greater than 15 N, an explosive reaction occurs at 100°C with a flash producing a large amount of thiosulfate, a small amount of elemental sulfur and sulfide, and traces of sulfate and sulfamate.

Figs. 5 and 6 give the results of the decomposition of tetrasulfur tetranitride in the presence of sulfite ion and copper ion, respectively. Sulfite reacts with tetrasulfur tetranitride in an aqueous ammonia solution to form sulfate and sulfamate ion, quantitatively.

Addition of copper ion improves the yield of sulfamate but depresses that of thiosulfate. Fig. 7 shows the results of thin layer chromatographic analyses of tetrasulfur tetranitride in aqueous

ammonia solution. Thiosulfate and trithionate were present in the decomposition of tetrasulfur tetranitride, but no higher polythionate was observed.

Discussion

From the reactions

$$S_4N_4 + 20HI = 4H_2S + 4NH_3 + 10I_2 \quad (5)$$

$$S_4N_4 + 6(O) + 10H_2O = 4H_2SO_4 + 4NH_3 \quad (6)$$

we see that the oxidation states of sulfur and nitrogen in tetrasulfur tetranitride are +3 and −3, respectively. The electropositive nature of sulfur in tetrasulfur tetranitride is in agreement with Pauling's electro-negativity scale (N 3.0, S 2.5).

Nair and Murthy[5] assumed the derivative of S^{3+} *viz.* "sulfur trihydroxide" $S(OH)_3$ to be a primary product in the alkaline hydrolysis of tetrasulfur tetranitride. Such a compound will be extremely unstable and will have only a transient existence, being transformed into sulfoxylic acid and sulfurous acid:

$$S_4N_4 + 12H_2O = 4S(OH)_3 + 4NH_3 \quad (7)$$

$$4S(OH)_3 = 2S(OH)_4 + 2S(OH)_2 \quad (8)$$

$$S(OH)_4 = H_2SO_3 + H_2O \quad (9)$$

Sulfoxylic acid which is not isolated in a pure state or in solution, is known to be a highly reactive species as is seen from studies on its derivatives.[7] Formation of various compounds in the hydrolysis of tetrasulfur tetranitride can be easily explained by the secondary reactions as follows:

$$S(OH)_2 + 2H_2SO_3 = H_2S_3O_6 + 2H_2O \quad (10)$$

$$2S(OH)_2 = H_2S_2O_3 + H_2O \quad (11)$$

$$2S(OH)_2 = H_2S + H_2SO_4 \quad (12)$$

$$3S(OH)_2 = H_2S + 2H_2SO_3 \quad (13)$$

$$S_3O_6^{2-} + OH^- = S_2O_3^{2-} + SO_4^{2-} + H^+ \quad (14)$$

$$2S_3O_6^{2-} + 6OH^- = S_2O_3^{2-} + 4SO_3^{2-} + 3H_2O \quad (15)$$

From results obtained so far, it is apparent that the mechanism of the decomposition of tetrasulfur tetranitride in an aqueous ammonia solution is partly in conformity with the above reaction except for the explosive reaction which occurs at high temperature and high ammonia concentration. The result differs in the following aspects as compared with alkaline hydrolysis: no formation of sulfide ion, formation of trace sulfite ion and formation of sulfamate ion in the reaction of tetrasulfur tetranitride ammonolysis. Thus, we might conclude that the reactions (12) and (13) do not occur in tetrasulfur tetranitride ammonolysis.

Formation of sulfamate is caused by the ammonolysis of trithionate:

$$S_3O_6^{2-} + NH_3 + OH^- = S_2O_3^{2-} + SO_3NH_2^- + H_2O \quad (16)$$

Trithionate is known to be hydrolysed in the presence of sodium hydroxide in two ways as shown in Eqs. (14) and (15) depending upon the concentration of hydroxyl ion, but in an aqueous ammonia solution Eq. (16) will take place instead of Eq. (14).

The abundant presence of sulfite increases the yields of thiosulfate, sulfate and sulfamate. This can be explained by the fact that the formation of trithionate is improved by the addition of sulfite as indicated by Eq. (10), and that trithionate decomposes to thiosulfate, sulfate and sulfamate according to Eq. (16).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3453—3456 (1970)

The Effect of Impurities upon the Physical Properties of Silica Gel by the Heat-Treatment

Masaaki MUROYA

Osaka Electro-Communication University, Hatsumachi, Neyagawa, Osaka

and Seiichi KONDO

Osaka University of Education, Tennoji-ku, Osaka

(Received May 18, 1970)

The effects of various kinds of inorganic salts upon the physical properties of silica gel heated in the range up to 1200°C were studied. We measured the polymorphic behavior by means of X-ray diffraction, the simultaneous measurement of the differential thermal analysis, and the thermogravimetric analysis, and the specific surface area by means of the BET N_2 method and by means of studying the water-adsorption capacity. The cationic impurities which were found to have strong effects upon the physical properties mentioned above are Na^+, K^+, Ca^{2+}, Pb^{2+}, Cd^{2+}, Zn^{2+}, and Sb^{3+}. Cations such as Al^{3+}, Cr^{3+}, Mn^{3+}, and Co^{2+} were shown to have weak but positive effects upon the physical properties of silica gel.

The physical properties, such as the specific surface area and the water-adsorption capacity, of silica gel are known to be changed by heating at high temperatures. For instance, the specific surface area of silica gel is decreased by heating, as has been shown by Bastik,[1] and crystal growth was observed by Hirata[2] upon heating the precipitated silica. These changes seem partly due to the presence of impurities in silica gel. Also, Imelik and others[3] have studied the effects of sodium, potassium, calcium, and several other metal hydroxides upon the specific surface area, the pore volume, the mean pore radius, and crystallization by the high-temperature treatment of silica gel. However, the role of impurities was not made clear enough in these experiments. Moreover, quite a number of investigations of silica gel seem to have more or less ignored the effects of impurities when this material was subjected to high temperatures. Therefore, the influence of impurities upon the properties of silica gel heated at elevated temperatures was studied and will be described in this report.

Experimental

The material used in this study was Japan Industrial Standard Type-A and Fuji-Davison Co. Type-RD silica gel; it was purified by repeated washing with dilute hydrochloric acid and distilled water. The physical and chemical properties of the samples before and after purification are shown in Table 1, where the methods of measurements of these values are the same as those previously described.[4]

TABLE 1. SOME OF PHISICAL AND CHEMICAL PROPERTIES OF SILICA GEL USED IN THIS REPORT

Type of silica gel	Surface area (m^2/g)	Water adsorption capacity (wt %)		Na_2O (wt %)
		20% RH	90% RH	
RD as received	720	12.2	38.2	0.03
RD purified	720	12.2	38.2	0.007
A as received	650	11.0	35	0.2
A purified	650	11.0	35	0.01

The experimental procedures of impregnating various impurities and of pH adjustment are as follows; silica gel was suspended in aqueous solutions of various inorganic salts at given pH values at 50°C for 24 hr; then, after the mother liquid had been thoroughly removed from silica gel, it was used for further heat treatment at temperatures ranging from 200°C to 1200°C in air for 24 hr. The degree of the crystallization of amorphous silica as a function of the temperature was estimated from the ratio of the intensities of the X-ray diffraction lines of the (111) plane of β-cristobalite, the (101) and (100) planes of α-quartz, and the (101) planes of β-tridymite relative to that of the (211) plane of the precipitated calcium carbonate used as an inner standard (by mixing the latter material of 10% by weight with the samples). Flame spectroscopy was used for the determination of the Na^+, K^+, and Ca^{2+} ions, while photometric chelate titration was used for the deter-

mination of the other metal cations. All data per unit weight of silica were obtained by heating silica gel at 1100°C.

Results and Discussion

(1) Polymorphism. In order to see the effect of the pH upon the thermal behavior of silica gel, X-ray diffraction patterns were taken on powder samples which had been adjusted to pH values of 3, 6, and 9 with acids and bases, such as hydrochloric, sulfuric, phosphoric, and boric acids and ammonium and sodium hydroxide, and which had then been heated at 1000°C for 24 hr. Marked diffraction lines of β-cristobalite, α-quartz, and β-tridymite were observed on the sample adjusted to pH 9 with sodium hydroxide, the rest of these samples showed very weak diffraction lines, except for the one adjusted to pH 3 with hydrochloric acid, which showed no diffraction lines. Figure 1 shows the X-ray powder diffraction lines of the samples prepared by suspending

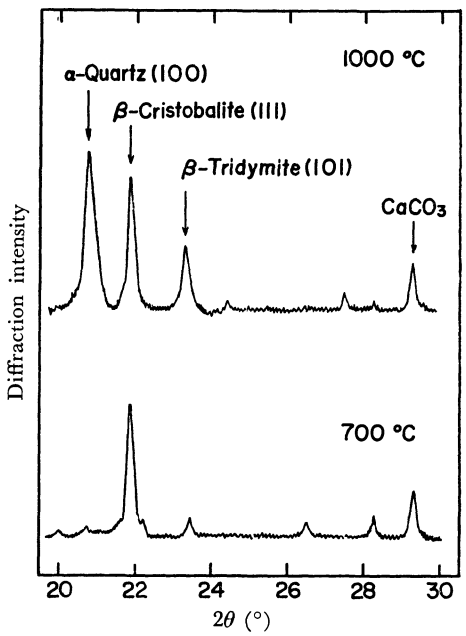

Fig. 1. X-Ray powder diffraction lines of silica gel containing 870 ppm Na^+ cation and heated at 700° and 1000°C for 24 hr.

silica gel in an aquous solution of sodium hydroxide (1% by weight (870 ppm Na^+)) and by then heating it at 700° and 1000°C for 24 hr respectively. At temperatues as low as 700°C, the crystallization from the amorphous state to β-cristobalite was seen very clearly, and α-quartz and β-tridymite seem to have grown at 1000°C. Well-shaped crystals were observed under the electron microscope on these samples. It seems clear from the

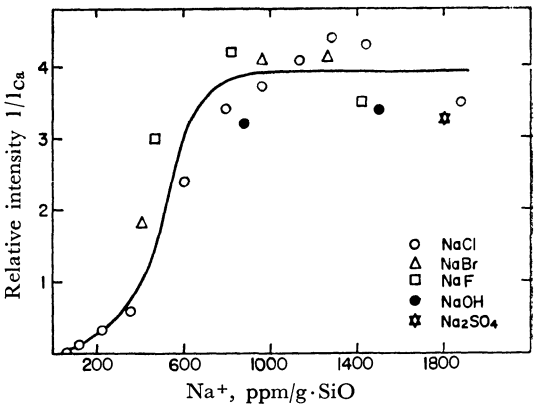

Fig. 2. The curve for plot of the relative intensity of X-ray diffraction lines of (111) planes of β-cristobalite grown by heating silica gel at 1000°C against the concentration of Na^+ cation contained in silica gel.

results mentioned above that only sodium hydroxide had a marked effect on crystallization, but had little effect on the pH adjustment. Since Na^+ and/or OH^- ions seem to play a major role in crystallization, the effects of other sodium salts with various anions, such as F^-, Cl^-, Br^- and SO_4^{2-}, of varied concentrations were examined under the same experimental conditions as above. The relative diffraction intensities of the (111) planes of β-cristobalite which appeared on these samples were dependent upon the concentration of the Na^+ cation, but not on the kind of anion, within the range of experimental error. Figure 2 shows the relation between the relative diffraction intensities of the (111) planes of β-crystobalite and the concentration of the Na^+ cation in the form of various sodium salts. As may be seen in this figure, crystal growth becomes remarkable in the presence of more than about 800 ppm of Na^+ cations, but is almost negligible in the presence of less than 100 ppm of Na^+ cations. The reason for the absence of diffraction lines on the sample adjusted to pH 3, mentioned previously, in that the sample was purified in that preparation.

(2) Differential Thermal Analysis and Thermogravimetric Analysis. The DTA and TGA measurements were carried out on the sample containing 600 ppm of a Na^+ cation in the form of NaCl, as may be seen in Fig. 3, in order to ascertain the thermal behavior of silica gel accompanied by the phase transition from the amorphous to the crystalline phase or from one crystalline phase to another crystalline phase. The experimental conditions for DTA and TGA measurements were the same as have been described before.[5] As may be seen in this figure, four endothermic peaks accompanied by a weight decrease in TGA and two exthothermic peaks with no discontinuous change in TGA were observed. The mechanisms

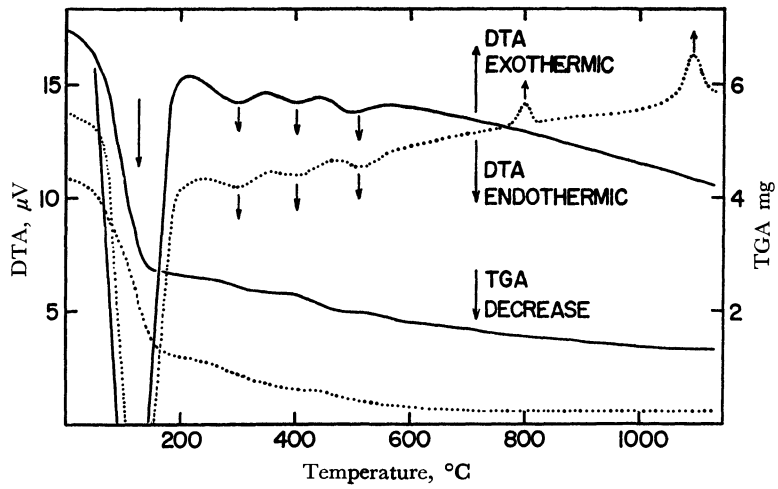

Fig. 3. DTA and TGA curves of silica gel. Full lines and dotted lines show those of silica gel containing 50 and 600 ppm Na^+ cation respectively.

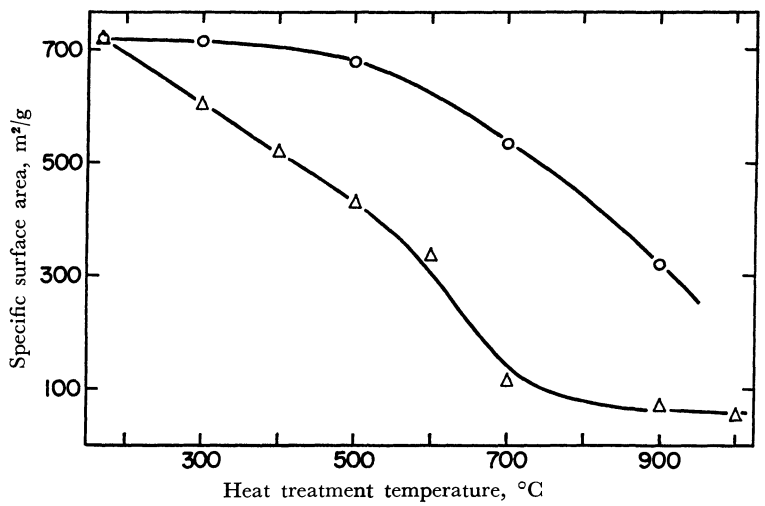

Fig. 4. Curves of the specific surface area *versus* heat-treatment temperature of RD type silica gel. Circles and triangles show results of the sample containing 50 and 600 ppm of Na^+ cation respectively.

of these four endothermic reactions were discussed in a previous paper[5] from the point of view of the dehydration of surface silanol. Since the two exothermic reactions had no discontinuous weight change, the one at 800°C can be attributed to the phase change to β-cristobalite, and the other, at 1100°C, to the phase change to α-quartz and/or β-tridymite; this is supported by the results of the X-ray diffraction experiments described above. On the other hand, no exothermic peak was observed in this temperature range on the sample containing 50 ppm of the Na^+ cation. Since it is now clear that the Na^+ cation has a major effect upon the crystal growth of silica gel, the effects of the salts of other cations, such as chlorides, sulphates, and nitrates of cations such as K^+, Ca^{2+}, Mn^{2+}, Ni^{2+}, Co^{2+}, Cd^{2+}, Zn^{2+}, Pb^{2+}, Fe^{3+}, Al^{3+}, Cr^{3+}, and Sb^{3+}, were tested by the procedures described above. The results of these experiments can be summerized as follows.

1) The influence on the growth of β-cristobalite was marked in the cases of cations such as Na^+, K^+, Pb^{2+}, and Sb^{3+}, and very weak but positive in the cases of cations such as Cr^{3+} and Al^{3+}; 2) the growth of α-quartz was influenced strongly by cations such as Ca^{2+}, Cd^{2+}, and Zn^{2+}, and less strongly by cations such as Mn^{2+}, and Co^{2+}, and 3) the rest of the cations tested had no observable effect upon the growth of either crystal. The combination of group 3) cations with those of group 1) or 2) did not also have an observable

5) S. Kondo and M. Muroya, This Bulletin, **43**, 2657 (1970).

effect on the crystal growth.

(3) Specific Surface Area and Water-adsorption Capacity. In the above section it was shown that many of the cationic impurities had a strong influence on the crystal growth at higher temperatures; this was studied by means of X-ray diffraction. Therefore, it is interesting to see the effect of those ions not only at high temperatures, but also over a wider temperature range, upon other properties of silica gel, such as the specific surface area (SA) and the water-adsorption capacity. The SA values of the RD-type samples containing 50 and 600 ppm of the Na^+ cation as a function of the temperature of heating for 24 hr are shown in Fig. 4. The SA of the sample containing 600 ppm of the Na^+ cation shows a big decrease in the range from 200°C to 700°C, and becomes almost constant at higher temperatures. On the other hand, that of a relatively pure sample remains almost constant up to 500°C and starts to decrease gradually at higher temperatures. Figure 5 shows the influence of the Na^+ cation concentration upon the SA of RD-type samples heated at 700°C for 24 hr. In this figure, the effect of the Na^+ cation becomes bigger at concentrations of approximately more than 100 ppm. These results indicate the remarkable effect of some of the impurity ions on the decrease of SA, even at relatively low temperatures.

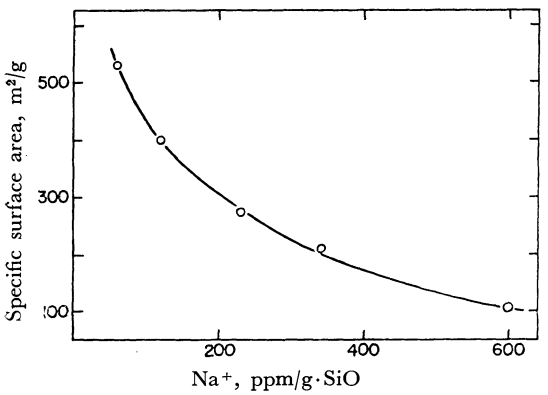

Fig. 5. The relation between the specific surface area and the concentration of Na^+ cation contained in RD type silica gel heated at 700°C for 24 hr.

Figure 6 shows the curves of the plot of the water-adsorption capacities at relative humidities (RH) of 20 and 90% at 23°C against the heat-treatment temperatures on the samples discussed in the above section. In Fig. 6, the values of the purer samples are much higher than those of the less pure samples. The general tendency of the curves of 20% RH is similar to that of the SA-temperature curves. Since the amount of water adsorbed at 20% RH corresponds approximately

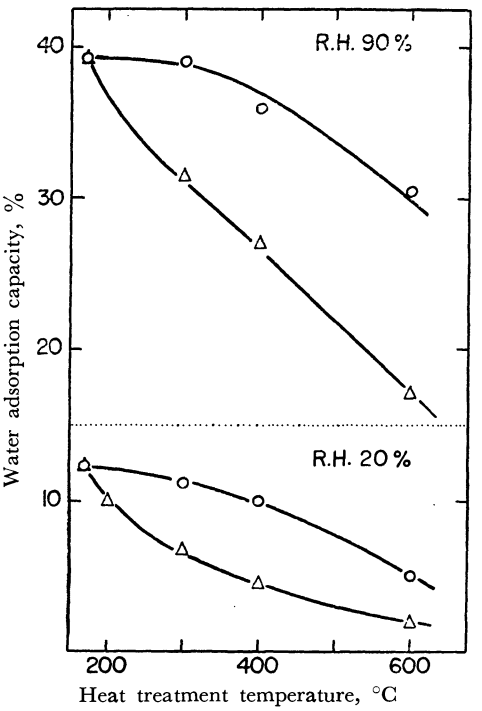

Fig. 6. Curves of the water adsorption capacity *versus* the temperature of heat-treatment. Circles and triangles show those of RD type samples containing 50 and 600 ppm Na^+ cation respectively.

to an amount a little more than a monomolecular layer, it is reasonable to see a close similarity between the curve of 20% RH in Fig. 6 and that in Fig. 4. Because the adsorption capacity at 90% RH is usually compared with the pore volume, the big decrease in the value at 90% RH at higher temperatures of heat-treatment can be interpreted as a decrease in pore volume or as the effect of sintering.

Summary

Such physical properties as the polymorphic behavior, the thermal properties, the specific surface area, and the water-adsorption capacity of silica gel are largely changed when it is heated in the presence of cationic impurities such as Na^+, K^+, Pb^{2+}, Ca^{2+}, Cd^{2+}, Zn^{2+}, and Sb^{3+}. Weak effect upon the physical properties mentioned above were observed in the cases of such cationic impurities as Al^{3+}, Cr^{3+}, Mn^{3+}, and Co^{2+}.

Thanks are due to Miss Fumiko Matsuyama and Messes. Minori Yabuno, Yukio Betsuyaku, and Osamu Tsukide for their experimental help and interest.

The Stability of Fused Rings in Metal Chelates. VII. Copper(II) Complexes of Schiff Bases Derived from 2-Acetylpyridine or Pyridine-2-aldehyde and Dipeptides Containing Glycine, β-Alanine and/or α-Aminoisobutyric Acid

Yasuo NAKAO, Hiroyuki ISHIBASHI and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received May 25, 1970)

Eight new copper(II) complexes of Schiff bases derived from 2-acetylpyridine or pyridine-2-aldehyde and dipeptides containing glycine, β-alanine and/or α-aminoisobutyric acid have been prepared, and their relative stability was discussed on the basis of numerical data obtained by spectrophotometric, polarographic and other measurements. As a result, it was found that the stability of fused-ring systems decreases in the order 5-5-6-≃5-6-5->5-5-5->5-6-6-system (the first number represents the number of ring members containing pyridine derivatives and the second and third numbers represent those of ring members containing dipeptide moieties). The conclusion proposed previously that Schiff base chelates of aldehydes are generally less stable than those of corresponding ketones, has been proved to be valid also for the copper(II) chelates. It was found that transamination reactions take place in the copper(II) chelates of Schiff bases with pyridine-2-aldehyde and glycylglycine or glycyl-β-alanine.

In a previous paper,[1] it was pointed out that a fused-ring system with two six-membered rings is less stable than that with one six- and one five-membered ring or two five-membered rings in the case of copper(II) chelates of dipeptides. We also investigated the relative stability of copper(II) chelates with various multidentate aldehyde- and ketone-Schiff bases.[2,3]

As an extension of the investigations dealing with the relative stability of metal-multidentate-chelates, the isolation of eight copper(II) complexes of Schiff bases derived from 2-acetylpyridine or pyridine-2-aldehyde and dipeptides containing glycine and/or β-alanine have been performed. Structural formulae of these compounds are illustrated in Fig. 1, (I—VIII). This paper describes the preparations and the relative stabilities of the metal chelates. The temperature of decomposition, absorption maxima for the *d-d* transition band in aqueous solution and the half-wave potentials for the reduction of copper(II) at the dropping mercury electrode of the chelate compounds are tabulated in Tables 3 and 4. The relative stability of copper(II) chelates has been determined on the basis of the numerical data.

We have found that there occur transamination reactions in pyridine-2-aldehyde-glycylglycine- and pyridine-2-aldehyde-glycyl-β-alanine-Cu(II) systems. The correlation between the transamination reaction and the structure of fused-ring system is also described.

Copper(II) Complexes of Schiff Bases derived from 2-Acetylpyridine and Glycylglycine, Glycyl-β-alanine, β-Alanylglycine or β-Alanyl-β-alanine(I—IV). The new compounds have been prepared by the ordinary reaction[2-4] between equimolar amounts of each components. They have been concluded to have the structures, I—IV on the basis of analytical data and the quadricoordinating character of copper(II) complexes. As is clear from their structural formulae, the central copper(II) links, in all cases, to the Schiff base ligand through the pyridine-nitrogen, Schiff base-nitrogen, peptide-nitrogen and carboxylate-oxygen, forming copper(II) tetradentate chelates. Thus the four chelates I—IV differ from one another only in the size of ring containing the peptide moieties. The skeletal structure of I consists of 5-5-5-*1 membered fused rings, and in the same way II, III and IV consist of 5-5-6-, 5-6-5- and 5-6-6-membered fused rings, respectively. Table 3 shows that the polaro-

*1 The abbreviation 5-5-5 indicates the fused-chelate-ring structure containing 5,5 and 5-membered rings in a counter-clockwise direction in the expression of structural formula I.

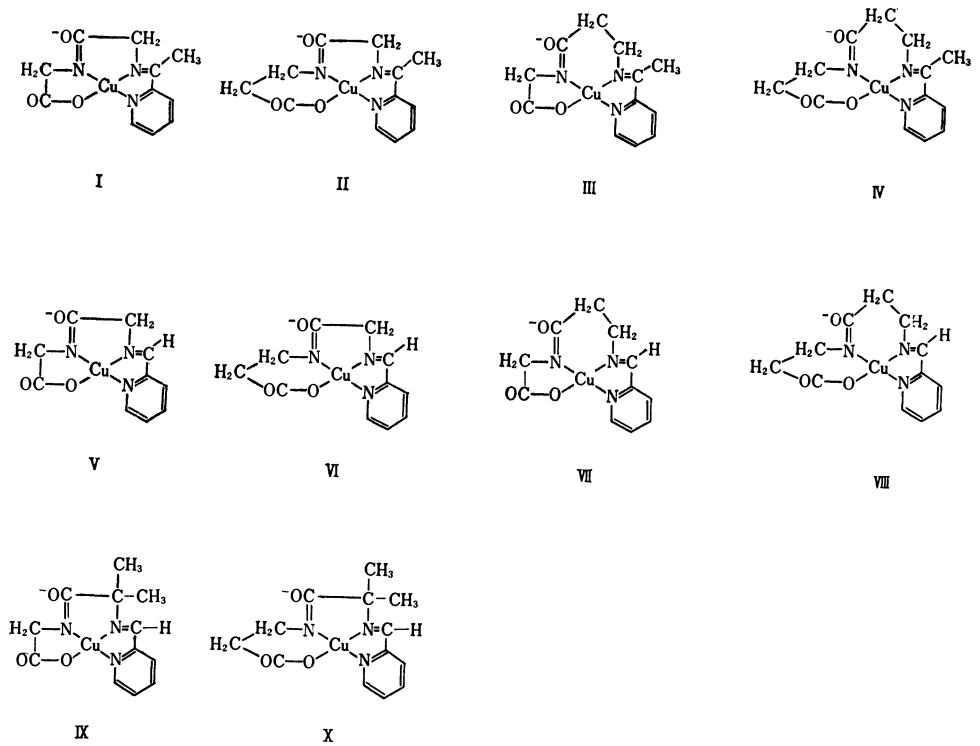

Fig. 1. Structural formulae of copper(II) chelates of aldehyde- and ketone-Schiff bases.

graphic half-wave potentials for the reduction of copper(II) in all the chelates(I—IV) are nearly independent of pH in the region 6–9.5. Only at about pH 11, the half-wave potential becomes slightly more negative. It can also be seen from Table 3 that there is no remarkable difference between the half-wave potential of chelates, II and III. On the other hand, the half-wave potential of I is a little less negative and that of IV is even less negative compared with those of II and III. It may be concluded from the above polarographic data that the stability of chelates I–IV decreases in the order II(5-5-6)$\simeq$III(5-6-5)$>$I(5-5-5)$>$IV(5-6-6). The numerical data for the decomposing temperatures and the maxima of absorption bands due to the ligand field splitting of *d*-orbitals also support the order in the stability of chelates I—IV. In the case of the copper(II) chelates of dipeptides (apart from the Schiff base chelates), copper(II) glycylglycinate is determined to be most stable[1]; but in complexes I—IV, copper(II)-2-acetylpyridine-glycylglycine fused-chelate ring system is less stable than either 2-acetylpyridine-glycyl-*β*-alanine- or -*β*-alanylglycine-Cu(II) systems. This is considered as due to the increasing strain in the 5-5-5-fused ring system.[4] It is of interest that the chelates produced from copper(II), 2-acetylpyridine and *β*-alanyl-*β*-alanine can easily be isolated as stable crystals, whereas the copper(II) *β*-alanyl-*β*-alaninate cannot be isolated.[1]

Copper(II) Complexes of Schiff Bases derived from Pyridine-2-aldehyde and Glycylglycine, Glycyl-*β*-alanine, *β*-Alanylglycine or *β*-Alanyl-*β*-alanine(V—VIII). Preparation of copper(II) complexes of Schiff bases containing pyridine-2-aldehyde instead of 2-acetylpyridine (V—VIII) was carried out. Isolation in the crystalline state was achieved only in cases of chelates with pyridine-2-aldehyde-*β*-alanylglycine(VII) and pyridine-2-aldehyde-*β*-alanyl-*β*-alanine (VIII). The half-wave potentials for the reduction of copper(II), temperatures of decomposition and absorption maxima in the visible region of the chelates VII—VIII are shown in Tables 3 and 4, from which a similar conclusion as in the preceding section is easily obtained: VII(5-6-5)$>$VIII(5-6-6). It can also be concluded from the comparison of III and VII, or IV and VIII, that if the skeletal structure is the same, ketone-Schiff base chelates are more stable than the corresponding aldehyde-Schiff base chelates(III$>$VII; IV$>$VIII). Apart from the relative stability of fused-chelate-rings, it has been found that transamination reactions take place as shown in Fig. 2 in the cases of copper(II) chelates with pyridine-2-aldehyde-glycylglycine- or pyridine-2-aldehyde-glycyl-*β*-alanine. Transamination has been observed by paper chromatographic test of the reaction solutions containing copper(II), pyridine-2-aldehyde, and glycylglycine or glycyl-*β*-alanine. Existence of 2-aminomethylpyridine in the paper chromatogram was distinctly observed

Fig. 2. The transamination reaction of pyridine-2-aldehydeglycine-Cu(II) system.

in the above reaction mixture as is clear from Fig. 2. On the other hand, no transamination was observed in the reaction solution for VII and VIII. Difficulty in isolating complexes V and VI might be elucidated by taking this tendency in transamination reaction into account. Investigation of transamination reactions between oligopeptides and various aldehydes is now under way.

Copper(II) Complexes of Schiff Bases derived from Pyridine-2-aldehyde and α-aminoisobutyrylglycine or α-Aminoisobutyryl-β-alanine(IX—X). In order to isolate copper(II) chelate which consists of 5-5-5- or 5-5-6-fused-ring system and at the same time possesses pyridine-2-aldehyde as carbonyl moiety in Schiff base ligand, the syntheses of pyridine-2-aldehyde-α-aminoisobutyrylglycine- and pyridine-2-aldehyde-α-aminoisobutyryl-β-alanine-copper(II) complexes, IX and X, have been carried out. As is clear from structural formulae IX—X, the transamination reaction cannot be expected in these systems. Thus it was possible to obtain both the chelates in crystalline state. Some properties of the compounds are tabulated in Tables 3 and 4. From the numerical data, it is concluded that X is a little more stable as compared to IX(X(5-5-6)> IX(5-5-5)). The conclusion is consistent with the result obtained through a comparison of I and II.

Experimental*2

Preparation of dipeptides. *Glycylglycine* and *glycyl-β-alanine* were prepared according to the diketopiperazine method[5,6] and chloroacetyl chloride method,[7] respectively.

Carbobenzoxy-β-alanine and -α-Aminoisobutyric Acid. There are several papers on the preparation of these compounds.[8,9] The present procedure is a slightly modified one by Winitz *et al.*[10] One-fifth mole each of β-alanine or α-aminoisobutyric acid were dissolved in 100 m*l* of 2N sodium hydroxide solution. To this was alternately added 52 m*l* of 4N NaOH and 34 m*l* of carbobenzoxy chloride over a period of 30—40 min, under constant stirring and cooling in an ice bath. After completion of the reaction, the reaction mixtures were extracted with ether and the aqueous fraction acidified with 6N HCl to pH 2—3. This was further extracted by ethyl acetate; the ethyl acetate fraction was dried over anhydrous magnesium sulfate. The filtrates were concentrated *in vacuo* to crystalline or oily residues. Recrystallization was carried out by using ethyl acetate and petroleum benzine.

β-Alanine Benzyl Ester p-Toluenesulfonate was prepared from β-alanine, benzyl alcohol and *p*-toluenesulfonic acid monohydrate according to the direction of Izumiya and Makisumi.[11]

Glycine Benzyl Ester p-Toluenesulfonate[12] was prepared by a similar procedure as that for the β-alanine derivative, except that chloroform was used as the solvent. The four materials described above were identified by comparing their melting points with those in literature.

Carbobenzoxy-β-alanylglycine Benzyl Ester. This was prepared in a similar procedure as that reported by Winitz *et al.*[10] To a solution of 15.6 g of carbobenzoxy-β-alanine, 23.6 g of glycine benzyl ester *p*-toluenesulfonate and 9.8 m*l* of triethylamine in 160 m*l* of chloroform was added 14.5 g of dicyclohexylcarbodiimide. The reaction mixture was stirred at 25°C overnight. After removal of white precipitated dicyclohexylurea, the filtrate was washed with water, dilute HCl, saturated $NaHCO_3$ aqueous solution and water. After the chloroform fraction had been dried over anhydrous magnesium sulfate, the filtrate was evaporated to dryness. The crystalline materials obtained were recrystallized from ethyl acetate and petroleum benzine. mp 107—109°C. Found: C, 64.57; H, 5.98; N, 7.97%. Calcd for $C_{20}H_{22}O_5N_2$: C, 64.84; H, 6.00; N, 7.56%.

Carbobenzoxy-β-alanyl-β-alanine Benzyl Ester. This was prepared from carbobenzoxy-β-alanine and β-alanine benzyl ester *p*-toluenesulfonate in the same way as described for carbobenzoxy-β-alanylglycine benzyl ester. mp 99—100°C.

Found: C, 65.96; H, 6.38; N, 7.32%. Calcd for $C_{21}H_{24}O_5N_2$: C, 65.60; H, 6.30; N, 7.29%.

Carbobenzoxy-α-aminoisobutyrylglycine Benzyl Ester and Carbobenzoxy-α-aminoisobutyryl-β-alanine Benzyl Ester were also prepared by the same method as described above. Z-α-NH_2-isoBu-GlyOBz. mp 91—92°C.

Found: C, 65.57; H, 6.45; N, 7.32%. Calcd for $C_{21}H_{24}O_5N_2$: C, 65.60; H, 6.30; N, 7.29%. Z-α-NH_2-isoBu-β-AlaOBz. mp 102—104°C.

Found: C, 66.32; H, 6.70; N, 6.90%. Calcd for $C_{22}H_{26}O_5N_2$: C, 66.30; H, 6.59; N, 7.03%.

β-Alanylglylcine, β-Alanyl-β-alanine, α-Aminoisobutyryl-glycine and α-Aminoisobutyryl-β-alanine were obtained by catalytic reduction of the corresponding carbobenzoxypeptide benzyl ester using palladium black catalyst. In all cases, methanol containing a small volume of glacial acetic acid was used as solvent. The peptides obtained by the procedure described above were re-

*2 Melting points and decomposing temperatures were determined on a micro melting point apparatus and uncorrected.

crystallized from water and ethanol. β-Alanylglycine, β-alanyl-β-alanine and α-aminoisobutyrylglycine were identified by means of elementary analysis and melting points. Melting point and analytical data of α-aminoisobutyryl-β-alanine are as follows: mp 209—212°C. Found: C, 47.75; H, 8.29; N, 15.80%. Calcd for $C_7H_{14}O_3N_2$: C, 48.25; H, 8.12; N, 16.08%.

Preparation of Metal Chelates. *Copper(II) Chelates of Schiff Bases derived from 2-Acetylpyridine and Dipeptides (I—IV).* To a mixture of 0.005 mol each of 2-acetylpyridine and dipeptide in 10 m*l* of aqueous ethanol(one-to-one volume mixture) was added 0.005 mol of copper(II) acetate monohydrate. The pH-values of each reaction solution were adjusted to 9—11 by using concentrated NaOH solution. The reaction mixture was then stirred at room temperature for half an hour. It was allowed to stand for a few hours in a refrigerator; hereupon crystals were deposited. The products were filtered and recrystallized from aqueous ethanol(seven-to-three by volume mixture). The results of elementary analyses are shown in Table 1.

Copper(II) Chelate of Schiff Base derived from Pyridine-2-aldehyde and β-Alanylglycine (VII). Into 10 m*l* of a water : ethanol mixture(one-to-one by volume) were dissolved 0.37 g of β-alanylglycine and 0.27 g of pyridine-2-aldehyde, and then 0.5 g of copper(II) acetate monohydrate. The reaction mixture was adjusted to pH 8—9 by sodium ethoxide, and was then kept at room temperature for an hour under constant stirring. Bluish violet crystals were precipitated from the reaction solution. After it had been filtered, recrystallization from aqueous ethanol(one-to-one by volume) was carried out. Analytical data are given in Table 2.

Copper(II) Chelate of Schiff Base derived from Pyridine-2-aldehyde and β-Alanyl-β-alanine (VIII). A mixture of 0.40 g of β-alanyl-β-alanine and 0.27 g of pyridine-2-aldehyde was dissolved in 8 m*l* of aqueous ethanol (one-to-one by volume). To the solution was added 0.5 g of copper(II) acetate monohydrate, and the pH was adjusted to about 8—9 by powdered sodium carbonate. After it had been stirred at room temperature for one hour, the reaction mixture was allowed to stand overnight in a desiccator equipped with phosphorous pentoxide; thereupon blue crystals were obtained. The precipitates were collected by filtration and washed several times with an ethanol : acetone mixture (four-to-one by volume). Analytical data are given in Table 2.

Copper(II) Chelate of Schiff Base derived from Pyridine-2-aldehyde and α-Aminoisobutyrylglycine(IX). To a solution of 0.64 g of α-aminoisobutyrylglycine in 6 m*l* of a water : ethanol mixture (1 : 1 by volume) were added 0.43 g of pyridine-2-aldehyde and 0.80 g of cupric acetate monohydrate. The resulting mixture was adjusted to pH 7—8 by sodium hydroxide solution and stirred at 25°C for half an hour. After filtration, the filtrate was allowed to stand in a desiccator equipped with silica gel under reduced pressure until syrupy material was obtained. The material was recrystallized from ethanol containing a small amount of water. Analytical data are given in Table 2.

Copper(II) Chelate of Schiff Base derived from Pyridine 2-aldehyde and α-Aminoisobutyryl-β-alanine (X). A similar procedure to that in the preparation of complex IX was adopted. Compound X was isolated in crystalline state over silica gel. The crystal was washed by a water : ethanol mixture (1 : 4 by volume) and then with acetone. The result of elementary analysis is shown in Table 2.

Transamination Study. The following procedure was employed to estimate the transamination reaction in the fused-ring systems of chelates. To a mixture of 0.0025 mol each of pyridine-2-aldehyde and the dipeptide in 10 m*l* of aqueous ethanol (1 : 1 by volume mixture) was added 0.5 g (0.0025 mol) of copper(II) acetate monohydrate. The reaction mixture was adjusted to pH 9—11 by sodium hydroxide solution and was stirred at 25°C for an hour. After it had been filtered, cupric ion was precipitated as sulfide and filtered. The filtrate was used as a sample solution for the paper-chromatographic test for which the solvent system, *n*-butanol : acetic acid : water (4 : 2 : 1) and Toyo filter paper No. 50 were used. Spots of 2-aminomethylpyridine were detected by spraying a ninhydrine

solution.

Spectroscopic Measurements. Visible absorption spectra were obtained with a Shimadzu Spectrophotometer MPS-50L and QR-50 at room temperature. Water was used as a solvent. The concentration of the solutions was 5×10^{-3} M. The numerical data for absorption band are listed in Table 3.

Polarographic Measurements. Measurements were carried out by the same method as described previously.[2] Water was used as a solvent. Concentration of the copper(II) complexes was 5×10^{-4} M. The supporting electrolyte used was 0.1 M potassium nitrate. Triton X-100 (0.002%) was used as a maximum suppressor. The pH-values of each solution were adjusted by potassium hydroxide solution.

The authors express their sincere thanks to Dr. Toshishige Inui for his helpful suggestions in synthesizing peptides.

A part of the expenses for this work was defrayed by a grant from the Ministry of Education.

Spectroscopic Studies of Polynuclear Complexes. II.[1] Preparation and Optical Resolution of μ-Amido-μ-superoxo and μ-Amido-μ-peroxo Tetrakis(α-di-imine)dicobalt(III) Ions

Yoichi Sasaki, Junnosuke Fujita and Kazuo Saito

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received June 15, 1970)

New binuclear cobalt(III) complexes of the type, $[L_2Co(\mu\text{-}NH_2,O_2)CoL_2](ClO_4)_n$, where L is 1,10-phenanthroline or 2,2′-bipyridyl, and $n=3$ and 4, correspond to the so-called μ-peroxo and μ-superoxo form, respectively, were prepared and resolved into their optical isomers. Their absorption spectra have been compared with those of analogous ethylenediamine complexes and the structures have been discussed. The absolute configuration of these complexes has been determined by their circular dichroism spectra. The μ-peroxo complexes seem to be more stable than the corresponding μ-superoxo complexes in aqueous solution.

It is well known that cobalt(II) salts in aqueous ammonia solutions react with molecular oxygen to form diamagnetic brown complex,[2] $[(NH_3)_5Co(\mu\text{-}O_2)Co(NH_3)_5]^{4+}$, which can be oxidized to paramagnetic green complex,[3] $[(NH_3)_5Co(\mu\text{-}O_2)Co(NH_3)_5]^{5+}$. Recently, House *et al.*[4,5] prepared many oxygen-bridged complexes of these types containing polyamines such as ethylenediamine (en) and triethylenetetramine. We have studied those complexes which have μ-amido group as a second bridge, and reported on optically active $[(l\text{-pn})_2Co(\mu\text{-}NH_2,O_2)Co(l\text{-pn})_2]^{4+}$ (*l*-pn=*l*-propylenediamine) and its derivatives.[1]

This paper concerns the preparation and optical resolution of $[(\alpha\text{-di-imine})_2Co(\mu\text{-}NH_2,O_2)Co(\alpha\text{-di-imine})_2](ClO_4)_n$ ($n=3$ and 4, α-di-imine=2,2′-bipyridyl (bip) and 1,10-phenanthroline (phen)), and their geometrical and optical structures were determined by absorption (AB) and circular dichroism (CD) spectroscopy. These are first examples of cobalt(III) binuclear complexes which contain oxygen bridge and aromatic ligands, and their optical spectra will provide useful information in elucidating the electronic state of binuclear complexes.

Experimental

Preparation of the complexes. (1) *μ-Amido-μ-superoxo-octaammine-dicobalt(III) Perchlorate.* $[(NH_3)_4Co(\mu\text{-}NH_2,O_2)Co(NH_3)_4](ClO_4)_4$ (**1**). This complex was prepared from the corresponding sulfate dihydrate.[6] To a suspension containing 10 g of the sulfate dihydrate in 50 m*l* of water was added 50 m*l* of 60% perchloric acid slowly with frequent stirrings. The crude complex was precipitated by cooling in an ice bath, filtered off, washed with methanol-ether (1 : 1) and ether, and dried *in vacuo*. Dark green crystals, recrystallized from warm water acidified with perchloric acid, are soluble in water, methanol, ethanol and acetone, but insoluble in ether.

Nitrogen analysis of this complex gave always 1—2% over than the expected value, probably because of the instability of the complex. The dark green crystals changed into an unknown black product in a week. However, the absorption spectrum of this perchlorate in water was identical with that of the corresponding nitrate.[1]

(2) μ-Amido-μ-peroxo-tetrakis(1,10-phenanthroline)-dicobalt(III) Perchlorate Monohydrate, $[(phen)_2Co(\mu\text{-}NH_2,O_2)Co(phen)_2](ClO_4)_3\cdot H_2O$ (**2**). A mixture of 8 g of freshly prepared **1** and 10 g of 1,10-phenanthroline in 300 m*l* of methanol was warmed at 60°C for 10 hr with stirring and cooled in an ice bath. Brown precipitate obtained by adding 2 g of sodium perchlorate was filtered off, washed with cold methanol and ether, and air dried. The product was recrystallized from warm water (60°C) by adding sodium perchlorate. Yield: about 8 g.

Found: C, 47.75; H, 2.72; N, 10.29%. Calcd for $C_{48}H_{36}N_9O_{15}Co_2Cl_3$: C, 47.76; H, 3.01; N, 10.44%.

(3) μ-Amido-μ-peroxo-tetrakis(2,2′-bipyridyl)dicobalt(III) Perchlorate Dihydrate, $[(bip)_2Co(\mu\text{-}NH_2,O_2)Co(bip)_2](ClO_4)_3\cdot 2H_2O$ (**3**). This complex was prepared by the same method as that for **2** by use of 8 g of 2,2′-bipyridyl instead of 1,10-phenanthroline. Yield: about 8 g.

Found: C, 42.99; H, 3.31; N, 11.45%. Calcd

for $C_{40}H_{38}N_9O_{16}Co_2Cl_3$: C, 42.71; H, 3.41; N, 11.21%.

(4) μ-Amido-μ-superoxo-tetrakis(1,10-phenanthroline)dicobalt(III) Perchlorate Dihydrate, $[(phen)_2Co(\mu\text{-}NH_2,O_2)Co(phen)_2](ClO_4)_4\cdot 2H_2O$ (**4**). To a solution of 2 g of **2** in 50 ml of 7 N nitric acid was added 3 g of solid sodium perchlorate, and the solution was cooled in an ice bath for an hour. Brown fine crystals were filtered off, washed with aqueous sodium perchlorate solution, cold methanol and ether, and dried. Yield: 1—1.5 g.

Found: C, 43.60; H, 2.94; N, 9.34%. Calcd for $C_{48}H_{38}N_9O_{20}Co_2Cl_4$: C, 43.66; H, 2.90; N, 9.55%.

This complex is unstable in water and gives the μ-peroxo complex **2** and other unidentified materials.

(5) μ-Amido-μ-superoxo-tetrakis(2,2′-bipyridyl)dicobalt(III) Perchlorate Monohydrate, $[(bip)_2Co(\mu\text{-}NH_2,O_2)Co(bip)_2](ClO_4)_4\cdot H_2O$ (**5**). This complex was obtained as green crystalline powder from the μ-peroxo complex **3** by a similar method to that for **4**. This complex also unstable in water, as **4**. Yield: 1—1.5 g.

Found: C, 39.69; H, 3.11; N, 10.50%. Calcd for $C_{40}H_{36}N_9O_{19}Co_2Cl_4$: C, 39.82; H, 3.10; N, 10.45%.

(6) $(+)_D$*-μ-Amido-μ-peroxo-tetrakis(1,10-phenanthroline)dicobalt(III) Perchlorate Hexahydrate,* $(+)_D$-$[(phen)_2Co(\mu\text{-}NH_2,O_2)Co(phen)_2](ClO_4)_4\cdot 6H_2O$ (**6**). Ten grams of **2** was converted into chloride with 50 ml of water and Dowex CG 400 ion-exchange resin in the chloride form by a batch method. The resin was filtered off, and washed with a small amount of water. To the filtrate silver antimonyl *d*-tartrate (12 g) was added, stirred for half an hour, and then silver chloride was filtered off. The filtrate was poured into 100 ml of methanol and stored in a refrigerator with occasional stirring. Addition of methanol to the solution gave an oily product which could not be crystallized. After a day, the precipitated crude antimonyl *d*-tartrate of $(+)_D$-isomer was filtered off, washed with a small amount of cold water, methanol and ether, and dried. The filtrate was stored to obtain $(-)_D$-isomer (filtrate *a*).

Pure perchlorate of $(+)_D$-isomer was obtained as follows; the aqueous solution of the antimonyl *d*-tartrate salt was treated with a small amount of solid sodium perchlorate, and stirred for an hour in an ice bath. At this stage, the other enantioisomer was precipitated as less soluble racemate and filtered off. The $(+)_D$-isomer was obtained by adding excessive sodium perchlorate to the filtrate. This procedure was repeated to give a constant rotation.

Found: C, 44.63; H, 3.19; N, 9.49%. Calcd for $C_{48}H_{46}N_9O_{24}Co_2Cl_4$: C, 44.58; H, 3.59; N, 9.74%.

The $(-)_D$-isomer was obtained from the filtrate *a*. The filtrate was evaporated to 50 ml at about 40°C, and then a small amount of sodium perchlorate was added to remove less soluble racemate as stated above. Pure perchlorate of $(-)_D$-isomer was obtained from the filtrate by adding excessive sodium perchlorate.

(7) $(+)_D$*-μ-Amido-μ-peroxo-tetrakis(2,2′-bipyridyl)dicobalt(III) Perchlorate Trihydrate,* $(+)_D$-$[(bip)_2Co(\mu\text{-}NH_2,O_2)Co(bip)_2](ClO_4)_3\cdot 3H_2O$ (**7**). This isomer was prepared from **3** by a similar procedure to that for **6**. The antimonyl *d*-tartrate of $(+)_D$-isomer was precipitated by cooling at 0°C for 5 hr without adding methanol.

Found: C, 42.03; H, 3.53; N, 11.03%. Calcd for $C_{40}H_{40}N_9O_{17}Co_2Cl_3$: C, 41.96; H, 3.49; N, 10.83%.

The $(-)_D$-isomer was obtained also by the procedure as described for the $(-)_D$-isomer of the (phen) complex.

(8) $(+)_D$*-μ-Amido-μ-superoxo-tetrakis(1,10-phenanthroline)dicobalt(III) Perchlorate,* $(+)_D$-$[(phen)_2Co(\mu\text{-}NH_2,O_2)Co(phen)_2](ClO_4)_4$(**8**), *and* $(+)_D$*-μ-Amido-μ-superoxo-terakis(2,2′-bipyridyl)dicobalt(III) Perchlorate Monohydrate,* $(+)_D$-$[(bip)_2Co(\mu\text{-}NH_2,O_2)Co(bip)_2](ClO_4)_4\cdot H_2O$ (**9**). These $(+)_D$-isomers were prepared from **6** and **7**, by the procedures for **4** and **5**, respectively.

Found: C, 45.22; H, 3.05; N, 10.33%. Calcd for $C_{48}H_{34}N_9O_{18}Co_2Cl_4$: C, 44.88; H, 2.67; N, 9.81%. Found: C, 39.88; H, 3.27; N, 10.33%. Calcd for $C_{40}H_{36}N_9O_{19}Co_2Cl_4$: C, 39.82; H, 3.01; N, 10.45%.

Measurements. Visible and ultraviolet absorption spectra were obtained with a Hitachi 124 recording spectrophotometer. The CD curves were recorded with a Model ORD/UV-5 spectrophotometer of Japan Spectroscopic Co. with its CD attachment. The μ-peroxo complexes were measured in water, and the μ-superoxo complexes in 60% perchloric acid to avoid decomposition. Magnetic susceptibilities were measured with a magnetic balance of the Gouy type. The balance was calibrated with $HgCo(NCS)_4$. The effective magnetic moment, μ_{eff}, per one molecule was calculated from the expression $\mu_{eff}=2.83\sqrt{\chi_M\cdot T}$ B.M., where χ_M is the molar susceptibility corrected using Pascal's constant[7] and T absolute temperature.

All the measurements were made at room temperature.

Results and Discussion

Synthetic Method and the Structure of the Complexes. As stated in the experimental section, the complexes **2** and **3** of the type, $[(\alpha\text{-diimine})_2Co(\mu\text{-}NH_2,O_2)Co(\alpha\text{-diimine})_2]^{3+}$, can be prepared easily from $[(NH_3)_4Co(\mu\text{-}NH_2,O_2)Co(NH_3)_4](ClO_4)_4$ (**1**) and 1,10-phenanthroline and 2,2′-bipyridyl, respectively, by substitution reactions in methanol. The complex **1** is useful for a reaction in a non-aqueous solution, since it is soluble in organic solvents such as methanol or ethanol. The reaction in water always produced a large amount of tris-(phen) or -(bip) complex. It will be interesting to note, however, that the reaction between phenanthroline and nitrate of the complex **1** in water gives an insoluble dark green crystalline product with the formula $[Co_2(phen)_2(NH_3)_4(\mu\text{-}NH_2,O_2)](NO_3)_4$ in a few minutes. Detailed studies of this product will be published later.

As Table 1 shows, the μ-superoxo complexes have a magnetic moment corresponding to one unpaired electron, while the μ-peroxo complexes are diamagnetic. The elementary analyses and the fact that the formers derived from the latters by oxidation with nitric acid are paramagnetic indicate that all the complexes contain bridging μ-dioxygen group.[8,9]

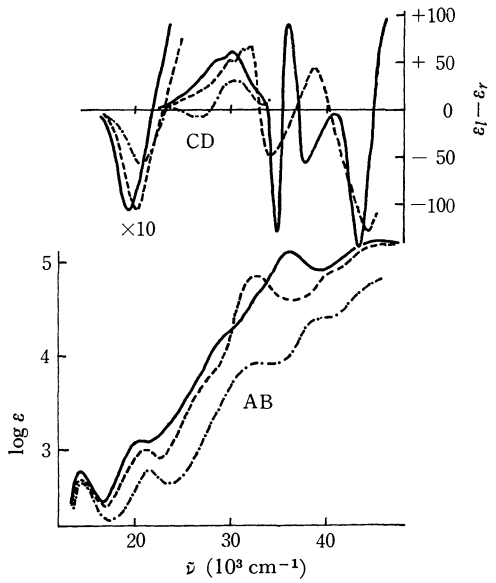

Fig. 1. The AB and CD spectra of $(+)_D$-$[(phen)_2Co(\mu\text{-}NH_2, O_2)Co(phen)_2](ClO_4)_4$ (——), $(+)_D$-$[(bip)_2Co(\mu\text{-}NH_2, O_2)Co(bip)_2](ClO_4)_4 \cdot H_2O$ (----) in 60% perchloric acid and $\Delta\Delta$-$[(en)_2Co(\mu\text{-}NH_2, O_2)Co(en)_2](NO_3)_4$ (—·—·) in water.

Figure 1 shows that the AB spectra of the μ-superoxo complexes (**4**, **5**) in the visible region are very similar to that of the ethylenediamine analog reported previously.[1] This result suggests that these complexes have a similar structure to one another. On the other hand, such a similarity in spectral pattern is not seen among the μ-peroxo complexes (**2**, **3**) and ethylenediamine analog, as shown in Fig. 2. The present μ-peroxo complexes exhibit a distinct absorption maximum at about 15500 cm^{-1}, whereas the ethylenediamine analog does not. Further consideration with

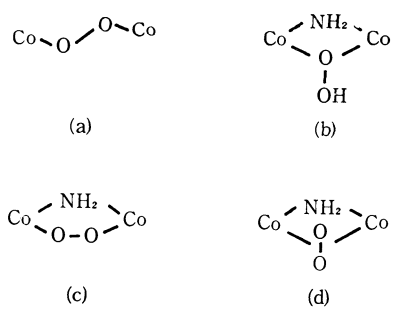

Fig. 3. Possible structures of μ-peroxo bridges.

reference to the structure of the bridge part would be needed.

Although no X-ray analysis has been made on a double bridged complex containing μ-peroxo group, the result for $[(NH_3)_5Co(\mu\text{-}O_2)Co(NH_3)_5](SO_4)_2\cdot 4H_2O$[10] revealed that each oxygen atom of the μ-peroxo group coordinates to each cobalt ion forming the σ-type bonding as shown in Fig. 3(a).

Mori and Weil,[9] on the basis of kinetic and spectroscopic measurements, inferred the isomerization scheme as shown in Fig. 4 for the $[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{3+}$ ion. In this figure, [B] corresponds to the ordinarily prepared brown μ-amido-μ-peroxo-tetrakis-ethylenediamine complex. The [AH] was isolated as red nitrate[9,11] and its structure was determined by X-ray analysis.[12] This complex involves three bonded oxygen atom, as shown in Fig. 3(b). For the brown [B] form, Mori and Weil suggested the σ-type structure which is similar to that in $[(NH_3)_5Co(\mu\text{-}O_2)Co(NH_3)_5]^{4+}$ (Fig. 3(c)), They further considered that the [BH] and the [A] were intermediate species, and that their bridging structures would be similar to those of the [B] and [AH], respectively. In these arguments, however, there remain some ambiguities about the bridging structure of [A], for which a possibility of the π-type bonding structure (Fig. 3(d)) can not be excluded, since the interconversion between the Fig. 3(c) type and the π-type (Fig. 3(d)) seems to be easy.

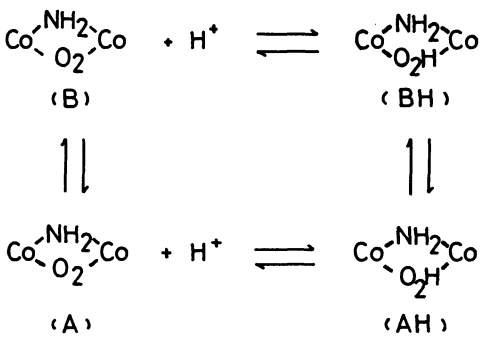

Fig. 4. Reaction scheme of μ-peroxo dicobalt ions. (From Ref. 9).

From the analysis of kinetic data, Mori and Weil[9] obtained absorption spectra of the three species, [B], [BH] and [AH]. The spectra of the present μ-peroxo complexes (**2**, **3**) in water do not seem to correspond to any of these species.

In order to make clear the structure of the present μ-peroxo complexes, we have measured the spectra in the solid state and in various solvents at different pH's. As Fig. 5 shows, the solid spectra of the μ-peroxo complexes (**2**, **3**) show a peak at about 15400 cm^{-1} which seems to correspond to the band at about 15500 cm^{-1} in aqueous solution. No significant difference was either observed between the spectra in water and in a basic solution. These results may indicate that each complex ion exists as a single chemical species under the given conditions, in solid state and in neutral and basic solutions. In acid solutions, on the other hand, the spectra vary remarkably according to the acid concentration, and have no isosbestic point. (Fig. 6). At acid concentrations

12) U. Thewalt and R. Marsh, *J. Amer. Chem. Soc.*, **89**, 6364 (1967).

over 12 N, a constant curve is observed with an absorption maximum at 20400 cm^{-1}, and is similar to that of the μ-hydroperoxo ethylenediamine complex, [AH] (Fig. 1 in Ref. 9). Therefore, we can conclude that the complexes exist as μ-hydroperoxo form corresponding to the [AH] in strong acid solutions.

If the complexes had a structure corresponding to the [A] form in the solid state and in basic solutions, the predominant species in acid solutions should be two, [A] and [AH], and the spectra at various acid concentrations should have isosbestic points. Thus, the most probable bridging structure in the present μ-peroxo complexes (**2**, **3**) will be the σ-type as shown in Fig. 3(c), although their spectra in the visible region are different from that of ethylenediamine analog. More detailed studies, however, would be necessary to elucidate the structure of such μ-dioxygen complexes.

Chemical Behavior of the Complexes. The present μ-superoxo complexes, (**4**, **5**) decompose gradually in water and in basic solutions, giving the μ-peroxo complexes in 60—70% yield. The other 30—40% products were not characterized. The yield of the μ-peroxo ions was determined by their absorption intensities at 15500 cm^{-1}. The reduction with iodide ions in water produced the μ-peroxo complexes almost quantitatively. Thompson and Wilmarth[8] considered that $[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{4+}$ in a basic solution is reduced to the μ-peroxo complex by hydroxide ion. Garbett and Gillard[13] examined the yield of this reduction and gave about 60%. However, the fact that the present μ-superoxo complexes are reduced in a neutral aqueous solution, in which the concentration of hydroxide ions is only 10^{-7} mol/*l*, suggests that in our case, the hydroxide ion would not be a main reducing agent. This suggestion will be supported further by the results that the yields of the μ-peroxo complex reduced in a neutral and in a basic solution are almost equal, 60—70%, but the reduction with another reducing agent such as the iodide ion proceeds almost quantitatively. However, we could not give a definite conclusion about such reductions at present.

It should be noted that when the reduction of racemic μ-superoxo complexes (**4**, **5**) is caused to proceed in water containing a large excess of potassium antimonyl *d*-tartrate, the resulting solution shows similar CD spectra to those of the $(-)_D$-μ-peroxo complexes. From their CD intensites, the optical purity of the products is known to be about 10%. The aqueous solutions of racemic μ-peroxo complexes containing potassium antimonyl *d*-tartrate exhibit very weak CD which originates probably from the second sphere coordination.[14,15] Therefore, such a phenomenon may suggest that the antimonyl *d*-tartrate ion interacts with reaction species stereoselectively in the reduction process.

d-Tartaric acid and *d*-bromocamphorsulfonate ions have no such effect.

Spectra and Absolute Configurations of the Complexes. The AB spectra of the μ-superoxo complexes (**4**, **5**) in the visible region are similar to that of ethylenediamine analog, as stated previously. The band at about 14000 cm^{-1} which is characteristic of μ-superoxo complexes might owe to the charge transfer transitions between the μ-superoxo group and the cobalt(III) ions.[1] The band at about 21000 cm^{-1} may correspond to the first band of a uninuclear cobalt(III) complex.[1] These bands, however, are located from the longer to shorter wavelength in the order of phenanthroline, bipyridyl and ethylenediamine complex (Fig. 1). This order is the reverse order of the spectrochemical series.[16] On the other hand, the location of the bands in the ammine and ethylenediamine analogs is in accord with this series.

As Fig. 1 shows, the $(+)_D$-μ-superoxo complexes show a fairly strong negative CD band in the first band region, which can be compared well with that of the $\Delta\Delta$*1 isomer of ethylenediamine analog. This result indicates that these isomers have $\Delta\Delta$ configuration. Both $(+)_D$-isomers of the μ-peroxo complexes, from which the $\Delta\Delta$-μ-superoxo complexes were prepared, therefore, should have also $\Delta\Delta$ configuration, since it is very unlikely that inversion would take place during the oxidation. The CD spectra of these μ-peroxo complexes in the *d-d* transition region are very similar to each other, but are entirely different from that of the $\Delta\Delta$ isomer of ethylenediamine analog.[1]

All the complexes prepared here show strong absorption bands in the region 30000 to 40000 cm^{-1}, which can be assigned to the long-axis π–π^* transitions of the coordinated aromatic ligands.[17,18] It is known that these transitions are not largely modified from those of the free ligands.[18] According to the theory,[19–22] when two or three such

conjugated ligands are present in an octahedral complex, the CD spectrum corresponding to their transitions consists of two strong components with different signs. For a Δ configuration, their signs are minus and plus from longer to shorter wavelength. As Fig. 1 shows, the $(+)_D$-μ-superoxo-(phen) complex exhibits two strong, sharp CD peaks with minus and plus sign from longer to shorter wavelength in the π–π^* transition region, indicating that the absolute configuration around each cobalt(III) ion is Δ. This result agrees with the previous assignment obtained from the sign of CD band in the *d-d* transition region. The $(+)_D$-μ-peroxo-(phen) complex shows also such a CD pattern in this region, although the bands are somewhat broader than those of the μ-superoxo complex.

Neither $(+)_D$-isomer of the bipyridyl complexes, on the other hand, gives such a CD for the bands corresponding to the π–π^* transitions. In the bipyridyl complexes, the bands due to these transitions are at a longer wavelength region as compared with those of the phenanthroline complexes, and overlap with the so-called polynuclear bands.[1] Accordingly, it is supposed that the CD bands due to the π–π^* transitions of coordinated bipyridyl might be cancelled by overlapping or interacting with the other CD bands due to such polynuclear bands.

All the $(+)_D$-(bip) and -(phen) complexes exhibit strong negative CD bands at about 45000 cm^{-1}. In particular, those of (phen) complexes are strong and sharp. Mason and Norman[23] measured the CD spectrum of $(+)_D$-$[Co(phen)_3]^{3+}$ and claimed to have only a weak CD in this region. As Fig. 7 shows, however, this tris complex shows a strong negative CD band at 44600 cm^{-1}. Although the origin of such a discrepancy is not clear at present, there seems to be an optically active transition in this region for a cobalt(III) complex containing two or three phenanthroline molecules.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3468—3471 (1970)

The Thermal Decomposition of $CuBr_2 \cdot 2NH_3$ and $CuBr_2$

Nobuyuki TANAKA and Masahiro KAGAWA*

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received July 8, 1970)

The thermal decomposition of $CuBr_2 \cdot 2NH_3$ has been examined at the constant temperature, about 220°C. Copper(II) was reduced to copper(I), when bromine gas was found as one of the decomposition products, indicating that bromide anion may be the reducing agent for copper(II). The decomposition reaction of $CuBr_2$ has been investigated by measuring the weight loss under the condition of the constant temperature. In a closed system, the reaction,

$$CuBr_2(s) \leftrightarrows \gamma\text{-}CuBr(s) + \frac{1}{2}Br_2(g)$$

attained to equilibrium, and ΔG° for this reaction was determined in the range from 160°C to 220°C to be given by the equation,

$$\Delta G^\circ(\text{cal.}) = 1.10 \times 10^4 - 19.3\ T\ (160°C—220°C).$$

While the pressure of bromine gas was kept zero, $CuBr_2$ decomposed following a first-order rate law in the beginning of the decomposition, and the activation energy was found to be 25.4 kcal/mol.

When hexammine-[1-3] or aquopentammine-copper(II)[4] halides are heated, they lose ammonia or ammonia and water to form diammine complexes, $CuX_2 \cdot 2NH_3$ (X=Cl, Br and I). At higher temperatures, diammine complexes decompose with an electron transfer reaction and produce copper(I) halides, ammonia and other decomposition products. Smith and Wendlandt[3] showed that the primary reducing agent for copper(II) was ammonia in the case of the bromide and the chloride. There is, however, still left the possibility that halide anion may take part in reducing copper(II). In this investigation, therefore, the electron transfer reaction of $CuBr_2 \cdot 2NH_3$ was reexamined carefully. In addition, the thermal decomposition of $CuBr_2$ was studied as a simpler case of the electron transfer reaction of copper(II) complexes.

Experimental

The Thermal Decomposition of $CuBr_2 \cdot 2NH_3$. Figure 1 shows the apparatus used in this experiment. $CuBr_2$ was put into a crucible, and ammonia gas (about 1 atm.) was introduced into the reaction tube with checking a manometer. $[Cu(NH_3)_6]Br_2$ was formed one or two days later. The reaction tube was heated at about 220°C by an electric furnace. In heating, the pressure of ammonia was kept 1 atm., because ammonia was evolved from $[Cu(NH_3)_6]Br_2$. Then, $CuBr_2 \cdot 2NH_3$ was formed. A trap was cooled with the freezing mixture, alcohol-dry ice. Ammonia gas was rapidly removed from the reaction tube by operating a vacuum pump and opening the cock A. The pyrolysis products were condensed in a cooled trap.

The Thermal Decomposition of $CuBr_2$. The same apparatus as shown in Fig. 1 was used. The manometer was detached when $CuBr_2$ was treated, because mercury reacts with bromine gas evolved from $CuBr_2$. $CuBr_2$ was put into a quartz crucible (121 mg), which was hung on a quartz spring balance (4.10 mg/mm in sensitivity). The contraction due to the weight loss of the sample was measured with a cathetometer (0.05 mm in accuracy). The reaction tube of Pyrex glass was kept at a constant temperature in the range of ± 1°C with the electric furnace. As bromine gas reacts with mercury even at room temperature, the pressure of bromine gas cannot be directly measured with a mercury manometer. It, however, could be calculated from the equation, $PV=nRT$, P being the pressure of bromine gas, V, the volume of the reaction tube (0.162 l), n, moles of bromine gas calculated from the observed weight loss, T, absolute temperature, and R, gas constant. As the upper part of the reaction tube, however, was left at room temperature, the correction due to this difference in temperature must be considered in calculating the pressure. The values for this correction were obtained experimentally as follows. The trap was removed and the manometer was directly connected to the reaction tube so that the volume between the reaction tube and the manometer could be made as small as possible. From the weight loss at t°C, the pressure of bromine gas, P_{25} was calculated when the whole part of the reaction tube was supposed to be at room temperature, 25°C. Nitrogen gas, the pressure of which was P_{25} was introduced at the room temperature into the reaction tube with checking the manometer. When the reaction tube was heated under the same experimental condition as in the treatment of $CuBr_2$, the pressure of nitrogen gas increased to P_t. From P_t and P_{25}, the correction coefficient, γ_t, characteristic to only this apparatus was obtained as,

$$\gamma_t = P_t/P_{25} \text{ (1.12 at 160°C, 1.14 at 215°C).}$$

Assuming that γ_t was applicable to the case of bromine gas, P_{Br_2} which means the pressure of bromine gas at t°C is given by

$$P_{Br_2} = \gamma_t \times P_{25}$$

In this correction, the volume change of the reaction tube due to heating and the quantity of adsorbed bromine on the wall of the reaction tube were neglected.

After the reaction,

$$CuBr_2(s) \rightleftharpoons CuBr(s) + \frac{1}{2}Br_2(g),$$

had reached to the equilibrium completely, a vacuum pump was operated and the cock A was opened. The reaction proceeded to the right side. The time when the cock A was opened was defined as time zero, and the weight loss was followed. The weight loss was converted to the degree of decomposition, α (α equals 0 when the sample was $CuBr_2$, and 1 when the reaction finished and $CuBr_2$ was changed completely to CuBr), and, then, α *vs.* t(time) curves were obtained. Though α at time zero was different according to the temperature, the largest value of α in this experiment was 0.05, which was found in the measurement at 134°C. The sample taken for the measurement ranged from 15 to 25 mg. $CuBr_2$ used in the kinetic investigation had been pulverized as small as possible using an agate mortar in the room where relative humidity was kept under 40%, because $CuBr_2$ was very deliquescent.

Results and Discussion

The Thermal Decomposition of $CuBr_2 \cdot 2NH_3$. $CuBr_2 \cdot 2NH_3$ did not decompose in a closed system as long as ammonia coexisted. It, however, decomposed when the pressure of ammonia was suddenly reduced, and bromine was found to condense on the wall of the cooled trap. These results indicate that the equilibrium has established between ammonia gas and solid $CuBr_2 \cdot 2NH_3$ before the electron transfer reaction occurs, and that bromide anion takes part in reducing copper(II). The latter result is inconsistent with that of Smith and Wendlandt.[3] They reported that, as the temperature was raised, higher ammine complexes such as $[Cu(NH_3)_6]Cl_2$, $[Cu(NH_3)_6]Br_2$ and $[Cu(NH_3)_4]I_2$ reversibly dissociated ammonia, and diammine complexes, $CuX_2 \cdot 2NH_3$ (X=Cl, Br and I) were formed. Upon further heating, the irreversible reduction of copper(II) to copper(I) took place, of which stoichiometries were

$$6CuX_2 \cdot 2NH_3 \rightarrow 6CuX + 6NH_4X + N_2 + 4NH_3 \quad (X=Cl, Br)$$

$$2CuI_2 \cdot 2NH_3 \rightarrow 2CuI + I_2 + 4NH_3$$

These equations indicate that iodide anion reduces copper(II) in the case of the iodide whereas ammonia does in the case of the chloride and the bromide.

Some questions, however, arose about their discussion on the electron transfer reactions, and a new explanation will be given to their results.

(1) The above stoichiometries may be explained from the standpoint that halide anions reduce copper(II). After the halide anion donates an electron to copper(II), it reaches to the active state of atom or forms halogen gas, which in turn reacts with ammonia. Consequently, nitrogen and ammonium halide are formed by the following reaction.

$$8NH_3 + 3X_2 \text{ (or X*)} \rightarrow 6NH_4X + N_2$$

X=Cl, Br; X*=active atom

Really this reaction proceeds very fast at room temperature.

(2) The temperature at which the reduction of copper(II) took place was found to increase in the following order:

the iodide < the bromide < the chloride

As this order is consistent with that of the depolarizability, halide anions are suggested to be the reducing agent for copper(II).

(3) If ammonia reduces copper(II), the electron transfer reaction is expected to take place easily at the state of hexammine complexes where copper(II) is coordinated with six ammonia molecules. It, however, took place after $CuX_2 \cdot 2NH_3$

was formed in which halide anions were coordinated with copper(II).

(4) Gažo[5] has already discussed the effect of coordinated ammonia on the reduction of copper (II). CuI_2 does not exist at room temperature whereas $CuI_2 \cdot 2NH_3$ is stable even when it is heated at 100°C in ammonia atmosphere. Usually the reduction temperature of $CuX_2 \cdot 2NH_3$ (X=Cl, Br) is higher than that of CuX_2. These facts suggest that coordinated ammonia can not promote the reduction of copper(II), but can hinder the electron transfer from halide anion to copper(II).

These explanations suggest that the coordinated halide anion can have more chance to reduce copper(II) than the coordinated ammonia. Although the results obtained in this investigation cannot completely deny that ammonia is reducing agent, its possibility might be considered less. Therefore, the following reactions may be the main paths of the decomposition.

$$CuBr_2 \cdot 2NH_3 \rightleftharpoons CuBr_2 \cdot NH_3 + NH_3 \quad (1)$$

$$CuBr_2 \cdot NH_3 \rightleftharpoons CuBr_2 + NH_3 \quad (2)$$

$$CuBr_2 \rightarrow CuBr + \frac{1}{2}Br_2 \quad (3)$$

$$CuBr_2 \cdot NH_3 \rightarrow CuBr \cdot NH_3 + \frac{1}{2}Br_2 \quad (4)$$

$$CuBr \cdot NH_3 \rightarrow CuBr + NH_3 \quad (5)$$

$$8NH_3 + 3Br_2 \rightarrow 6NH_4Br + N_2 \quad (6)$$

The equilibrium reactions (1) and (2) well explain the fact shown by Smith and Wendlandt[3] that the reduction temperatures observed with mass spectrometry were lower than those obtained by thermomagnetic analysis; the former was carried out in vacuum while the latter was in ammonia atmosphere.

The Thermal Decomposition of $CuBr_2$. When $CuBr_2$ was heated in vacuum after the cock A was closed, bromine gas was evolved and the weight loss was observed. The weight loss reached to a constant value within one or two hours, which did not change even after twenty four hours. When the evolved bromine was evacuated from the system, the weight loss began again and arrived at a new constant value. When $CuBr_2$ was heated in vacuum, the weight loss reached to a value which would be obtained when all of $CuBr_2$ was assumed to change completely to CuBr. This suggests that there must be the equilibrium reaction

$$CuBr_2(s) \rightleftharpoons CuBr(s) + \frac{1}{2}Br_2(g)$$

The weight loss in equilibrium was measured under the following conditions: (1) The quantity and the grain size of $CuBr_2$ were changed, (2) inert gas, N_2, was introduced into the system, (3) the equilibrium was made to establish from the side of $CuBr_2$ or from that of $CuBr + 1/2\ Br_2$. As the result, the weight loss was found to be independent of these conditions, but dependent only on temperature. This means that the pressure of bromine gas is constant provided that the temperature is given, *i.e.*, the equilibrium of the electron transfer of $CuBr_2$ is dependent on the pressure of bromine gas or temperature.

The weight loss was measured at various temperatures and it was converted to the pressure by following the procedure described in the experimental section. The linearity was obtained between $\log P_{Br_2}$ and $1/T$ as shown in Fig. 2, which is represented by

$$\log P_{Br_2} = 8.43 - \frac{4.79 \times 10^3}{T}$$

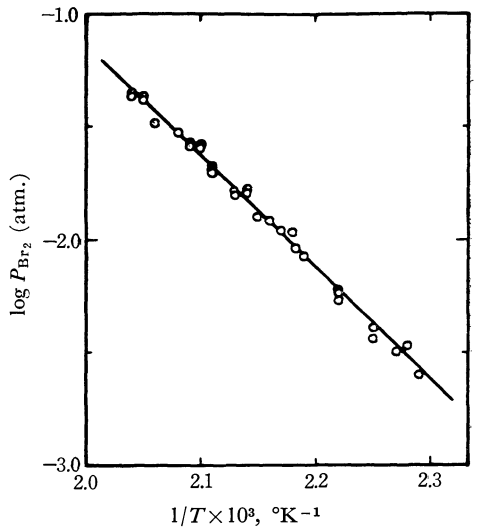

Fig. 2. Temperature dependence of the equilibrium pressure of bromine gas.

As the standard free energy change, $\Delta G°$, is expressed by

$$\Delta G° = -RT \ln K_p = -RT \ln P_{Br_2}^{1/2}$$

where K_p is the equilibrium constant, $\Delta G°$ for the reaction is given by

$$\Delta G° \text{ (cal.)} = 1.10 \times 10^4 - 19.3\ T$$

in the range from 160°C to 220°C.

The structural investigations of $CuBr_2$[6] and CuBr[7] have been reported. $CuBr_2$ has the polymeric chain structure in which a bromine atom bridges two copper(II) atoms and a copper(II) atom is coordinated with four bromine atoms. The bond Cu–Br largely bears covalency. CuBr has three modifications of α-, β- and γ-forms, and transition temperatures are 385°C for γ to

6) L. Helmholz, *J. Amer. Chem. Soc.*, **69**, 886 (1947).

7) S. Hoshino, *J. Phys. Soc. Jap.*, **7**, 560 (1952).

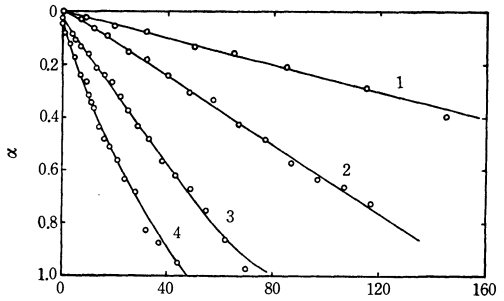

Fig. 3. Typical decomposition curves of $CuBr_2$ *in vacuo* obtained at (1) 105°, (2) 115°, (3) 125° and (4) 134°C.

β and 470°C for β to α. γ-CuBr is of a zinc-blend type, but it shows an anomalous change with temperature. In this investigation, as the temperature was lower than 220°C, CuBr belonged to γ-type. The reaction, therefore, must be expressed as,

$$CuBr_2(s) \rightleftarrows \gamma\text{-}CuBr(s) + \frac{1}{2}Br_2(g)$$

Figure 3 shows the plots of α, *vs.* t. The decomposition reaction was found to follow a first-order rate law expressed by

$$d\alpha/dt = k_1 (1-\alpha)$$

at the beginning of the reaction, and a second-order rate law given by

$$d\alpha/dt = k_2\alpha (1-\alpha)$$

at the intermediate stage of the reaction. This result indicates that the reaction in the beginning may be controlled only by the process of the electron-transfer reaction, while the reaction at the intermediate period may be affected by the formation of decomposition product, CuBr.

This may be well understood by the consideration of the structure of $CuBr_2$. As $CuBr_2$ has polymeric chain structure and covalent bond, the structure change in the formation of Cu(I) might give a great effect to its neighboring chains successively. In view of this, the reaction in the beginning will be discussed so that some informations on the electron-transfer reaction can be obtained.

Since the integral form of the equation

$$d\alpha/dt = k_1 (1-\alpha)$$

is expressed by

$$-\ln(1-\alpha) = k_1 t + C$$

where C is constant, k_1 can be obtained from the slope of the plots of $-\log(1-\alpha)$ *vs.* t. Really, these plots gave straight lines in the beginning of the reaction as shown in Fig. 4. The value of k_1 was independent of the quantity and the grain

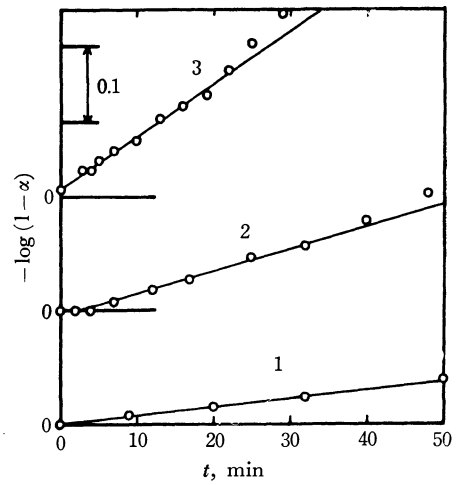

Fig. 4. Linear relationship between $-\log(1-\alpha)$ and time obtained at (1) 105°, (2) 115° and (3) 125°C.

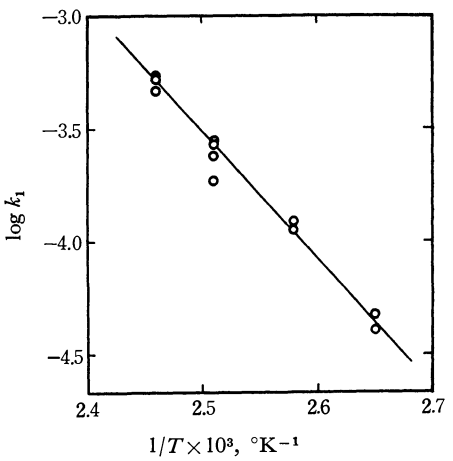

Fig. 5. Arrhenius plots of the first-order reaction rates for the decomposition reaction of $CuBr_2$ *in vacuo*.

size of $CuBr_2$ within the experimental error. Figure 5 shows the plots of $\log k_1$ *vs.* $1/T$, from which activation energy (E) and the frequency factor (A) were calculated to be 25.4 kcal/mol and $10^{10.4}$, respectively. Both of the values are almost the same as those of hexamminecobalt(III) complexes.[8] Though $CuBr_2$ had a polymer structure while hexamminecobalt(III) complexes had a monomer one, the difference could not be distinguished by the kinetic investigation.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

Competitive Inhibition of Pepsin by Carboxylic Acids

Hong Dae SHIN

Department of Chemistry, College of Liberal Arts and Sciences, Pusan National University, Pusan, Korea

(Received July 25, 1969)

In order to obtain evidence for Tang's hypothesis that pepsin (EC 3.4.4.1) forms a hydrophobic bond with the nonpolar side chain or its substrates, the inhibitory effect of carboxylic acids (from formic acid to isobutyric acid) on the activity of pepsin to the synthetic dipeptide, *N*-carbobenzoxy-L-glutamyl-L-tyrosine, was studied. Kinetic study showed that the inhibition by carboxylic acids was of competitive type. The inhibitor constant K_i decreased with an increase in the size of the inhibitor molecule. The free energy change of formation of complex between pepsin and hydrocarbon chain of carboxylic acid, $-\Delta F_{HC}$, increased linearly with the increase in the number of carbon atoms in the hydrocarbon chain of the inhibitor. It was suggested that the hydrophobic interaction between the side chain of amino acid residues in the binding region of the active center of pepsin and the hydrocarbon side chain of the inhibitor was the cause of the inhibition.

A theory[1,2] that a part of the binding region of their active center is hydrophobic was presented for various proteolytic enzymes. In pepsin (EC 3.4.4.1), it is known that substrates are bound to pepsin through hydrophobic bond.[2] The data given by Tang[1] indicated that pepsin exhibits preference for aromatic amino acid residues on both sides of the susceptible peptide bond. Judging from the fact that phenylalanyl residues are bound to pepsin more strongly than tyrosyl residues, binding of substrates with pepsin is supposed to be hydrophobic in nature. In this communication, the effect of carboxylic acids with aliphatic side chain on pepsin-catalyzed hydrolysis is described in order to examine the hydrophobic character of binding. If the hypothesis is correct, the hydrocarbon group of carboxylic acids and the substrate will bind competitively to the hydrophobic region of the active center of pepsin. Thus the carboxylic acids will act as competitive inhibitor against pepsin-catalyzed hydrolysis. In fact, the competitive inhibition of aliphatic alcohols against pepsin was observed by Tang.[2] Moreover, it was reported by Cann[3] that the formation of the enzyme-substrate complex between serum alubumin and pepsin is inhibited by a long chain fatty acid.

The inhibition of carboxylic acids ranging from formic acid to butyric acid on the pepsin-catalyzed hydrolysis of *N*-carbobenzoxyl-L-glutamyl-L-tyrosine (Z-Glu-Tyr) was studied to see the effect of hydrocarbon side chain of the carboxylic acids.

Experimental

Materials. Ninhydrin and methylcellosolve were obtained from E. Merck, and were purified by the E. Zeffren method.[4] Crystalline porcine pepsin and α-chymotrypsin (twice crystallized) were obtained from Worthington Biochemical Corp. *N*-Carbobenzoxyl-L-glutamyl-L-tyrosine substrate, *N*-benzoyl-L-arginine amide and *N*-acetyl-L-tyrosine amide were obtained from the Institute for Protein Research, Osaka University (Japan), and boving hemoglobin from Difco Laboratory. Carboxylic acids of highest purity were used.

Purification of Enzyme. Purification was carried out following Tang's method.[1,2]

Enzyme Activity. The activity of pepsin was measured with bovine hemoglobin by the Rajagopalan method.[5] The optical density was measured with a spectrophotometer (Unicam SP 500) at 280 mμ. From the results, the specific activity of pepsin was found to be 2505 ± 125 units/mg (mean of five determinations), when assayed with denatured hemoglobin (1.77%) as substrate at pH 1.8 and 30°C. One pepsin unit was defined as the amount of enzyme that produces (in the assay) an increase in the optical density of 0.01 above the blank. The increase in optical density was proportional to enzyme concentration, within the range of pepsin concentration used in the assay with hemoglobin as the substrate. In calculating the molar pepsin concentration, a molecular weight of 35000 was assumed (1 mg=0.0286 μmole). The activity of trypsin was measured with *N*-benzoyl-L-arginine amide as substrate by the Laskowski method[6]. The activity of α-chymotrypsin was also measured with *N*-

acetyl-L-tyrosine amide as substrate by the Laskowski method.[6]

Kinetic Measurements. The rate of enzyme action was measured by modified Moore's method.[7] In order to observe the effect of inhibition, the solution of reactant was incubated at various concentrations of the carboxylic acids added. Incubation mixtures consisted of 1.0 m*l* of inhibitor solution at pH 3.5, 1.0 m*l*, of stock substrate solution*, 0.2 m*l*, of stock enzyme solution**, and 0.1 m*l* of HCl in order to adjust the pH of final mixture to 3.5. Ionic strength of incubation mixture was adjusted to 0.1 with 0.1 M KCl. (*, **, Each stock solution was prepared with 0.2 M sodium citrate buffer, pH 3.5).

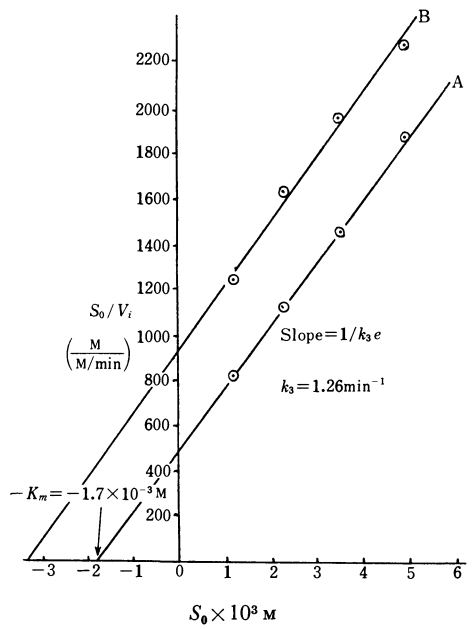

Fig. 1. Hofstee plots for the pepsin-catalyzed hydrolysis of Z-Glu-Tyr with or without the inhibition by acetic acid. The inhibitor concentrations are; A, no inhibitor; and B, 90 mM acetic acid.

7) S. Moore and W. H. Stein, *J. Biol. Chem.*, **176**, 367 (1948).

Results

Effect of Carboxylic Acids on Pepsin Action. The inhibitory effect of the carboxylic acids from formic acid to butyric acid upon the pepsin activity was observed with the use of Z-Glu-Tyr as substrate. The result shows that the degree of inhibition is roughly proportional to the increase in the molecular weights of carboxylic acids as shown in Table 1. However, in the case of formic acid, inhibition was non-competitive. For the purpose of comparing the inhibitory effects of carboxylic acids upon different proteolytic enzymes, the same study was carried out with α-chymotrypsin and trypsin. With α-chymotrypsin was observed such

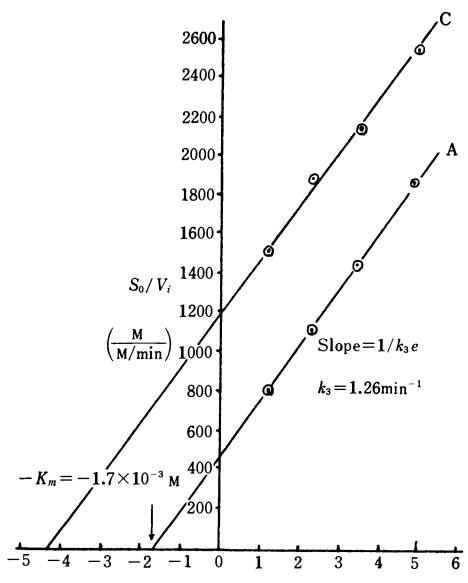

Fig. 2. Hefstee plots for the pepsin-catalyzed hydrolysis of Z-Glu-Tyr with or without the inhibition by *n*-butyric acid. The inhibitor concentrations are; A, no inhibitor, and C, 70 mM *n*-butyric acid.

an inhibitory effect by carboxylic acids as the in case of pepsin. The inhibitory effect on trypsin did not appear up to 1.4% concentration of carboxylic acids. Reversibility of inhibition was confirmed by the removal of carboxylic acids by dialysis.

Kinetics. The Hofstee plot for the hydrolysis of Z-Glu-Tyr showed straight lines as shown in Figs. 1 and 2 in accordance with the Michaelis-Menten equation (1).

$$\text{Pepsin} + \text{Z-Glu-Tyr} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \overset{\text{Pepsin}}{\dot{\text{Z}}\text{-Glu-Tyr}} \xrightarrow{k_3} \text{Pepsin} + \text{Z-Glu}\cdot\text{COOH} + \text{Tyr}\cdot\text{COOH} \quad (1)$$

$$S_0/V_0 = S_0/V_{max} + K_m/V_{max} \quad (2)$$

$$S_0/V_i = S_0/V_{max} + K_m/V_{max}(1+i/K_i) \quad (3)$$

$$V_0/V_i = 1 + K_m/K_i[i/(K_m+S_0)] \quad (4)$$

where

S_0=initial substrate concentration
V_0=initial velocity of the reaction without inhibitor
V_i=initial velocity of the reaction with inhibitor
V_{max}=maximum velocity without inhibitor
K_m=Michaelis constant without inhibitor
K_i=inhibitor constant
i=inhibitor concentration

The results with acetic acid and *n*-butyric acid as inhibitor, are shown in Figs. 1 and 2 as the plot S_0/V_i *vs.* S_0 according to Eqs. (2) and (3). It is obvious that the two kinds of acid were competitive inhibitors within the concentration range

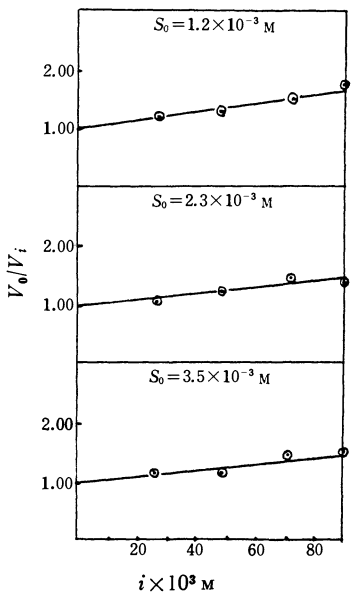

Fig. 3. V_0/V_i *vs.* i plots for the hydrolysis of Z-Glu-Tyr by pepsin inhibited by acetic acid at pH 3.5 (0.2 M sodium citrate buffer); temperature, 37°C.

TABLE 2. VALUES FOR $-\Delta F_i^{0a)}$, $-\Delta F_{HC}^{0b)}$

Carboxylic acids	average $K_i\times10^3$ (M)	$-\Delta F_i^0$ kcal/mol	$-\Delta F_{HC}^0$ kcal/mol

b) ΔF_{HC}^0: Standard free energy change of formation of complex between pepsin and the hydrocarbon chain of carboxylic acid. The date was obtained by subtracting ΔF_i^0 of acetic acid from all the values of ΔF_i^0.

studied. It has been observed that *n*-butyric acid is a stronger competitive inhibitor than acetic acid. The competitive inhibition did not appear up to 90 mM concentration of acetic acid and 71 mM concentration of *n*-butyric acid. In Fig. 3 plots V_0/V_i *vs.* i by Eq. (4) shows the inhibitory effect at different concentrations of each acid. From the plots, K_i of each competitive inhibitor was determined, and the result is shown in Table 1. We see in Tables 1 and 2, that K_i decreases as the number of carbon atoms in the carboxylic acid molecule increases, as was observed with a series of aliphatic alcohols.[2]

Discussion

The results of the present study show that the pepsin clearly underwent competitive inhibition by carboxylic acids. Since the concentration of carboxylate ion does not affect the rate of pepsin-catalyzed reaction,[8] it is not likely that the observed competitive inhibition is caused by the carboxyl group of carboxylic acids. Thus, it is probable that the effect of competitive inhibition by acid is caused by the hydrocarbon group in the acid molecule. This is supported by the fact that the degree of the inhibition increases with the increase in the number of the carbon atoms in the acid molecule (*cf.* Table 1). Thus the binding site of the active center of enzyme may be considered to be hydrophobic, in line with Tang's result.[1,2] In other words, inhibition by carboxylic acid depends on the competition between the hydrocarbon group of carboxylic acid molecule and the substrate on the hydrophobic binding site of enzyme. It is likely that hydrophobic bond is formed between the side chain of amino acid residue in the substrate molecule and the hydrophobic region of the binding site of the active center of enzyme.

Acid-Catalyzed Oxidation of Olefins with Selenium Dioxide

Khan A. JAVAID, Noboru SONODA and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita-shi, Osaka

(Received August 25, 1969)

A drastic deviation from the usually accepted reaction path was observed when oxidation of olefins was carried out in acetic acid with selenium dioxide in the presence of concentrated sulfuric acid. Oxidation of cyclohexene gave a mixture of *cis*- and *trans*-1,2-diacetoxycyclohexane. It was shown that in the oxidation of cyclohexene the organoselenium intermediate which produced 3-acetoxy-1-cyclohexene on pyrolysis, is not the intermediate in the present reaction. A study on reaction variables, such as effect of molar ratio of cyclohexene to selenium dioxide, amount of sulfuric acid, and water, reaction time and temperature, was undertaken. The reaction was extended to 1-octene and 1-hexene. A general structure for the organoselenium compound produced in the oxidation of terminal olefins in acetic acid without sulfuric acid, has been proposed. On the basis of our data and some previous concepts a reaction scheme has also been given.

It is generally accepted that oxidation of olefins with selenium dioxide essentially takes place at α position in the most substituted end of the double bond leading to an allylic product that is a function of the solvent used, and order of preference for oxidation is $CH_2 > CH_3$. In a previous paper[1] we reported that addition of two acetoxyl groups to the double bond occurs when the olefins without α-methyl or α-methylene carbon atom are oxidized with selenium dioxide in acetic acid. It is also accepted now that the oxidation follows an ionic path resulting from the electrophilic attack of selenium dioxide or conjugate acid of selenium dioxide on the double bond of the olefin.[2-4] Thus it was thought that addition of a strong acid might either increase the rate of the reaction or change its course by changing the active species. Actually both phenomena were observed. In the oxidation of cyclohexene and 1-octene, the course of the reaction deviated drastically from the generallized path when a small of concentrated sulfuric acid as catalyst was added. We wish to report this new trend in the selenium dioxide oxidation of olefins.

The structure of the organoselenium intermediate resulting from the non-catalytic oxidation of a terminal olefin with selenium dioxide in acetic acid has not been determined. We have proposed a structure for it.

Results and Discussion

Oxidation of Cyclohexene Cyclohexene was selected as a model olefin. Oxidation of cyclohexene has been studied by several researchers. It has been reported that 3-acetoxy-1-cyclohexene is produced in a yield of 48—50% when cyclohexene is treated with selenious acid in acetic anhydride at 80—85°C.[5] 3-Acetoxy-1-cyclohexene is obtained in a yield of 32% together with a trace of 3,6-diacetoxy-1-cyclohexene, when cyclohexene is treated with selenium dioxide in a mixture of acetic acid and acetic anhydride at 80—85°C.[6]

Cyclohexene was oxidized with equimolar amount of selenium dioxide in glacial acetic acid at 110°C for 10 hr in a 200 m*l* glass autoclave in the presence of a small amount of concentrated sulfuric acid to give mainly 1,2-diacetoxycyclohexane in a yield of 32%, as a mixture of *cis* (56%) and *trans* (44%) isomers. Cyclohexenone and cyclohexyl acetate were obtained as minor products. It was interesting to note that no 3-acetoxy-1-cyclohexene was produced and no organoselenium compound could be characterized. Metallic selenium was produced as the final reduced state of the oxidant. This reaction revealed two important features:

i) Addition to the double bond, instead of the allylic oxidation, took place.

ii) *Cis* addition as much as 56% was observed whereas electrophilic additions to cyclohexene molecule are known to give *trans* isomers generally.

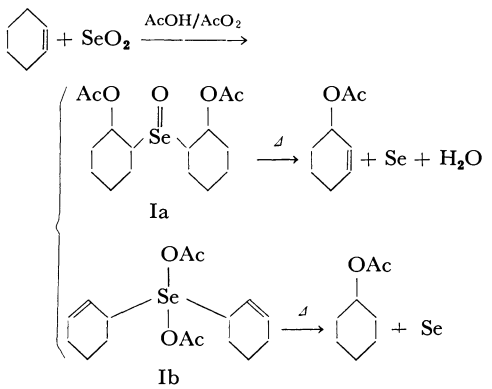
Study of the Reaction Variables. The reaction was very sensitive to the change in the molar ratio of olefin to selenium dioxide and the amount of sulfuric acid. Hardly any reaction took place when molar ratio of cyclohexene to selenium dioxide was 3. The yield of 1,2-diacetoxycyclohexene and the rate of the reaction increased with the decrease in the molar ratio of cyclohexene to selenium dioxide. The amount of sulfuric acid was important since it controlled the stereospecificity of the reaction. The increase in the amount of sulfuric acid increased the *trans* isomer (expts. 2, 4). Explanation for this effect is shown in the reaction scheme. Use of the large amount of catalyst resulted in decomposition of the products. The effect of water is also shown in Table 1. The monoacetate formed in each experiment was found to be almost all *cis* isomer, a part of which turns into the *trans* isomer on acid-catalyzed esterification during the reaction. Thus increase in the amount of water increased the *cis* monoacetate and consequently increased the *trans* diacetate (expts. 2 and 7, 4 and 6). The effects of the reaction time and reaction temperature were not so remarkable. The best results were obtained at 110—115°C. The reaction was very slow at 90—100°C and the residue remained in a large amount after distillation of the products at high temperatures. Some results from the study of the different reaction variables are given in Table 1.

Organoselenium Compounds in the Oxidation of Cyclohexene. We were interested in why the addition of a strong acid changes the reaction path of selenium dioxide oxidation of olefins so much. Two explanations can be given: 1) It is known that oxidation of cyclohexene without sulfuric acid first produces an organoselenium compound which on pyrolysis gives 3-acetoxy-1-cyclohexene.[3] The same organoselenium compound might also have been produced in the present reaction and the subsequent acid catalyzed decomposition may have given 1,2-diacetoxycyclohexene.

2) Addition of strong acid changed the active species at an early stage of the reaction, leading to different products.

A detailed study of organoselenium compounds was undertaken. The organoselenium compound from cyclohexene, responsible for the allylic oxidation products, was prepared by the method given by Arbuzov *et al.*[5] and purified by column chromatography. Wiberg and Neilsen[3] proposed two structures (Ia and Ib) for the compound emphasizing the probability in favor of Ia. The infrared spectrum of the compound purified by column chromatography showed it to be an acetate and absorptions for –OH or C=C were not found. NMR spectrum indicated the presence of –CHOAc. No absorption peak for the olefinic proton could be detected. These spectroscopic data confirm the structure Ia.



To investigate whether Ia is also an intermediate in the acid-catalyzed oxidation of cyclohexene or not, the compound was decomposed in acetic acid containing a small amount of sulfuric acid under similar conditions as those applied for the acid-catalyzed oxidation of cyclohexene. A large amount of metallic selenium was produced. Among the products, 3,6-diacetoxy-1-cyclohexene and a small amount of 1,2-diacetoxycyclohexane could be detected. The former product was considered to be formed by further oxidation of 3-acetoxy-1-cyclohexene. The discrepancies in the nature of the products, and the percentage composition

Table 1. Oxidation of cyclohexene

	Reaction conditions						Products %		Isomers % of diacetate

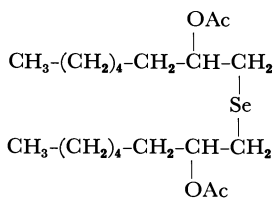
2	0.098	0.072	0.27	—	9	110	20.0	3.6	50	50
3	0.098	0.098	0.27	—	9	110	30.0	2.0	50	50
4	0.098	0.072	0.18	—	9	110	21.0	2.0	56	44
5	0.098	0.072	0.13	2.5	9	110	18.0	4.0	44	56
6	0.098	0.072	0.18	5.0	12	110	15.2	6.8	37	63
7	0.098	0.072	0.27	18.0	9	110	14.5	9.0	25	75

of the stereoisomers obtained from the direct acid-catalyzed oxidation of cyclohexene and acid-catalyzed decomposition of the organoselenium compound from cyclohexene, lead us to the conclusion that the compound Ia is not the intermediate in the acid-catalyzed oxidation of cyclohexene, and that the addition of sulfuric acid has changed the active species at an early stage of the reaction.

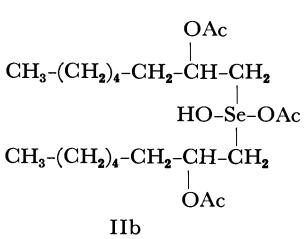
Oxidation of 1-Octene. On the basis of the results obtained from the oxidation of cyclohexene, studies were extended to some terminal olefins such as 1-octene and 1-hexene to investigate the scope of the reaction. Oxidation of 1-octene with equimolar amount of selenium dioxide in acetic acid at 115°C for 10 hr in the presence of concentrated sulfuric acid as a catalyst, gave 1,2-diacetoxyoctane (35%) and a trace of 1-acetoxy-2-octene. When 1-octene was oxidized with selenium dioxide in a mixture of acetic acid and acetic anhydride without sulfuric acid, an organoselenium compound was produced as a major product with a small amount of 1-acetoxy-2-octene. Thermal decomposition of the organoselenium compound gave again 1-acetoxy-2-octene. The acid-catalyzed decomposition of the organoselenium compound in acetic acid containing a small amount of sulfuric acid under similar conditions to those subjected to the acid-catalyzed oxidation of 1-octene, also produced 1-acetoxy-2-octene as a major product and a small amount of 3-acetoxy-1-octene. The result indicates that the organoselenium compound also, is not the intermediate in the acid-catalyzed oxidation of 1-octene.

Organoselenium Compounds in the Oxidation of 1-Octene. Recently oxidation of 1-octene was studied by bubbling air through the reaction mixture, and the formation of two organoselenium compounds IIa and IIb with a small amount of 1-acetoxy-2-octene was reported.[7]

$$CH_3\text{-}(CH_2)_5\text{-}CH{=}CH_2 + SeO_2 + AcOH \xrightarrow{Air}$$



IIa



IIb

Decomposition of IIa and IIb in acetic acid containing a small amount of sulfuric acid under similar conditions to those used for the acid-catalyzed oxidation of 1-octene produced again 1,2-diacetoxyoctane. Reaction conditions and stoichiometric calculations indicate that this may be formed from IIb. We assume from the results that in the direct formation of 1,2-diacetoxyoctane from 1-octene, active species resembling IIb may be involved, but IIb can not be considered as the major intermediate in the acid-catalyzed oxidation of 1-octene because of the difference in the yield of the products from the two cases. We can also conclude that organoselenium compound formed in the oxidation of 1-octene is different when (a) air is bubbled, and (b) air is not bubbled. The decomposition in (a) leads to diacetate formation while that in (b) leads to allylic oxidation products. No structure has been assigned to the organoselenium compound resulting from the non-catalytic oxidation of the terminal olefins. In the present work it was purified by column chromatography and its structure III was assigned on the basis of its infrared and NMR spectral data and the results of thermal and acid-catalyzed decompositions. Thermal decomposition of III should be facile and may proceed through a cyclic transition state to give the allylic oxidation product. (Scheme 1)

The effect of air is not understood except that bubbling of it reduced the selenium deposition.[7] It was thought that the following reaction takes place.

$$Se \xrightarrow{Air} SeO$$

$$III \longrightarrow IIa + SeO_2$$

Oxidation of 1-Hexene. Almost the same results as obtained in the oxidation of cyclohexene or 1-octene, except that considerable amounts of allylic oxidation products were obtained along with the addition products, were observed. Thus, oxidation of 1-hexene with an equimolar amount of selenium dioxide in acetic acid at 105°C for 10 hr in the presence of a small amount of concentrated sulfuric acid produced 1,2-diacetoxyhexane (35%), 3-acetoxy-1-hexene, (12%) and 1-acetoxy-2-hexene (5%). Identification of the products was carried out by infrared and NMR spectral analyses and GLC.

In order to compare the reaction with a known one, 1-hexene was oxidized with selenium dioxide following the procedure of Guillemonat[8] to give mainly the organoselenium compound which on pyrolysis and acid-catalyzed decomposition in acetic acid separately produced a mixture of 1-

acetoxy-2-hexene and 3-acetoxy-1-hexene.

Reaction Scheme. Schaefer *et al.*[2] suggested a reaction mechanism for the oxidation of olefins. Olson[9] gave a modified mechanism for the oxidation of ethylene. In view of the basic concepts postulated by these workers, a reaction scheme may be given from the consideration of the data presented above and our previous results indicating the *exo-cis* addition of acetoxyl groups to the double bond of norbornene molecule.[1]

According to the reaction scheme (Scheme 2), if no catalyst the reaction will follow path 1 to give there is the organoselenium compound which consequently leads to the allylic oxidation products. In the presence of a small amount of sulfuric acid as the catalyst the reaction will mainly deviated to path 2, whereas the large amount of the catalyst will tend to change the reaction path to 3. The production of the *cis* isomers may be attributed to the interamolecular acetoxylation through a cyclic transition state (VIII) formed by the addition of sulfuric acid as a strong proton donor. The scheme also explains the production of monoacetates as primary products.

Experimental

All the reactions were conducted in a 250 m*l* graduated glass autoclave with a mechanically operated stainless steel stirrer, which can be operated up to a pressure of 15 kg/cm^2. Infrared spectra were taken with a Shimadzu IR-27C spectrophotometer. The proton NMR spectra were taken on a Japan Electron Optics Lab. JNM C-60 spectrometer in deuteriochloroform with TMS as an internal standard. For mass spectral analysis, a Hitachi RMU-60 mass spectrometer was employed with the electron beam energy at 80 eV.

Acid-catalyzed Oxidation of Cyclohexene. A typical example is given here to cover the general reaction procedure. Selenium dioxide (11 g) was suspended in 50 m*l* of glacial acetic acid in the glass autoclave, cyclohexene (8 g) was diluted with a small amount of

9) D. H. Olson, *Tetrahedron Lett.*, **1966**, 2053.

acetic acid and transferred to the autoclave, 0.18 m*l* of concentrated sulfuric acid was added as a catalyst and the total volume was made up to 150 m*l* with acetic acid. The autoclave was heated at 110°C for 10 hr with stirring preventing the settling of selenium dioxide. The color of the reaction mixture changed from yellow to brown and ultimately to black due to the deposition of metallic selenium. After the reaction was over, selenium was filtered off and acetic acid was removed by vacuum distillation. The distillate collected at 40°C/3 mmHg, was found to be a mixture of cyclohexyl acetate and cyclohexenone by GLC. The second fraction boiling at 95°C/3 mmHg was characterized as 1,2-diacetoxycyclohexane (5.5 g). NMR spectrum: τ 5.1 (multiplet, 2H, >CH–OAc), 7.95 (singlet, 6H, $-OCOCH_3$), 7.9—8.8 (multiplet, 8H, ring methylenes).

Non-catalytic Oxidation of Cyclohexene. The procedure given by Arbuzov *et al.*[5] was followed to give a small amount of 3-acetoxy-1-cyclohexene and an organoselenium compound mainly as residue. The residue was divided into three parts. One part was subjected to pyrolysis in a distillation flask at 250°C under the reduced pressure of 20 mmHg to give 3-acetoxy-1-cyclohexene and a small amount of 3,6-diacetoxy-1-cyclohexene. Second part of the residue (about 10 g) was dissolved in 120 m*l* of acetic acid in the glass autoclave, and thermal decomposition was carried out at 110°C for 8 hr in the presence of 0.18 m*l* of concentrated sulfuric acid. Metallic selenium was filtered off and acetic acid was removed by vacuum distillation. The distillate at 95—100°C/3 mmHg was characterized as a mixture of 3,6-diacetoxy-1-cyclohexene, *trans* 1,2-diacetoxycyclohexane and an unknown product. Silica gel column chromatography was employed for the purification of the organoselenium compound. The residue (about 1 g) was diluted with 4 m*l* of *n*-hexane and transfered to a 35 cm×2.5 cm column containing 40 g of silica gel in 80 m*l* of *n*-hexane. The eluents used were *n*-hexane, a mixture of 50% *n*-hexane and 50% benzene, pure benzene and a mixture of 95% benzene and 5% ether. On the basis of its infrared and NMR spectra and the results of thermal and acid-catalyzed decompositions, the structure Ia was confirmed. NMR: τ 5.2 (multiplet, 2H, >CHOAc), 7.1 (multiplet, 2H, >CH–SeO–), 7.95 (singlet, 6H, $-OCOCH_3$), 7.9—8.8 (multiplet, 16H, ring methylenes).

Acid-catalyzed Oxidation of 1-Octene. Selenium dioxide (8 g) was suspended in 50 m*l* of acetic acid in the glass autoclave and 1-octene (8 g) was added. The total volume was made up to 140 m*l* with acetic acid and 0.18 m*l* of concentrated sulfuric acid was added as a catalyst. The reaction was carried out at 115°C for 10 hr. After metallic selenium was removed by filtration, acetic acid was distilled off under the reduced pressure. The distillate boiling at 105—110°C/3 mmHg was almost pure 1,2-diacetoxyoctane (6.5 g). Redistillation of the fraction gave pure 1,2-diacetoxyoctane, 107°C/3 mmHg. NMR: τ 5.1 (multiplet, 1H, –CHOAc), 5.9 (multiplet, 2H, $>CH_2OAc$), 7.95 (singlet, 6H, $-OCOCH_3$), 8.2—9.5 (multiplet, 13H, $-C_6H_{13}$).

Non-catalytic Oxidation of 1-Octene. Selenium dioxide (5 g) was suspended in 120 m*l* of glacial acetic acid and 15 m*l* of acetic anhydride in the glass autoclave and 1-octene (10 g) was poured in. The autoclave was heated at 100—105°C for 8 hr. No deposition of metallic selenium was observed. The solvents and the unreacted 1-octene were removed by vacuum distillation. A small amount of product was obtained at 55°C/3 mmHg and a dark brown residue remained. The product was identified as 1-acetoxy-2-octene by GLC. The residue was pyrolysed in a distillation flask to give 1-acetoxy-2-octene. The acid-catalyzed decomposition of the residue in acetic acid at 115°C for 8 hr in the presence of 0.18 m*l* of concentrated sulfuric acid gave 1-acetoxy-2-octene and a small amount of 3-acetoxy-1-octene. The organoselenium compound was purified by silica gel column chromatography. The method applied was the same as that used for the purification of the organoselenium compound (Ia) from cyclohexene. Structure III was assigned on the basis of its infrared and NMR analyses. NMR spectrum: τ 5.15 (multiplet, 2H, >CHOAc), 7.25 (doublet, 4H, $-CH_2$–SeO–), 7.95 (singlet, 6H, $-OCOCH_3$), 8.2—9.3 (multiplet, 26H, $-C_6H_{13}$).

Acid-catalyzed Oxidation of 1-Hexene. Selenium dioxide (5.5 g) was suspended in 50 m*l* of acetic acid in the glass autoclave and 1-hexene (4 g) was added. The total volume was made up to 140 m*l* with acetic acid and 0.14 m*l* of concentrated sulfuric acid was added as a catalyst. Oxidation was carried out at 105°C for 10 hr with stirring. The deposited metallic selenium was filtered off and acetic acid was removed by vacuum distillation. The fraction boiling at 40—45°C/3 mmHg was found to be a mixture of 1-acetoxy-2-hexene (5%) and 3-acetoxy-1-hexene (12%) by GLC. The second distillate collected at 85°C/2 mmHg was found to be 1,2-diacetoxyhexane (35%). Its structure was confirmed by comparison with an authentic sample. NMR spectrum: τ 5.1 (multiplet, 1H, –CHOAc), 5.9 (multiplet, 2H, $-CH_2OAc$), 7.95 (singlet, 6H, $-OCOCH_3$), 8.2—9.2 (multiplet, 9H, $-C_4H_9$).

Non-catalytic Oxidation of 1-Hexene. The procedure of Guillemonat[8] was followed. Organoselenium compound was the major product. Pyrolysis of the compound at 250°C/23 mmHg in a distillation flask gave a mixture of 1-acetoxy-2-hexene and 3-acetoxy-1-hexene in the ratio 3 to 1. The acid-catalyzed decomposition of the organoselenium compound (10 g) in 120 m*l* of acetic acid containing 0.14 m*l* of concentrated sulfuric acid at 105°C for 8 hr gave 1-acetoxy-2-hexene and 3-acetoxy-1-hexene in the ratio 2 to 1.

Khan A. Javaid expresses his thanks to the Ministry of Education of Japan, for a scholarship.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3480—3485 (1970)

Aromatic Metalation Reactions by Palladium(II) and Platinum(II) on Aromatic Aldoximes and Ketoximes

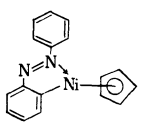
Hiroshi ONOUE, Kyoji MINAMI and Kunio NAKAGAWA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

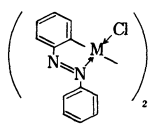
(Received September 25, 1969)

Ortho metalation by palladium(II) was observed in the reaction of lithium tetrachloropalladate(II) with various aromatic aldoximes and ketoximes in methanol in the presence of sodium acetate. The obtained chloro-bridged complexes(**7**) possessed both *ortho*-attached palladium-carbon σ-bonding and palladium-nitrogen coordinate bonding to oximes. Reactions of *O*-acyl and *O*-methyl oximes with lithium tetrachloropalladate(II) were also carried out. An *ortho* metalation was observed in the former case, but dichlorobis(*O*-methyl oxime)palladium(II) type complexes containing no palladium-carbon σ-bonds were predominantly formed in the latter case. The bridge-splitting reaction of chloro-bridged complexes with triphenylphosphine and the metathetic reaction with sodium bromide in acetone were carried out. In the case of potassium tetrachloroplatinate(II), an *ortho* metalation reaction was observed giving the complexes(**10**) but chloro-bridged complexes could not be isolated.

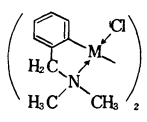
It has recently been shown that direct electrophilic aromatic substitution reactions by nickel(II), palladium(II), and platinum(II) on azobenzene,[1,2] *N,N*-dimethylbenzylamine,[3] 2-phenylpyridine,[4] and benzylidenaniline[5] gave the following complexes (**1**—**5**), respectively.



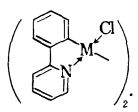
1



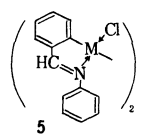
2



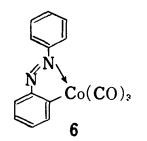
3



4



5



6

M=Pd, Pt

Transition metal complexes containing carbon-metal σ-bonds are usually very unstable[6] but the above complexes are surprisingly stable against air and heat. On the other hand, palladium-aromatic ring σ-bonded complexes may be regarded as intermediates in the reactions,[7-11] although they are unstable and not isolated.

Heck[12] prepared complex **6** and considered it to be the reaction intermediate of the carbonylation of azobenzene catalyzed by dicobalt octacarbonyl; this reaction was first discovered by Horiie and Murahashi.[13] Tsuji *et al.* obtained 2-(dimethylaminomethyl)stilbene by the reaction of complex **3** with styrene in acetic acid.[14]

From the above arguments, transition metal-aromatic ring σ-bonded complexes are important for studying the mechanism of aromatic substitution reactions and the study of the properties of these complexes will help to find out new synthetic methods.

Here we report a new metalation reaction by palladium(II) and platinum(II) on aromatic aldoximes and ketoximes.[15]

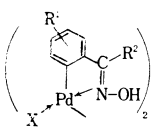
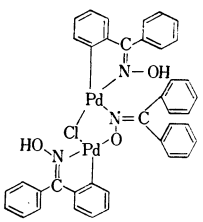
Results and Discussion

It was found that benzophenone oxime gave 3-phenylphthalimidine by carbonylation in the presence of dicobalt octacarbonyl[19] or palladium chloride[20] in benzene. We studied the reaction benzophenone oxime with palladium chloride in the absence of carbon monoxide.

The reaction of benzophenone oxime with lithium tetrachloropalladate(II) in methanol at room temperature gave dichlorobis(benzophenone oxime) palladium(II) having no palladium-carbon σ-bondings. When the reaction was carried out by adding sodium acetate, we obtained complex **7a** ($R^1=H$, $R^2=C_6H_5$, X=Cl) and a small amount of complex **8**. The structure of **7** will be discussed in detail later. Complex **8** was tentatively assigned as follows by analysis and molecular weight determination. This complex seems to be obtained from **7a** and benzophenone oxime by eliminating hydrogen chloride. A similar reaction of opening the palladium-chlorine bond in π-allylic palladium(II) chloride with cyclohexanone oxime was reported by Imamura *et al.*[17]



7a—j



8

The procedure of adding sodium acetate as an acceptor of hydrogen chloride formed by the reaction was successfully applied to various aromatic aldoximes and ketoximes. The resulting complexes analogous to **7a** are shown in Table 1. The corresponding bromo-bridged complexes were obtained by the metathetic reaction of the chloro-complexes with sodium bromide in acetone. All the complexes were stable against air and heat, and complexes except for those from benzophenone, *n*- and isobutyrophenone oxime were insoluble in the usual organic solvents. The reaction product was deposited from the reaction mixture, but in some cases it was necessary to add water to isolate a complex. In the case of acetophenone oxime and its derivatives, their complexes were also obtained in the absence of sodium acetate but the yields were lower and the rate of the reaction slower judging from the disappearing rate of the black-red color of lithium tetrachloropalladate(II). Although *syn*- and *anti*-isomers exist in general in oximes, we used stable *syn*-aldoximes

Table 1. Aromatic metalation by palladium (II) on various aromatic oximes 
Compound	R^1	R^2	X	Yield (%)	Mp (°C)	ν_{O-H} (cm^{-1})*1	$\nu_{C=N}$ (cm^{-1})*1
7a	H	C_6H_5	Cl	67.8	150—152	3343	1625

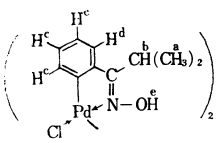
and *anti*-phenylalkyl ketoximes. In the case of isobutyrophenone oxime, both isomers were stable and the isolated isomers were tested for the reaction. As suggested by the structure of the complexes, and *anti*-isomer gave an expected complex (**7f**) in good yield, but the *syn*-isomer gave a different complex, which was not studied further.

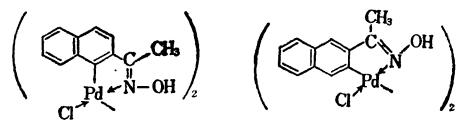
The structure of the complexes was established by the following data. The molecular weights of complexes **7a**, **7e** and **7f** in chloroform coincided well with the values calculated for the chloro-bridged dimers. The IR spectra showed the characteristic O–H stretching frequency in the 3310—3460 cm^{-1} region and the C=N stretching frequency in the 1615—1640 cm^{-1} region as shown in Table 1. On the other hand, the C=N stretching frequency in conjugated oximes in solution is known to fall in the range 1630—1660 cm^{-1}, with slightly lower values for solides.[21] It was concluded therefore that the coordination of oximes to palladium in the complexes was established through the lone pair of nitrogen but not through the C=N π-system.[5,22] The NMR spectrum of complex **7f** was in good agreement with the proposed structure, showing a doublet at 1.38 (J= 7 Hz, 6H), a septet at 3.35 (J=7 Hz, 1H), two multiplets at 6.76—7.13 (3H) and 7.23—7.46 (1H) and a singlet at 8.20 ppm (1H), each corresponding to a, b, c, d and e, respectively. This result shows that one aromatic ring proton *ortho* to the C=N group was substituted by palladium(II).



7f

Lithium aluminum deuteride reduction[23] of the acetophenone oxime-palladium(II) chloride complex gave deuterated *dl*-α-phenylethylamine.[24] Its NMR spectrum showed that the incorporation of deuterium had occurred in the phenyl ring and the methine group, a triplet at 1.32 ppm corresponding to methyl protons (J=1 Hz, 3H) and a singlet at 7.25 ppm corresponding so phenyl protons (4H). After treatment with water to exchange deuterium of the amino group with proton, its acetyl derivative was prepared. It was determined by mass spectrometry that the acetyl derivative contained 2% of d_0, 18% of d_1 and 80% of d_2 species.

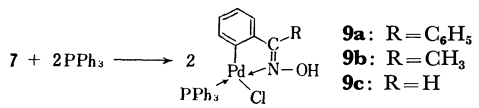
Although the *ortho* metalation by palladium(II) was confirmed, there are two positions in 2-acetonaphthon oxime, 1 and 3, susceptible to metalation by palladium(II), giving the following complexes, **A** and **B**, respectively.



A **B**

The obtained complex was reduced with lithium aluminum deuteride to give deuterated 2-(α-aminoethyl)naphthalene. From the ratio of α- to β-protons on the naphthalene ring calculated from its NMR spectrum, it was established that **B** was the correct one. The structure of the 1-acetonaphthon oxime complex (**7h**) was confirmed by the same method.

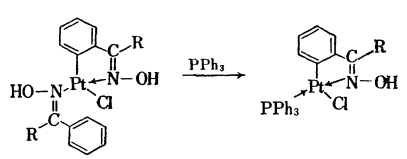
The chloro-bridged complexes (**7**) reacted with triphenylphosphine to give the corresponding bridge-splitted complexes (**9**). In contrast to the other complexes, complex **7i** reacted with a theoretical amount of triphenylphosphine to give complex **9c**,



9a: R=C_6H_5
9b: R=CH_3
9c: R=H

but with an excess of triphenylphosphine to give a new complex containing two moles of triphenylphosphine per palladium.

The metalation reaction by palladium(II) was extended to the reaction of oximes with platinum(II). However, the reaction of one-molar quantity of acetophenone oxime and sodium acetate with potassium tetrachloroplatinate(II) in aqueous methanol gave only an intractable black material which deposited platinum metal on dissolving in dichloromethane. When the reaction was carried out in the absence of sodium acetate, complex **10a** was obtained. The IR spectrum was the same as that of the palladium analogue which was prepared from complex **7b** by a bridge-splitting reaction with acetophenone oxime. Complex **10a** reacted with triphenylphosphine giving complex **11**. *anti*-Isobutyrophenone oxime gave also complex **10b**.



10a: R=CH_3
10b: R=$CH(CH_3)_2$
11: R=CH_3

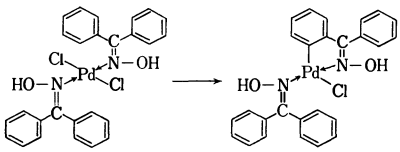
22) M. Orchin and P. J. Schmidt, *Coord. Chem. Rev.*, **2**, 345 (1968).
23) Metal hydride reduction of carbon-metal σ-bonds was often tried. See Ref. 3 and the references cited.
24) Reduction of oxime to amine is a well-known reaction.

Thus the electrophilic attack by platinum(II) on the aromatic ring of oximes could occur but the chloro-bridged complexes could not be obtained. It is probable that the differences observed in the case of palladium(II) and platinum(II) are partly attributed to the poor reactivity of platinum(II) compared to palladium(II).

These reactions by palladium(II) and platinum(II) on aromatic oximes would probably proceed through an initial coordination of nitrogen to the metal followed by an electrophilic substitution by the metal at an *ortho* position on the aromatic ring. In fact, the following metalation reaction occurred in boiling tetrahydrofuran yielding complex **12**.



12

Thus it can be expected that if nitrogen coordinates strongly to the metal, dichlorobis(oxime)-metal type complexes are formed and no metalation reaction can take place. We studied the reaction of *O*-methyl and *O*-acyl derivatives with lithium tetrachloropalladate(II).

O-Methyl oxime of benzophenone and acetophenone yielded predominantly dichlorobis(*O*-methyl oxime)palladium(II) even in the presence of sodium acetate. It may be concluded that the strong coordination to palladium with nitrogen due to the presence of the electron donating methyl group reduced the formal charge of palladium(II), preventing its electrophilic attack on the aromatic ring.

On the other hand, *O*-acetyl and *O*-benzoyl acetophenone oxime, in which the coordinating power of nitrogen would be reduced by the presence of electron withdrawing acyl groups, gave complex **7b** in the absence of sodium acetate. In addition, methyl benzoate was isolated in the reaction of *O*-benzoyl acetophenone oxime. It is uncertain whether the methanolysis of *O*-acyl groups occurred before or after the formation of a palladium-carbon σ-bond.

Experimental

Melting points were determined on a Yanagimoto micro-stage apparatus and uncorrected. IR spectra were recorded with Nippon Bunko IR-S and Nippon Bunko Model DS-402G Spectrometers. NMR spectra were determined at 60MHz with a Varian A-60 Spectrometer in deuteriochloroform using tetramethylsilane as an internal standard. Molecular weights were determined with a Mechrolab Model 301A vapor pressure osmometer in a chloroform solution.

Materials. Anhydrous palladium chloride was obtained from Nippon Engelhard, Ltd. Potassium tetrachloroplatinate(II) was obtained from Wako Pure Chemicals Industries, Ltd. Lithium aluminum deuteride was obtained from Metal Hydrides, Inc. A lithium tetrachloropalladate(II) solution in methanol (0.5 M) was prepared by stirring two equivalents of anhydrous lithium chloride and one equivalent of anhydrous palladium chloride in methanol until a homogeneous solution was formed. Each oxime was prepared from the corresponding aldehyde or ketone, hydroxylamine hydrochloride and sodium hydroxide in the usual manner and purified by recrystallization or distillation before use. *Syn-* and *anti*-isobutyrophenone oximes were separated from the mixture by fractional crystallization from *n*-hexane.[25]

Reaction of Benzophenone Oxime with Lithium Tetrachloropalladate(II). When a solution containing 3.95 g (0.02 mol) of benzophenone oxime and 0.01 mol of Li_2PdCl_4 in 40 m*l* of methanol was allowed to stand for 5 days at room temperature, 2.86 g of red-yellow crystals, mp 180°C dec., was obtained. IR spectrum (Nujol): 3280 and 3200 cm^{-1} (ν_{O-H}); 1629 cm^{-1} ($\nu_{C=N}$).

Found: C, 54.45; H, 4.03; N, 5.05; Pd, 18.53%. Calcd for $C_{26}H_{22}N_2O_2PdCl_2$: C, 54.61; H, 3.89; N, 4.90; Pd, 18.61%.

A solution of 2.00 g of the complex in 30 m*l* of tetrahydrofuran was boiled for 1 hr and cooled to give 0.84 g of the starting complex. Upon addition of *n*-hexane to the filtrate, 0.13 g of the complex was further recovered. Pale yellow solids were then formed from this filtrate by a further addition of *n*-hexane followed by standing for 2 days. Solids were recrystallized from chloroform-*n*-hexane to give 0.71 g of complex **12**, mp 192—200°C. IR spectrum (Nujol): 3245 sh, 3160 and 3105 cm^{-1} (ν_{O-H}); 1619 cm^{-1} (broad, $\nu_{C=N}$).

Found: C, 58.04; H, 4.18; Cl, 6.81%. Calcd for $C_{26}H_{21}N_2O_2PdCl$: C, 58.33; H, 3.96; Cl, 6.62%. The complex was also prepared from complex **7a** by a bridge-splitting reaction with benzophenone oxime.

Preparation of Halogen-Bridged Complexes. All complexes were prepared as yellow or orange-yellow solids by the following general procedures. Complexes **7a**, **7a'**, **7e** and **7f** were soluble in dichloromethane, chloroform, acetone and tetrahydrofuran, but other complexes were insoluble in ordinary organic solvents. The yields and physical properties and analytical data are summarized in Tables 1 and 2.

(a) Complexes **7a**, **7d**, **7f**, **7h**, **7i** and **7j**. To a solution containing 0.02 mol of Li_2PdCl_4 in 40 m*l* of methanol, a methanol solution of 0.02 mol of oxime and 0.02 mol of oxime and 0.02 mol of sodium acetate trihydrate was added. When the solution was allowed to stand for one or two days at room temperature, small amounts of precipitates were formed and the black-red colour of the solution turned pale yellow. The mixture was filtered and water was added to the filtrate to give yellow solids. Other oximes except for benzophenone, anisaldehyde, and 1-acetonaphthon oxime gave analytically pure complexes **7d**, **7f** and **7i**.

Yellow solids obtained in the case of benzophenone

[*1] mol wt, 732 (676.18). [*2] mol wt, 622 (608.16). [*3] mol wt, 597 (608.16).

oxime were separated into two complexes **7a** and **8** by fractional crystallization from dichloromethane-*n*-hexane. Complex **8** was obtained as pale yellow crystals, 0.97 g, mp 200—216°C dec.

Found: C, 56.39; H, 3.78; N, 4.99; Cl, 4.82%; mol wt, 806. Calcd for $C_{39}H_{30}N_3O_3Pd_2Cl$: C, 55.96; H, 3.62; N, 5.02; Cl, 4.24%; mol wt, 836.97.

Yellow solids from anisaldexime were dissolved in dichloromethane. When the solution was concentrated, complex **7j** was obtained which, once isolated, was insoluble in most organic solvents.

Treatment of yellow solids from 1-acetonaphthon oxime with boiling chloroform left pure complex **7h**.

(b) Complexes **7b**, **7c**, **7e** and **7g**. Reactions were carried out according to the same procedure as above, but in these cases the expected complexes precipitated from the solution. The reaction mixtures were then filtered, washed with methanol and water and dried to give pure complexes.

(c) Complexes **7a'** and **7b'**. Complex **7a** or **7b** reacted with sodium bromide in aqueous acetone for an hour at room temperature or by refluxing on a water bath. The yellow solution was concentrated and water was added to give yellow solids.

Preparation of Complexes (9). To a suspension of complex **7a** (0.10 g) in dichloromethane (0.5 m*l*) was added triphenylphosphine (0.10 g). The resulting solution was diluted with *n*-hexane, whereupon complex **9a** was obtained as pale yellow crystals (0.159 g, 89%), mp 203—210°C dec. Purification was accompanied by recrystallization from dichloromethane-*n*-hexane. IR spectrum (Nujol): 3180 cm^{-1} (ν_{O-H}).

Found: C, 62.00; H, 4.26; Cl, 6.07%; mol wt, 558. Calcd for $C_{31}H_{25}NOPPdCl$: C, 62.01; H, 4.21; Cl, 5.90%; mol wt, 600.39.

Similarly complex **9b** was prepared from complex **7b** as yellow crystals, mp 205—211°C dec. IR spectrum (Nujol): 3195 cm^{-1} (ν_{O-H}); 1266 cm^{-1} (CH_2Cl_2). Found: C, 53.39; H, 4.20%. Calcd for $C_{26}H_{23}NOPPdCl\cdot 3/4CH_2Cl_2$: C, 53.37; H, 3.88%.

Complex **9c** was similarly prepared from complex **7i**, as orange crystals, mp 173—174°C dec. IR spectrum (Nujol): 3220 cm^{-1} (ν_{O-H}).

Found: C, 56.88; H, 4.34%. Calcd for $C_{25}H_{21}NOPPdCl$: C, 57.27; H, 4.04%.

Reaction of Complex (7i) with an Excess of Triphenylphosphine. A suspension of 0.262 g (0.5 mmol) of complex **7i** in 1 m*l* of chloroform turned to a yellow solution on adding 0.577 g (2.2 mmol) of triphenylphosphine. Addition of *n*-hexane to the solution gave 0.720 g (93%) of pale yellow crystals, melting at 188—192°C and then solidifying, followed by decomposition at 196—197°C. The complex was found to be completely dissociated in solution from its IR spectrum in chloroform and the molecular weight. IR spectrum (ν_{O-H}): 3390 cm^{-1} (in Nujol); 3220 cm^{-1} (chloroform).

Found: C, 65.03; H, 4.59%; mol wt, 395. Calcd for $C_{43}H_{36}NOP_2PdCl$: C, 65.05; H, 4.62%; mol wt, 786.59.

Reduction of Complexes (7) with Lithium Aluminum Deuteride. To a mixture of 1.00 g of the complex to be reduced in 20 m*l* of absolute tetrahydrofuran was added 0.50 g of lithium aluminum deuteride with stirring. After stirring for 30 min at room temperature, the resulting black mixture was worked up by careful addition of 2 m*l* of deuterium oxide followed by the addition of anhydrous sodium sulfate. The

mixture was filtered and washed well with tetrahydrofuran. Removal of tetrahydrofuran gave crude amine. This was purified by distillation or by transformation to its hydrochloride or acetyl derivative.

Reaction of Oxime with Potassium Tetrachloroplatinate (II). A solution of 2.41 mmol of oxime in 10 m*l* of methanol was added to a solution of 2.41 mmol of K_2PtCl_4 in 20 m*l* of water. The initially clear red solution became lighter in colour and dark yellow solids precipitated. After standing for 2 days, the solids were filtered and purified by passing a short silica gel column with dichloromethane followed by recrystallization from dichloromethane-*n*-hexane.

Complex **10a** was obtained from acetophenone oxime, as yellow crystals (0.158 g), mp 190—193°C. IR spectrum (Nujol): 3310 and 3230 cm^{-1} (ν_{O-H}); 1644 and 1633 cm^{-1} ($\nu_{C=N}$).

Found: C, 38.48; H, 3.53; Pt, 38.69%. Calcd for $C_{16}H_{17}N_2O_2PtCl$: C, 38.44; H, 3.43; Pt, 39.03%.

Complex **10b** was obtained from *anti*-isobutyrophenone oxime, as yellow crystals (0.045 g), mp 178—180°C. IR spectrum (Nujol): 3360 and 3230 cm^{-1} (ν_{O-H}); 1630 sh and 1623 cm^{-1} ($\nu_{C=N}$).

Found: C, 43.11; H, 4.59; Pt, 34.57%. Calcd for $C_{20}H_{25}N_2O_2PtCl$: C, 43.20; H, 4.54; Pt, 35.09%.

A solution of complex **10a** (0.050 g) in 0.5 m*l* of dichloromethane was treated with triphenylphosphine (0.050 g) and *n*-hexane was added, whereupon complex **11** (0.058 g, 92%) was obtained as yellow crystals, mp 254—256°C. Its IR spectrum was consistent with that of the palladium analogue (**9b**) and showed a band at 1266 cm^{-1} due to dichloromethane. Found: C, 47.40; H, 3.82; Cl, 10.60%. Calcd for $C_{26}H_{23}NOPPtCl \cdot 1/2CH_2Cl_2$: C, 47.55; H, 3.62; Cl, 10.59%.

Reaction of *O*-Methyl Benzophenone Oxime with Lithium Tetrachloropalladate (II). Reaction was carried out in the same manner as the preparation of complex **7a** using 0.01 mol of *O*-methyl benzophenone oxime and other reactants. After standing for 16 hr, the resulting yellow solids were filtered. More solids were obtained from the filtrate by extracting with chloroform. The solids were separated into two kinds of compounds by fractional crystallization from chloroform-*n*-hexane. Dichlorobis(*O*-methyl benzophenone oxime)palladium(II), the more soluble compound in chloroform, was obtained as yellow-brown crystals (1.94 g, 71.3%), melting at 174—175°C and then solidyfying, followed by decomposition at 248°C. IR spectrum in the range 800—650 cm^{-1} (Nujol): 799, 773, 749 and 696 cm^{-1}.

Found: C, 55.99; H, 4.37; Pd, 17.63%; mol wt, 524. Calcd for $C_{28}H_{26}N_2O_2PdCl_2$: C, 56.06; H, 4.38; Pd, 17.74%; mol wt, 599.86. The less soluble compound in chloroform was obtained as yellow crystals, 0.26 g, mp 254—258°C dec. IR spectrum (Nujol): 1212 cm^{-1} ($CHCl_3$); 789, 770, 749, 723 and 699 cm^{-1} (in the range 800—650 cm^{-1}).

Found: C, 46.67; H, 3.41; N, 3.68; Cl, 13.19%. Calcd for $C_{28}H_{24}N_2O_2Pd_2Cl_2 \cdot 1/8CHCl_3$: C, 46.21; H, 3.33; N, 3.82; Cl, 13.28%.

Reaction of *O*-Methyl Acetophenone Oxime with Lithium Tetrachloropalladate (II). In the same manner, we obtained 2.13 g (89.2%) of dichlorobis (*O*-methyl acetophenone oxime)palladium(II) as yellow crystals, mp 204°C dec.

Found: C, 45.62; H, 4.74; Pd, 22.07%; mol wt, 466. Calcd for $C_{18}H_{20}N_2O_2PdCl_2$: C, 45.44; H, 4.67; Pd, 22.37%; mol wt, 475.72.

Reaction of *O*-Acetyl and *O*-Benzoyl Acetophenone Oxime with Lithium Tetrachloropalladate (II). A methanol solution of 0.01 mol of each oxime was mixed with 20 m*l* of 0.5 M Li_2PdCl_4 in methanol. After standing for 20 hr, yellow crystals were formed and more solids were obtained by adding water. The yield of complex **7b** was about 80%. In the case of *O*-benzoyl acetophenone oxime, the filtrate was extracted with ether. After ether was removed, the residue was distilled *in vacuo* to give 0.88 g of colorless liquid. This was identified to be methyl benzoate by comparing its IR spectrum with that of an authentic sample.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3486—3489 (1970)

4-Alkyloxazolidinedione. VI. The Polymerization of α-Amino Acid *N*-Carboxy Anhydride

Masanao Oya and Mayumi Tomizawa,*1

College of Technology, University of Gunma, Tenjin-cho, Kiryu-shi, Gunma

and Keikichi Uno and Yoshio Iwakura

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 14, 1970)

The relationships between the polymerization solvents and the conformation of the polypeptides formed were studied on the basis of the infrared absorption spectra and the X-ray diffraction diagrams of the polymers. Poly-L-α-amino-*n*-butyric acid and poly-L-*n*-valine, prepared in dimethylsulfoxide (DMSO) as a polymerization solvent, formed a β-conformation, but the respective polypeptides obtained in acetonitrile had an α-conformation. The conformational structure of poly-L-α-amino-*n*-butyric acid changed from β to α upon reprecipitation from a solution in dichloroacetic acid with ether. On the other hand, the conformational structure of poly-DL-α-amino-*n*-butyric acid did not change upon reprecipitation from a solution in formic acid and dichloroacetic acid.

In our previous papers in this series, we reported the solvent effect in the polymerization of DL-and L-alanine NCA on the conformation of the formed polypeptides.[1-3] The conformation of the polypeptides was influenced by the polymerization solvent: the polyalanine obtained in acetonitrile had an α-conformation, but the polyalanine obtained in DMSO had a β-conformation.[2] Further relationships between the conformation of the growing chains of poly-L-alanine and poly-L-leucine in DMSO during the polymerization of L-alanine NCA and L-leucine NCA and the polypeptides isolated from DMSO have also been discussed.[4]

The present study will report on the relationships between the conformations of the polypeptides obtained by the polymerization of several kinds of NCA's and the solvents used.

Results and Discussion

Infrared Spectra of L- Configurational polypeptides. The infrared absorption frequencies of the L-configurational polypeptides obtained in acetonitrile and DMSO are shown in Table 1. The spectra of poly-L-α-amino-*n*-butyric acid, poly-L-*n*-valine, poly-L-*n*-leucine, and poly-L-leucine obtained in acetonitrile all gave absorption bands at 1660 cm^{-1}, such bands are characteristic of α-polypeptides.[5] However, the spectra of poly-L-α-amino-*n*-butyric acid and poly-L-*n*-valine obtained in DMSO gave absorption bands at 1635 cm^{-1} and 1535 cm^{-1}, these bands are characteristic of β-conformational polypeptides.[5] These results showed that the L-configurational polypeptides obtained in acetonitrile had an α-conformation, while those obtained in DMSO had a β-conformation. Similar results have been obtained in the polymerization of DL- and L-alanine NCA's. On the other hand, the spectra of each poly-L-valine obtained in acetonitrile and in DMSO gave an absorption band at 1635 cm^{-1} which is characteristic of β-conformational polypeptides.

IR Spectra of DL-Configurational polypeptides. It has been reported that the conformation of poly-DL-alanine obtained in acetonitrile had an α-form and that the one obtained in DMSO had a β-form.[2] However, many polypeptides obtained in acetonitrile and DMSO, such as poly-DL-α-amino-*n*-butyric acid, poly-DL-*n*-valine, poly-DL-*n*-leucine, and poly-DL-valine, showed absorption bands at 1635 cm^{-1} and 1535 cm^{-1}. In the case of the poly-DL-leucine obtained in acetonitrile and DMSO, though,

the absorption bands of the polymers were found at 1655 and 1545 cm^{-1}.

The IR spectra of polyglycine obtained in acetonitrile was very similar to that of the polyglycine obtained in DMSO. These results are shown in Table 2.

X-Ray-Diffracion Diagrams. The X-ray diffraction pattern of oriented poly-γ-methyl-L-glutamate and poly-L-alanine have been extensively studied.[6-8] The diffraction pattern of oriented poly-γ-methyl-L-glutffmate of the α-form shows very strong peaks at 10.35 Å ($d_{10\bar{1}0}$) and around 4.4 Å. The diffraction diagram of this polymer obtained by the powder method showed strong peaks at 2θ=7.9° (d=10.25 Å) and 19.6° (d=4.4 Å), as is shown in Fig. 1. These peaks agreed with the peaks in the pattern of the oriented polymer, but the other peaks in the diagram were not observed clearly. The X-ray-diffraction pattern of oriented poly-L-alanine of the α-form showed strong peaks at 7.4 Å ($d_{10\bar{1}0}$) and 4.4 Å which belong to the flexible side chain in the polymer.[7] On the other hand, peaks at 4.37 Å (d) and 5.35 Å ($b/2$) have been observed in the poly-L-alanine of the β-form (d is the back-bone

peptides. X-Ray–diffraction diagrams obtained by the powder method of poly–peptides consisting of L-configurational α-amino acid obtained by polymerization in acetonitrile are shown in Fig. 3. All these diagrams showed two peaks like those of poly-DL- and poly-L-alanine obtained in acetonitrile. On the other hand, the diagrams of poly-L-α-amino-*n*-butyric acid and poly-L-*n*-valine obtained in DMSO showed three or four peaks, like those of poly-L-alanine obtained in DMSO with the β-form.[2] These patterns are shown in Fig. 4. The diagram of poly-L-α-amino-*n*-butyric acid showed peaks at $2\theta=12.4°$, 19.5,° and $2\theta=23.3°$, while that of poly-L-*n*-valine showed peaks at $2\theta=11.1°$, 19.5°, and $2\theta=22.7°$.

For polyglycine and poly-L-valine, the infrared spectra were not affected by the polymerization solvent used, but the diagrams of both these polymers were different from each other (Fig. 5). Diffraction diagrams obtained by the powder method of almost DL-configurational polypeptides showed two strong peaks in spite of the fact that these polypeptides showed β-conformational spectra. These results are shown in Fig. 6.

Reprecipitation Treatment of the polymers. It has been reported that poly-DL- and L-alanine are changed from the α- to the β-form when treated in dichloroacetic acid and in formic acid.[2] Poly-L-α-amino-*n*-butyric acid was changed from the β- to the α-form by treatment in dichloroacetic acid. However, poly-DL-α-amino-*n*-butyric acid did not change its conformation upon treatment with formic acid and dichloro acetic acid. These conclusions are based on the infrared spectra and X-ray-diffraction diagrams.

Experimental

The NCA's used in this study were prepared in a high purity (chlorine content less than 0.02%) by a method reported previously.[1] The polypeptides were also prepared by a method reported previously.[1] The results are shown in Tables 1 and 2.

The X-ray-diffraction diagrams and IR spectra were obtained as has been reported previously.[2]

The authors wish to thank the Ajinomoto Co., Ltd. for its gift of α-amino acids.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3490—3495 (1970)

A Study of the Partial Catalytic Oxidation of Hydrocarbons. V. The Effect of Phosphorus Addition to the Vanadium Catalyst on the Oxidation of Butene, Butadiene, and Furan

Mamoru Ai

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 18, 1970)

In the present investigation, the vapor-phase partial oxidation of *cis*-2-butene, butadiene, and furan was carried out over V_2O_5 and V_2O_5-P_2O_5, (1 : 1.6 atomic ratio), with various contact times, at 350°C, and at the concentration of 0.6—1.6% in air, in order to elucidate the effect of phosphorus addition to V_2O_5, on the selectivity and mechanism of butene oxidation. Oxidation activity decreased remarkably with an increase in the phosphorus content. In the presence of phosphorus (P/V=1.6), selectivity for the $C_4H_8 \rightarrow C_4H_6$ step and $C_4H_6 \rightarrow C_4H_4O$ step were considerably increased, from 46 to 88 and from 72 to 93 mol% respectively, while selectivity for the $C_4H_4O \rightarrow$maleic anhydride (MA) step fell from 60 to 50 mol%, due to the increase in polymer formation. From the results, it was concluded that V_2O_5 and V_2O_5-P_2O_5 catalysts show similar oxidation activity with regard to butene, butadiene, and furan, and that the quantities of the intermediate products are fairly much affected by the activity of the catalyst as well as by the difference in reactivity between the starting material and the intermediate over the catalyst.

Previous papers have studied the mechanism of the partial catalytic oxidation of butene, butadiene, crotonaldehyde, furan, (C_4H_4O), *etc.* over V_2O_5, V_2O_5-P_2O_5 and V_2O_5-MoO_3 catalysts,[1-4] and it has been proposed that, on V_2O_5-P_2O_5 (1 : 1.6 atomic ratio), the main reaction pathway for the catalytic oxidation of butene to maleic anhydride (MA) proceeds through the following successive steps:

$$C_4H_8 \rightarrow C_4H_8\ \text{ads.} \rightarrow C_4H_6\ \text{ads.} \rightarrow C_4H_4O\ \text{ads.} \rightarrow \text{MA}$$

Moreover, side reactions destined to complete combustion proceed parallel to the main pathway in each consecutive step, and the selectivity and the rate of maleic anhydride formation are determined by the steps after furan.[1]

By the addition of phosphorus to the V_2O_5 catalyst, the selectivity for maleic anhydride formation from butene was considerably increased; this may attributed to the increase in selectivity for the $C_4H_8 \rightarrow C_4H_4O$ steps, not for the $C_4H_4O \rightarrow$MA steps.[2]

In the present work, we attempted to ascertain how the phosphorus addition to the V_2O_5 catalyst affects each reaction step in the step-by-step oxidation of butene to maleic anhydride formation, and to elucidate this effect on the mechanism and the selectivity of the partial catalytic oxidation of butene, butadiene, and furan.

Experimental

The vapor-phase air oxidation of butene, butadiene, and furan was carried out over vanadium and vanadium-phosphorus (V : P=1 : 1.6 atomic ratio) oxide catalysts in an ordinary flow-type reaction system at atmospheric pressure as has been shown in previous papers.[1,2] The reactor was a steel tube (1.8 cm id) whose surface was coated with aluminium; it was immersed in a molten lead bath.

The volume concentrations of the reactants were 0.6—1.0% in air, the flow rate (at 25°C) was kept at 1.5 *l*/min, and the contact time, which was defined as the ratio of the catalyst volume (m*l*) to the flow rate, was varied from 0.006 to 1.8 sec. The reaction temperature was always kept at 350°C. The exit gases leaving the reactor passed first through a series of three hot, and then four cold, packed water scrubbers in order to recover the solid and volatile acids and carbonyl compounds. At the end of 2 hr, the contents of the scrubbers were collected and a sample was titrated with 0.1 N NaOH, using a pH meter. The yields of maleic and other acids were calculated from the titration curves. The reactant gas, the exit gas, and a sample of the water-scrubber contents were analyzed by means of gas chromatography.

The following method was employed to prepare the catalysts. V_2O_5 catalyst: NH_4VO_3 was disolved in hot water by using oxalic acid, and then pumice, with a mesh size of from 10 to 20, was added; the solution was then evaporated with constant stirring, and finally dried in an oven at 130°C. The amount of pumice was 400 m*l*/g atom of vanadium. V_2O_5-P_2O_5 catalyst:

1) M. Ai, K. Harada and S. Suzuki, *Kogyo Kagaku Zasshi*, **73**, 524 (1970).
2) M. Ai, T. Niikuni and S. Suzuki, *ibid.*, **73**, 165 (1970).
3) M. Ai, *ibid.*, **73**, 946 (1970).
4) M. Ai, *ibid.*, **73**, 950 (1970).

NH_4VO_3 and H_3PO_4 were dissolved in water (P/V= 1.6 atomic ratio), and the solution was heated with constant stirring. After it had evaporated nearly to dryness, the paste-like substance remaining was molded into pellets 3×3 mm in size, and finally these were dried at 130°C. The activation of the catalysts was performed under flowing air, at 500°C, for 5 hr.

In an earlier paper dealing with the oxidation of butene[2], we used a series of unsupported V_2O_5-P_2O_5 catalysts and learned that P_2O_5-poor catalysts show a failure in mechanical strength. Therefore, in this work, we used pumice for the V_2O_5 catalyst in order to increase its mechanical strength. It was confirmed that this supported V_2O_5 catalyst showed the same catalytic performance as the unsupported V_2O_5 catalyst prepared by the simple evaporation of the NH_4V_3O-$C_2H_2O_4$ solution.[2] It can be considered, therefore, that the external surface of the pumice is coated with a thick layer of V_2O_5 that there is no practical difference in surface structure between supported and unsupported V_2O_5 catalysts.

Results and Discussion

Effects of Phosphorus Addition on the Oxidation Activity. The rates of the oxidation of butene, butadiene, and furan over V_2O_5 or V_2O_5-P_2O_5 catalysts can be considered to be of the first order*1 for the reactant concentration under the reaction conditions used here. The rate constants at 350°C (k sec^{-1}) over both V_2O_5 and V_2O_5-P_2O_5 were calculated for each reactant from the conversion-contact time data, they are shown as functions of the phosphorus content in Fig. 1. The oxidation activity of the catalyst decreased markedly upon the addition of phosphorus to V_2O_5, even when the quantity added was very small. The reactivities of all these reactants on these catalysts were of about the same magnitude. For example, the activity of V_2O_5-P_2O_5 (1 : 1.6 atomic ratio) catalyst was about one-thirtieth that of the V_2O_5 catalyst alone. However, the extent of the deactivation by phosphorus addition was about the same for the butene, butadiene, and furan oxidations. The results are listed in Table 1.

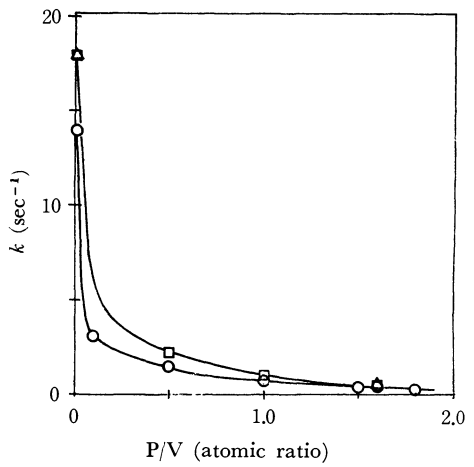

Fig. 1. Oxidation rate constant at 350°C (k sec^{-1}) as a function of P_2O_5/V_2O_5 ratio.
○: butene △: butadiene □: furan

*1 log (C_0/C) is proportional to the contact time (W/F).

Table 1. Oxidation rate constant at 350°C: k (sec^{-1})

Reactant	C_4H_8	C_4H_6	C_4H_4O
$k^{I}(V_2O_5)$	14	18	18
$k^{II}(V_2O_5$-$P_2O_5)$	0.4	0.6	0.6
k^{II}/k^{I}	1/35	1/35	1/30

Effects of Phosphorus Addition on the Maleic Anhydride Formation. The formation of maleic anhydride from butene, butadiene, and furan over V_2O_5 and V_2O_5-P_2O_5 catalysts at 350°C is shown is a function of the reactant conversion in Figs. 2 and 3. Selectivities to maleic anhydride are given as a slope of the curves.

The V_2O_5 catalyst has a high oxidation activity in comparison with V_2O_5-P_2O_5, but it showed only a poor selectivity to maleic anhydride: less than 20%. When butene conversion was more than 70%, the formation of maleic anhydride decreased; therefore, it did not exceed 15 mol%. In the case of butadiene oxidation, however, the selectivity to maleic anhydride was 43%, fairly good in comparison with that from butene. From

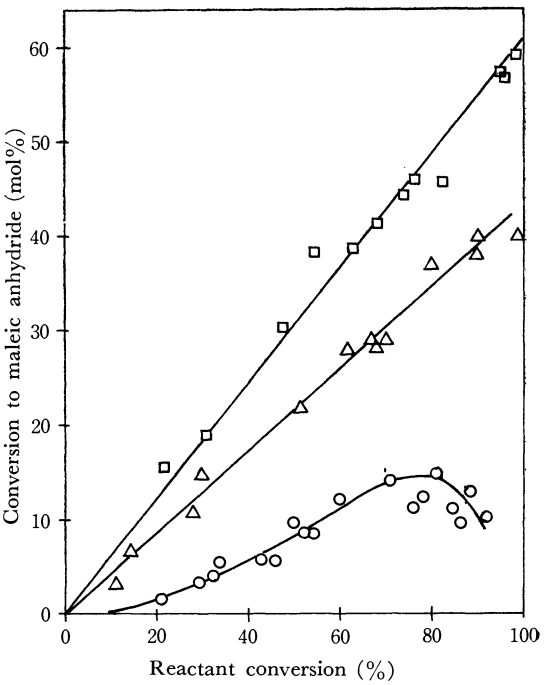

Fig. 2. Effect of reactants on maleic an hydride formation over V_2O_5 catalyst.
○: butene △: butadiene □: furan

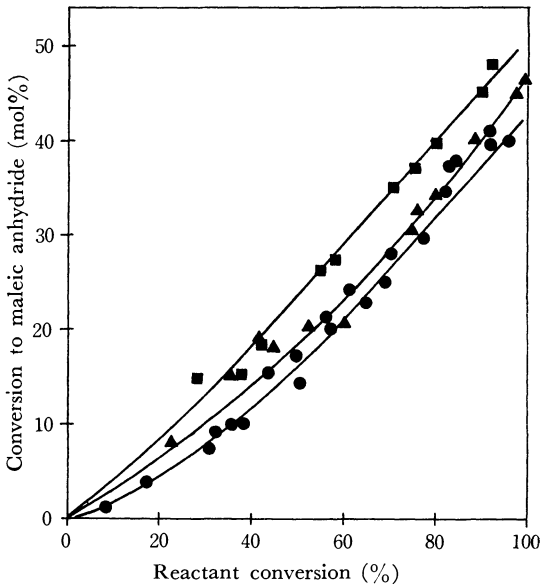

Fig. 3. Effect of reactants on maleic anhydride formation over V_2O_5-P_2O_5 (1 : 1.6).
●: butene ▲: butadiene ■: furan

furan oxidation, the selectivity to maleic anhydride became higher, as was expected, and reached 60 mol%. The decrease in selectivity to maleic anhydride at high conversion may be caused by the destruction of the maleic anhydride formed (Fig. 6); this tendency was more remarkable in the case of butene oxidation than in the cases of butadiene and furan. This phenomenon is probably to be attributed at least in part, to the fact that the reactivity of butene is lower than that of butadiene or furan, *i.e.*, the oxidation of butene requires severer condition, but for a more definite explanation, more studies will be required.

On the other hand, the V_2O_5-P_2O_5 (1 : 1.6) catalyst, whose activity was fairly low, showed a good selectivity, for butene to maleic anhydride (42%), while, in the selectivity to maleic anhydride, no marked difference was observed among the butene, butadiene, and furan oxidations, although it increased slightly in this order, as had been expected. The results are summairzed in Table 2.

Table 2. Selectivity to maleic anhydride (%)

Catalyst	Reactant		
	C_4H_8	C_4H_6	C_4H_4O
V_2O_5	20	43	60
V_2O_5-P_2O_5 (1 : 1.6)	42	46	50

Effect of Phosphorus Addition on the Reaction Pathway. From a perusal of the data in Table 2, the selectivities towards the main reaction pathway in each consecutive step, such as $C_4H_8 \rightarrow C_4H_6 \rightarrow C_4H_4O \rightarrow MA$, were calculated; for example, the selectivity in the $C_4H_6 \rightarrow C_4H_4O$ step over the V_2O_5 catalyst was found to be that, from 100 mol of C_4H_6, 43 mol of MA are formed. As the selectivity in the $C_4H_4O \rightarrow MA$ step is 60%, the portion destined to become by-products in the $C_3H_4O \rightarrow MA$ step is $40/60 \cdot 43 = 29\%$. The sum $(43+29=72)$ corresponds to the selectivity in the $C_4H_6 \rightarrow C_4H_4O$ step. In the same manner, the selectivity in $C_4H_8 \rightarrow C_4H_6$ step can also be obtained. The results are shown in Table 3.

Table 3. Selectivities of the steps (%)

Steps	$C_4H_8 \rightarrow C_4H_6$	$C_4H_6 \rightarrow C_4H_4O$	$C_4H_4O \rightarrow MA$
V_2O_5	46	72	60
V_2O_5-P_2O_5	88	93	50

On the other hand, the portions of the main and the side reactions in each consecutive step, based on 100 mol of reacted butene, can be calculated from the value of the selectivity in each step (Table 3). From the results obtained, the probable scheme of butene oxidation over V_2O_5 and V_2O_5-P_2O_5 catalysts may be proposed to be as follows (the notations in brackets mean selectivity):

V_2O_5 catalyst

$$100\ C_4H_8 \xrightarrow[(54/46)]{46} C_4H_6 \xrightarrow[(28/72)]{33}$$
$$\downarrow 54 \qquad \downarrow 13$$

$$C_4H_4O \xrightarrow[(40/60)]{20} MA$$
$$\downarrow 13 \leftarrow \text{by-products}$$

V_2O_5-P_2O_5 catalyst (P/V=1.6)

$$100\ C_4H_8 \xrightarrow[(12/88)]{88} C_4H_6 \xrightarrow[(7/93)]{83}$$
$$\downarrow 12 \qquad \downarrow 5$$

$$C_4H_4O \xrightarrow[(50/50)]{42} MA$$
$$\downarrow 41 \longrightarrow \text{by-products}$$

The results reveal that:

(1) With the V_2O_5 catalyst, the selectivity to maleic anhydride from butene oxidation is mainly determined by the low selectivity of the $C_4H_8 \rightarrow C_4H_4O$ step (33%), especially in the $C_4H_8 \rightarrow C_4H_6$ step (46%).

(2) In the case of butene oxidation, selectivity to the side pathway destined to form by-products was twice that in the butadiene oxidation.

(3) The presence of phosphorus in V_2O_5 increases the selectivities of both the $C_4H_8 \rightarrow C_4H_6$ and $C_4H_6 \rightarrow C_5H_4O$ steps: from 46 to 88% and from 72 to 93% respectively, while in the $C_4H_4O \rightarrow MA$ step, on the other selectivity to maleic anhydride falls from 60 to 50%.

(4) The incorporation of phosphorus with

V_2O_5 has little effect on the selectivity of butadiene to maleic anhydride. It may be considered that, even over the V_2O_5 catalyst, the selectivity to the side pathway in the $C_4H_6 \rightarrow C_4H_4O$ step is not very important (28%), that the favorable effect of phosphorus addition is not very efficient in this step, and that it is cancelled by its unfavorable effect in the $C_4H_4O \rightarrow$MA step.

Side Reaction in the $C_4H_4O \rightarrow$MA Step. On both V_2O_5 and V_2O_5-P_2O_5 catalysts, the major products from furan oxidation were maleic anhydride, CO_2, CO, the polymer, and a small amount of acetic acid (3—5% for the maleic anhydride formed). Since the reactivity of acetaldehyde, ketones, *etc.* were not great in these reaction conditions, they had to be found in the product gases, if they existed at all. Thus, it can be considered that furan was oxidized directly to maleic anhydride, CO, CO_2, and the polymer, without proceeding *via* some stable intermediate products. The selectivities in this process may be listed as follows:

	Catalyst	V_2O_5	V_2O_5-P_2O_5
Furan →	MA	60%	50%
	$CO + CO_2$	30%	30%
	polymer	10%	20%

The amount of the polymer was obtained as the remainder in the mass-balance of the products (Fig. 4).

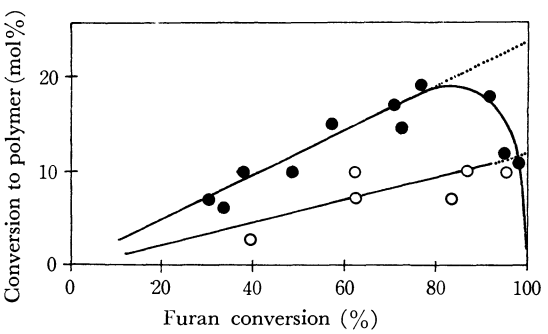

Fig. 4. Polymer formation *verses* furan conversion.
○: V_2O_5 ●: V_2O_5-P_2O_5 (1 : 1.6)

With the addition of phosphorus in V_2O_5, the formation of the polymer doubled at the expense of a decrease in the maleic anhydride formation. It may be considered that polymer formation is promoted by phosphorus, which probably produces some acid species in the catalyst.

Side Reaction in $C_4H_8 \rightarrow C_4H_4O$ Steps. Many sorts of products from butene, butadiene, and furan oxidation on the V_2O_5-P_2O_5 catalyst have been already reported in the previous paper[1], while on the V_2O_5 catalyst, the major by-products were CO and CO_2, with the others being almost negligible except for small quantities of acetone and acrolein (2—3%). From butene oxidation on V_2O_5, very much acetaldehyde (AcH) and acetic acid (AcOH) were formed (Fig. 5). We have represented here the value of the conversion AcH+AcOH, assuming that two moles of AcOH+AcH are formed from one mole of butene, although it is not clear if two moles are formed or only one mole.

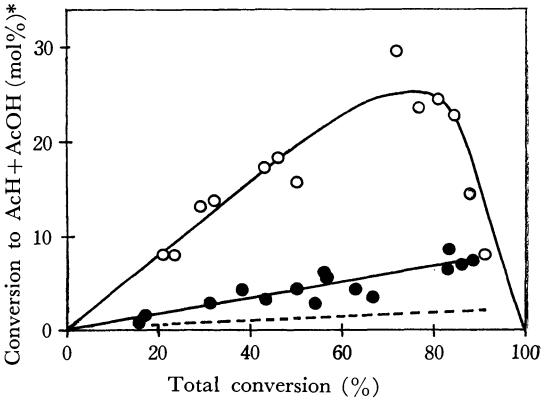

Fig. 5. Conversion to AcH+AcOH* *versus* total conversion.
* basing on the assumption that 2 mol of AcH+AcOH are formed from 1 mol of C_4 compound.
solid line: butene oxidation (○: V_2O_5, ●: V_2O_5-P_2O_5)
dashed line: butadiene oxidation on V_2O_5 or V_2O_5-P_2O_5

The results reveal that:

(1) On both V_2O_5 and V_2O_5-P_2O_5 catalysts, about one half of the side reaction in the $C_4H_8 \rightarrow C_4H_6$ step leads to AcOH+AcH formation, and the other half, to complete combustion: CO, CO_2, *etc.*

(2) Selectivity to the side reaction of butene is twice as much as that of butadiene, a difference which may be attributed to the tendency to scission of a double-bond of butene. Therefore, it may be concluded that the selectivities to complete combustion are of about the same magnitude between butene and butadiene.

CO and CO_2 formation are shown as functions of the maleic anhydride formed in Figs. 6 and 7. The selectivity ratio of CO or CO_2 formation to maleic anhydride is described as a slope of the curve. Over the V_2O_5-P_2O_5 catalyst, the CO_2 formation was independent of the sort of reactants; this indicates that the sources of the CO_2 formation are the $C_4H_4O \rightarrow$MA steps. Moreover, the selectivity ratio of CO_2 to maleic anhydride decreased with an increase in the reactant conversion. In the $C_4H_8 \rightarrow C_4H_4O$ steps, only CO was formed as a complete combustion product, and the ratio increased with the reactant conversion. On the other hand, on the V_2O_5 catalyst, CO_2 is formed also in the $C_4H_8 \rightarrow C_4H_4O$

steps, but CO is still predominant.

Amounts of Intermediate Products. The amounts of the intermediates formed in the oxidation of butene and butadiene to maleic anhydride are plotted as a function of the reactant conversion (Figs. 8 and 9). In all the cases investigated, they passed through a maximum at a reactant conversion of about 50%.

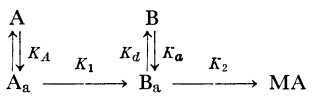
The consecutive reaction on the catalyst surface can be explained by the following reaction scheme[5]:



where A is the starting material; B, the intermediate, and MA, the fully-oxygenated compound (maleic anhydride), and where the subscript "a" means "adsorbed."

A steady-state treatment based on the assumption that A_a is in equilibrium with A results, after the elimination of the time and integration[5], in:

5) J. H. de Boer and R. J. A. M. van der Borg, Actes du Deuxieme Congres Internationale de Catalyse, Editions Thechiq, Paris, (1961), p. 919., and P. Zwietering and F. Hartog, *J. Catal.*, **2**, 79 (1963).

$$B = \frac{S}{r-1}(A-A^r)$$

where:

$$r = \frac{K_a K_2}{K_1 K_A (K_2+K_d)}, \quad S = \frac{K_d}{K_2+K_d}$$

A and B are the mole fractions of the starting material and the intermediate in the reaction product. K_a is adsorption equilibrium constant; K_1 and K_2, the reaction rate constants, and K_a and K_d, the adsorption and desorption rate constants.

The values of r and S for butene and butadiene oxidation over both V_2O_5 and V_2O_5-P_2O_5 were calculated from the maximum amount of the primary intermediate products (butadiene from butene and furan from butadine) and the reactant conversion at this point. They are shown in Table 4.

Table 4. r and S values

Steps	$C_4H_8 \rightarrow C_4H_6 \rightarrow$		$C_4H_6 \rightarrow C_4H_4O \rightarrow$	
Catalyst	V_2O_5	V_2O_5-P_2O_5	V_2O_5	V_2O_5-P_2O_5
r	2	2	2	2
S	0.14	0.41	0.13	0.31
k*	18	0.6	18	0.6

* for intermediate oxidation at 350°C

The results reveal that the value of r, which represents the reactivity ratio of feed to the primary intermediate, remains almost unchanged with the variation in reactants and catalyst composition, and that V_2O_5 and V_2O_5-P_2O_5 catalysts show similar oxidation activities for butene, butadiene and furan. It can be concluded that a satisfactory yield of oxygenated intermediates can not be expected from these vanasium-type catalysts.

On the other hand, the value of S, which represents the portion of the intermediate that leaves the surface, increases with a decrease in the oxidation activity of the catalyst; this means that the higher the catalyst activity becomes, that is, the stronger the intermediate adsorption becomes, the larger the portion of the adsorbed intermediate species which goes directly into the next step, without desorbing to the gas phase.

The amount of the intermediate products was considerably affected by the activity of the catalyst as well as by the difference in reactivity between the starting material and the intermediate over the catalyst. Therefore, a mild catalyst is indispensable in order to obtain good yields of intermediate products.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3496—3500 (1970)

The Acetylation of 2,3-Dimethyl-*bz*-halobenzofurans and Some Reactions of the Products*[1]

Yoshiyuki KAWASE and Sachiko HORI

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received March 12, 1970)

The acetylation of *bz*-chloro- and *bz*-bromo-2,3-dimethylbenzofurans with acetyl chloride and aluminum chloride in carbon disulfide at room temperature was studied; it was found that the acetylation occurred at the 6- or 4-position, which is activated by the furan ring, regardless of whether the halogen atom is at the *o*-, the *m*-, or the *p*-position. In the cases of 7-halo compounds, diacetylation occurred to give the 4,6-diacetyl compounds, and the migration of the bromine atom of 6-acetyl-5-bromo-2,3-dimethylbenzofuran and of the methyl ester of the corresponding carboxylic acid occurred, as a result of the action of aluminum bromide in carbon disulfide at room temperature, to give the 4-bromo compounds. The haloketones thus obtained were then converted to the corresponding carboxylic acids by the bromoform reaction.

The acetylation of 2,3-dimethylbenzofuran and its derivatives, which have various substituents, *e.g.*, hydroxyl,[1] methoxyl,[2] alkyl,[3–5] acetamide,[6] methoxycarbonyl,[7] and acetyl[7–9] groups on the benzene ring, has previously been reported. It has been reported that the acetylation of 7-chloro-2,3-dimethylbenzofuran (**18a** afforded the 4-acetyl compound[10] (**19a**).

Now, in the present experiments, the acetylation of several halo-2,3-dimethylbenzofurans (**5a**, **8a**, **11a**, **11b**, **18a**, and **18b**) was carried out, the acetyl group of the compounds was converted to the carboxyl group, and the bromine atom of 5-bromo-6-acetyl and -6-methoxycarbonyl compounds (**12b** and **16**) migrated to the 4-position as a result of the action of aluminum bromide.

2,3-Dimethyl-5-[11] and -7-halobenzofurans[10,12] (**11a**, **11b**, **18a**, and **18b**) were prepared readily by the reported method through the cyclodehydration of 3-aryloxybutanones, but the 4- and 6-halo compounds (**5a**, **5b**, **8a**, and **8b**) could not be prepared by a similar procedure; the cyclization of 3-(*m*-halophenoxy)butanones (**2a** and **2b**) by sulfuric acid or polyphosphoric acid afforded only crude products, which were found by NMR spectroscopy to be mixtures of the 4- and 6-halo compounds (**5a** and **8a** or **5b** and **8b**). Therefore, the pure 4- and 6-chloro-2,3-dimethylbenzofurans (**5a** and **8a**) were prepared by the Sandmeyer reaction of the corresponding amino compounds[13] (**1** and **3**) (see Chart 1). In the NMR spectra, the 4-halo compounds have the peaks corresponding to the 3-methyl protons in the field lower by about 0.3 ppm than the isomeric 6-halo compounds have; the ratio of the 4- and 6-halo compounds of the mixtures was determined by estimating areas of the peaks.

The acetylation of 4- and 6-chlorobenzofurans (**5a** and **8a**) with acetyl chloride and aluminum chloride in carbon disulfide at room temperature afforded the 6- and 4-acetyl compounds (**6** and **9**) respectively, in which the positions of the acetyl groups were determined by NMR spectroscopy. They have two doublets of $J=1$—3 Hz corresponding to aromatic, two-meta protons. The

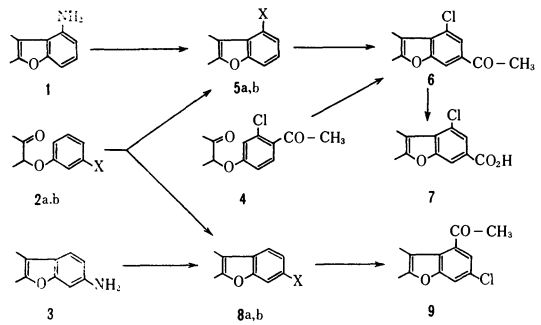
chloroketone **6** was also unexpectedly obtained from 3-(*p*-acetyl-*m*-chlorophenoxy)butanone (**4**) by cyclization with polyphosphoric acid; this also caused a migration of the acetyl group (see Chart 1).

The acetylation of 5-chloro- and 5-bromo-2,3-dimethylbenzofurans (**11a** and **11b**) afforded the 6-acetyl compounds (**12a** and **12b**), while that of 7-chloro- and 7-bromobenzofurans (**18a** and **18b**) afforded the 4-acetyl compounds (**19a** and **19b**) (see Charts 2 and 3). The positions of the acetyl groups were determined by NMR and UV spectroscopy. In the NMR spectra, **12a** and **12b** have two singlets corresponding to aromatic, two-para protons, while **19a** and **19b** have two doublets of $J=7$ Hz corresponding to aromatic, two-ortho protons. However, the positions of the acetyl groups of **19a** and **19b** were not clear from the NMR data; they might be at the 4- or 6-positions, although they seemed to be at the 4-positions, judging from the patterns of the UV spectra, which were comparable to each other and to that of 4-acetyl-2,3-dimethylbenzofuran[14] (see Table 4). The isomeric 5-acetyl-2,3-dimethyl-7-halobenzofurans (**24a** and **24b**) were also prepared by the cyclization of 3-(*p*-acetyl-*o*-halophenoxy)butanones (**23a** and **23b**), which had been prepared by the action of 3-chlorobutanone on *m*-halo-*p*-hydroxyacetophenones (**22a** and **22b**). In the case of the acetylation of the 7-halobenzofurans (**18a** and **18b**), diacetylation occurred to give 4,6-diacetyl compounds (**21a** and **21b**) when double amounts of the reagents were used, analogously to the case of 7-alkyl compounds.[5,8,9] The diacetyl, compound **21a** was also obtained by the acetylation of the ketone **19a**.



For all chart: a) X=Cl, b) X=Br

Chart 1

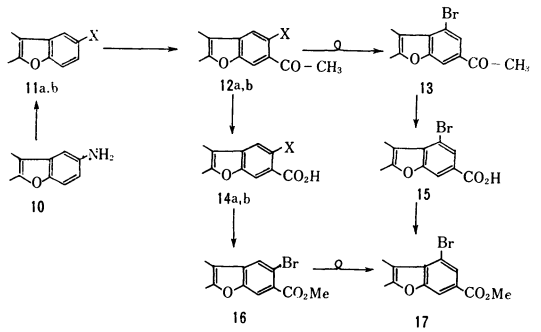


Chart 2

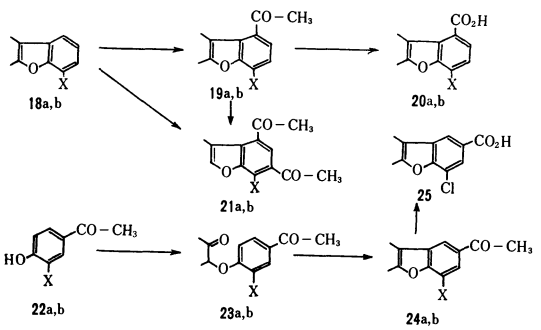

Chart 3

It is found from these results that, in the electrophilic substitution, all the positions on the benzene ring of 2,3-dimethylbenzofuran, especially the 6- and then 4-positions, are activated by the furan ring, and that the acetylation occurs at the 6- or 4-position, regardless of the position of the halogen atom.

The action of aluminum bromide in carbon disulfide at room temperature on the 5-bromoketone (**12b**) thus obtained caused a migration of the bromine atom to the 4-position to give 4-bromoketone (**13**), analogously to the case of 6-acetyl-5-alkyl-2,3-dimethylbenzofurans.[5,8,14] The structure of the migrated compound (**13**) was confirmed by NMR and UV spectroscopy. In the NMR spectra, it has two doublets of $J=2$ Hz corresponding to aromatic, two-meta protons, and the peak corresponding to the 3-methyl protons is in a low field, indicating that the halogen atom is at the 4-position. In the UV spectra, the haloketones (**12a** and **12b**) have two peaks, at around 225 and 290 mμ, while the haloketones (**6** and **13**) have additional peaks at around 240 mμ, such as do 6-acetyl-4- and -5-alkylbenzofurans.[14]

Further, the haloketones (**6**, **12a**, **12b**, **13**, **19a**, **19b**, and **24a**) thus obtained were converted to the corresponding carboxylic acids (**7**, **14a**, **14b**, **15**, **20a**, **20b**, and **25** respectively) by the bromoform reaction. The bromine atom of the methyl ester (**16**) of 5-bromo-6-carboxylic acid (**14b**) also migrated, as a result of the action of aluminum bromide, to the 4-position, to give methyl 4-bromobenzofuran-6-carboxylate (**17**), which was identical with the sample obtained by the esterification of the acid (**15**).

Experimental

All the melting points and boiling points are uncorrected, the UV spectra were measured on a Hitachi

139 spectrophotometer, and the NMR spectra were measured on a JEOL JNM-C-60H (60 MHz) spectrometer. Detailed data are summarized in Tables 1—4.

Aryloxybutanones (2a, 2b, 4, 23a, and 23b). Potassium carbonate (80 g) was added to a solution of *m*-chlorophenol (25 g) and 3-chlorobutanone (22.7 g) in acetone (200 m*l*), and the mixture was refluxed for 8 hr. Most of the acetone was distilled off, and the residue was treated with water and then extracted with ether. The ethereal solution was washed with an aqueous sodium hydroxide solution, and the residual product from the ether solution was distilled to give 3-(*m*-chlorophenoxy)butanone (**2a**), bp 136—143°C/18 mmHg, 20.5 g (53%). Similarly, 3-(*m*-bromophenoxy)butanone (**2b**), 3-(*p*-acetyl-*m*-chlorophenoxy)butanone (**4**), and 3-(*p*-acetyl-*o*-chloro- and -bromophenoxy)butanones (**23a** and **23b**) were also prepared by this procedure.

Cyclization of the Aryloxybutanones. *a) By Sulfuric Acid.* Concentrated sulfuric acid (10 g) was stirred into **2a** (10 g) with cooling below 30°C, and the mixture was kept at 30°C for 1 hr. The cooled mixture was then poured into ice water and extracted with ether, and the residual product from the

a) s: Shoulder.

ether solution was distilled to give a crude product, bp 135—138°C/27 mmHg, 6.8 g (75%), which was found by the NMR spectrum to be a mixture of 4- and 6-chlorobenzofurans (**5a** and **8a**). Analogously, the product from **2b** was also a mixture of 4- and 6-bromo compounds (**5b** and **8b**).

b) By Polyphosphoric Acid. A mixture of **2a** (10 g) and polyphosphoric acid (n=2.5, 200 g) was heated at 100°C for 1.5 hr. The cooled mixture was poured into ice water and extracted with ether, and the residual product from the ether solution was distilled to give a mixture of the 4- and 6-chloro compounds (**5a** and **8a**), bp 132—135°C/19 mmHg, 6.4 g (70%). Analogously, a mixture of **5b** and **8b** was also obtained from **2b**. 6-Acetyl-2,3-dimethyl-7-halobenzofurans (**24a** and **24b**) were obtained from **23a** and **23b** by the same procedure; in the case of the aryloxybutanone (**4**), there was also a migration of the acetyl group to give 6-acetyl-4-chloro-2,3-dimethylbenzofuran (**6**).

Chlorobenzofurans (5a, 8a, and 11a) by the Sandmeyer Reaction. 4-Amino-2,3-dimethylbenzofuran[13] (**1**) (3 g) was diazotized and then treated with cuprous chloride in the usual manner[15] to give **5a**, bp 120—130°C/20 mmHg, 1.2 g (35%). Similarly, 5- and 6-chloro-2,3-dimethylbenzofurans (**11a** and **8a**) were also prepared from amines (**10** and **3**).

Acetylation of Halobenzofurans (5a, 8a, 11a, 11b, 18a, and 18b) and Chloroketone (19a). Anhydrous aluminum chloride (1 g) was stirred, with cooling, into a solution of **5a** (1 g) and acetyl chloride (0.5 g) in carbon disulfide (50 m*l*); after the mixture had then been stirred at room temperature for 4 hr, it was poured into ice water. The resulting mixture was extracted with chloroform, and the chloroform solution was washed with an aqueous sodium hydroxide solution. The residual product from the chloroform solution was distilled and then crystallized from cyclohexane to give 6-acetyl-4-chloro-2,3-dimethylbenzofuran (**6**), mp 89.5—90°C, 0.7 g (58%). Similarly, 4-acetyl-6-chloro-, -7-chloro-, and -7-bromo-2,3-dimethylbenzofurans (**9**, **19a**, and **19b**), and 6-acetyl-5-chloro- and -5-bromo-2,3-dimethylbenzofurans (**12a** and **12b**) were also obtained. The acetylation of 7-chloro- and 7-bromobenzofurans (**18a** and **18b**) by double amounts of reagents afforded 7-chloro- and 7-bromo-4,6-diacetyl-2,3-dimethylbenzofurans (**21a** and **21b**); **21a** was also obtained by the acetylation of the haloketone **19a**.

Migration of the Bromine Atom of Bromoketone (12b) and Bromoester (16). Anhydrous aluminum bromide (10.4 g) was stirred into a solution of **12b** (5.2 g) in carbon disulfide (70 m*l*); after the mixture had been stirred for 4 hr, it was then treated such as has been described for the acetylation. The product was distilled and crystallized from cyclohexane to give 6-acetyl-4-bromo-2,3-dimethylbenzofuran (**13**), mp 98—99.5°C. 2 g (38.5%). Similarly, methyl 4-bromo-2,3-dimethylbenzofuran-6-carboxylate (**17**) was obtained from **16**.

Haloacids (7, 14a, 14b, 15, 20a, 20b, and 25) by the Bromoform Reaction. A solution of the chloroketone **6** (1 g) in dioxane (20 m*l*) was stirred, with cooling, into an aqueous sodium hypobromite solution, prepared by the addition of bromine (3.4 g) to a cold mixture of sodium hydroxide (2 g), water (6 m*l*), and ice (6 g); the mixture was stirred for 30 min at 15°C and then for 1.5 hr at 45°C. The cooled solution was extracted with ether, and the aqueous layer was acidified after the addition of a small amount of sodium sulfite. The precipitates thus formed were crystallized from methanol to give 4-chloro-2,3-dimethylbenzofuran-6-carboxylic acid (**7**), mp 220—221°C, 0.7 g (63%). Similarly, 4-bromo-, 5-chloro-, 5-bromo-, and 7-chloro-2,3-dimethylbenzofuran-6-carboxylic acids (**15**, **14a**, **14b**, **and 25**) and 7-chloro- and 7-bromo-2,3-dimethylbenzofuran-4-carboxylic acids (**20a** and **20b**) were also prepared.

Esterification of the Acids (14b and 15). The acids were esterified by refluxing them for 8 hr with methyl sulfate and sodium carbonate in acetone; the product was crystallized from cyclohexane to give two esters (**16** and **17**).

The authors are grateful to the members of the Laboratory of Analysis, Faculty of Pharmacology, Toyama University, for doing the microanalyses and NMR spectroscopy.

Liquid Phase Chlorination of Olefins with Cupric Chloride. II. Stereochemistry of the Reactions of 2-Butenes and Cyclohexene

Takashi KOYANO

Central Research Laboratory, Toa Nenryo Kogyo Co., Oi-machi, Iruma-gun, Saitama

(Received April 13, 1970)

Chlorination of *cis*-and *trans*-2-butenes with cupric chloride yields a mixture of *meso*- and *dl*-2,3-dichlorobutanes with *meso*/*dl* ratio of about 60/40, which is almost independent of the starting olefin configuration. For cyclohexene, *trans*-1,2-dichlorocyclohexane is accompanied with the *cis*-dichloride, the amount of which depends upon the solvent polarities. In all cases the starting olefins and the product dichlorides are sufficiently stable under the reaction conditions. The results indicate that open ionic intermediates are involved in the chlorination of simple olefins in liquid phase reaction.

The stereochemical sequence of addition of molecular chlorine to olefins in polar media varies with the structure of the substrate. Stereospecific *trans* addition has been observed for the reactions with 2-butenes in acetic acid,[1] di-*t*-butylethylenes in methanol,[2] and 2-pentenes in various polar solvents including acetic acid and methanol.[3] Chlorination of 1-phenylpropenes in acetic acid and in methanol,[1] and phenanthrene[4] or methyl *trans*-cinnamate[5] in acetic acid leads to mixtures of stereoisomeric dichlorides. It is generally accepted that the chlorination of simple alkenes proceeds *via* a chloronium ion intermediate, while that of conjugated olefins occurs *via* an open carbonium ion. The same conclusion has been drawn for non-polar chlorination, evidenced by reactions with 2-butenes,[6] cyclohexene,[7] and *trans*-stilbene.[8]

Similarly, chlorination of 2-butenes with cupric chloride is highly stereoselective in vapor phase reaction.[9] The formation of *cis*-addition products has been attributed to olefin isomerization and interconversion of 2,3-dichlorobutane diastereomers.[10] The chlorination product of cyclohexene with cupric chloride in acetic acid has been reported to be *trans*-dichloride practically with no *cis*-isomer,[11,12] and a bridged type intermediate has been proposed.[13]

However, when 2-butenes were treated with cupric chloride in methanol, isomeric dichlorides were formed where the product composition is almost the same regardless of the starting olefin configuration.[14] The present studies were undertaken in order to obtain further evidence on the stereochemistry of the cupric chloride chlorination in liquid phase. The results with 2-butenes and cyclohexene give a clue to solve the nature of the reaction intermediate.

Results

Chlorination of either *cis*- or *trans*-2-butene with cupric chloride was carried out in several polar solvents at 100—150°C. The principal products were *dl*- and *meso*-2,3-dichlorobutanes with a small amount of 2-chloro-3-methoxybutanes.[14] The compositions of the dichlorides are shown in Table 1.

Comparing results from the same reaction conditions, we see that the ratios of *meso* to *dl* dichlorides are very similar for both 2-butenes, although slightly larger for *trans*-2-butene. The extent of 2-butene isomerization was too small to account for. Isomerization between the dichlorides was not observed in methanol under the reaction conditions,[14] and no significant variation in the dichloride com-

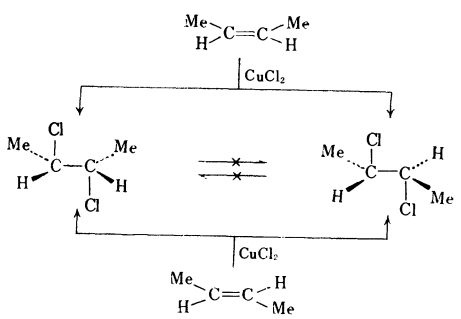
position with the reaction time was observed, *e.g.*, in the case of *cis*-2-butene at 120°C. It appears that the results reflect the kinetically controlled product composition.



The stereochemistry of chlorination of cyclohexene with cupric chloride was also studied at 150°C (Table 2). The reaction products were mainly dichlorides with small quantities of by-products which were not analyzed. The composition of dichlorides was determined by means of gas chromatography. The results with two different columns (C and D) coincided well with each other (within a variation of 0.5%), proving the identity of *cis*-dichloride. The portion of *cis* compound increases with decrease in polarity of the solvent. In this case also no isomerization occurred between two isomeric dichlorides at 150°C in the presence of cupric chloride, so that the *cis* dichloride must have been formed directly from the starting olefin.

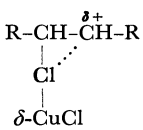
Discussion

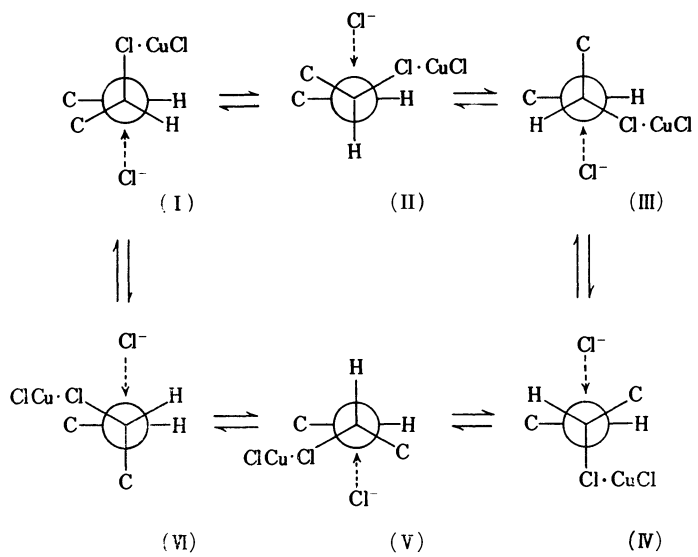
The lack of stereospecificity in the results cannot be ascribed to prior isomerization of the olefin or to secondary isomerization of the product dichlorides, since the olefins and the dichlorides have been shown to be stable under the reaction conditions. The results of the 2-butene chlorination are most reasonably interpreted by an assumption that the intermediate consists of two convertible isomeric species, one being the precursor to the *meso* dichloride and the other to the *dl* compound, the composition of which is the same for both starting *cis*- and *trans*-olefins. This can only be attained by rotation along the central C=C bond of the substrate. Therefore, the intermediate complex resembles an open type cation, in which the rotation is faster than the attack of second chlorine to establish an equilibrium, rather than a bridged chloronium ion. Radical mechanisms are improbable in such polar solvent reactions in the presence of oxygen and in the dark.

There is a tendency that *dl* formation is comparatively favored in less polar solvents, obviously in the hydroxylic series. The reason for the slight discrepancy in acetic acid and nitromethane is not clear, but it is probably due to their somewhat different solvent characters.*1

The chlorine species in the reaction intermediate should not be a free cationic chlorine as is suggested in the addition of a chlorine molecule to simple alkenes[1-3] where a strong chlorine bridging is characteristic. Thus, when chlorine of cupric chloride attacks olefin in an electrophilic manner, a fairly large interaction can be expected between the attacking chlorine and the remaining CuCl group. Then, because of some electron cloud localization on Cl–CuCl bond, polarizability of the chlorine is decreased, which is reflected in almost no bridging interaction to the cationic center and leaves the intermediate open enough for free rotation. However, a faint bridging might still exist in view of the slight preference for *trans* addition, which appears in the slightly larger *meso*/*dl* ratio for *trans*-2-butene than for *cis*-2-butene reaction.



Among six possible relative configurations of the intermediate complexes of free rotation, III and IV are assumed to be the most stable rotamers as the *dl* and the *meso* precursors, respectively, since they are less crowded and suffer less interference between the substituents than the other four. The less polar the solvents, the larger the interaction between Cl and CuCl in attacking $CuCl_2$ should be, due to disadvantage in charge separation. Therefore, in such cases, the bulkiness of the first attacking group increases, so that IV would have a tendency to shift toward III owing to increasing steric repulsion between Cl–CuCl group and methyl group on the adjacent carbon. Thus, the *meso* dichloride formation becomes less favorable in less polar solvents.



*1 In acetic acid, there is some evidence that it reacts on cupric chloride to form copper(II) acetate by releasing hydrogen chloride.[12] On the other hand, methanolysis of cupric chloride is improbable and no green solid (Cu(OMe)Cl)[16] or blue solid $(Cu(OMe)_2)$[16,17] was detected in the reaction mixture.

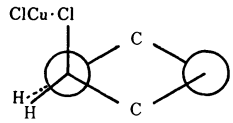
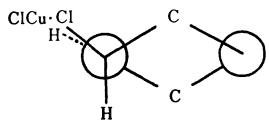
17) G. Costa, A. Camus and N. Marsich, *ibid.*, **27**, 281 (1965).

The formation of some *cis*-1,2-dichlorocyclohexane from cyclohexene strongly suggests that the intermediate complex is also of an open type. By analogy with photochlorination of chlorocyclohexane,*2 the intermediate may assume an *axial* conformation (VII) rather than an *equatorial* one (VIII). The latter is unfavoravle because



(VII)



(VIII)

of repulsion between eclipsing Cl–CuCl group and hydrogen. Thus, chloride ion*3 attacks VII preferentially from the *axial* side to yield the *trans* product, since the two incoming chlorine species are farther apart in transition state than in the case of an *equatorial* attack. However, in less polar solvents, increasing tightness of Cl–CuCl bond causes the first attacking group to be more bulky. As a result of greater repulsion between Cl–CuCl group and *axial* hydrogens on the ring, some inversion (or distortion) toward the *equatorial* conformation (VIII) would occur. In VIII, the difference in steric requirements between *axial* attack and *equatorial* attack is not pronounced and *cis* compound would result from the *axial* attack.

Experimental

Materials. *cis*- and *trans*-2-Butenes (pure grade, Takachiho Chemical Industrial Co.) were used. Cyclohexene (Koso Chemical Co.) was distilled under N_2 after drying over Na_2SO_4, which was gas chromatographically pure. Cupric chloride was of anhydrous GR grade (Koso). Methanol (GR, Koso) was distilled from $Mg(OMe)_2$, and acetic acid (GR, Koso) from $B(OAc)_3$[19] under N_2. The other solvents were commercially available purest reagents, distilled prior to use. Authentic *meso*- and *dl*-2,3-dichlorobutanes were synthesized by addition of chlorine to *trans*- and *cis*-2-butenes.[20] *trans*-1,2-Dichlorocyclohexane was prepared by chlorine addition to cyclohexene,[21] and *cis*-dichloride was prepared by chlorination of *trans*-2-chlorocyclohexanol[22] with $SOCl_2$[21].

Analytical Methods. The reaction products were analyzed by gas chromatography with He as a carrier gas. The apparatus, column and temperature were as follows. For dichlorobutanes: (A) Shimadzu GC-2C, dioctyl sebacate (plus sebacic acid) on Chromosorb W, 120°C; (B) Shimadzu GC-4APT, Igepal CO-990 on Diasolid L, 100°C. For dichlorocyclohexanes: (C) the same as B, 180°C; (D) Shimadzu GC-4APT, Ucon -50-HB5100 on Chromosorb P, 160°C. For analysis of 2-butenes: (E) Shimadzu GC-3AH, propylene carbonate plus glutaronitrile on Chromosorb W, room temp.

Reaction of 2-Butenes. In a 500 m*l* glass-lined autoclave (with a glass-coated thermo-well and an agitator made of Ta metal) were placed cupric chloride (6.05 g, 0.045 mol) and solvent (150 m*l*), and after slight evacuation on cooling 2-butene (*ca.* 17 g, 0.30 mol) was introduced from a pressure bottle. The autoclave was heated in an oil bath (+1.0°C) with stirring. After the reaction, the autoclave was cooled to room temperature and the reaction solution was immediately subjected to gas chromatographic analysis. The results were shown in Table 1.

When *cis*-2-butene (containing 0.4% *trans*) was reacted with cupric chloride in methanol at 150°C for 2 hr, the waste gas consisted of 97.1% *cis* and 2.9% *trans*. For *trans*-2-butene (100% *trans*) under the same reaction conditions, the composition of the waste gas was 99.0% *trans* and 1.0% *cis*.

Reaction of Cyclohexene. Cyclohexene (0.82 g, 0.01 mol), cupric chloride (1.34 g, 0.01 mol) and solvent (30 m*l*) were sealed in a 50 m*l* glass tube, which was then placed in a 500 m*l* autoclave. The autoclave was heated at 150°C (±1.0°C) with an oven for 2 hr with shaking (75/min). The reaction solution was taken out and analyzed by gas chromatography. The results are summarized in Table 2.

Stability of Dichlorocyclohexane. *trans*-1,2-Dichlorocyclohexane (1.53 g, 0.01 mol) was treated with cupric chloride (1.34 g, 0.01 mol) in methanol or acetic acid (30 m*l*), being placed in a 50 m*l* glass sealed tube, at 150°C for 2 hr with shaking. No *cis*-1,2-dichlorocyclohexane was detected in the reaction mixture by gas chromatography. Similarly, when a mixture (*cis* 47.1%, *trans* 52.9%) of dichlorides (0.51 g, 3.3 mmol) in methanol (10 m*l*) was heated with cupric chloride (0.45 g, 3.3 mmol) or cuprous chloride (0.33 g, 3.3 mmol) in a 15 m*l* glass sealed tube at 150°C for 8 hr, no fluctuation of the composition of dichlorides was observed.

The author is indebted to Professor Naoki Inamoto for valuable discussions and also to Dr. Shozo Wada for encouragement in this work.

*2 2-Chlorocyclohexyl radicals were discussed in literature.[18] The present intermediate should resemble this radical closely because of its open chain character.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3505—3510 (1970)

A Study on the Photochemistry of α,β-Unsaturated γ-Lactones. I. The Structures of the Photodimers of 4-Hydroxycrotonic Acid γ-Lactone*1

Kazuya OHGA and Taku MATSUO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received April 27, 1970)

The structures of the photodimers obtained from 4-hydroxycrotonic acid γ-lactone under several conditions were determined. The products of irradiations in the solution were a pair of *anti* dimers: one is a *head-to-head* cyclo-adduct, and the other a *head-to-tail* adduct. The corresponding product in the solid state, on the other hand, was a *head-to-head* cyclo-adduct in the *syn* form.

Irradiation of 2-cyclopentenone and 2-cyclohexenone has been well known to afford the photodimers only in the *anti* forms.[1] In the case of coumarine, however, a photodimer in the *syn* form was obtained provided that the reaction was carried out in polar solvents.[2] The stereo-specificities of these photo-dimerizations are very important both from theoretical and from practical points of view. In this connection, we studied the photochemical reactions of 4-hydroxycrotonic acid γ-lactone (I), the most simple α,β-unsaturated γ-lactone, in the liquid phase*2 and also in the solid state. Three photodimers with a cyclobutane ring were obtained: two from the liquid phase and one from the solid state irradiations. The molecular structures of these photodimers were determined as described in the present paper.

Results and Discussion

Irradiation of I in polar solvents with a low-pressure mercury lamp yielded white, crystalline materials (yields calculated as the dimers, 20—30%). The solid material was later confirmed to consist of two components, Ia and Ib. At first, Ia was separated by recrystallizations. Several chemical treatments on the remaining fraction eventually yielded Ib″, which was identified with Ib as described in the experimental section. Irradiation of I in the solid state at low temperature (−78°C) with the same low-pressure mercury lamp yielded Ic (yield calculated as the dimer, 26%). The molecular weights, the results of elementary analyses, and the characteristic IR absorption bands indicate that Ia, Ib″(Ib), and Ic are isomeric dimers of I as shown in Table 1.

On the basis of the results of treating Ia, Ib″ and Ic with alkaline and then with acidic reagents, each of the above isomeric dimers is suggested to possess a lactone ring in the molecular structure. The NMR spectra also are in agreement with the proposed structure with a cyclobutane ring for each isomer as shown in Fig. 1. All of the conceivable structures of the dimers are listed in Fig. 2.

In order to distinguish the above stereo-isomers, the isolated products were oxidized at first. Ia was oxidized with potassium permanganate in acidic media, and then esterified with diazomethane. The product (overall yield, 54%) was identified with the authentic sample of 1,2,3,4-*cis, trans, cis*-tetramethoxycarbonyl cyclobutane (abbreviated to *cis, trans, cis*-TMCCB, hereafter), as prepared according to the method of Griffin *et al.*[3] by the NMR and IR spectra and the mixed melting-point measurements. *cis, trans, cis*-TMCCB was also obtained (yield, 69%) by the esterification of the oxidation products of Ib′, which was a dimer of 4-hydroxycrotonic acid obtained by the

*1 Contribution No. 207 from the Department of Organic Synthesis, Faculty of Engineering, Kyushu University.

*2 Photodimerization of the same compound was reported also by Odaira and his associates at the Discussion Meeting on the Photochemistry (Tokyo, November, 1967), where the present authors partially presented their results reported here.

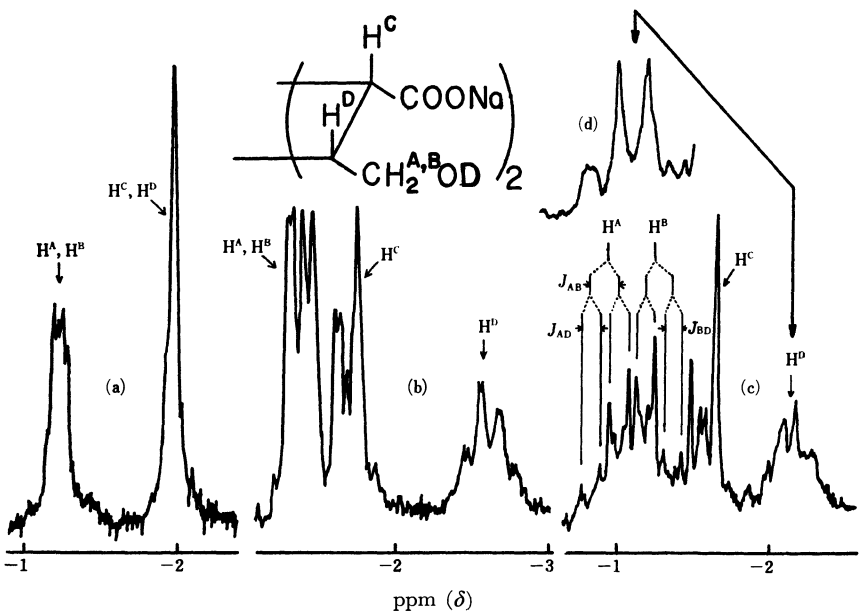

Fig. 1. NMR spectra of photodimers in 4 N NaOD/D_2O solution.
(a): Ia, (b): Ib'', (c): Ic (ν_{AB}=18, J_{AB}=11, J_{AD}=8, and J_{BD}=7 Hz), and (d): the methylene proton signals of Ic when H^D protons were decoupled (difference frequency, +65 Hz). The chemical shifts were measured from the internal H_2O signal.

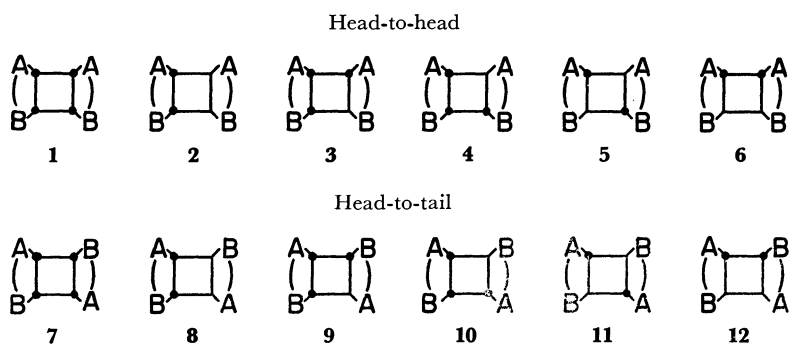

Fig. 2. Conceivable geometrical isomers of the photodimers.
The symbols A and B stand for C=O and CH_2O groups, respectively.

hydrolysis of Ib as described in the experimental section. As to TMCCB, it has been established that the most stable isomer is the one with the four methoxycarbonyl groups in all *trans* form.[3] Among the twelve isomers in Fig. 2, the isomers 5 and 11 are surely expected then to give *trans, trans*-TMCCB. Four other isomers (**3**, **4**, **9** and **10**) will end up with either *cis, cis, trans*- or *trans, trans, trans*-TMCCB. Thus, the experimental results of oxidations are taken to indicate that neither Ia nor Ib could be one of the above six stereo-isomers (**3**, **4**, **5**, **9**, **10** and **11**). Since the

yield of *cis, trans, cis*-TMCCB is fairly high, the isomers **1** and **7** should be also eliminated from the list of the possible isomers.

At this point, one should notice that among the remaining four isomers (**2, 6, 8** and **12**), the isomer **2** alone does not have any symmetry element. In other words, one can expect that the isomer **2** exists as a racemate. This expectation was verified by resolving Ib′ into a pair of optically active isomers as described in the experimental section. The optical activities still remained even after the lactone ring was formed again (Fig. 3). Therefore, Ib (Ib″) is uniquely assigned to a racemate corresponding to the structure **2** in Fig. 2.

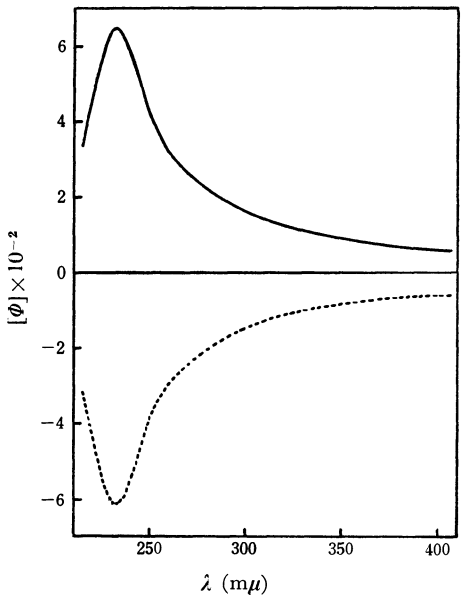

Fig. 3. ORD curves of Ib″(Ib) in acetonitrile at 24°C. The solid line represents (+)-enantiomer, and dotted line represents (−)-enantiomer.

For the rest, the isomers **6** and **12** are *trans* adducts, where the presence of extremely high steric strain is expected of the *trans*-fused lactone ring. Once such highly-strained lactone ring is opened, it will be quite difficult to be restored. Since **Ia** can be recovered from the alkaline solution, however, more easily than Ib, Ia can not be one of those *trans* adducts. Consequently, Ia may be assigned to the remaining *anti* dimer as represented by the structure **8** in Fig. 2.

On the other hand, Ic was converted into *cis, cis, cis*-TMCCB by the oxidation followed by the esterification (yield, 10%). From thermodynamicals points of view, *cis, cis, cis*-TMCCB is the most unstable among the stereo-isomers under discussion. Hence, Ic is suggested to be one of the two *syn* dimers (**1** and **7**) in Fig. 2, which will afford *cis, cis, cis*-TMCCB without any epimerization.

The structure of Ic may be further elucidated by the investigation of the NMR spectra. The methylene proton signals of Ic are much more complicated than those of Ia and Ib (Fig. 1). Then, the geminal protons of the methylene group in Ic are suspected to be in magnetically non-equivalent environments. In agreement with this suggestion, the methylene proton signals of Ic appear as a pattern close to AB type when H^A and H^B protons are decoupled from H^D (Fig. 1). The NMR parameters (J_{AB}=11 Hz. ν_{AB}=18 Hz), thus obtained, are successfully applied to analyze the original signals of the methylene protons of Ic. In the case of the isomer **1** in Fig. 2, the geminal protons are certainly in magnetically non-equivalent environments. This is not true in the case of the isomer **7**, however, because there is a plane of symmetry which contains the carbon atom of the methylene group under consideration. Therefore, Ic is assigned to the isomer **1** in conclusion.

In short, the photodimerization of I in solution was found to afford a pair of *anti* dimers. One of them was a *head-to-tail* dimer (Ia), and the other was a *head-to-head* dimer (Ib). The scheme for the chemical separation and the structures of the dimers, thus determined, are summarized in Fig. 4. Because of the extremely low solubilities of the photodimers, the IR spectra could not be used in order to determine the isomer ratio. On the same reason, it could not be possible either to convert the dimers into more soluble derivatives suited to quantitative analysis. Then, the NMR spectra obtained in NaOD solutions were used to estimate the relative yield of the isomers. Even in this case, however, accurate data could not be obtained either because the signals of the two isomers overlapped each other. On the basis of the NMR spectra, anyhow, the relative yield of Ia was approximately the same as that of Ib, when the aqueous solution of I (0.2 M) was irradiated with a low-pressure mercury lamp. The relative yield of Ia with respect to Ib increased as the solvent was changed from water to acetonitrile and then to acetic acid.

The effect of internal irradiations with a high-pressure mercury lamp was also investigated. The same photodimers as above were obtained from the benzene or formic acid solutions of 4-hydroxycrotonic acid γ-lactone, provided that acetone was present in the solution. The relative yield of Ib with respect to Ia was higher in formic acid than that in benzene. Since the water jacket surrounding the lamp was made of pyrex glass, the most of the light should have been absorbed by acetone in these cases. In other words, the dimerization of I could be sensitized by acetone.

Although more quantitative data are required to clarify the mechanistic details of the present

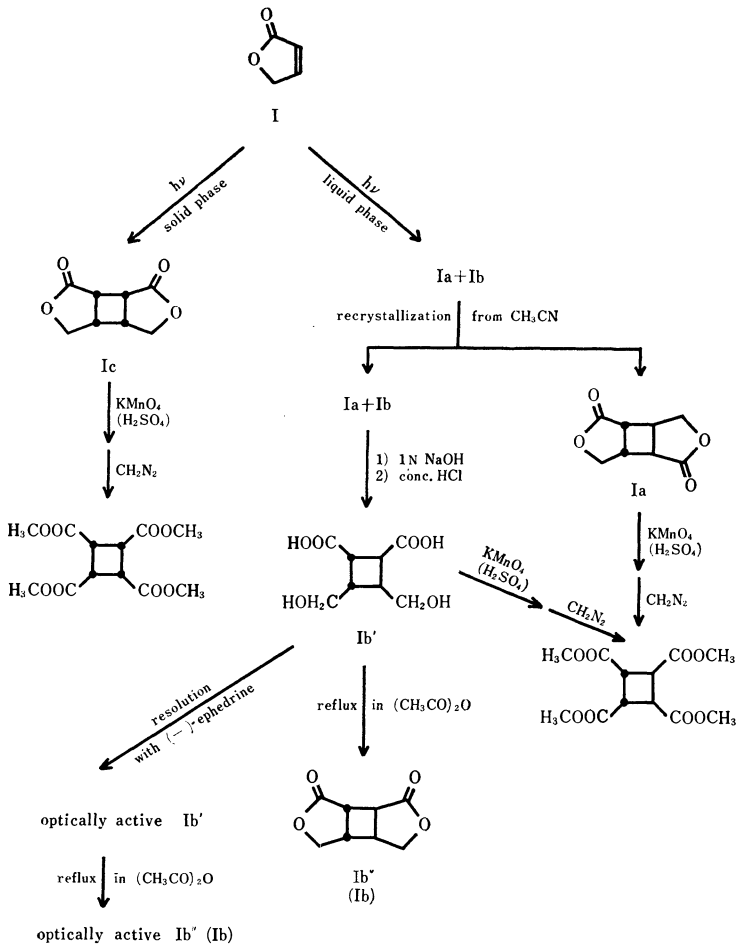

Fig. 4. The scheme for the chemical separation and the structure determination of the photodimers.

reaction, one may conclude now that at least a part of the reaction proceed *via* a triplet state. It is not clear, however, whether the photodimerization induced by the direct excitation of 4-hydroxycrotonic acid γ-lactone also proceeds *via* a triplet state or not. In any case, it should be noticed that the products of the present reactions are *anti* dimers just as in the cases of 2-cyclopentenone and 2-cyclohexenone. The solvent dependence of the isomer ratio is also interesting enough to be investigated. The investigation of this kind, however, should be waited until some reliable means for quantitative analysis are established in future.

Irradiation of I in the solid state with the low-pressure mercury lamp, on the other hand, yielded a *head-to-head, syn* dimer (Ic). The structure of the molecular crystal may be responsible for the unique mode of dimerization.

Experimental

Instrumental Analysis. The IR spectra were obtained with KBr disk on a JASCO Model DS-301 IR spectrophotometer. The NMR spectra were measured with a Varian Model A-60 analytical NMR spectrometer combined with a Varian Model V-5068A spin decoupler. The photodimers were dissolved in 4N deuterated alkali metal hydroxide solutions and the water signal was used as the internal standard. 1,2,3,4-Tetramethoxycarbonylcyclobutanes were measured as the deuteriochloroform solution with tetramethylsilane as the internal standard. The mass spectrum of Ia was recorded on a Hitachi Model RMU mass spectrometer, and the rest on a JEOL Model JMS-01SG spectrometer. The optical rotatory dispersion curves were measured with a JASCO Model ORD/UV-5 optical rotatory dispersion recorder by the use of a 1 dm cell. The melting points were measured on a Yanagimoto micro melting-point measurement apparatus and are uncorrected.

Preparation of 4-Hydroxycrotonic Acid γ-Lactone (I). The preparation of I was carried out, according to the method of a literature,[4] through hydrolysis of glycerol-α-cyanohydrin and purification with

4) J. W. E. Glattfeld, G. Leavell G. E. Spieth and D. Hutton, *ibid.*, **53**, 3164 (1931).

aqueous silver nitrate solution, followed by distillation under reduced pressure (bp 90.0°C/13 mmHg). The distillate showed a single peak on inspection by the gas chromatography (25% Silicon DC200 on Shimalite, 2.25 m×3 mm). The NMR spectra were also in good agreement with that reported by Freeman.[5] UV absorptions: ε, 8.0×10^3 (at 206 mμ, the absorption maximum), 1.6×10^1 (at 254 mμ) in water; ε, 3.4×10^3 (at 216 mμ), 2.5×10^1 (at 254 mμ) in *n*-hexane.

Irradiation of the Solution with a Low-Pressure Mercury Lamp. In the experiments with various solvent such as acetic acid, acetonitrile, and water, the solution (0.2—0.6 M) was internally irradiated with a 30 W low-pressure mercury lamp (Riko-Sha UVL 303 Q) equipped with a quartz jacket. The reactions were carried out at temperatures between 20 and 30°C in nitrogen atmosphere. White crystals had separated out of the solution during the irradiation which continued for the period of 20—30 hr.

Irradiation of the Solution with a High-Pressure Mercury Lamp. Either benzene solution (0.6 M) or formic acid solution (0.4 M) of I was internally irradiated with a high-pressure mercury lamp (Riko-Sha UVL-700P) equipped with a pyrex water-jacket for the period between 40 and 50 hours at 20°C. Acetone was added as the sensitizer: 0.7 M for the benzene solution and 0.1 M for the formic acid solution, respectively.

Irradiation of I in the Solid State. The reaction vessel containing neat liquid of I was held so that one side could be dipped into a dry ice-methanol mixture. The vessel was rotated slowly. After a short period of time, the wall was coated with a thin film of I. Then the vessel was held in the dry ice-methanol mixture, and was internally irradiated with the above-mentioned low-pressure mercury lamp under nitrogen flow.

Isolation of the Isomers. After the irradiation of the solution, the solvent and the raw material were removed by distillation under reduced pressure to leave white crystalline materials. Recrystallization of the crystalline materials from acetonitrile afforded pure samples of Ia (mp 292—293°C). The filtrate was dissolved into 1 N sodium hydroxide solution, and the pH of the solution was adjusted with concentrated hydrochloric acid to a value between 2 and 4. At this point, Ib′ separated out as white crystals. The presence of both hydroxyl and carbonyl groups was indicated by the IR spectra (KBr disk, 3360 (broad); 3260; 3100—2400 (broad); 1722 and 1700 cm^{-1}). Since the same treatments on Ia could only reproduce Ia, the origin of Ib′ must be a compound Ib but not Ia. Ib′ was quantitatively converted into a lactone Ib″ (mp 280—281°C, as recrystallized from acetonitrile) by refluxing the acetic anhydride solution for 3 hr. Ib′ was also converted into Ib″ during the measurement of the melting point. On the basis of the above behaviors, Ib′ was suggested to be a dimer of 4-hydroxycrotonic acid obtained by the hydrolysis of Ib. In agreement with this suggestion, the mass spectra of Ib′ showed a peak (m/e= 168) which corresponded to a fragmention formed on the release of two water molecules from the molecular ion. Furthermore, Ib′ was resolved into a pair of optically active isomers as described later. The results of elementary analyses of the isomers were also in good agreement with the values calculated from the dimer of 4-hydroxycrotonic acid.

On the treatment with alkaline and then with acid solutions, Ib″ afforded Ib′. Hence Ib″ was identified with Ib, the counterpart of Ia in the original mixture. This suggestion was verified by comparing the IR, far IR, and NMR spectra of the concerning materials.

Ic was easily separated from I, after the irradiation, by the same procedure as described in the cases of the irradiation of the solution. The obtained solid material was purified by recrystallization from acetone (mp 235—236°C). Ic was recovered again when the sample was dissolved into sodium hydroxide solution, and then acidified with hydrochloric acid.

Oxidation and Esterification of Ia. Ia (168 mg) was suspended in 15 m*l* of 0.7 N sulfuric acid, and aqueous solution (20 m*l*) of potassium permanganate (520 mg) was added dropwise into it under vigorous stirring. The reaction temperature was kept to 60°C by the use of a water bath. After 2 hr, sodium hydrogensulfite was added to the solution, and then 2 N sodium hydroxide solution was added until the solution became basic to litmus. The solution was acidified with concentrated hydrochloric acid. The acidic solution was evaporated to dryness and the residue was extracted with 100 m*l* of dry acetone by the use of a Soxlet extractor. Diazomethane in ether was added to the extracts dissolved in methanol at 0°C. The solution was evaporated to dryness. The residue was purified by the column chromatography on a silica gel column with benzene-ethyl acetate (20 : 1) as the eluting solvent, and then recrystallized from benzene. Yield, 154 mg (54%); mp 149.0—150.5°C; Found: C, 50.08; H, 5.64%. Calcd for $C_{12}H_{16}O_8$: C, 50.00; H, 5.60%. The product was identified with *cis*, *trans*, *cis*-TMCCB by means of the mixed melting point measurements and comparison of the NMR and IR spectra with those of the authentic sample, prepared by the method of Griffin *et al.*[3]

Oxidation and Essterification of Ib′. Ib′ (77 mg) was oxidized at 70°C by the similar procedure applied to Ia (1.6 N sulfuric acid, 240 mg $KMnO_4$/5 m*l* H_2O). After the reaction was completed, methanol was added to the solution, which was succeedingly made basic to litmus with 2 N sodium hydroxide solution. Manganese dioxide was filtered off and the filtrate was acidified with concentrated hydrochloric acid, and thne evaporated to dryness. The residue was extracted, treated with diazomethane as described in the case of Ia. The product was also purified as above, and was identified with *cis*, *trans*, *cis*-TMCCB. Yield, 77 mg (69%); mp 148—150°C; Found: C, 50.07; H, 5.66%. Calcd for $C_{12}H_{16}O_8$: C, 50.00; H, 5.60%.

Oxidation and Esterification of Ic. Ic (163 mg) was oxidized and esterified by the same procedure as applied to Ia. The product was purified by the column chromatography on a silica gel column with ethyl acetate as the eluting solvent and then recrystallized from methanol. Yield, 29 mg (10%); mp 222—223°C; Found: C, 49.97; H, 5.57%. Calcd for $C_{12}H_{16}O_8$: C, 50.00; H, 5.60%. The IR spectra (KBr) presented the same characteristic absorption bands as those of *cis*, *cis*, *cis*-TMCCB[6] at 2990 (m), 2940 (m), 2845 (w),

5) R. Freeman *Mol. Phys.*, **5**, 499 (1962).

6) M. Avram, I. G. Dinulescu, E. Marica, G. Mateescu, E. Slaim and C. D. Nenitzescu, *Chem. Ber.*, **97**, 382 (1964); G. W. Griffin and D. Veber, *J. Amer. Chem. Soc.*, **82**, 6417 (1960).

1743 (vs), 1452 (m), 1437 (m), 1350 (s), 1220 (s), 1195 (vs), 1175 (vs), 1115 (m), 1072 (m), 955 (m), 830 (m), 770 (m) cm^{-1} (w: weak, m: medium, s: strong, vs: very strong). The NMR spectrum ($CDCl_3$ solution) consisted of two singlet peaks at 3.64 and 3.73 ppm (the ratio of the area under the peak, 1 : 3). The mass spectrum gave the base peak at *m/e* 257, which corresponds to the loss of a methoxyl group from the molecular ion. On the basis of these data, the product is identfied with *cis, cis, cis*-TMCCB.

Resolution of Ib′. Ib′ (342 mg) was dissolved into 30 m*l* of methanol containing 508 mg of (−)-ephedrine. The solution was concentrated to 2 m*l* and then 15 m*l* of acetonitrile was added to it. After the solution was allowed to stand overnight, the salt crystallized out (334 mg, mp 130—136°C). Recrystallization was repeated twice by the similar procedure (yield, 193 mg; mp 134.5—135.5°C). The purified salt was decomposed with dilute hydrochloric acid. The separated white needles were filtered off and washed with water and methanol. Yield, 68 mg; Found: C, 46.40; H, 6.14%. Calcd for $C_8H_{12}O_6$: C, 47.06; H, 5.92%. The characteristic IR absorption bands (KBr disk) were found at 3400 (broad), 3320, 3100—2400 (broad), 1715 and 1693 cm^{-1}. This compound, (+)-Ib′, exhibited a positive Cotton effect curve in 0.2 N sodium hydroxide solution (C, 0.600) at 24°C: $[\Phi]_{690}$ +20°, $[\Phi]_{589}$ +28°, $[\Phi]_{235}$ +311° (infl.), $[\Phi]_{218}$ +492°. The filtrate, which contained the fraction of more soluble ephedrine salt of Ib′, was treated with dilute hydrochloric acid as above. The isolated acid was purified by the treatment with aqueous sodium hydroxide solution and then with concentrated hydrochloric acid. Yield, 59 mg. Found: C, 46.62; H, 6.13%. Calcd for $C_8H_{12}O_6$: C, 47.06; H, 5.92%. The IR spectrum was similar to that of (+)-Ib′. This compound, (−)-Ib′, exhibited a negative Cotton effect curve in 0.2 N sodium hydroxide (C, 0.695) at 24°C: $[\Phi]_{690}$ −23°, $[\Phi]_{589}$ −32°, $[\Phi]_{235}$ −327° (infl.), $[\Phi]_{218}$ −522°.

Preparation of Optically Active Ib. Dehydration of (+)-Ib′ with acetic anhydride gave optically active Ib which exhibited a negative Cotton effect curve in acetonitrile. Repeated recrystallization from acetonitrile afforded a pure sample (mp 288—289°C). In the same way, (−)-Ib′ was dehydrated to give the other enantiomer which exhibited a positive Cotton effect curve in acetonitrile (mp 290.0—290.5°C). These enantiomers showed characteristic IR absorption bands at 1778, 1755, 1179 and 1160 cm^{-1}. The ORD curves of the same compounds (Fig. 3) in acetonitrile at 24°C are as the following: (a) the (+)-enantiomer (C, 0.250): $[\Phi]_{690}$ +20°, $[\Phi]_{589}$ +23°, $[\Phi]_{232}$ +646° (peak), $[\Phi]_{214}$ +332°, and (b) the (−)-enantiomer (C, 0.642): $[\Phi]_{690}$ −19°, $[\Phi]_{589}$ −22°, $[\Phi]_{232}$ −614° (trough), $[\Phi]_{214}$ −317°.

The authors are grateful to Dr. H. Kobayashi and Mr. H. Saito at the Department of Organic Synthesis of Kyushu University, for their helpful suggestions in the resolution of the optical isomers. Thanks are also due to Dr. I. Aiga and T. Matsui. at the Biotron Institute of the same university, and Miss. Y. Inatsu at the Faculty of Medicine, for their helps in the measurements of ORD and mass spectra, respectively. The authors are also indebted to Hitachi Manufacturing Co., Ltd., and Japan Electron Optics Laboratory Co., Ltd. for the measurements of mass spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3511—3514 (1970)

Synthesis of Poly-malonylpolymethylenes*1

Kiyotada MATSUI, Sadaichi MUROTANI,*2 Tetsuro NOJIRI and Masatoshi MOTOI

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa

(Received May 4, 1970)

Treatment of acetic anhydride with aliphatic dibasic acid chloride in the presence of 3 equivalents of aluminum chloride in nitrobenzene at 50°C afforded a polymer with the structure assigned to poly-malonylpolymethylene, R–[$(CH_2)_m$–$COCH_2CO]_n$–$(CH_2)_m$–R, (R=–COOH and/or $-COCH_3$, n=8—16). Polymalonyl-heptamethylene, -hexamethylene and -pentamethylene were prepared and their properties were recorded. The product obtained by the reaction of acetic anhydride with adipoyl chloride seems to have a few cross-linkings in its structure.

In a previous report[1] it was suggested that polymalonylphenylene could be synthesized by the reaction of ethyl acetoacetate with terephthaloyl chloride in the presence of aluminum chloride according to the following reaction:

$$CH_3COCH_2COOC_2H_5 + C_6H_5COCl \xrightarrow[-CH_3COCl,\ -CO_2,\ -C_2H_5Cl]{AlCl_3} (C_6H_5CO)_2CH_2$$

However, a polymer was obtained which might be considered to be an aluminum chelate polymer consisting of phenylene and malonyl groups, some of which have a carbethoxy group. The polymer insoluble in ordinary organic solvents could not be freed from aluminum, and therefore was supposed to have three-dimensional structure containing some methine carbon atoms as in tribenzoylmethane, a minor product in the above reaction.

This paper deals with the synthesis of polymalonylpolymethylene with a linear structure. In order to exclude reactions favorable for cross-linking formation as much as possible, several comparative and preliminary experiments using azelaoyl chloride in the presence of aluminum chloride were carried out with ethyl acetoacetate, acetyl chloride or acetic anhydride. The product was separated into a benzene-soluble and a benzene-insoluble fraction, from which an acetone-insoluble substance (if present) was removed, then the molecular weights of the fractions were determined. The reaction conditions and results are summarized in Table 1.

Treatment of ethyl acetoacetate with an equimolar quantity of azelaoyl chloride in the presence of aluminum chloride in nitrobenzene gave only a benzene-soluble product of low molecular weight at 50°C. Use of acetyl chloride in place of ethyl acetoacetate afforded a benzene-insoluble product contaminated with an acetone-insoluble substance, which increased with incease of acetyl chloride. In the case of acetic anhydride the benzene-insoluble product of relatively high molecular weight, obtained in a slightly lower yield, increased slightly with the increase of aluminum chloride. When the amount of azelaoyl chloride increased from 0.2 to 1 molar excess, an acetone-insoluble substance was formed and obtained as a single product in a high yield. The acetone-insoluble substance, from which aluminum could not be removed by the usual procedure, seems to have a three-dimensional structure owing to the acylation caused by the excess of acid chloride. For preparation of the required linear polymer, use of acetic anhydride is found to be most suitable.

Other than polymalonylheptamethylene, polymalonyl-hexamethylene and -pentamethylene were also prepared in a similar manner from acetic anhydride using suberoyl and pimeloyl chloride, respectively. Treatment with adipoyl chloride gave a benzene-insoluble product containing a small amount of an acetone-insoluble substance. The details and properties of the polymers are given in Table 2.

From the fact that dibenzoylmethane is obtained by the reaction[2] of acetic anhydride or acetyl chloride with benzoyl chloride under a similar reaction condition, it seems that the polymer consists of malonyl and polymethylene groups. This is also supported by the formation of either its alkali salt insoluble in water only in the case of a polymer of higher molecular weight, or its copper complex (*e.g.*, copper content of the polymalonyl-

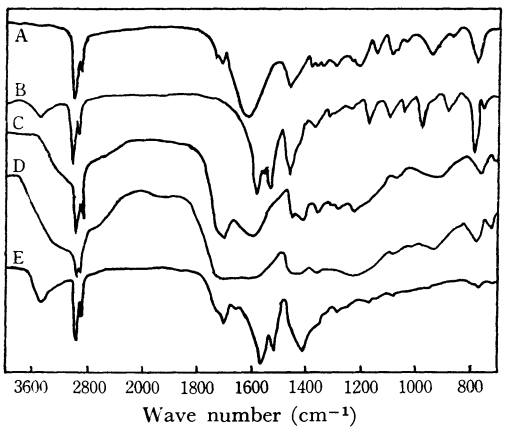

Fig. 1. Infrared spectrum of di-*n*-butyrylmethane (NaCl plate)(A); its copper chelate(KBr disk)(B); benzene-soluble polymalonylheptamethylene (NaCl plate)(C); benzene-insoluble polymalonylheptamethylene(NaCl plate)(D); and its copper chelate(KBr disk)(E).

heptamethylene complex was 11—15%; calculated for $Cu(C_8H_{15}C_2O_2)_2$: about 16%).

General aspects of the IR spectra of the benzene-soluble and -insoluble polymalonylheptamethylene resemble each other, except that absorptions at 1728 (sh), 1710 (m) and 1613 (br) cm^{-1} for the former are replaced by a broad band in the region 1742—1548 cm^{-1} for the latter. The spectrum of the former corresponds to that of di-*n*-butyrylmethane which exhibits absorptions at 1730 (w), 1708 (w) and 1616 (br) cm^{-1}. However, the spectrum of each polymer differs from that of di-*n*-butyrylmethane in having a broad band in 3500—3100 cm^{-1} region due to a hydroxy and a carboxyl group. The spectrum of the copper chelate of the benzene-insoluble polymer, though having the same absorption peaks at 1573 and 1522 cm^{-1} as those for the copper chelate of di-*n*-butyrylmethane, shows two additional absorptions. One is observed at 1710 cm^{-1}, which seems to be due to a carbonyl group not complexed with copper and to acetyl end group from the decarboxylation of *β*-ketonic acid group, and the other is a broad band centered at 3440 cm^{-1} attributed to hydroxy group, without an absorption due to carboxyl group. The NMR spectrum of the benzene-insoluble polymalonylheptamethylene shows two broad singlets at 6.40 τ ($COCH_2CO$), and 4.53 τ (vinyl proton on COCH=C(OH)), a sharp singlet at 7.95 τ ($COCH_3$ as end group). A similar spectral evidence was also observed generally from the IR and NMR spectra of the other polymers. On being burnt, all acetone-soluble polymers give ash, which is considered to be alumina derived from a small amount of the condensing agent (*e.g.*, less than 0.5% in the case of the benzene-insoluble polymalonylheptamethylene). However, no NMR signals were observed due to a methine group. Thus, the structure of the benzene-insoluble polymer can be assigned to poly-malonylpolymethylene:

$$R\text{-}[\text{-}(CH_2)_m\text{-}COCH_2CO\text{-}]_n\text{-}(CH_2)_m\text{-}R$$

$R = -COOH$ and/or $-COCH_3$; $m = 5, 6, 7$; $n = 8-16$.

In the case of a polymer from adipoyl chloride which becomes easily dark brown in the presence of aluminum chloride, a small singlet at 7.14 τ attributed to a methine group appears even after removal of the acetone-insoluble substance. This suggests the presence of a few cross-linkings.

Experimental

Materials. Ethyl acetoacetate, acetyl chloride and acetic anhydride, commercial materials, were distilled and each stored in an ampul. Their bp were 75—77°C/15 mmHg, 52°C and 139°C, respectively. Commercial dibasic acids, azelaic, suberic and adipic acid, were converted into methyl esters, which were rectified *in vacuo* to give their glc charts showing sufficient purities, and were hydrolyzed to the original dibasic acids. Pimelic acid was prepared according to literature[3] and purified similarly. Acid chlorides of these acids were prepared by a modification of the methods in literature,[4] then rectified twice and stored separately in an ampul, bp 125—126°C/5 mmHg for azelaoyl chloride, by 126—127°C/6 mmHg suberoyl chloride, bp 106—107°C/4 mmHg pimeloyl chloride and bp 103—105°C/7 mmHg adipoyl chloride. Di-*n*-butyrylmethane was prepared according to literature,[5] bp 82—84°C/11 mmHg.

Measurements. The melting and softening points were determined on a Yanagimoto micro-melting point apparatus model MP-S 1 and uncorrected. The molecular weight was determined with a Hitachi model-115 vapor pressure osmometer in a 0.10—0.15/25 m*l* acetone solution at 35°C. The IR spectra (KBr for copper chelates, NaCl plate for polymers) were obtained on a Nihon Bunko model DS-301 infra-red spectrometer. The NMR spectra were measured on a Nihon Denshi-JEOL model C-60 H spectrometer operating at 60 MHz in 10—20 wt/vol% deuteriochloroform solutions with tetramethylsilane as internal standard.

Procedure. To a cold solution of aluminum chloride and substrate in dry nitrobenzene, which was placed a 50 m*l* flask equipped with a calcium chloride tube, dibasic acid chloride was added, and the mixture was kept in a thermostat at 50°C. The reddish brown gelatinous reaction mixture was stirred into a mixture of hydrochloric acid and crushed ice and then allowed to stand for 0.5 hr. The mixture was shaken with chloroform on a mechanical shaker for 1 hr. The

organic layer separated was washed repeatedly by shaking with fresh 6 N hydrochloric acid for 15 min until the aqueous layer gave no detectable amount of aluminum compound, then was steam-distilled *in vacuo* to remove organic solvent. The residue dissolved in a small amount of chloroform was washed repeatedly with warm water to remove the dibasic acid and then was shaken with hot benzene to separate into a benzene-soluble and a benzene-insoluble fraction. The former, after partial evaporation, afforded an oil on addition of petroleum ether. From the latter an acetone-insoluble substance (if present) was separated by treatment with acetone followed by filtration. Evaporation of the filtrate gave an oil. Each oil obtained was dried *in vacuo* to a constant weight at 50°C.

Studies of Acenaphthene Derivatives. XX.[1] The Reactions of Benzylideneacenaphthenones with Sulfonium Ylides

Otohiko Tsuge and Ichiro Shinkai

Research Institute of Industrial Science, Kyushu University Hakozaki, Fukuoka

(Received May 9, 1970)

The reactions of benzylideneacenaphthenones with sulfonium ylides were studied extensively. Although the reactions of benzylidene- and *p*-methylbenzylideneacenaphthenone with dimethylsulfonium methylide gave only resinous materials, the *p*-chlorobenzylidene derivative condensed with the ylide to afford the corresponding spiroxirane compound in a good yield. In the reactions with dimethyloxosulfonium methylide and carbonyl-stabilized sulfonium ylides such as ethyl (dimethylsulfuranilidene)acetate and dimethylsulfonium phenacylide, benzylideneacenaphthenones gave the corresponding spirocyclopropyl ketones in good yields. The products obtained in the latter reactions were established to be *cis*-cyclopropyl compounds on the basis of NMR spectral studies. On the other hand, ethoxycarbonylmethyleneacenaphthenone condensed with carbonyl-stabilized sulfonium ylides to give *trans*-cyclopropyl ketones. On the basis of these results, the reaction mechanism was discussed. Also, bis-2,2′-methyleneacenaphthenone reacted with ethyl (dimethylsulfuranilidene)acetate to give the bis-spirocyclopropyl ketone.

From the study of the reactions of benzylideneacenaphthenones (I)[2] with hydrazines[3] and Grignard reagents,[1,4] it has been established that I behaves differently from ordinary α,β-unsaturated ketones such as chalcones, and that the β-carbon atom in I acts as a strong Michael acceptor toward the above reagents. In connection with our current studies of the reactivity of I, we wish to obtain further information concerning the ability of the conjugate addition of I, which are cyclic α,β-unsaturated ketones possessing a cisoid arrangement of the conjugated double bond with the carbonyl group.

Recently, it has been reported that reactive dimethylsulfonium methylide (II) interacts with chalcones to afford oxiranes, while less reactive dimethyloxosulfonium methylide (III) and carbonyl-stabilized sulfonium ylides (IV) such as dimethylsulfonium phenacylide react to give cyclopropyl ketones exclusively.[5-7] However, there have been few investigations of the reactions of cyclic α,β-unsaturated ketones with sulfonium ylides.

In the present work, the reactions of I with sulfonium ylides II—IV were studied in order to prepare spiroxiranes and spirocyclopropanes, and

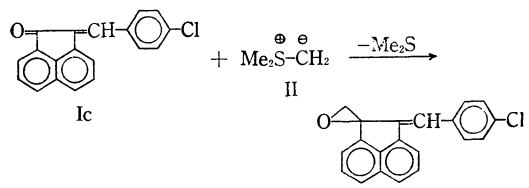
the stereochemistry of the products were investigated on the basis of NMR spectral studies. In addition, the reactions of ethoxycarbonylmethylenacenaphthenone (V) and bis-2,2′-methyleneacenaphthenone (VI) with sulfonium ylides were studied.

Results and Discussion

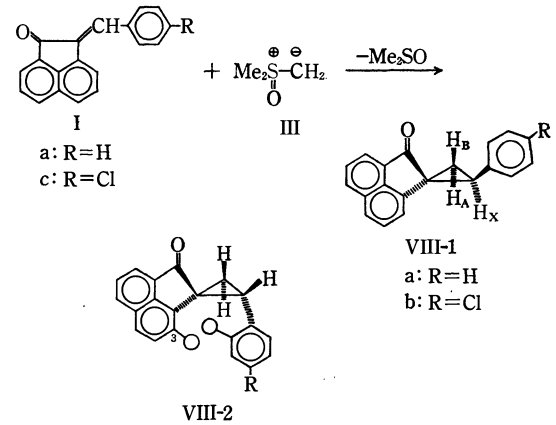
Although the reactions of benzylidene- (Ia) and *p*-methylbenzylideneacenaphthenone (Ib) with II which had been generated *in situ* by the treatment of trimethylsulfonium iodide with potassium *t*-butoxide in dimethylsulfoxide (DMSO) gave only resinous materials, the *p*-chlorobenzylidene analogue (Ic) condensed with II under similar conditions to give the expected spiroxirane (VII), mp 113—114°C (decomp), in an 85% yield. The structure of VII was confirmed by a study of the mass (M^+ *m/e* 304), infrared, and NMR spectra as well as by elemental analysis. The infrared spectrum did not show any bands due to the carbonyl group, while the NMR spectrum in deuterochloroform ($CDCl_3$) exhibited signals at τ 7.60 (2H, methylene-protons, singlet), 3.26 (1H, olefinic proton, singlet), and 2.0—2.9 (10H, aromatic protons, multiplet).



The compound VII was relatively unstable and decomposed on standing at room temperature for a few days. Although it is well known that epoxides rearrange to the corresponding aldehydes upon treatment with boron trifluoride, VII did not give the aldehyde, but only resinous materials.

When Ia was allowed to react in tetrahydrofuran (THF) at room temperature with III which had been generated *in situ* from trimethyloxosulfonium chloride and sodium hydride, the expected spirocyclopropyl ketone (VIIIa), mp 118—119°C, was obtained in a 74% yield. Its structure was established by a study of the mass (M^+ *m/e* 270), infrared, and NMR spectra as well as by elemental analysis. The infrared spectrum showed the band ascribed to the carbonyl group at 1705 cm^{-1}, while the NMR spectrum in $CDCl_3$ did not reveal any signals for olefinic protons, but did show a typical ABX pattern for cyclopropyl-protons: double-doublets appeared at τ 6.65 (1H, H_X), 7.70 (1H, H_A) and 7.90 (1H, H_B) with J_{AX} (*cis*)=9.0, J_{BX} (*trans*)=8.7 and J_{AB} (*gem*)=3.3 Hz, and a multiplet at τ 1.8—2.9 (11H, aromatic protons).[8]

A similar reaction of Ic with III gave the spirocyclopropyl analogue (VIIIb), mp 141—142°C, in a 93% yield. Its infrared spectrum showed the carbonyl band at 1691 cm^{-1}, and the NMR spectrum in $CDCl_3$ exhibited double-doublets at τ 6.60 (1H, H_X), 7.71 (1H, H_A) and 7.93 (1H, H_B) with J_{AX} (*cis*)=9.0, J_{BX} (*trans*)=8.4 and J_{AB} (*gem*)=3.5 Hz, and a multiplet at τ 1.8—2.9 (10H, aromatic protons).[8]



Two geometrical isomers resulting from the conformation of the spiro-carbon atom are, then, possible for the structure of VIII: one (VIII-1) in which the phenyl group overlooks the carbonyl group, and the other (VIII-2) in which it sees the acenaphthenone ring.

An inspection of Dreiding models for VIII indicates that the hydrogen atom on the *ortho* position of the phenyl ring interacts with that on the 3-position of the acenaphthenone ring in VIII-2, but does not interact in VIII-1. Consequently,

8) J. D. Graham *et al.* observed that the values of $J_{cis}+J_{trans}+J_{gem}$ in 1,1,2-trisubstituted cyclopropanes are virtually constant (about 21 Hz), regardless of the nature of the substituents.[9] The values of $J_{cis}+J_{trans}+J_{gem}$ are 21 and 20.9 Hz in VIIIa and VIIIb respectively. These observations are also in agreement with the structures of 1,1,2-trisubstituted cyclopropane derivatives proposed for VIIIa and VIIIb.

it may be deduced that VIII-1 is a more favorable configuration than that of VIII-2.

The treatment of Ia with ethyl (dimethylsulfuranilidene)acetate (IVa) which had been generated *in situ* from the corresponding sulfonium bromide and sodium hydride in THF gave the spirocyclopropyl ketone (IXa). Similar reactions of I with carbonyl-stabilized sulfonium ylides (IVa—IVc) gave the corresponding spirocyclopropyl ketones (IXb—IXf).

The yields, physical properties, elemental analyses, and spectral data are summarized in Tables 1 and 2.

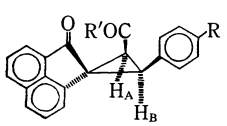
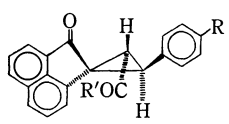
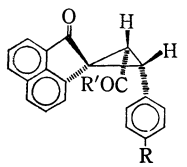
1) NMR spectra were measured in $CDCl_3$.



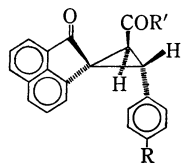
IX-1 (*cis*)



IX-2 (*trans*)



IX-3 (*cis*)



IX-4 (*trans*)

As a result of the conformation of the spiro-carbon atom and the *cis-trans* configuration of hydrogens in the cyclopropyl ring of IX, the following four isomers (IX-1—IX-4) are possible for the structure of IX.

As is illustrated in Fig. 1, the NMR spectrum of IXa in $CDCl_3$ exhibits peaks at τ 8.76 (3H, methyl-protons, triplet) 6.43 (1H, H_A, doublet), 5.99 (1H, H_B, doublet) (J_{AB}=9.0 Hz), and 5.75 (2H, methylene-protons, quartet), besides aromatic protons.

It is well known that *cis*-cyclopropanes exhibit higher coupling constants (8—10,[10] 7.9—9.3 Hz[9]) than those (4—7,[10] 5.3—6.6 Hz[9]) of the corresponding *trans* isomers.

As is shown in Table 2, the vicinal coupling constants (J_{AB}=8.4—9.0 Hz) of IX correspond to those of *cis*-cyclopropanes. In addition, the configurations, IX-3 and IX-4, in which the phenyl group sees the acenaphthenone ring may be disregarded as unreasonable because of the steric hindrance mentioned in the case of VIII-2.

Consequently, it may be deduced that the most reasonable structure for IX is the configuration IX-1, in which H_A and H_B are situated *cis*, and in which the phenyl group overlooks the carbonyl group in acenaphthenone. As will be described below, this conclusion is also supported by the fact that the shielding effect of the acenaphthenone ring does not exert any effect on the methyl resonance of the ethoxycarbonyl group in the respective NMR spectrum of IXa, IXb, or IXc.

The fragmentation on electron impact was compatible with the proposed structure for IX. For example, the mass spectrum of IXa shows peaks at *m/e* 342 (M^+), 298 ([M–MeCHO]$^+$), 270

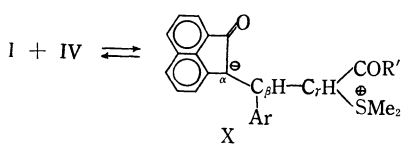
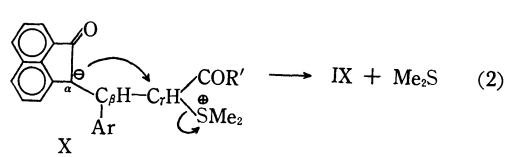
([298-CO]$^+$), 240 ([270-CH_2O]$^+$), and 163 ([240-Ph]$^+$), as is shown in Fig. 2.

It has been reported that dimethylsulfonium phenacylide (IVb) condensed with chalcone to afford a mixture of *cis*- and *trans*-cyclopropane in the ratio of 1 : 2.[11] Also, Payne[12] found that the corresponding *trans*-cyclopropanes were obtained predominantly in the reactions of IVa with α,β-unsaturated carbonyl compounds, such as acrolein and mesityl oxide.



(1)



(2)

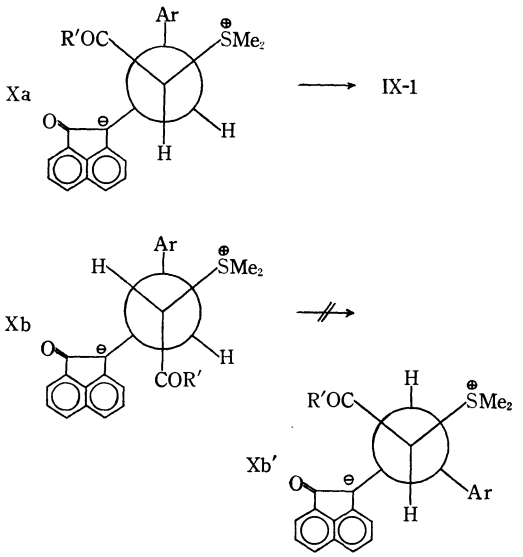
Although the exact course of the reaction of I with IV is not clear, it is thought to consist of step 1, a reversible nucleophilic attack by the ylide carbanion on the β-carbon atom in I to form a betain intermediate X, followed by step 2, an irreversible intramolecular ring closure with the *trans*-elimination of dimethyl sulfide.

As is shown in Table 1, all the reactions of I with IV gave the corresponding *cis*-cyclopropyl ketones exclusively. The relative amounts of *cis*-(IX-1) and *trans*-cyclopropyl ketone (IX-2) must be reflected by the relative energies of the *threo*-precursor (Xa) of IX-1 and the *erythro*-precursor (Xb) of IX-2; the betains which are precursors of IX-3 and IX-4 are excluded from our discussion.[13]

The Newman projections clearly indicate that Xa is a more unfavorable conformation than Xb, because the four bulky groups in Xa are in a *gauche* position relative to each other.

13) In this paper, the prefixes of *threo* and *erythro* are used assuming that the substituent COR′ is larger than SMe_2.

However, an inspection of the Dreiding models indicates that the free rotation of the C_α-C_β bond in Xb to form Xb′ is hindered by the steric interaction between the acenaphthenone ring and the phenyl group, and that, in an intramolecular ring closure with a backside attack of the carbanion on the γ-carbon atom (step 2), there is a significant repulsion between the substituent COR′ and the acenaphthenone ring in Xb.



Accordingly, it will be very difficult for the ring-closure reaction of Xb to IX-2 to take place and Xb will return to the starting materials, I and IV. These situations result in the stereoselective formation of the *cis*-cyclopropyl ketone IX-1 from the precursor Xa.

If the free rotation of the C_α-C_β bond in a betain were possible, one might expect the formation of the *trans*-cyclopropyl ketone from the *erythro*-betain in a lower energy. In order to make this point clear, the reactions of two isomeric ethoxycarbonylmethyleneacenaphthenone, V[2] and V′[2], which have an ethoxycarbonyl group in place of a phenyl group in I, with sulfonium ylides were investigated.

The reaction of V, whose ethoxycarbonyl group overlooks the carbonyl group in acenaphthenone, with IVa afforded the expected *trans*-spirocyclopropyl ketone (XI), mp 110—111°C, in a good yield. In order to confirm whether or not the conformation of the ethoxycarbonyl group in V is maintained in XI, the reaction of the isomer V′, in which the ethoxycarbonyl group sees the acenaphthenone ring, with IVa was carried out; the same product, XI, was thus obtained in an excellent yield. This shows that the free rotation of the C_α-C_β bond in a betain takes place, as was expected.

The structure of XI was confirmed by the infrared, mass, and NMR spectra as well as by the results of the elemental analyses.

As is shown in Fig. 3, the NMR spectrum of XI in $CDCl_3$ exhibits signals at τ 8.82, 8.75 (each 3H, methyl-protons, triplet, J=4.2 Hz), 6.56 (2H, methine-protons H_A and H_B), 5.84, 5.77 (each 2H, methylene-protons, quartet, J=4.2 Hz), 1.8—2.5 (6H, aromatic protons). The vicinal coupling constant is very small ($J \fallingdotseq 0$); this indicates that H_A and H_B are situated *trans*. Furthermore, it is clear that the two ethoxycarbonyl groups in XI are in an unequivalent situation. This phenomenon can be understood in terms of the shielding effect of the acenaphthenone ring in

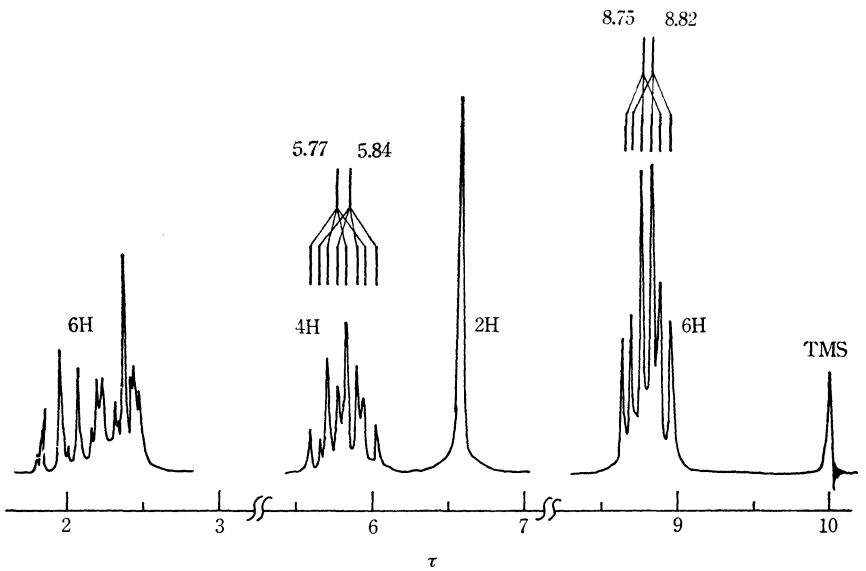


Fig. 3. NMR spectrum of XI in $CDCl_3$.

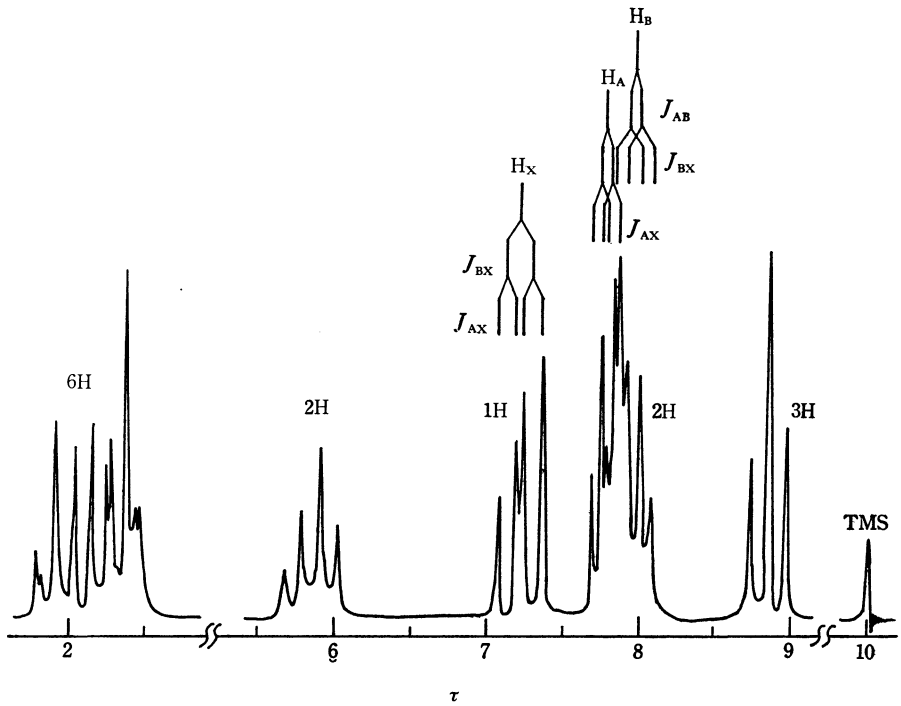

Fig. 4. NMR spectrum of XII in $CDCl_3$.

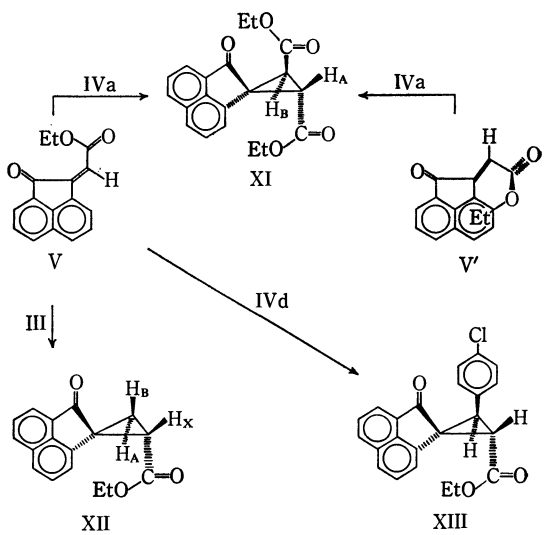
XI: one (methyl at τ 8.82) sees the acenaphthenone ring, and the other (methyl at τ 8.75) overlooks the carbonyl group in acenaphthenone.

Similar reactions of V with III and dimethylsulfonium *p*-chlorophenacylide (IVd) afforded spirocyclopropyl ketones, XII (mp 74—75°C) and XIII (mp 147—148°C) respectively. The structures for XII and XIII were established by spectral studies as well as by elemental analyses.

The NMR spectrum of XII in $CDCl_3$ is illustrated in Fig. 4. Signals appear at τ 8.82 (3H, methyl-protons, triplet), 5.86 (2H, methylene-protons, quartet), and 1.8—2.5 (6H, aromatic protons), besides a typical ABX pattern for cyclopropylprotons at τ 7.25 (1H, H_X), 7.75 (1H, H_A), and 7.95 (1H, H_B) with J_{AX} (*trans*)=6.5, J_{BX} (*cis*)=9.9 and J_{AB} (*gem*)=4.5 Hz. On the basis of the above observations, XII can be said to be consistent with the cyclopropyl ketone, in which the ethoxycarbonyl group sees acenaphthenone ring.[14]

On the other hand, the NMR spectrum of XIII in $CDCl_3$ showed signals at τ 8.81 (3H, methyl-protons, triplet), 6.25 and 6.17 (each 1H, methine-proton, doublet, J=5.8 Hz), 5.84 (2H, methylene-protons, quartet) and a lower field (10H, aromatic protons); XIII is compatible with the *trans*-cyclopropyl ketone, in which the ethoxycarbonyl group sees the acenaphthenone ring.

The original conformation of the ethoxycarbonyl group in V is not maintained in either XII or XIII.



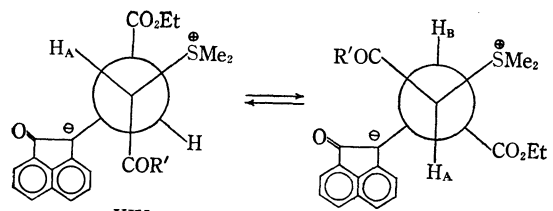
The methyl-protons signals of ethoxycarbonyl groups in IXa, IXb, and IXc appeared at τ 8.76, 8.75 and 8.77 respectively in the NMR spectra.

14) The value of $J_{cis}+J_{trans}+J_{gem}$ is 20.9 Hz.[8] In the reaction of diazoacenaphthenone with ethyl acrylate in refluxing benzene, XII and the isomeric spirocyclopropyl ketone in which the ethoxycarbonyl group overlooks the carbonyl group in acenaphthenone were obtained; these results will be reported shortly in more detail.

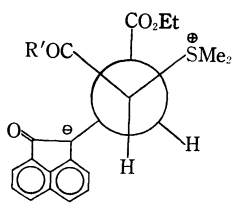
No ethoxycarbonyl group in IX is affected by the shielding effect of the acenaphthenone ring, but each overlooks the carbonyl group in acenaphthenone. This fact indicates that IX is compatible with the proposed structure, IX-1.

The formation of the *trans*-cyclopropyl ketone in the reaction of V with IV can, then, be understood in terms of the following considerations.

As has been pointed out in the discussion of the formation of IX, it must be determined by the relative energies of *erythro*- (XIV) and *threo*-betain (XV) which isomer, the *trans* or the *cis*, is formed predominantly in the reaction of V with IV.[13] The Newman projections indicate that the precursor, XIV, of the *trans*-isomer is a more favorable conformation than the precursor, XV, of the *cis*-isomer.



XIV XIV'

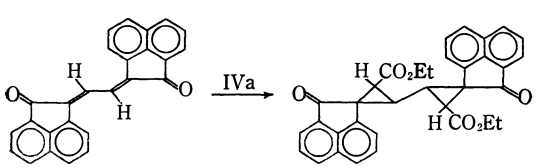


XV

The exclusive formation of the *cis*-cyclopropyl ketone IX-1 in the reaction of I with IV may be attributed to the fact that the transformation of *erythro*-betain Xb to the *trans*-isomer IX-2 can not occur because of the steric repulsion between the acenaphthenone ring and COR′ at the step 2, but Xb reverts to the starting materials.

Contrary to the case of Xb, it becomes feasible of the C_α- C_β bond in XIV to rotate, as is shown by the fact that the reactions of both V and V′ with IVa gave the same product, XI. That is, XIV can convert to XIV′, in which the steric repulsion between the acenaphthenone ring and COR′ is absent in the ring-closure reaction.

Thus, the above situation leads to the formation of the *trans*-cyclopropyl ketone, whose ethoxycarbonyl group does not retain the original conformation in V, from the preferred betain, XIV′.



VI XVI

The reaction of bis-2,2′-methyleneacenaphthenone (VI)[2] with IVa afforded the bis-spirocyclopropyl ketone (XVI), mp 225°C (decomp), in a 57% yield. However, the stereochemistry of XVI is not yet clear.

Experimental

All the melting points are uncorrected. The infrared spectra were measured in KBr disks, while the NMR spectra were recorded on a 60 MHz Hitachi R-20 NMR spectrometer, using TMS as an internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer, using a direct inlet and an ionization energy of 70 eV.

Benzylideneacenaphthenones (I), ethoxycarbonylmethyleneacenaphthenone (V), and bis-2,2′-methyleneacenaphthenone (VI) were prepared by a previously-reported method.[2]

Trimethylsulfonium iodide,[5] trimethyloxosulfonium chloride[5] dimethylethoxycarbonylmethyl-,[15] dimethylphenacyl-[15], dimethyl-*p*-bromo-,[15] and -*p*-chlorophenacylsulfonium bromides[16] were prepared by methods described in the literature.

The Reaction of *p*-Chlorobenzylideneacenaphthenone (Ic) with Dimethylsulfonium Methylide (II). A solution of the ylide II was prepared by stirring a mixture of trimethylsulfonium iodide (1.0 g), potassium *t*-butoxide (0.56 g), and DMSO (20 m*l*) for 25 min under a nitrogen atmosphere. A solution of Ic (350 mg) in DMSO (10 m*l*) was then slowly added, drop by drop, to the solution of II, and the reaction mixture was stirred at room temperature for 1 hr. After the mixture had been poured into 15 m*l* of cold water, yellow crystals were collected by filtration, washed with water, and dried. Yield, 310 mg (85%). Recrystallization from petroleum benzine (bp 40—65°C) gave spiroxirane (VII), mp 113—114°C (decomp), as yellow needles.

Found: C, 78.60; H, 4.00%. Calcd for $C_{20}H_{13}OCl$: C, 78.95; H, 4.28%.

Similar reactions of benzylidene- (Ia) and *p*-methylbenzylideneacenaphthenone (Ib) with the ylide II gave only resinous materials.

The Reaction of Ic with Dimethyloxosulfonium Methylide (III). A solution of the ylide III was prepared by refluxing a mixture of trimethyloxosulfonium chloride (450 mg), sodium hydride (200 mg) as a 50% mineral oil dispersion, and THF (20 m*l*) for 3.5 hr under a nitrogen atmosphere. To a stirred solution of Ic (1.0 g) in THF (15 m*l*) was then slowly added, drop by drop, the solution of the ylide III at 0°C, after which the reaction mixture was stirred at room temperature for 2 hr. After the mixture had been concentrated *in vacuo*, methanol (10 m*l*) was added to the residue and the mixture was allowed to stand at room temperature for several hours, thus giving 974 mg (93%) of colorless crystals. Recrystallization from methanol gave the spirocyclopropyl ketone (VIIIb), mp 141—142°C, as colorless needles.

Found: C, 78.80; H, 4.19%. Calcd for $C_{20}H_{13}$-

15) K. W. Ratts and A. N. Yao, *J. Org. Chem.*, **31**, 1185 (1966).
16) K. W. Ratts and A. N. Yao, *ibid.*, **33**, 70 (1968).

OCl: C, 78.95; H, 4.28%. M^+: *m/e* 304.

A similar reaction of Ia with III afforded the spirocyclopropyl ketone (VIIIa), mp 118—119°C, as colorless prisms (from methanol). Yield, 74%.

Found: C, 88.55; H, 5.06%. Calcd for $C_{20}H_{14}O$: C, 88.86; H, 5.22%.

The Reaction of I with the Carbonyl-stabilized Sulfonium Ylide (IV). The procedure used is illustrated with the reaction of Ia with ethyl (dimethylsulfuranilidene)acetate (IVa).

A solution of the ylide IVa was prepared by the following procedure. To a stirred suspension of dimethylethoxy-carbonylmethylsulfonium bromide (1.2 g) in THF (10 m*l*), sodium hydride (0.3 g) was added as a 50% mineral oil dispersion in one portion. After the mixture had then been stirred at room temperature for 3 hr, it was filtered to remove the sodium bromide, thus giving a yellow solution of IVa.

After the solution of IVa had been added to a solution of Ia (1.2 g) in THF (10 m*l*) at 0°C, the reaction mixture was stirred at room temperature for 12 hr and then at 70—80°C for 30 min. The mixture was concentrated *in vacuo*, and methanol (10 m*l*) was added to the residue. It was then allowed to stand at room temperature for several hours, giving 1.23 g (77%) of colorless crystals, mp 148—150°C. Recrystallization from methanol afforded the *cis*-spirocyclopropyl ketone (IXa) as colorless needles.

Similar reactions of Ia Ib, and Ic with IVa, dimethylsulfonium phenacylide (IVb), and dimethylsulfonium *p*-bromophenacylide (IVc) gave the corresponding *cis*-spirocyclopropyl ketones (IX-IXf).

The yields, physical properties, spectral data, and elemental analyses are summarized in Tables 1 and 2.

The Reaction of Ethoxycarbonylmethyleneacenaphthenone (V) with the Ylide IVa. A solution of the ylide IVa, prepared from the corresponding sulfonium bromide (250 mg) and sodium hydride (65 mg) as a 50% mineral oil dispersion in THF (15 m*l*), was slowly added to a solution of V (250 mg) in THF (10 m*l*) at 0°C, and then the reaction mixture was stirred at room temperature for 3.5 hr. After the mixture had been concentrated *in vacuo* to leave a residue, the addition of methanol (10 m*l*) to the residue gave 290 mg (88%) of colorless crystals. Recrystallization from methanol gave the *trans*-spirocyclopropyl ketone (XI), mp 110—111°C, as colorless prisms.

Found: C, 71.29; H, 5.27%. Calcd for $C_{20}H_{18}O_5$: C, 70.99; H, 5.36%. M^+: *m/e* 338. IR: $\nu_{C=O}$ 1735, 1724 and 1712 cm^{-1}.

The same spirocyclopropyl ketone, XI, was obtained in a 90% yield from a similar reaction of isomeric ethoxycarbonylmethyleneacenaphthenone (V′) with the ylide IVa.

The Reaction of V with the Ylide III. To a solution of V (250 mg) in THF (5 m*l*) added a solution of the ylide III, prepared from the corresponding sulfonium chloride (250 mg) and sodium hydride (90 mg) as a 50% mineral oil dispersion in THF (10 m*l*); the reaction mixture was then stirred at room temperature for 20 hr, and then at 70—80°C for 10 min. After the mixture had been concentrated *in vacuo*, petroleum ether (10 m*l*) was added to the residue, giving 145 mg (54%) of colorless crystals. Recrystallization from petroleum ether gave the spirocyclopropyl ketone (XII), mp 74—75°C, as colorless prisms.

Found: C, 76.78; H, 5.04%. Calcd for $C_{17}H_{14}O_3$: C, 76.67; H, 5.30%. M^+: *m/e* 266. IR: $\nu_{C=O}$ 1708 cm^{-1}.

The Reaction of V with Dimethylsulfonium *p*-Chlorophenacylide (IVd). A solution of the ylide IVd, prepared from the corresponding sulfonium bromide (310 mg) and sodium hydride (60 mg) as a 50% mineral oil dispersion in THF (15 m*l*), was added to a solution of V (250 mg) in THF (10 m*l*) at 0°C. After the reaction mixture had been stirred at room temperature for 3 hr and then at 70—80°C for 30 min, the mixture was concentrated *in vacuo* to leave a residue. To the residue then added methanol (10 m*l*), giving 230 mg (57%) of colorless crystals. Recrystallization from methanol afforded the *trans*-spirocyclopropyl ketone (XIII), mp 147—148°C, as colorless prisms.

Found: C, 71.43; H, 3.79%. Calcd for $C_{24}H_{17}O_4Cl$: C, 71.29; H, 4.21%. M^+: *m/e* 404. IR: $\nu_{C=O}$ 1730, 1710 and 1675 cm^{-1}.

The Reaction of Bis-2,2′-methyleneacenaphthenone (VI) with the Ylide IVa. After a solution of the ylide IVa, prepared from the corresponding sulfonium bromide (300 mg) and sodium hydride (75 mg) as a 50% mineral oil dispersion in THF (15 m*l*), was added to a solution of VI (180 mg) in THF (10 m*l*), the reaction mixture was stirred at room temperature for 3 hr and then at 70—80°C for an additional hour. The mixture was concentrated *in vacuo* to give a residue, to which methanol was then added, giving 150 mg (57%) of colorless crystals. Recrystallization from petroleum benzine afforded the *bis*-spirocyclopropyl ketone (XVI), mp 225°C (decomp), as colorless prisms.

Found: C, 76.99; H, 5.01%. Calcd for $C_{34}H_{26}O_6$: C, 76.97; H, 4.94%. M^+: *m/e* 530. IR: $\nu_{C=O}$ 1730 and 1710 cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3522—3527 (1970)

Reactions of Ferrocenylcarbene. III. The Addition Reactions of Some α-Ferrocenylcarbenes to 1,1-Diphenylethylene*1

Akio SONODA and Ichiro MORITANI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received May 11, 1970)

The addition reactions of α-ferrocenylcarbenes (ferrocenyl, ferrocenylmethyl, and ferrocenylphenyl carbene) to 1,1-diphenylethylene have been examined by means of the thermal decomposition of the corresponding acylferrocene tosylhydrazone sodium salts. Then, the reactivities of the ferrocenylcarbenes have been compared with those of the corresponding phenyl and *p*-anisylcarbenes. It has been found that, of the carbenes investigated, the ferrocenylcarbenes show the lowest reactivity in addition reactions to the olefin. It has been established by a study of the NMR spectra that, in the ferrocenylcyclopropanes only, there is a restricted rotation about the bond between ferrocenyl and cyclopropyl groups. On this basis, the reactivity of the ferrocenylcarbenes has been discussed in terms of the steric hindrance of the bulky ferrocenyl group.

In previous papers[1] on the reactions of ferrocenylcarbenes, we have reported that the α-ferrocenylcarbenes (Ia, Ib, and Ic) are all triplets. Thus, it has been revealed that these ferrocenylcarbenes abstract hydrogen atoms or halogen atoms from solvents and easily react with oxygen to form the corresponding carbonyl compounds. Further, they add to particular olefins bearing effective radical-stabilizing group(s), such as phenyl or ferrocenyl, to form ferrocenylcyclopropane derivatives.

It is known that a triplet carbene adds to 1,1-diphenylethylene, yielding a cyclopropane derivatives.[2] This carbene trapping ability of the olefin is probably due to the intermediary formation of a stable diphenylmethylradical. In order to elucidate the reactivity of ferrocenylcarbenes, the addition reactions of these carbenes to 1,1-diphenylethylene has been investigated and compared with those of phenyl and *p*-anisylcarbenes.[3]

Results and Discussion

When the thermal decompositions of acylferrocene tosylhydrazone sodium salts[4] were carried out in a mixed solution of dry pyridine and about a tenfold excess of 1,1-diphenylethylene, as addition products 1,1-diphenyl-2-ferrocenylcyclopropane derivatives were obtained, plus a small amount of azine derivatives.

The yields of ferrocenylcyclopropane derivatives might directly reflect the addition reactivity of ferrocenylcarbenes formed in the thermal decomposition of the tosylhydrazone salts. Therefore, the reactions of the corresponding phenyl and *p*-anisylcarbenes with 1,1-diphenylethylene were investigated under similar conditions in order to estimate the effect of the ferrocenyl group on the reaction of an adjacent divalent carbon by comparing it with phenyl and *p*-anisyl groups. The yields of the cyclopropane derivatives are listed in Table 1.

TABLE 1. THE YIELDS OF CYCLOPROPANE DERIVATIVES FORMED BY THE THERMAL DECOMPOSITION OF SODIUM SALTS OF I IN 1,1-DIPHENYLETHYLENE

R′	R-		
	Ferrocenyl	Phenyl	*p*-Anisyl
H	13%	6%	35%
CH_3	41	59	75
C_6H_5	14	23	27

It appears from Table 1 that the reactivity of carbenes increases in the following sequence; ferrocenyl<phenyl<*p*-anisyl. Thus, when R′ is methyl or phenyl, the yield of ferrocenylcyclopropane was found to be the lowest. It should be

d:	C_6H_5	H
e:	C_6H_5	CH_3
f:	C_6H_5	C_6H_5
g:	$CH_3OC_6H_4$	H
h:	$CH_3OC_6H_4$	CH_3
i:	$CH_3OC_6H_4$	C_6H_5

noted that the reactivity of the ferrocenylcarbenes is the lowest. This fact is of interest, since the radical stabilizing effect of the ferrocenyl group may be considered to be not less than that of the *p*-anisyl group, as deduced from their resonance stabilizing effect on the α-carbonium ions.[5] Table 1 also shows that the effecs of R′ on the reactivity increases in the order of: $H \ll Ph < CH_3$. This result indicates that a steric factor palys an important role, since the expected order of the radical-stabilizing effect between phenyl and methyl groups appears to be reversed.

The structural elucidation of the addition products suggests that there is a significant steric crowding in the 1,1-diphenyl-2-ferrocenyl cyclopropane derivatives. Thus, in the NMR spectra of IIa—c, it was found that the signal of one *ortho* (adjacent to the cyclopropyl group) proton of the ferrocenyl ring shifted unusually to a higher field.[6] This phenomenon can reasonably be explained in terms of an anisotropic effect of a spacially-fixed phenyl ring attached to the cyclopropane ring in *cis* configuration to the ferrocenyl group.[7]

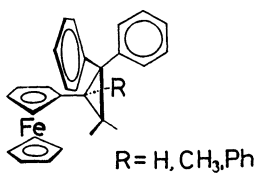

Fig. 1.

For example, in the NMR spectrum of 1,1-diphenyl-2-ferrocenylcyclopropane (IIa), ferrocenyl ring proton signals were observed at τ 5.97, 6.19,

IIb in diphenylether. (HMDS internal standard)

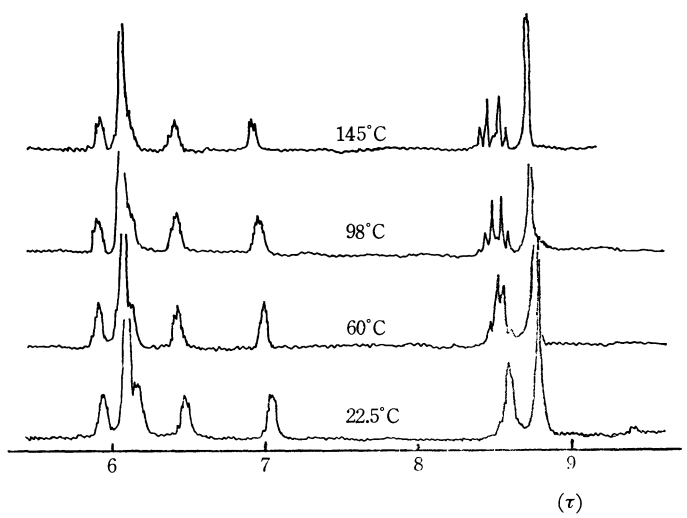

Fig. 2. Temperature dependence of NMR spectra of IIb (100 MHz).

5) T. G. Traylor and J. C. Ware, *J. Amer. Chem. Soc.*, **89**, 2304 (1967).

6) It is known that in ferrocene system, electron donating groups such as alkyl substituents exert an effect of some higher field shifts on the ferrocenyl ring protons: M. Rosenblum, "Chemistry of the Iron Group Metallocenes," Interscience Publishers, New York, N. Y. (1965), p44. But, such an extraordinary high field signal of ferrocenyl ring proton as appeared in this ferrocenylcyclopropane system has not been reported.

7) In *o*-ferrocenyl-biphenyl derivatives, the ferrocenyl ring protons of 2 and 5 position are known to be considerably shielded by a phenyl ring current: Ref. 6, p. 217. This situation resemble to our case. On the other hand, the shilding by cyclopropane ring might be estimated to be less extensive in five membered ring system than that in phenylcyclopropane.

6.41 (each one proton), τ 6.09 (five protons), and τ 6.88 (one proton). The methylene and methine protons of the cyclopropane ring gave signals of an ABX pattern at a high field. This great upfield shift of a proton signal of the ferrocenyl ring can also be observed in two other ferrocenylcyclopropanes; in both IIb and IIc the signal appears at τ 7.05. These NMR data are listed in Table 3.

By the examination of molecular models, it is found that the rotation of the bond between the ferrocenyl group and the cyclopropane ring is greatly restricted by the conflict of the *cis* phenyl group with the unsubstituted cyclopentadienyl ring.

When the temperature dependence of the NMR spectrum of 1,1-diphenyl-2-ferrocenyl-2-methylcyclopropane (IIb) was investigated in a diphenyl ether solution, using HMDS as the internal standard and at 22.5, 60, 98, and 145°C, it was observed that the higher-field one-proton signal tended to move slightly down field with an increase in the temperature, while the other signals, with the exception of the methylene signal, remained almost unchanged. The results are shown in Fig. 2.

It should be noticed here that the methylene protons of the cyclopropane in IIb, which unexpectedly give a singlet peak at τ 8.51 in CS_2 at room temperature (Table 3), split into an AB pattern with an increase in the temperature in diphenyl ether. This interesting NMR behavior the methylene signal might be reasonably interpreted as follows; at room temperature the chemical shifts of the two proton signals under the most favorable conformation of IIb become, by chance, coincident, resulting in a singlet peak, while at an elevated temperature they are split by thermal perturbation.

These observations obviously indicate that the rotation of the bond between ferrocenyl and cyclopropyl groups is highly hindered and that even at elevated temperatures, the rotation is completely restricted.

On the other hand, in the NMR spectra of 1,1-diphenyl-2-(*p*-anisyl)cyclopropanes (IIg—i), and 1,1,2-triphenylcyclopropanes (IId—e), no such anisotropy was observed. In these NMR spectra of IIg—i, the ring protons of the *p*-anisyl group showed the usual AB splitting pattern. It may safely be said that the anisyl and phenyl groups are freely rotating.

After these discussions, it can be concluded that, among these reaction products (IIa—i), there exists strongly restricted rotation only in 1,1-diphenyl-2-ferrocenylcyclopropanes, and that the addition of ferrocenylcarbenes to 1,1-diphenylethylene, producing these ferrocenylcyclopropanes, must overcome a much greater steric hindrance than those of phenyl and *p*-anisylcarbenes. Accordingly, the low reactivity of the ferrocenylcarbenes can be attributed to the steric hindrance of a bulky ferrocenyl group.

Experimental

The infrared spectra were recorded on a Hitachi EPI-S2 spectrophotometer, the visible and ultra violet spectra, on a Hitachi EPS-2U, and the NMR spectra, on a JEOLCO JNM-4H-100 at 100 MHz. All the reactions were carried out under an atmosphere of high-purity nitrogen gas or argon gas. All the temperatures are uncorrected.

Materials. The 1,1-diphenylethylene was prepared by the usual Grignard reaction of phenylmag-

* VPO in benzene.

nesium bromide with acetophenone in ether, followed by dehydration with dil. sulfuric acid. The resulting crude substance was distilled twice through a short column under reduced pressure. Bp 114—115°C/3 mmHg, (lit,[9] 113°C/2 mmHg).

All the tosylhydrazones used in this study were prepared by the reactions of the corresponding ketones or aldehydes with a slight excess of tosylhydrazine in boiling ethanol. Among the starting materials, formylferrocene,[10] acetylferrocene,[10] benzoylferrocene,[11] *p*-methoxyacetophenone,[12] and *p*-methoxybenzophenone,[12] were prepared by known synthetic routes. The others were obtained from a commercial source.

The melting points and analytical data of these tosylhydrazones are summarized in Table 2.

Thermal Decomposition of Ia-i in a Pyridine-1,1-diphenlethyleyne Mixture. The physical properties, analytical data, and spectral data of the reaction products, IIa-i, are summarized in Tables 3 and 4.

Reaction of Ia. To a solution of Ia (7.65 g, 0.02 mol) in 50 m*l* of dry pyridine (over BaO), sodium hydride (1.38 g, 50% in oil) was added in one portion. Then the solution was mixed with mechanical stirring. After the rapid hydrogen gas evolution had been completed, 35 g (0.2 mol) of 1,1-diphenylethylene was added to the mixture. After the reaction system had then been flushed with Ar gas, the mixture was stirred vigorously at 90—98°C until the nitrogen gas evolution ceased (2 hr). The resulting mixture was cooled to room temperature, and then decomposed by adding 30 m*l* of water. The resulting solution was extracted with 300 m*l* of ether. The organic phase was separated and combined with extracts of the aqueous phase. The ether solution was washed with 100-m*l* portions of water seven times and dried over sodium sulfate. After the ether had then been evaporated, the residual oil was distilled under reduced pressure. The unreacted 1,1-diphenylethylene was recovered at 105—110°C/3 mmHg (31 g). The dark brown residual oil (8.5 g) was subjected to alumina-column elution chromatography (100 g of Al_2O_3). IIa was eluted with pentane as yellow needles; 0.93 g (12.5%); mp 114—118°C. Recrystallization from hexane afforded yellow needles; mp 120—120.5°C. IR spectrum (Nujol): 1603, 1496, 1102, 1073, 1050, 1030, 1015, 998, 961, 825, 810, 755, and 698 cm^{-1}.

Benzene-hexane (1 : 1) eluted orange-red crystals of formylferrocene azine; mp 267—268°C (lit,[10] 245°C). Found: C, 62.11; H, 4.92; N, 6.40%. Calcd for $C_{22}H_{20}N_2Fe$: C, 62.31; H, 4.75; N, 6.61%. IR spectrum (Nujol): 1635 (C=N), 1410, 1105, 1000, and 830 cm^{-1}. This azine was identified by means of comparing its mp with that of an authetic sample synthesized from the reaction of formylferrocene with hydrazine hydrate in boiling ethanol. The elution with methanol afforded a black polymeric material which was unidentified (ca. 3 g).

Reaction of Ib. The reaction of Ib was performed with 15.2 g (0.038 mol) of the tosylhydrazone in 95 m*l* of dry pyridine and 65 g (0.36 mol) of diphenylethylene under conditions similar to those above. An alumina chromatography of reaction mixture afforded 6.03 g (40.5%) of IIb, (mp 127—128°C), from hexane. IR spectrum (Nujol): 1598, 1492, 1178, 1135, 1102, 1042, 1030, 1015, 1000, 981, 943, 913, 860, 822, 808, 766, 751, and 702 cm^{-1}.

12) R. Adams and C. R. Noller, "Organic Syntheses," Coll. Vol. I, p. 111 (1956).

From the benzene-hexane eluate, small amounts of two crystalline materials (mp 149—150°C, M.W. 880, and mp 147—148°C, M.W. 392) were isolated, besides a trace amount of azine. These structures have not yet been elucidated.

Reaction of Ic. Ic, 9.15 g (0.02 mol) were reacted in 50 m*l* of pyridine and 36 g of diphenylethylene under similar conditions. This reaction afforded IIc: 1.22 g; mp 175—176°C, (13.5%). IR spectrum (Nujol): 1601, 1495, 1103, 1072, 1035, 1026, 1000, 975, 900, 813, 800, 771, 750, 712, 700, and 690 cm^{-1}. Benzene-hexane eluted benzoylferrocene azine, 1.9 g, mp 155—157°C, which was identified by comparison with an authentic specimen (mixed mp and IR).

Reactions of Id-f. Each of the tosylhydrazones, Id, Ie, and If, (0.038 mol) was reacted in the usual manner. IId was obtained as a colorless liquid; 0.580 g (5.7%); 150—155°C/1.5 mmHg. IR spectrum (liquid film): 3120, 3080, 1605, 1500, 1450, 1072, 1030, 963, 772, 760, 733, and 695 cm^{-1}. IIe was obtained as colorless crystals; 6.35 g (58.7%); mp 161—162°C. IR spectrum (liquid film): 1598, 1490, 1440, 1075, 1064, 1011, 770, 746, and 700 cm^{-1}. IIf was obtained as colorless crystals; 3.08 g (23.4%); mp 165—166°C, (lit[2b] 165—165.5°C). IR spectrum (Nujol): 1600, 1495, 1072, 1031, 1006, 907, 795, 755, 717, and 695 cm^{-1}.

Reactions of Ig-i. Ig, Ih, and Ii (0.040 mol) were all reacted as usual. However in the reactions of Ih and Ii the temperature was raised to 120°C in order to smooth the decomposition of the salts. IIg was obtained as colorless crystals; 4.20 g (35.0%); mp 111—112°C. IR spectrum (Nujol): 1610, 1600, 1514, 1495, 1300, 1245, 1185, 1030, 967, 835, 812, 766, 757, 733, and 700 cm^{-1}. IIh (9.43 g, 75%) was obtained. Mp 82—83°C. IR spectrum (liquid film): 3100, 3070, 2960, 1612, 1603, 1512, 1495, 1450, 1380, 1245, 1180, 1030, 829, 770, 750, 706, and 695 cm^{-1}. IIi (4.10 g 27%) was obtained. Mp 142.5—143.5°C. IR spectrum (Nujol): 1612, 1602, 1510, 1495, 1245, 1173, 1106, 1029, 782, 750, 730, and 699 cm^{-1}.

The authors wish to thank Mr. Katsuhiko Maruo for his technical assistance and Dr. Koji Yamamoto for his helpful discussions.

Tri(hetero)substituted Carbonium Ions. IV. Reactions of *N,N*-Dimethyl-*S,S'*-dimethyldithiocarbamidium Ion with Various Nucleophiles*

Takeshi NAKAI and Makoto OKAWARA

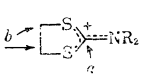
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 13, 1970)

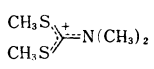
A wide spectrum of electrophilic reactivity has been shown by *N,N*-dimethyl-*S,S'*-dimethyldithiocarbamidium perchlorate (II). Results obtained reveal that II behaves toward nucleophiles as an ambident electrophile with two reactive sites, a centered electron-definicent carbon and *S*-methyl carbon atom. The electrophilic behavior of II has been compared with that of a cyclic analog, 2-dimethylamino-1,3-dithiolanylium ion, and of a sulfur analog, tris(methylthio)-carbonium ion. Attempts to utilize II for synthetic reactions were made. Reactions of II with active methylene compounds gave ketone *N,S*-acetals which are of great interest from the standpoint of structural chemistry. *o*-Phenylenediamine and *o*-aminophenol reacted with II to give 2-dimethylamino-benzimidazole and -benzoxazole, respectively, in good yields. The reactions may provide a new method of introducing 2-dialkylamino groups into these heterocycles. Reactions of II with two equivalents of primary amines afforded tetrasubstituted guanidines. Reactions of II with *p*-toluenesulfonylhydrazine and an enamine were also studied.

In our previous papers[1-3] information on the characterization and electrophilic reactivity, of 2-dialkylamino-1,3-dithiolanylium ions (I) was given. The stable carbonium ions behave toward nucleophiles as an ambident electrophile with two reactive sites. *a* and *b* in formula (I) and the reaction course are greatly affected by the nucleophilicity of the reagent used.

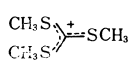
In the present work the electrophilic behavior of an open-chain analog of I, *N,N*-dimethyl-*S,S'*-dimethyldithiocarbamidium ion (II),[4] has been investigated in detail. Our previous studies on I lead us to expect a similar ambident behavior of II. The reactions of a sulfur analog of II, tris-(methylthio)carbonium ion (III) with nucelophiles have been reported.[5]



I



II



III

The purpose of this work is to clarify differences in the electrophilic behavior between open-chain cation II and cyclic I or sulfur analog III, and to utilize II for synthetic reactions.

Results and Discussion

N,N-Dimethyl-*S,S'*-dimethyldithiocarbamidium perchlorate (IIa) was obtained in 78% yield by methylation of methyl *N,N*-dimethyldithiocarbamate with dimethyl sulfate[6] followed by treatment with sodium perchlorate. The white crystals melted at 84—86°C and its NMR spectrum showed two singlet signals at δ 2.85 (SCH_3) and 3.70 ppm (NCH_3).

Reactions with Simple Nucleophiles. In order to demonstrate the spectrum of reactivity of II, the reactions of IIa with a variety of nucleophiles including hydroxide, alkoxides, mercaptides, cyanide and dimethyldithiocarbamate ions were investigated. Scheme 1 indicates products obtained and the possible reaction sequences. Characterization of products isolated includes comparisons of their IR and NMR spectra, boiling and melting points, and refractive indexes with those of authentic compounds.

After our preliminary communication ap-

peared,*1 Tarbell and co-workers briefly reported on reactions of the iodide of II with triethylamine and dimethyl sulfide[7]; II reacts with these nucleophiles to produce the methylated compounds of the nucleophiles and methyl *N,N*-dimethyldithiocarbamate. The behavior of II toward nucleophiles are summarized in Table 1 together with those of I and III.

Table 1 shows that, as expected, carbonium ion II is an ambident electrophile with two reactive sites, the centered carbon (*a*) and *S*-methyl carbon atom (*b*) and that, on the whole, II directs the attack of nucleophiles in the same manner as I and III. However, some significant differences between II and I or III were observed; (i) II directs the attack of $^-$SEt to position *a*, while I reacts with the anion at position *b*; (ii) under the given conditions II resists reacting with $^-SC_6H_4$-CH_3-*p* (see Experimental), but I readily reacts with the anion at position *b*; (iii) II reacts with $^-$CN at *a*, while III directs the attack of the anion to *b*; (iv) II directs the attack of NEt_3 to *b*, while I reacts with the amine to afford *S*-vinyl dithiocarbamates *via* hydrogen abstraction reactions. Difference (i) is the first example that the reaction course undergoes with a change in the structure of carbonium ion having the same three α-hetero atoms.

These differences cannot be reasonably explained in the present stage. In the case of the reaction with $^-$SEt, however, the difference in reaction course between I and II might be interpreted in terms of the stability of the two carbonium ions described below.

According to our classification of reactions, the reaction at site *a* is mode A and the reaction at *b* is mode B, and the former is controlled kinetically and the latter thermodynamically.[2,3] In consequence, the free activation energy for mode A always much less than that for mode B since mode A corresponds to a simple association between the cation and the anion. It might be assumed that the position of equilibrium between the cation and the adduct in mode A should depend upon the difference in free energy (ΔF_A). On the other hand, the fact that II is greatly less stable than I has been confirmed not only by the kinetic observation that the rate of reaction of II with $^-$OH is about 10^4 times larger than that of I,[3] but also by the spectral observation that the absorption maximum of II appears at a longer wavelength (276 mμ) than

7) J. L. Richard, D. S. Tarbell and E. H. Hoffmeister, *Tetrahedron*, **24**, 6485 (1968).

that of I (249 mμ).[8] It may be further expected that adduct IV from II and $^-$SEt is comparable to or slightly less stable than adduct V from I and the anion. Accordingly, it may be said that the difference in free energy between II and IV is larger than that between I and V, *i.e.*, $\Delta F_A(II) > \Delta F_A(I)$. Alternatively, the position of equilibrium in Eq. 1 is shifted to the right leading to the formation of IV, while the position in Eq. 2 is shifted to the left, which, in turn, results in the formation of β-(ethylthio)ethyl dithiocarbamate (VI) *via* mode B, as found experimentally. These considerations confirm the postulate previously proposed that the major factor deciding the reaction course is the relative position of kinetically controlled product such as IV and V in the energy diagram.

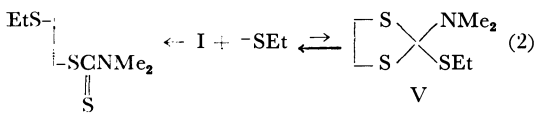
IV

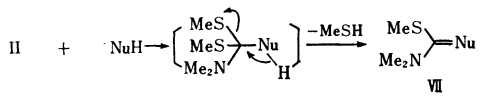


(2)

V

VI

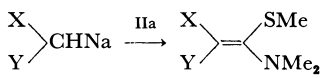
Furthermore, it is interesting to note that as exemplified in the reaction of II with hydroxide ion, II may be expected to react with nucleophiles bearing an active hydrogen atom ($^-$NuH) to afford compounds of a type of ketene *N,S*-acetal (VII), which are of some use from the preparative point of view.



VII

Thus, the reactions of IIa with active methylene compounds, primary amines and an enamine were studied and the results are described below.

Reactions with Active Methylene Compounds. A suspension of IIa and the sodium enolate of active methylene compound in dioxane was stirred at 80°C to afford ketene *N,S*-acetal (VIII) accompanied by evolution of methylmercaptan. These products were identified by IR and NMR spectra. Yields and physical properties of VIII are shown in Table 2.



VIII

These ketene *N,S*-acetals are of special interest from the standpoint of structural chemistry because observations of unusually low barriers to internal rotation around the carbon-carbon double bond may be anticipated.[9] Table 3 shows the

8) For the α-hetero atom effects on electronic spectra of tri(hetero)substituted carbonium ions, a definite trend has been observed. As SCH_3 in tris(methylthio)-carbonium ion (III) is progressively replaced by the more electron-donating $N(CH_3)_2$, there is a strong shift of absorption maxima to short wavelengths (high energies). This trend suggests that as the carbonium ion becomes more stabilized, the absorption maximum appears at shorter wavelength. The conclusion has been confirmed by simple Hückel molecular orbital calculations: T. Nakai, K. Hiratani and M. Okawara, unpublished results.

9) Recently Sandström and co-workers have reported on the observations of low barriers to internal rotation around the C=C bonds in ketene mercaptals and the aminals: G. Isakson, J. Sandström and I. Wennerbeck, *Tetrahedron Lett.*, **1967**, 2233.

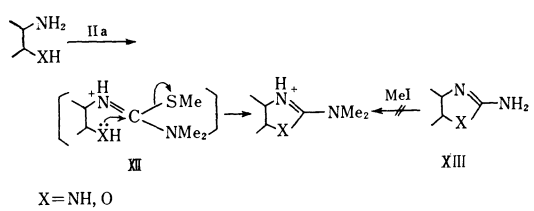
- - -: VIIIa (neat).

spectral data of VIII. It is interesting to note that the IR spectra of compounds (VIIIa, b, c and d) showed the carbonyl stretching band ($\nu_{C=O}$) at lower wave numbers than those of the parent methylene compounds. A typical example is shown in Fig. 1. This spectral trend suggests that the polar structures such as VIIIa′ and VIIIa″ significantly contribute to the ground state.

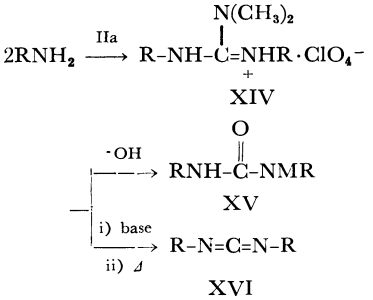
Recently Sandström has reported on unusually low barriers to internal rotation around the C=C bonds in ketene *N,S*-acetals by means of temperature variable NMR spectroscopy.[10] The significant contribution of the polar structures would be responsible for the unusually low barriers to internal rotation. In consequence, it seems to be impossible to determine the geometric configuration of VIIIb and VIIIc at room temperature since a fast interconversion between the *cis* and *trans* isomers occurs.

Reactions with Primary Amines. Carbonium salt IIa reacted with ethylenediamine at 50°C to give an imidazolium salt (IX) in 50% yield. Similarly, carbonium salt IIa reacted with *o*-phenylenediamine and *o*-aminophenol followed by treatment with base to afford 2-dimethylaminobenzimidazole (X) and the benzoxazole derivative (XI), respectively. The formation of these heterocyclic compounds may be explained by the following scheme which involves an intramolecular reaction of intermediate XII of type of VII. Table 4 shows yields and physical properties of these products.

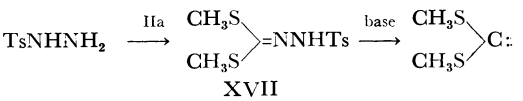


These reactions are of some avail since they provide a new method for introducing dialkylamino groups into the 2 position of these heterocyclic systems; 2-dialkylamino-benzimidazoles and the benzoxazole analogs cannot be prepared by alkylation of easily obtainable 2-amino derivatives owing to the basic properties of the nitrogen atom in the rings. Recently Eilingsfeld and Möbius have reported that compound X was obtained in 57% yield from *N,N*-dimethyl-(2-methoxycarbonylethylmercapto)-formamide chloride and *o*-phenylenediamine.[11]

It was found that IIa reacted with two equivalents of primary amines (cyclohexylamine and aniline) to afford tetrasubstituted guanidium salts (XIV) *via* an intermolecular reaction of the intermediate of a VII type with the amine. These salts were hydrolyzed to produce disubstituted ureas (XV). The formation of the guanidium salts is of some interest since there is the possibility that guanidine obtained by treatment of XIV with an appropriate base thermally decomposes to give carbodiimides (XVI) accompanied by elimination of dimethylamine[12] (see Experimental).



In contrast to these primary amines, *p*-toluenesulfonylhydrazine reacted with IIa to give hydrazone XVII accompanied by elimination of dimethylammonium salt. Hydrazone XVII has been employed as a precursor of bis(methylthio)-carbene.[13]



Reaction with An Enamine. Carbonium salt IIa reacted with 1-*N*-morpholino-1-cyclo-

10) For ketene *N,S*-acetal VIIIc, the following data was available: coalescene temperature (Tc) is −67.5°C and free activation energy for internal rotation (ΔG^*) is 10.4 kcal/mol: J. Sandström, private communication.

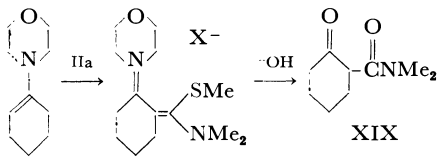
hexene to give iminium salt XVIII, a compound of type of VII, which was isolated as tetraphenylborate in 43% yield. Hydrolysis of the salt gave α-(*N,N*-dimethylcarbamoyl)cyclohexanone (XIX), which was identified by IR spectrum and by conversion to the 2,4-dinitrophenylhydrazone. The reaction sequences are shown below.



XVIII, X = ClO_4, BPh_4 XIX

Experimental

General. All melting and boiling points are uncorrected. Infrared and ultraviolet spectra were recorded on Hitachi EPI-S2 and EPS-2 spectrometers, respectively. NMR spectra were obtained with a Japan Electron Optics C-60 spectrometer. Chemical shifts are given in parts per million (ppm) from tetramethylsilane as an internal standard. Multiplicity of signals is indicated as follows; s=singlet, t=triplet, q=quartet and m=multiplet.

N,N-Dimethyl-S,S′-dimethyldithiocarbamidium Perchlorate (IIa). Methyl *N,N*-dimethyldithiocarbamate (13.5 g, 0.10 mol) was dissolved in 12.5 g (0.10 mol) of dimethyl sulfate. When the mixture was heated to 60°C, a vigorous exothermic reaction occurred. The reaction temperature was kept below 100°C. After the exothermic reaction stopped the mixture was stirred at 90°C for an additional 30 min. The mixture was poured into 100 m*l* of a saturated aqueous solution of sodium perchlorate giving 19.0 g (76%) of pale yellowish precipitate. The precipitate was washed with ether and recrystallized from methanol giving white crystals: mp 84—86°C.

Found: C, 23.73; H, 4.68; N, 5.13%. Calcd for $C_5H_{12}ClNO_4S_2$: C, 24.05; H, 4.85; N, 5.61%.

Hydrolysis of IIa. Carbonium salt IIa (12.5 g, 0.05 mol) was added to a solution of water (1.0 g, 0.05 mol) and triethylamine (5.0 g, 0.05 mol) in 50 m*l* of dioxane. The mixture was stirred at 80°C for 6 hr, then poured into water. The ethereal extract was dried over anhydrous sodium sulfate and the solvent evaporated *in vacuo*. Distillation of the residue gave 3.7 g (62%) of methyl *N,N*-dimethylthiolcarbamate; bp 91—92°C/31 mmHg; n_D(21°C) 1.4964 (lit, [11] bp 115—116°C/89 mmHg; n_D(30°C) 1.4932); IR (neat) 1650 cm^{-1} (C=O); NMR (CCl_4): δ 2.26 (s, SCH_3) and 3.00 ppm (s, NCH_3). The infrared spectrum of this distillate was in agreement with that of the authentic sample.

Reactions with Sodium Alkoxides. A suspension of IIa (0.05 mol) and sodium methoxide (8.0 g, 0.15 mol) in 70 m*l* of dioxane was stirred at 70°C for 2 hr. Work-up gave methyl *N,N*-dimethylthiolcarbamate in 69% yield.

The reaction of IIa with sodium ethoxide carried out as in the case of sodium methoxide gave the same product in 60% yield.

Reaction with Sodium Cyanide. Carbonium salt IIa (0.05 mol) and sodium cyanide (7.5 g, 0.15 mol) were dissolved in 50 m*l* of dimethylformamide (DMF). The mixture was stirred at 60°C for 5 hr, then poured into an aqueous solution of sodium carbonate. After being put to stand overnight, the mixture was extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate and the solvent evaporated *in vacuo*. Distillation of the residue gave 4.4 g (90%) of *N,N*-dimethylcarbamoyl cyanide; bp 39—41°C/1.0 mmHg (lit,[15] 202—203°C); n_D(22°C) 1.4873; IR (neat): 2270 (C≡N) and 1670 cm^{-1} (C=O).

Attempts made to isolate the initial adduct, bis(methylthio)-*N,N*-dimethylaminocarbinyl cyanide, failed.

Reaction with Sodium N,N-Dimethyldithiocarbamate. Carbonium salt IIa (0.01 mol) and sodium *N,N*-dimethyldithiocarbamate (1.8 g, 0.01 mol) were dissolved in 20 m*l* of DMF. The mixture was stirred at 70°C for 3 hr, then poured into cold water giving 1.1 g (41%) of white precipitate of methyl *N,N*-dimethyldithiocarbamate: mp 44—46°C. The IR spectrum of the product was in agreement with that of the authentic sample. The low yield might be due to dissolution of the product in the solvents.

Reactions with Sodium Mercaptides. A suspension of carbonium salt IIa (20.0 g, 0.08 mol) and sodium ethylmercaptide (5.0 g, 0.05 mol) in 50 m*l* of dioxane was stirred at 80°C for 5 hr under a nitrogen atmosphere. The reaction mixture was poured into water, then extracted with ether. The ethereal extract was dried over anhydrous sodium sulfate and the solvent evaporated *in vacuo*. Distillation of the oily residue gave two distillates: bp 55—57°C/51 mmHg (4.7 g) and bp 125—140°C/39 mmHg (1.6 g).

The IR spectrum of the former product showed a strong absorption band at 1650 cm^{-1} (C=O) and the NMR spectrum showed proton signals at δ 2.25 (s, SCH_3), 3.00 (s, NCH_3), 1.25 (t, $C\underline{H}_3CH_2S$) and 4.65 ppm (q, $CH_3C\underline{H}_2S$). Results indicate that the former product is a mixture of *S*-methyl *N,N*-dimethylthiolcarbamate and its *S*-ethyl analog.

On the other hand, the IR spectrum of the latter product exhibited no absorption band due to carbonyl groups and the NMR spectrum showed proton signals at δ 1.25 (t, $C\underline{H}_3CH_2S$), 2.06 (s, SCH_3), 2.33 (s, NCH_3) and 4.65 ppm (q, $CH_3C\underline{H}_2S$). The data indicate that the latter prodact seems to be $(MeS)_2(EtS)C(NMe_2)_2$.

The reaction of IIa with sodium *p*-tolylmercaptide carried out as in the case of sodium ethylmercaptide gave no organic products.

Reactions with Active Methylene Compounds. Sodium (1.2 g, 0.050 mol) was added to a solution of an active methylene compound (0.055 mol) in 75 m*l* dioxane. The mixture was heated at 50°C giving a precipitate of sodium enolate accompanied by evolution of hydrogen gas. Carbonium salt IIa (0.050 mol) was then added to the suspension and the mixture was stirred at 80°C for 2 hr under a nitrogen atmosphere. Sodium perchlorate formed on cooling was filtered off. Distillation of the filtrate under reduced pressure gave ketene *N,S*-acetal (VIII). In the case of malononitrile, the solvent was removed from the filtrate giving a solidified residue. The residue was recrystallized

15) F. K. Beilstein, "Handbuch der Organischen Chemie," Vol. 5, Suppl. II, p. 330 (1943).

from acetonitrile.

Yields and physical properties of VIII are shown in Tables 2 and 3.

Reaction with Ethylenediamine. Carbonium salt IIa (5.0 g, 0.02 mol) and ethylenediamine (1.2 g, 0.02 mol) were dissolved in 40 m*l* of ethanol. The mixture was refluxed for 5 hr, and the solvent was evaporated *in vacuo* to give precipitates of IX: mp 159—160°C (ethanol).

Reaction with *o*-Phenylenediamine. The reaction of IIa (0.02 mol) and *o*-phenylenediamine (2.0 g, 0.02 mol) carried out as in the case of the reaction with ethylenediamine gave benzimidazolium perchlorate (Xa); mp>310°C (ethanol). Treatment of Xa with an ethanolic solution of sodium methoxide gave 2-dimethylamino-benzimidazole (X).

Reaction with *o*-Aminophenol. The reaction of IIa (0.02 mol) with *o*-aminophenol (2.0 g, 0.02 mol) carried out as in the case of the reaction with *o*-phenylenediamine gave 2-diaethylamino-benzoxazole (XI) (recrystallized from ethanol).

Yields and physical properties of products from reactions with the three amines are shown in Table 4.

Reactions with Primary Amines. *With Cyclohexylamine.* A solution of IIa (0.02 mol) and cyclohexylamine (4.0 g, 0.04 mol) in 50 m*l* of ethanol was heated at 50°C for 5 hr. The solvent was removed *in vacuo* giving a viscous residue. An aqueous solution of $NaBPh_4$ was added to the residue giving a white precipitate of guanidinium salt (XIV; R=C_6H_{11}, X=BPh). However, the precipitate did not give satisfactory data of elementary analysis. On the other hand, an aqueous solution of sodium carbonate was added to the viscous residue (XIV, X=ClO_4) giving a white precipitate accompanied by evolution of dimethylamine. Recrystallization of the precipitates from ethanol gave colorless needles of *N,N'*-dicyclohexylurea: mp 227—228°C. The IR spectrum of the precipitate was in agreement with that of the authentic sample.

Some attempts were made to prepare carbodiimide from guanidinium salt; a solution of potassium *t*-buthoxide in *t*-buthanol was added to the viscous residue (XIV, X=ClO_4) and anhydrous ether was then added to the resulting mixture giving a precipitate of potassium perchlorate. The precipitate was filtered off and the solvents were evaporated from the filtrate giving an oily residue. The residue was heated at 150°C for 2 hr under reduced pressure (30 mmHg). The IR spectrum of the resulting residue showed a strong band at 2200 cm^{-1} presumably due to the –N=C=N– group. However, isolation of dicyclohexylcarbodiimide in pure form was unsuccessful.

With Aniline. The reaction of IIa (0.02 mol) with aniline (3.6 g, 0.04 mol) carried out as in the case of cyclohexylamine gave a viscous residue of guanidinium salt (XIV; R=Ph, X=ClO_4). Addition of a solution of $NaBPh_4$ to the residue gave a precipitate of tetraphenylborate: mp 130—132.5°C (from ethanol). However, the data of elementary analysis were unsatisfactory. Treatment of the viscous residue with an aqueous solution of sodium carbonate gave a precipitate of *N,N'*-diphenylurea: mp 233—235°C. The IR spectrum of the precipitate was in agreement with that of the authentic sample.

Reaction with Tosylhydrazine. Tosylhydrazine (3.7 g, 0.02 mol) was suspended in a solution of IIa (0.02 mol) in 40 m*l* of ethanol. The suspension was heated with stirring at 55—60°C for 4 hr. The resulting clear solution was cooled in an ice box giving 2.7 g (61%) of precipitates of XVII. Recrylstallization from ethanol gave colorless needles: mp 149—150°C (lit,[13] 150.5—151.5°C).

Found: C, 41.27; H, 4.92; N, 9.87%. Calcd for $C_{10}H_{14}N_2O_2S_3$: C, 41.38; H, 4.86; N, 9.65%.

Reaction with An Enamine. Carbonium salt IIa (0.02 mol) was added to a solution of 1-*N*-morpholino-1-cyclohexene (0.02 mol) in 30 m*l* of dioxane. The suspension was heated with stirring at 50—60°C for 30 min. The solvent was then evaporated *in vacuo* producing a viscous residue containing iminium salt (XVIII; X=ClO_4). An aqueous solution of $NaBPh_4$ was added to the residue giving a precipitate (43%) of iminium salt XVIII (X=BPh_4): mp 187—189°C; IR (KBr): 1565 cm^{-1} (C=N).

Found: N, 4.42%. Calcd for $C_{38}N_{45}BN_2OS$: N, 4.76%.

The viscous residue was treated with a dilute aqueous solution of sodium hydroxide and the mixture was extracted with ether. The ethereal layer was dried over anhydrous sodium sulfate. The solvent was then evaporated *in vacuo* affording an oily residue, 2-*N,N*-dimethylcarbamoylcyclohexanone (XIX); IR (neat): 1695 (ketone) and 1645 cm^{-1} (amide). Treatment of the oily residue with 2,4-dinitrophenylhydrazine gave a precipitate of the corresponding hydrazone; mp 83—85°C (ethanol).

Found: C, 51.84; H, 5.30%. Calcd for $C_{13}H_{18}N_5O_5$: C, 51.57; H, 5.48%.

The authors are grateful to Dr. J. Sandström, University of Lund, Sweden, for disclosing the results of his work on internal rotation prior to publication, and to Mr. Y. Ueno for his technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3535—3539 (1970)

The Preparation, Lithium Aluminum Hydride Reduction, and Electronic Spectra of Halogen-substituted 3,4-Bis(diphenylmethylene)-cyclobutenes and -cyclobutanes

Fumio TODA, Kunihiro KUMADA, Nobuo ISHIGURO and Katsuhiko AKAGI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

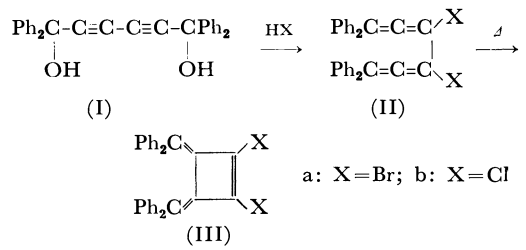
(Received May 20, 1970)

The title compounds were prepared, and their physical and chemical properties were investigated. The reduction of the cyclobutenes with lithium aluminum hydride afforded halogen-free cyclobutane. The mechanism of the reduction is discussed. The cyclobutenes showed their K-bands in a wavelength region *ca.* 100 nm shorter than in the cases of the corresponding cyclobutanes. Furthermore, the K-band of the cyclobutenes is comparable to that of 1-phenylbuta-1,3-diene. On the basis of the electronic spectral data, a puckered structure was postulated for the cyclobutenes.

Molecular orbital calculations have indicated that dimethylenecyclobutene has a delocalization energy of 1.21 β, which is almost equal to that of cyclobutenedione, 1.24 β.[1-3] Those calculated values, however, might not always show the stability or aromaticity of such a small-ring system, since calculations are carried out without consideration of any ring-strain factor.

Some anomalous ultraviolet spectral data of dimethylenecyclobutenes have been discussed. Since the two strong absorption bands of dimethylenecyclobutenes having no conjugated substituents, 209—213 and 245—249 nm, are comparable to those of 1,2-dimethylenecyclobutane, 237, 246, and 255 (sh) nm, it has been suggested that dimethylenecyclobutene is better viewed as a cross-conjugated diene rather than as a conjugated triene.[3-5] On the other hand, the absorption bands of 1,2-diphenyldimethylenecyclobutene, 237, 262, and 328 nm, are not derivable by the simple overlap of the spectra of dimethylenecyclobutane and *cis*-stilbene, 285 nm.[3,6,7]

The discrepancy of the calculated delocalization energy and the spectral data of dimethylenecyclobutene probable arises because of the *endo*-double bond's causing ring strain. In order to clarify the nature of such *endo*-double bonds, we have studied the electronic spectra and lithium aluminum hydride (LAH) reduction of the title compounds (III—X). Electronic spectral studies of those compounds have shown that bis(diphenylmethylene)cyclobutanes (IV, V, VII, IX and XII) absorbed at a much longer wavelength region, *ca.* 390 nm, than did bis(diphenylmethylene)-cyclobutenes (III, VIII and X) (*ca.* 290 nm). The reduction of the compounds of both series by LAH afforded bis(diphenylmethylene)cyclobutane (XII). Studies of the reduction mechanism, disclosed that the reduction of the *endo*-double bond of III and X to afford XII proceeds by way of competing addition and elimination processes.



Scheme 1

Preparation of Compounds. The treatment of 1,1,6,6-tetraphenylhexa-2,4-diyne-1,6-diol (I) with hydrohalogeno acid in acetic acid at about 0°C afforded 3,4-dihalo-1,1,6,6-tetraphenylhexa-1,2,4,5-tetraene (II).*1 By heating a benzene solu-

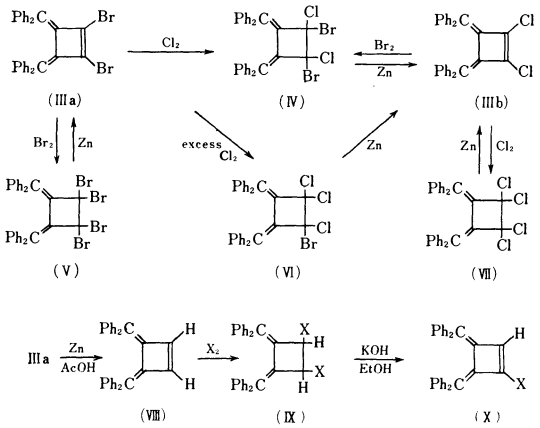
*1 The preparation of IIa and its transformation to 2,5,6,6-tetraphenyl-3-bromofulvene by protonation, accompanied by the cyclization and migration of phenyl, have been reported in a preliminary communication: M. Higashi, F. Toda and K. Akagi, *Chem. Ind.* (London), **1969**, 491.

tion of II under reflux for 1 hr in a nitrogen atmosphere, a cyclization product, 1,2-dihalo-3,4-bis(diphenylmethylene)cyclobutene (III), was obtained in a quantitative yield. The IIIa and IIIb thus obtained showed the medium band of the *endo*-double bond at 1510 and 1530 cm^{-1} respectively, in addition to the weak band of the *exo*-double bond at 1660 cm^{-1}. The method of preparing III from II is comparable to that used for preparing dimethylenecyclobutene from 1,5-hexadiyne by pyrolysis at 350°C.[8] The reaction is believed to proceed through an intermediate diallene.[8]



a: X=Br; b: X=Cl

Scheme 2

The addition of bromine to IIIa and that of chlorine to IIIb in chloroform afforded tetrabromide (V) and tetrachloride (VII) respectively, in almost quantitative yields. Heating the tetrahalides with zinc powder in ethanol gave the corresponding dihalides (III) quantitatively. The action of chlorine on IIIa, which affords mainly monobromotrichloride (VI) (71%), is in contrast to that of bromine on IIIb, which gives dibromodichloride (IV). The addition of chlorine, however, under carefully-controlled conditions afforded mainly IV. Both IV and VI afforded IIIb when treated with zinc powder in boiling ethanol. Since the cross-addition reactions of IIIa and IIIb afforded the same product, IV, it is clear that the addition occurs on the *endo*-double bond. Furthermore, the structures of the tetrahalides (IV, V, VI, and VII) were determined on the basis of the electronic spectral data: those data showed that all the tetrahalides absorbed at nearly the same region, 400—388 nm (Table 2).

It has been reported[3,9] that the reduction with zinc powder of the tetrachloride (VII, mp 202°C) prepared by the thermal dimerization of 1,1-diphenyl-3,3-dichloropropadiene afforded benzophenone, but not cyclobutene (IIIb). This finding differs widely from the present observation that VII (mp 210—211°C) was easily dehalogenated with zinc powder to IIIb.

Bis(diphenylmethylene)cyclobutene (VIII), 3,4-dihalo-bis(diphenylmethylene)cyclobutane (IX), and 1-bromo-3,4-bis(diphenylmethylene)cyclobutene (X) were successively prepared from IIIa by the manner shown in Scheme 2. Adding an equimolar amount of bromine to a chloroform solution of VIII at room temperature afforded IXa in an 82% yield. The reaction of VIII with an excess of chlorine afforded IXb in a 36% yield, together with the tetrachloride (VII) and an unidentified tetrachloride (mp 183—184.5°C) in 18 and 26% yields respectively. The tetrachloride (VII) must be produced by the chlorine substitution on the IXb initially formed, since the same treatment of IXb with chlorine yielded VII.

The structure of IX was determined by comparing its NMR spectral data with those reported for the same compound which had been prepared by the dimerization of 1,1-diphenyl-3-halopropadiene.[10,11] The τ-values of the methyne proton signal of IXa (mp 145—146°C), 4.85, and of IXb (mp 189—190°C), 4.96, were almost the same as the reported values for IXa (mp 143—144°C), 4.87[10], and for the *cis*-isomer of IXb (mp 191—192°C), 4.98.[11] Since the *cis*-addition of halogen to olefin is unlikely, dihalide (IX) must have a *trans*-geometry. Therefore, the reported *cis*-geometry of the dichloride (IXb)[11] is doubtful. After our work had been finished, the fact that the *cis*-geometry of IXb is erroneous was reported.[12] Therefore, the reaction of IX with base to afford X proceeds by means of *cis*-elimination.

Few additions of halogen to the *endo*-double bond of dimethylenecyclobutene have been known. It has, however, been reported[13] that the addition of chlorine to 1,2-dichloro-3,4-bis(dichloromethylene)cyclobutene to afford perchloromethylenecyclopentene probably proceeds *via* the intermediate 1,1,2,2-tetrachloro-3,4-bis(dichloromethylene)-cyclobutane initially produced by the addition of chlorine to the *endo*-double bond.

Reduction by Lithium Aluminum Hydride. Heating a mixture of IIIa, IIIb or Xa, and LAH

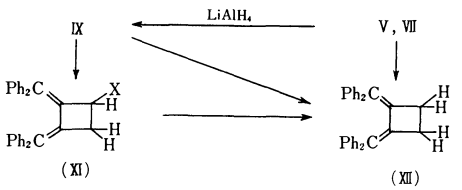
THF-ether under reflux for 2 hr afforded 1,2-bis-(diphenylmethylene)cyclobutane (XII) and 2,3-bis(diphenylmethylene)-1,4-butanedial (XVIII) in the yields summarized in Table 1. In order to clarify the reaction mechanism, V, VII, and IXa were also treated with LAH under the same conditions as above, but this yielded XII, not XVIII. By the same treatment, however, VIII afforded XVIII quantitatively. Those results are also shown in Table 1.

Table 1. Yields (%) of the reduction products

Product	Reactant						
	IIIa	IIIb	Xa	VIII	V	VII	IXa
XII	33	41	30	—	71	67	78
XVIII	8	9	15	100	—	—	—

The transformation of V, VII, and IX into XII may be due to direct and/or successive substitution, as is shown in Scheme 3, since it has been well established[14,15] that halogen at an allylic position is easily reduced by LAH. On the other hand,



Scheme 3

the reduction of III and X to afford XII and XVIII must proceed by the following two competing paths. One consists of addition followed by substitution, such as III→XIII→XII and X→XIV (and/or XV)→XII. The other one consists of substitution, III→X→VIII, finally yielding the photooxidation product XVIII, probably *via* the cyclic intermediate (XVII). It is clear that the VIII formed initially by the substitution is converted to XVIII during the procedure of isolation, since it has been reported that VIII is easily photooxidized into XVIII even in the course of recrystallization from a usual organic solvent,[16] and since the same treatment of VIII with LAH afforded XVIII quantitatively. The above speculation on the two competing paths is further supported by the observation that the reduction of X afforded XVIII in a yield about twice that of the XVIII obtained from III, Table 1.

Since no LAH reduction of carbon-carbon double bonds has yet been reported, except where the double bond is conjugated with an electronegative group, such as carbonyl, nitro, or cyano, the present results show an anomalous reactivity of the strained *endo*-double bond of III and X. However, the results of LAH reduction differ from those of the sodium borohydride reduction[16] of IIIa in ethanol to Xa by the addition-elimination process.

Electronic Spectra. The K-bands of the electronic spectra are summarized in Table 2. Those data show distinct difference in the absorption maxima between cyclobutene (III, VIII, or X) and cyclobutane (IV, V, VI, VII, IX, or XII). The former, formally conjugated triene. absorbs at a wavelength region shorter by about 100 nm than the latter, conjugated diene. It is

Table 2. K-Bands of 3,4-bis(diphenylmethylene)-cyclobutenes and -cyclobutanes in chloroform

K-Band	Cyclobutenes				Cyclobutanes					
	IIIa	IIIb	Xa	VIII	V	IV	VI	VII	IXa	XII
λ_{max} (nm)	290	285	285	280	400	395	390	388	378	357
$\varepsilon_{max} \times 10^{-2}$	364	364	306	287	162	140	159	159	145	209

very clear that the cyclobutene is not to be viewed as a conjugated triene, since the K-band of the cyclobutene differs widely from those of such conjugated trienes as *trans*-1,6-diphenyl-[17] and *trans*-1,1,6,6-tetraphenyl-hexa-1,3,5-triene.[18] 358 and 370 nm respectively.

Since the K-band of the cyclobutane, 357—400 nm, is comparable to those of 1,4-diphenyl-[19] and 1,1,4,4-tetraphenyl-buta-1,3-diene,[20] 328 and 342 nm, respectively, the cyclobutane can be considered as a conjugated diene. On the other hand, the K-band of cyclobutene, 284—290 nm, is comparable to that of 1-phenylbuta-1,3-diene,[21] 283 and 308 nm, rather than to those of 1,4-diphenyl- and 1,1,4,4-tetraphenyl-buta-1,3-diene.

The above data of cyclobutene can reasonably be interpreted by assuming the puckered structure shown in Fig. 1, in which one diphenylmethylene group is out of the plane containing the other diphenylmethylene and the *endo*-double bond. It is not unreasonable to assume that the four-membered ring with the large ring strain, which is due to the combination of the *endo*-double bond and to steric crowding among the four phenyl rings, is stabilized, with relaxation from the steric crowding among the four phenyl rings by means of the puckering. Recently, a similar puckered structure of a cyclobutenone derivative has been reported.[22]

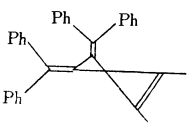

Fig. 1. Puckered structure of 3,4-bis(diphenylmethylene)cyclobutenes.

Experimental

All the melting points were uncorrected. The electronic spectra were measured in chloroform on a Hitachi spectrophotometer, model 124. The infrared spectra were recorded on a grating spectrophotometer, IR-G, of the Japan Spectroscopic Co. The NMR spectra were recorded in deuterochloroform on a Japan Electron Optics Laboratory H-100 spectrometer, TMS being used as the internal standard.

Thermal Isomerization of II into 1,2-Dihalo-3,4-bis(diphenylmethylene)cyclobutene (III). A solution of IIa* in benzene was heated under reflux in a nitrogen atmosphere for 1 hr. The crude crystals obtained by the subsequent evaporation of the solvent were recrystallized from ethyl acetate to afford IIIa as colorless needles in a practically quantitative yield; mp 190—191°C. IR ($CHCl_3$), 1510 cm^{-1} (C=C); the NMR spectrum showed only aromatic protons.

Found: C, 66.97; H, 3.49; Br, 29.41%; mol wt (benzene), 551. Calcd for $C_{30}H_{20}Br_2$: C, 66.67; H, 3.70; Br, 29.58%; mol wt, 540.

The chloro-analog (IIb) afforded IIIb quantitatively when treated like IIa; mp 195°C. IR ($CHCl_3$), 1530 cm^{-1} (C=C).

Found: C, 80.01; H, 4.25; Cl, 15.99%; mol wt (benzene), 455. Calcd for $C_{30}H_{20}Cl_2$: C, 79.84; H, 4.44; Cl, 15.72%; mol wt, 450.9.

Addition of Halogen to III. An equimolar amount of bromine was added to, or an equimolar amount of chlorine was bubbled through a stirred solution of III in chloroform at room temperature. After the subsequent evaporation of the solvent, curde crystals were recrystallized from ethyl acetate, affording the corresponding tetrahalide (IV, V or VII) almost quantitatively in all cases. All the tetrahalides are orange yellow prisms. The melting points and analytical data of those tetrahalides were as follows: IV, mp 208—209°C (dec).

Found: C, 58.86; H, 3.21%. Calcd for $C_{30}H_{20}Br_2Cl_2$: C, 58.92; H, 3.27%. V, mp 203—204°C (dec).

Found: C, 51.18; H, 2.73%. Calcd for $C_{30}H_{20}Br_4$: C, 51.43; H, 2.85%. VII, mp 210—211°C (lit[9], mp 202°C).

Found: C, 69.29; H, 3.60%. Calcd for $C_{30}H_{20}Cl_4$: C, 68.98; H, 3.87%. When IIIa was treated with an excess of chlorine, monobromotrichloride (VI) was obtained as the main product. An excess of chlorine was bubbled through a solution of IIIa (1.0 g, 1.85 mmol) in chloroform (10 *ml*) at room temperature. The residue obtained on evaporation was recrystallized from ethyl acetate to afford VI; 0.88 g (71%); mp 179—181°C.

Found: C, 63.51; H, 3.43%. Calcd for $C_{30}H_{20}BrCl_3$: C, 63.77; H, 3.54%.

The treatment of V and VII with zinc powder in boiling ethanol for 5 min afforded IIIa and IIIb respectively. By a similar treatment, both IV and VI afforded IIIb.

Preparation of 3,4-Bis(diphenylmethylene)-cyclobutene (VIII). A mixture of IIIa (1.08 g, 2 mmol), zinc powder (1 g), and glacial acetic acid (30 ml) was heated under reflux for 30 min. An insoluble

solid was then removed by decantation. After the organic layer had been cooled, colorless needles which spearated out were collected by filtration, washed with water, and dried to give VIII; 0.61 g (80%); mp 182°C. NMR, 2.68 (m, Ph, 10H), 2.94 (s, =CH, 2H) and 3.16τ (m, Ph, 10H). The analytical sample was made by recrystallization from ethyl acetate in the dark, since VIII was easily photooxidized in daylight during the course of the recrystallization into the dialdehyde (X-VIII). Upon the recrystallization, however, its mp did not change.

Found: C, 93.60; H, 5.68%. Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%.

Photooxidation of VIII into 2,3-Bis(diphenylmethylene)-1,4-butanedial (XVIII). A solution of VIII (0.382 g, 1 mmol) in ethyl acetate (20 m*l*) was irradiated using a high-pressure Hg-lamp under oxygen for 1 hr. The curde product obtained on the evaporation of the solvent was recrystallized from ethyl acetate to yield XVIII, 0.29 g (70%), as pale yellow rhombs; mp 208.5°C. λ_{max}, 300 (16100) and 335 sh nm (ε, 11600); IR ($CHCl_3$), 2870 and 2750 (CHO), 1670 and 1655 (CO), and 1580 and 1555 cm^{-1} (C=C); NMR, 0.45 (s, CHO, 2H) and 2.90τ (m, Ph, 20H).

Found: C, 86.65; H, 5.39%. Calcd for $C_{30}H_{22}O_2$: C, 86.93; H, 5.35%.

Addition of Halogen to VIII. An equimolar amount of bromine (0.38 g) was added to a solution of VIII (0.8 g. 2.1 mmol) in chloroform (15 m*l*) at room temperature. After the subsequent removal of the solvent by distillation, the crude crystals which remained were recrystallized from ethanol to afford IXa, 0.95 g (82%), as yellow rhombs; mp 145—146°C (lit,[10] mp 143—144°C). NMR, 2.64 (s, Ph, 10H), 3.12 (s, Ph, 10H) and 4.85τ (s, CH, 2H).

Found: C, 66.73; H, 4.15%. Calcd for $C_{30}H_{22}Br_2$: C, 66.42; H, 4.06%.

Through a solution of VIII (0.5 g, 1.3 mmol) in chloroform (30 m*l*) an excess of chlorine was bubbled at room temperature. The residue obtained by the evaporation of the solvent was fractionated into three components by means of fractional recrystallization from acetone. The orange-yellow crystals which separated out initially were collected by filtration and recrystallized from acetone. The product was VIIb, 0.12 g (18%), the structure of which was identified by a comparison of its spectral data with those of an authentic sample prepared by the addition of chlorine to IIIb. The second crop obtained from the above filtrate was recrystallized from acetone to afford IXb as pale yellow needles; 0.21 g (36%); mp 189—190°C (lit,[11] mp 191—192°C): NMR, 2.72 (s, Ph, 10H), 3.22 (s, Ph, 10H) and 4.90τ (s, CH, 2H).

The acetone mother liquor which remained after the removal of VIIb and IXb was concentrated to dryness, and the residue was recrystallized from ethyl acetate to give an unidentified tetrachloride ($C_{30}H_{20}Cl_4$) as pale yellow needles; 0.18 g (26%); mp 183—184.5°C. λ_{max}, 245 (25000) and 288 nm (ε, 28800).

Found: C, 68.42; H, 3.60%. Calcd for $C_{30}H_{20}Cl_4$: C, 68.97; H, 3.83%.

Preparation of 1-Bromo-3,4-bis(diphenylmethylene)cyclobutene (Xa). A mixture of IXa (0.54 g, 1 mmol), potassium hydroxide (0.3 g), and ethanol (20 m*l*) was heated under reflux for 10 min. After cooling, the reaction mixture was decomposed with water, and the solid formed was filtered and washed with water. The dried solid was recrystallized from ethyl acetate-ethanol to afford Xa as colorless needles; 0.45 g (97%), mp 172—173°C (lit,[16] mp 172—173°C). NMR, 2.67 (m, ph, 10H), 2.80 (s, =CH, 1H) and 3.15τ (m, Ph, 10H). The UV (Table 1) and NMR spectral data were identical with those of an authentic sample prepared by the sodium borohydride reduction of IIIa according to the reported method.[16]

LAH Reduction of Halogen-substiuted 3,4-Bis(diphenylmethylene)cyclobutanes (V, VII, and IXa). To a solution of LAH (0.11 g, 3 mmol) in ether (15 m*l*) under nitrogen, a solution of V (0.62 g, 1 mmol) in tetrahydrofuran (10 m*l*) was added, drop by drop, over a period of 1 hr. Then, the mixture was boiled under reflux for 2 hr in a nitrogen atmosphere. After cooling, the reaction mixture was decomposed with water and then with hydrochloric acid, and diluted with ether. The organic layer was repeatedly washed with water and dried over sodium sulfate. The crude product obtained on the evaporation of the solvent was recrystallized from acetone to give XII; 0.27 g (71%): mp 179.5—180°C. NMR, 2.89 (s, Ph, 10H), 3.30 (s, Ph, 10H) and 7.16τ (s, CH_2, 4H).

Found: C, 93.29; H, 6.36%. Calcd for $C_{30}H_{24}$: C, 93.71; H, 6.29%.

Upon similar treatment, VII and IXa also afforded XII; the yields are shown in Table 1.

LAH Reduction of Halogen-substituted 3,4-Bis(diphenylmethyene)cyclobutenes (IIIa, IIIb, and Xa). A solution of IIIb (1.0 g, 2.22 mmol) in tetrahydrofuran (20 m*l*) was treated with a solution of LAH (0.25 g, 6.66 mmol) in ether (30 m*l*) by the same procedure as that employed for V. After decomposition with water and then with hydrochloric acid, the product was taken up in ether. The ether layer was repeatedly washed with water and dried over sodium sulfate. The residue obtained on the evaporation of the solvent was fractionated into two compounds by fractional recrystallization from acetone. The yellow prisms which crystallized initially were recrystallized from acetone to afford XVIII; 0.74 g (8%); mp 208.5°C. The structure was determined by a comparison of its spectral data with those of an authentic sample prepared by the photooxidation of VIII. The pale yellow crystals obtained by the concentration of the acetone mother liquor remaining after the isolation of XVIII were recrystallized from acetone to give XII; 0.28 g (33%); mp 179.5—180°C. The structure was determined by a comparison of its spectral data with those of an authentic specimen.

Upon similar treatment, IIIa and Xa afforded XII and XVIII in the yields shown in Table 1.

LAH Reduction of 3,4-Bis(diphenylmethylene) cyclobutene (VIII). The treatment of a solution of VIII (0.9 g, 2.36 mmol) in tetrahydrofuran (20 m*l*) with a solution of LAH (0.27 g, 7.0 mmol) in ether (20 m*l*) under the conditions employed for V and IIIb afforded XVIII; 0.98 g (100%).

The authors wish to express their thanks to Mr. Shoichi Kato for his elemental analyses and to Miss Toshiko Matsutomo for the measurement of the electronic spectra and molecular weights.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3540—3542 (1970)

The Synthesis of 1-Methyl-2-pyridones from 2-Chloromethylpyridines

Eizo MATSUMURA, Takeo NASHIMA and Fumihide ISHIBASHI

Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka

(Received May 20, 1970)

The reaction of 2-chloromethylpyridine (Ia) and its homologs, 5-ethyl- (Ib), 6-methyl- (Ic), and 4-methyl-2-chloromethylpyridine (Id), with pyridine gave the corresponding 1-(2′-pyridylmethyl)-pyridinium chlorides (II), from which, on heating with dimethyl sulfate, 1-methyl-2-(pyridiniomethyl)-pyridinium salts (III) were obtained. The pyridinium salts were treated with aqueous alkali at a low temperature to yield 1-methyl- (IVa), 5-ethyl-1-methyl- (IVb), 1,6-dimethyl- (IVc), and 1,4-dimethyl-2-pyridone (IVd). The reaction sequence, in combination with the 1-oxidation of 2-picolines and followed by the reaction of the 1-oxides with tosyl chloride to yield 2-chloromethylpyridines, is recommended as a convenient route for the synthesis of 1-methyl-2-pyridones starting with 2-picolines.

There have been reported a variety of methods for the synthesis of 1-methyl-2-pyridones, of which the following procedures are typical. The method of Decker for the synthesis of 1-methylpyridones consists, as is well known, of the treatment of pyridines with dimethyl sulfate, followed by oxidation with ferricyanide. Berson and Cohen[1] obtained 1-methyl-2-pyridone by heating a mixture of 2-picoline methiodide and iodine in a pyridine solution and by treating the resultant dipyridinium salt with aqueous alkali. The 1-methylation of 2-pyridones has also been reported.[2,3]

In previous papers,[4,5] we reported that the reaction of the 1-oxides of pyridine and thiazole derivatives bearing a methyl group at the 2-position with tosyl chloride gave 2-chloromethyl derivatives in a good yield, and suggested that the 2-chloromethylpyridines thus obtained might be used to synthesize a variety of pyridine derivatives.

In the present paper, a study of the conversion of 2-chloromethylpyridines into the corresponding 1-methyl-2-pyridones will be reported.

Results and Discussion

2-Chloromethylpyridine (Ia) and its homologs, 5-ethyl- (Ib) and 6-methyl-2-chloromethylpyridine (Ic), were prepared from the 1-oxides of the corresponding parent bases, that is, 2-picoline, 5-ethyl-2-picoline, and 2,6-lutidine respectively, by a reaction with tosyl chloride. 4-Methyl-2-chloromethylpyridine (Id) was also prepared by the same method from 2,4-lutidine 1-oxide. The identification of Id was not carried out with the free base, because of its facile decomposition during fractionation. The results of the elemental analysis of the picrate obtained from Id agreed with the calculated value required for the methyl-chloromethylpyridinium picrate. The position attacked by the chloride anion was not confirmed directly, but on the bases of the results of a series of reactions described below it was found that the 2-methyl group rather than the 4-methyl group was chlorinated.

The reaction of Ia—d with pyridine proceeded readily upon warming. The removal of the excess pyridine from the reaction mixture *in vacuo* gave a hygroscopic residue which consisted mainly of 1-(2′-pyridylmethyl)-pyridinium chlorides (IIa—d). Thus, on the addition of a silver nitrate solution to an aqueous solution of the residue, silver chloride was deposited immediately, and the dipicrates were subsequently obtained from the alcoholic solution of the residue.

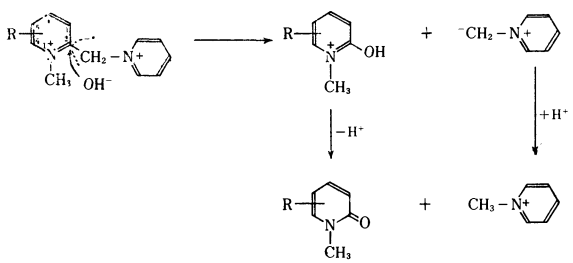
A gentle heating of the mixture of crude IIa—d and dimethyl sulfate gave, with the liberation of methyl chloride, a hygroscopic residue of crude 1-methyl-2-(pyridiniomethyl)-pyridinium salts (IIIa—d). The formation of the cation of III was confirmed by an elemental analysis of the dipicrate formed from an ethanolic solution of the residue.

On the treatment of crude IIIa—d with an aqueous potassium hydroxide solution at a low temperature, 1-methyl-2-pyridones (IVa—d) were obtained.

In the cation of III, *i.e.*, the 1-methyl-2-(pyridiniomethyl)-pyridinium ion, the 2-position is greatly activated to be attacked by a nucleophilic reagent due to the quaternization of the nitrogen atoms of both the pyridine rings. Therefore, the attack by a hydroxide ion under mild conditions at that site, resulting in the cleavage of the C_2-methylene linkage and eventually in the formation of 1-methyl-2-pyridones, proceeds through the course depicted in Scheme 1. This step in the reaction sequence is essentially the same as that proposed by Berson and Cohen.[1]



IV

Scheme 1

IVa, IVc and IVd were identified as the corresponding picrates by a mixed-melting-point determination with authentic samples.[3,6] The fact that VId was obtained from Id confirmed that the chloromethyl and methyl groups in Id were, as expected, attached to the 2- and 4-positions respectively. In the case of the reaction sequence starting with Ib, the structure of the resulting IVb was established by the following observations. The elemental analysis of the IVb supported the required molecular formula, the melting point of the picrate agreed with that reported by Sugasawa and Kirisawa,[7] and the IR spectrum of IVb showed its absorption maximum at 1660 cm^{-1}, suggesting the presence of a carbonyl group. Sugasawa and Kirisawa[7] reported that the oxidation of 3-ethylpyridine by the method of Decker afforded a mixture in which 1-methyl-3-ethyl-2-pyridone greatly predominated over the 5-ethyl isomer (IVb). Therefore, they synthesized IVb by a tedious method which involved the conversion of 3-ethylpyridine into 3-acetylpyridine, subsequent Decker's oxidation to 1-methyl-5-acetyl-2-pyridone, and the reconversion of the acetyl into the ethyl group. Also, IVc and IVd, which could not be prepared by the direct Decker method and which were, therefore, prepared by the same tedious procedure, were easily obtained by the present method.

This method is thus recommended as a convenient route for the synthesis of 1-methyl-2-pyridones starting with 2-picolines, since 2-chloromethylpyridines can readily be obtained by the reaction of 2-picoline 1-oxides with tosyl chloride.

Experimental

2-Chloromethyl-4-methylpyridine (Id). A solution of 2,4-lutidine 1-oxide (12.0 g) and tosyl chloride (24.1 g) in dry benzene (70 m*l*) was allowed to stand at room temperature for 15 min. After the subsequent removal of the solvent, the residue was heated at 70°C for 2 hr, and then at 100°C for 1 hr. Water was added to the cooled reaction mixture, the excess tosyl chloride was removed by filtration, and the filtrate, after the adjustment of the pH to 6.0 with sodium carbonate, was steam-distilled. The distillate was extracted with ether, the extract was dried over sodium sulfate, and the solvent was removed *in vacuo* to give crude Id as a stimulative oil (9.8 g, 68.0%); this oil was used for the next step without purification. Picrate: mp 138—139°C.

Found: C, 42.37; H, 3.03; N, 15.22%. Calcd for $C_{13}H_{11}O_7N_4Cl$: C, 42.10; H, 3.00; N, 15.11%.

1-Methyl-2-pyridone (IVa). A mixture of dry pyridine (10.0 g) and Ia (8.0 g) was heated at 80°C for 5 hr. At the end of the reaction time, a dark red, oily material separated at the bottom of the reaction vessel. The removal of the excess pyridine *in vacuo* and the washing of the residue with ether gave crude IIa as a hygroscopic syrup. Dipicrate: mp 168—169°C.

Found: C, 43.84; H, 2.51; N, 17.96%. Calcd for $C_{23}H_{16}O_{14}N_8$: C, 43.96; H, 2.57; N, 17.83%.

A mixture of dimethyl sulfate (23.8 g) with the crude IIa was kept for 20 min at room temperature and then heated at 80°C for 3 hr until a homogeneous solution was formed; this gave a hygroscopic syrup consisting mainly of IIIa. Dipicrate: mp 192—193°C.

Found: C, 44.75; H, 2.91; N, 17.15%. Calcd for $C_{24}H_{18}O_{14}N_8$: C, 44.87; H, 2.83; N, 17.44%.

A solution of potassium hydroxide (17.1 g) in water (150 m*l*) was stirred, drop by drop, into a solution of crude IIIa in water (76 m*l*) over a period of 3 hr at 2—5°C; the stirring was then continued for another 2 hr at the same temperature. The mixture was extracted with ether using a continuous extractor, the extract was evaporated, and the residue was distilled *in vacuo* to yield IVa as a yellow oil (4.5 g, 65.0%) boiling at 117°C/10 mmHg. The melting point of the picrate of IVa (142—143°C) was undepressed in a mixed-melting-point determination with an authentic sample.

1-Methyl-5-ethyl-2-pyridone (IVb). A solution of dry pyridine (9.5 g) and Ib (15.5 g) in ether (106

ml) was allowed to stand at room temperature for 30 min. After the removal of the solvent, the residue was heated at 50°C for 6 hr, and then at 80°C for 3 hr. The same treatment as with IIa gave a hygroscopic oil of IIb. Dipicrate: mp 155°C.

Found: C, 45.48; H, 3.06; N, 17.17%. Calcd for $C_{25}H_{20}O_{14}N_8$: C, 45.74; H, 3.07; N, 17.07%.

A mixture of dimethyl sulfate (36.8 g) and the crude IIb was heated at 80°C for 3 hr to give a hygroscopic syrup consisting mainly of IIIb. Dipicrate: mp 163°C.

Found: C, 46.39; H, 3.34; N, 16.58%. Calcd for $C_{26}H_{22}O_{14}N_8$: C, 46.57; H, 3.31; N, 16.71%.

A solution of potassium hydroxide (20.7 g) in water (186 ml) was stirred, drop by drop, into a solution of crude IIIb in water (392 ml) over a period of 2 hr at −7—−10°C; the stirring was then continued for another 2 hr at the same temperature. Subsequent treatment similar to that used with IVa gave IVb as a yellow oil (8.4 g, 64.0%) boiling at 114—115°C/3 mmHg. The product showed its absorption maximum at 1660 cm^{-1} in the IR spectrum, and the picrate recrystallized from ethanol melted at 122—123°C.[7] Picrate: mp 122—123°C.

Found: C, 45.90; H, 3.85; N, 15.30%. Calcd for $C_{14}H_{14}O_8N_4$: C, 46.00; H, 3.94; N, 15.31%.

1,6-Dimethyl-2-pyridone (IVc). A mixture of dry pyridine (23.3 g) and Ic (13.8 g) was allowed to stand at room temperature for 30 min, and then heated at 60°C for 3 hr and subsequently at 70°C for 2 hr. The removal of the excess pyridine *in vacuo* gave hygroscopic crystals of IIc. Dipicrate: mp 179°C.

Found: C, 44.83; H, 2.98; N, 17.48%. Calcd for $C_{24}H_{18}O_{14}N_8$: C, 44.87; H, 2.83; N, 17.44%.

A mixture of dimethyl sulfate (27.6 g) and crude IIc was heated at 80°C for 3 hr, subsequent treatment like that of IIIa gave IIIc as hygroscopic crystals. Dipicrate: mp 186°C.

Found: C, 45.52; H, 3.03; N, 17.12%. Calcd for $C_{25}H_{20}O_{14}N_8$: C, 45.72; H, 3.07; N, 17.07%.

A solution of potassium hydroxide (24.2 g) in water (217.8 ml) was stirred, drop by drop, into a solution of crude IIIc in water (278 ml) over a period of 2 hr at −10—−12°C. The stirring was then continued for another 4 hr at the same temperature. Subsequent treatment similar to that of IVa gave IVc as hygroscopic crystals (7.5 g, 62.8%) boiling at 116—117°C/3 mmHg.

Found: C, 68.27; H, 7.36; N, 11.37%. Calcd for C_7H_9ON: C, 68.27; H, 7.36; N, 11.68%.

The IR spectrum of IVc agreed with that of the authentic sample,[2] and the melting point of the picrate of IVc (133—134°C) was undepressed upon a mixed-melting-point determination with an authentic sample.

1,4-Dimethyl-2-pyridone (IVd). A mixture of dry pyridine (11.7 g) and Id (15.0 g) was heated at 80°C for 5 hr. Subsequent treatment similar to that of IIa gave IId as a hygroscopic oil. Dipicrate: mp 185.5—186.5°C.

Found: C, 45.01; H, 2.92; N, 17.55%. Calcd for $C_{24}H_{18}O_{14}N_8$: C, 44.87; H, 2.83; N, 17.44%.

A mixture of dimethyl sulfate (37.8 g) and IId in water (295 ml) was heated at 80°C for 3 hr. When it was then treated as IIIa had been, a hygroscopic syrup of IIId was obtained. Dipicrate: mp 202.5°C.

Found: C, 45.41; H, 3.17; N, 17.30%. Calcd for $C_{25}H_{20}O_{14}N_8$: C, 45.74; H, 3.07; N, 17.07%.

A solution of potassium hydroxide (26.6 g) in water (234 ml) was stirred, drop by drop, into a solution of IIId over a period of 2 hr at −7—−10°C, after which the stirring was continued for 3 hr. Subsequent treatment of the mixture much like that of IVa gave IVd of hygroscopic crystals (6.9 g, 53.6%) boiling at 110—111°C/3 mmHg. The IR spectrum of IVd was identical with that of the authentic sample,[2] and the melting point of the picrate of IVd was undepressed by a mixed-melting-point determination with an authentic sample. Picrate: mp 163—164°C.

Found: C, 44.32; H, 3.36; N, 15.62%. Calcd for $C_{13}H_{12}O_4N_8$: C, 44.32; H, 3.43; N, 15.91%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3543—3549 (1970)

The Cycloaddition Reactions of Benzoylsulfene with Anils

Otohiko TSUGE and Sumio IWANAMI

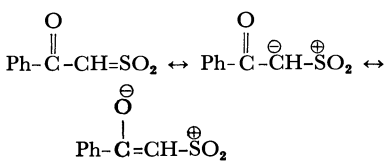
Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

(Received May 30, 1970)

The reactions of benzoylmethanesulfonyl chloride with various anils (Ar–CH=N–R) in the presence of triethylamine have been studied. It has been found that the corresponding (4+2) and/or (2+2) cycloadducts of benzoylsulfene and the anil were obtained, depending on the nature of the substituents, R, in the anils. The reaction of the chloride with benzylidene-*n*-propylamine in the absence of triethylamine gave only the (2+2) cycloadduct, while the (4+2) cycloadduct was exclusively obtained in the presence of triethylamine. The chloride reacted with dibenzylidenethylenediamine in the presence of triethylamine to give the corresponding bis(4+2) cycloadduct.

Recently, Fusco and his co-workers[1] found that the treatment of benzoylmethanesulfonyl chloride (I) with triethylamine (NEt_3) afforded the 1,2,4-oxadithin tetroxide. Later, it has been shown in a review[2] that, in the presence of NEt_3, I reacted with isobutenyl ether to give the 1,4-oxathin dioxide, while it reacted with 2-methyl-1-pyrrolidino-1-propene to give the thiethane dioxide (Scheme 1). These reactions can be formulated as below, assuming a benzoylsulfene ($PhCOCH{=}SO_2$) intermediate.

The above observations indicate that, in the cycloaddition reaction with unsaturated substances benzoylsulfene behaves as a 1,2- and/or 1,4-dipole, depending on the nature of the unsaturated substances.



The reactions of sulfenes ($RCH{=}SO_2$), generated *in situ* from alkanesulfonyl chlorides and NEt_3, with electron-rich olefins, such as enamines or ketene acetals, have been extensively investigated. However, the study of the cycloaddition of sulfene to the C=N bond has not been extended beyond of Staudinger and Pfenninger,[3] who reported that the reaction of diphenylsulfene, generated from diphenyldiazomethane and sulfur dioxide, with benzylidenaniline gave the four-membered cyclic compound.

New heterocyclic compounds may be formed by the cycloaddition of benzoylsulfene to the C=N bond, because the electron-attracting benzoyl group will make benzoylsulfene more reactive than sulfenes ($RCH{=}SO_2$).

In the present paper we wish to report on the formation of (2+2) and (4+2) cycloadducts *via* the reactions of benzoylsulfene with various benzylidenamines. In this cycloaddition reaction, for the first time, a sulfene, generated from sulfonyl chloride and a base, reacted with a C=N bond

to give a cycloadduct.

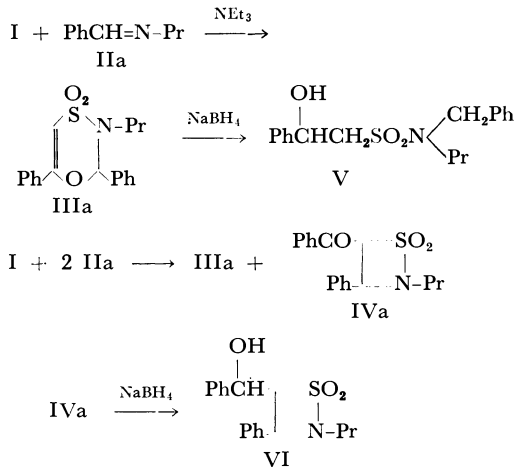
Results and Discussion

The reaction of I with equimolar benzylidene-*n*-propylamine (IIa) and NEt_3 in dioxane at room temperature for 15 hr gave a crystalline compound IIIa, mp 123°C (decomp.), in a 57% yield, besides triethylammonium chloride in a quantitative yield. The results of elemental analysis and the molecular weight (M^+ *m/e* 329) of IIIa were consistent with those of the expected 1 : 1 adduct of benzoylsulfene and IIa.

On the other hand, I reacted with two molar quantities of IIa in the absence of NEt_3 at room temperature for 3 hr, thus affording IIIa and its isomeric 1 : 1 adduct, IVa, mp 148°C, in 57 and 13% yields respectively, together with benzylidene-*n*-propylamine hydrochloride.

The infrared spectrum of IIIa showed characteristic bands at 1575 ($\nu_{C=C}$), 1150, and 1335 cm^{-1} (ν_{SO_2}), while the NMR spectrum in deuteriochloroform ($CDCl_3$) exhibited singlets at τ 3.56 (1H, methine proton) and 3.00 (1H, olefinic proton), besides signals of *n*-propyl and aromatic protons. These observations indicate that IIIa is the (4+2) cycloadduct of benzoylsulfene, and IIa, 2,6-diphenyl-3-*n*-propyl-1,4,3-oxathiazine 4,4-dioxide. The mass spectrum was also in harmony with the proposed structure: peaks appeared at *m/e* 329 (M^+), 300 (M^+-29[Et]), 288 (M^+-41[CH_2=CH-CH_2]), and 265 (M^+-64[SO_2]) in the spectrum. Furthermore, IIIa was reduced with sodium borohydride in methanol at 30°C for 20 min to *N*-benzyl-*N*-*n*-propyl-2-hydroxy-2-phenylethane-1-sulfonamide (V) in a 73% yield (Scheme 2). The structure for IIIa is also supported by this fact.

On the other hand, IVa was confirmed to be the (2+2) cycloadduct, 4-benzoyl-3-phenyl-2-*n*-propyl-1,2-thiazetidine 1,1-dioxide, by the spectral studies as well as by the chemical transformation. The infrared spectrum showed strong bands at 1690 ($\nu_{C=O}$), 1165, and 1315 cm^{-1} (ν_{SO_2}), and the NMR spectrum in deuterionitromethane (CD_3NO_2) revealed two pairs of doublets, at τ 5.07 and 4.42 (each 1H, J=6 Hz), besides the peaks of the *n*-propyl and aromatic protons. Although the molecular ion peak was not observed, the peak of *m/e* 265 (M^+-64[SO_2]) appeared in the mass spectrum of IVa.



Scheme 2

When IVa was treated with sodium borohydride under the same conditions as were used for IIIa, a ring cleavage did not take place, but IVa was reduced to the 4-(α-hydroxybenzyl)thiazetidine VI in an 84% yield (Scheme 2).

In order to make it clear whether or not IVa is virtually formed in the reaction under the influence of NEt_3, the amounts of products and reactants in the reaction system were estimated by NMR spectroscopy. As is shown in Table 1, in the presence of NEt_3 only IIIa was formed.

The effect of the amount of IIa on the yields of IIIa and IVa was investigated in the absence of NEt_3; the results are also shown in Table 1. It is shown that IIIa and IVa were formed even when I was caused to react with an equimolar amount of IIa. As the adduct IIIa proved rather unstable and decomposed during purification, however, the yield isolated was lower than that estimated by NMR spectroscopy.

The interconversion of IIIa and IVa was not observed under these reaction conditions. The reason why benzoylsulfene behaves differently depending on the nature of the dehydrochlorinating agents is not clear.

In the reaction of I with benzylidenaniline (IIb) under the influence of NEt_3 for 1 hr, the (4+2) cycloadduct, 2,3,6-triphenyl-1,4,3-oxathiazine 4,4-dioxide (IIIb), was exclusively formed, but it

Table 1. Reaction of I with IIa in the presence or absence of NEt_3 in dioxane at room temperature for 3 hr

I	IIa	NEt_3	Products (%)		Unreacted reactants (%)	
	(molar ratio)		IIIa	IVa	I	IIa
1	1	1	82	0	0	9
1	1	0	36	6	40	0
1	2	0	82	13	0	0
1	3	0	84	14	0	33

could not be isolated in a pure form because of its instability. On the other hand, a similar reaction for 24 hr gave the (2+2) cycloadduct, 4-benzoyl-2,3-diphenyl-1,2-thiazetidine 1,1-dioxide (IVb), in a 22% yield, but here the formation of IIIb was not observed.

The structures for IIIb and IVb were confirmed by the spectral studies as well as by the chemical transformations. The infrared spectrum of a relatively pure IIIb showed bands at 1570 ($\nu_{C=C}$), 1150, and 1335 cm^{-1} (ν_{SO_2}), while the NMR spectrum in dioxane revealed a singlet at τ 3.05 (1H, methine proton) and a vinyl proton signal in a region of aromatic protons. When IIIb was refluxed in methanol for several minutes, a ring cleavage took place to give the sulfonamide VII in a 64% yield (Scheme 3).

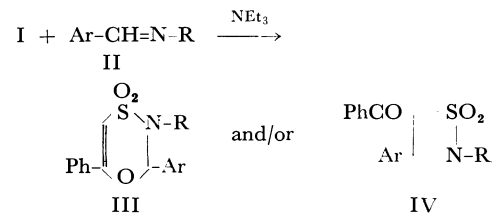
On the other hand, the infrared spectrum of IVb showed strong bands at 1685 ($\nu_{C=O}$), 1151, and 1324 cm^{-1} (ν_{SO_2}), while the NMR spectrum in CD_3NO_2 revealed two pairs of doublets, at τ 3.85 and 4.19 (each 1H, $J=6$ Hz). The structure for IVb was also supported by the mass spectrum: peaks of *m/e* 363 (M^+) and 299 (M^+-64[SO_2]) appeared in the spectrum.

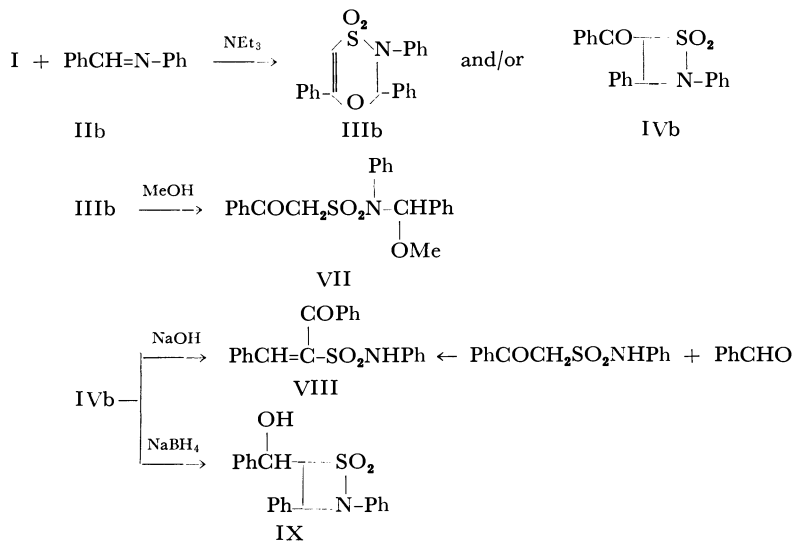
The treatment of IVb with methanolic sodium hydroxide gave β-benzoyl-β-phenylsulfamoylstyrene (VIII), which was identical with the authentic sample prepared from benzoyl methanesulfonanilide and benzaldehyde. Furthermore, IVb was reduced with sodium borohydride to give the 4-(α-hydroxybenzyl)thiazetidine compound, IX (Scheme 3).

The effect of the reaction time on the yields of IIIb and IVb was investigated by the quantitative estimation of IIIb and IVb, using NMR spectroscopy. The results are shown in Table 2.

The data in Table 2 indicate that, when the reaction is carried out under the same conditions, the quantity of unreacted IIb is essentially independent of the reaction time, and that the quantity of IIIb decreases, and that of IVb increases with an increase in the reaction time.

The reactions of I with various benzylidenamines (II) were investigated in the presence of NEt_3; the results are summarized in Table 3.





Scheme 3

TABLE 2. REACTION OF I WITH IIb IN THE PRESENCE OF NEt_3 IN DIOXANE AT ROOM TEMPERATURE

I	IIb (molar ratio)	NEt_3	Time (hr)	Products (%) IIIb	Products (%) IVb	Unreacted IIb (%)

f	Ph	$PhCH_2$	100	32	5
g	Ph	Cyclohexyl	15	27	0

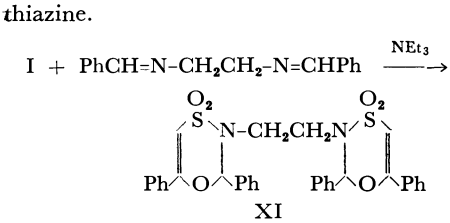
* Unreacted IId and IIe were recovered in 25 and 10% yields respectively.

The structures of the products were established by the spectral studies as well as by the elemental analyses (Table 4).

When the substituent, R, in II is aliphatic, such as *n*-propyl and cyclohexyl, only the (4+2) cycloadduct III was obtained in the presence of NEt_3. On the other hand, the reaction with II when R is aromatic, such as phenyl and *p*-tolyl, for a long time gave the (2+2) cycloadduct IV exclusively; this can presumably be attributed to the fact that the 3-aryl-1,4,3-oxathiazine compound is unstable compared with the corresponding 3-alkyl compound. On the other hand, benzylidenebenzylamine (IIf) exhibited an intermediate character to give both the (4+2) and (2+2) cycloadducts. A similar reaction of I with diphenylmethylenaniline for 25 hr did not give the expected cycloadduct of benzoylsulfene and the anil, but rather the dimer of benzoylsulfene, 3-benzoyl-6-phenyl-1,2,4-oxadithin tetroxide,[1] in a 55% yield.

It may be assumed that benzoylsulfene reacts with a compound with two C=N bonds, thus leading to the formation of a mono-, bis(2+2), bis(4+2), or mixed biscycloadduct.

When dibenzylidenethylenediamine (X) was caused to react with two molar quantities of I in the presence of NEt_3, the expected 2 : 1 adduct of benzoylsulfene and X was obtained in a 52% yield, together with a small amount of an unidentified substance. Although the NMR spectrum of XI could not be measured because of its poor solubility, the infrared spectrum was very similar to that of IIIa and did not show any carbonyl bands except the band ascribed to the C=C bond at 1572 cm^{-1}. This fact indicates that XI is a bis-oxathiazine.



XI

The mass spectrum was in harmony with the proposed structure: the molecular ion peak was not observed, but peaks of *m/e* 418 (M^+-182[PhCOCH=SO_2]), 354 (418$^+$-64[SO_2]), and 250 (354$^+$-104[PhCNH]) appeared in the spectrum.

Experimental

All the melting and boiling points are uncorrected. The infrared spectra were measured in KBr disks, and the NMR spectra were determined at 60 MHz with a Hitachi R-20 NMR spectrometer, using TMS as an internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer, using a direct inlet and an ionization energy of 70 eV.

Materials. Benzoylmethanesulfonyl chloride (I), mp 88°C (lit,[4] mp 87.5—88.2°C), was prepared according to the method of Truce and Vriesen.[4] Benzylidenamines (II) and dibenzylidenethylenediamine (X) were prepared from the corresponding aldehyde and amine. Benzylidene-*n*-propylamine (IIa), bp 101—102°C/15 mmHg (lit,[5] bp 208—210°C/744 mmHg); -aniline (IIb) mp 54°C (lit,[6] mp 53.5°C); -*p*-toluidine (IIc), bp 176—177°C/10 mmHg (lit,[7] bp 178°C/10 mmHg); -*p*-anisidine (IId), mp 73—74°C (lit,[8] mp 72°C); -benzylamine (IIf), bp 200—201°C/18 mmHg (lit,[9] bp 205°C/20 mmHg); -cyclohexylamine (IIg), bp 154°C/18 mmHg (lit,[10] bp 136°C/16 mmHg); *p*-nitrobenzylidenaniline (IIe), mp 93°C (lit,[11] mp 93°C); dibenzylidenethylenediamine (X), mp 54°C (lit,[12] mp 53—54°C). Diphenylmethylenaniline was prepared from benzophenone dichloride and aniline; mp 116—117°C (lit,[13] mp 116°C).

General Procedure for the Reaction of I with II in the Presence of NEt_3. To a vigorously stirred solution of 0.01 mol of II and 1.0 g (0.01 mol) of NEt_3 in 10 m*l* of dioxane, a solution of 2.2 g (0.01 mol) of I in 40 m*l* of dioxane was added, drop by drop, at room

* The H_B signal appeared in a region of phenyl protons.

** A molecular ion peak was not observed but [M^+-SO_2] peak appeared at *m/e* 313 in the mass spectrum.

temperature over a period of 30 min. After the reaction mixture had been stirred at the same temperature for a long while, triethylammonium chloride was removed by filtration. The filtrate was evaporated *in vacuo* to leave an oily substance, which was then crystallized on trituration with methanol or petroleum benzine (bp 45—60°C).

The reaction conditions, yields, physical properties, and elemental analyses of adducts are summarized in Tables 3 and 4.

Reaction of I with IIa in the Absence of NEt_3. To a solution of 3.0 g (0.02 mol) of IIa in 10 m*l* of dioxane, was added, drop by drop, a solution of 2.2 g (0.01 mol) of I in 40 m*l* of dioxane. After the mixture had then been stirred at room temperature for 2.5 hr, the precipitated benzylidene-*n*-propylamine hydrochloride was removed by filtration. The filtrate was evaporated *in vacuo* to give 3.4 g of a viscous oily substance, found to be a mixture of IIIa (85%) and IVa (15%) by NMR spectroscopy. Although IIIa could not be isolated in a pure state because of its instability, the recrystallization of the mixture from methanol gave IVa, mp 148°C, as colorless prisms.

Found: C, 65.85; H, 6.22; N, 4.24%. Calcd for $C_{18}H_{19}O_3NS$: C, 65.64; H, 5.82; N, 4.25%.

Reduction of IIIa with Sodium Borohydride. A mixture of 0.45 g of IIIa and 0.5 g of sodium borohydride in 20 m*l* of methanol was stirred at 30°C for 20 min. To the mixture was added 50 m*l* of water, and then the mixture was extracted with benzene. The benzene-extract was washed twice with water, dried over sodium sulfate, and then evaporated *in vacuo* to give a colorless, viscous oil (0.3 g, 73%), which crystallized on standing for a long while. Recrystallization from petroleum benzine (bp 45—60°C) gave *N*-benzyl-*N*-*n*-propyl-2-hydroxy-2-phenylethane-1-sulfonamide (V), mp 48—49°C, as colorless needles.

Found: C, 64.68; H, 6.82; N, 4.25%. Calcd for $C_{18}H_{23}O_3NS$: C, 64.85; H, 6.95; N, 4.20%.

IR: 3520 (ν_{OH}), 1325, 1137 cm^{-1} (ν_{SO_2}). NMR ($CDCl_3$): τ 2.67 (10H, singlet, aromatic protons), 4.76 (1H, quartet, $\geqslant$CH), 5.63 (2H, singlet, $-C\underline{H}_2Ph$), 6.17 (1H, broad signal, OH, exchanged with D_2O), 6.5—7.1 (4H, multiplet, $-C\underline{H}_2SO_2-$ and $-\underline{N}-C\underline{H}_2-$), 8.3—8.9 (2H, quintet, $-CH_2-C\underline{H}_2-Me$), 9.13 (3H, triplet, CH_3).

The mass spectrum gave a parent peak at *m/e* 333 (M^+) and other peaks at *m/e* 316 (M^+-OH), 304 (M^+-Et), and 242 ($M^+-C_7H_7$).

Reduction of IVa with Sodium Borohydride. A mixture of 0.12 g of IVa and 0.15 g of sodium borohydride in 10 m*l* of methanol was stirred at 30°C for 20 min. Fifty m*l* of water were then added to the mixture, affording 0.1 g (84%) of colorless crystals. Recrystallization from a mixture of benzene-petroleum benzine gave 4-(α-hydroxybenzyl)-3-phenyl-2-*n*-propylthiazetidine 1,1-dioxide (VI), mp 103—104°C, as colorless needles.

Found: C, 65.46; H, 6.47; N, 4.22%. Calcd for $C_{18}H_{21}O_3NS$: C, 65.24; H, 6.39; N, 4.23%.

IR: 3480 (ν_{OH}), 1300, 1147 cm^{-1} (ν_{SO_2}). NMR ($CDCl_3$): τ 2.6—3.1 (10H, multiplet, aromatic protons), 4.76 (1H, doublet, $Ph\underline{C}H-N\langle$), 5.58 (1H, quartet, $\rangle CH-SO_2-$), 6.14 (1H, doublet, OH, exchanged with D_2O), 6.6—7.5 (3H, multiplet, $-CH_2-\underline{N}-$ and $PhC\underline{H}-$(OH)-), 8.2—8.8 (2H, quintet, $-CH_2-CH_2-Me$), 9.10 (3H, triplet, CH_3).

The mass spectrum showed a parent peak at *m/e* 331 (M^+) and other peaks at *m/e* 313 (M^+-H_2O), 301 ($M^+-C_2H_4$), and 267 (M^+-SO_2).

A similar reduction of IVb with sodium borohydride gave the corresponding 4-(α-hydroxybenzyl)thiazetidine IX, mp 195°C (decomp.), as colorless prisms (from acetonitrile). Yield, 83%.

Found: C, 68.76; H, 5.45: N, 3.58%. Calcd for $C_{21}H_{19}O_3NS$: C, 69.03; H, 5.24; N, 3.83%.

IR: 3550 (ν_{OH}), 1315, 1170 cm^{-1} (ν_{SO_2}). NMR (CD_3CN): τ 2.4—3.3 (15H, multiplet, aromatic protons), 4.65 (1H, quartet, $ph\underline{C}H(OH)-$), 5.2—5.5 (2H, multiplet, $-\underline{C}H-SO_2-$ and $PhC\underline{H}-\underline{N}-$), 5.86 (1H, doublet, OH, exchanged with D_2O).

Methanolysis of IIIb. A solution of 0.5 g of IIIb in 50 m*l* of methanol was refluxed for several minutes and then cooled to give the sulfonamide VII, mp 120—121°C, as colorless needles. Yield, 0.35 g (64%).

Found: C, 66.60; H, 5.28; N, 3.40%. Calcd for $C_{22}H_{21}O_4NS$: C, 66.82; H, 5.35; N, 3.54%.

IR: 1680 (ν_{CO}), 1250, 1150 cm^{-1} (ν_{SO_2}). NMR ($CDCl_3$): τ 1.9—3.0 (15H, multiplet, aromatic protons), 3.6 (1H, singlet, $\geqslant$CH), 5.25 (2H, double doublet, J=14 Hz, $-CH_2-$), 6.36 (3H, singlet, OCH_3).

The mass spectrum showed peaks at *m/e* 395 (M^+), 364 (M^+-OMe), 275 (364^+-PhC), 182 (275^+-PhNH_2), and 105 ($PhCO^+$).

***β*-Benzyl-*β*-phenylsulfamoylstyrene (VIII).** *i*) After a solution of 0.4 g of IVb and 0.1 g of sodium hydroxide in aqueous methanol (methanol 20 m*l* and water 5 m*l*) had been refluxed for 20 min, the mixture was extracted with benzene. The benzene-extract was evaporated *in vacuo*, affording 52 mg (13%) of colorless crystals. Recrystallization from petroleum benzine (bp 45—60°C) gave VIII, mp 188—189°C, as colorless needles.

Found: C, 69.54; H, 4.68; N, 3.77%. Calcd for $C_{21}H_{17}O_3NS$: C, 69.41; H, 4.72; N, 3.86%.

IR: 3230 (ν_{NH}), 1635 (ν_{CO}), 1615 ($\nu_{C=C}$), 1340, 1150 cm^{-1} (ν_{SO_2}). The mass spectrum showed peaks at *m/e* 363 (M^+), 299 (M^+-SO_2), 271 (M^+-PhNH), and 105 ($PhCO^+$).

ii) A solution of 1.0 g of benzoylmethanesulfonanilide, 0.5 g of benzaldehyde, and 2 m of 1 N sodium hydroxide aqueous solution in 50 m*l* of ethanol was fluxed for 2 hr and then evaporated *in vacuo* to give an oily substance. A benzene solution of it was chromatographed over alumina, affording colorless crystals which were proved, by a study of their infrared spectrum, to be identical with VIII. Yield, 0.1 g (8%). The other products were not examined.

Spectroscopic Determination. After the reac-

TABLE 5. KEY SIGNALS FOR I, II AND III

Compound	Key signal
I	4.31 (singlet, $-CH_2-$)
IIa	1.82 (singlet, $-CH=N-$)
IIb	1.50 (singlet, $-CH=N-$)
IIIa	3.26 (singlet, $\geqslant$CH)
IIIb	3.05 (singlet, $\geqslant$CH)
IVa	4.43 (doublet, $\geqslant$CH)
IVb	3.88 (doublet, $\geqslant$CH)

tion of I with IIa or IIb in the presence or absence of NEt_3 had been carried out in dioxane for a definite time, 1-m*l* aliquots of the mixture were withdrawn by means of a pipet and triethylammonium chloride or benzylidene-*n*-propylamine hydrochloride was removed by filtration. The quantitative estimation of the reactants and products in the filtrate was done by means of NMR spectroscopy. The key signals for the reactants and products are shown in Table 5, while the results are summarized in Tables 1 and 2.

Reaction of I with X. To a stirred solution of 1.6 g (6.8 mmol) of X and 1.4 g (13.8 mmol) of NEt_3 in 10 m*l* of dioxane, a solution of 3.0 g (13.8 mmol) of I in 40 m*l* of dioxane was added, drop by drop, at room temperature over a period of 30 min. After the reaction mixture had then been stirred at room temperature for 14.5 hr, colorless crystals were collected by filtration and washed three times with 10 m*l* of methanol to leave 2.1 g (52%) of the bis(4+2) cycloadduct XI, mp 153°C (decomp.).

Found: C, 63.83; H, 4.88; N, 4.74%. Calcd for $C_{32}H_{28}O_6N_2S_2$: C, 63.99; H, 4.70; N, 4.66%.

Triethylammonium chloride was obtained from the methanol washings; yield, 1.9 g (quantitative). On the other hand, the dioxane filtrate was after the reaction, evaporated *in vacuo* to give an oily substance which solidified on treatment with methanol. Recrystallization from methanol gave colorless prisms, mp 139°C. Yield, 0.4 g. This compound could not be identified (Found: C, 60.97; H, 5.58; N, 4.27%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3549—3552 (1970)

Structure and Reactivity of α,β-Unsaturated Ethers. XI. Cationic Copolymerization and Acetal Addition of *cis*- and *trans*-Styryl Ethyl Ethers

Tadashi OKUYAMA, Nobuhiro ASAMI and Takayuki FUENO

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received June 1, 1970)

The cationic copolymerization between *cis*- and *trans*-styryl ethyl ethers in methylene chloride was investigated in the temperature range from −70 to 0°C with boron trifluoride etherate as catalyst. It was found that at lower temperatures the *trans* ether is more reactive than its *cis* isomer, although the relative reactivities are reversed at 0°C. Addition reactions of various acetals to *cis*- and *trans*-styryl ethyl ethers were carried out at 0°C with the same Lewis acid as catalyst. The relative *cis-trans* reactivities are largely dependent on the bulkiness of an attacking oxycarbonium ion. It was concluded that the *cis* isomer, which is electronically more reactive toward cations, is liable to suffer adverse steric effect, especially when the attacking carbonium ion is bulky.

β-Substituted vinyl ethers are known to be easily polymerized by cationic mechanism. Previous investigations dealt mostly with alkenyl[1-4] and β-chlorovinyl[5] alkyl ethers. In all these cases, *cis* isomers were found to be more reactive than the corresponding *trans* isomers. In the case of β-methylstyrene, however, the *trans* isomer proved to be more reactive.[6,7] The relative *cis-trans* reactivities of α,β-disubstituted olefins in cationic polymerization are apparently not simple and the origin remains to be clarified.

In terms of chemical constitution, styryl alkyl ethers may be regarded as derivatives of either vinyl ether or styrene. Mizote *et al.* reported that the *cis* ether can readily be polymerized by cationic agents.[8] Our interest in the relative reactivities of geometrical isomer pairs of α,β-unsaturated ethers led us to compare the cationic polymerizabilities of *cis*- and *trans*-styryl ethyl ethers.

In the present study, we first investigated the mutual copolymerization between *cis*- and *trans*-styryl ethyl ethers (SEE) at various temperatures. Next, addition reactions of various acetals[4,9]

toward *cis*- and *trans*-SEE's were studied kinetically in order to obtain information on the steric effect of attacking carbonium ions on the reactivities of SEE.

$$RCH(OC_2H_5)_2 + BF_3 \rightarrow RCH(OC_2H_5)^+ + BF_3\cdot C_2H_5O^-$$

$$C_6H_5CH{=}CH(OC_2H_5) \xrightarrow{+RCH(OC_2H_5)^+}$$

$$RCH(OC_2H_5)-CH(C_6H_5)-CH(OC_2H_5)^+ \xrightarrow[-BF_3]{+BF_3\cdot C_2H_5O^-}$$

$$RCH(OC_2H_5)-CH(C_6H_5)-CH(OC_2H_5)_2$$

From the results obtained, the factors influencing the *cis-trans* reactivities have been discussed.

Experimental

Materials. SEE was obtained as described previously[10] and distilled from calcium hydride under dry nitrogen immediately before use.

1,1-Diethoxyethane and 1,1-diethoxypropane were prepared by the method described previously.[4] 1,1-Diethoxybutane and 1,1-diethoxy-2-methylpropane were prepared from appropriate aldehydes and ethanol.[4,11] The boiling points were 144—146°C and 136—137°C, respectively. All the acetals were purified by distillation from metallic sodium.

Methylene chloride, tetralin, *o*-dichlorobenzene and boron trifluoride etherate ($BF_3\cdot OEt_2$) were purified as described previously.[1,12]

Cationic Polymerization. Polymerization technique was essentially the same as that described previously.[1]

Polymerization temperature (−70 to −20°C) was controlled to within ±0.5°C with a bath filled with dry ice-cold methanol. Monomer concentrations were determined by means of a Shimadzu gas chromatograph Model 4APT. A 3-m column packed with Apiezon Grease L was operated at *ca.* 130°C with hydrogen as a carrier gas. The internal standard method with half-height width evaluation of peak areas was applied for determining the monomer concentrations. Tetralin or dichlorobenzene was used as internal standard.

For experiments conducted at −70°C, the monomer reactivity ratios were evaluated with the aid of the integral form of the Mayo-Lewis copolymerization equation.[1] In all other cases, the monomer reactivities were evaluated from the slopes of the linear plots of the logarithms of instantaneous concentrations of *cis*-SEE *vs.* those of the *trans*-SEE isomer.

Acetal Addition. The method of the reaction was the same as that described previously.[4] The reaction was allowed to take place in excess acetal at 0°C with $BF_3\cdot OEt_2$ as catalyst. The residual ethers were determined by gas chromatography as in cationic polymerization.

Results

Cationic Copolymerization. A nearly equimolar mixture of *cis*- and *trans*-SEE's was copolymerized in methylene chloride at temperatures between 0 and −70°C. Concentration of each comonomer decreased with the progress of reaction in such a way that a linear relationship held between log[*cis*-SEE] and log[*trans*-SEE] down to at least 80% conversion of the *trans* isomer. The linear relationships at various temperatures are shown in Fig. 1. These results evidently indicate that no geometrical isomerization accompanies the polymerization reaction in the temperature range we studied. The slopes of these linear relationships may then be taken as indicating the relative reactivity *r* of *cis*- to *trans*-SEE at the given temperatures:

$$r = \frac{\log [cis\text{-SEE}]/[cis\text{-SEE}]_0}{\log [trans\text{-SEE}]/[trans\text{-SEE}]_0} \quad (1)$$

where the subscript 0 indicates initial concentrations.

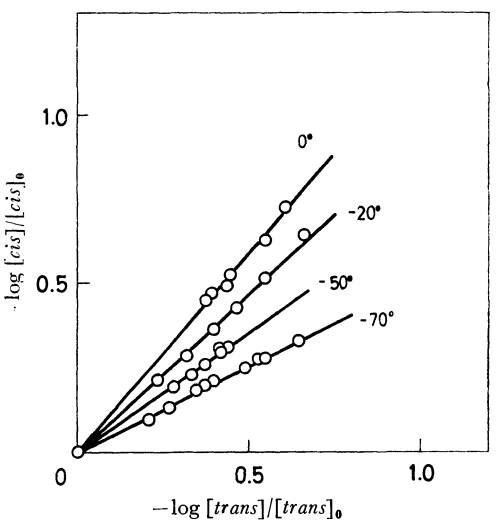

Fig. 1. Variations of monomer concentrations in the mutual copolymerization between *cis*- and *trans*-styryl ethyl ethers at various temperatures. Solvent, methylene chloride. Initial monomer concentration, 7 vol%, in which $[cis\text{-SEE}]_0/[trans\text{-SEE}]_0 = 1.08—1.34$. Catalyst, $BF_3\cdot OEt_2$.

In principle, the above treatment is based on the assumption that the monomer selection in the chain growth is governed by the statistics of the Bernoullian type:

$$r_{cis}r_{trans} = 1 \quad (2)$$

Strictly, it is only when Eq. (2) is satisfied that the

12) T. Fueno, T. Okuyama, I. Matsumura and J. Furukawa, *J. Polym. Sci. A*-1, **7**, 1447 (1969).

customary equation for binary copolymerization can be replaced by an expression of the type of Eq. (1).

In order to examine whether the relative reactivity as determined from Eq. (1) really makes sense, we have undertaken the usual copolymerization experiments between *cis*- and *trans*-SEE's of varying isomeric ratios at −70°C. The least-squares treatment[12] (Fig. 2) of the data with the aid of the integral form of the Mayo-Lewis copolymerization equation gave $r_{cis}=0.46\pm0.08$ and $r_{trans}=1.42\pm0.25$. The monomer reactivity ratios thus obtained lead to the $r_{cis}r_{trans}$ product value amounting only to 0.65 ± 0.26, which clearly violates the requirement (2). In such a case, the relative reactivity may best be estimated[1,2] from the value of $(r_{cis}/r_{trans})^{1/2}$. The relative reactivity thus evaluated turned out to be 0.57, which is in perfect agreement with the value 0.58 obtained from Eq. (1) at the same temperature. Thus, the convenient log—log method for evaluating the relative reactivity seems to be useful for copolymerization systems including the cases where the condition (1) is not rigorously satisfied.

The relative reactivity data evaluated from the plots in Fig. 1 are listed in Table 1. At lower temperatures, *cis*-SEE is less reactive than *trans*-SEE. However, the relative reactivity of the former isomer tends to increase with the rise in temperature and exceeds that of the latter at 0°C.

Acetal Additions. Additions of various acetals to SEE have been carried out at 0°C with the use of $BF_3\cdot OEt_2$ as catalyst in excess of acetals themselves. An example of the kinetic courses is shown in Fig. 3. From such kinetic courses which are first-order in SEE (for *cis* and *trans* separately), relative reactivities of geometrical isomers have been evaluated and given in Table 2. The relative reactivities are largely dependent on the attacking acetals. For acetals of normal aldehydes, the *cis* isomer is more reactive, while, for the acetals of

branched aldehydes, the *trans* isomer is more reactive.

Discussion

Orientation in Polymerization. The head-to-tail orientation of SEE in cationic polymerization might not be intuitively obvious. Mizote *et al.*[8] concluded from the studies on polymerization kinetics that styryl alkyl ethers polymerize through the β-addition of a polymer chain end.

$$C_6H_5CH{=}CHOR \xrightarrow{-C^+} C_6H_5\overset{H}{\underset{}{\diagdown}}\overset{\vdots}{C}\overset{+}{-}\overset{H}{\underset{OR}{\diagup}} \qquad (3)$$

The conclusion seems to be reasonable from the stability of an intermediate carbonium ion. An alkoxycarbonium ion is recognized to be more stable than benzyl-type cations.[13] The previous investigation[10] on the acid-catalyzed hydrolysis ascertained that the protonation of SEE takes place at the β-carbon atom:

$$C_6H_5CH{=}CHOC_2H_5 \xrightarrow{+H^+} C_6H_5\overset{+}{C}H_2CHOC_2H_5$$
$$\xrightarrow{+H_2O} C_6H_5CH_2CHO + C_2H_5OH \qquad (4)$$

a fact which lends support to the reaction mode as represented by (3).

***cis-trans* Polymerizability.** At lower temperatures, *cis*-SEE is less reactive than *trans*-SEE. However, the relative reactivity is considerably dependent on temperature as is seen in Table 1. From the Arrhenius-type plots of the data, the differences in activation parameters have been evaluated to be $\delta\Delta H^{\neq} = 1.4$ kcal/mol and $\delta\Delta S^{\neq} = 5.6$ e.u. That is, the *trans* isomer is energetically more reactive by 1.4 kcal/mol. This is contradictory to the expectationfrom the ground-state stability[16] and seems to be ascribable to the structural difference between the geometrical isomers; *cis*-SEE is non-planar whereas *trans*-SEE is planar as has been concluded previously.[10,17]

One possible interpretation is that the twisted phenyl group in *cis*-SEE hinders an attacking carbonium ion from approaching the olefinic bond, thus rendering the transition state of polymerization far less stable for *cis*-SEE than for *trnas*-SEE. The looser activated complex for the *cis* isomer might be rationalized from its greater entropy of activation as compared with that for the *trans* isomer. The situation seems to be similar to that in the acid-catalyzed hydrolysis.[10]

A greater reactivity of *trans* isomer has been noted or the cationic polymerization of β-methylstyrene and a similar reasoning has been presented.[6,7] In the investigation of the cationic oligomerization of stilbene, Brackman and Plesch[18] estimated that the rate of reaction of a stilbene ion with *trans*-stilbene is at least one hundred times as great as that of its reaction with *cis*-stilbene. The large difference in reactivity was likewise ascribed to steric reasons.

Acetal Additions. The addition reaction of an acetal to α,β-unsaturated ethers is essentially an addition of the alkoxycarbonium ion formed from the acetal to the double bond of ethers.[4,9] Thus, the primary reaction is the same as that of the propagation step of the cationic polymerization of ethers.[4]

The data given in Table 2 indicate that the relative reactivities of *cis*- and *trans*-SEE's are largely dependent on the attacking carbonium ions, $RCH(OC_2H_5)^+$. The magnitude of reactivity seems to be influenced primarily by the bulkiness of carbonium ion. Reactivity of the *cis* isomer relative to the *trans* isomer tends to decrease with the increasing bulkiness (Taft's steric substituent constants E_s[19]) of group R.

The present observation is consistent with the conclusion that the greater reactivity of the *trans* isomer in the cationic polymerization of SEE is due to steric reasons. The steric hindrance in the reaction becomes greater as the attacking species becomes bulkier, and thus the *cis* isomer becomes less reactive with the increasing bulkiness of R in acetals.

In terms of the electronic factor, on the other hand, *cis*-SEE may be considered to be more reactive than *trans*-SEE, as has been observed with a simple acetal. This seems to be related with the observation[1,2,5] that all the β-substituted vinyl ethers studied so far are more reactive in the *cis* form in cationic polymerization, irrespective of the relative thermochemical stabilities of geometrical isomer pairs. The coincidence is reasonable, since from the viewpoint of reaction mode SEE can be considered as a vinyl ether derivative rather than a styrene derivative.

13) The appearance potential of $CH_3OCH_2^+$ is lower than that of $C_6H_5CH_2^+$,[14] and α-chloromethyl ethers are easily solvolyzed as compared with benzyl chloride.[15]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3553—3556 (1970)

Structure and Reactivity of α,β-Unsaturated Ethers. XII. Cationic Copolymerization of Ring-Substituted Styryl Ethyl Ethers

Tadashi OKUYAMA, Nobuhiro ASAMI and Takayuki FUENO

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received June 1, 1970)

Several ring-substituted derivatives of *cis*- and *trans*-styryl ethyl ethers were copolymerized with the unsubstituted *trans* ether in methylene chloride at −70°C with the use of boron trifluoride etherate as a catalyst. The ring substituents investigated include *p*-CH_3O, *p*-CH_3, *m*-CH_3, *p*-Cl, and *m*-Cl. It was found that the effects of substituents on the polymerizability obey the Hammett $\rho\sigma$ relationship with reaction constants $\rho=-2.4$ and -2.0 for *cis* and *trans* isomers, respectively. The structure of the transition state of the cationic polymeization was discussed.

There are many reports concerning the effects of ring substituents on various types of side-chain reactions of benzene derivatives.[1,2] In polymer chemistry, styrene and its derivatives are a typical class of compound which can be subjected to investigation. Thus, the effects of ring substituents on the polymerizability of styrene have been studied under various polymerization conditions.[3-6] Studies have recently been extended to the cationic copolymerization of phenyl vinyl ethers.[7]

We reported the cationic polymerization of styryl ethyl ether (SEE) with particular attention to the relative reactivities of its geometrical isomers.[8] Cationic polymerization of SEE takes place through the addition of a polymer chain-end on the carbon *alpha*[9] to the phenyl group.

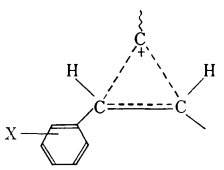
$$C_6H_5CH{=}CHOC_2H_5 \longrightarrow \cdots C^+ \quad \begin{matrix} C_6H_5 \\ | \\ H \end{matrix} \!\!>\!\! C \!-\! C \!<\!\! \begin{matrix} H \\ | \\ OC_2H_5 \end{matrix} \quad (1)$$

This presents a striking contrast to the cationic polymerization of styrene, in which a chain-end addition occurs on the *beta*-carbon.[9]

$$C_6H_5CH{=}CH_2 \longrightarrow \cdots CH_2{-}C^+ \!<\!\! \begin{matrix} H \\ | \\ C_6H_5 \end{matrix} \quad (2)$$

Thus, it seems interesting to compare the effects of ring substituents on the cationic polymerizability of SEE with those of styrene.

In the present investigation, *trans*-SEE has been copolymerized with several of its own ring-substituted derivatives as well as various *cis*-SEE derivatives in methylene chloride at −70°C, using $BF_3\cdot OEt_2$ as a catalyst. The results have been examined in comparison with those of related reactions. From the magnitude of the reaction constants, it has been suggested that the cationic polymerization of SEE as well as that of styrene takes place through a cyclic intermediate.



Experimental

Materials. SEE and its ring-substituted derivatives were obtained as described previously[10] and distilled from calcium hydride under nitrogen atmosphere immediately before use.

Methylene chloride, tetralin and boron trifluoride etherate ($BF_3\cdot OEt_2$) were purified as before.[7,11]

Procedure. Polymerization technique was the same as that described previously.[11] The relative reactivities were evaluated by the method of log-log plots.[8]

Results

Polymerization was carried out in methylene chloride at the dry ice-methanol temperature (*ca.* −70°C) with the use of $BF_3 \cdot OEt_2$ as a catalyst. *trans*-SEE was used as a reference monomer for all runs of copolymerization.

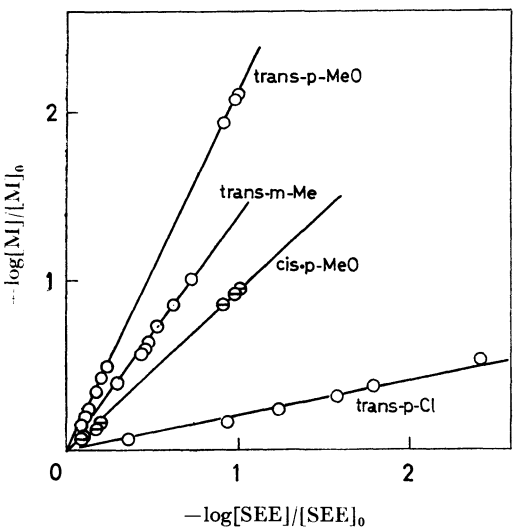

Fig. 1. Variations of monomer concentrations in the copolymerization of various ring-substituted SEE's with *trans*-SEE at −70°C: Solvent, methylene chloride; Catalyst, $BF_3 \cdot OEt_2$.

Examples of the courses of copolymerization between substituted SEE's and *trans*-SEE are shown in Fig. 1. Slopes of the linear relationships provide the relative reactivities[8] of the relevant SEE derivatives. The reactivity data thus obtained are summarized in Table 1.

Table 1. Relative polymerizabilities of ring-substituted styryl ethyl ethers at −70°C

Substituent	Relative polymerizability	
	cis	*trans*
p-CH_3O	0.92	2.11
p-CH_3	0.65	1.98
m-CH_3	—	1.41
H	0.57	1.00
p-Cl	0.17	0.22
m-Cl	0.06	0.09

The reactivity of *trans*-*m*-CH_3-SEE (M_2) relative to *trans*-SEE (M_1) was also evaluated by the usual copolymerization experiments, in which variations of the comonomer composition were analyzed by the aid of the Mayo-Lewis copolymerization equation in an integral form. The *m*-*b* plot[7,8] pertinent to this analysis is shown in Fig. 2. The monomer reactivity ratios obtained were $r_1 = 0.62 \pm 0.01$ and

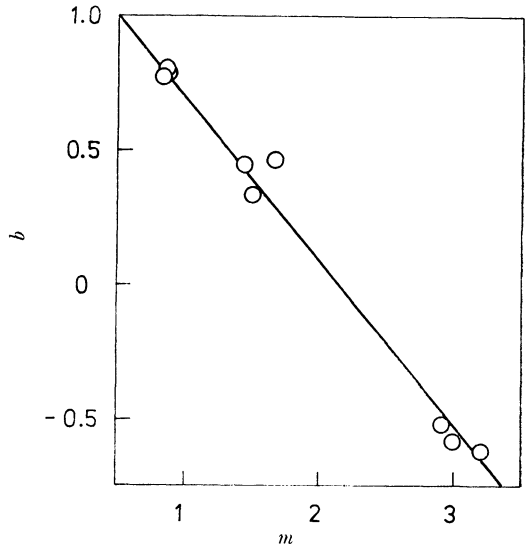

Fig. 2. The *m*–*b* plots for the copolymerization of *trans*-SEE (M_1) and *trans*-*m*-CH_3-SEE (M_2) at −70°C: Solvent, methylene chloride; Initial monomer concentration=8 vol%; Catalyst, $BF_3 \cdot OEt_2$ (0.024M).

$r_2 = 1.32 \pm 0.01$, which lead to the relative reactivity $(r_2/r_1)^{1/2} = 1.45$, in essential agreement with the value, 1.41, listed in Table 1.

At the present polymerization temperature, the *trans* isomers are more reactive than the corresponding *cis* isomers. The polymerizability of SEE derivatives is clearly enhanced with the increase in the electron-releasing character of the ring substituents.

Discussion

Effects of Substituents. Figure 3 shows the Hammett plots of the observed polymerizabilities.

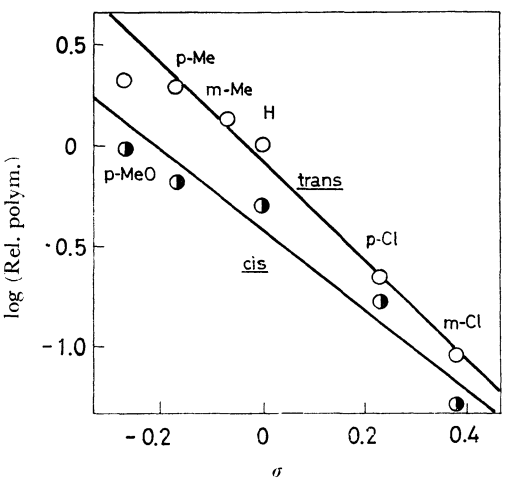

Fig. 3. The Hammett plots of cationic polymerizability of SEE derivatives.

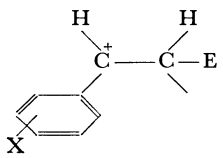
Although the substituents adopted for the plots are few in number, they still suffice to show a general trend. It appears that linear relationships hold for both *cis* and *trans* isomers. The reaction constants, ρ, are roughly −2.0 and −2.6 for *cis* and *trans* isomers, respectively.

These ρ values are comparable in magnitude with the value (−2.03) for the cationic polymerization of styrenes,[4] even though the reaction sites of SEE and styrene are different; the former polymerizes through the addition of polymer chain end on the carbon *alpha* to the phenyl group while the latter polymerizes through the addition on the *beta*-carbon. Therefore, it seems interesting to further examine the magnitudes of substituent effects in these reactions.

Magnitude of the ρ Values. The reaction constants of the Hammett $\rho\sigma$ relations for various electrophilic reactions of styryl compounds related to the present reaction range from −4.3 to −0.7, depending on the type of reaction. Examples in the literature are compared in Table 2.

The reactions listed in Table 2 can be classified by the magnitude of the ρ values into three groups; $\rho = -3.8 \pm 0.5$ (Nos. 1—5), *ca.* −2 (Nos. 6—9) and *ca.* −1 (Nos. 10 and 11).

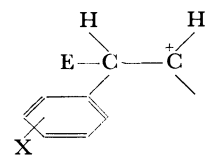
The first group undoubtedly consists of reactions involving an *alpha*-carbonium ion intermediate (I), which is produced by the electrophilic attack of reagents on the *beta*-carbon (with respect to the phenyl group).



I. *alpha*-Carbonium ion

The ρ values around −4 for the reactions involving the rate-determining formation of the *alpha*-carbonium ions (I) are also known for the solvolyses (S_N1) of benzyl-type compounds, $C_6H_5C(CH_3)_2Cl$ and $C_6H_5CH(CH_3)Cl$.[19] In this type of intermediate, charge delocalization into the phenyl group is very important and the effect of substituents on the charge delocalization should be great.

The last group of reactions with $\rho \simeq -1$ include those taking place with the attack of an electrophile on the carbon attached by the phenyl group, thus forming a *beta*-carbonium ion intermediate like II.



II. *beta*-Carbonium ion

This type of reaction has hitherto been known only in a very limited number; there are only two examples reported so far.[10,16] The smaller effects

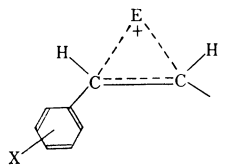
19) *E. g.*, H. C. Brown and Y. Okamoto, *J. Amer. Chem. Soc.*, **79**, 1913 (1957).

of substituents are easily understandable since the carbonium-ion center is insulated from the ring by an intervening methylene group.

The second group, which have ρ values intermediate in magnitude (*ca.* -2), include the reactions of some intermediate character. In these reactions, addition of sulfenyl chlorides to olefins (No. 6) is well established to take place through cyclic episulfonium ions.[17,20] Bromination of styrenes (No. 7) carrying an electron-attracting substituent has been confirmed to occur with the formation of cyclic bromonium ions like III.[21]



III. α,β-Intermediate

Thus, the reactions seem to take place with simultaneous attack of an electrophile on both the α- and β-carbons forming an intermediate like III. Cationic polymerization of both styrenes and SEE's apparently belongs to this category and should involve the cyclic α,β-intermediate III.[22]

Styrene and SEE differ from each other in product orientation. The identical magnitudes of the ρ values for these two reactions may be reconciled if we assume a common mechanism involving the formation of a cyclic α,β-intermediate of type III. The cationic polymerization of vinyl ethers proceeds through the cyclic α,β-intermediate, which agrees with our previous conclusion obtained from the results of calculations of the transition state stability.[23] An experimental investigation[7] of the ring-substituent effects on the phenyl vinyl ether polymerizability also supports the low carbonium-ion character of the transition state. Our recent results on the cationic polymerizations of benzofuran derivatives lend further support to the validity of the α,β-intermediate mechanism.[24]

20) W. H. Mueller and P. E. Butler, *ibid.*, **90**, 2075 (1968); and references cited therein.

21) The conclusion was based on a comparison of the ρ-values of the first and second groups of reactions.[18]

22) This intermediate does not necessarily mean a symmetrical one with respect to the strength of the bonds which an electrophile formed with the α- and the β-carbons. Rather, some asymmetry must be present in view of the definite product orientation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3556—3560 (1970)

The Syntheses of 2-Phenethyl-2,3-dihydro-4(1*H*)-pyridones

Noboru SUGIYAMA, Makoto YAMAMOTO and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received June 15, 1970)

In the presence of three moles of potassium amide in liquid ammonia, the reactions of β-diketones with cinnamylidenaniline gave derivatives of 1-phenyl-2-styryl-2,3-dihydro-4-pyridone. By the catalytic hydrogenation of 6-methyl-1-phenyl-2-styryl-2,3-dihydro-4-pyridone, 6-methyl-2-phenethyl-1-phenyl-2,3-dihydro-4-pyridone was obtained. When β-diketones were treated with cinnamaldehyde azine, instead of cinnamylidenaniline, 1-cinnamylidenamino-2-styryl-2,3-dihydro-4-pyridones were produced; these were then catalytically hydrogenated to the corresponding 2-phenethyl-2,3-dihydro-4(1*H*)-pyridones, accompanied with 2-phenethyl-1-(3-phenylpropylamino)-2,3-dihydro-4-pyridones.

In the presence of three moles of potassium amide in liquid ammonia, dihydropyridone derivatives (A) which contain two phenyl groups at the 1- and 2-positions have been synthesized from β-diketones and benzylidenaniline.[1] The reactions of acetylacetone (**1**) with ethylidenaniline or benzylidenemethylamine, instead of benzylidenaniline, did not give the corresponding 1-phenyl- or 2-phenyldihydropyridone.[1]

The condensation of β-diketones with benzaldazine yielded 1-benzylidenamino-2,3-dihydro-4-pyridones,[2] which were then catalytically hydro-

(A) (B)

Fig. 1.

genolyzed to the corresponding 2,3-dihydro-4(1*H*)-pyridones (B). According to this procedure, dihydropyridone with a phenyl group at the 2-position was obtained.

The condensation of *β*-diketones with cinnamylidenaniline gave 2-styryl-dihydropyridones, which were then catalytically hydrogenated to the dihydropyridones with the phenethyl group at the 2-position.

Results and Discussion

In an attempt to synthesize dihydropyridones with aliphatic substituents, 1-phenyl-dihydropyridones with an aliphatic substituent at the C-2 position was synthesized first.

The reaction of acetylacetone (**1**) with cinnamylidenaniline (**4**) in the presence of sodium or potassium amide in liquid ammonia produced 6-methyl-1-phenyl-2-styryl-2,3-dihydro-4-pyridone (**5**). When three moles of sodium amide and one mole of **4** to **1** were used, the yield of **5** was 4.5%. When two moles of potassium amide were used, the yield of **5** was 5.8%. The mole ratio of 1 : 1 : 3 for **1**, **4** and potassium amide is the best condition for this reaction; this yield was 13.1%.

Fig. 2.

The structure of **5** was determined by studying the spectral data and by elemental analyses.

The condensation of 6-phenyl-2,4-hexanedione (**2**) with **4** gave 6-phenethyl-1-phenyl-2-styryl-2,3-dihydro-4-pyridone (**6**) and its isomer, 3-benzyl-6-methyl-1-phenyl-2-styryl-2,3-dihydro-4-pyridone (**7**) in 13.5 and 4.5% yields respectively. Thus, in the reaction of **2** with benzylidenaniline, C-1 methyl was more reactive than the C-5 methylene of **2**.[1]

It was shown that the dihydropyridone ring is not changed in ethanol during catalytic reduction with a palladium charcoal or a platinum oxide catalyst,[3] but in acetic acid it is hydrogenated by a platinum oxide catalyst to piperidone or piperidinol.[4] These results suggested that when dihydropyridones with a styryl group at the C-2 position are treated with platinum oxide in ethanol, dihydropyridones with a phenethyl group at C-2 may be produced.

The catalytic hydrogenation of **5** gave the expected product, 6-methyl-2-phenethyl-1-phenyl-2,3-dihydro-4-pyridone (**8**) in a poor yield. The ultraviolet spectrum of **8** showed an absorption maximum at 324 m*μ* which is attributable to the *α*,*β*-unsaturated *β*-aminoketone chromophore, but the absorption at 254 m*μ*, corresponding to that of the cinnamyl group, disappeared. This proved the formation of **8**.

On the basis of these results and those described in a previous paper,[4] the condensation products of *β*-diketones with cinnamaldehyde azine (**9**) can be said to be, in fact, catalytically hydrogenated to 2-phenethyl-dihydropyridones.

The condensation of one mole of **1** with a half mole of **9** in the presence of three moles of potassium amide in liquid ammonia gave 1-cinnamylidenamino-6-methyl-2-styryl-2,3-dihydro-4-pyridone(**10**) in a 14.0% yield. Under the same conditions, from benzoylacetone (**3**) and **9**, 1-cinnamylidenamino-6-phenyl-2-styryl-2,3-dihydro-4-pyridone(**11**) was obtained in a poor yield. Similarly, **2** condensed

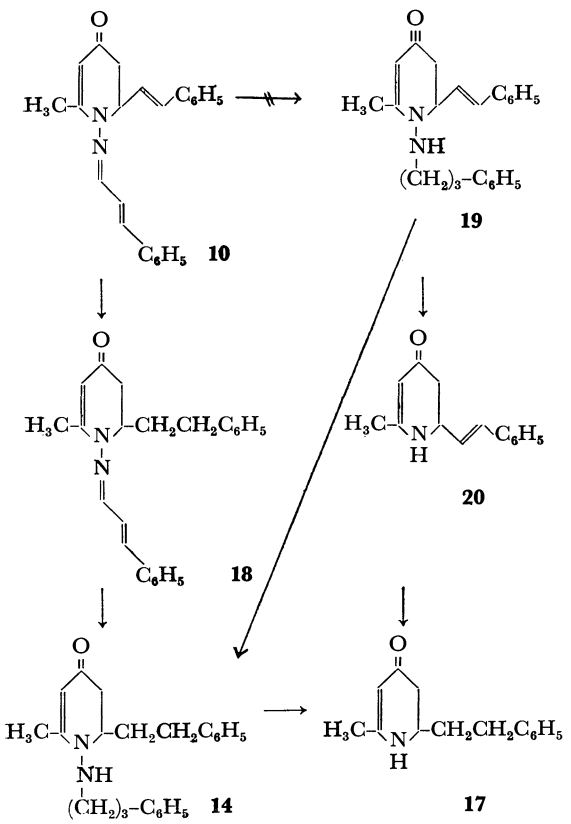
with **9** to give 1-cinnamylidenamino-6-phenethyl-2-styryl-2,3-dihydro-4-pyridone (**12**) and its isomer, 3-benzyl-1-cinnamylidenamino-6-methyl-2-styryl-2,3-dihydro-4-pyridone (**13**) in 15.7 and 5.0% yields respectively. In this reaction of **9**, C-1 is more reactive than the C-5 of **2**.

The structures of **10** and **12** were confirmed by a study of their spectral data and by elemental analyses, but those of both **11** and **13** had to be assigned only from the spectral data.

Compounds **10**, **12**, and **13** were hydrogenated with platinum oxide in ethanol. The hydrogenation of **10** gave 6-methyl-2-phenethyl-1-(3-phenylpropylamino)-2,3-dihydro-4-pyridone (**14**) and 6-methyl-2-phenethyl-2,3-dihydro-4(1*H*)-pyridone (**17**) in 19 and 52% yields respectively. The structures of **14** and **17** were confirmed by studying their spectral data.

In the hydrogenation of **10**, many intermediate products were expected to be obtained, as is illustrated in Scheme 1. The hydrogenation of **10** was interrupted after about 1.7 mol of hydrogen to **10** had been absorbed. From this reaction mixture, 1-cinnamylidenamino-6-methyl-2-phenethyl-2,3-dihydro-4-pyridone (**18**) and **14** were obtained, both in 29% yields, accompanied by a trace of **17**, but neither **19** nor **20** was detected. The further hydrogenation of **18** with platinum oxide in ethanol gave **14** and **17**, while the same treatment of **14** gave only **17**. These results suggest that the hydrogenation proceeds through the route **10**→**18**→**14**→**17**.



Scheme 1.
Intermediates of the Hydrogenation of **10** to **17**

The hydrogenation of **12** gave **15** and **21**, and that of **13** gave **16** and **22**. The structures of **15**, **16**, **21**, and **22** were confirmed by a study of their spectral data,[5,6] and, in the case of **21**, by elemental analyses.

By the use of the procedure described above, dihydropyridones with aliphatic substituents can be synthesized. This procedure consists of simple reaction steps, so that it can be a general method of dihydropyridone synthesis.

Experimental

The Condensation Reaction in Liquid Ammonia. General Procedure. In a 500-m*l*, three necked flask, about 300 m*l* liquid ammonia was placed. A small amount of sodium or potassium was added and dissolved completely. Into the resulting blue solution a catalytic amount of ferric chloride was stirred, and then 0.09 g atom of sodium or potassium in small portions. The color of the solution changed from blue to dark gray within 60—90 min. To this solution 0.03 mol of β-diketone in 30 m*l* of anhydrous ether was added in small portions. After stirring for an hour, 0.03 mol of cinnamylidenaniline (**4**) or cinnamaldehyde azine (**9**) in 50 m*l* of anhydrous ether was added in small portions. After stirring for four hours at −33°C, the reaction mixture was neutralized with solid ammonium chloride (8.0 g). The liquid ammonia was evaporated rapidly on a water bath, and 100 m*l* of ether was added gradually to the residue. The ethereal layer was separated. The ether-insoluble layer was dissolved in 150 m*l* of dilute hydrochloric acid, and then extracted with chloroform. The ether and chloroform layers were washed with water and dried over anhydrous sodium sulfate. The ether and chloroform were evaporated to give the same condensation product.

6-Methyl-1-phenyl-2-styryl-2,3-dihydro-4-pyridone (5). According to the general procedure, 0.03 mol of **1** and 0.03 mol of **4** were allowed to react in the presence of 0.09 mol of sodium amide. The reaction mixture was chromatographed on a silica gel (Merck 7734, 0.05—0.2 mm) column with a benzene - ethyl acetate (2 : 1 v/v) mixture. A fraction that showed a brownish green ferric chloride test was collected, worked up as usual, and recrystallized from benzene to give 0.39 g (4.5%) of **5** as pale yellow prisms; mp 62—63°C.

Found: C, 83.05; H, 6.80; N, 4.87%. Calcd for $C_{20}H_{19}NO$: C, 83.01; H, 6.62; N, 4.84%.

IR(KBr): 1630 (ν C=O), 1550 cm^{-1} (ν C=C).

UV: λ_{max}^{EtOH} mμ(ε): 254 (16900), 286 (5400), 295 (6750) and 325 (17100).

NMR(in $CDCl_3$)(τ): 8.18 (singlet, 3H, C-6 methyl protons), 7.67—6.78 (multiplet, 2H, C-3 methylene

5) H. E. A. Kramer, *Ann. Chem.*, **696**, 15 (1966).
6) C. Kashima, M. Yamamoto and N. Sugiyama, *J. Chem. Soc., C.* **1970**, 111.

protons), 5.60—5.30 (multiplet, 1H, C-2 methine proton), 4.81 (singlet, 1H, C-5 olefin proton), 3.63 (doublet, 1H, β-olefin proton of C-2 styryl group), and 2.77—2.50 (11H, multiplet, aromatic and α-olefin proton of C-2 styryl group).

The reaction of 0.015 mol of **1** with equimolar **4** was carried out in the presence of 0.03 mol of potassium amide by the general procedure. The purification of the reaction product by column chromatography gave 0.25 g (5.8%) of **5**. The reaction of 0.04 mol of **1**, 0.04 mol of **4**, and 0.12 mol of potassium amide yielded 1.52 g (13.1%) of **5**.

6-Phenethyl-1-phenyl-2-styryl-2,3-dihydro-4-pyridone (6). The reaction of 0.015 mol of **2** with an equimolar amount of **4** was carried out in the presence of 0.045 mol of potassium amide by the general procedure. By the chromatography of the reaction product on a silica-gel (Merck 7734) column with a benzene - ethyl acetate (2 : 1 v/v) mixture, a fraction with the R_f-value of 0.27 (on the thin-layer chromatography of silica-gel (Wako gel B-5) with benzene - ethyl acetate (2 : 1 v/v)) was collected. When this fraction was worked up by the usual procedure and recrystallized from benzene, 764 mg (13.5%) of **6** were afforded as colorless plates; mp 174—176°C.

Found: C, 85.64; H, 6.73; N, 3.75%. Calcd for $C_{27}H_{25}NO$: C, 85.45; H, 6.64; N, 3.69%.

IR(KBr): 1630 (ν C=O), 1550 (ν C=C), and 700 cm^{-1} (phenyl).

UV: λ_{max}^{EtOH} mμ(ε): 254 (19800), 285 (4900), 295 (5000) and 331 (17700).

NMR(in $CDCl_3$)(τ): 7.64—7.16 (multiplet, 4H, ethylene protons of the C-6 phenethyl group), 7.78—6.76 (multiplet, 2H, C-3 methylene protons), 5.73—5.45 (multiplet, 1H, C-2 methine proton), 4.70 (singlet, 1H, C-5 olefin proton), 3.60 (doublet, 1H, β-olefin proton of the C-2 styryl group), and 3.20—2.57 (multiplet, 16H, aromatic protons and α-olefin proton of the C-2 styryl group).

3-Benzyl-6-methyl-1-phenyl-2-styryl-2,3-dihydro-4-pyridone (7). Compound **7** was obtained from the same reaction mixture as **6**. By column chromatography with benzene - ethyl acetate (2 : 1 v/v), **7** was eluted ahead of **6**. On silica-gel (Wako gel B-5) thin-layer chromatography with benzene - ethyl acetate (2 : 1 v/v), **7** showed an R_f-value of 0.35, while that of **6** was 0.27. The fraction containing **7** was concentrated and recrystallized from ethyl acetate to give 255 mg (4.5%) of **7** as pale yellow prisms; mp 155—156°C.

Found: C, 85.49; H, 6.66; N, 3.79%. Calcd for $C_{27}H_{25}NO$: C, 85.45; H, 6.64; N, 3.69%.

IR(KBr): 1635 (ν C=O), 1560 (ν C=C) and 705 cm^{-1} (phenyl).

UV: λ_{max}^{EtOH} mμ(ε): 253 (18300), 285 (4950), 294 (5460) and 328 (17900).

NMR(in $CDCl_3$)(τ): 8.10 (singlet, 3H, C-6 methyl protons), 7.60—6.64 (multiplet, 3H, C-3 methine and methylene protons of the C-3 benzyl group), 5.94 (quartet, 1H, C-2 methine proton), 4.80 (singlet, 1H, C-5 olefin proton), 3.98—3.31 (multiplet, 1H, β-olefin proton of the C-2 styryl group), and 2.85—2.55 (multiplet, 16H, α-olefin proton of the C-2 styryl group, and aromatic protons).

6-Methyl-2-phenethyl-1-phenyl-2,3-dihydro-4-pyridone (8). A mixture of 30 ml of ethanol, 150 mg of **5**, and 100 mg of platinum oxide was stirred under the atmospheric pressure of hydrogen. After absorbing 49 ml of hydrogen, the reaction mixture was treated in the usual manner and then purified by chromatography on a silica-gel (Merck 7729, 0.08 mm) column, using a benzene - ethyl acetate (2 : 1 v/v) mixture. A fraction with an R_f-value of 0.25 was collected on silica-gel (Wako gel B-5) thin-layer chromatography, using a benzene - ethyl acetate (2 : 1 v/v) mixture; this value was different from that of **5**, 0.16. However, this fraction was proved to contain a trace of **8** and 111 mg (74%) of recovered **5**.

Syntheses of 1-Cinnamylidenamino-2,3-dihydro-4-pyridones. According to the general procedure, 1-cinnamylidenamino-2,3-dihydro-4-pyridones were prepared from 0.015 mol of β-diketone and 0.015 mol of cinnamaldehyde azine (**9**). The crude product was chromatographed on a silica-gel (Merck 7734) column, using a benzene - ethyl acetate (4 : 1 v/v) mixture. A fraction which showed a green color with ferric chloride was collected and then again chromatographed on a silica-gel (Merck 7729) column, using a benzene - ethyl acetate (2 : 1 v/v) mixture. A fraction which showed a green color with ferric chloride was collected, concentrated, and recrystallized from the appropriate solvent to yield pure dihydropyridones, **10**, **11**, **12** and **13**.

1-Cinnamylidenamino-6-methyl-2-styryl-2,3-dihydro-4-pyridone (10). Compound **10** was prepared from 0.015 mol of **1** and 0.015 mol of **9**. Yield, 0.70 g (14.0%); yellow prisms (recrystallized from benzene); mp 185—186°C.

Found: C, 80.57; H, 6.61; N, 8.08%. Calcd for $C_{23}H_{22}N_2O$: C, 80.67; H, 6.48; N, 8.10%.

IR(KBr): 1640 (ν C=O), 1590 (ν C=N) and 1555 cm^{-1} (ν C=C).

UV: λ_{max}^{EtOH} mμ(ε): 238 (18700), 246 (21500), 256 (22000), 286 (16000), 372 (40400) and 382 (40400).

NMR(in $CDCl_3$)(τ): 7.70 (singlet, 3H, C-6 methyl protons), 7.42 (quartet, 1H, C-3 methylene proton, ABX type), 6.85 (quartet, 1H, C-3 methylene proton, ABX type), 4.95 (multiplet, 1H, C-2 methine proton, ABX type), 4.85 (singlet, 1H, C-5 olefin proton), 4.04 (quartet, 1H, α-olefin proton of the C-2 styryl group), 3.67(doublet, 1H, β-olefin proton of the C-2 styryl group), 3.15 (multiplet, 2H, β′-, γ′-olefin protons of the 1-cinnamylidenamino group), and 2.76—2.30 (multiplet, 11H, α′-olefin proton of the 1-cinnamylidenamino group and aromatic protons).

1-Cinnamylidenamino-6-phenyl-2-styryl-2,3-dihydro-4-pyridone (11). Compound **11** was prepared from 0.015 mol of **3** and an equimolar amount of **9** in a poor yield (yellow solid). UV spectrum of **11**: λ_{max}^{EtOH} 251, 295 and 378 mμ.

1-Cinnamylidenamino-6-phenethyl-2-styryl-2,3-dihydro-4-pyridone (12). From 0.015 mol of **2** and an equimolar amount of **9**, 1.02 g (15.7%) of **12** were prepared. Yellow prisms; mp 131—134°C (recrystallized from ethanol).

Found: C, 83.11; H, 6.65; N, 6.43%. Calcd for $C_{30}H_{28}N_2O$: C, 83.30; H, 6.53; N, 6.48%.

IR(KBr): 1635 (ν C=O), 1580 (ν C=N) and 1550 cm^{-1} (ν C=C).

UV: λ_{max}^{EtOH} mμ(ε): 247 (23100), 256 (22400), 286 (15700), 293 (14400), 373 (42300) and 385 (42500).

NMR(in $CDCl_3$)(τ): 7.00 (singlet, 3H, ethylene protons of the C-6 phenethyl group), 6.64—7.58 (ABX type double quartet, 2H, C-3 methylene protons, J_{AB}=16.5, J_{AX}=7.2 and J_{BX}=1.5 Hz), 4.85 (multiplet, 1H, C-2

methine proton), 4.83 (singlet, 1H, C-5 olefin proton), 4.00 (quartet, 1H, α-olefin proton, $J_{\alpha X}$=4.5 Hz), 3.58 (doublet, 1H, β-olefin proton, $J_{\alpha\beta}$=15.7 Hz), 3.10 (multiplet, 2H, β′- and γ′-olefin protons of the 1-cinnamylidenamino group), and 2.75—2.30 (multiplet, 16H, α′-olefin proton of the 1-cinnamylidenamino group and aromatic protons).

3-Benzyl-1-cinnamylidenamino-6-methyl-2-styryl-2,3-dihydro-4-pyridone (13). Compound **13** was obtained from the same reaction mixture as **12**. The fraction which was eluted first showed an R_f-value of 0.21 on silica-gel (Wako gel B-5) thin-layer chromatography with a benzene - ethyl acetate (10 : 1 v/v) mixture. However, **12** showed an R_f-value of 0.10. When it was worked up as usual, 0.32 g (5.0%) of **13** was yielded as a viscous yellow oil.

IR(liquid film): 1630 (ν C=O), 1585 (ν C=N) and 1550 cm^{-1} (ν C=C).

Catalytic Hydrogenation of 10. A solution of 390 mg of **10** in 50 m*l* of ethanol was hydrogenated with 100 mg of platinum oxide at room temperature and under an atmospheric pressure. After absorbing about 105 m*l* of hydrogen (calculated 111 m*l*), the absorption of hydrogen almost ceased. After the catalyst had then been filtered off, the ethanol solution was worked up as usual. It was chromatographed on a silica-gel (Merck 7729) column with a benzene - ethyl acetate (1 : 1 v/v) mixture. Two fractions which showed brown and green colors with ferric chloride were collected. The brown-colored fraction was again chromatographed on a silica-gel (Merck 7729) column with a benzene - ethyl acetate (2 : 1 v/v) mixture to give 76 mg (19%) of 6-methyl-2-phenethyl-1-(3-phenylpropylamino)-2,3-dihydro-4-pyridone (**14**) as a yellow oil.

NMR(in $CDCl_3$)(τ): 8.00 (singlet, 3H, methyl protons), 8.43—7.00 (multiplet, 12H, C-3 methylene protons and ethylene protons of the C-2 phenethyl group and trimethylene protons of the 1-(3-phenylpropylamino-group), 6.54—6.20 (multiplet, 1H, C-2 methine proton), 6.05 (broad singlet, 1H, NH; this signal disappeared upon treatment with D_2O[2]), 5.17 (singlet, 1H, C-5 olefin proton), and 2.89—2.55 (multiplet, 10H, aromatic protons).

The fraction which showed a green color with ferric chloride was again chromatographed on a silica-gel (Merck 7729) column with a benzene - ethyl acetate (1 : 2 v/v) mixture to give 128 mg (52%) of 6-methyl-2-phenethyl-2,3-dihydro-4(1*H*)-pyridone (**17**) as colorless needles; mp 143—145°C.

Found: C, 77.93; H, 8.08; N, 6.45%. Calcd for $C_{13}H_{17}NO$: C, 78.10; H, 7.96; N, 6.51%.

IR(KBr): 3220 (ν NH), 1600 (ν C=O) and 1575 cm^{-1} (ν C=C).

UV: λ_{max}^{EtOH} mμ(ε): 314 (15400) and $\lambda_{max}^{HCl/EtOH}$ 307 (10300).

NMR(in $CDCl_3$)(τ): 8.10 (singlet, 3H, C-6 methyl protons), 8.02—7.12 (multiplet, 6H, C-3 methylene protons and ethylene protons of the C-2 phenethyl group), 6.50—6.20 (multiplet, 1H, C-2 methine proton), 5.10 (singlet, 1H, C-5 olefin proton), 4.73 (broad singlet, 1H, NH), and 2.85—2.70 (multiplet, 5H, aromatic protons).

According to the same procedure, from the compound **12**, **15** and **21** were obtained, and from the compound **13**, **16** and **22** were prepared. The compounds **15**, **16** and **22** could not be purified well, so the structures of these compounds were confirmed only by the spectral data.

2,6-Diphenethyl-1-(3-phenylpropylamino)-2,3-dihydro-4-pyridone (15). From 1.40 g of **12**, 380 mg (26.8%) of **15** and 264 mg (26.7%) of **21** were obtained.

IR of **15** (liquid film): 3250 (ν NH), 1610 (ν C=O) and 1540 cm^{-1} (ν C=C).

UV: λ_{max}^{EtOH} 329 mμ, $\lambda_{max}^{HCl/EtOH}$ 325 mμ.

NMR(in $CDCl_3$)(τ): 8.45—6.95 (multiplet, 16H), 6.96—6.69 (broad singlet, 1H, NH), 6.50—6.18 (multiplet, 1H, C-2 methine proton), 5.10 (singlet, 1H, C-5 olefin proton), 2.79, 2.80, 2.82 (singlets, 15H, aromatic protons).

2,6-Diphenethyl-2,3-dihydro-4(1*H*)-pyridone (21). Mp 144—146°C; colorless needles.

Found: C, 82.46; H, 7.55; N, 4.54%. Calcd for $C_{21}H_{23}NO$: C, 82.58; H, 7.59; N, 4.59%.

IR(KBr): 3250 (ν NH), 1605 (ν C=O) and 1570 cm^{-1} (ν C=C).

UV: λ_{max}^{EtOH} mμ(ε): 316 (15000), $\lambda_{max}^{HCl/EtOH}$ 310 (10200).

3-Benzyl-6-methyl-2-phenethyl-1-(3-phenylpropylamino)-2,3-dihydro-4-pyridone (16). From 400 mg of **13**, 158 mg of **16** were obtained. $FeCl_3$ test: brown.

IR(liquid film): 3250 (ν NH), 1615 (ν C=O), and 1555 cm^{-1} (ν C=C).

From the above reaction mixture, a trace of 3-benzyl-6-methyl-2-phenethyl-2,3-dihydro-4(1*H*)-pyridone (**22**) was obtained. $FeCl_3$ test: green.

UV: λ_{max}^{EtOH} 318 mμ, $\lambda_{max}^{HCl/EtOH}$ 310 mμ.

1-Cinnamylidenamino-6-methyl-2-phenethyl-2,3-dihydro-4-pyridone (18). A solution of 2.0 g of **10** in 50 m*l* of ethanol was hydrogenated with 150 mg of platinum oxide. After the mixture had absorbed about 24 m*l* (calculated 56 m*l*) of hydrogen, absorption was stopped. After the catalyst had been filtered off and the ethanol solution worked up as usual, the reaction product was purified by a column chromatography similar to that described above to afford 575 mg (29%) of **18** as a viscous orange oil.

UV: λ_{max}^{EtOH} 244, 249, and 340 mμ.

NMR(in $CDCl_3$)(τ): 7.91 (singlet, 3H, C-6 methyl protons), 7.78—7.00 (multiplet, 6H, ethylene protons of the phenethyl group and C-3 methylene protons), 6.15—5.75 (multiplet, 1H, C-2 methine proton), 5.01 (singlet, 1H, C-5 olefin proton), 3.52 (triplet, 1H, β′-olefin proton of the 1-cinnamylidenamino group) and 2.90—2.60 (multiplet, 12H, α′-, γ′-olefin protons of the 1-cinnamylidenamino group and aromatic protons).

As well as **18**, 460 mg (29%) of **14** and a trace of **17** were afforded.

Hydrogenation of 18. Compound **18** (120 mg) was hydrogenated with 50 mg of platinum oxide in 30 m*l* of ethanol. After about 20 m*l* of hydrogen had been absorbed, the absorption of hydrogen was stopped. The reaction mixture was then treated as usual; we thus obtained **14** and **17** which were identified with authentic samples by means of thin-layer chromatography.

Hydrogenation of 14 to 17. In the presence of 100 mg of platinum oxide in 50 m*l* of ethanol, 400 mg of **14** were hydrogenated. After about 50 m*l* of hydrogen had been absorbed, the absorption of hydrogen almost ceased. When the reaction mixture was worked up as usual it gave **17**, which was identified with an authentic sample by means of thin-layer chromatography.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3561—3566 (1970)

Linear Conjugated Systems Bearing Aromatic Terminal Groups. II. The Synthesis and the Electronic Spectra of 9,9′-Dianthrylpoly-ynes

Shuzo AKIYAMA and Masazumi NAKAGAWA

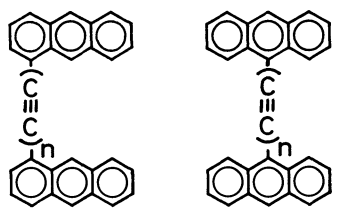
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received June 15, 1970)

A series of 9,9′-dianthrylpoly-ynes (II_1–II_6) were prepared, and their electronic spectra were measured. It was found that the novel linear relation between λ_{max} and the square of the number of the triple bond (n^2) which has been found in the spectra of 1,1′-dianthrylpoly-ynes (I_1–I_6) also held in the 9,9′-series.

The present authors have pointed out in previous papers that the plot of the λ_{max} of the electronic spectra of 1,1′-dianthrylpoly-ynes (I_n) against the square of the number of the triple bond (n^2) gave a straight-line relationship;[1] this novel relationship has been explained in terms of HMO, applying a modified bond-alternation approximation.[2]

This interesting spectral behavior prompted the authors to the synthesis of 9,9′-dianthrylpoly-ynes (II_1–II_6) in order to get further information on



I_n II_n

the role of the terminal groups on the electronic spectra of diarylpoly-yne compounds.

Synthesis. The synthesis of 9,9′-dianthrylacetylene (II_1) by means of an intramolecular Wittig reaction will be reported in the following paper, together with the synthesis of other diarylacetylenes. The higher members (II_2–II_6) have been synthesized according to the sequence depicted in the following scheme, starting from the common precursor, 9-formylanthracene (III).[3]

The color of the crystals and the melting points of 9,9′-dianthrylpoly-ynes (II_1–II_6) are compared with those of 1,1′-analogs in Table 1.

Infrared Spectra. Just as in the case of the 1,1′-series,[1] a remarkable intensification of the absorption ($A=1-I/I_0$) due to $\nu_{C\equiv C}$ with an increase in the number of n was also observed in the case of II_n, as is illustrated in Fig. 1. The absorption intensity of the $\nu_{C\equiv C}$-band relative to the intensity of the 880 cm^{-1}-band (ν_{C-H} of the isolated hydrogen atom in the anthryl groups) and to the 730 cm^{-1}-band (ν_{C-H} of the adjacent four hydrogen atoms in the terminal groups) is summarized in Table 2. It seems to be noteworthy that the $\nu_{C\equiv C}$-band of the tetraacetylene (II_4) exhibited the highest wavenumber, as in the cases of diphenyl-, dimethyl-,[4] and 1,1′-dianthrylpoly-ynes.[1]

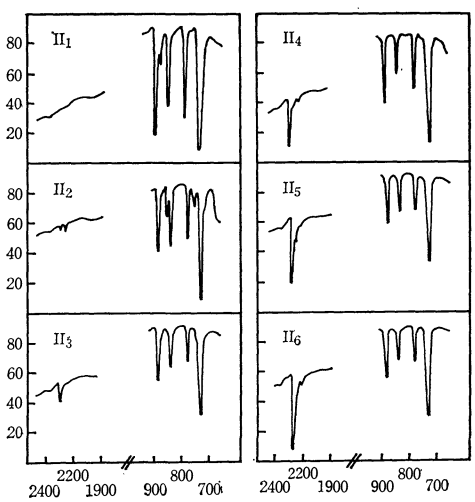

Fig. 1. Infrared spectra of 9,9′-dianthrylpoly-ynes (II_1–II_6) in the 1900—2400 cm^{-1} and 700—900 cm^{-1} region.

Table 2. The wave numbers and the relative absorption intensities of $\nu_{C\equiv C}$ -band of II_n (KBr-disk)

II_n	$\nu_{C\equiv C}$-band	Relative absorption intensities	
		Ratio to the 880 cm^{-1} -band	Ratio to the 730 cm^{-1} -band
II_1	—	—	—
II_2	2180†, 2115	0.07	0.04
II_3	2185†, 2150*	0.52	0.32
II_4	2200†, 2060	1.26	0.76
II_5	2150†, 2100, 2040*	1.95	1.09
II_6	2120†, 2010	2.30	1.29

The daggers indicate the absorption bands used in the calculation.
The asterisks denote the shoulders.

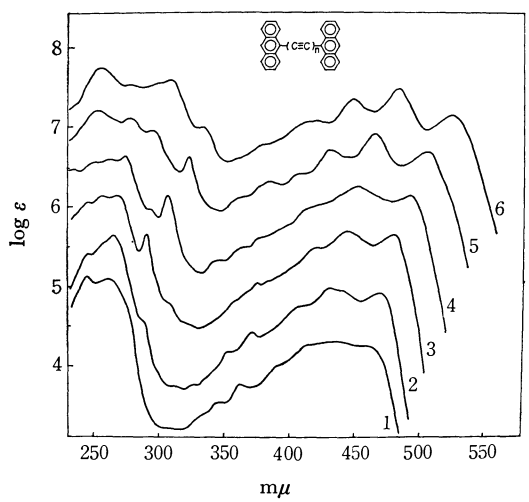

Fig. 2. The absorption curves of 9,9′-dianthrylpoly-ynes (II_1–II_6) . The curves, with the exception of the monoacetylene at the bottom, have been displaced upward on the ordinate axis by 0.5 log ε unit increments from the curve immediately below (in tetrahydrofuran).

The asterisks indicate the shoulders.

Electronic Spectra. The absorption curves and the numerical data of the electronic spectra of II_n are shown in Fig. 2 and Table 3. Similarly to the case of 1,1′-dianthrylpoly-ynes (I_n),[1] the electronic spectra of II_n could be divided into three groups, *i. e.*, the short-wavelength band (240—280 mμ), the medium-wavelength band (280—330 mμ), and the long-wavelength band (330—500 mμ). The appearance of the medium-wavelength band and the distinct vibrational fine structure of the long-wavelength maxima are characteristics of the spectra of the poly-ynes (I_n and II_n). However, the long-wavelength band of II_1 was found to be rather broad, and the peak corresponding to the longest-wavelength sub-bands in II_2–II_6 could not be observed. The bathochromic shift of the longest-wavelength maximum (λ_L) caused by the addition of an acetylenic linkage becomes progressively greater as the length of the polyacetylenic chain is increased. The shifts were found to be 9, 12, 14, and 18 mμ respectively in the II_2–II_6 series. Just as in the case of I_n, the ratios of λ_L to the wavelength of the medium-wavelength maxima (λ_M) were found to be almost constant, regardless of the length of the poly-yne chain (n) and the nature of the solvent (Table 4).

A good correlation between the λ_L of II_2–II_6 and the square of the number of the acetylenic bond (n^2) has also been observed. A plot of this relation is shown in Fig. 3, together with that of the I_n-series.*1 The linear relationship could be expressed by the following empirical formulae, which shows excellent agreement with the observed values, as is summarized in Table 5. As is clearly shown in Fig. 3, II_n absorbs at a longer wavelength

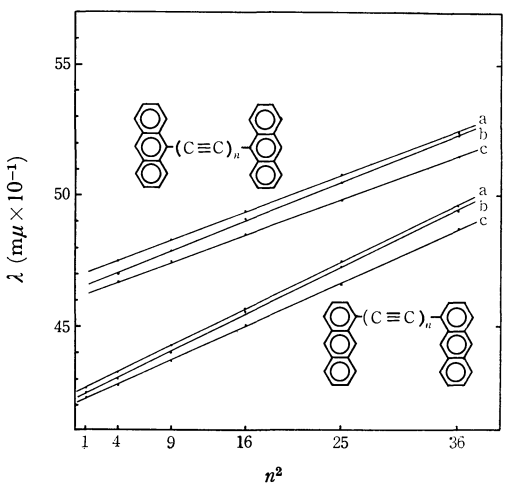

Fig. 3. Plot of λ_{max} *versus* n^2 for 9,9′-dianthrylpoly-ynes (II_1–II_6) and 1,1′-dianthrylpoly-ynes (I_1–I_6).

*1 The synthesis of 1,1′-dianthrylacetylene (I_1) will be reported in the following paper.

Table 5. The longest wavelength absorption maxima (mμ)

II_n	Benzene		Tetrahydrofuran		Cyclohexane	
	Obsd	Calcd	Obsd	Calcd	Obsd	Calcd
II_2	475	475	470	471	467	467
II_3	483	483	479	479	475	475
II_4	494	494	491	490	485	485
II_5	508	508	505	505	498	499
II_6	524	525	523	523	515	515

$\lambda_{max} = 1.50\,n^2 + 461$ mμ (cyclohexane)

$\lambda_{max} = 1.65\,n^2 + 464$ mμ (tetrahydrofuran)

$\lambda_{max} = 1.55\,n^2 + 469$ mμ (benzene)

than the corresponding I_n. However, the slopes of the straight lines of the 1,1′-series (I_n) are steeper than those of the 9,9′-series (II_n). Accordingly, the difference in the wavelength between the corresponding members of these two series diminishes with the increase in the length of the poly-yne chain (n=2, 42; n=3, 40; n=4, 37; n=5, 30 and n=6, 28 mμ) in tetrahydrofuran. The solvent effect is found to be more pronounced in the case of II_n, even in the lower members.

It seems to be important to obtain the knowledge regarding electronic spectra of 2,2′-dianthrylpoly-ynes, as the polyacetylenic chromophore extends in the direction of the polarization of the ^1B_b-band of the anthracene nucleus, whereas in the cases of 1,1′- and 9,9′-dianthrylpoly-ynes (I_n and II_n) the direction of the polyacetylenic chromophore is parallel with the direction of the polarization of the ^1L_a-band of the aromatic nucleus.[5] Unfortunately, all attempts to prepare 2,2′-dianthrylpoly-ynes impeded by the extremely poor solubilities of the 2-substituted anthracene derivatives.

The studies of the synthesis and the spectral properties of dinaphthylpoly-ynes will be reported in the following paper.

Experimental

All the melting points are uncorrected. The electronic spectra were obtained on a Hitachi EPS-3T spectrophotometer at room temperature using a well-matched pair of 1-cm cells. A Hitachi EPI-2 spectrophotometer was used for the infrared spectroscopy.

1,4-Di(9-anthryl)-1,4-dihydroxy-2-butyne (IV). 9-Anthraldehyde (III[3], 6.18 g, 0.03 mol) in tetrahydrofuran (100 m*l*) was added to an ice-cooled solution of acetylene dimagnesium bromide [from excess acetylene, magnesium (1.75 g, 0.073 g atom), and ethyl bromide (9.70 g, 0.088 mol)] in benzene - tetrahydrofuran (50m*l*). The mixture was stirred overnight at room temperature, and then the strongly cooled mixture (ice-salt bath) was treated with a saturated aqueous solution of ammonium chloride. After the separation of the organic layer, the aqueous layer was extracted with benzene. The combined organic layer was dried (magnesium sulfate). The orange-red viscous liquid obtained by evaporating the solvent under reduced pressure was dissolved in benzene (40 m*l*). The solution was filtered through a short column of alumina (8 g). The filtrate was concentrated under reduced pressure, and a small amount of benzene - cyclohexane (1 : 1) was added to the residue. The mixture was warmed on a water bath, resulting in crystallization (4.7 g, 71%). The crystals were recrystallized twice from benzene, yielding IV, mp 204—207°C (dec.), as pale yellow needles.

Found: C, 88.06; H, 5.32%. Calcd for $C_{17}H_{12}O$: C, 87.64; H, 5.06%. IR (KBr-disk): 3400 (O–H), 1040 (C–O) cm^{-1}. *Cf.* IRDC Cards No. 3642.

9,9′-Dianthryldiacetylene (II_2). *The Preparation of the Dichloride (V).* A mixture of thionyl chloride (0.36 g, 3 mmol), pyridine (0.24 g, 3 mmol), and ether (5 m*l*) was added, drop by drop over a 30-min period to a cooled solution (−20°C) of IV (0.440 g, 1 mmol) in tetrahydrofuran (10 m*l*) under vigorous shaking. The immediate deposition of a yellow crystalline solid was observed. Shaking was then continued for an additional hour.

The Dehydrochlorination of V. The above-mentioned reaction mixture was added, in one portion, to a stirred suspension of sodium amide [from sodium 0.40 g (0.017 g atom)] in liquid ammonia (50 m*l*) at −70°C. After 1 hr, ammonium chloride (2.0 g) was added to the mixture and the ammonia was allowed to evaporate. The residue, after the organic solvent had been removed under reduced pressure, was mixed with water. The insoluble material was washed with small amounts of ethanol and benzene successively, resulting in a yellowish brown powder. This was dissolved in benzene (100 m*l*) and passed through a short column of alumina (8 g). Yellowish brown crystals obtained by evaporating the filtrate were recrystallized from benzene, yielding II_2, as orange cubes; 0.160 g (40%). An analytical specimen was obtained by recrystallizing the crystals twice from benzene; mp 290—292°C (dec.).

Found: C, 95.64; H, 4.58%. Calcd for $C_{32}H_{18}$: C, 95.49; H, 4.51%. IR: *Cf.* IRDC Cards No. 3717.

9-Anthryl-2-propyn-1-ol (VI). A solution of 9-anthraldehyde (III, 16.0 g, 0.078 mol) in tetrahydrofuran (300 m*l*) was added to a suspension of lithium acetylide [from lithium 1.6 g (0.24 g atom)] at −70°C over a 1-hr period. The mixture was stirred a further 5.5 hr at −50°C, and then ammonium chloride (8.0 g) was added. After the evaporation of the ammonia, a saturated aqueous solution of ammonium chloride was added to the residue. The aqueous layer was extracted with benzene and combined with the organic layer. The combined organic layer was dried (magnesium sulfate) and concentrated under reduced pressure. The residue was dissolved in hot benzene (40 m*l*) to yield crude crystals of VI (14.4 g, 72%). The second crop of VI (1.3 g, 7%) was obtained from the mother liquor. Recrystallization of the crude material from tetrahydrofuran-benzene yielded pure VI as pale yellow plates; mp 124—125°C.

Found: C, 87.73; H, 5.30%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.21%. IR (KBr-disk): 3570 (O–H), 1022, 1013 (C–O), 3280 (≡CH) and 2130 (C≡C) cm^{-1}. *Cf.* IRDC Cards, No. 4161.

1,6-Di(9-anthryl)-1,6-dihydroxy-2,4-hexadiyne

5) *Cf.* R. N. Jones, *Chem. Rev.*, **41**, 365 (1947).

(VII). A mixture of the anthrylpropynol (VI, 2.32 g, 0.01 mol), cuprous chloride (0.10 g, 1 mmol), ammonium chloride (0.07 g), and methanol (40 m*l*) was vigorously stirred at room temperature under an atmosphere of oxygen at a slight elevated pressure. After 30 min, a minor amount of the cuprous acetylide which deposited was dissolved, two drops of concentrated hydrochloric acid were added, and the stirring was continued overnight. The coupling product thus deposited was collected by filtration, washed with methanol, and dissolved in acetone (40 m*l*) to remove any inorganic material. The oily residue obtained by concentrating the acetone solution was triturated with hot benzene, resulting in crystallization (1.79 g, 78%; mp *ca.* 220°C (dec.)). This was recrystallized three times from acetone - benzene to yield pure VII as pale yellow cubes; mp *ca.* 220°C (dec.).

Found: C, 88.40; H, 4.93%. Calcd for $C_{34}H_{22}O_2$: C, 88.29; H, 4.79%. IR (Nujol): 3350 (OH), 1009 (C–O), 2130 (C≡C) cm^{-1}. *Cf.* IRDC Cards, No. 3270.

9.9′-Dianthryltriacetylene (II_3). *The Preparation of the Dichloride (VIII).* A mixture of thionyl chloride (0.24 g, 2 mmol), and pyridine (0.16 g, 2 mmol) in ether (5 m*l*) was added, drop by drop, a cooled solution (−20°C) of the glycol (VII, 0.308 g, 0.67 mmol) in tetrahydrofuran (15 m*l*) over a 15 min-period, and then the mixture was shaken for an additional hour. The orange-yellow reaction mixture containing a yellow precipitate was directly subjected to the following dehydrochlorination reaction.

Dehydrochlorination of VIII. To a vigorously-stirred suspension of sodium amide [from sodium 0.35 g (0.016 g atom)] in liquid ammonia (60 m*l*) the above-mentioned solution of the dichloride (VIII) was added in one portion at −70°C. After 1 hr, ammonium chloride (2.0 g) was added and the ammonia was allowed to evaporate. The organic solvent which remained was removed under reduced pressure. The residue was mixed with water, and the resulting insoluble material was washed with a small amount of methanol and benzene, affording a yellowish brown, crystalline mass (0.255 g, 90%; mp *ca.* 280°C (dec.)). The crude material was recrystallized from toluene to give pure II_3, as deep orange needles; mp 295°C (dec.); 0.203 g (71%).

Found: C, 95.72; H, 4.17%. Calcd for $C_{34}H_{18}$: C, 95.75; H, 4.25%. IR: *Cf.* IRDC Cards, No. 3719.

1-(9-Anthryl)-2-butyne-1,4-diol (IX). To a stirred and ice-cooled solution of the Grignard derivative of propargyl alcohol in tetrahydrofuran (170 m*l*), which had been prepared from magnesium (8.65 g (0.36 g atom)), ethyl bromide (32.2 g (0.36 mol)), and propargyl alcohol (10.1 g (0.18 mol)), there was added a solution of 9-anthraldehyde (III, 12.4 g, 0.06 mol) in tetrahydrofuran (180 m*l*) over a 30 min-period. The mixture was stirred a further 30 min, refluxed for 3 hr, and allowed to stand overnight. A saturated aqueous solution of ammonium chloride was added to the reaction mixture, and the organic layer was separated. The aqueous layer was extracted 4 times with tetrahydrofuran - benzene (total 400 m*l*). The combined organic layer was dried (magnesium sulfate) and concentrated under reduced pressure. The residue was treated with hot benzene (10 m*l*), affording fine, pale yellow crystals; 6.9 g (44%); mp 224—228°C (dec.). A second crop of crystals (1.1 g (7%)) was obtained from the mother liquor. The crystals were recrystallized from tetrahydrofuran to yield pure IX as tiny, pale yellow cubes; mp 227—229°C (dec.).

Found: C, 82.27; H, 5.41%. Calcd for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%. IR (KBr-disk): 3220 (OH), 1019 (C–O) cm^{-1}. *Cf.* IRDC Cards, No. 3640.

9-Butadiynylanthracene (XI). *The Preparation of the Dichloride (X).* A solution of thionyl chloride (6.0 g, 0.05 mol) in tetrahydrofuran (10 m*l*) was added to a stirred and ice-cooled solution of the anthrylbutyne diol (IX, 2.60 g, 0.01 mol), and pyridine (3.0 g, 0.04 mol) in tetrahydrofuran (20 m*l*) over a period of 50 min. The stirring was continued for 30 min at room temperature, and then the mixture was gradually heated to the boiling point. After refluxing for 1 hr, cracked ice was added to the chilled reaction mixture (ice-salt bath) and it was extracted with benzene (70 m*l*). The extract was washed with water, a sodium hydrogen carbonate solution, and water successively, dried (sodium sulfate), and concentrated under reduced pressure. The resulting dark red oil (crude X) was subjected to the subsequent reaction without further purification.

The Dehydrochlorination of X. The above-mentioned crude X in tetrahydrofuran (25 m*l*) was added to a stirred suspension of sodamide [from sodium (4.6 g (0.2 g atom))] in liquid ammonia (150 m*l*) at −70°C over a 30-min period and then stirred for 1.5 hr. Ammonium chloride (10 g) was added to the mixture, and the ammonia was allowed to evaporate. The residue was repeatedly digested with *n*-hexane (total, 1000 m*l*). The hexane solution was concentrated to 350 m*l* and percolated through a short column of alumina (13 g). The resulting pale yellow solution, with a strong lavender fluorescence, was concentrated under reduced pressure thus affording XI as yellow cubes (0.36 g (16% based on the glycol, IX)). The diacetylene, XI, was found to be a fairly unstable substance, and an explosive decomposition at *ca.* 130°C was observed. Also, the crystals rapidly turned black at room temperature.

Found: C, 95.32; H, 4.54%. Calcd for $C_{18}H_{10}$: C, 95.54; H, 4.46%. IR (KBr-disk): 3280 (≡CH), 2190 (C≡C) cm^{-1}. UV (in *n*-hexane): λ_{max} (mμ) (log ε): 226 (3.47), 260.5 (5.11), 283 (4.09), 355 (3.70), 371 (4.04), 392 (4.28), 414.5 (4.29).

9,9′-Dianthryltetraacetylene (II_4). Cupric acetate monohydrate (5.3 g) was added to a stirred solution of the diacetylene (XI, 0.27 g, 0.013 mol) in pyridine (35 ml);[6] the mixture was then stirred for 45 min at 23°C, and for 2 hr at 40°C. Further stirring was continued overnight at room temperature, after which insoluble material was collected by filtration, and washed with water. This yielded fine, orange-brown crystals; 0.23 g (79%); mp 255°C (dec.). The mother liquor was concentrated under reduced pressure and mixed with water to afford crude II_4 (0.05 g, 17%). The combined crystals were recrystallized from benzene and toluene successively to give pure II_4, as orange-red needles; mp 265°C (dec.).

Found: C, 95.86; H, 4.00%. Calcd for $C_{36}H_{18}$: C, 95.97; H, 4.03%. IR: *Cf.* IRDC Cards, No. 4164.

9,9′-Dianthrylpentaacetylene (II_5). *The Preparation of 9-Anthrylbutadiynyl Carbinol (XII).* 9-Anthraldehyde (III, 3.05 g, 0.015 mol) in tetrahydrofuran (50 m*l*) was added to a suspension of lithium diacetylide in liquid ammonia at −70°C, which was prepared by the reaction

6) G. Eglinton and A. R. Galbraith, *J. Chem. Soc.*, **1959**, 889.

of 1,4-dichloro-2-butyne (2.40 g, 0.059 mol) in ether (5 ml) with lithium amide [from lithium 1.24 g (0.177 g atom)] in liquid ammonia (80 ml). The temperature of the reaction mixture was raised to −45°C, and the mixture was stirred for a further 2 hr at the temperature. Ammonium chloride (2 g) was then added, and the ammonia was allowed to evaporate. The residue was digested with benzene (50 ml). The extract was washed with water and dried (magnesium sulfate). The solvent was removed under reduced pressure, resulting in an unstable, viscous, light brown oil. The absence of carbonyl and the presence of hydroxyl and ethynyl groups were revealed by the IR sepectroscopy of the crude material (XII). This was used without further purification in the subsequent oxidative coupling.

The Oxidative Coupling of XII. A mixture of the above-mentioned crude XII, cuprous chloride (0.30 g), ammonium chloride (0.20 g), and methanol (50 ml) was vigorously stirred in an atmosphere of oxygen at room temperature. Two drops of concentrated hydrochloric acid was added to prevent the precipitation of the cuprous acetylide, and then the stirring was continued overnight. The crystalline material thus deposited was collected by filtration, washed with a small amount of methanol, and dissolved in tetrahydrofuran (15 ml). The insoluble material was removed by filtration. The filtrate was passed through a short column of alumina (5 g) and concentrated under reduced pressure. The tarry residue was triturated with benzene, resulting in light brown needles; 1.37 g (36%); mp *ca.* 160°C (dec.). A second crop of the crystals (0.22 g (6%)) was obtained from the mother liquor. The tetraacetylene glycol (XIII) thus obtained was found to be a rather unstable substance, and repeated recrystallizations from acetone - benzene gave only a somewhat impure material whose IR spectrum was in accord with that expected for XIII.

The Preparation of the Dichloride (XIV). To a stirred solution of the crude glycol (XIII, 0.130 g, 0.23 mol) in tetrahydrofuran (20 ml), there was added a mixture of thionyl chloride (0.090 g, 0.76 mmol), pyridine (0.055 g, 0.76 mmol), and ether (5 ml) over a period of 30 min at −20°C. The mixture was stirred for a further 2 hr and then directly subjected to the subsequent reaction.

The Dehydrochlorination of XIV. The above-mentioned solution of XIV was added in one portion to a vigorously-stirred suspension of sodium amide [from sodium (0.10 g) 4.4 mg atom) in liquid ammonia (80 ml)] at −70°C. After 2 hr, ammonium chloride (0.5 g) was introduced into the reaction mixture and the ammonia was allowed to evaporate. The organic solvent was removed under reduced pressure. The residue was mixed with water, and the insoluble material was collected by filtration and washed with small amounts of methanol and benzene. Recrystallization from toluene (400 ml) yielded fine, red needles; 0.046 g (38%); mp *ca.* 245°C (dec.). The second crop [0.33 g (27%); mp 245°C (dec.)] was obtained from the mother liquor. Recrystallization from the same solvent afforded the pure pentaacetylene, II_5, as fine, red needles; mp *ca.* 250°C (dec.).

Found: C, 96.21; H, 3.88%. Calcd for $C_{38}H_{18}$: C, 96.18; H, 3.82%.

1-(9-Anthryl)-2,5-hexadiyn-1,4-diol (XV). A solution of 9-anthraldehyde (III, 6.10 g, 0.03 mol) in tetrahydrofuran (120 ml) was added to a stirred and ice-cooled solution of the Grignard derivative of 2,4-pentadiyn-3-ol, which had been prepared from 2.64 g (0.033 mol) of the alcohol according to a previously-reported method.[1] The mixture was stirred overnight at 17—18°C, and then a saturated aqueous solution of ammonium chloride was added. The organic layer was separated, and the aqueous layer was extracted with ether. The combined organic layer was dried (sodium sulfate) and evaporated under reduced pressure; this yielded a dark red oil. This crystallized on standing; after treatment with hot benzene (20 ml), it was filtered and washed with benzene to afford a pale yellow crystalline powder; 3.60 g (45%); mp *ca.* 150°C (dec.). The crude material was recrystallized four times from benzene to give pure XV, as pale yellow leaflets; mp 195—198°C (dec.).

Found: C, 83.62; H, 4.88%. Calcd for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93%. IR (Nujol): 3300 (O–H, C≡CH), 2110 (C≡C), 1050, 1015, 1001 (C–O) cm^{-1}. *Cf.* IRDC Cards, No. 3715.

9-Anthryltriacetylene (XVII). *The Chlorination of XV.* A mixture of thionyl chloride (1.43 g, 0.012 mol), pyridine (0.95 g, 0.012 mol), and ether (7 ml) was added, over a period of 30 min, to a solution of the glycol (XV, 0.860 g, 3 mmol) in tetrahydrofuran (15 ml) at −15°C. The mixture was stirred for a further 30 min and then subjected to the dehydrochlorination reaction without the isolation of the dichloride (XVI).

The Dehydrochlorination of XVI. To a vigorously-stirred suspension of sodium amide [from sodium (0.30 g) (0.013 mol)] in liquid ammonia held at −70°C, there was added the above-mentioned solution of XVI in one portion. Stirring was continued for one more hour, and then ammonium chloride (2 g) was added. After the evaporation of the ammonia, the organic solvent was removed under reduced pressure. The residue was repeatedly digested with petroleum ether (bp 40—60°C; total 150 ml). The orange yellow solution was percolated through a short alumina column (5 g). The concentration of a small portion of the filtrate under reduced pressure gave XVII as yellow needles; this substance was found to extremely unstable, and the color of the crystals rapidly changed from green to a brownish grey, forming an entirely insoluble decomposition product. The petroleum ether solution was used directly for the subsequent reaction. The triacetylene (XVII) gave red cuprous and yellow silver acetylides. UV (petroleum ether): the longest wavelength absorption maximum, 429 mμ.

9,9′-Dianthrylhexaacetylene (II_6). A mixture of the above-mentioned solution of the triacetylene (XVII), cupric acetate monohydrate (2.0 g), and pyridine (15 ml) was concentrated to *ca.* 15 ml under reduced pressure. The concentrated solution was then stirred overnight at room temperature. After the addition of a small amount of water to the mixture, the insoluble material was collected and washed with water, acetone, and benzene successively, yielding a dark red powder (68 mg) [9% based on the glycol (XV)]. This was recrystallized twice from toluene to give the pure hexaacetylene (II_6), as fine, dark red needles; mp *ca.* 200°C (dec.). II_6 was found to have a poor solubility in common organic solvents.

Found: C, 96.19; H, 3.84%. Calcd for $C_{40}H_{18}$: C, 96.36; H, 3.64%.

Linear Conjugated Systems Bearing Aromatic Terminal Groups. III. The Synthesis and the Electronic Spectra of 1,1′-Dinaphthyl- and 2,2′-Dinaphthylpoly-ynes

Kazuhiro NAKASUJI, Shuzo AKIYAMA, Kazuko AKASHI and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received June 15, 1970)

1,1′-Dinaphthylpoly-ynes (I_n, $n=1$—6) and 2,2′-dinaphthylpoly-ynes (II_n, $n=1$—6) were synthesized, and their electronic spectra were measured. The I_n-series gave an excellent agreement with the $\lambda_{max} \propto n^{1.5}$ relationship, and the II_n-series followed a straight line, $\lambda_{max} \propto n^{1.3}$. These relationships are different from those of 1,1′-dianthryl- and 9,9′-dianthrylpoly-ynes, in which the plots of λ_{max} *versus* n^2 give excellent straight lines (*Bull. Chem. Soc. Jap.*, **39**, 2320 (1966); **40**, 340 (1967)). The new linear relationships found in the dinaphthyl-series offer further evidence of the prominent effect of the terminal groups upon the electronic spectral properties of the conjugated poly-yne system.

In previous papers,[1,2] two of the present authors (S. A and M. N.) have reported the novel electronic spectral properties of 1,1′-dianthryl- and 9,9′-dianthrylpoly-ynes. In the two series of dianthrylpoly-ynes, the variation in λ_{max} with an increase in the number of acetylenic bonds (n) is expressed by the linear relation: $\lambda_{max}=An^2+B$.

We now hoped to synthesize the poly-ynes bearing different types of aromatic terminal groups in order to clarify the role of terminal groups on the electronic spectral regularity of the poly-yne system.

II_n

$n=1, 2, 3, 4, 5, 6$

Synthesis. The synthesis of the mono-, di-, tri-, and tetra-acetylenes (I_{1-4} and II_{1-4}) has been carried out according to the reaction sequence outlined in Scheme 1. The dinaphthylacetylenes (I_1 and II_1) were prepared according to the method of Curtius.[3] The dinaphthyldi-, tri-, and tetra-acetylenes (I_{2-4} and II_{2-4}) were synthesized employing 1- and 2-naphthaldehydes as the starting materials. As is shown in Scheme 2, the naphthylpropargylaldehydes (XVII and XVII′), which had been derived from the acetylnaphthalenes (XV and XV′), were used as the starting materials for the synthesis of the penta- and the hexa-acetylenes (I_5, I_6 and II_5 and II_6). It was found that the replacement reaction of the hydroxyl group in the acetylenic alcohol or glycol by the chlorine atom by means of the action of thionyl chloride and pyridine in tetrahydrofuran was rather sensitive to the reaction conditions, a good result was obtained only under limited reaction conditions (see, the Experimental section).

The colors, the melting points, and the wave-numbers of the IR absorptions due to $\nu_{C\equiv C}$ are summarized in Tables 1 and 2.

Table 1. Physical properties of 1,1′-dinaphthylpoly-ynes (I_n)

Electronic Spectra. The absorption curves and the numerical data of the electronic spectra of the two series of dinaphthylpoly-ynes (I_n and II_n) are shown in Figs. 1 and 2 and in Tables 3 and 4. In both series, the spectra can be regarded as consisting of two groups of absorption bands, *i. e.*, the short-wavelength absorption bands and the long-wavelength absorption bands. The most characteristic feature of the spectra of I_n and II_n is found in the pronounced vibrational structure in the long-wavelength band, which is more distinct than that of the dianthrylpoly-ynes.[1,2]

The long-wavelength band can reasonably be attributed to the interaction of the polyacetylenic chromophore with the ^1L_a-band of the naphthalene nucleus. As the direction of the polarization of the ^1L_a-band is parallel to the short axis of the naphthalene nucleus, the red shift of the long-wavelength bands in the 1,1′-dinaphthyl-series (I_n) as compared with that in the 2,2′-series (II_n) can be ascribed to the more effective extension of conjugation by the polyacetylenic substituent in the 1,1′-series, which extends parallel to the short axis of the nucleus. The difference in wavelength of

the longest-wavelength maxima between I_n and II_n was found to decrease with an increase in the number of n (Table 5). This fact seems to indicate a diminishing contribution of the terminal groups with an increase in the length of the polyacetylenic chain. The intensities of the strongest sub-bands in the long-wavelength absorption increase with an

increase in the number of n. However, the intensities of the longest-wavelength sub-bands reach their maxima at $n=3$ in the 1,1′-series (I_n) and at $n=2$ in the 2,2′-series (II_n), and then decrease monotonously with an increase in the number of n. As is summarized in Table 6, the spacing between the longest-wavelength sub-band and the second-longest-wavelength sub-band diminishes with an increase in the number of n. This tendency seems to reflect the decrease in the triple-bond character, *i.e.*, the increasing contribution of a cumulene-type structure in the excited state with an increase in the length of the poly-yne chain. The short wavelength bands in I_n and II_n clearly relate to the ^1B_b-band of naphthalene. The direction of the polarization of the ^1B_b-band has been known to be parallel to the long axis of the naphthalene nucleus. Therefore, the introduction of a poly-acetylene chain at the 2-position, thus extending the conjugation of the naphthalene nucleus, should exert a more prominent effect than such an introduction at the 1-position. In fact, as is summarized in Table 7, we observed a remarkable bathochromic shift of the absorption maximum in the short-wavelength band in II_n as compared with that in I_n. Just as in the case of the ^1L_a-band, the extent of the bathochromic shift decreases with an increase in the number of the acetylenic linkage, suggesting a diminishing contribution of the terminal groups.

In the previous series of this series,[1,2] it was pointed out that the plots of λ_{max} against the square of the number of the acetylenic bond (n^2) gave an excellent straight line in the cases of 1,1′-dianthryl- and 9,9′-dianthrylpoly-ynes. In the case of 1,1′-dinaphthylpoly-ynes (I_n), it was found that the variation in the wavelength of the longest-wavelength maximum (λ_{max}) with an increase in the number of the acetylenic bond (n) can be expressed by the linear relation:

$$\lambda_{max} = 9\, n^{1.5} + 350 \text{ (tetrahydrofuran)}$$

The plots of λ_{max} *versus* $n^{1.5}$ are illustrated in Fig. 3. The observed and the calculated values of λ_{max} are compared in Table 8.

Obs.	359	375	397	422	451	482
$\Delta\lambda$	0	0	0	0	−1	3

A good correlation between the wavelength of the longest-wavelength maxima (λ_{max}) and $n^{1.3}$ was observed in the case of 2,2′-dinaphthylpoly-ynes (II_n). The linear relation is well expressed by the empirical formula:

$$\lambda_{max} = 15.5\, n^{1.3} + 319 \text{ (tetrahydrofuran)}$$

The observed and the calculated values of λ_{max} are listed in Table 9, while the plots of λ_{max} against $n^{1.3}$ are shown in Fig. 4. As is shown by the B lines in Figs. 3 and 4, the second-longest-wavelength peaks of I_n and II_n also gave straight lines when plotted against $n^{1.5}$ and $n^{1.3}$ respectively.

In both series, the deviation from the straight line is distinct in the case of $n=6$. This fact seems to indicate that the diminishing contribution of the terminal groups to the electronic excitation as the number of n increases causes a gradual change in the spectral properties of these diarylpoly-ynes. If the length of the poly-yne chains in these diarylpoly-ynes is large enough, the spectral shift might be similar to that of simple poly-yne or dialkylpoly-yne. However, it is evident that the regularities in the relationship between λ_{max} and the length of the conjugated polyacetylene chain (n) are markedly influenced by the nature of the aromatic terminal groups, at least in the range of a small number of n. Further studies along this line are now in progress.

Experimental

All the melting points are uncorrected. The electronic spectra were obtained on a Hitachi EPS-3T Spectrophotometer at room temperature using a well-matched pair of 1-cm cells. The infrared spectra were determined with a Hitachi EPI-2 Infrared Spectrophotometer.

1,1′-Naphthil Dihydrazone (V). A mixture of 1,1′-naphthil[5] (IV, 3.10 g, 0.01 mol), 80% hydrazine hydrate (3.10 g, 0.05 mol), and *n*-propanol (80 m*l*) was refluxed for 43.5 hr. The mixture was then cooled in an ice-bath. The crystalline solid which was thus separated was collected by filtration and washed with a small amount of methanol to yield V as fine colorless crystals; 1.15 g; mp 270—275°C (dec.). The mother liquor was refluxed for a further 48 hr to afford additional V; 0.5 g (total yield, 49%).

Found: C, 78.25; H, 5.31; N, 16.14%. Calcd for $C_{22}H_{18}N_4$: C, 78.08; H, 5.36; N, 16.56%.

1,1′-Naphthil Monohydrazone (colorless cubes; 0.35 g; 11%; mp 173—175°C) was obtained by concentrating the filtrate.

Found: C, 81.12; H, 5.06; N, 8.69%. Calcd for $C_{22}H_{16}N_2O$: C, 81.46; H, 4.97; N, 8.64%.

1,1′-Dinaphthylacetylene (I). A mixture of the dihydrazone (V, 1.52 g, 4.5 mmol), yellow mercuric oxide (4.0 g, 0.018 mol), sodium sulfate (0.9 g), powdered potassium hydroxide (0.8 g), and toluene (200 m*l*) was refluxed for 3.5 hr and then filtered. The concentration of the filtrate under a reduced pressure yielded light brown needles; 1.03 g (82%); mp 120—126°C. The crystals were dissolved in benzene and percolated through a small column of alumina (10 g). The filtrate was then concentrated to yield colorless needles; 0.99 g (79%); mp 127—128°C. The crystals were recrystallized twice from methanol to give pure I; mp 129°C*1.

Found: C, 95.00; H, 5.04%. Calcd for $C_{22}H_{14}$; C, 94.93; H, 5.07%.

1,4-Di(1-naphthyl)-1,4-dihydroxy-2-butyne (VII). A solution of 1-naphthaldehyde (VI, 6.20 g, 0.04 mol) in tetrahydrofuran (30 m*l*) was added to a stirred and ice-cooled solution of acetylene dimagnesium bromide [from magnesium 1.92 g, 0.08 g atom and ethyl bromide 8.72 g, 0.08 mol] in benzene - tetrahydrofuran (60 m*l*) over a period of 15 min. After this mixture had been stirred overnight at room temperature, a saturated aqueous solution of ammonium chloride was added under cooling with an ice-salt bath. The aqueous layer was removed and extracted with ether. The extract was combined with the organic layer and dried (magnesium sulfate). It was concentrated under reduced pressure to yield an oily material which crystallized on standing. The crude material was treated with a small amount of benzene to give colorless crystals; 4.80 g (71%). Two recrystallizations of the crystals from benzene gave pure VII; mp 186.5—187.5°C.

Found: C, 85.61; H, 5.38%. Calcd for $C_{24}H_{18}O_2$: C, 85.18; H, 5.36%. IR (in Nujol): 3300—3400 (O–H), 1010 (C–O) cm^{-1}.

1,1′-Dinaphthyldiacetylene (I_2). *The Preparation of the Dichloride (VIII).* To an ice-cooled and stirred mixture of the glycol (VII, 1.01 g, 3 mmol), pyridine (0.95 g, 0.012 mol), and tetrahydrofuran (10 m*l*), there was added a solution of thionyl chloride (1.40 g, 0.012 mol) in tetrahydrofuran (3 m*l*) over a period of 30 min, then the mixture was warmed to 40°C over a period of 1 hr, after which it was stirred an additional hour at that temperature. Cracked ice was added to the reaction mixture, and it was extracted with benzene. The extract was washed with water and aqueous sodium hydrogen carbonate successively, and then dried (magnesium sulfate). The crude dichloride (VIII, 1.00 g, 90%) which was obtained as a yellowish-brown mass by evaporating the solvent *in vacuo* was used in the following reaction without purification.

The Dehydrochlorination of VIII. A solution of the above-mentioned crude chloride (VIII) in tetrahydro-

*1 It should be noted that the description of 1,1′-dinaphthylacetylene in Beilstein, Bd. V, p. 735, is erroneous. It concerns the 2,2′-isomer.

furan (7 ml) was added over a period of 5 min to a stirred suspension of sodium amide [from sodium 0.7 g, 0.03 g atom] in liquid ammonia (50 ml) at −70°C. After 4 hr, ammonium chloride (2.5 g) was added to the reaction mixture, and the ammonia was allowed to evaporate. The residue was repeatedly digested with benzene (total 250 ml), and the benzene solution was concentrated to 50 ml and passed through a short column of alumina (15 g). The yellow crystals [0.28 g, (31% based on VII), mp 171—175°C] which were obtained by concentrating the filtrate under a reduced pressure were recrystallized twice from benzene to give pure I_2; mp 175—177°C. [lit. value, mp 171°C[6]].

Found: C, 95.32; H, 4.69%. Calcd for $C_{24}H_{14}$: C, 95.33; H, 4.67%.

The Oxidative Coupling of 1-Ethynylnaphthalene (XVI). The diacetylene (I_2) was obtained in a quantitative yield by stirring a mixture of 1-ethynylnaphthalene (XVI, 0.86 g, 5.7 mmol), cupric acetate monohydrate (3.0 g), pyridine (8 ml), and methanol (0.5 ml) at 30°C overnight. The crystals thus obtained were recrystallized 3 times from benzene and once from acetone to give pure I_2; mp 175—177°C.

Found: C, 95.42; H, 4.79%. Calcd for $C_{24}H_{14}$: C, 95.33; H, 4.67%.

1-(1-Naphthyl)-2-propyn-1-ol (IX). A solution of 1-naphthaldehyde (VI, 56 g, 0.36 mol) in tetrahydrofuran (300 ml) was added to a stirred solution of lithium acetylide [from lithium 7.45 g (1.08 g atom)] in liquid ammonia (1.2 l) at −70°C over a period of 30 min. Stirring was then continued for 28 hr at −60——65°C. After the addition of ammonium chloride (36 g), the ammonia was allowed to evaporate. The organic layer was separated, and the residue was digested with benzene. The combined organic layer was evaporated *in vacuo*, resulting in a viscous red oil which crystallized on standing. The crude material was treated with benzene - cyclohexane (2 : 5), filtered, and washed with the same solvent to yield a light brown, crystalline powder; 45.4 g (69%). This was recrystallized 5 times from the same solvent to give pure IX as colorless needles; mp 61—63°C.

Found: C, 85.68; H, 5.37%. Calcd for $C_{13}H_{10}O$: C, 85.69; H, 5.53%. IR (Nujol): 3200—3300 (OH), 3300 (≡CH), 2100 (C≡C), 1060 (C–O) cm^{-1}.

1,6-Di(1-naphthyl)-1,6-dihydroxy-2,4-hexadiyne (X). A mixture of the ethynyl carbinol (IX, 6.90 g, 0.038 mol), *N,N,N',N'*-tetramethylethylenediamine (0.22 g, 0.002 mol), cuprous chloride (0.19 g, 0.002 mol), and acetone (50 ml) was vigorously stirred in an atmosphere of oxygen for 2 hr at room temperature and then for 4 hr at 40°C.[4] The oily material which was obtained by evaporating the solvent was dissolved in tetrahydrofuran (100 ml). Benzene (25 ml) was added to the solution, and it was washed with a saturated aqueous solution of sodium chloride, diluted sulfuric acid, a sodium chloride solution and an aqueous sodium hydrogen carbonate solution successively, and then dried (magnesium sulfate). The residue obtained by evaporating the solvent *in vacuo* was mixed with benzene (30 ml), resulting in crude brown crystals; 5.76 g(80%). Five recrystallizations from benzene and two from ethanol - benzene yielded pure X as fine colorless needles; mp 156—176°C.[7]

Found: C, 85.89; H, 4.97%. Calcd for $C_{26}H_{18}O_2$: C, 86.16; H, 5.01%. IR (Nujol): 3200—3300 (OH), 1065 (C–O) cm^{-1}.

1,1'-Dinaphthyltriacetylene (I_3). *The Preparation of the Dichloride (XI).* To a stirred mixture of the glycol (X, 1.09 g, 3 mmol), pyridine (0.71 g, 9 mmol), and tetrahydrofuran (10 ml), there was added a solution of thionyl chloride (1.07 g, 9 mmol) in tetrahydrofuran (3 ml) over a period of 30 min at 0°C. After further stirring for 1 hr at room temperature and then 30 min at 40°C, cracked ice was added to the reaction mixture and it was extracted with benzene. The extract was washed with water, a sodium hydrogen carbonate solution, and water successively, and then dried (magnesium sulfate). The crude dichloride (XI), which was obtained as a deep brown oil by evaporating the solvent *in vacuo*, was subjected to the subsequent reaction without purification.

The Dehydrochlorination of XI. A solution of the crude dichloride (XI) in tetrahydrofuran (10 ml) was added, over a period of 5 min, to a suspension of sodium amide [from sodium 0.41 g, 0.018 g atom] in liquid ammonia (50 ml) at −70°C. After 1 hr, ammonium chloride (2 g) was added to the mixture, and the ammonia was allowed to evaporate. The residue was repeatedly digested with petroleum benzine (total 300 ml). The extract was concentrated under reduced pressure to yield crude I_3, as yellow crystals; 0.26 g (27% based on X). This was dissolved in benzene and percolated through a short column of alumina. The crystals obtained by concentrating the filtrate *in vacuo* were recrystallized twice from acetone to afford pure I_3 as yellow needles; mp 192—193°C.

Found: C, 95.56; H, 4.30%. Calcd for $C_{26}H_{14}$: C, 95.68; H, 4.32%.

1-(1-Naphthyl)-2-butyne-1,4-diol (XII). A solution of propargyl alcohol (11.20 g, 0.2 mol) in tetrahydrofuran (30 ml) was added, over a period of 30 min, to a stirred and water-cooled solution of ethylmagnesium bromide [from magnesium 9.60 g (0.40 g atom) and ethyl bromide 43.9 g (0.40 mol)] in the same solvent (150 ml). After it had refluxed for 1 hr, the mixture was cooled in an ice-bath. 1-Naphthaldehyde (VI, 15.60 g, 0.1 mol) in the same solvent (80 ml) was introduced to the cooled mixture, and it was stirred overnight at 20°C. After refluxing for 1.5 hr, the reaction mixture was then mixed with 4N sulfuric acid (100 ml) and extracted with ether. The extract was washed successively with a saturated solution of sodium chloride and a sodium hydrogen carbonate solution, and then dried (magnesium sulfate). The removal of the solvent *in vacuo* resulted in a dark red oil which crystallized on standing. The crude crystals were treated with a small amount of benzine - cyclohexane (1 : 1), collected by filtration, and washed with the same mixed solvent to yield fine pale yellow cubes; mp 120—123°C; 14.20 g (67%). The crystals were recrystallized 4 times from benzene to give pure XII as colorless needles; mp 125—126°C.

Found: C, 78.97; H, 5.70%. Calcd for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%. IR (KBr-disk): 3200—3300 (OH), 1020 (C–O) cm^{-1}.

1-Butadiynylnaphthalene (XIV). *The Preparation*

6) V. Grignard and H. Perrichon, *Ann. Chim. et Phys.*, **5**, 5 (1926).

7) This is a mixture of meso- and rac-isomers of X. *Cf.* I. Iwai and T. Konotsune, *Yakugaku Zasshi*, **78**, 505 (1958).

of the Dichloride (XIII). To an ice-cooled mixture of the glycol (XII, 4.24 g, 0.02 mol), pyridine (4.80 g, 0.06 mol), and tetrahydrofuran (50 m*l*), we added, drop by drop, a solution of thionyl chloride (7.20 g, 0.06 mol) in tetrahydrofuran (10 m*l*) over a period of 30 min. The temperature of the reaction mixture was gradually raised to 40°C in 60 min. After stirring for 30 min at that temperature, crushed ice was added to the ice-cooled reaction mixture. The reaction product was extracted with ether. The extract was washed with water, and aqueous sodium hydrogen carbonate successively, and then dried (magnesium sulfate). The crude dichloride (XIII) obtained by evaporating the solvent *in vacuo* was subjected to the following dehydrochlorination without further purification.

The Dehydrochlorination of XIII. A solution of the above-mentioned crude dichloride (XIII) in tetrahydrofuran (10 m*l*) was added, over a 5-min period to a suspension of sodium amide [from sodium 3.5 g, 0.152 g atom] in liquid ammonia (150 m*l*) at −70°C. The mixture was stirred for 1.5 hr, and then the ammonia was allowed to evaporate after the addition of ammonium chloride (9.0 g). The organic solvent was removed under reduced pressure. The residue was extracted with petroleum ether (400 m*l*). The concentrated extract (*ca.* 150 m*l*) was passed through a short column of alumina (5 g). The light yellow filtrate was concentrated under reduced pressure to yield crude XIV as yellow leaflets; 1.39 g (40%); mp *ca.* 40°C. The crude XIV was dissolved in petroleum ether and passed through a thin-layer of alumina (4 g). The filtrate was chilled in a dry ice-ethanol-bath to yield analytically pure XIV as pale yellow leaflets; mp 44—45°C. XIV gave orange yellow cuprous and pale yellow silver acetylide. XIV was found to be a fairly unstable substance. The crystals rapidly changed to an insoluble brown substance.

Found: C, 95.11; H, 4.55%. Calcd for $C_{14}H_8$: C, 95.42; H, 4.58%. IR (Nujol): 3270 (≡CH), 2190, 2205 (C≡C) cm^{-1}.

1,1′-Dinaphthyltetraacetylene (I_4). Cupric acetate monohydrate (4.0 g) was added to a solution of the diacetylene (XIV, 0.50 g, 2.8 mmol) in pyridine (20 m*l*), after which the mixture was stirred for 1 hr at 45°C.[8] The stirring was continued overnight at room temperature. The reaction mixture was then chilled in an ice-bath, and the insoluble material was collected by filtration, and washed successively with a small amount of methanol and with water, thus affording crude I_4 as fine greenish-yellow needles; 0.37 g (77%); mp *ca.* 200°C (dec.). A second crop of I_4 (0.07 g) was obtained from the filtrate. A benzene solution of the crude I_4 was passed through a short column of alumina. The crystals obtained by concentrating the filtrate were recrystallized twice from acetone to yield pure I_4 as yellow needles; mp 205—206°C (dec.).

Found: C, 95.70; H, 4.04%. Calcd for $C_{28}H_{14}$: C, 95.97; H, 4.03%.

1-Ethynylnaphthalene (XVI). Phosphorus pentachloride (168 g, 0.81 mol) was added to a solution of 1-acetylnaphthalene (134 g, 0.79 mol) in dry benzene (250 m*l*). After the vigorous reaction had subsided, the mixture was gradually heated and refluxed for 1.5 hr. The reaction mixture was poured onto ice water, and the organic layer was separated. The aqueous layer was extracted with benzene. The combined benzene layer was washed successively with water and with aqueous sodium hydroxide, and then dried (sodium sulfate). After the solvent had been removed under reduced pressure, the residue was distilled *in vacuo* to yield 1-(α-chlorovinyl)-naphthalene; 141.3 g (95%); bp 113—114°C/3 mmHg.

Found: C, 76.33; H, 4.79; Cl, 19.02%. Calcd for $C_{12}H_9Cl$: C, 76.40; H, 4.81; Cl, 18.79%.

The chloride thus obtained (75.5 g, 0.40 mol) was dissolved in ether (100 m*l*), and the solution was added, drop by drop, to a suspension of sodium amide [from sodium 33 g, 1.44 g atom] in liquid ammonia (1.2 *l*) at −70°C over a period of 1 hr. After stirring for a further 2.5 hr, the ammonia was allowed to evaporate. Petroleum benzine (350 m*l*) and then a saturated solution of ammonium chloride were added to the residue at −40°C. The organic layer was separated, and the aqueous layer was extracted with the same solvent. The combined benzine solution was dried (sodium sulfate), and the solvent was removed under reduced pressure. The residue was distilled *in vacuo* to yield XVI; 56.3 g (92%); bp 76—77°C/0.1 mmHg [lit. values: bp 143°C/25 mmHg;[9] bp 45°C/0.25 mmHg;[10] bp 92°C/4 mmHg[11]].

Found: C, 94.78; H, 5.30%. Calcd for $C_{12}H_9$: C, 94.70; H, 5.30%.

3-(1-Naphthyl)-prop-2-ynal (XVII). Into an ice-cooled solution of ethylmagnesium bromide [from magnesium (10.8 g, 0.44 g atom) and ethyl bromide (57.8 g, 0.53 mol)] in tetrahydrofuran (300 m*l*), there was added, drop by drop, a solution of XVI (56 g, 0.37 mol) in tetrahydrofuran (100 m*l*) under stirring, the mixture was then refluxed for 1 hr. *N,N*-Dimethylformamide (84 m*l*) in the same solvent (100 m*l*) was added in one portion to the mixture chilled in an ice-salt-bath. After 30 min stirring, the cooling bath was removed and the stirring was continued for a further 2 hr at 30°C. The reaction mixture was then mixed with 5% sulfuric acid (2 *l*) under vigorous agitation, after which the stirring was continued overnight. The mixture was then extracted with benzene. The extract was washed with water and aqueous alkali, and dried. The viscous liquid obtained by evaporating the solvent under reduced pressure was mixed with cyclohexane - ether (2 : 1). The solution was then cooled, yielding crude XVII, 35 g (52%). This was recrystallized twice from the same solvent to afford pure XVII; mp 20.5—21.5°C; colorless needles.

Found: C, 86.22; H, 4.37%. Calcd for $C_{13}H_8O$: C, 86.65; H, 4.48%. [lit. value: bp 85—86°C/0.5 mmHg[10]].

1-(1-Naphthyl)-1,4-pentadiyne-3-ol (XVIII). A solution of the aldehyde (XVII, 4.68 g, 0.026 mol) in tetrahydrofuran (30 m*l*) was added to a stirred and ice-cooled solution of ethynylmagnesium bromide[12] [from magnesium (1.37 g, 0.057 g atom) and ethyl

bromide (6.6 g, 0.06 mol)] in tetrahydrofuran (100 ml), after which the mixture was stirred for a further hour at the same temperature. Then the cooling-bath was removed and the mixture was stirred overnight at room temperature. The ice-cooled reaction mixture was then treated with a saturated aqueous solution of ammonium chloride and extracted with benzene. The extract was dried (magnesium sulfate), and the solvent was removed *in vacuo*, resulting in crude crystals. A benzene solution of the crude material was percolated through a short column of alumina (10 g). The filtrate was concentrated under reduced pressure, and the residue was treated with charcoal in methanol. Recrystallization from benzene - petroleum ether (1 : 3) gave XVIII; 3 g (56%). An analytical specimen was obtained by recrystallizing the crystals 3 times from the same solvent; mp 86—87°C.

Found: C, 87.09; H, 4.85%. Calcd for $C_{15}H_{10}O$: C, 87.35; H, 4.89%. IR (KBr-disk): 3280 (≡CH), 2100 2220 (C≡C), 1015 (C–O) cm^{-1}.

1,10-Di(1-naphthyl)-1,4,6,9-decatetrayne-3,8-diol (XIX). A solution of the diyne-ol (XVIII, 1.03 g, 0.005 mol) in methanol (15 ml) was mixed with cuprous chloride (0.1 g, 0.001 mol) and ammonium chloride (0.075 g, 0.0014 mol); then one drop of concentrated hydrochloric acid was added. The mixture was vigorously stirred at 32°C in an atmosphere of oxygen under a slightly elevated pressure until the uptake of oxygen ceased (4 hr). The inorganic material was removed by filtration, and the filtrate was concentrated under reduced pressure. The residue was mixed with ether and treated with 2N hydrochloric acid. The organic layer was washed successively with water, aqueous sodium hydrogen carbonate, and water, and then dried (magnesium sulfate). The crude crystals obtained by evaporating the solvent under reduced pressure were recrystallized from benzene, resulting in XIX; 0.80 g (80%). This was recrystallized 3 times from the same solvent to yield pure XIX; mp 165°C (dec.).

Found: C, 87.34; H, 4.42%. Calcd for $C_{30}H_{18}O_2$: C, 87.78; H, 4.42%. IR (KBr-disk): 3100—3300 (≡CH, OH), 2220 (C≡C), 1005 (C–O) cm^{-1}.

1,1′-Dinaphthylpentaacetylene (I_5). *The Preparation of the Dichloride (XX).* To a cooled (ice-salt-bath) mixture of the tetraacetylene glycol (XIX, 0.62 g, 0.0015 mol), pyridine (0.36 g, 0.0045 mol), and tetrahydrofuran (10 ml), there was added, over a period of 20 min, a solution of thionyl chloride (0.54 g, 0.0045 mol) in tetrahydrofuran (10 ml). After stirring for an additional hour at the same temperature, crushed ice was added to the reaction mixture. The organic layer was washed successively with water and with aqueous sodium carbonate, and then dried. The organic layer was concentrated *in vacuo* to *ca.* 10 ml. The solution of XX thus obtained was used immediately for the following reaction.

The Dehydrochlorination of XX. The above-mentioned solution of XX was added, drop by drop and over a 5-min period, into a suspension of sodium amide [from sodium 0.20 g (0.0087 g atom)] in liquid ammonia (30 ml) at −70°C. After stirring for 1 hr at that temperature, ammonium chloride (1.0 g) was added to the reaction mixture; then the ammonia was allowed to evaporate. The residue was repeatedly digested with petroleum benzine. The crude crystals obtained by removing the solvent under reduced pressure were dissolved in benzene. The benzene solution was passed twice through a thin-layer of alumina (each 6 g). The filtrate was then concentrated, yielding I_5 as orange yellow crystals; 114 mg (20% based on XIX). This was recrystallized twice from benzene to give pure I_5; mp *ca.* 195°C (dec.).

Found: C, 96.14; H, 3.81%. Calcd for $C_{30}H_{14}$: C, 96.23; H, 3.77%.

1-(1-Naphthyl)-1,4-hexadiyne-3,6-diol (XXI). Propargyl alcohol (11.20 g, 0.2 mol) in tetrahydrofuran (30 ml) was added, over a period of 30 min, into a stirred solution of ethylmagnesium bromide [from magnesium (9.60 g, 0.40 g atom) and ethyl bromide (43.9 g, 0.40 mol)] in tetrahydrofuran (150 ml) at a temperature lower than 30°C. The mixture was refluxed for 1 hr, and then greatly cooled in an ice-salt-bath. A solution of the aldehyde (XVII, 18 g, 0.1 mol) in tetrahydrofuran (80 ml) was then added, drop by drop, to the cooled mixture. The cooling bath was removed, and the reaction mixture was stirred overnight. A saturated aqueous solution of ammonium chloride was added to the ice-cooled reaction mixture. The organic layer was separated, and the aqueous layer was repeatedly extracted with benzene. The combined organic layer was dried (magnesium sulfate). The crystals obtained by evaporating the solvent *in vacuo* were recrystallized from benzene to yield XXI; 15.6 g (66%). The crude material was recrystallized 3 times from benzene, thus affording pure XXI; mp 113—114°C.

Found: C, 80.93; H, 5.14%. Calcd for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12.% IR (KBr-disk): 3100—3400 (OH), 2220 (C≡C), 1025 (C–O) cm^{-1}.

1,1′-Dinaphthylhexaacetylene (I_6). *The Preparation of the Dichloride (XXII).* A solution of thionyl chloride (3.1 g, 0.026 mol) in tetrahydrofuran (10 ml) was added, drop by drop and over a 30-min period, into a cooled (in an ice-salt-bath) and stirred mixture of the diacetylenic glycol (XXI, 2.04 g, 0.0086 mol), pyridine (2.06 g, 0.026 mol), and tetrahydrofuran (25 ml). The temperature of the reaction mixture was gradually raised to room temperature, and then the mixture was stirred at 40°C for 30 min. Cracked ice was added to the ice-cooled reaction mixture, and the product was extracted with benzene. The extract was washed successively with water and with aqueous sodium hydrogen carbonate, and then dried (magnesium sulfate). The extract was concentrated to *ca.* 10 ml under reduced pressure and immediately subjected to the following reaction.

The Preparation of 1-Naphthyltriacetylene (XXIII). To a suspension of sodium amide [from sodium 1.2 g (0.052 g atom)] in liquid ammonia (50 ml), there was added the above-mentioned solution of XXII over a period of 5 min at −70°C. After the mixture had been stirred for 1.5 hr at the same temperature, ammonium chloride (3.6 g) and petroleum benzine (120 ml) were added and the ammonia was allowed to evaporate. The organic layer was then separated, and the residue was digested with petroleum benzine. The orange-yellow organic layer was concentrated to *ca.* 200 ml under reduced pressure and passed through a short column of alumina (3.5 g), thus yielding a colorless filtrate. As the triacetylene was found to be a fairly unstable substance, the colorless filtrate was used in the subsequent reaction without isolation. UV (measured with an uncertain concentration in petroleum benzine): λ_{max} 350, 329, 308 and 296 mμ.

The Oxidation Coupling of XXIII. To a stirred solution of cupric acetate monohydrate (3.0 g) in pyridine (15 m*l*), there was added a 30 m*l* portion of the above-mentioned solution of the triacetylene (XXIII), and then the petroleum benzine was removed under reduced pressure at room temperature; the second portion (30 m*l*) of the solution was then added, and the benzine was removed again *in vacuo*. The entire benzine solution was added, portion by portion to the oxidizing reagent, repeating the above procedure. After the addition of the solution and the removal of the benzine had been completed, the mixture was stirred for 1.5 hr at 40°C. The reaction mixture was greatly chilled in an ice-salt-bath, and the precipitated solid was collected by filtration and washed with a small amount of cold pyridine. The brown crystals which were obtained by washing the solid thoroughly with water were dissolved in benzene and percolated through a short column of alumina (8 g). The filtrate was concentrated *in vacuo*, thus yielding orange crystals; 118 mg (14% based on XXI). They were recrystallized from benzene to give pure I_6; mp 175°C (dec.).

Found: C, 96.15; H, 3.54%. Calcd for $C_{32}H_{14}$: C, 96.46; H, 3.54%.

2,2′-Naphthil (IV′). The compound IV′ was prepared according to the method used in the case of the 1,1′-isomer (IV).

2,2′-Naphthil Dihydrazone (V′). The method used in the preparation of the 1,1′-isomer (V) was applied successfully in this case. mp 187—188°C. Yield, 83%.

Found: C, 77.86; H, 5.46; N, 16.51%. Calcd for $C_{22}H_{18}N_4$: C, 78.08; H, 5.36; N, 16.56%.

2,2′-Dinaphthylacetylene (II_1). Exactly the same procedure used in the preparation of I_1 was followed, yielding 0.95 g (77%) of crude light yellow II_1. This crude material was recrystallized successively from benzene - ethanol and from benzene, thus yielding pure II_1; colorless needles; mp 228—229°C. [lit. value: mp 225°C[13]].

Found: C, 94.55; H, 5.30%. Calcd for $C_{22}H_{14}$: C, 94.93; H, 5.37%.

1,4-Di(2-naphthyl)-1,4-dihydroxy-2-butyne (VII′). 2-Naphthaldehyde (VI′, 6.20 g, 0.04 mol) gave 5.3 g (85%) of slightly crude VII′ when treated by the method described in the case of the 1-naphthyl isomer. The crude material was recrystallized 3 times from benzene-ethanol to give pure VII′ as fine colorless crystals; mp 159—160°C.

Found: C, 85.33; H, 5.41%. Calcd for $C_{24}H_{18}O_2$: C, 85.18; H, 5.36%. IR (KBr-disk): 3100—3400 (OH), 1000 (C–O) cm^{-1}.

2,2′-Dinaphthyldiacetylene (II_2). The acetylene glycol (VII′, 1.0 g, 3 mmol) was treated according to the procedure used in the case of VII, thus yielding crude II_2; 297 mg (33%). A benzene solution of the crude material was passed through a thin-layer of alumina. The crystals obtained from the filtrate were recrystallized twice from benzene, thus affording pure II_2 as colorless fine leaflets; mp 202—203°C.

Found: C, 95.44; H, 4.75%. Calcd for $C_{24}H_{14}$: C, 95.33; H, 4.67%.

1-(2-Naphthyl)-2-propyn-1-ol (IX′). 2-Naphthaldehyde (VI′, 12.5 g, 0.08 mol) was treated with lithium acetylide in liquid ammonia according to the procedure described in the case of IX; this afforded slightly impure IX′; 7.7 g (52%); mp 58—62°C.

IR (KBr-disk): 3300—3400 (OH), 3290 (≡CH), 2110 (C≡C), 1015 (C–O) cm^{-1}.

1,6-Di(2-naphthyl)-1,6-dihydroxy-2,4-hexadiyne (X′). A mixture of the ethynyl carbinol (IX′, 4.6 g, 0.025 mol), cuprous chloride (0.5 g, 0.005 mol), ammonium chloride (0.375 g, 0.007 mol), and methanol (75 m*l*) containing 3 drops of concentrated hydrochloric acid was vigorously stirred at room temperature under an oxygen atmosphere at a slightly elevated pressure for 9 hr. An inorganic material was then removed by filtration and washed with a small amount of methanol. The combined filtrate and washings were concentrated *in vacuo*. The residue was dissolved in ether containing a small amount of tetrahydrofuran and treated with 2N hydrochloric acid to remove the inorganic material. The organic layer was washed with water and dried. The crystals, 4.1 g (90%) obtained by evaporating the solvent under reduced pressure were recrystallized 3 times from benzene - methanol to afford pure X′ as colorless cubes; mp 170°C (dec.).

Found: C, 86.28; H, 5.20%. Calcd for $C_{26}H_{18}O_2$: C, 86.16; H, 5.01%. IR (KBr-disk): 3200—3400 (OH), 1010 (C–O) cm^{-1}.

2,2′-Dinaphthyltriacetylene (II_3). *The Preparation of the Dichloride (XI′).* Thionyl chloride (1.07 g, 0.009 mol) in tetrahydrofuran (5 m*l*) was added, drop by drop, into a cooled (in an ice-salt-bath) and stirred mixture of the diacetylene glycol (X′, 1.09 g, 0.003 mol), pyridine (0.71 g, 0.009 mol), and tetrahydrofuran (15 m*l*). After 1 hr, the cooling bath was removed, after which the stirring was continued for an additional hour at room temperature. Then the ice-cooled reaction mixture was mixed with cracked ice and extracted with benzene. The extract was washed successively with water and sodium carbonate, and dried. The crude dichloride (XI′, a deep-brown liquid) obtained by evaporating the solvent *in vacuo* was immediately subjected to the following reaction without purification.

The Dehydrochlorination of XI′. The above-mentioned crude XI′ was treated according to the procedure used in the case of XI, thus affording crude II_3; 246 mg (25% based on X′). The crude material was recrystallized 4 times from acetone to give pure II_3; pale yellow needles; mp 173—174°C.

Found: C, 95.40; H, 4.42%. Calcd for $C_{26}H_{14}$: C, 95.68; H, 4.32%.

1-(2-Naphthyl)-2-butyne-1,4-diol (XII′). The procedure used in the synthesis of XII was employed. 2-Naphthaldehyde (VI′, 10 g, 0.064 mol) gave 9.7 g (71%) of XII′. Three recrystallizations of the crystals from benzene gave pure XII′ as colorless leaflets; mp 74—75°C.

Found: C, 78.91; H, 5.68%. Calcd for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%. IR (KBr-disk): 3100—3300 (OH), 1005 (C–O) cm^{-1}.

2-Butadiynylnaphthalene (XIV′). The acetylene glycol (XII′, 8.0 g, 0.038 mol) gave 2.4 g (36%) of XIV′ according to the method used in the preparation of the 1-isomer (XIV). This was recrystallized from petroleum ether to give pure XIV′ as colorless needles; mp 58—60°C (dec.).

Found: C, 95.20; H, 4.70%. Calcd for $C_{14}H_8$: C, 95.42; H, 4.58%. IR (KBr-disk): 3270 (≡CH), 2200 (C≡C) cm^{-1}.

13) J. Grabowsky, *Ber.*, **11**, 298 (1878).

2,2'-Dinaphthyltetraacetylene (II_4). The oxidative coupling of 2-butadiynylnaphthalene (XIV', 1.3 g, 7.4 mmol) according to the method used for the 1-isomer (I_4) afforded crude II_4; 680 mg (53%). The crude material was recrystallized twice from acetone - benzene to yield pure II_4 as fine pale yellow crystals; mp 172°C (dec.).

Found: C, 95.90; H, 4.07%. Calcd for $C_{28}H_{14}$: C, 95.97; H, 4.03%.

2-Acetylnaphthalene (XV'). A solution of 2-naphthoic acid chloride (190 g, 1 mol) in benzene (500 m*l*) was added, drop by drop, to a solution of ethoxymagnesiomalonate [prepared from magnesium (44.3 g, 1.7 g atom), diethyl malonate (315.4 g, 1.7 mol), dry ethanol (156.4 g, 3.4 mol) and dry benzene (500 m*l*). The excess of the ethanol was removed by azeotropic distillation with benzene] in benzene (500 m*l*) at 20°C, and then the mixture was refluxed for 3.5 hr. Aqueous sulfuric acid (concentrated sulfuric acid 50 m*l*, water 350 m*l*) was added, drop by drop, to the mixture under cooling. The organic layer separated was washed with water and dried (magnesium sulfate). The crude keto-malonate obtained by evaporating the solvent *in vacuo* was mixed with propionic acid (500 m*l*) and concentrated sulfuric acid (5 m*l*), and the mixture was gradually heated. After 2 hr refluxing, 4N sulfuric acid (500 m*l*) was added and the mixture was refluxed for a further 6 hr. The organic layer was separated after the addition of water, and the aqueous layer was extracted with benzene. The combined benzene layer was washed successively with aqueous sodium hydroxide and with water, and then dried. The residue obtained by removing the solvent under reduced pressure was distilled *in vacuo*, thus affording XV'; 128 g (75%); bp 120—123°C/3 mmHg, mp 52—54°C. [lit. value: mp 53°C[14]].

2-Ethynylnaphthalene (XVI'). The methyl ketone (XV', 68 g, 0.4 mol) was converted to XVI' (32 g (52%), mp 40.5—41.5°C) according to the method used in the preparation of XVI.

Found: C, 94.82; H, 5.41%. Calcd for $C_{12}H_8$: C, 94.70; H, 5.30%.

3-(2-Naphthyl)-prop-2-ynal (XVII'). According to the procedure used in the synthesis of XVII, the 2-ethynyl compound (XVI', 30 g, 0.198 mol) gave XVII' (25 g (70%)). Recrystallization from cyclohexane - ether (2 : 1) afforded pure XVII' as colorless leaflets; mp 52—53°C.

Found: C, 86.77; H, 4.50%. Calcd for $C_{13}H_8O$: C, 86.65; H, 4.48%.

1-(2-Naphthyl)-1,4-pentadiyne-3-ol (XVIII'). The procedure used in the case of XVIII was followed. XVII' (9.4 g, 0.052 mol) gave XVIII' (7.0 g (65%)). This was then recrystallized from cyclohexane - benzene (1 : 1) to give pure XVIII'; mp 91—92°C.

Found: C, 87.25; H, 4.93%. Calcd for $C_{15}H_{10}O$: C, 87.35; H, 4.89%. IR (KBr-disk): 3290 (≡CH), 2110, 2230 (C≡C), 1000—1040 (C–O) cm^{-1}.

1,10-Di(2-naphthyl)-1,4,6,9-decatetrayne-3,8-diol (XIX'). The oxidative coupling used in the synthesis of XIX was applied to XVIII' (3.1 g, 0.015 mol), thus yielding XIX', 1.4 g (45%). An analytical specimen was obtained by recrystallizing the crystals 3 times from benzene; fine needles; mp 150°C (dec.).

Found: C, 87.91; H, 4.60%. Calcd for $C_{30}H_{18}O_2$: C, 87.78; H, 4.42%. IR (KBr-disk): 3200—3300 (OH), 2220 (C≡C), 1000—1030 (C–O) cm^{-1}.

2,2'-Dinaphthylpentaacetylene (II_5). The same reaction sequence under the same reaction conditions as were used in the synthesis of I_5 from XIX were employed. The tetraacetylene glycol (XIX', 0.5 g, 1.2 mmol) gave 110 mg of II_5 (22% based on XIX'). Pure II_5, mp 180°C (dec.). Yellow needles were obtained by recrystallizing the crystals twice from benzene.

Found: C, 96.27; H, 3.82%. Calcd for $C_{30}H_{14}$: C, 96.23; H, 3.77%.

1-(2-Naphthyl)-1,4-hexadiyne-3,6-diol (XXI'). The reaction of the Grignard derivative of propargyl alcohol with the aldehyde (XVII', 8.0 g, 0.044 mol) according to the method used in the preparation of XXI afforded XXI'; 6.0 g (58%). This was recrystallized from benzene - ethanol to yield pure XXI'; mp 126—127°C; fine needles.

Found: C, 81.45; H, 5.15%. Calcd for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12%. IR (KBr-disk): 3200—3400 (OH, ≡CH), 2200 (C–C), 1010—1035 (C≡O) cm^{-1}.

2,2'-Dinaphthylhexaacetylene (II_6). *The Preparation of 1-(2-Naphthyl)-1,3,5-hexatriyne (XXIII').* According to the procedure described in the case of XXIII, the diacetylenic glycol (XXI', 2.7 g, 0.0113 mol) was converted to the dichloride (XXII') and dehydrochlorinated to yield the triacetylene (XXIII'). Because of the unstable nature of XXIII', the petroleum benzine solution of the crude XXIII' was immediately used in the following reaction. UV (measured with an uncertain concentration in petroleum benzine): λ_{max} 339, 318, 296 and 285 mμ.

The Oxidative Coupling of XXIII'. The oxidative coupling of the above-mentioned crude XXIII' according to the procedure used in the synthesis of I_6 gave 120 mg of II_6 (11% based on XXI'). This was recrystallized 3 times from benzene to give pure II_6 as orange yellow needles; mp 200°C (dec.).

Found: C, 96.25; H, 3.51%. Calcd for $C_{32}H_{14}$: C, 95.46; H, 3.54%.

Aminocyclitols. XXIV. Synthesis of Inosamines from Bromodeoxyinositols

Tetsuo SUAMI, Seiichiro OGAWA and Masaru UCHIDA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received June 16, 1970)

Seven inosamines (*scyllo*, *chiro*-1, *myo*-2, *myo*-4, *allo*-5, *neo*-1 and *chiro*-3) have been prepared from four bromodeoxyinositols (*scyllo*, *chiro*-1, *allo*-5 and *neo*-1). When bromodeoxyinositols were treated with sodium azide in boiling aqueous 2-methoxyethanol or dimethylformamide, followed by acetylation, pentaacetyl azidodeoxyinositols were obtained in 60—80% yield. On catalytic hydrogenation using Adams' platinum oxide, the azido compounds yielded hexaacetyl inosamines in good yields. Proton magnetic resonance (PMR) spectra of acetyl azidodeoxyinositols have been studied.

In the course of synthetic studies on aminocyclitols derivatives,[1] it has been recognized that some derivatives showed remarkable biological activities against certain bacteria and Hela cells. Therefore, these findings led us to further investigations of a convenient synthesis of inosamines from a readily accessible material.

Wolfrom and his co-workers[2] have first succeeded

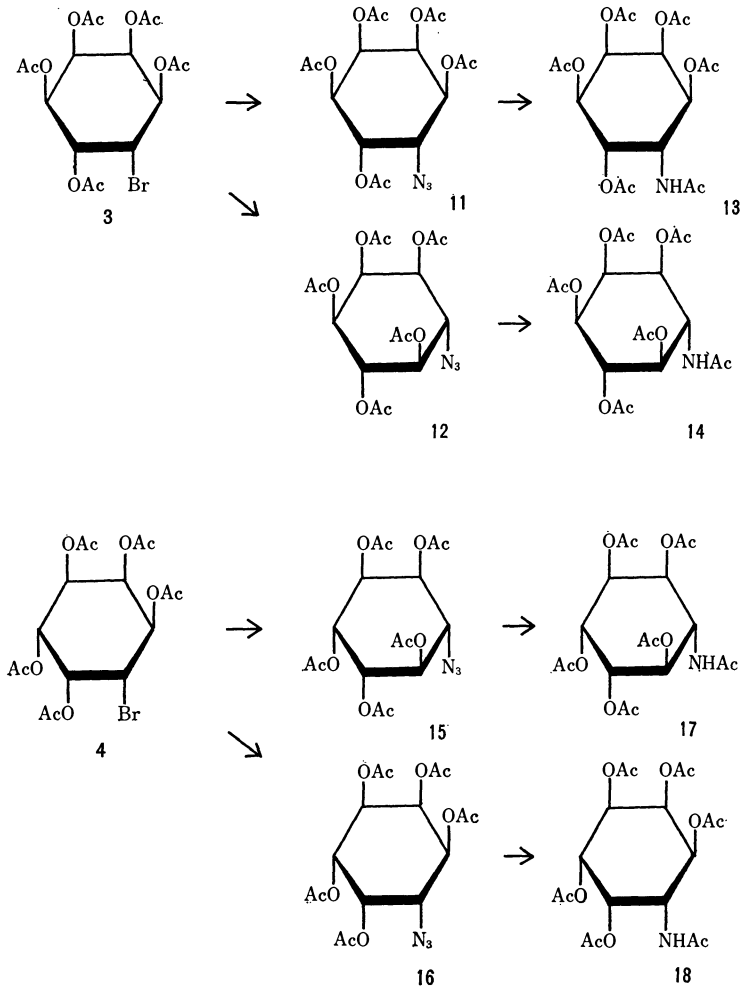

Fig. 2

in converting bromodeoxyinositols to aminodeoxyinositols (inosamines) by heating with ammonia in a sealed tube. By such treatment of crude pentaacetyl 1-bromo-1-deoxy-*scyllo*-inositol (**1**), though in a small yield, two inosamines could be isolated and the structures were proposed by the reaction sequence.

Later, we have reported that 2,4-dibromo-2,4-dideoxy-*chiro*-inosamine-3, on treatment with sodium azide, followed by hydrogenation, gave rise to two inosadiamines in a comparatively good yield.[3] Also, Nakajima and his co-workers[4] have described the synthesis of streptamine from dibromodideoxyinositol by the similar procedure.

The present article reports a facile synthesis of inosamines from readily available bromodeoxyinositols.

According to a modified method of McCasland,[5] two bromodeoxyinositols: **1** and pentaacetyl 1-bromo-1-deoxy-*chiro*-inositol (**2**) were prepared by drastic bromination of *myo*-inositol with acetyl bromide and acetic anhydride at 130—140°C. Analogously, pentaacetyl 5-bromo-5-deoxy-*allo*-inositol (**3**) and 1-bromo-1-deoxy-*neo*-inositol (**4**) were obtained from *epi*-inositol.[6,7]

When **1** was refluxed with an excess amount of sodium azide in 90% aqueous 2-methoxyethanol for 50 hr and subsequently acetylated, an unknown pentaacetyl azidodeoxyinositol (**5**) was obtained together with pentaacetyl 1-azido-1-deoxy-*scyllo*-inositol (**6**)[8] in 64 and 12% yield, respectively.

7) T. Suami, A. Suzuki, M. Uchida and S. Yanagida, This Bulletin, **42**, 2672 (1969).

8) T. Suami, F. W. Lichtenthaler and S. Ogawa, *ibid.*, **39**, 170 (1966).

Also, on a similar treatment with sodium azide, **2** gave **5** and **6** in 67 and 6% yield, respectively.

The assignment of the structures of azidodeoxyinositols so obtained was carried out by a conversion to known inosamines, along with PMR spectra.

Hydrogenation of **5** using Adams' platinum oxide afforded hexaacetyl *chiro*-inosamine-1 (**7**)[2,9] in 76% yield. Then **5** could be assigned to be pentaacetyl 1-azido-1-deoxy-*chiro*-inositol. These result showed that the azidation reaction of **1** and **2** proceeded through a formation of a same acetoxonium ion intermediate and its preferential diaxial opening by an azide ion.

On the other hand, according to the preferred all equatorial conformation of **1**, it might be proposed that, if dipolar aprotic solvent was used as a reaction solvent, a direct S_N2 attack of azide ion would be possible. Analogous result had been observed in the case of the reaction of 1,3-di-*O*-acetyl-2-*O*-methanesulfonyl-1,2,3-cyclohexanetriol and sodium azide.[10]

Then the reaction of **1** and sodium azide was carried out in boiling aqueous dimethylformamide, instead of 2-methoxyethanol, and a successive acetylation of the reaction product yielded hitherto unknown pentaacetyl azidodeoxyinositol (**9**) in 61% yield. Hydrogenation of **9** gave hexaacetyl *myo*-inosamine-2 (**10**)[11] in 70% yield. Therefore, **9** could be assigned as pentaacetyl 2-azido-2-deoxy *myo*-inositol.

Compound **3**, by a similar treatment with sodium azide, gave pentaacetyl 5-azido-5-deoxy-*allo*-inositol (**11**) and pentaacetyl 4-azido-4-deoxy-*myo*-inositol (**12**) in 46 and 11% yield, respectively. On hydrogenation, **11** and **12** afforded corresponding hexaacetyl *allo*-inosamine-5 (**13**)[12] and hexaacetyl *myo*-inosamine-4 (**14**)[9,13] in 82 and 91% yield, respectively.

From **4**, pentaacetyl 3-azido-3-deoxy-*chiro*-inositol (**15**) and pentaacetyl 1-azido-1-deoxy-*neo*-inositol (**16**) were obtained by the analogous procedure in 68 and 10% yield, respectively. On hydrogenation, **15** and **16** gave corresponding hexaacetyl *chiro*-inosamine-3 (**17**)[9] and hexaacetyl *neo*-inosamine-1 (**18**)[12] in 78 and 68% yield, respectively.

Considering from the products obtained, the azidation reaction of **3** and **4** also proceeded through a formation of an acetoxonium ion intermediate.

PMR data for the pentaacetyl azidodeoxyinositols are given in Table 1. The signals of the equatorial

Table 1. PMR data of pentaacetyl azidodeoxyinositol[a]

	**21**[e]	6.16 (t) J=10.5 Hz	7.80 (3)	7.80 (3) 7.94 (6)

a) Chemical shifts are expressed in τ-values. Values in parenthesis show number of protons. First order coupling constants are expressed.

b) Abbreviations: m, multiplet; t, triplet; q, quartet.

c) Measurement is difficult, because of the poor solubility of **6** in $CDCl_3$.

d) It might be considered that, owing to the distortion of chair conformation, signals of the axial acetoxy groups are somewhat up-shifted and have the same chemical shifts as that of equatorial one does.

e) The PMR spectrum of hexaacetyl *myo*-inosadiamine-4,6, which was obtained by hydrogenation of **21**, showed four peaks at τ 8 region: τ 7.81 (3), 7.94 (3), 8.00 (6) and 8.10 (6). Therefore it is apparent that, in the PMR spectrum of **21**, the signal of equatorial acetoxy group on C-5 and that of axial one on C-2 overlap, because of the down-shift of the former.

acetoxy methyl groups adjacent to azido groups, which are either in an equatorial or an axial conformation, appeared at a region of τ 7.90—7.95 and whose chemical shifts are substantially in a down field (0.05—0.07 ppm in all cases studied) from those of equatorial ones which are adjacent to acetoxy or acetamide groups (τ 7.93—8.03[14]). This phenomenon is readily explained by a strong local magnetic field exerted by an azido group. In the case of tetraacetyl diazidodideoxyinositols listed in Table 2, the similar effect of azido groups on the chemical shifts of vicinal acetoxy groups is recognized. The signal of acetoxy methyl protons on C-5 in tetraacetyl 1,3-diazido-1,3-dideoxy-*scyllo*-inositol (**19**)[15] appears at τ 7.99, but those on C-4 and C-6 are down-shifted by 0.09 ppm (τ 7.90) and a signal of that on C-2 which are surrounded by two azido groups is considerably downshifted (τ 7.80). Similar results are also obtained in tetraacetyl 1,3-diazido-1,3-dideoxy-*myo*-inositol (**20**)[15] and tetraacetyl 4,6-diazido-4,6-dideoxy-*myo*-inositol (**21**).[16]

While, the signals of protons on carbon atoms bearing azido groups appeared at τ 6.06—6.36 (axial) and τ 5.70—5.90 (equatorial). Therefore, it may be possible to distinguish axial protons from equatorial ones by the differences of about 0.40 ppm. But the considerable down-shift effects on chemical shift of the axial proton are observed in the case of **11** by the possibility of serious distortion of the chair conformation or a long range deshielding effect of 1,3-diaxial acetoxy groups.

Experimental

The melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. The PMR spectra were determined with a Japan Electron Optics Laboratory JNM-C-60 spectrometer or a Varian Associates A-60D spectrometer at the frequency of 60 MHz in deuteriochloroform with tetramethylsilane as an internal standard. Evaporations were accomplished under reduced pressure at 40—50°C with a Tokyo Rikakikai rotary evaporator.

Pentaacetyl 1-Bromo-1-deoxy-*scyllo*-inositol (1) and Pentaacetyl 1-Bromo-1-deoxy-*chiro*-inositol (2). These compounds were prepared from *myo*-inositol following a modified method of McCasland.[5]

Throughly dried *myo*-inositol (2.5 g) was treated with acetyl bromide (2.2 m*l*) and acetic anhydride (7.8 m*l*) in a sealed tube at 130—140°C for 8 hr. Then the reaction mixture was poured into ethanol (10 m*l*) and resulting precipitates were collected by filtration. Ten sealed tubes gave 37.5 g of crude **1**, mp 220—235°C. Two recrystallizations from ethylacetate and acetone afforded pure crystals of **1** (36.5 g), mp 238—240°C (lit,[5] mp 241—241.5°C). The yield was 29%. Then the mother liquor of **1** yielded crude **2** (39.0 g), mp 96—103°C, after allowing to stand at room temperature for several weeks. Three recrystallizations from ethanol gave practically pure **2** (31.4 g, 24.8%), mp 114—116°C (lit,[5] mp 124—125°C). (Found: C, 42.30; H, 4.79; Br, 17.79%).

Pentaacetyl 5-Bromo-5-deoxy-*allo*-inositol (3) and 1-Bromo-1-deoxy-*neo*-inositol (4). These compounds were prepared from *epi*-inositol following a modified method of McCasland.[6,7]

Pentaacetyl 1-Azido-1-deoxy-*chiro*-inositol (5) and Pentaacetyl 1-Azido-1-deoxy-*scyllo*-inositol (6). a) A mixture of **2** (2.0 g), sodium azide (1.5 g) and 90% aqueous 2-methoxyethanol (80 m*l*) was refluxed for 50 hr. Then the reaction mixture was evaporated to dryness and the residue was treated with a mixture of pyridine (20 m*l*) and acetic anhydride (20 m*l*) at room temperature overnight. An insoluble material was filtered off and the filtrate was evaporated to give a solid residue. The crude compound was recrystallized from ethanol to afford needles (110 mg, 6.3%), mp 206—207°C, which was identified with an authentic sample of **6** (lit,[8] mp 205—205.5°C) by mixed melting point and comparing with IR spectra. The second and third crops obtained from the mother liquor of **6** were combined and recrystallized from ethanol to give crystals (1.5 g, 66.8%) of **5**, mp 111—113°C. Analytical sample was obtained by recrystallization from methanol, mp 115.5—117°C.

Found: C, 46.18; H, 5.25; N, 10.33%. Calcd for $C_{16}H_{21}N_3O_{10}$: C, 46.26; H, 5.10; N, 10.12%.

b) A mixture of **1** (1.2 g), sodium azide (1.8 g) and 90% aqueous 2-methoxyethanol (30 m*l*) was refluxed for 64 hr. An insoluble material was filtered off and the filtrate was evaporated to dryness. The residue was dried by codistillation with toluene and then treated with a mixture of acetic anhydride (10 m*l*) and pyridine (10 m*l*) at 80°C for 2 hr. A filtered reaction mixture was poured into ice and water. An oily precipitate solidified gradually to give a white solid, which was collected by filtration. The crude product was fractionally crystallized from ethanol to yield **6** (0.12 g, 12%), mp 200—205°C. On evaporation, followed by trituration with methanol, the mother liquor afforded **5** (0.68 g, 64%), mp 110—113°C.

When **1** was treated with sodium azide similarly as described in (a), **5** was obtained only in 17% yield and **1** was recovered in 50% yield.

Hexaacetyl *chiro*-Inosamine-1 (7). A solution of **5** (270 mg) in ethanol (40 m*l*) was hydrogenated in the presence of Adams' platinum oxide (20 mg) in a Parr shaker type apparatus for 20 hr (at the initial hydrogen pressure of 3.4 kg/cm^2). The catalyst was filtered off and the filtrate was evaporated to dryness. The residue was treated with a mixture of acetic anhydride (5 m*l*) and pyridine (5 m*l*) at room temperature overnight. The reaction mixture was evaporated to give a solid residue, which was crystallized from ethyl acetate yielding 210 mg (76.2%) of **7**, mp 157—159°C (lit,[9] mp 156—157°C). **7** was identified with an authentic sample[9] by mixed melting point and IR spectra. (Found: C, 50.42; H, 6.17; N, 3.00%).

Hexaacetyl *scyllo*-Inosamine (8). A 67 mg portion of **6** was hydrogenated in a mixture of ethanol (30 m*l*) and dimethylformamide (10 m*l*) in the presence of

15) S. Ogawa, T. Abe, H. Sano, K. Kotera and T. Suami, This Bulletin, **40**, 2405 (1967).

16) T. Suami and S. Ogawa, *ibid.*, **38**, 2026 (1965).

Adams' platinum oxide (15 mg) for 20 hr. Filtering off the catalyst, the filtrate was evaporated to dryness and the residue was acetylated to give crude **8**, which was recrystallized from ethanol to afford needles (45 mg, 80.0%), mp 272—283°C with decomposition (lit,[2,11] mp 275—280°C). The product was identified with an authentic sample by mixed melting point and IR spectra.

Pentaacetyl 2-Azido-2-deoxy-*myo*-inositol (9). A mixture of **1** (2.0 g), sodium azide (1.5 g) and 90% aqueous dimethylformamide (80 m*l*) was refluxed for 25 hr. The reaction mixture was treated similarly as described in the preparation of **5** and **6**. The crude product was acetylated to give crude **9** (1.1 g), mp 200—210°C. Recrystallization from ethanol afforded needles (0.85 g, 61%), mp 207.5—209°C.

Found: C, 46.10; H, 5.26; N, 9.93%. Calcd for $C_{16}H_{21}N_3O_{10}$: C, 46.26; H, 5.10; N, 10.12%.

Hexaacetyl *myo*-Inosamine-2 (10). A solution of **9** (1.0 g) in 2-methoxyethanol (80 m*l*) was hydrogenated in the presence of Adams' platinum oxide (50 mg) for 20 hr. The hydrogenated product was acetylated to give crude **10** (0.81 g), mp 240—245°C. Recrystallization from ethanol afforded needles (0.76 g, 70%), mp 248—250°C (lit.[11] mp 242°C). (Found: C, 50.08; H, 6.06; N, 3.17%).

Pentaacetyl 5-Azido-5-deoxy-*allo*-inositol (11) and Pentaacetyl 4-Azido-4-deoxy-*myo*-inositol (12). A mixture of **3** (2.0 g), sodium azide (1.5 g) and 90% aqueous 2-methoxyethanol (60 m*l*) was refluxed for 20 hr. The reaction mixture was treated similarly as described in the preparation of **5** and **6**. The crude crystalline product was fractionally crystallized from ethanol to afford **11** (0.64 g, 46%), mp 129—130°C, and **12** (0.16 g, 11%), mp 147—150°C. Recrystallization of **11** from ethanol or methanol did not raise its melting point. Analytically pure **12** was obtained by recrystallization from methanol, mp 149—151°C.

11: Found: C, 46.40; H, 5.33; N, 9.80%.

12: Found: C, 46.30; H, 5.30; N, 10.03%.

Calcd for $C_{16}H_{21}N_3O_{10}$: C, 46.26; H, 5.10; N, 10.12%.

Hexaacetyl *allo*-Inosamine-5 (13). A 0.42 g portion of **11** was hydrogenated in the presence of Adams' platinum oxide (20 mg) in ethanol (50 m*l*) for 20 hr. The hydrogenated product was treated with acetic anhydride and pyridine at room temperature overnight. The crude product was crystallized from ethanol and ether to yield crude **13**, mp 180—196°C. Recrystallization from ethanol gave pure crystals (0.36 g, 82%), mp 195—196°C (lit,[12] mp 195°C). (Found: C, 50.50; H, 5.94; N, 3.47%).

Hexaacetyl *myo*-Inosamine-4 (14). A 0.10 g portion of **12** was hydrogenated in ethanol (50 m*l*) in the presence of Adams' platinum oxide (20 mg) for 12 hr. The hydrogenated product was treated with acetic anhydride and pyridine at room temperature overnight. The crude product was crystallized from ethanol to give **14** (95 mg, 91%), mp 228—236°C. Recrystallization from ethanol gave pure sample, mp 234—236°C (lit,[9] mp 236°C). The compound was identified with an authentic sample[9] by mixed melting point and IR spectra.

Pentaacetyl 3-Azido-3-deoxy-*chiro*-inositol (15) and Pentaacetyl 1-Azido-1-deoxy-*neo*-inositol (16). A mixture of **4** (1.0 g), sodium azide (1.0 g) and 90% aqueous 2-methoxyethanol (50 m*l*) was refluxed for 40 hr. The reaction mixture was treated similarly as described in the preparation of **5** and **6**. The crude crystals were fractionally crystallized from ethanol to afford **15** (1.2 g, 68%), mp 153—156°C, and **16** (0.17 g, 10%), mp 185—187°C.

15: Found: C, 46.66; H, 5.39; N, 10.37%.

16: Found: C, 46.85; H, 5.48; N, 10.11%.

Calcd for $C_{16}H_{21}N_3O_{10}$: C, 46.26; H, 5.10; N, 10.12%.

Hexaacetyl *chiro*-Inosamine-3 (17). A 0.55 g portion of **15** was hydrogenated in ethanol (50 m*l*) in the presence of Adams' platinum oxide (20 mg) for 5 hr. The hydrogenated product was acetylated to give crude **17**, which was crystallized from ethanol and ether to afford crystals (0.39 g, 78%), mp 184—187°C. Recrystallization from the same solvent gave a pure sample, mp 186—188°C (lit,[9] mp 189—191°C). (Found: C, 50.35; H, 5.70; N, 3.40%).

Hexaacetyl *neo*-Inosamine-1 (18). A 0.10 g portion of **16** was hydrogenated in ethanol (50 m*l*) in the presence of Adams' platinum oxide (20 mg) for 5 hr. The hydrogenated product was acetylated and crystallized from ethanol to give **18** (70 mg, 68%), mp 237—240°C (lit,[12] mp 240°C). (Found: C, 49.83; H, 5.87; N, 3.21%).

The authors wish to thank Professor Sumio Umezawa for his helpful advices and Mr. Saburo Nakada for his elementary analyses. This research has been financially supported by a grant of the Japanese Ministry of Education.

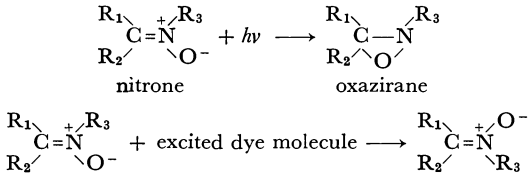
(Received July 1, 1970)

Fifteen nitrones, *N*-butylidenecyclohexylamine *N*-oxide, *N*-benzylidenemethylamine *N*-oxide, *N*-diphenylmethylenemethylamine *N*-oxide, *N*-benzylidenaniline *N*-oxide, and its derivatives, were irradiated with light in solution, each at its longest-wavelength absorption band. Each nitrone isomerized to the corresponding oxazirane. The quantum yield of this photo-rearrangement, Φ, was measured. For each nitrone, the value of Φ is larger in cyclohexane solution than in ethanol solution. In the series of *N*-benzylidenaniline *N*-oxide and its *para*-substituted derivatives, the substituent lowers Φ, and the more electron-donating or the more electron-withdrawing the substituent is, the smaller is Φ. These facts are explained on the basis of a hypothesis that Φ should increase with the change in the π-bond order between the carbon and oxygen atoms of the nitrone group upon the lowest-energy electron excitation, $\Delta P_{C,O}$, calculated by the simple MO method.

It has been reported that nitrones isomerize to oxaziranes by light absorption,[2-7)] while photosensitization by dye molecules results in the geometrical isomerization about the C=N bond.[7)]



We have concluded previously that nitrone molecules in the lowest excited singlet state isomerize to the corresponding oxaziranes by oxygen atom rearrangement and that nitrone molecules excited to a triplet state as a result of energy transfer from triplet dye molecules undergo the *cis-trans* isomerization.[6,7)]

In the present paper it is elucidated how the groups R affect the quantum yield of the photochemical nitrone→oxazirane rearrangement.

Experimental

The nitrones used in this work are as follows: *N*-butylidenecyclohexylamine *N*-oxide (I), *N*-benzylidenemethylamine *N*-oxide (II), *N*-diphenylmethylenemethylamine *N*-oxide (α-phenyl-II), *N*-benzylidenaniline *N*-oxide (α,*N*-diphenylnitrone, III; see Fig. 1), and its

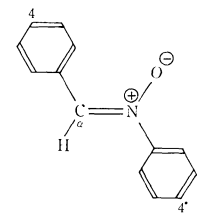


Fig. 1. α,*N*-Diphenylnitrone (*N*-benzylidenaniline *N*-oxide).

derivatives, which are listed in Table 1 and are hereafter referred to with the entry numbers in this table. The synthesis and some physical properties of the nitrones except 1, 3, 5, and 15[8)] were described in previous papers.[9,10)]

Ultraviolet absorption spectra were measured with a Hitachi Spectrophotometer EPS2U at room temperature. Cyclohexane and ethanol were used as solvents. Cyclohexane was purified by being passed through silica gel and distilled. Ethanol of guaranteed reagent grade was used without further purification.

The procedure of the irradiation experiment is quite similar to that described in a previous paper.[6] Three different light sources were used: (a) a 253.7 nm light source, a low pressure mercury lamp without filter; (b) a 313.0 nm light source, a high pressure mercury lamp with a combination of filters of cobalt - nickel sulfate solution and a glass which completely absorbs light below 300 nm; (c) a 365.0 nm light source, a high pressure mercury lamp with a combination of filters of Toshiba UVD1 and a glass. For each nitrone the light source was selected so that the light was absorbed by the nitrone at its longest-wavelength absorption band. The irradiation was carried out at room temperature. The intensity of the incident light was measured by potassium ferrioxalate actinometry.[11] The ratio of the decrease in the number of nitrone molecules to the number of photons absorbed was taken as the quantum yield of the photo-rearrangement.

Results and Discussion

Absorption Spectra and the Quantum Yield. The ultraviolet absorption spectra of the nitrones in solution changed markedly on irradiation, as exemplified by Fig. 2. The products are considered to be oxaziranes since their absorption bands appear at much shorter wavelength than those of the nitrones, indicating the break of the π bond between the α-carbon and the nitrogen atom. The formation of oxaziranes from nitrones 2, 3, 4, and 5 was confirmed by the fact that the products liberated iodine from acid solution of potassium iodide.[12,13]

In Table 1 are listed the values of the wavenumber (ν_{max}) and molar extinction coefficient (ε_{max}) at the peak of the longest-wavelength absorption bands of the nitrones, the quantum yield of the photo-rearrangement (Φ), and the wavelength at the peak of the absorption bands of the products (λ_{max}). There are some correlations between ν_{max} and Φ as follows.

(i) The values of Φ for the nitrones except 11 are larger in cyclohexane solution than in ethanol solution, and the values of ν_{max} for most of the nitrones are smaller in cyclohexane solution than in ethanol solution.

(ii) The values of Φ and ν_{max} for nitrone 1 are larger than the corresponding values for the other nitrones. In each solvent, a nitrone having a higher ν_{max} value has a larger Φ value than does a nitrone having a lower ν_{max} value. There seems to be no clear relation between ε_{max} and Φ. The introduction of the second phenyl group to the α-carbon atom decreases the value of ε_{max} to about a half, but

does the values of Φ only slightly. (Compare nitrones 3 and 5 with 2 and 4, respectively.)

(iii) The value of Φ and ν_{max} for α,*N*-diphenylnitrone (nitrone 4) are larger than those for the 4-substituted derivatives (nitrones 6—15). In the case where the substituent is electron-donating, the more electron-donating the substituent is, the smaller are the values of Φ and ν_{max}. Thus, the decreasing order of Φ and ν_{max} is $CH_3 > Cl \approx Br > CH_3O > (CH_3)_2N$, and this is in accordance with the increasing order of the absolute value of the Hammett σ constant. In the case where the substituent is electron-withdrawing, the values of Φ and ν_{max} decrease in the order $CN > CH_3COO > NO_2$. This order is the increasing order of the electron-withdrawing property of the substituent, that is, the increasing order of the Hammett σ constant. The values of Φ and ν_{max} for nitrone 15 are the lowest of all. The relation between Φ and ν_{max} is shown in Fig. 3. From the fact that both the electron-donating and the electron-withdrawing substituents decrease Φ, it is evident that the reactivity of the nitrone group ($C{=}N^+{-}O^-$) can not be interpreted in terms of the polarity of the group or the electron density of the atoms involved.

Simple MO Calculation. The reactivity of nitrones can be elucidated in terms of simple molecular orbitals. The molecular orbitals of the nitrone group were calculated by the use of parameters $\alpha_C = \alpha + 0.5\beta$, $\alpha_N = \alpha + 1.6\beta$, $\alpha_O = \alpha + 1.2\beta$, and $\beta_{CN} = \beta_{NO} = \beta$. These parameter values are the values used by Kubota and Yamakawa in simple MO calculation on the π electron system of *N*-benzylidenalkylamine *N*-oxides, that is, the α-phenylnitrone π electron system.[14] The results are given in Table 2. In the ground state MO's ϕ_1 and

TABLE 2. THE SIMPLE MOLECULAR ORBITALS OF THE NITRONE GROUP ($C{=}\overset{+}{N}{-}\overset{-}{O}$)*

MO	Energy	Coefficients of AO's		
		C	N	O
ϕ_1	$\alpha + 2.7129\beta$	0.3527	0.7806	0.5159
ϕ_2	$\alpha + 0.8927\beta$	−0.5990	−0.2352	0.7654
ϕ_3	$\alpha - 0.3056\beta$	0.7188	−0.5791	0.3846

* The parameter values used: $\alpha_C = \alpha + 0.5\beta$, $\alpha_N = \alpha + 1.6\beta$, $\alpha_O = \alpha + 1.2\beta$, and $\beta_{CN} = \beta_{NO} = \beta$.

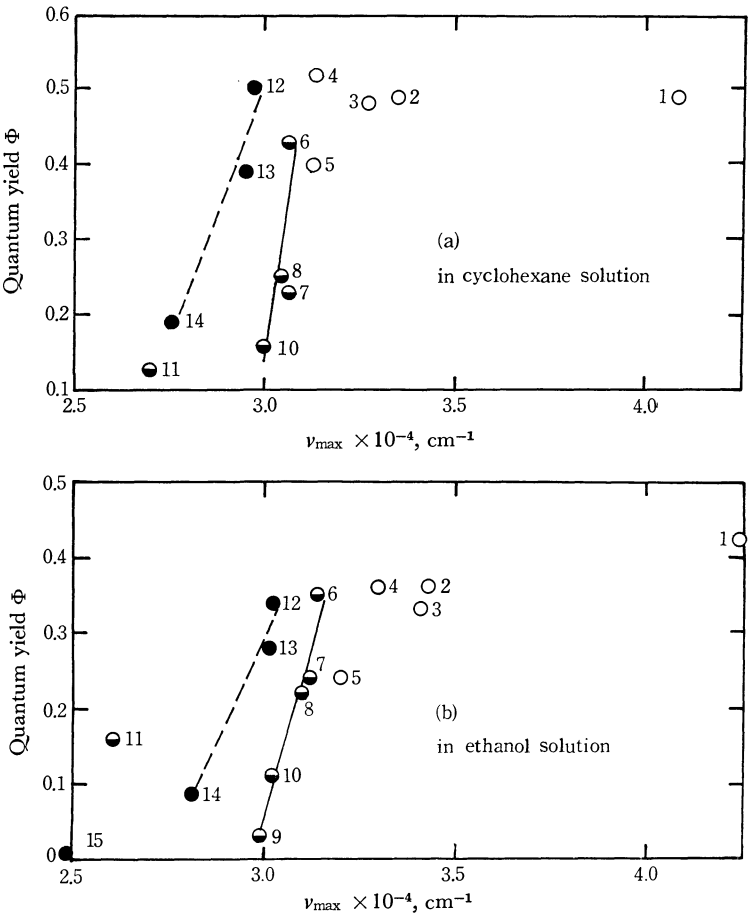

Fig. 3. The relation between Φ and ν_{max}: (a) in cyclohexane; (b) in ethanol. ◒, for 4-X-α,*N*-diphenylnitrones in which X is an electron-donating substituent; ●, for those in which X is an electron-withdrawing substituent; ○, for the other nitrones. The numbers are the entry numbers of the nitrones in Table 1.

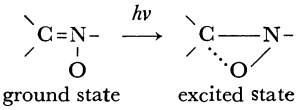
ϕ_2 are filled with electrons.

The π-bond order of the C=N bond, P_{CN}, is calculated to be 0.832 in the ground state and 0.275 in the excited state where one electron has been excited from ϕ_2 to ϕ_3. The π-bond order of the N–O bond, P_{NO}, is 0.445 in the ground state and 0.403 in the excited state. The π-bond order of the hypothetical bond between the chemically non-bonded carbon and oxygen atoms, $P_{C,O}$, is −0.553 in the ground state and 0.182 in the excited state. Thus, on the excitation, P_{CN} decreases largely, P_{NO} decreases slightly, and $P_{C,O}$ increases largely. This tendency remains unchanged when the values of parameters α_N and α_O are changed in the ranges between $\alpha+1.5\beta$ and $\alpha+3.0\beta$ and between $\alpha+1.0\beta$ and $\alpha+2.0\beta$, respectively. The photo-rearrangement of nitrones to oxaziranes is safely interpreted as the result of the decrease in bonding character of the C=N bond and the large increase in bonding character of the hypothetical C···O bond caused by light absorption.



Correlation of the Quantum Yield with the Change in the π-Bond Order. The longest-wavelength absorption bands of the nitrones are attributed approximately to the one-electron excitation from the highest occupied π orbital to the lowest vacant one. The energy of this excitation is denoted by ΔE, and the changes in the π-bond orders associated with this excitation are denoted by ΔP. The effects of solvent and substituent on Φ can be interpreted in terms of the change in the $\Delta P_{C,O}$ value, and those on ν_{max} can be interpreted in terms of the change in the ΔE value.

(a) As the value of α_O becomes negatively arger, the value of $\Delta P_{C,O}$ decreases and the value

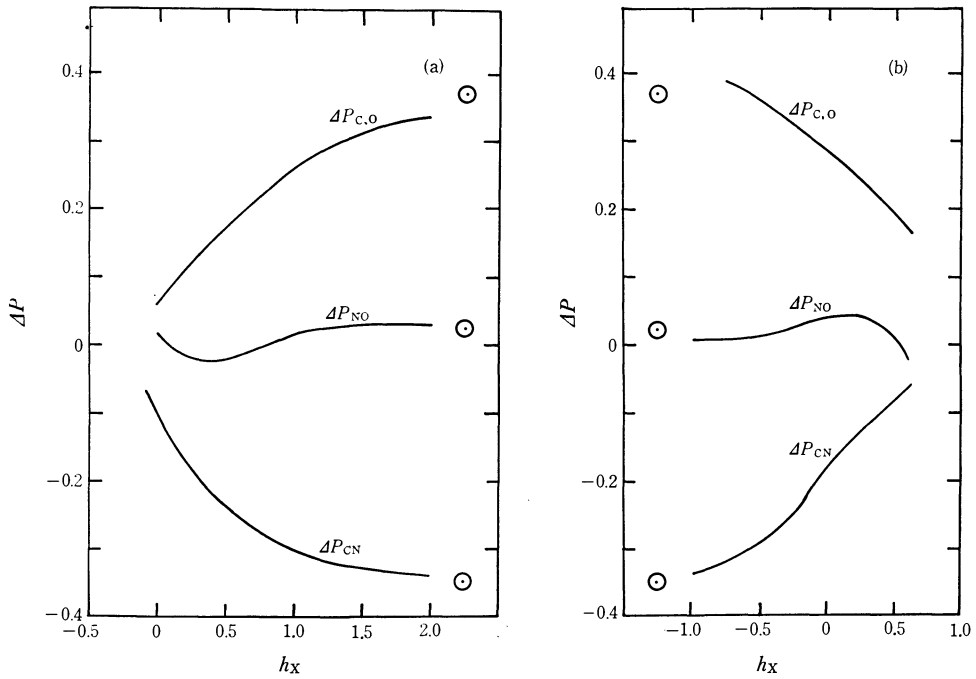


Fig. 4. The relations between ΔP's and h_X in the 4-X-α,N-diphenylnitrone π electron system: (a) in the case where X is an electron-donating substituent; (b) in the case where X is an electron-withdrawing substituent. The marks ⊙ represent ΔP's for the unperturbed α,N-diphenylnitrone π electron system.

of ΔE increases. The formation of a hydrogen bond has been found between the solvent alcohol and nitrone molecules, the oxygen atom of the nitrone group acting as a proton acceptor.[15] The value of the Coulomb integral for a hydrogen-bonding oxygen atom should be larger than that for a non-hydrogen-bonding oxygen atom. This can interpret well the solvent effects on Φ and ν_{max}.

The possible increase in the energy dissipation rate due to hydrogen bond formation in ethanol solution may also decrease the quantum yield.

(b) The simple molecular orbitals were calculated for the 4-X-α,N-diphenylnitrone π electron system by using various values for parameter h_x in the Coulomb integral of the substituent X, $\alpha_x = \alpha + h_x\beta$. In the case where X is an electron-donating substituent, 18 electrons participate in the π electron system, and the lowest-energy-electron excitation takes place from the 9th to the 10th orbital. In this case a smaller value of h_x correponds to a stronger electron-donating power of X. On the other hand, in the case where X is electron-withdrawing, it is assumed that 16 electrons participate in the π electron system. In this case, the lowest-energy electron excitation takes place from the 8th to the 9th orbital, and a larger value of h_x cor-

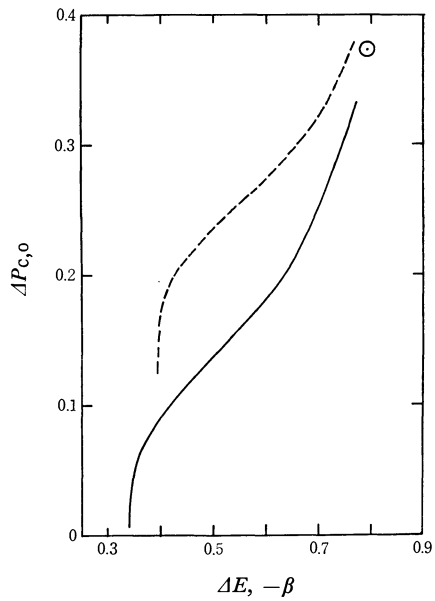

Fig. 5. The relation between $\Delta P_{C,O}$ and ΔE in the 4-X-α,N-diphenylnitrone π electron system. The solid line represents the relation in the case where X is electron-donating, and the broken line represents the relation in the case where X is electron-withdrawing. The mark ⊙ is for the case where X is absent.

15) T. Kubota, M. Yamakawa and Y. Mori, This Bulletin, **36**, 1552 (1963).

responds to a stronger electron-withdrawing power of X.

The relations between ΔP's and h_x are shown in Fig. 4.[16] As is seen in this figure, the value of $\Delta P_{C,O}$, which is positive in the range shown in the figure, is almost at its maximum when X is absent, and decreases as the effect of X increases, whether it is electron-donating or electron-withdrawing. This explains well the effect of X on Φ.

The value of ΔE decreases as the value of h_x decreases when X is electron-donating, and as the value of h_x increases when X is electron-withdrawing. This means that the first absorption band should shift to longer wavelength as the 4-substituent becomes more electron-donating or more electron-withdrawing, in accordance with the observation. The relation between $\Delta P_{C,O}$ and ΔE is shown in Fig. 5. This relation corresponds to the relation between Φ and ν_{max} shown in Fig. 3.

In nitrone 15, which has an electron-donating substituent at the 4-position and an electron-withdrawing substituent at the 4′-position, both the values of $\Delta P_{C,O}$ and ΔE must be small.

(c) The variation in the value of Φ in the series of α,*N*-diphenylnitrone and its 4-substituted derivatives has so far been explained well by saying that the value of Φ decreases as the value of $\Delta P_{C,O}$ decreases. The values of $\Delta P_{C,O}$ for the α,*N*-diphenylnitrone, α-phenylnitrone, and nitrone group π electron systems are 0.370, 0.508, and 0.735, respectively. Therefore, the value of Φ would be expected to increase rapidly in this sequence. In fact, however, the values of Φ for nitrones 1 and 2 are not much different from the values for nitrone 4. Thus, in this series of nitrones, it appears that the value of Φ does not monotonously increase with the value of $\Delta P_{C,O}$, but approaches a limiting value of about 0.5. There seem to be some fast processes which deactivate excited nitrone molecules and thereby depress Φ.

16) The energies of the lowest vacant and highest occupied orbitals of α,*N*-diphenylnitrone are calculated to be $\alpha-0.1830\beta$ and $\alpha+0.6103\beta$, respectively. In Fig. 4, in the case where X is electron-donating (case a) values larger than -0.1830 were taken for h_x, and in the case where X is electron-withdrawing (case b) values smaller than 0.6103 were taken for h_x. The case a where the value of h_x is sufficiently large and the case b where the value of h_x is sufficiently small correspond to the case where the α,*N*-diphenylnitrone π electron system is not perturbed by the substituent X.

2*H*,5*H*-Triazolo[4,5-*d*]triazoles. A New Heteroaromatic System

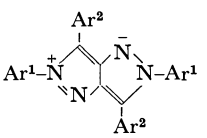
Masayuki YOSHIDA, Akira MATSUMOTO and Osamu SIMAMURA

Department of Chemistry, Faculty of Science, Tokyo University, Hongo, Tokyo

(Received July 8, 1970)

2-Aryl-5-phenyltriazolo[4,5-*d*]triazoles and related compounds, a new heteroaromatic system, have been prepared from 4,5-diamino-2-phenyl-1,2,3-triazole. The meso-ionic character of the new ring system is discussed on the basis of proton NMR shifts.

Syntheses of 2,3,5,6-tetraaryl-1,2,4,5-tetraazapentalenes (I), meso-ionic heteroaromatics, have recently been described.[1] A further replacement of the ring carbon atoms by nitrogen may yield another stable azapentalene. This paper presents the synthesis of 2-aryl-5-phenyl-1,2,3,4,5,6-hexaazapentalenes (2-aryl-5-phenyltriazolo[4,5-*d*]triazoles, II: $R^1=C_6H_5$, $R^2=Ar$) and related compounds.



I

azole, yellow needles, $C_{14}H_{10}N_8$ (V, 76%), which did not show any definite melting point owing to gradual decomposition on heating, the structure being confirmed on the basis of its IR spectrum (ν_{N_3} 2120 cm^{-1}) and analytical data. On being heated gently in decahydronaphthalene until nitrogen evolution ceased, it gave an almost quantitative yield of colorless leaflets, $C_{14}H_{10}N_6$, mp 249°C, sparingly soluble in ordinary organic solvents. This compound shows ultraviolet absorption maxima at 231 and 342 nm (log ε 4.1 and 4.6, respectively) in ethanol. The mass spectrum shows a molecular ion at 262, which was 53% of the base peak at 77. Thus, the compound was assigned the structure of 2,5-diphenyltriazolo[4,5-*d*]triazole (II: Ar=C_6H_5) on the ground of its mode of formation and of its spectral and analytical data.

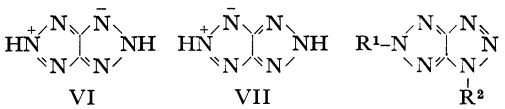
IV: $R^1=C_6H_5N_2$, $R^2=NH_2$
V: $R^1=C_6H_5N_2$, $R^2=N_3$

The following triazolo[4,5-*d*]triazoles have been prepared in a similar way: II (Ar=*p*-$CH_3\cdot C_6H_4$), mp 233—234°C; II (Ar=*p*-$Cl\cdot C_6H_4$), mp 265.5—266.0°C; II (Ar=*p*-$(CH_3)_2N\cdot C_6H_4$), mp 285—286°C.

The parent structure underlying these compounds, 2*H*,5*H*-triazolo[4,5-*d*]triazole, comprises ten π-electrons distributed over the two rings and is satisfactorily represented only by the resonance of several charge-separated structures such as VI and VII, while its isomer, 1*H*,5*H*-triazolo[4,5-*d*]triazole, is represented by structure VIII without any charge-separation in the ground state. The effect of positive charge situated on positions 2 and 5 in derivatives of 2*H*,5*H*-isomer should be reflected in low field shift of proton NMR signals of substituents at positions 2 and 5. The following observations substantiate this view.



VI VII

VIII: $R^1=R^2=H$
IX: $R^1=C_6H_5$, $R^2=H$
X: $R^1=C_6H_5$, $R^2=CH_3$

Treatment of the silver salt of 5-phenyl-1*H*-triazolo[4,5-*d*]triazole[2] (IX) with excess of methyl iodide in boiling benzene afforded two mono-methylated products, $C_9H_8N_6$ (X, 51%), mp 139.2—139.8°C and $C_9H_8N_6$ (XI, 27%), mp 149.0—149.8°C. The NMR spectrum of X shows a sharp singlet at τ 5.72 (3H) and two multiplets centered at τ 2.54 (3H) and 1.87 (2H) corresponding to methyl and phenyl protons, respectively. The NMR spectrum of XI exhibits three signals at τ 5.47, 2.48 and 1.69 quite similar in appearance to those of X. The fact that the signals from XI are all shifted to lower field regions relative to the corresponding ones of X leads to the assignment of the structure of 2-methyl-5-phenyltriazolo[4,5-*d*]triazole to XI and that of 1-methyl-5-phenyltriazolo[4,5-*d*]triazole to X, because the low field shift is attributable to positive charges at positions 2 and 5 due to the meso-ionic structure of XI causing deshielding of the relevant protons, while such a charge is absent from structure VIII. Analogous deshielding of protons due to positive nature of nuclear positions is found in the methyl protons (τ 5.99) of 1,3-dimethylimidazolium iodide[3] in comparison with those (τ 6.33) of 1-methylimidazole.[4]

Catalytic hydrogenation of II (Ar=C_6H_5) with platinum oxide in acetic acid at room temperature gave two products without ring-opening, $C_{14}H_{16}N_6$ (XII, 30%), mp 128.5—129.5°C, and $C_{14}H_{22}N_6$ (XIII, 15%), mp 171.0—171.2°C. XII was assigned the structure of 2-cyclohexyl-5-phenyltriazolo-[4,5-*d*]triazole, and XIII, that of 2,5-dicyclohexyltriazolo[4,5-*d*]triazole on the basis of spectral and analytical data. The NMR shifts of these compounds are recorded in Experimental part; the phenyl protons and the methine protons in a cyclohexyl group are found shifted more or less to lower field regions than the usual positions, obviously because of the deshielding effect of the positively charged nitrogen at positions 2 and 5.

Experimental

4-Amino-2-phenyl-5-phenylazo-1,2,3-triazole (IV). To a suspension of 4,5-diamino-2-phenyl-1,2,3-triazole[2] (8.5 g) in a mixture of 5 m*l* of benzene and 85 m*l* of 50% sodium hydroxide solution heated at 60°C was added nitrosobenzene (5.1 g) in small portions over a period of 10 minutes. The mixture was stirred for a further 10 minutes at 60°C. On pouring it into 900 m*l* of water it gave 4-amino-2-phenyl-5-phenylazo-1,2,3-triazole as brownish red precipitate (9.5 g, 72%), mp 206—208°C (from benzene).

Found: C, 63.64; H, 4.34; N, 31.96%. Calcd for $C_{14}H_{12}N_6$: C, 63.62; H, 4.58; N, 31.80%.

4-Azido-2-phenyl-5-phenylazo-1,2,3-triazole (V). 4-Amino-2-phenyl-5-phenylazo-1,2,3-triazole (4.3 g) was dissolved by heating in 70 m*l* of concentrated hydrochloric acid. A slurry of the amine hydrochloride formed upon cooling was diluted with 14 m*l* of water and diazotized by addition of a solution of sodium nitrite (1.2 g) in 15 m*l* of water over a period of 30 min at 0—5°C. The mixture was stirred for an additional hour to complete the reaction at 0—5°C. The resulting diazonium solution was filtered to remove a small amount of insoluble material. A solution of sodium azide (1.5 g) in 20 m*l* of water was added to the filtrate over a period

3) C. G. Overberger, J. C. Salamone and S. Yaroslavsky, *J. Org. Chem.*, **30**, 3580 (1965).

4) G. S. Reddy, R. T. Hobgood, Jr., and J. H. Goldstein, *J. Amer. Chem. Soc.*, **84**, 336 (1962).

of 30 min at 0—5°C, during which violent nitrogen evolution was observed. Stirring was continued for 10 min to complete the reaction at 0—5°C. The yellow solid deposited was collected to yield 3.6 g of 4-azido-2-phenyl-5-phenylazo-1,2,3-triazole (76%). This crude material was carefully recrystallized from methanol to give yellow needles, which softened at 159—161°C, but changed to infusible white crystals at elevated temperatures.

Found: C, 58.05; H, 3.20; N, 38.47%. Calcd for $C_{14}H_{10}N_8$: C, 57.93; H, 3.47; N, 38.60%.

2,5-Diphenyltriazolo[4,5-*d*]triazole (II: Ar=C_6H_5). 4-Azido-2-phenyl-5-phenylazo-1,2,3-triazole (2.5 g) in 300 m*l* of decahydronaphthalene was heated gently at 105—115°C with stirring. After vigorous evolution of nitrogen had ceased, the temperature was raised to 160°C to complete the decomposition. The reaction mixture, upon cooling to room temperature, deposited crystals of 2,5-diphenyltriazolo[4,5-*d*]triazole, which were filtered off, and the filtrate was concentrated to 20 m*l* under reduced pressure to give a second crop. The total yield of the crude products was almost quantitative. The combined products were recrystallized three times from benzene (with active charcoal) to give 1.74 g of colorless leaflets, mp 249°C.

Found: C, 64.39; H, 3.84; N, 32.14%. Calcd for $C_{14}H_{10}N_6$: C, 64.11; H, 3.84; N, 32.05%.

2-Phenyl-5-*p*-tolyltriazolo[4,5-*d*]triazole (II: Ar=*p*-$CH_3\cdot C_6H_4$). This compound (Found: C, 65.04; H, 4.41; N, 30.50%. Calcd for $C_{15}H_{12}N_6$: C, 65.20; H, 4.38: N, 30.42%.), mp 233—234°C (from ligroin and benzene), was prepared from 4,5-diamino-2-phenyl-1,2,3-triazole and *p*-methylnitrosobenzene through 4-amino-2-phenyl-5-*p*-tolylazo-1,2,3-triazole, mp 208°C (Found: C, 64.88; H, 4.99; N, 30.26%. Calcd for $C_{15}H_{14}N_6$: C, 64.73; H, 5.03; N, 30.20%.), and 4-azido-2-phenyl-5-*p*-tolylazo-1,2,3-triazole, mp 115°C (dec.), in a way similar to the above.

5-*p*-Chlorophenyl-2-phenyltriazolo[4,5-*d*]triazole (II: Ar=*p*-Cl$\cdot C_6H_4$). This compound (Found: C, 56.90; H, 3.48; N, 29.12%. Calcd for $C_{14}H_9N_6Cl$: C, 56.67; H, 3.06; N, 28.32%.), mp 265.5—266.0°C (from benzene), was prepared from 4,5-diamino-2-phenyl-1,2,3-triazole and *p*-chloronitrosobenzene, through 4-amino-5-*p*-chlorophenylazo-2-phenyl-1,2,3-triazole, mp 239°C (Found: C, 56.21; H, 4.03; Cl, 11.18%. Calcd for $C_{14}H_{11}N_6Cl$: C, 56.28; H, 3.71; Cl, 11.53%.), and 4-azido-5-*p*-chlorophenylazo-2-phenyl-1,2,3-triazole, in a way similar to the above except for the preparation of the azidoazotriazole.

This azidoazotriazole was prepared as follows: 4-Amino-5-*p*-chlorophenylazo-2-phenyl-1,2,3-triazole (0.71 g) in 15 m*l* of concentrated sulphuric acid was added to a solution of sodium nitrite (0.195 g) in 10 m*l* of concentrated sulphuric acid over a period of 10 min at room temperature. The mixture was stirred for 20 min at room temperature and poured into a large amount of ice water. It was treated with sodium azide (0.20 g) and left at room temperature with stirring for an hour. 4-Azido-5-*p*-chlorophenylazo-2-phenyl-1,2,3-triazole was obtained as yellow precipitate (0.70 g, 91%), which did not show any definite melting point owing to gradual decomposition on heating. The infrared spectrum showed a peak at 2130 cm^{-1} corresponding to the azido stretching vibration.

5-Dimethylaminophenyl-2-phenyltriazolo[4,5-*d*]-triazole (II: Ar=*p*-$(CH_3)_2N\cdot C_6H_4$). 4-Amino-5-*p*-dimethylaminophenylazo-2-phenyl-1,2,3-triazole[2] was converted, as described for the preparation of II (Ar=C_6H_5), into 5-dimethylaminophenyl-2-phenyltriazolo-[4,5-*d*]triazole (Found: C, 62.88; H, 4.72; N, 32.29%. Calcd for $C_{16}H_{15}N_7$: C, 62.94; H, 4.95; N, 32.11%.), mp 285—286°C (from benzene and dioxane).

1-Methyl- and 2-Methyl-5-phenyltriazolo[4,5-*d*]-triazole (X and XI). 5-Phenyl-1*H*-triazolo[4,5-*d*]-triazole[2] (0.50 g) was dissolved in 10 m*l* of concentrated ammonium hydroxide and treated with a solution of silver nitrate (0.60 g) in 5 m*l* of concentrated ammonium hydroxide. The mixture was stirred for 10 min at room temperature and the pale yellow precipitate was collected and washed with water to yield 0.79 g of the silver salt of 5-phenyl-1*H*-triazolo[4,5-*d*]triazole (92%). The silver salt (0.77 g) was heated in a mixture of benzene (15 m*l*) and methyl iodide (1.5 m*l*) under reflux for 3 hr. On cooling, the supernatant solution was separated from precipitate by decantation and the residue was treated with benzene—methyl iodide solution twice more as above. Then, the precipitate was separated by filtration and washed with benzene. The combined benzene solutions gave 0.495 g of a light yellowish brown solid on evaporation of the solvent under reduced pressure. The crude material (0.20 g) was subjected to purification by preparative thin-layer chromatography on silica gel. After development with dichloromethane, the bands having R_f values of 0.24—0.36 and 0.37—0.44 were scraped off the plates and eluted with ethanol. Evaporation of the eluants gave 0.118 g of X (51%) and 0.064 g of XI (27%).

1-Methyl-5-phenyltriazolo[4,5-*d*]triazole (Found: C, 53.92; H, 3.78; N, 42.05%. Calcd for $C_9H_8N_6$: C, 53.99; H, 4.03; N, 41.98%.), X: mp 139.2—139.8°C (from ethanol); UV max. (ethanol) 299, 223 nm (log ε=4.33, 3.86, respectively).

2-Methyl-5-phenyltriazolo[4,5-*d*]triazole (Found: C, 54.11; H, 4.11; N, 41.89%. Calcd for $C_9H_8N_6$: C, 53.99; H, 4.03; N, 41.98%.), XI: mp 149.0—149.8°C (from ethanol); UV max. (ethanol) 301, 226 nm (log ε=4.40, 3.79, respectively).

Catalytic Hydrogenation of 2,5-Diphenyltriazolo-[4,5-*d*]triazole. 2,5-Diphenyltriazolo[4,5-*d*]triazole (0.99 g) in 250 m*l* of acetic acid was hydrogenated over platinum oxide (0.206 g) for 58 hr at room temperature. Insoluble starting material (0.125 g) was recovered by filtration. The filtrate was concentrated to 20 m*l* and poured into a large volume of water. The precipitate formed was filtered off to yield 0.615 g of colourless material. The crude material (0.13 g) was subjected to purification by preparative thin-layer chromatography on silica gel. After development with benzene, the bands having R_f values of 0.08—0.16, 0.18—0.32 and 0.35—0.52 were scraped off the plates and eluted with ethanol and chloroform and gave, on evaporation of the eluant, 0.022 g of 2,5-dicyclohexyltriazolo[4,5-*d*]triazole (XIII, 15%), 0.044 g of 2-cyclohexyl-5-phenyltriazolo[4,5-*d*]-triazole (XII, 30%) and 0.036 g of the starting material, respectively.

2-Cyclohexyl-5-phenyltriazolo[4,5-*d*]triazole (Found: C, 62.94; H, 5.95; N, 28.77%. Calcd for $C_{14}H_{16}N_6$: C, 62.67; H, 6.01; N, 31.32%.), XII: mp 128.5—129.5°C (from ethanol); UV max. (ethanol) 304, 216 nm (log ε=4.52, 3.93, respectively); NMR ($CDCl_3$) τ 8.27 (m, 10H, cyclohexyl *H*), 5.22 (broad s, 1H, methine *H*),

2.55 (m, 3H, phenyl *H*), 1.74 (m, 2H, phenyl *H*).

2,5-Dicyclohexyltriazolo[4,5-*d*]triazole (Found: C, 61.07; H, 8.33; N, 30.33%. Calcd for $C_{14}H_{22}N_6$: C, 61.29; H, 8.08; N, 30.63%.), XIII: mp 171.0—171.2°C (from ethanol); UV max. (ethanol) 258 nm (log ε=4.43); NMR ($CDCl_3$) τ 8.2 (m, 10H, cyclohexyl *H*), 5.4 (broad s, 1H, methine *H*).

Homolytic Aromatic Isopropyloxycarbonyloxylation Induced by Oxygen*1

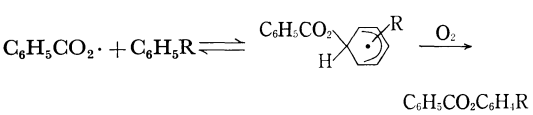
Toshio NAKATA, Katsumi TOKUMARU and Osamu SIMAMURA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received July 20, 1970)

Thermal decomposition of diisopropyl peroxydicarbonate in benzene was carried out at several temperatures ranging from 40 to 70°C under an atmosphere of nitrogen, air or oxygen; the presence of oxygen caused the production of isopropyl phenyl carbonate. For this aromatic isopropyloxycarbonyloxylation induced by oxygen, a mechanism is proposed, which involves reversible addition of an isopropyloxycarbonyloxy radical to an aromatic nucleus to give a cyclohexadienyl intermediate, followed by oxidation with oxygen to produce the carbonate ester. The reaction in a mixture of benzene and hexadeuteriobenzene showed isotope effects for the formation of the ester, $k_H/k_D=2.1$—2.3, thus supporting the reversibility of the addition step of the isopropyloxycarbonyloxy radical to benzene.

In a previous communication[1] we reported that the decomposition of benzoyl peroxide in aromatic solvents under oxygen resulted in the aromatic benzoyloxylation and proposed a mechanism, in which the reversible addition of a benzoyloxy radical to an aromatic nucleus takes place to give a benzoyloxycyclohexadienyl radical, followed by oxidation with molecular oxygen to afford aryl benzoate.



In order to obtain further evidence for this mechanism we have extended the study to other aromatic acyloxylation. Thermal decomposition of diisopropyl peroxydicarbonate in benzene under an atmosphere of nitrogen, oxygen or air was carried out, and the effect of temperature and the isotope effect, utilizing hexadeuteriobenzene, in the aromatic isopropyloxycarbonyloxylation induced by oxygen was examined.

Experimental

Materials. Commercial diisopropyl peroxydicarbonate (purchased from Nippon Oils and Fats Co., Ltd.; purity as determined by iodometric titration, 100%) was used without further purification. Thiophene-free benzene was dried over calcium chloride and fractionated through a Vigreux column. Hexadeuteriobenzene (supplied by Showa Denko Co., Ltd.) was used without further purification.

Gas Chromatography. Gas chromatographic analysis was carried out with a Perkin-Elmer 154D Vapour Fractometer. Isopropyl phenyl carbonate was determined with the use of a 2 m-column of 10% Apiezon M grease on Diasolid H (40 mesh) at 170°C or a 2 m-column of 10% HV DC Silicone grease on Diasolid H at 167°C with *p*-chloroanisole as an internal standard. A mixture of phenyl and phenyl-d_5 isopropyl carbonates was collected from reaction mixtures using the above-mentioned column of Silicone grease at 132°C, and subjected to mass spectrometric analysis.

Decomposition of Diisopropyl Peroxydicarbonate in Benzene. A solution of diisopropyl peroxydicarbonate (8 mmol) in benzene (300 m*l*) was placed in a three-necked flask, fitted with a stirrer, a thermometer, a gas inlet tube and a condenser. An appropriate gas (nitrogen, oxygen or air) after purification was bubbled through the solution to produce the desired atmosphere and the bubbling was continued during the whole reaction time. The flask was immersed in an oil bath maintained at a constant temperature (40—70±1°C). The peroxide was allowed to decompose completely and the reaction mixture was concentrated to 5—10 m*l* by distillation of benzene through a Vigreux

*1 Most part of this article was presented at the 21st (April, 1968, Osaka) and the 22nd (April, 1969, Tokyo) Annual Meetings of the Chemical Society of Japan.

b) Biphenyl (about 3%) was detected by VPC.

column on a water bath. The concentrated solution was subjected to gas chromatographic analysis to determine isopropyl phenyl carbonate. Determination of carbon dioxide was carried out by passing the exist gas from the top of a condenser attached to the reaction flask successively through a trap cooled with dry ice-ethanol, a tube with anhydrous calcium chloride and one with Ascarite, which was finally weighed.

Decomposition of Diisopropyl Peroxydicarbonate in a Mixture of Benzene and Hexadeuteriobenzene. Diisopropyl peroxydicarbonate (*ca.* 2 mmol) was dissolved in an equimolar mixture (25 m*l*) of benzene and hexadeuteriobenzene and allowed to decompose completely at 60°C under an atmosphere of oxygen or air. The reaction mixture was concentrated carefully to a volume of 1—2 m*l* by using a spinning band distillation column. From a portion of the concentrated solution a mixture of phenyl and phenyl-d_5 isopropyl carbonate was collected by gas chromatography. Both the concentrated solution and the collected ester-mixture were analyzed by using a Hitachi mass spectrometer RMU-E6 with ionizing beam of 70 eV to determine the ratio of phenyl to phenyl-d_5 isopropyl carbonates by comparison of the relative intensities of the following pairs of ion peaks:[2] *i*-$PrOCOOC_6H_5^+$ at *m/e* 180 and *i*-$PrOCOOC_6D_5^+$ at *m/e* 185; $C_6H_5OCO^+$ and $C_6H_5OCHCH_3^+$ at *m/e* 121 and $C_6D_5OCO^+$ and $C_6D_5OCHCH_3^+$ at *m/e* 126; $C_6H_5OH^+$ at *m/e* 94 and $C_6D_5OH^+$ at *m/e* 99.

Results and Discussion

The results of the decomposition of diisopropyl peroxydicarbonate in benzene at several temperatures (40—70°C) under nitrogen, oxygen or air are summarized in Table 1 and Fig. 1.

While decomposition of diisopropyl peroxydicarbonate in benzene at 60°C under nitrogen gave carbon dioxide and isopropyl phenyl carbonate in 183 and 1%, respectively, passage of oxygen through the reaction mixture under otherwise the same reaction conditions caused a remarkable increase in the yield of isopropyl phenyl carbonate (57%) with the corresponding decrease of carbon dioxide (136%). The balance of the CO_2 group originally contained in the peroxide was accounted

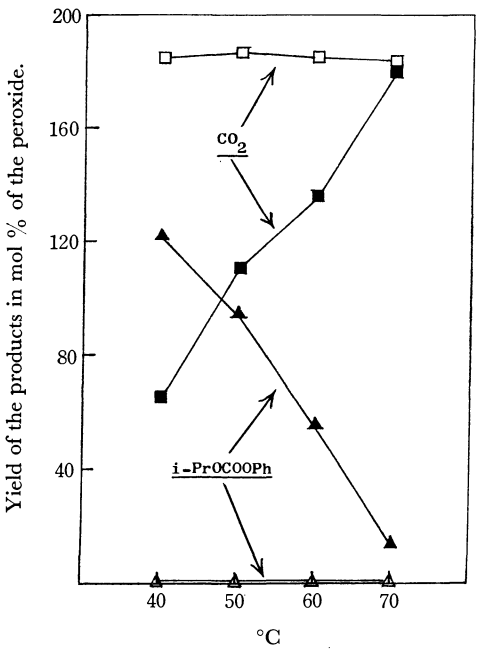

Fig. 1. Thermal decomposition of diisopropyl peroxydicarbonate (1.6 g) in benzene (300 m*l*): □, CO_2 under N_2; ■, CO_2 under O_2; △, *i*-PrOCOOPh under N_2; ▲, *i*-PrOCOOPh under O_2.

for nearly quantitatively under nitrogen and oxygen (92 and 97%, respectively). These results are satisfactorily explained by a mechanism similar to that proposed for the aromatic benzoyloxylation induced by oxygen[1]

$$(i\text{-PrOCOO})_2 \xrightarrow{k_1} 2\,i\text{-PrOCOO}\cdot \quad (1)$$

$$i\text{-PrOCOO}\cdot \xrightarrow{k_2} i\text{-PrO}\cdot + CO_2 \quad (2)$$

$$i\text{-PrOCOO}\cdot + C_6H_6 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} i\text{-PrOCOO}\text{-}C_6H_6\cdot \quad (\mathrm{I}) \quad (3)$$

$$(\mathrm{I}) + O_2 \xrightarrow{k_4} i\text{-PrOCOOC}_6H_5 + HO_2\cdot \quad (4)$$

The formation of isopropyl phenyl carbonate, aromatic isopropyloxycarbonyloxylation, consists of two steps, the reversible addition of an isopropyloxycarbonyloxy radical to an aromatic nucleus

2) P. Brown and C. Djerassi, *J. Amer. Chem. Soc.*, **88**, 2469 (1966).

to give an isopropyloxycarbonyloxycyclohexadienyl radical (reaction (3)), which proceeds competitively with decarboxylation (reaction (2)), and its subsequent oxidation by oxygen to afford isopropyl phenyl carbonate (reaction (4)). The proposal of a reversible addition step (reaction (3)) is based on the following reasons. If the addition were not reversible, in the first place, the decomposition, irrespective of the nature of the atmosphere, would give rise to carbon dioxide in approximately constant yield at a given temperature; and secondly, the decomposition under nitrogen might afford the carbonate ester in fairly good yield, by way of, for example, the disproportionation between isopropyloxycarbonyloxycyclohexadienyl radicals (I), similarly to that between phenylcyclohexadienyl radicals to yield biphenyl and dihydrobiphenyl.[3] The fact that the yield of the ester was dependent on the concentration of oxygen dissolved in the reaction mixture as shown (by the result under air) in Table 1 clearly indicates that the oxidation of the isopropyloxycarbonyloxycyclohexadienyl radical by molecular oxygen competes with its reversible dissociation to an isopropyloxycarbonyloxy radical and benzene.

The above mechanism is further supported by the study of the effect of temperature on the yield of the products under nitrogen or oxygen; the results are shown in Fig. 1. Under oxygen, the yield of isopropyl phenyl carbonate increased with lowering the reaction temperature, being 15 and 123% at 70 and 40°C, respectively, whereas the yield under nitrogen was invariably very low (less than 1%). With lowering the temperature, the yield of carbon dioxide did not change under nitrogen (about 185%), but decreased under oxygen with the corresponding increase of the carbonate ester. The effect of temperature on the yield of the ester under oxygen is certainly due to increase in the concentration of oxygen dissolved in the reaction mixture as well as decrease in the rate of decarboxylation from the isopropyloxycarbonyloxy radical with decrease in the reaction temperature.

In order to obtain further evidence for the reversibility of the addition of isopropyloxycarbonyloxy radicals to benzene, decomposition of diisopropyl peroxydicarbonate in large excess of an equimolar mixture of benzene and hexadeuteriobenzene was carried out at 60°C under oxygen and air, the apparent isotope effect for the formation of isopropyl phenyl carbonate being determined. The apparent isotope effect k_H/k_D is defined by

$$\frac{k_H}{k_D} = \frac{(\text{yield of } i\text{-PrOCOOC}_6H_5)}{(\text{yield of } i\text{-PrOCOOC}_6D_5)} \times \frac{[C_6D_6]}{[C_6H_6]} \quad (5)$$

According to the reaction sequence (reactions (3) and (4)) shown above, the ratio between the isotopic esters formed is given by

$$\frac{(\text{yield of } i\text{-PrOCOOC}_6H_5)}{(\text{yield of } i\text{-PrOCOOC}_6D_5)} = \frac{k_4^H}{k_4^D} \times \frac{[C_6H_6]}{[C_6D_6]} \times K_{H/D} \times \frac{(1+k_4^D[O_2]/k_{-3}^D)}{(1+k_4^H[O_2]/k_{-3}^H)} \quad (6)$$

where $K_{H/D}=\frac{k_3^H/k_{-3}^H}{k_3^D/k_{-3}^D}$ and superscripts H and D refer to the reactions involving ordinary benzene and deuterated benzene, respectively.

			B	1.67	1.38	1.75	

a) Diisopropyl peroxydicarbonate was allowed to decompose at 60°C in an equimolar mixture of benzene and hexadeuteriobenzene under a specified atmosphere. The initial peroxide concentration was 0.07—0.1 mol/*l*.

b) The hexadeuteriobenzene used was found to contain less than 3.3% of pentadeuteriobenzene, by mass spectrometric analysis with ionizing beam of 15 eV.

c) A denotes the carbonate collected from concentrated reaction mixtures by VPC; B, concentrated reaction mixtures.

d) Average of three measurements. I is the intensity of a mass spectrometric peak at *m/e* indicated as subscript of I.

3) D. F. DeTar and R. A. J. Long, *J. Amer. Chem. Soc.*, **80**, 4742 (1958).

Table 2 contains values, as determined by mass spectrometry, for the ratio of the resulting isotopic esters, which is equal to the apparent isotope effect because of the use of equimolar amounts of benzene and hexadeuteriobenzene. Fairly large isotope effects, 2.1—2.3 under oxygen and 1.5—1.8 under air, were observed. If the rate of dissociation of the isopropyloxycarbonyloxycyclohexadienyl radical (I) is much lower than that of the reaction with oxygen, *i.e.*, $k_4[O_2] \gg k_{-3}$, the apparent isotope effect would be expressed by $k_H/k_D = k_3^H/k_3^D$. Numerical estimation of this ratio is difficult, since there has hitherto been no experimental results concerning the secondary isotope effect in the homolytic aromatic substitution. Small reverse secondary isotope effects have been noticed for the radical addition to deuterio-olefins,[4] however; it would therefore seem reasonable to assume that k_3^H/k_3^D is unity or slightly less than unity. The observed apparent isotope effects are distinctly greater than this estimate. On the other hand, if $k_{-3} \gg k_4$ $[O_2]$, Eq. (6) reduces to

$$\frac{(\text{yield of } i\text{-PrOCOOC}_6H_5)}{(\text{yield of } i\text{-PrOCOOC}_6D_5)} = \frac{k_4^H}{k_4^D} \times K_{H/D} \times \frac{[C_6H_6]}{[C_6D_6]}$$

and $$k_H/k_D = (k_4^H/k_4^D) \times K_{H/D}$$

so that a fairly large apparent isotope effect is to be observed owing to the primary isotope effect for the oxidation step (reaction (4)), $K_{H/D}$ being not appreciably different from unity as mentioned above. Whether or not the actual situation corresponds to this extreme condition is not certain, but the observed isotope effects as a whole clearly indicate that the dissociation step competes favorably with the reaction with oxygen to give isopropyl phenyl carbonate, thus corroborating the reversibility of the addition step of the isopropyloxycarbonyloxy radical to an aromatic nucleus.*2

It is worth noting that the present results of isotope effect measurements for the production of the carbonate ester in the presence of oxygen, contrast with the observation of no apparent isotope effect in the presence of cupric chloride as an oxidant in place of oxygen reported by Kurz, Kovacic, Bose and Kugajevsky.[5] In the presence of cupric chloride, isopropyl phenyl carbonate has been proposed to arise by the following oxidative reaction:

$$i\text{-PrOCOOC}_6H_6\cdot + CuCl_2 \xrightarrow{k_4'} i\text{-PrOCOOC}_6H_5 + CuCl + HCl$$

The absence of apparent isotope effect leads to the conclusion that $k_4' \cdot [CuCl_2]$ is much larger than k_{-3}, in contrast with the present result that $k_4 \cdot [O_2]$ is smaller than k_{-3}. The fact that $k_4 \cdot [O_2]$ is, thus, much smaller than $k_4' \cdot [CuCl_2]$ is probably attributable both to higher efficiency (k_4') of cupric chloride than oxygen ($k_4' > k_4$) in oxidizing the cyclohexadienyl intermediate and to the higher concentration of cupric chloride used than that of oxygen dissolved in benzene.*3

Finally, it must be pointed out that the present observation of the isotope effect is in keeping with Denney and Klemchuk's finding of isotope effect, $k_H/k_D = 1.32$, for the intramolecular formation of 3,4-benzocumarin from 2-(2-deuteriophenyl)benzoyl peroxide, which led to the postulation of the intramolecular reversible cyclization of the *o*-phenylbenzoyloxy radical to give a cyclohexadienyl intermediate, followed by oxidation to the benzocumarin, without mention of the nature of the oxidant.[6]

The authors wish to thank Drs. M. Fukuyama and M. Anbe of Sagami Research Center for mass spectrometric measurements.

*2 The observation of somewhat smaller isotope effects for the reaction under air than under oxygen was contrary to the prediction from Eq. (6). The cause for this is unknown.

5) M. E. Kurz, P. Kovacic, A. K. Bose and I. Kugajevsky, *J. Amer. Chem. Soc.*, **90**, 1818 (1968).

*3 In connection with the aromatic isopropyloxycarbonyloxylation caused by cupric chloride, Kurz and Kovacic examined the effect of several non-metallic oxidants in the reaction of diisopropyl peroxydicarbonate with toluene in acetonitrile at 60°C, and stated that oxygen brought about a small, but real, increase in isopropyl tolyl carbonate (in 6.6% yield), whereas, without any oxidant, the yield was very low (0.7%) (M. E. Kurz and P. Kovacic, *J. Org. Chem.*, **33**, 266 (1968)). In a preliminary experiment carried out during the present investigation, the presence of oxygen in the decomposition of diisopropyl peroxydicarbonate in toluene at 60°C caused a remarkable increase of isopropyl tolyl carbonate (in about 20% yield).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3594—3596 (1970)

The Constituents of Hops. V.[1] The Volatile Composition of *Humulus japonicus* Sieb. et Zucc.

Yoko NAYA and Munio KOTAKE

The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka

(Received July 13, 1970)

The steam-volatile constituents of *Humulus japonicus* Sieb. et Zucc. have been studied, and 50 compounds of the oil have been identified mainly by means of the temperature-programmed capillary GLC mass-spectra method. Beside the previously-reported principal components of hops (α-humulene, caryophyllene, α-copaene, α- and β-selinenes, γ-cadinene, caryophyllene-oxide, and humulene-epoxide-II), benzyl alcohol and phenethyl alcohol were found in high concentrations, whereas the myrcene was negligible. The proportion of the main compound, humulene, to the next highest one, caryophyllene, was approximately in the ratio of two to one, as in the essential oil of *H. lupulus*. As far as the chemical composition of the essential oils is concerned, *H. japonicus* seems to be related rather more closely to *H. lupulus* than to *H. cordifolius*.

The genus *Humulus* is represented by two species, the common hop, *Humulus lupulus* L., and the annual climbing plant from Japan, *H. joponicus* Sieb. et Zucc., which is synonymous with *H. scandens* Merr. and which belongs to the natural family *Cannabiaceae*. The wild hops of North America, *H. americanus* and *H. neomexicanus*, and the Asian *H. cordifolius*, the chemical composition of which was recently reported,[1] are generally considered to be varieties of *H. lupulus*. In this paper, the identification of the volatile constituents contained in the above-ground parts with the cones of *H. japonicus* is reported for the first time, and the chemical similarities between the above-mentioned species are discussed.

Experimental

Separation. The above-ground parts with the cones of *H. japonicus* (18 kg) gathered in the suburbs of Osaka at the beginning of October, 1969, were extracted with

ether. The extract was steam-distilled to obtain the essential oil (1.8 g). This oil was subjected to selective adsorption chromatography on neutral alumina to separate it into hydrocarbon (0.8 g) and oxygenated constituents (0.6 g). Each fraction was divided into several parts by programmed preparative gas-liquid chromatography (Carbowax 20 M), and then examined by means of the temperature-programmed capillary GLC mass spectra method. In addition, the major constituents were isolated by a combination of adsorption chromatography and preparative gas-liquid chromatography (Carbowax 20 M) and were identified by comparing their IR spectra with those of authentic samples.

Apparatus. The mass spectrometer employed was a Hitachi Model RMU-6 instrument; the operating conditions were as follows: ionization energy, 80 eV; accelerating voltage, 2000 V; ionization chamber, 150°C.

For the GLC, a Hitachi Model K-53 was used. The capillary column used for the analysis was 45 m long by 0.25 mm in I.D., made of stainless steel and coated with HB 2000; the column temperature was programmed non-linearly from 100 to 150°C. The helium-carrier gas-inlet pressure was set at 1.5 kg/cm^2 for initiation and 2.5 kg/cm^2 at the end.

For preparative gas-chromatography, a model 90-P Varian Aerograph equipped with a thermal conductivity detector was employed. A 10-ft.$\times$3/8 in. aluminum column packed with 20% Carbowax 20 M on Chromosorb W (60—80 mesh) was used. Helium was used as the carrier gas, and the column temperature was set at 100—220°C.

Results and Discussion

The compounds identified from the oil of *H. japonicus* are listed in Table 1 and 2, together with the peak number on the programmed GLC (Fig. 1). The authentic compounds used for identification were obtained from reliable sources and were purified by GLC separation before use. α-Humulene and the related oxides, together with humulol and humulenol-II, were found in great abundance. α-Copaene, caryophyllene and its oxide, α- and β-selinenes, and γ-cadinene have been found to be the common major components of the "Shinshu-wase" (*H. lupulus*).[2,3] It is significant, compared with the composition of "Shinshu-wase," that myrcene is here found to be negligible, whereas benzyl alcohol and phenethyl alcohol are detected in abnormally high concentrations. Mention has been made previously of the botanical relationship among the *H. lupulus*, *H. cordifolius*, and *H. japonicus*. It is interesting that the similarities in the essential oil of *H. lupulus* and *H. japonicus*, are however, distinct from that of *H. cordifolius* to some extent; this seems to be in disagreement with the botanical relationship of the three concerned plants. That is, the former two are humulene-rich, and the later is caryophyllene-rich, in the ratio of approximately two to one. The proportion of humulene-epoxide-II to caryophyllene-oxide corresponds with that in the corresponding hydrocarbons. In addition, in *H. cordifolius*, bisabolene-type sesquiterpenes (zingiberene and α-curcumene, together with β-bisabolene and β-sesquiphellandrene), selina-3,7(11)-diene, and selina-4(14), 7(11)-diene were found in abnormally high concentrations, as has previously been reported.[1]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3597—3601 (1970)

High Resolution NMR Study of Vinyl Chloride-Ethylene Copolymers

Akira MISONO and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

and Kunikazu YAMADA

Research Laboratory, Sekisui Chemical Co., Shimamoto-cho, Mishima-gun, Osaka

(Received May 14, 1970)

The high resolution NMR spectra of vinyl chloride-ethylene copolymers obtained by trialkylboron catalyst have been analyzed. The copolymer composition could be determined from the resonance peak area, and the monomer reactivity ratios thus obtained were in good consistency with those determined from the results of elementary analysis. The fine structure of the copolymers have been elucidated in terms of the run number concept, and the distribution of dyads as well as the average sequence lengths of the monomer unit have been determined. It was found that the observed values fitted theoretical values, indicating that a terminal model holds in this copolymerization.

High resolution NMR spectroscopy has been proved to be a superior method in investigation of fine structures of copolymers, and many copolymer systems have been analyzed thus for the purpose of obtaining precise information concerning the nature of copolymerization.[1-12] Vinyl chloride copolymers have been prepared and consumed on an industrial scale since long ago. However, they have not been studied by high resolution NMR spectroscopy probably because of complexities of the spectra. Vinyl chloride - ethylene copolymer, in which the ethylene unit has no substituent group, gives a more simple NMR spectrum than the vinyl copolymers with substituted ethylenic comonomers. We have presented a qualitative interpretation of the spectra.[13-15] Schaefer[16] as well as Wilkes and coworkers[17] have also reported on the NMR studies of vinyl chloride - ethylene copolymers. In this paper, we wish to report results of our high resolution NMR study of the copolymer concerning the determination of the monomer reactivity ratios as well as the elucidation of the fine structure of the copolymer obtained by the tri-*n*-butylboron/*t*-butyl hydroperoxide catalyst system.

Experimental

The samples were prepared by using a catalyst system consisting of tri-*n*-butylboron and *t*-butyl hydroperoxide in a water-methanol mixture (1 : 1 by volume) at 0°C.[13] Most of the copolymer samples were obtained in conversions lower than 10%. However, a few samples were obtained in conversions between 10 and 13%. The composition of the copolymer was determined from the results of elementary analysis of C and Cl. The NMR spectrum of the copolymer was measured with a Japan Electron Optics high resolution NMR spectrometer, model, JNM-C-60, in a 10wt/vol% monochlorobenzene solution of the sample at 60 MHz and 110°C using tetramethylsilane as an internal standard. The NMR spectrum was copied and each peak was separated by cutting, and then weighed for the determination of relative peak area.

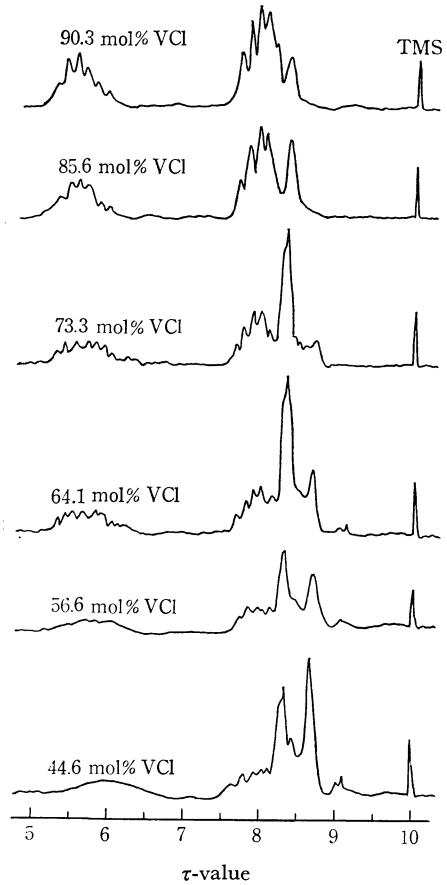

Fig. 1. NMR spectra of copolymers.

Results and Discussion

Peak Assignment. In Fig. 1 are shown the NMR spectra of several copolymers. A multiplet observed between 5.5 and 6.0 τ can be assigned to the methylene proton of vinyl chloride sequence based on the results of other workers.[18-21] The multiplet shifts to higher magnetic fields and becomes weaker in intensity as the vinyl chloride content of copolymer decreases. Since no methine proton absorption is observed at lower fields than those observed for pure polyvinyl chloride, and the infrared spectrum of the copolymer shows no absorption due to the $-(CH_2)_2-$ and the $-(CH_2)_4-$ sequences,[22] occurrence of the head-to-head or tail-to-tail linkage of vinyl chloride units can be ruled out.

In the region of methylene proton resonance, three groups of peaks can be observed in the spectrum of the copolymer; a multiplet centered at 7.85 τ, a singlet at 8.35 τ and a singlet at 8.65 τ. An additional peak is observed at 8.55 τ in the spectrum of the copolymer with a higher ethylene content. Hereafter, the methylene peaks are denoted by A, B and C, respectively, for the sake of convenience. The position of these methylene peaks does not seem to shift with change in copolymer composition.

The NMR spectra of polyvinyl chloride and polyethylene are shown in Fig. 2 and those of 2,6-di-

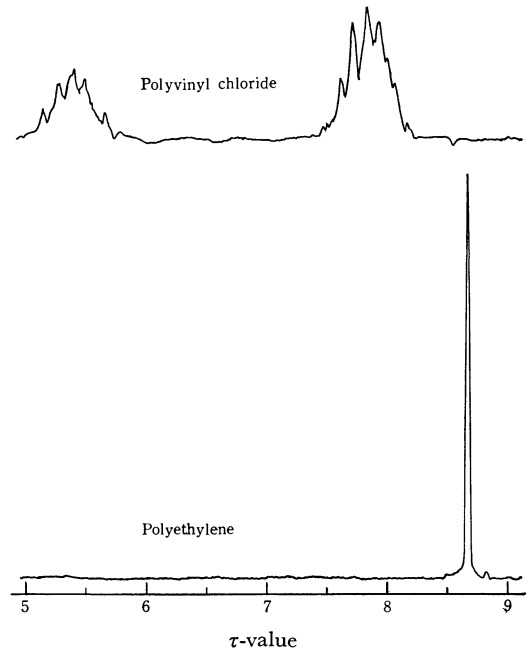

Fig. 2. NMR spectra of polyvinyl chloride and polyethylene.

21) F. A. Bovey and G. V. D. Tiers, *Chem. & Ind.*, **1962**, 1826.
22) A. Misono, Y. Uchida and K. Yamada, This Bulletin, **40**, 2696 (1967).

chloroheptane in Fig. 3. Peaks A and C are also observed in the spectrum of polyvinyl chloride and polyethylene, respectively, and thus can be assigned to the methylene proton absorption of $(CH_2\text{–}CHCl)_m$ and $(CH_2\text{–}CH_2)_n$ sequence, respectively, where m and n are greater than two. The observations of the NMR spectrum of the copolymer enable us to deduce that peak B can be assigned to the methylene group of a boundary structure located at a junction point of vinyl chloride unit and ethylene unit. In the spectrum of 2,6-dichloroheptane, a resonance peak is observed at 8.55 τ which can be assigned to a methylene group having two methylene groups in both nearest neighbors. Accordingly, the methylene peak mentioned previously appearing in the copolymer richer in ethylene may arise from the structure CHCl–CH_2–CH_2*–CH_2–CHCl. Thus, it seems reasonable to assign peak B to the methylene group having a methine and a methylene group in the nearest neighbors, namely CHCl–CH_2*–CH_2.

Table 1. Assignment of dyads

Dyad	Chemical shift (τ)	Structure
V–V	7.85	CH_2–CHCl–CH_2*–CHCl
V–E	8.35	CH_2–CHCl–CH_2*–CH_2
E–V	8.35	CH_2–CH_2–CH_2*–CHCl
E–E	8.65	CH_2–CH_2*–CH_2*–CH_2

If one describes the fine structure of the copolymer in terms of dyads, the above mentioned relationship can be summarized as shown in Table 1. Since each vinyl chloride unit contains one methylene group and each ethylene unit contains two, the mole fraction of each dyad can be easily calculated by using the following relationships taking into account the double counting of methylene group belonging to the E–E dyad, a part of which consists of the V–E or the E–V dyad.

$$f(\mathrm{V-V}) = 2a/\{2a+2b+(c-b/2)\} \quad (1)$$

$$2f(\mathrm{V-E}) = 2b/\{2a+2b+(c-b/2)\} \quad (2)$$

$$f(\mathrm{E-E}) = (c-b/2)/\{2a+2b+(c-b/2)\} \quad (3)$$

$$f(\mathrm{V-V}) + 2f(\mathrm{V-E}) + f(\mathrm{E-E}) = 1 \quad (4)$$

where a, b and c denote the relative peak areas of peaks A, B and C, respectively.

Determination of Monomer Reactivity Ratios. In Table 2 are shown the copolymer composition and the percentage of the methylene peak areas a, b and c. The vinyl chloride or ethylene mole fraction of the copolymer can be readily calculated by using the following equations derived from the above relationships of dyad distribution, where $F(\mathrm{V})$ and $F(\mathrm{E})$ denote the mole fraction of vinyl chloride and ethylene in the copolymer, respectively.

Table 2. Relative peak of methylene resonance

Copolymer composition (VCl mol%)	f_A	f_B	f_C
44.6	12.5	33.5	53.9
56.6	20.5	39.2	40.4
64.1	28.7	36.6	34.8
73.3	39.0	40.7	20.3
78.8	52.6	32.3	15.1
81.0	53.3	32.4	14.3
85.6	69.3	21.7	9.0
90.3	79.5	15.0	5.5
99.0	94.5	5.5	0

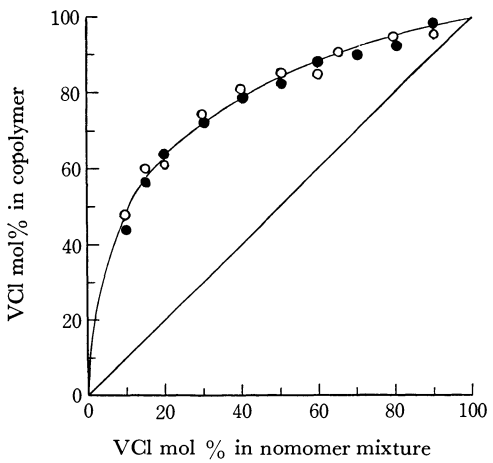

Fig. 4. Determination of copolymer composition.
open circle: from NMR peak area
closed circle: from C analysis

$$F(\mathrm{V}) = f(\mathrm{V-V}) + 2f(\mathrm{V-E})/2 = (a+b)/(2a+3b/2+c) \quad (5)$$

$$F(\mathrm{E}) = f(\mathrm{E-E}) + 2f(\mathrm{V-E})/2 = (b/2+c)/(2a+3b/2+c) \quad (6)$$

In Fig. 4 are compared the copolymer composition calculated from the results of elementary analysis and those obtained from NMR peak areas. Coincidence between the results from the two methods is obvious. Figure 5 shows the result of the determination of the monomer reactivity ratios using the fraction of the V–E dyad with the relationship given by Kinsinger and Colton.[23]

$$F_0\{1-2f(\mathrm{V-E})\}/f(\mathrm{V-E}) = r_2 + r_1F_0^2 \quad (7)$$

where F_0 denotes the monomer feed ratio, namely vinyl chloride/ethylene molar ratio in initial monomer mixture. The monomer reactivity ratios determined by means of the two methods are good agreement with each other:

23) J. B. Kinsinger and D. Colton, *J. Polym. Sci.*, **B3**, 797 (1965).

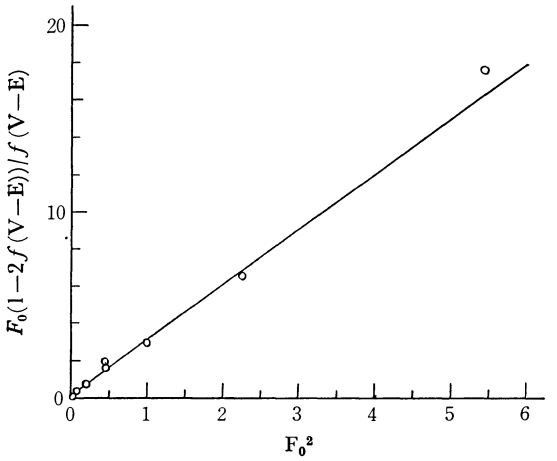

Fig. 5. Determination of monomer reactivity ratios by Kinsinger-Colton relationship

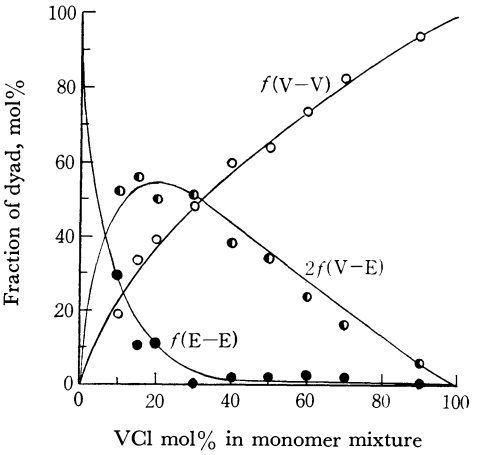

Fig. 6. Change in fraction of dyad as a function of monomer composition.

From elementary analysis,

$$r_1\,(\mathrm{V}) = 3.39 \text{ and } r_2\,(\mathrm{E}) = 0.20$$

From NMR peak area,

$$r_1\,(\mathrm{V}) = 2.96 \text{ and } r_2\,(\mathrm{E}) = 0.20$$

Elucidation of Fine Structure. Fine structures of copolymers have been nicely characterized by means of the run number (R) concept proposed by Harwood.[24] R has been defined as the average number of monomer sequences (runs) occurring in the copolymer per 100 monomer units. According to the definition, R can be easily calculated by means of Eq. (2) because R equals the mole fraction of the V–E and E–V dyads. Hence

$$R_{\mathrm{obs}} = 2f(\mathrm{V-E}) = 2b/(2a+3b/2+c) \qquad (8)$$

In an ideally random copolymerization in the sense of Mayo-Lewis statistics of copolymerization, R should be expressed by the relationship[24]

$$R_{\mathrm{calc}} = 200/(r_1x+r_2/x+2) \qquad (9)$$

where x represents the monomer feed ratio. If R_{obs} is greater than R_{calc} the monomer units tend to alternate in the copolymer, and if R_{obs} is smaller than R_{calc} the monomer units tend to cluster in blocks of like units.

The mole fractions of the V–V and E–E dyads can be calculated by using the theoretical run number with the following equations.

$$f(\mathrm{V-V})_{\mathrm{calc}} = F(\mathrm{V}) - R_{\mathrm{calc}}/2 \qquad (10)$$

$$f(\mathrm{E-E})_{\mathrm{calc}} = F(\mathrm{E}) - R_{\mathrm{calc}}/2 \qquad (11)$$

In Fig. 6 are compared the observed and calculated mole fractions of the three dyads as a function of the monomer feed ratio. We see that the observed points fit well the calculated lines over the whole range of the monomer feed ratio. This indicates that the copolymerization initiated by the trialkylboron catalyst should be described as a random or zeroth-order Markoffian process.[25] This means that the rates of four propagation processes involved in the copolymerization depend only on the kind of terminal monomer unit (terminal model), and is in agreement with what has been found in most cases of radical copolymerization, though an exceptional case has been reported.[9]

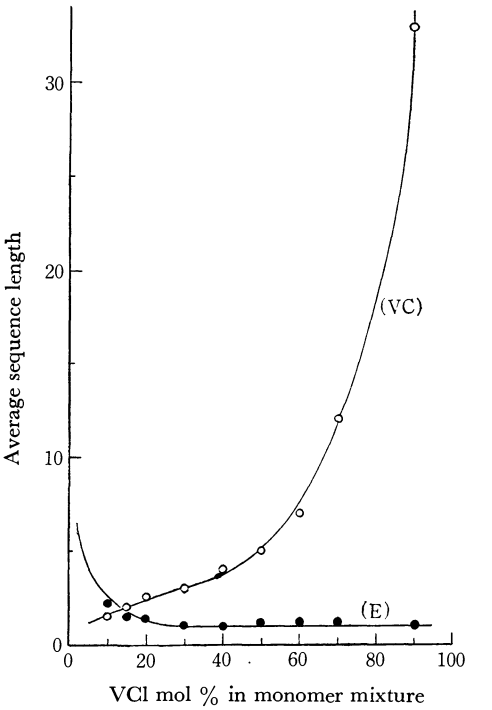

Fig. 7. Change in average sequence length as a function of monomer composition.

24) H. J. Harwood and W. M. Ritchey, *J. Polym. Sci.*, **B2**, 610 (1964).

25) F. P. Price, *J. Chem. Phys.*, **36**, 209 (1962).

Recently, the occurrence of the complexed radical propagation mechanism has been proposed by Arimoto[26] in order to elucidate the ineffectiveness of radical inhibitors on vinyl polymerization initiated by trialkylboron. Hydroquinone did not inhibit the reaction at all in our case of copolymerization either. In spite of this appreciable existence of complexed radical propagation, it might have only a little, if any, significance on the monomer reactivity ratios and the fine structure of the copolymer.

Figure 7 shows the observed and calculated average monomer sequence lengths as a function of the monomer feed ratio. The following relationships were used for the calculation.

$$\text{av. sequence length of } V = F(\mathrm{V})/R/2 \tag{12}$$

$$\text{av. sequence length of } E = F(\mathrm{E})/R/2 \tag{13}$$

where R is the observed or calculated run number.

The average sequence length of vinyl chloride unit decreases rapidly as the vinyl chloride fraction in the monomer feed decreases, whereas that of ethylene unit increases only slowly from unity according to the increase in ethylene fraction in the monomer feed. It seems interesting to note that the average sequence lengths of both monomer units reach *ca.* 2 when the copolymer composition approaches 50 : 50 molar ratio. As in the dyad distribution the observed average sequence lengths fit the calculated values.

Studies of the *N*-Oxides of *N,N*-Dialkylamino Acids. III. The Syntheses of *N,N*-Dimethyl Acidic Amino Acids and Related Compounds

Yoshikazu IKUTANI

Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka

(Received December 30, 1969)

In the previous papers of this series, the preparations of *N,N*-dimethyl neutral amino acid *N*-oxides,[1] and *N,N*-dialkylglycine *N*-oxides[2] were investigated. In the present studies, the preparations of *N,N*-dimethyl acidic amino acid *N*-oxides have been investigated. The *N,N*-dimethylations of acidic amino acids by catalytic reductive condensation with formaldehyde were performed by means of a procedure similar to that reported in the previous papers. The results obtained are summarized in Table 1.

The oxidations of *N,N*-dimethyl L- and DL-glutamic acid with a mixture of aqueous hydrogen peroxide and acetic acid gave the corresponding *N*-oxides in good yields after treatment as described in the previous paper. However, in the similar reaction of *N,N*-dimethyl-L-aspartic acid, the expected *N*-oxide could not be obtained with a similar treatment, rather, fumaric acid, the decomposition product of the corresponding *N*-oxide, was obtained in an almost pure state in a good yield. This type of decomposition is well-known as "Cope elimination".[3] Unfortunately, all attempts to obtain the corresponding *N*-oxide in the pure state were unsuccessful. The results obtained are summarized in Table 2.

When water was used instead of aqueous hydrogen peroxide in the above reaction, no reaction occurred under the same reaction conditions and the unchanged starting material was recovered.

TABLE 1. *N,N*-DIMETHYL ACIDIC AMINO ACIDS

Parent amino acid	Reduction period (50°C)	Yield (%)	Mp (°C)	R_f Value[a]	C%		H%		N%	
					Found	Calcd	Found	Calcd	Found	Calcd
L-Asp	7 hr	88	198	0.27	44.57	44.71	6.74	6.88	8.63	8.69
DL-Asp	7	89	195	—	44.74	44.71	6.84	6.88	8.68	8.69
L-Glu	6	89	196	0.36	47.87	47.99	7.56	7.48	7.84	8.00
DL-Glu	6	90	199	—	47.94	47.99	7.45	7.48	8.02	8.00

a) A 1-butanol-acetic acid-water (60:15:25) solvent system was used. The location of the paper chromatogram was detected by spraying 50% aqueous ethanol solution of bromophenol blue.

TABLE 2. OXIDATION PRODUCT OF *N,N*-DIMETHYL ACIDIC AMINO ACIDS

Starting amino acid	Oxidation period (60°C)	Yield of product (%)	Mp (dec.) (°C)	R_f Value[a]	C%		H%		N%		ν_{N-O} cm^{-1}

However, on prolonged heating at an elevated temperature, deamination occurred to afford dimethylammonium hydrogen fumarate.

A similar reaction partially occurred in the aqueous solution of *N,N*-dimethyl-L-aspartic acid, and dimethylammonium hydrogen fumarate and *N,N*-dimethyl-DL-aspartic acid were thus obtained in 42 and 40% yields respectively. *N,N*-Dimethyl-L-glutamic acid was not decomposed under similar conditions, but a complete racemization occurred.

Experimental

***N,N*-Dimethyl-L-glutamic Acid.** A mixture of 15 g of L-glutamic acid, 1.5 g of a silk-palladium catalyst, 50 m*l* of 37% aqueous formaldehyde, and 150 m*l* of water was shaken in an autoclave at 50—55°C for 6 hr. The catalyst was then removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. A small amount of paraformaldehyde was present in the product; it was removed by re-evaporation with water. The resulting solid was crude *N,N*-dimethyl-L-glutamic acid. It was collected, washed with acetone several times, and dried. The crude product was dissolved in a minimum volume of hot 50% aqueous ethanol, decolorized with a small amount of charcoal, and filtered. About the same volume of acetone was then added in small portions, and the mixture was stored in a refrigerator overnight. Fine crystals of *N,N*-dimethyl-L-glutamic acid were collected by filtration, washed with acetone, and dried under reduced pressure. The yield was 15.5 g (89%).

***N,N*-Dimethyl-L-glutamic Acid *N*-Oxide.** A mixture of 4.0 g of *N,N*-dimethyl-L-glutamic acid, 20 m*l* of 30% aqueous hydrogen peroxide, and 40 m*l* of acetic acid was warmed at 60°C for 8 hr. To the reaction mixture, about 50 m*l* of water was then added, after which the mixture was concentrated to about a half volume under reduced pressure while being gently warmed below 40°C. After this procedure had been repeated until the distillate gave a negative reaction to a potassium iodide starch test, the solution was evaporated to dryness under reduced pressure. The crude products were collected by filtration with a small amount of acetone, washed with acetone, and dried under reduced pressure. The crude *N,N*-dimethyl-L-glutamic acid *N*-oxide thus obtained was dissolved in a minimum volume of hot water, decolorized with a small amount of charcoal, and filtered. About the same volume of acetone was then added in small portions, and the mixture was stored in a refrigerator overnight. Fine crystals were then collected by filtration, washed with acetone, and dried under reduced pressure. The yield was 4.0 g (87%).

The Oxidation of *N,N*-Dimethyl-L-aspartic Acid. A mixture of 4.0 g of *N,N*-dimethyl-L-aspartic acid, 20 m*l* of 30% aqueous hydrogen peroxide, and 40 m*l* of acetic acid was warmed at 60°C for 7 hr. The reaction product was then treated in a manner similar to that in the experiment described in the case of *N,N*-dimethyl-L-glutamic acid. The residue thus obtained was fumaric acid in an almost pure state; it was collected by filtration with a small amount of cold water. The yield was 2.1 g (72%). (Found: C, 41.73; H, 3.47%.)

The Decomposition of *N,N*-Dimethyl-L-aspartic Acid with Aqueous Acetic Acid. A mixture of 4.0 g of *N,N*-dimethyl-L-aspartic acid, 20 m*l* of water, and 40 m*l* of acetic acid was heated on a boiling water bath for 24 hr. The residual solution was then dried up under reduced pressure. The residual syrup was dissolved in a small volume of water, and the solution was dried up under reduced pressure. This procedure was repeated twice; the residue was then solidified, collected by filtration with a small amount of acetone, and dried under reduced pressure. This substance was identified as dimethylammonium hydrogen fumarate by a comparison with an authentic sample prepared from equimolar fumaric acid and dimethylamine. The yield was 3.3 g (83%). (Found: C, 44.43; H, 6.82; N, 8.81%.)

The Decomposition and Racemization of *N,N*-Dimethyl-L-aspartic Acid in an Aqueous Solution. A solution of 5.0 g of *N,N*-dimethyl-L-aspartic acid in 100 m*l* of water was heated on a boiling water bath for 24 hr. The residual solution was then evaporated to dryness under reduced pressure. The residue was suspended in a small volume of ethanol, and the suspension was dried up under reduced pressure to remove a trace of water. This procedure was repeated twice; then the residue was collected by filtration with a small amount of acetone, washed with acetone, and dried under reduced pressure. The residue was extracted with a small amount of hot ethanol several times; *N,N*-dimethyl-DL-aspartic acid was thus separated as precipitates from the mixture because of its insolubility. The yield was 2.0 g (40%). (Found: C, 44.74; H, 6.84; N, 8.68%.) The extract was dried up under reduced pressure; 2.1 g (42%) of dimethylammonium hydrogen fumarate were thus obtained.

The Racemization of *N,N*-Dimethyl-L-glutamic Acid. A mixture of 4.0 g of *N,N*-dimethyl-L-glutamic acid, 20 m*l* of water, and 40 m*l* of acetic acid was heated on a boiling water bath for 20 hr. The residual solution was then treated in a manner similar to that used in the experiment described in the case of *N,N*-dimethyl-L-aspartic acid, The product thus obtained was *N,N*-dimethyl-DL-glutamic acid, weighing 3.8 g (95%). (Found: C, 47.87; H, 7.58; N, 8.10%).

The author is indebted to Professor Eizo Matsumura for his constant guidance in the course of the work, and to Professor Yoshiharu Izumi of Osaka University for his valuable advice and encouragement.

Cobalt(II) Complexes Containing Diacetylacetone and Its Thio Derivative

Akiko FURUHASHI

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Megurisawa, Setagaya-ku, Tokyo

(Received March 27, 1970)

The complex compounds of many metal ions containing β-diketones have already been synthesized and studied.[1,2] The metal complexes of thio-derivatives of β-diketones were reported first by Martin and Stewart.[3]

These thio-β-diketonates were obtained by passing hydrogen chloride and hydrogen sulfide through ethanol solutions containing acetylacetone and metal halide because of the difficulty of the isolation of dithioacetylacetone, which has a tendency to dimerize.

Diacetylacetone is also expected to form metal complexes as β-diketones. Moreover as it has three carbonyl groups in each molecule, it probably acts as both a bidentate and a tridentate ligand.

Sagara and his co-workers[4] reported on Cu(II) and Ni(II) chelates containing bidentate or tridentate diacetylacetone. It has also been reported that trithiodiacetylacetone can be synthesized and isolated by the reaction of diacetylacetone and phosphorus pentasulfide.[5] The present author has previously synthesized the Rh(III) and Pt(II) trithiodiacetylacetone complexes[6] from the metal salts and the ligand. As an extension of this work, although the attempts at the synthesis of the cobalt complexes of trithiodiacetylacetone have not yet been successful, the monothiodiacetonates were obtained.

In this paper the synthesis and properties of Co(II) complexes of $C_7H_{10}SO_2$ as well as of $C_7H_{10}O_3$ will be described.

Experimental

Starting Materials. The cobalt(II) chloride hexahydrate ($CoCl_2 \cdot 6H_2O$) and cobalt(II) bromide hexahydrate ($CoBr_2 \cdot 6H_2O$) of a G. R. Grade were used without further purification. The diacetylacetone (DAA) was synthesized from dehydroacetic acid by the method of Bethell and Maitland.[7] The trithiodiacetylacetone (TTDAA) was obtained by the method of Arndt[5] from DAA and phosphorus pentasulfide.

Syntheses of the Complexes. $Co(C_7H_{10}SO_2)_2X_2$: Powdered Co(II) halide hexahydrate and TTDAA were mixed (1 : 2 mole ratio) for 1 hr in an agate motor. During the procedure, the mixture turned green. The unreacted TTDAA was removed by washing with hot benzene. The crude product thus obtained was dissolved into chloroform, and the insoluble, unreacted cobalt halide was filtered off. The filtrate was concentrated using a rotary evaporator at about 50°C, and from the solution a green product was precipitated by adding

an equivolume of petroleum ether.

$Co(C_7H_{10}O_3)_2X_2$: $Co(C_7H_{10}O_3)_2X_2$ was similarly synthesized using cobalt halide hexahydrate and DAA. The product was blue.

Instruments. The magnetic moments of the compounds were measured by Gouy's method at room temperature (25°C). The infrared spectra were obtained on a KBr disk sample by using a Model IR-G infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. The electronic spectra were obtained with a Shimadzu MPS-50-type automatic recording spectrophotometer. The NMR spectra were obtained with a Hitachi Perkin-Elmer Model-R-20 NMR spectrometer.

Results and Discussion

The analytical data and magnetic moments are summarized in Table 1.

The magnetic data show that these compounds have magnetic moments of 4.5—4.8 B.M. In the case of cobalt(II) complexes, the magnetic moment of the tetrahedral form is found mostly in the 4.4—4.7 B.M. range, that of the octahedral form in the 4.7—5.2 B.M. range and that of the square-planar form in the 2.4—2.8 B.M. range, because of the orbital angular momentum contribution. In view of these facts, it is reasonable to conclude that the compounds are tetrahedral.

The infrared spectra data of the compounds are summarized in Table 2.

As there are almost no differences between the spectra of chloro and bromo complexes, the chlorine or bromine can be said not to have any serious effect on the vibrational frequencies in the complexes. Two strong characteristic bands which seem to be ν (C=O) appear near the 1962—1650 cm^{-1} range.

It is rather difficult to assign the ν (C=S) bands of these compounds. Barraclough[8] has reported that the ν (C=S) bands appear near 660—750 cm^{-1}; he based the conclusion on the results of the coordination analyses as well as on the experimental data of the metal dithioacetylacetonato complexes. As the 698 cm^{-1} band of the $Co(C_7H_{10}SO_2)_2X_2$ seems to correspond to the 740, 698 and 665 cm^{-1} bands of $C_7H_8S_3$, it is probably the ν (C=S) band or at least one containing ν (C=S), although the intensity of the band of the metal complexes was not so strong as that of the bands of $C_7H_8S_3$. This fact seems to indicate that the $Co(C_7H_{10}SO_2)_2X_2$ has only one C=S bond, as is also shown by the analytical data. As the shift of the ν(C=S) band by the formation of the coordination bond with the central metal is not extensive, the bond between sulfur and the metal atom in the complex seems not to be strong.

The findings regarding the NMR spectra also support the above conclusion. The NMR spectra of TTDAA in $CDCl_3$ (standard : TMS) shows four peaks, at 7.45, 6.84, 2.60, and 2.18 ppm; the ratio of the areas of the peaks was 1 : 1 : 3 : 3. This can probably be explained by the fact that TTDAA has a five-membered ring containing as S–S bond and a free C=S bond, as is shown by Fig. 1.

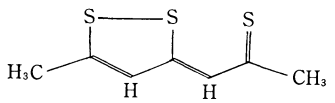

Fig. 1. Structure of TTDAA.

Therefore, both the methyl groups and the hydrogen atoms combined with 3rd and 5th carbon atoms are indifferent. The NMR spectra of both $Co(C_7H_{10}SO_2)_2X_2$ and $Co(C_7H_{10}O_3)_2X_2$ show only one peak, at about 2.58 ppm. Therefore, the two methyl groups of the ligand of the cobalt(II) compounds are symmetric; however, as these compounds are hardly soluble into $CDCl_3$, the peaks due to the hydrogen atoms bonding to the 3rd and 5th carbon atoms can not be deserved. The peaks of the latter hydrogen atoms were, however, found in the case of the DMF solution, 6.74 ppm for $Co(C_7H_{10}SO_2)_2X_2$ and 5.75 ppm for $Co(C_7H_{10}O_3)_2X_2$, although the effect of the solvent on the species may be a little different in this case. Consequently, in the case of $Co(C_7H_{10}O_3)_2X_2$, the central oxygen atoms of the ligand seem to bond with the cobalt atom, and in the case of $Co(C_7H_{10}SO_2)_2X_2$ the sulfur atom, which replaces the central oxygen atom of the $C_7H_{10}O_3$ ligand, is probably combined with the cobalt atom.

The electronic spectra of these compounds of a chloroform solution are summarized in Table 3.

The bands at about 38000—40000 cm^{-1} seem to be the π–π bands of the ligands. Trithiodiacetylacetonates of Cu(I) and Pt(II)[5] also show the band at 38000 cm^{-1}. Therefore, the band due to ligands moves to the lower wave number side as the number

of sulfur atoms in a ligand molecule increases.

The bands at about 22000—26000 cm^{-1} seem to be mixtures of d–d and d-π bands. Generally, tetrahedral cobalt(II) complexes have an intense band at about 15000 cm^{-1}. Although the solid compounds have an intense color, the solution of these compounds lost its intense color and turned pink rapidly. This is probably because the complexes decompose and change into octahedral complexes in such a dilute solution.

The results suggest that these compounds have a tetrahedral configuration and that the ligand works as a zero-valent monodentate in it. The structure shown in Fig. 2 is proposed for these compounds.

The author wishes to express her gratitude to Dr. A. Ouchi of The University of Tokyo for his frequent, stimulating, and helpful discussions. The author is also indebted to Mr. N. Tashiro for his assistance and to Professor Yasumasa Hayakawa and the staff of the Department of Chemistry of Aoyama Gakuin University for their encouragement.

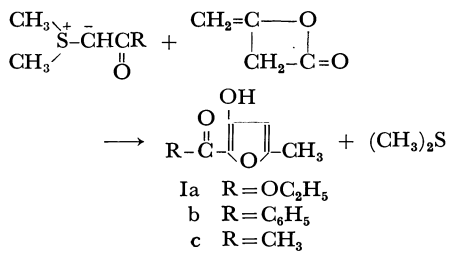
2-Hydroxy-3-oxo-2,3-dihydrofuran-2-carboxylic Ester: The Oxidation Product of 3-Hydroxyfuran-2-carboxylic Ester

Hisashi TAKEI and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 1, 1970)

In a preceding communication,[1] it was shown that carbonyl-stabilized sulfonium ylides reacted with ketene dimer to give 2-acyl-3-hydroxy-5-methylfurans in good yields. For example, the reaction of ethyl dimethylsulfuranilideneacetate with ketene dimer in THF in an atmosphere of nitrogen afforded ethyl 3-hydroxy-5-methylfuran-2-carboxylate (Ia), mp 49—50°C, in a 60% yield. In this case, the furan was purified by distillation and analytical sample was obtained by subsequent sublimation.



Ia R=OC_2H_5
b R=C_6H_5
c R=CH_3

It was found by the present experiment that when the reaction mixture was chromatographed over silica gel, colorless needles (IIa), mp 102—103°C, were isolated instead of Ia. Elemental analyses showed that IIa might be an oxidized product of Ia. Therefore, it is suggested that Ia was oxidized in the course of process for purification. Indeed, it was also found that the repetition of recrystallization from petroleum ether or the exposure of crystalline Ia to air for a long time resulted in the formation of IIa by air oxidation.

The structure of IIa was assigned to be ethyl 2-hydroxy-5-methyl-3-oxo-2,3-dihydrofuran-2-carboxylate, which is thought to be a cyclic hemiketal of III, on the basis of UV, NMR and IR spectra.

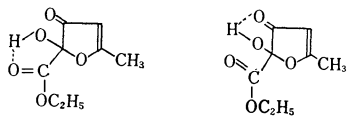
b R=C_6H_5
c R=CH_3

The UV spectrum of Ia in methanol showed a single peak at 265 mμ with εm 18000. Whereas, that of IIa in methanol gave εm 9200 at 269 mμ. This peak coincides with that reported[2] for 5-alkyl-3-oxo-2,3-dihydrofurans at 260—265 mμ with εm 8750—12200. The NMR spectrum has a singlet at 7.68 τ (3H, methyl), a triplet at 8.70 τ and a quartet at 5.65 τ (3H and 2H, ethyl ester) and a singlet at 4.43 τ (2H, furan nuclear proton and hydroxy proton). The last signal may be inadvertently superposed upon each other. The IR spectrum in KBr showed a band at 3170 cm^{-1} which suggested the presence of hydrogen bonding hydroxyl and three bands in carbonyl region at 1760, 1700 and 1600 cm^{-1} due to the carbonyl of five membered ring, hydrogen bonded ester carbonyl

1) H. Takei, M. Higo, K. Saito and T. Mukaiyama, This Bulletin, **41**, 1738 (1968).

2) R. E. Rosenkranz, K. Allner, R. Good, W. V. Philisborn and C. H. Eugster, *Helv. Chim. Acta*, **46**, 1259 (1963).

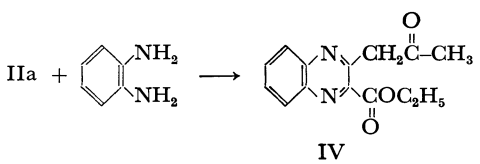
and carbon–carbon double bond, respectively. Whereas IIa in methylene chloride solution gave three peaks in carbonyl region at 1740, 1720 and 1600 cm^{-1} attributable to hydrogen bonded carbonyl, ester carbonyl and carbon–carbon double bond, respectively. These facts suggest that the IIa may exist as IIa′ in crystalline, whereas IIa″ in solution.



IIa′ IIa″

On the other hand, it was found that analogous furans such as Ib, the methyl ether of Ib, and Ic were stable towards air oxidation. Then these furans were treated with various oxidizing agents in order to obtain IIb and IIc. But, all attempts were unsuccessful and in the cases of Ib and of its methyl ether, benzoic acid was obtained as a main product.

Finally the reaction of IIa was tried with the expectation that it would be used as a useful intermediate in the field of synthetic chemistry. When IIa was allowed to react with *o*-phenylenediamine, ethyl 3-(2-oxopropyl) quinoxaline-2-carboxylate (IV) was obtained in a 69% yield.[3]



IV

3) In this connection, Lutz *et al.* have reported that 2-hydroxy-3-oxo-2,3-dihydrofuran, hemiketal of enol form of 1,2,4-triketone, reacts with *o*-phenylenediamine to give quinoxaline derivative. Condensed Pyridazine and Pyrazine Rings," Interscience Publishers Inc., New York (1953), p. 293.

Experimental

Reaction of Ethyl Dimethylsulfuranilideneacetate with Ketene Dimer. a) To a solution of ethyl dimethylsulfuranilideneacetate (1.48 g, 0.01 mol) in THF, ketene dimer (0.84 g, 0.01 mol) in the same solvent was added dropwise under ice cooling in an atmosphere of nitrogen. The reaction mixture was allowed to stand at room temperature for an hour and then was refluxed for 20 min. After removal of the solvent, the resulting dark brown syrup was distilled to give crude Ia (1.00 g, 60%), bp 80—90°C/2 mmHg, which solidified immediately. The analytical sample was obtained by the subsequent sublimation under reduced pressure, mp 49—50°C.

Found: C, 56.59; H, 5.93%. Cacld for $C_8H_{10}O_4$: C, 56.46; H, 5.92%.

b) When the dark brown syrup in the above experiment was submitted to silica gel column chromatography, semi-crystalline material was eluted by benzene-methylene chloride. The crystals were collected and recrystallized twice from cyclohexane with small amount of benzene to give colorless needles, IIa, (0.62 g, 33%) mp 100—103°C.

Found: C, 51.72; H, 5.25%. Calcd for $C_8H_{10}O_5$: C, 51.61; H, 5.41%.

Reaction of IIa with *o*-Phenylenediamine. A mixture of IIa (0.19 g, 0.001 mol), *o*-phenylenediamine (0.11 g, 0.001 mol) and two drops of acetic acid in ethanol was kept at room temperature for 2 days. After evaporation of the solvent, the residue was submitted to preparative thinlayer chromatography. When it was developed by ethyl acetate, pale orange crystals, IV, were obtained from the part of R_f value about 0.7—0.85, which were recrystallized from dilute alcohol, mp 86—87.5°C (0.18 g, 69%). The infrared spectrum (KBr) showed strong absorptions at 1740 (ester carbonyl) and at 1720 cm^{-1} (ketone).

Found: C, 64.87; H, 5.46; N, 10.92%. Calcd for $C_{14}H_{14}N_2O_3$: C, 65.10; H, 5.46; N, 10.85%.

An Acyl Migration with Oxalic Acid

Hideki KINOSHITA and Hiroshi KOTAKE

Faculty of Science, Kanazawa University, Kanazawa

(Received April 17, 1970)

In the past few years, the structures of a number of new antibiotics have been reported in the literature; all have had the common feature of a lactone that is formed from the carboxyl function of an amino acid and the hydroxyl group of a hydroxy-amino acid.

For the synthesis of these peptide lactone antibiotics, it is necessary to synthesize a chain that will include the desired ester bond. As a preliminary investigation for this purpose, we have first prepared an ester chain, namely, *O*-(*t*-butyloxycarbonyl-L-phenylglycyl)-*N*-benzyloxycarbonyl-L-threonine (I), which has already been reported by Ondetti and Thomas.[1)]

The coupling of *t*-butyloxycarbonyl-L-phenylglycine and *N*-benzyloxycarbonyl-L-threonine was carried out by the method reported by Ondetti and Thomas; then the reaction mixture was separated by Sephadex LH-20, using chloroform as the elution solvent. By this separation method, we easily obtained the desired ester chain as an oily substance, which was then crystallized as dicyclohexylammonium salt (II) by treatment with dicyclohexylamine in an acetone - hexane solution.

The values of the physical constant and the spectroscopic data of this dicyclohexylammonium salt (II) were identical with those of the dicyclohexylammonium salt of I reported in the literature.[1)] From this finding, it is obvious that the substance containing the ester bond obtained here was the compound I. For the purification of this salt, II, it was dissolved in acetone while being heated and then allowed to stand for several hours at room temperature; this gave crystals which melted at 154—155°C, but its IR spectrum showed that this product was not the ester-bond compound, but a compound resulting from the *O*,*N* acyl migration. This migration has also been seen when II was dissolved in chloroform or benzene without heating and allowed to stand at room temperature. We have assumed that this *O*,*N* acyl migration product was *t*-butyloxycarbonyl-L-phenylglycyl-*N*-benzyloxycarbonyl-L-threonine (III), which was obtained in this case as its dicyclohexylammonium salt (IV); this structure was confirmed by synthesis, as is shown in Fig. 3.

The salt IV was treated with equal moles of oxalic acid in acetone, and then the deposited ammonium salt of oxalic acid was filtered and the acetone was removed; this left an oily substance which was crystallized as its salt in a 96% yield by the addition of dicyclohexylamine. Since the

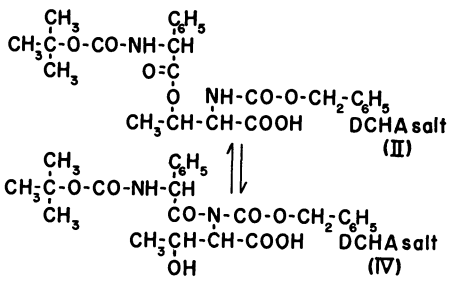

Fig. 2

IR spectrum of this salt was identical with that of the salt II, it is clear that the *N,O* acyl migration had occurred upon the treatment of the oxalic acid. Though the melting point and the specific rotation value of the salt obtained by the *N,O* acyl migration are higher than the values of the salt II, it is possible, in view of the value of specific rotation, that the purity of the former compound is slightly higher.

In the present case it was also found that the *N,O* acyl migration with oxalic acid did not affect the *N*-protecting *t*-butyloxycarbonyl- and benzyloxycarbonyl- groups and that no racemization occurred.

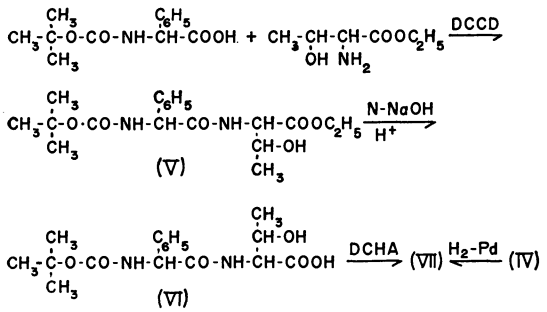

Fig. 3

t-Butyloxycarbonyl-L-phenylglycyl-L-theronine (VI) was prepared in the following way. *t*-Butyloxycarbonyl-L-phenylglycyl-L-threonine ethyl ester (V), obtained by the coupling of *t*-butyloxycarbonyl-L-phenylglycine and L-threonine ethyl ester in the presence of dicyclohexylcarbodiimide in acetonitrile, was hydrolyzed by 1N sodium hydroxide at room temperature to give VI. The dicyclohexylammonium salt of VI was found to be identical with the debenzyloxycarbonylation product of IV in melting point, IR spectra, and specific rotation value.

Experimental

***O*-(*t*-Butyloxycarbonyl-L-phenylglycyl)-*N*-benzyloxycarbonyl-L-threonine Dicyclohexylammonium Salt (II).** *t*-Butyloxycarbonyl-L-phenylglycine (920 mg, 3.5 mmol) and *N*-benzyloxycarbonyl-L-threonine (1.75 g, 3.5 mmol) and *N*-benzyloxycarbonyl-L-threonine (1.75 g, 7 mmol) were treated by the method reported in the literature.[1] The crude reaction product thus obtained showed two spots (R_f 0.79 and 0.41) on thin-layer chromatography. This mixture was separated by Sephadex LH-20, using chloroform as the elution solvent. The compound, with an R_f value of 0.41, which was shown to be the desired product, was isolated from acetone - hexane in the form of a crystalline dicyclohexylammonium salt. Yield, 640 mg (38%); mp 146.5—149°C; $[\alpha]_D^{21}$ +34.0° (*c* 0.838, DMF) (lit. mp 145—147°C; $[\alpha]_D^{28}$ +35.1°).

Found: C, 66.48; H, 8.08; N, 6.38%. Calcd for $C_{37}H_{53}O_8N_3$: C, 66.57; H, 7.95; N, 6.30%.

***t*-Butyloxycarbonyl-L-phenylglycyl-*N*-benzyloxycarbonyl-L-threonine Dicyclohexylammonium Salt (IV).** The salt II (76.8 mg, 0.114 mmol) was dissolved in hot acetone (1 m*l*) and then allowed to stand for several hours at room temperature. By the addition of hexane to this solution, crystals of IV were precipitated. Yield, 69.5 mg (90%); mp 154—155°C; $[\alpha]_D^{25}$ +41.1° (*c* 0.953, DMF).

Found: C, 66.22; H, 8.26; N, 6.51%. Calcd for $C_{37}H_{53}O_8N_3$: C, 66.57; H, 7.95; N, 6.30%.

Migration of IV to II with Oxalic Acid. To a solution of IV (188 mg, 0.282 mmol) in hot acetone (1 m*l*), we added oxalic acid-$2H_2O$ (35.5 mg, 0.282 mmol); the solution was then refluxed for 5 min and subsequently left standing for 2 hr at room temperature. A dicyclohexylammonium salt of oxalic acid thus deposited was filtered off, the mother liquor was removed *in vacuo*, and the residue was dissolved in ethyl acetate. After the filtration of an insoluble oxalic acid, the solvent was removed and the residual oil was again dissolved in 0.5 m*l* of acetone. To this solution dicyclohexylamine (0.05 m*l*) in hexane was then added. After a short time, crystalline salts were obtained. Yield, 181 mg (96.2%); mp 154—155°C; $[\alpha]_D^{25}$ +40.1° (*c* 0.983, DMF). The IR spectrum of this salt was identical with that of II, and a mixed-melting-point determination with IV was depressed to 151—152°C.

***t*-Butyloxycarbonyl-L-phenylglycyl-L-threonine Ethyl Ester (V).** *t*-Butyloxycarbonyl-L-phenylglycine (200 mg, 0.8 mmol) and L-threonine ethyl ester (117 mg, 0.8 mmol) were dissolved in acetonitrile (4 m*l*) and cooled at −3°C. A solution of dicyclohexylcarbodiimide (165 mg, 0.8 mmol) in acetonitrile (2 m*l*) was added, with stirring and cooling below −1°C; stirring was continued for 3 hr at −1°C and then for 7 hr at room temperature. The precipitate of dicyclohexylurea was filtered, and the filtrate was concentrated to dryness *in vacuo*. The oily product was dissolved in ethyl acetate; then the solution was washed with 3% hydrochloric acid, 3% sodium bicarbonate, and then with water, and dried over anhydrous sodium sulfate. The concentration of the solution *in vacuo* left a crystalline product which was recrystallized twice from ethyl acetate - petroleum ether. Yield, 170 mg (68%); mp 107—108.5°C; $[\alpha]_D^{20}$ +48.0° (*c* 1.03, abs. ethanol).

Found: C, 59.87; H, 7.45; N, 7.41%. Calcd for $C_{19}H_{28}O_6N_2$: C, 59.98; H, 7.42; N, 7.36%.

***t*-Butyloxycarbonyl-L-phenylglycyl-L-threonine (VI).** Into a solution of V (150 mg, 0.4 mmol) in ethanol (3 m*l*), 1N aqueous sodium hydroxide (0.4 m*l*, 0.4 mmol) was added with stirring. After the solution had stood at room temperature for 1.5 hr, 2 m*l* of water as

added to the reaction mixture and ethanol was removed *in vacuo*. The aqueous residue was treated with ethyl acetate, and the aqueous layer was adjusted to pH 3 to give an oily product. This product was extracted with ethyl acetate, and the solution was washed with water and dried over anhydrous sodium sulfate. The concentration of the solution *in vacuo* left a crystalline product (112 mg, 80%), which was subsequently recrystallized from ethyl acetate - petroleum ether. Yield, 98 mg (70%); mp 150—151°C; $[\alpha]_D^{26}$ +60.9° (*c* 1.04, abs. ethanol).

Found: C, 57.61; H, 6.77; N, 7.99%. Calcd for $C_{17}H_{24}O_6N_2$: C, 57.94; H, 6.87; N, 7.95%.

The dicyclohexylammonium salt (VII) of this compound (VI) was prepared in the usual way; mp 145—146°C; $[\alpha]_D^{25}$ +45.3° (*c* 1.03, DMF). No depression of the melting point was observed on admixture with the debenzyloxycarbonylation product of IV.

Nuclear Magnetic Resonance for the Pathway of the Reaction of *N*-Sulfinylanilines with Ethylene Oxide

Fukiko YAMADA, Tomihiro NISHIYAMA, Motokazu KINUGASA and Masayoshi NAKATANI

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka

(Received May 14, 1970)

The reaction of *N*-sulfinylanilines (I) with either ethylene carbonate or alkene oxides have been well studied in recent years. For example, Tsuge and his co-workers[1] reported that, in the presence of catalytic amounts of lithium halide, I reacted with ethylene carbonate at temperatures above 140°C to form the corresponding *N,N'*-diarylpiperazines (V). Etlis *et al.*[2] confirmed that, in the presence of NEt_4-Br, I reacted with alkene oxide at 95—100°C in sealed ampules to give 2-oxo-3-aryl-1,2,3-oxathiazolidines (III). Recently Deyrup and Moyer[3] have prepared several derivatives of III by reactions of β-amino alcohol with thionyl chloride in the presence of a base; the general structure of these compounds was determined by means of their NMR spectra. In these circumstances, we thought it desirable to study how the reaction of I with ethylene oxide (II) takes place in the absence of a catalyst and at a low temperature. In this paper, the reaction of I with II and the NMR data of the resulting products will be reported. The reaction scheme will also be discussed.

Experimental

The NMR spectra were obtained at 60 MHz with a Japan Electron Optics, Model JNM 3H-60, spectrometer. The chemical shifts were described in ppm downfield from the internal TMS (δ). The IR spectra were recorded on a Hitachi, Model EPI-2, grating spectrophotometer. The molecular-weight determination was made by a vapor-pressure osmometer, Hewlett Packard 302.

Materials. *N*-Sulfinylaniline (Ia), *N*-sulfinyl-*p*-toluidine (Ib), and *N*-sulfinyl-*p*-chloroaniline (Ic) were prepared and purified by the reported method.[4] II was of a commercially-available, pure grade and was dried by using a potassium hydroxide tube just before use. All the reagents used were of an analytical grade.

The Reaction of I with II. In a three-necked, 100-m*l* flask, 30 g of I was placed, the flask was then kept at a constant temperature. A constant flow of II (4.5 *l*/hr) was introduced into the reaction mixture throughout the reaction. The progress of the reaction was periodically checked by measuring the NMR spectrum of the reaction mixture. After the reaction had been completed and the excess II had been evaporated, a red-brown sirup remained. For the isolation of pure compounds from the mixture, the following two procedures were employed.

Procedure A. Fractionation of the Products. The above mixture (10—20 g) was chromatographed on 100 g of silica gel, using methylene chloride and methanol as eluents. Each eluate was examined by means of its NMR spectrum. The eluates which showed the same NMR spectra were combined and then evaporated *in vacuo*. The combined solutions (1, 2, and 3) were classified as follows: the initial eluate (1) was almost entirely composed of compound III, the middle one (2) contained mainly a resinous compound, IV, and the third one (3) gave small amounts of *N*-(2-hydroxyethyl)anilines (1—2 wt%). 2-Oxo-3-phenyl-1,2,3-oxathiazolidine (IIIa, 12 wt% yield) or 2-oxo-3-*p*-tolyl-1,2,3-oxathiazolidine (IIIb, 12 wt% yield) was obtained from the reaction of II with Ia or Ib. 2-Oxo-3-*p*-chloro-

phenyl-1,2,3-oxathiazolidine (IIIc) was not isolated from the reaction of Ic. IIIa and IIIb were purified by recrystallization from methylene chloride and *n*-hexane. The analytical results and melting points of IIIa and IIIb coincided with those of the compounds previously reported.[2] The resinous compounds, IVa, IVb, and IVc, were purified by rechromatography on silica gel. IVa: 78 wt% yield, mol wt 579, Found: C, 55.83; H, 6.26; N, 6.79; S, 11.01%. IVb: 71 wt% yield, mol wt 403, Found: S, 13.41%. IVc: 85 wt% yield, mol wt 485, Found: S, 12.31%.

Precedure B. Thermal Decomposition. The mixture described above was maintained at 160°C for about 1 hr under reduced pressure, and then it was extracted with benzene. The benzene extract was evaporated to give V as a solid. This was recrystallized from benzene to give colorless needles. *N,N'*-Diphenylpiperazine (Va, 73 wt% yield), *N,N'*-di-*p*-tolylpiperazine (Vb, 56 wt% yield), and *N,N'*-di-*p*-chlorophenylpiperazine (Vc, 78 wt% yield) were obtained from the corresponding reaction mixture by Procedure B. The analytical results and melting points of Va, Vb, and Vc coincide with those of the compounds previously reported.[1]

Results and Discussion

The Reaction Process. In the case of the reaction of Ia with II, the changes in the NMR spectra with the reaction time are shown in Fig. 1. The two-proton and three-proton multiplets due to the ring protons of Ia appear in the regions of 8.0—8.2 and 7.6—7.7 ppm respectively. These signals changed with the reaction time. Of these signals, the three-proton signal changed most remarkably as a result of the overlapping of the ring-proton signal of the reaction product. The two-proton signal gradually decreased, and it disappeared when the reaction was over. However, the two-proton signal does not overlap with any other signal. Therefore, the conversion of Ia can be determined by means of the data of the integrated two-proton

IVb	1190	m 3.3—4.5 (8.5H)*		m 6.6—7.5	s 2.4
IVc	1133	m 3.0—4.8 (9.3H)*		m 6.5—7.8	

( )*: proton numbers

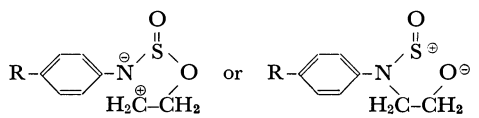
spectrum. The methylene-proton signal of II exhibits a singlet peak at 2.68 ppm. In the earlier stage of the reaction, new signals were observed in the region of 3.3—5.3 ppm and gradually increased with the reaction time. These signals consist of two parts; one (Region A) is in the region of 4.6—5.3 ppm, and the other (Region B) in the region of 3.3—4.3 ppm. The proton numbers of the signal in the A or B region can be evaluated by comparing the data of the integrated signal with those of the signals due to the phenyl protons, which are unchanged by the reaction. Plots of the conversion *versus* the reaction time and of the proton numbers in the A or B region against the time are shown in Figs. 2 and 3 respectively. The NMR data of III and IV are shown in Table 1, and the chemical shifts in the A and B regions are shown in Table 2.

Table 2. NMR data (δ) of the regions A and B

Reaction of II with	Region A	Region B
Ia	4.6—5.3	3.3—4.3
Ib	4.5—5.4	3.2—4.5
Ic	4.7—5.4	3.3—4.7

By comparing the NMR data of IIIa and IVa with those in the A and B regions, the signals in the regions can be assigned to the methylene groups of the oxathiazolidine ring produced by the reaction. The methylene proton numbers in the B region increased with the reaction time up to about 7 (Fig. 3). These facts may indicate, therefore, that the expansion of the oxathiazolidine ring is caused by the insertion of either II or IIIa into the ring.

Probable Mechanism. On the basis of the results presented above, the probable reaction pathway is that shown in Chart 1. The reaction proceeds gradually after an induction period (Figs. 2 and 3). The intermediate A may be expected to be formed in this induction period.



Intermediate A

The authors wish to thank Miss H. Nishikawa, the micro analytical laboratory of this department and the staff of the Research Laboratories, Fujisawa Pharmaceutical Co., Ltd. for the elementary analyses.

The Reaction of Nitric Oxide with Rhodium Complexes

Jitsuo KIJI, Susumu YOSHIKAWA and Junji FURUKAWA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received June 8, 1970)

There has been considerable interest in recent years in the preparation of d^8 complexes because of their significance in oxidative addition and their potentiality in catalysis. The formation and properties of the carbonyl complexes of rhodium have been studied extensively.[1] On the other hand, there have been few reports on the reaction of nitric oxide. Nitric oxide is unique among ligands in that it contains an unpaired electron. The present work stems from our interest in expanding the scope of rhodium complexes by reaction with nitric oxide. Recently Hughes has reported a reaction between nitric oxide and square-planar rhodium complexes of the $RhClL_3$ type to produce nitrosyl-nitro derivatives, $RhCl(NO)(NO_2)L_2$.[2] Both triphenylphosphine and triphenylarsine derivatives exhibit two infrared absorption bands in the N–O stretching region; this splitting is attributed to the presence of isomers.[2] This report prompted us to reveal the results of our own investigation.

This paper deals with the isolation of two nitrosyl complexes. We conclude that the lower band in the N–O stretching region can be assigned to a polymeric nitrosyl complex. Furthermore, we report here about the replacement of the nitrosyl group by carbon monoxide and about the reaction of a diphosphine complex with nitric oxide.

Experimental

Reaction of Nitric Oxide with $RhCl(PPh_3)_3$. Nitric oxide was introduced into 20 m*l* of a benzene solution containing 200 mg of $RhCl(PPh_3)_3$ and 500 mg of triphenylphosphine at room temperature over a 20-min period. The color of the solution thus changed from brown to green. The evaporation of the benzene and subsequent washing with ether gave 123 mg of $RhCl(NO)(NO_2)(PPh_3)_2$. IR: 818, 1310, 1415 (due to NO_2 group), and 1660 cm^{-1} (ν_{NO}).

Found: C, 59.27; H, 4.65; N, 2.95%; mol wt, 718. Calcd for $RhC_{36}H_{30}N_2O_3P_2Cl$: C, 58.52; H, 4.09; N, 3.78%; mol wt, 738.9.

Attempted Isolation of Complex I. A green solution, prepared by the method which has been described above except that triphenylphosphine was added, gradually formed a brown precipitate in a low yield. It was sparingly soluble in organic solvents. IR: 1635 cm^{-1} (ν_{NO}). The average values obtained from two sets of analyses are as follows: C, 56.74; H, 4.48; N, 4.02%.

Reaction of Carbon Monoxide with $RhCl(NO)(NO_2)(PPh_3)_2$. Into 20 m*l* of a benzene solution containing $RhCl(NO)(NO_2)(PPh_3)_2$, prepared from 200 mg of $RhCl(PPh_3)_3$ and 500 mg of triphenylphosphine as has been described above, carbon monoxide was introduced at room temperature over a 60-min period. The addition of ether to the concentrated solution gave 110 mg of a yellow solid, which was identified with $RhCl(CO)(PPh_3)_2$ on the basis of its mp and IR spectrum.

Reaction of Nitric Oxide with $RhCl(CO)(Ph_2PCH_2CH_2PPh_2)$. The treatment of 10 m*l* of a benzene solution containing 77 mg of $Rh_2Cl_2(CO)_4$ with 157 mg of bis(diphenylphosphino)ethane at room temperature for 3 hr gave 195 mg of $RhCl(CO)(Ph_2PCH_2CH_2PPh_2)$,*1 which had an IR absorption band due to ν_{CO} at 2000 cm^{-1}. Nitric oxide was introduced into 5 m*l* of a benzene solution containing 30 mg of the complex at room temperature. Yellow-green $RhCl(NO)(NO_2)(Ph_2PCH_2CH_2PPh_2)$ (25 mg) was thus precipitated from the solution. IR: 825, 1315, 1385 (due to NO_2 group) and 1655 cm^{-1} (ν_{NO}).

Found: C, 50.18; H, 4.49; N, 3.93%. Calcd for $RhC_{26}H_{24}N_2O_3P_2Cl$: C, 50.96; H, 3.94; N, 4.56%.

Results and Discussion

The reaction of $RhCl(PPh_3)_3$ or $RhCl(CO)(PPh_3)_2$ with nitric oxide proceeded smoothly at room temperature. When the benzene solution of $RhCl(PPh_3)_3$ or $RhCl(CO)(PPh_3)_2$ was treated with nitric oxide, a green solution was obtained. The evaporation of the benzene gave a green solid with infrared absorption bands at 1660 and 1635 cm^{-1}*2 ascribed to ν_{NO}. When the benzene solution was allowed to stand at room temperature under a nitrogen atmosphere, a dark brown complex (1) involving a band at 1635 cm^{-1} due to

1) J. A. Osborn, F. H. Jardine, J. F. Young and G. Wilkinson, *J. Chem. Soc., A*, **1966**, 1711.

2) W. B. Hughes, *Chem. Commun.*, **1969**, 1126.

*1 When the diphosphine complex (obtained from 55 mg of $Rh_2Cl_2(CO)_4$ and 110 mg of bis(diphenylphosphino)ethane) was allowed to stand in benzene at room temperature for 2 weeks, a yellow solid (30 mg) was separated out; this was identified with $[Rh(Ph_2PCH_2CH_2PPh_2)_2]Cl$. The evaporation of the benzene from the filtrate gave orange needles, which were identical with $Rh_2Cl_2(CO)_4$. These data suggest that the following reaction occurs:

$$2\,RhCl(CO)(Ph_2PCH_2CH_2PPh_2) \rightarrow [Rh(Ph_2PCH_2CH_2PPh_2)_2]Cl + 1/2\,Rh_2Cl_2(CO)_4$$

*2 W. D. Hughes has reported 1666 and 1640 cm^{-1} for ν_{NO}.

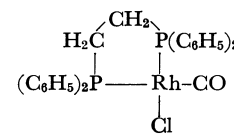
ν_{NO} gradually precipitated. No reliable information could be obtained on this complex because of the difficulty of purifying it. A reasonable formulation for I is, however, as a dimeric or polymeric nitrosyl complex involving bridging chlorine. We base this on the following facts: (1) I is sparingly soluble in organic solvents, (2) its formation is suppressed by the presence of an excess of triphenylphosphine (see below), and (3) there is no band due to the nitro group.

The reaction of nitric oxide with $RhCl(PPh_3)_3$ in the presence of an excess of triphenylphosphine led to a green, air-stable complex (II). The infrared absorption spectrum (KBr) showed a single nitrosyl band at 1660 cm^{-1} and the band assignable to the nitro group. Elemental analysis and molecular-weight measurement support the $RhCl(NO)(NO_2)(PPh_3)_2$ formula. Thus, an excess of triphenylphosphine can be used to prevent the formation of the polymeric nitrosyl complex (I) with the N–O stretching band at 1635 cm^{-1} and a nitrosylnitro complex (II) free from I can be obtained.

On treating a solution of a mixture of I and II with carbon monoxide, the nitrosyl (ν_{NO} at 1660 cm^{-1}) and the nitro groups were replaced by carbon monoxide than that in I. The displacement of the nitrosyl group in I by carbon monoxide was only possible when I was treated under pressure. A carbonyl complex formed from I had, however, an infrared absorption band due to ν_{CO} at 1985 cm^{-1} (KBr).

An attempt to reduce the coordinated nitrosyl group in I or II with molecular hydrogen was unsuccessful.

The reaction of nitric oxide with the diphosphine complex proceeded similarly at room temperature. The following formulation of $RhCl(CO)(Ph_2PCH_2CH_2PPh_2)$ is envisaged:



since the carbonyl group absorbs at 2000 cm^{-1}.[3-5] The treatment of the solution of $RhCl(CO)(Ph_2PCH_2CH_2PPh_2)$ in benzene with nitric oxide gave a yellow-green complex. The infrared spectrum showed a band at 1655 due to ν_{NO} and nitro-group bands at 1385, 1315, and 825 cm^{-1}. On the basis of the infrared spectrum and the elemental analysis, the complex may be formulated as $[RhCl(NO)(NO_2)(Ph_2PCH_2CH_2PPh_2)]_n$. The insolubility of this complex supported a dimeric or polymeric formulation involving a bridging diphosphine molecule. In contrast to the triphenylphosphine derivative, the diphosphine derivative exhibits only one band in the N–O stretching region.

The Influence of the Number of Sulfur Atoms on the PMR Chemical Shifts in Aryl Polysulfides

Tamotsu FUJISAWA and Gen-ichi TSUCHIHASHI

Sagami Chemical Research Center, Ohnuma, Sagamihara-shi, Kanagawa

(Received June 15, 1970)

The proton magnetic resonance for sulfur compounds has received major study.[1] But limited information for aromatic proton signals has been offered among aromatic sulfur derivatives because the aromatic signals were generally complex.[2] A number of aromatic sulfur compounds have been synthesized in our laboratory on the study of iron-catalyzed aromatic sulfuration.[3] During the course of the study, the aromatic proton signals are found to be influenced by increasing the sulfur chain length in the compounds. In this paper, the results of such observation and discussion for them are reported.

The ortho protons to sulfur atoms of aryl poly-

sulfides vary their PMR chemical shifts to lower field with increase of the number of the sulfur atoms. As shown in Tables 1 and 2, the number of the sulfur atoms exerts a considerable effect on the chemical shifts of H_a protons of anisole and phenetole derivatives in contrast with that of H_b. The slight shift of alkoxyl protons toward lower field was also observed. The similar effect of polysulfide linkage has already been reported in aliphatic series by Van Warzer and Grant,[4] although their data fit to an approximation based on the theory for the "neighbor anisotropy effect". The observation of the same tendency between aromatic and aliphatic protons is interesting because they often exist in different electronic circumstances. For example, in *p*-methoxyphenyl methyl sulfide, the signal for S-methyl protons (δ=2.36) appears at higher field than that for O-methyl protons (δ=3.70), but the situation is reverse in the chemical shift of ortho ring protons to oxygen (δ=6.69) and that to sulfur (δ=7.14). This is reasonably explained by inductive effect in aliphatics and by mobile π-electron system in aromatics. The chemical shift of the O-ortho protons moves considerably to higher field than that of benzene by electron releasing resonance by oxygen, whereas the signal of the S-ortho protons appears at about the same position of that of benzene because the conjugation between the ring and sulfur is suggested to be relatively small. In general, chemical shifts of ortho protons of substituted benzene ring are known to shift by influence of π-electron density and of anisotropy and/or inductive effect of the substituents.[5]

Signals for neighboring protons to electron-withdrawing group shift to lower field with the inductive order as shown in sulfide-sulfoxide-sulfone series (Table 1 and Ref. 6). Accordingly, it is reasonably assumed that as number of sulfur atoms in the polysulfide series increases, the strength of inductive effect becomes more intense. It is noteworthy that the same tendency has been also observed in the ultraviolet absorption spectra of di-*p*-tolyl polysulfides, in which as number of sulfur atoms increases, the shift toward the shorter wavelength occurs in primary band attributable to benzene ring and the absorbance becomes more intense.[7] This phenomenon suggests that the electron density of the benzene ring decreases by the localization of the electron to the center of polysulfide linkage with increasing chain length of sulfur atoms, coupled with the fact that the shift toward the longer wavelength occurs in secondary band attributable to linear sulfur–sulfur linkage. In other words, this is due to the electron-withdrawing effect of polysulfide linkage and strongly supports above inductive effect by polysulfide group.

A remarkable example of this tendency is found in the chemical shifts of thiobis(2,6-di-*t*-butylphenol) series as shown in Table 3. These chemical shifts of the ortho ring protons are particularly suited for the quantitative analyses of the mixture of the polysulfides with their integration ratio because independent singlet peaks for these absorptions can be assigned clearly.

As shown above, the data of the chemical shifts for polysulfides can be explained in terms of the inductive effect of polysulfide linkage, but a system illustrative of anisotropy effect was also observed. The chemical shifts of ortho protons of various

aromatic sulfur compounds are shown in Table 4. Of particular interest in the Table is sulfenyl chloride-thiosulfenyl chloride series. The chemical shifts in phenyl, *p*-tolyl and *p*-chlorophenyl derivatives move toward higher field as the number of sulfur atoms increases, which makes a marked contrast to the lower-field shift in polysulfide series. This tendency has been reported in methanesulfenyl chloride series.[4] This can be also explained in terms of the inductive effect attributable to the polarization of sulfur-chlorine bond as shown by $\overset{\delta+}{S}—\overset{\delta-}{Cl}$. On the other hand, the lower field shift was observed in ortho substituted benzenesulfenyl chloride series, which is accounted for by the anisotropy effect of sulfur-chlorine atoms because distance between the ortho ring proton and chlorodithio group becomes more close by the buttressing effect of ortho substituents. However, the chemical shifts in *p*-nitrophenyl derivatives move toward lower field with increasing chain length of sulfur atoms. This fact does not fit above explanation. The reason may be as follows: the ring protons may be affected mainly by anisotropy effect of chlorodithio group rather than by the inductive effect of chlorodithio group because strong electron-withdrawing effect of nitro group overshadows the inductive effect.

In summary, the above mentioned dependence of the chemical shifts of the aromatic protons on the chain length of polysulfide linkage, gives important informations for the qualitative and quantitative analyses of aromatic sulfur compounds by NMR.

Experimental

Materials. All known sulfur compounds used in this experiment were prepared by known methods or simple modifications thereof. 4,4′-Tetrathiobis(2,6-di-*t*-butylphenol) was prepared from the corresponding thiophenol and sulfur chloride, mp 106—107°C; found S, 23.52%, calcd S, 23.76%. Substituted benzenethiosulfenyl chlorides were prepared from corresponding thiophenols and sulfur dichloride. Bp (mp) and elementary analyses of sulfur (calcd.) of new thiosulfenyl chlorides are: 2,4-di-NO_2, (73—75°C), 23.66% (24.02%); 4-NO_2, (35—37°C), 29.03% (28.96%); 2-Cl, 77—79°C/0.2 mmHg, 29.97% (30.33%); 4-Cl, 73—74°C/0.08 mmHg, 30.12% (30.33%); 2-CH_3, 76—77°C/0.2 mmHg, 33.23% (33.60%); 4-CH_3, 67—68°C/0.1 mmHg, 34.07% (33.60%).

Measurement of the NMR. The PMR spectra were determined with a Varian HA-100 instrument. All the spectra without note were measured in carbon tetrachloride at a concentration of 10% (w/v) at room temperature with tetramethylsilane as an internal standard and the peak positions were expressed in δ-values.

The authors are grateful to Mr. Ken-ichi Sato for the measurement of the NMR spectra. Acknowledgement is made to Messrs. Mizuo Yamamoto and Takeo Kobori, and to Mrs. Noriko Ohtsuka for their assistances in the preparation of the samples.

The Magnetic Susceptibility of the 1,3-Bis-(4-methylphenyl)-5-phenyl-verdazyl Radical from 1.55 to 300°K

Kazuo MUKAI, Nagao AZUMA and Kazuhiko ISHIZU

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama

(Received June 20, 1970)

Recently, the magnetic properties of several species of stable crystalline neutral radicals, including hydrazyl,[1] nitroxide,[2] and phenoxyl[3] radicals, were reported. On the other hand, the verdazyls, a series of very stable neutral radicals containing four nitrogen nuclei, were previously studied by Kuhn, Neugebauer, and Trischmann.[4,5] However, the magnetic properties of the verdazyls have never been studied except for the preliminary susceptibility measurements, which showed the presence of one unpaired electron per molecule. We wish to describe here the magnetic susceptibility of a verdazyl radical in the temperature range from 1.55 to 300°K; this radical has the structure shown in Fig. 1.

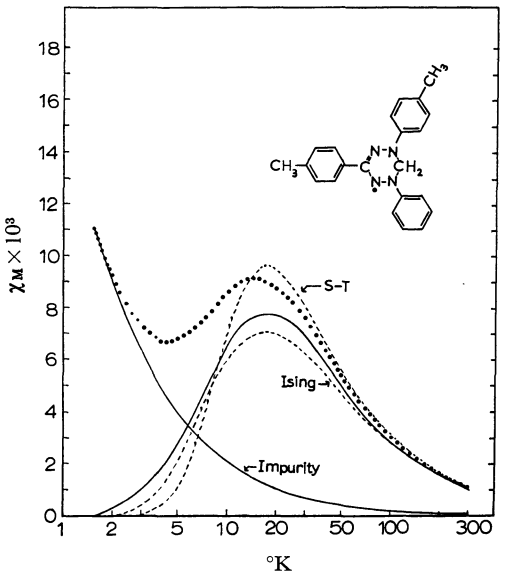

Fig. 1. Paramagnetic molar susceptibility of 1,3-Bis(4-methylphenyl)-5-phenyl-verdazyl radical. The "full circle" curve is the experimental curve. The "impurity" curve is an extrapolation of the low-temperature Curie-Weiss data. The solid line curve is the difference between experimental and impurity curves. The dashed curves are theoretical fits as explained in the text.

Experimental

1,3-Bis-(4-methylphenyl)-5-phenyl-verdazyl was prepared from the corresponding formazan by ring formation with formaldehyde, following the same process as that of Kuhn *et al.* After recrystallizing two times from methanol, a deep green crystalline compound, mp 116.0—116.3°C, was obtained.

The susceptibility measurements were carried out in the continuous temperature range between 1.55°K and 300°K, using a magnetic torsion balance on powder samples of about 100 mg in a heterogeneous magnetic field up to about 10 koe.[6]

Results and Discussion

The measured molar paramagnetic susceptibility, χ_p, shown in Fig. 1 as a function of the temperature, has been corrected for the diamagnetic contribution of $\chi_{dia} = -0.200 \times 10^{-3}$ emu/mol calculated by Pascal's method. Between 30°K and room temperature χ_p follows the Curie-Weiss law, with a Weiss constant of $\theta = -14.6 \pm 0.4$°K and a spin concentration of 93.9%. When the temperature is lowered from 30°K, the $\chi_p - T$ curve gradually deviates from the Curie-Weiss law and reaches a broad maximum at 14.2 ± 0.5°K. After passing through the maximum, χ_p falls off slowly till 4°K. However, below 4°K the susceptibility increases again as the temperature is lowered. In the region from 1.55°—1.8°K, the Curie-Weiss law was observed, corresponding to a spin concentration of 5.8% and a Weiss constant of -0.4 ± 0.1°K. When this low-temperature paramagnetic impurity curve

is extrapolated to higher temperatures and substracted from the experimental curve observed there, the corrected curve shown in Fig. 1 is obtained. The experimental curve has a general appearance very similar to that found in many organic free radical and radical salts; thus, the unpaired electrons on the verdazyl molecules also appear to be paired up by an negative exchange interaction.

In order to account for the experimental data on the verdazyl radical, we shall examine two typical models, that is, the singlet-triplet model[7] and the linear Ising model.[8]

In the singlet-triplet model (Case I), the susceptibility is given by:

$$\chi_p = \frac{N_0 g^2 \beta^2}{kT} \cdot \frac{1}{3+e^{\delta/kT}}$$

where δ is the singlet-triplet energy separation and equals to $2|J|$, and where N_0 is Avogadro's number. The other subscripts have the usual meanings.

In the linear Ising model (Case II), the susceptibility is expressed by:

$$\chi_p = \frac{N_0 g^2 \beta^2}{4kT} e^{J/kT}$$

The values of the exchange energy, J, in both models are determined from the temperature, T_{max}, at which the corrected susceptibility shows a maximum, by using the relations $J=-0.81kT_{max}$ for case I and $J=-kT_{max}$ for case II. Taking this temperature as 17.0°K, the values of J are estimated to be 9.5 cm^{-1} (Case I) and 11.8 cm^{-1} (Case II) respectively. The theoretical curves require multiplication by a constant p if they are to be compared with the experimental data. Thus, with $p=0.881$, the two theoretical curves can be fitted to the experimental data.

Figure 1 indicates that the linear Ising model gives rather a better fit with the observed susceptibility of the verdazyl. A good agreement may be obtained if Soos's alternating parameter is taken into account.[9]

The authors are much obliged to Professors H. Takaki and Y. Deguchi, and Drs. M. Mekata and H. Nishiguchi of Kyoto University for magnetic susceptibility measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3619—3620 (1970)

A Convenient Method for the Synthesis of Nucleoside Phosphorothioates

Tsujiaki HATA and Iwao NAKAGAWA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo, Japan

(Received July 4, 1970)

Recently, interest in polymers of nucleoside phosphorothioates was caused by strong induction effect of interferon[1] production. Eckstein[2] first prepared thymidine- and uridine-phosphorothioates by way of thiophosphorylation using tri-imidazoyl-1-phosphinesulfide and reported the enzymatic activities of dinucleoside phosphorothioates. Murray and Atkinson[3] synthesized adenosine 5′-phosphorothioate and tested the activity for some enzymes as a nucleotide analog.

In the present experiment, a general synthetic procedure for the preparation of nucleoside 5′-phosphorothioates starting from nucleoside and thiophosphoryl chloride, which is a readily available and inexpensive starting material, was investigated. For example, one equivalent of 2′,3′-*O*-isopropylidene uridine was allowed to react with two equivalent of thiophosphoryl chloride in dry pyridine at 0°C for 30 min. After hydrolysis of the resulting mixture under cooling, 2′,3′-*O*-isopropylidene uridine 5′-phosphorothioate was obtained in 85% yield. The structure was confirmed by elemental analysis, paper electrophoresis and UV spectrum.

In a similar manner, various nucleoside 5′-phosphorothioates were prepared in high yields as shown in Table 1.

It was found that phosphorothioate group was detected sensitively on paper chromatogram as a

3′-*O*-acetyl thymidine	1.42	83	0.18***

* Paper chromatography was carried out by descending technique using Toyo Roshi No. 51 paper. Solvent system used was: isopropyl alcohol-concentrated ammonium hydroxide-water (7 : 1 : 2 *v/v*).
** The reaction time was 1 hr.
*** The R_f value shows that after removal of protecting group.

brownish spot by spraying 10% aqueous copper(II) sulfate solution. It was further detected by Isherwood Reagent.[4]

In the above reactions, it was found that the yields of nucleoside 5′-phosphorothioates considerably decreased when just one equivalent of thiophosphoryl chloride was used, or when the reaction was carried out without ice-cooling.

In conclusion, it is noted that this procedure has two advantageous points over the previous method, namely, (1) satisfactory yields are obtained with respect to various nucleosides, (2) products can be handled by conventional organic technique on a relatively large scale without using column chromatography as described in the experimental part.

Experimental

Materials. 2′,3′-*O*-Isopropylidene adenosine,[5] 2′,3′-*O*-isopropylidene inosine,[6] 2′,3′-*O*-isopropylidene guanosine,[7] 2′,3′-*O*-isopropylidene uridine,[8] 2′,3′-di-*O*-benzoyl uridine[9] and 3′-*O*-acetyl thymidine[10] were prepared by literature procedures.

Preparation of Protected Nucleoside 5′-Phosphorothioate. *(A general procedure).* To a solution of freshly distilled thiophosphoryl chloride (1 m*l*, 10 mmol) in 25 m*l* of dry pyridine was added, portionwise, a protected nucleoside (5 mmol) (see Table 1) with stirring at 0°C. The stirring was continued for 30 min under cooling. Then, the reaction mixture was poured with stirring into 50 m*l* of ice water. After the addition of 5 m*l* of triethylamine (*ca.* 92 mmol), the resulting aqueous solution was concentrated under reduced pressure at a temperature below 30°C until white crystals appeared. The crystals, triethylammonium chloride, was filtered off by using Toyo Roshi No. 131 paper (for fine precipitates) and the filtrate was concentrated to dryness. The residual oil was still contaminated by triethylammonium chloride and then it was diluted with dry pyridine. The precipitate was filtered off by the No. 131 paper, and the filtrate was concentrated to dryness. The corresponding nucleoside phosphorothioate was isolated as triethylammonium salt by means of either method A or method B. Uridine- and thymidine-phosphorothioates were obtained according to method A and the other nucleoside phosphorothioates, such as adenosine, guanosine and inosine derivatives were isolated by method B.

Method A. The syrup was dissolved in 100 m*l* of dry chloroform and it was allowed to stand overnight in a refrigerator. Triethylammonium salt of inorganic thiophosphate was successively precipitated. After removal of the salt by centrifuge, (if the resulting supernant was a slightly cloudy solution, it should be again filtered by the No. 131 paper) the chloroform was removed by evaporation. Mono-triethylammonium salt of 2′,3′-*O*-isopropylidene uridine 5′-phosphorothioate (2.05 g, 4.26 mmol) was obtained in 85% yield (based on 2′,3′-*O*-isopropylidene uridine) as white powder.

Found: C, 44.43; H, 5.80; N, 8.48; S, 6.98%. Calcd for $C_{18}H_{32}N_3O_8PS$: C, 44.87; H, 6.65; N, 8.72; S, 6.65%. Ratio uridine : phosphorus, Found: 1.00 : 0.93. Required: 1 : 1.

Method B. The syrup was dissolved in 100 m*l* of isopropyl alcohol. A white precipitate soon appeared in the solution. The precipitate was collected by filtration. Mono-triethylammonium salt of 2′,3′-*O*-isopropylidene guanosine phosphorothioate (2.31 g, 4.44 mmol) was obtained in 89% yield (based on 2′,3′-*O*-isopropylidene guanosine) as white powder. Repeated reprecipitations by means of isopropyl alcohol and a small amount of methanol afforded white powder for analytical sample.

Found: C, 41.90; H, 5.90; N, 16.29; S, 6.25%. Calcd for $C_{19}H_{33}N_6O_7PS$: C, 43.85; H, 6.35; N, 16.15; S, 6.14%. Ratio guanosine : phosphorus, Found: 1.00 : 0.99. Required: 1 : 1.

We heartily thank Professor Dr. Teruaki Mukaiyama for his encouragement and discussion throughout the investigation. We also wish to thank Mr. Masaru Koezuka for his help with elemental analysis.

Photolysis of Acetylene at 1849 Å

Masao TSUKADA and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received July 17, 1970)

The direct photolysis of acetylene produces mainly diacetylene, benzene, and solid polymers. For the formation of benzene, Zelikoff and Aschenbrand[1] suggested an excited-molecule mechanism. Meanwhile, for the mercury photosensitization both the the free radical mechanism[2,3] and the modified excited-molecule mechanism[4] were proposed and final agreement has not yet been attained. The present work was undertaken as a re-examination of the reaction mechanism of the direct photolysis.

Experimental

Preparation, purification and purity of acetylene, acetylene-d_2, and nitric oxide were similar to those described before.[5] The light source was a low-pressure mercury resonance lamp. The reactant was circulated through a closed loop system (volume=680 m*l*). Total pressure change was measured with a Bourdon gauge. Special precaution was taken to keep the vacuum line free of mercury. The products were analyzed by gas chromatography (dioctyl phthalate column at 80°C). The analytical method of isotopically substituted benzenes was the same as that used before.[5]

Results and Discussion

Figure 1 shows the pressure dependence of the rates of the major products. The distinct differences between the mercury-photosensitized reaction[5] and the direct photolysis are that diacetylene is one of the major products and that the pressure dependence curves of benzene and of polymer have no maximum in the direct photolysis.

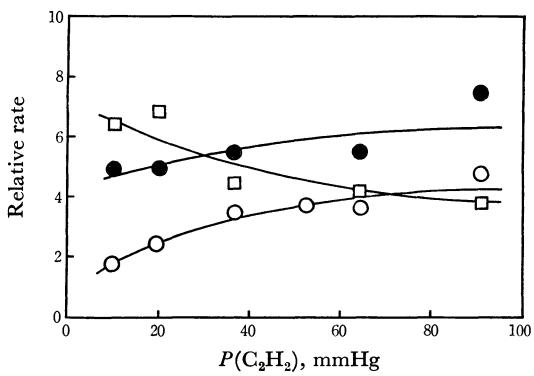

Fig. 1. Relative rate of product formation in the photolysis at 1849 Å against the acetylene pressure.

atoms are relatively large from the view-point of simple molecular mechanism and that the distribution is almost constant at higher pressures.

The distribution observed here may be quantitatively explained by the free radical mechanism initiated by hydrogen atom as suggested for the mercury photosensitization by LeRoy,[3] but it can be accounted for as well by the modified excited-molecule mechanism[4,5]; the isotopic distribution predicted on the basis of either mechanism is quite the same (Table 1, the last column).

In low pressure region, however, the observed distribution depends on the acetylene pressure (Table 1) and the yields of benzenes containing an odd number of H or D atoms tend to increase with decreasing acetylene pressure in the same manner as in the mercury photosensitization.[5] The free radical mechanism could not explain the change of the distribution at low pressures, because the distribution expected from the mechanism should be independent of the acetylene pressure.

If an excited acetylene dimer molecule is assumed to repeat dissociation and regeneration to form an excited acetylene molecule at low pressures as follows,

$$C_2H_2^* + C_2H_2 \rightarrow C_4H_4^* \quad (1)$$

$$C_4H_4^* \rightarrow C_2H_2^{**} + C_2H_2 \quad (2)$$

$$C_2H_2^{**} + C_2H_2 \rightarrow C_4H_4^{**} \quad (3)$$

$$C_4H_4^{**} \rightarrow C_2H_2^{**} + C_2H_2 \quad (4)$$

$$C_4H_4^{**} + C_2H_2 \rightarrow C_6H_6 \quad (5)$$

where $C_2H_2^{**}$ and $C_4H_4^{**}$ mean lower excited molecules, the yields of benzenes containing an odd number of H or D atoms should increase.

Figure 2 shows the effects of the addition of nitric oxide on the rate of pressure decrease and of product formation. Nitric oxide markedly suppresses the benzene formation. But this effect of nitric oxide on the benzene formation does not necessarily indicate the radical mechanism. It would be considered that the excited singlet acetylene is converted into the triplet state and the latter

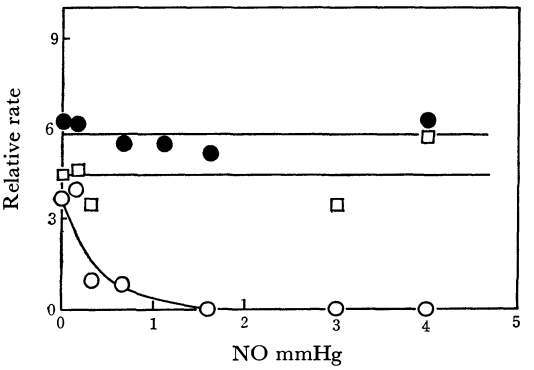

Fig. 2. Effect of nitric oxide on the relative rate of product formation. Acetylene initial pressure 37 mmHg.
—○— C_6H_6 (10^{-8} mol/min)
—□— C_4H_2 (10^{-8} mol/min)
—●— Pressure decrease (10^{-2} mmHg/min)

initiates the benzene formation. If it is the case, nitric oxide could quench the triplet acetylene.[6]

The diacetylene formation is not influenced practically by nitric oxide, but it has been found that ethynyl radicals do not react with NO.[7] Thus, it can be considered that diacetylene is produced by the radical reaction of ethynyl radicals.

Summarizing the above results, a possible reaction mechanism is depicted as follows.

$$C_2H_2 + h\nu \rightarrow C_2H_2^*$$

$$C_2H_2^* \rightarrow C_2H + H$$

$$C_2H_2^* \longrightarrow C_6H_6 + 2C_2H_2$$

$$C_2H + C_2H \rightarrow C_4H_2$$

$$H + nC_2H_2 \rightarrow \text{Polymer}$$

$$C_2H + nC_2H_2 \rightarrow \text{Polymer}$$

Multi-channel Possibility of Electron Transfer Reaction in the Excited State

Noboru MATAGA

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received July 18, 1970)

Recently, we have studied the quenching of pyrene fluorescence by several electron acceptors and donors in polar solvents.[1] We have observed extraordinary strong quenching in the case of pyrene-TCNE-acetonitrile system, where the value of δ in the equation of relative fluorescence yield, $\eta'/\eta=\delta/(1+k_q\tau[\mathrm{B}])$, is remarkably smaller than unity. We have further confirmed that k_q is not simply proportional to the diffusion coefficient, D, at low temperatures, *i. e.*, $k_q \propto D^m$ ($m<1$) in contrast to other systems where $k_q \propto D$. These facts for pyrene-TCNE system have been given a tentative interpretation that somewhat long range electron transfer process in a quite loose encounter pair is involved in the reaction.[1]

As we have pointed out previously,[2] the mechanism of fluorescence quenching reaction due to the electron transfer process in a polar solvent may be discussed on the basis of Marcus' theory of electron transfer.[3] According to Marcus,[3a] the reaction scheme may be written as,

$$\mathrm{A}^* + \mathrm{B} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathrm{A}^*\cdots\mathrm{B} \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} \mathrm{A}^{\pm}\cdots\mathrm{B}^{\mp} \xrightarrow{k_3} \quad (1)$$
$$\swarrow 1/\tau$$

Then, we have,

$$\begin{aligned} k_q &= k_1/[1+(k_{-1}/k_2)+(k_{-1}k_{-2}/k_2k_3)] \\ &= k_1/[1+(k_{-1}/k_2^0)\exp(\Delta F^*/RT) \\ &\quad +(k_{-1}/k_3)\exp(\Delta F^0/RT)] \end{aligned} \quad (2)$$

where $k_2=k_2^0\exp(-\Delta F^*/RT)$, $k_2/k_{-2}=\exp(-\Delta F^0/RT)$, ΔF^* and ΔF^0 are respectively the free energy of activation and the standard free energy for the electron transfer process. Rehm and Weller[4] have shown by measuring k_q for many systems that k_q is nearly constant and equal to $1.6\times10^{10}\mathrm{M}^{-1}\mathrm{sec}^{-1}$ for $\Delta F^0 \lesssim -10$ kcal/mol while it becomes much smaller for $\Delta F^0 > -10$ kcal/mol. They have derived also numerical values for rate constants of Eq. (2) and equations for ΔF^* in terms of ΔF^0, which reproduce satisfactorily the observed k_q values. ΔF^0 value can be estimated by Eq. (3),

$$\Delta F^0 = E^{(+)}(\mathrm{B}) - E^{(-)}(\mathrm{A}) - C - \Delta E(\mathrm{A}^*)$$
or (3)
$$\Delta F^0 = E^{(+)}(\mathrm{A}) - E^{(-)}(\mathrm{B}) - C - \Delta E(\mathrm{A}^*)$$

where $E^{(+)}$ and $E^{(-)}$ are oxidation and reduction potentials of electron donor and acceptor, respectively, ΔE is the excitation energy of A to the luminescent state and C is the coulomb interaction energy in $\mathrm{A}^{\pm}\cdots\mathrm{B}^{\mp}$. C is approximately given by $C\approx e^2/\varepsilon R_{ab}$, where R_{ab} is the inter-ionic distance and ε is the dielectric constant of solvent.

For several pyrene-quencher systems in acetonitrile, we have evaluated ΔF^0 as follows. $E^{(+)}$ and $E^{(-)}$ values in acetonitrile solution were taken from literature.[5] R_{ab} was assumed to be 7 Å. (Even if we take somewhat smaller or larger value for R_{ab}, our conclusion in this report remains unchanged.) Then, ΔF^0 values are -2.5 eV, -1.5 eV, -0.45 eV and -0.55 eV for the quenchers TCNE, TCNB (tetracyanobenzene), *p*-DCNB (*p*-dicyanobenzene) and DMA (*N,N*-dimethylaniline), respectively. TCNE, TCNB and *p*-DCNB work as electron acceptors while DMA works as a donor.

If the $|\Delta F^0|$ value is very large just as in the case of pyrene-TCNE system, it might be possible that the electron transfer reaction occurs not only to the ground state of $\mathrm{A}^{\pm}\cdots\mathrm{B}^{\mp}$ but also to its various excited states when the ion radicals have low energy excited levels. The pyrene cation and anion radicals have presumably three excited levels in the range of excitation energies of 1.5—2.0 eV and 1.3—2.0 eV, respectively.[6] Accordingly, the standard free energies of the electron transfer processes leading to the

excited states of $A^{\pm}\cdots B^{\mp}$, are all lower than -0.5 eV, in the case of pyrene-TCNE system. Thus, there are presumably four reaction paths of electron transfer, all of which have the rate constant of 10^{10}M^{-1} sec.$^{-1}$. On the other hand, only the electron transfer process to the ground state of $A^{\pm}\cdots B^{\mp}$ is possible when TCNB, p-DCNB and DMA are used as the quenchers. In these cases, the rate constant of the reaction to the excited states of $A^{\pm}\cdots B^{\mp}$ is much smaller than $10^{10}\text{M}^{-1}\,\text{sec}^{-1}$ according to the treatment of Marcus.[3]

From the reasoning described above, the reaction in the case of pyrene-TCNE system may be a multi-channel process, the rate constant of which is the sum of four rate constants, $k_q=\sum_i k_{qi}$. Accordingly, it may be possible for the electron transfer process from the excited pyrene to TCNE to occur at much larger intermolecular distance compared to the case of the other single channel systems.

Crystal Structure of *p*-Bromobenzylideneacetone

Kunio SUGIYAMA, Hirotaka SHIMANOUCHI and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 22, 1970)

The topochemical studies on the solid-state photodimerization of *trans*-cinnamic acid and its derivatives by Schmidt *et al.* have disclosed a correlation between crystal structure and photochemical behavior;[1] the dimerization takes place to form a cyclobutane ring between the carbon–carbon double bonds separated by no more than 4.1 Å, while no photoreaction occurs if the separation is more than 4.7 Å.

We found that benzylideneacetone, one of acyclic α,β-unsaturated ketones, readily yielded a photodimer in a solid state.[2] It may be interesting to see whether Schmidt's conclusion is also valid in this case. For convenience of X-ray anaylsis the *p*-bromo derivative was prepared, and examined for the photodimerization. The present paper will deal with the crystal structure of *p*-bromo-*trans*-benzylideneacetone in relation with photochemical reaction.

Experimental

p-Bromo-*trans*-benzylideneacetone was prepared by condensation of *p*-bromobenzaldehyde with acetone. Colorless tabular crystals, with well-developed (100), were obtained by recrystallization from acetone.

Photochemical Reaction. The solid-state ultraviolet irradiation (with a 125w high pressure mercury lamp) of the *p*-bromobenzylideneacetone for 12 days gave a dimer as a main product (48% yield, estimated from NMR data) and *cis*-benzylideneacetone (20%). The analytical and spectrometric data of the dimer are shown below; Found: C, 53.13; H, 4.03%, Calcd for $C_{20}H_{18}O_2Br_2$: C, 53.35; H, 4.02%. IR: ν_{max} 1707 cm^{-1} (C=O), UV: λ_{max} 261 nm (ε 540), NMR (100MHz): δ^{CDCl_3} 1.67 (s, 6H), 3.85 (q, J=11.0, 7.4 Hz, 2H), 4.56 (q, J=11.0, 7.4 Hz, 2H) and 7.37 (m, 8H). The mass spectrum showed a parent peak at *m/e* 448 and very strong peaks at 224 ($M^+/2$) and 209 ($M^+/2$—Me). These spectroscopic data well correspond to those of non-substituted benzylideneacetone. Therefore, the same conclusion can be drawn that the dimer is a centrosymmetric cyclobutane derivative.[2]

Crystallographic Data. Preliminary photographs taken with Cu$K\alpha$ radiation gave the crystallographic data as below: *p*-Bromobenzylideneacetone, $C_{10}H_9OBr$, M.W.: 225, mp 84°C, monoclinic: a=10.79, b=14.18, c=6.2 Å, β=91.2°, U=947.7 Å^3, Dm=1.59 g·cm^{-3}, Dx=1.59 g·cm^{-3}, Z=4. μ (Cu$K\alpha$)=61.4 cm^{-1}. Absent spectra: ($h0l$) when l is odd, ($0k0$) when k is odd, Space group is $P2_1/c$.

Three-dimensional intensity data were collected on multiple-film equi-inclination Weissenberg photographs taken with Cu$K\alpha$ radiation. Layer lines of zero to ten around the b axis and zero to four around the c axis were recorded. Measurement of the intensities was made by visual comparison with the standard intensity scale. Lorentz and polarization corrections were applied in the usual way and the structure factors obtained were put on a common scale by comparing those of the equivalent reflections appearing on different layers.

Structure Determination

The crystal structure was determined by the heavy atom method. Approximate coordinates of the bromine atom were derived from three-dimen-

* $B_{11}=0.00765$, $B_{22}=0.00826$, $B_{33}=0.04249$, $B_{12}=0.00168$, $B_{13}=0.00635$, $B_{23}=-0.00204$.

sional sharpened Patterson function without ambiguity. The three-dimensional Fourier synthesis, with the phases of bromine atom only, revealed all the non-hydrogen atoms. At this stage, $R=0.21$. The refinement of the structural parameters was carried out by the method of least-squares, using all the 1956 observed reflections. Three cycles of block-diagonal matrix refinement reduced the R to 0.148, only the bromine atom being treated as anisotropic. The final atomic coordinates and temperature factors are listed in Table 1.

Discussion

The bond lengths, angles and intermolecular contacts obtained show no unusual value in view of e. s. d. 's. The nearest carbon–carbon double bonds are those related by center of symmetry, at a center-to-center distance of 4.63 Å, and those by glide-plane at a center-to-center distance of 4.84 Å. In the latter pair, the molecules are somewhat farther and not parallel with each other. Therefore, dimerization of the latter pair may be less probable, according to the least motion principle,[3] which describes that the most favorable elementary reactions should be those involving the least change in atomic position and electronic configuration. On the other hand, the dimerization between the former pair might be more favorable and this is compatible with the conclusion that the main product of the solid-state photochemical reaction of *p*-bromobenzylideneacetone is a centrosymmetric dimer.[2]

We thank Professor Noboru Sugiyama, Tokyo University of Education, and Assistant Professor Kazutoshi Yamada, Chiba University, for helpful advice on the photochemical reaction.

Polarized Absorption Spectra of the TCNQ Crystal

Shoji HIROMA,*1 Haruo KURODA and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received July 23, 1970)

Tetracyano-*p*-quinodimethane (TCNQ) is known to be one of the strongest electron acceptor. A number of radical salts have been prepared from the reaction between TCNQ and an electron donor. Such salts are often organic semiconductors of high conductivity. Although extensive investigations have been carried out on the electrical properties of these salts,[1,2] little has been known on the electronic properties of the crystal of TCNQ itself. Recently we have noticed that the TCNQ crystal exhibits a photoconduction with a relatively high sensitivity in the visible region.*2 In connection with such phenomenon, we have examined the polarized absorption spectra of the single crystal.

Experimental

TCNQ was synthesized by the method described by Acker and Hartler,[3] and purified by recrystallization followed by twice sublimation *in vacuo*. Single crystals of microscopic size, for the measurement of absorption spectra, were prepared from such purified sample by vacuum sublimation onto cotton wool or by crystallization from acetone solution. The crystal spectra were measured with a microspectrophotometer which we have described elsewhere.[4]

Results and Discussions

According to Long *et al.*,[5] the TCNQ crystal is monoclinic, $C2/c$ with the lattice constants, $a=8.906$ Å, $b=7.060$ Å, $c=16.395$ Å, and $\beta=98.54°$, four molecules being contained in the unit cell. We obtained diamond-shaped crystals bounded with{110} with the developed face of (001).

The *a*-axis and *b*-axis polarized spectra were observed from the direction nomal to the (001) plane. The results are given in Fig. 1, and the wavenumbers and polarization ratios are listed in Table 1.

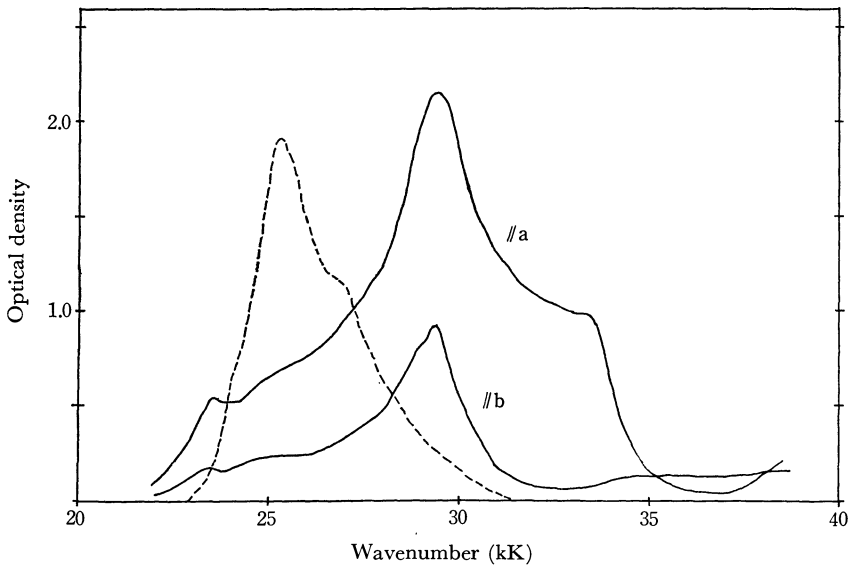

Fig. 1. The polarized absorptions spectra of TCNQ crystal.

Table 1. Wavenumbers and polarization ratios of absorption peaks (in kK)

$\tilde{\nu}_a$	$\tilde{\nu}_b$	I_a/I_b
23.6	23.6	3.1
24.9	24.9	2.8
29.4	29.4	2.4
33.0	~34	

In the near-ultraviolet region of the solution spectrum, TCNQ exhibits only one strong absorption band at 25.4 kK (f=0.94). By using oriented gas model, the polarization ratio, I_a/I_b, of the absorption band due to this transition ($^1B_{1u}\leftarrow{}^1A_g$) is estimated as 5.9. As we compare the crystal spectra with the solution spectra, we notice, first that the band is markedly broadened in the crystal state, and, second that its shape is quite asymmetric.

From the symmetry of the crystal lattice, we can predict that each intramolecular transition would give two optically-allowed factor group components, namely, A_u and B_u, which give the transitions polarized respectively in the b-axis and a-axis direction. We have carried out a theoretical estimation of the crystal shift and splitting on the 25.4 kK ($^1B_{1u}\leftarrow{}^1A_g$) and 43.9 kK ($^1B_{2u}\leftarrow{}^1A_g$) transitions of TCNQ molecule.*3 The energy levels of exciton states thus estimated are given in Table 2.

Table 2. Estimated energies of optically allowed exciton levels of TCNQ (in kK)

	Molecular transition	
	$^1B_{1u}$ (25.4 kK)*	$^1B_{2u}$ (43.9 kK)*
A_u (b-polarized)	32.3	43.8
B_u (a-polarized)	28.9	44.1
$\Delta\nu$**	3.36	−0.28

* Observed energy for solution spectrum.
** Splitting between the A_u and B_u components.

We could attribute the highest peak at 29.4 kK found in the a-axis spectrum to the B_u component of $^1B_{1u}$ transition. However, a corresponding peak is observed also in the b-axis spectrum. Situation is again puzzling as regards the A_u component, namely, although we can find a peak in the b-axis spectrum at about 34 kK as predicted by the calculation, the corresponding band appears also in the a-axis spectrum. Thus the observed polarization is difficult to be explained on the basis of the above treatment.

The observed spectra suggests the presence of another band in 23—27 kK region. The energy of the charge transfer from a TCNQ molecule to the neighboring one, is estimated as 20.5 kK, if we assume the electron affinity of TCNQ molecule as 2.88 eV and the ionization potential as 7.83 eV.*4 Thus it is likely that the absorption in the 23—27 kK region is associated with the intermolecular charge transfer. This assignment seems to be consistent with the polarization of the absorption in this region, although the observed polarization ratio is appreciably larger than the oriented gas value, 1.6.

Since the interaction between the neighboring molecules is expected to be the most important factor in the case of the TCNQ crystal, we have examined this from another point of view, by calculating the electronic structure of the molecular pair where the two molecules are taking the mutual orientation exactly the same as found for the two molecules closely contacting to each other in the TCNQ crystal. We have applied here a semiempirical SCF·MO·CI method treating the molecular pair as a single π-conjugated system.[5] The results of this calculation are shown in Table 3. It should

Table 3. Transitions predicted by the SCF·MO·CI calculation on the TCNQ molecule and the molecular pair (in eV)

	Monomer		Molecular pair	
	ΔE	f	ΔE	f
(CT)			2.68	0.02
$^1B_{1u}\leftarrow{}^1A_g$	2.68	1.99	3.06	4.65
$^1B_{2u}\leftarrow{}^1A_g$	4.21	0.60	4.36	0.89

be noted that the lowest transition of TCNQ molecule, ($^1B_{1u}\leftarrow A_{1g}$), is predicted to be shifted to higher energy by 3.5 kK in the molecular pair, and that a transition associated with intermolecular charge-transfer interaction is predicted at a lower energy. These results again support our tentative interpretation of the crystal spectra of TCNQ.

The authors are indebted to Mr. T. Ohta in this laboratory for his assistance in the computations presented here.

*3 Since the oscillator strength of this band is large, we treated the problem as a strong coupling case. We have taken the dipole-dipole approximation for the molecular pair separated larger than 30 Å, but estimated the interaction terms directly by use of the molecular wave-function assuming the point-charge model, for the molecular pair within 30 Å.

*4 Excitation energy was estimated by the equation, $\Delta E=I-A-C$, where I was estimated by using the highest occupied SCF MO, A is of electron capture measurement (A. L. Farragher and F. M. Page, *Trans. Faraday. Soc.*, **63**, 2369 (1967)], and the Coulomb attraction energy, C, was estimated by the point charge model.

*5 The details of the method are reported elsewhere (T. Ohta, T. L. Kunii and H. Kuroda, *Theor. Chim. Acta*, to be published).

SHORT COMMUNICATIONS

Red and Green Forms of Bis(*N*-isopropyl-3-methoxysalicylideneiminato) copper(II)

Akira TAKEUCHI and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received July 9, 1970)

The structural versatility of bis(*N*-alkylsalicylideneiminato)copper(II) complexes*1 now seems to be fairly well known,[1] and their geometries may be expected to become even more complicated, when the *N*-substituent R denotes an α-branched alkyl. For example, because of the steric effect caused by considerably bulky isopropyl groups, the complexes of the type Cu(X–SAL·*iso*–C_3H_7)$_2$ take either a tetrahedral or a planar configuration, depending upon the nature of X.[2,3] Only one of them, however, is usually obtained as crystals, and two forms of crystals consisting of complexes with different configurations have never been isolated for a set of X and R. The present communication deals with successful isolation of two forms of Cu(3-CH_3O-SAL·*iso*-C_3H_7)$_2$.

The compound Cu(3-CH_3O-SAL·*iso*-C_3H_7)$_2$ was obtained in two forms, one being olive-green (Form I) and the other red-brown (Form II). The crude product was prepared by the reaction between bis(3-methoxysalicylaldehydato)copper(II) (0.02 mol) and isopropylamine (0.045 mol) in 90% methanol (75 m*l*) at about 40°C for a few hours. Evaporation at about 30°C of a concentrated solution of the crude product in methanol, ethyl ether, chloroform or dioxane yielded pure red-brown crystals (Form II) of the required complex. Olive-green crystals (Form I) of the same complex were obtained by spontaneous evaporation of a concentrated methanolic solution of the crude product at 5—10°C.

Elementary analyses of both the red-brown and the olive-green forms agree with the formula Cu(3-CH_3O-SAL·*iso*-C_3H_7)$_2$. Found: C, 58.84; H, 6.08; N, 6.14% (for the red-brown form). C, 59.00; H, 6.46; N, 6.14% (for the olive-green form). Calcd for $C_{22}H_{28}N_2O_4Cu$: C, 58.98; H, 6.30; N, 6.25%. Both forms, when dissolved in chloroform, benzene or ethanol, show the same electronic absorption spectra.

The solid spectrum of Form II is almost the same as that of its solution in non-donor solvents, having absorption bands at about 9.0, 14.5 and 21.5 kK. This is also similar to that of Cu(H-SAL·*iso*-C_3H_7)$_2$, which was previously concluded to have a distorted tetrahedral configuration.[2–4]

On the contrary, the *d–d* absorption band of Form I in the solid state, which appears at about 13.5 kK with a shoulder at about 11.0 kK, is shifted toward a much lower frequency, as compared with the spectra of the planar copper(II) complexes such as Cu(H-SAL·*n*-C_4H_9)$_2$[5] and Cu(3-CH_3O-SAL·*n*-C_3H_7)$_2$. The solid spectrum of Form I is remarkably similar to the spectrum of the binuclear Cu_2(H-SAL·CH_3)$_4$ containing copper(II) ions with a bipyramidal five-coordination,[6] suggesting this geometry for Form I.

Form II melts at 121—122°C, while with the rise of temperature Form I is transformed into Form II (red-brown) at 101°C, whose X-ray powder diagram and solid spectrum agree with those of the red-brown crystals (Form II) obtained by evaporation at about 30°C of the solution.

In the case of the corresponding nickel(II) complex Ni(3-CH_3O-SAL·*iso*-C_3H_7)$_2$, there are brown tetrahedral (Form I) and green planar (Form II) forms, and with the rise of temperature the planar form is transformed into a tetrahedral one at 157—158°C.[7] Comparison seems to indicate that the bis(*N*-substituted salicylideneiminato)nickel(II)complexes have a greater tendency to assume a planar structure than the corresponding copper(II) complexes, in agreement with a previous result.[2]

*1 The complexes of this series are abbreviated as Cu(X-SAL·R)$_2$, where R and X denote an alkyl group on the nitrogen atom and a substituent on the benzene ring, respectively.

Isomerism and Configurational Change by Adduct Formation in Bis(*N*-cyclohexyl-3-methoxysalicylideneiminato)copper(II)

Akira TAKEUCHI and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received August 1, 1970)

In a previous communication,[1] we reported on the isolation of two forms having different configurations for bis(*N*-isopropyl-3-methoxysalicylideneiminato)copper(II) (abbreviated as Cu(3-CH_3O-isopropyl)$_2$). The steric effect arising from the isopropyl group is remarkable in that the complexes of the type Cu(X-SAL·*iso*-C_3H_7)$_2$ take either a tetrahedral or a planar configuration, depending upon the nature of X.[2,3] Since the cyclohexyl group is somewhat similar to the isopropyl group with respect to the steric effect in the complexes of this series,[2] we found it desirable to extend our study to the corresponding cyclohexyl complexes. This resulted in the successful isolation of green (Form I) and red forms (Form II) of Cu(3-CH_3O-SAL·Ch)$_2$, where the notation Ch denotes a cyclohexyl group. Moreover, it has been found that the green form absorbs chloroform and bromoform to yield red-brown adducts.

Form I was obtained as olive-green crystals by recrystallizing from methanol-chloroform or benzene the crude product, which had been prepared by a reaction of bis(3-methoxysalicylaldehydato)-copper(II) with cyclohexyl amine in methanol.

With the rise of temperature, Form I was converted into a red-brown substance (Form II) at about 180°C, the change being reversible. Elementary analysis of Form II agrees with that of Form I, both forms being represented by Cu(3-CH_3O-SAL·Ch)$_2$.

Electronic absorption spectra for many copper(II) complexes of this series have so far been reported, and it now seems to be possible to determine the configuration of a copper(II) complex on the basis of its spectra in many cases.[1-4] Examination of the solid spectra reveals that Forms I and II consist of planar and tetrahedral complexes, respectively. They show identical spectra in solution, and spectra typical of the distorted tetrahedral complex in non-donor solvents.

Red-brown crystals (Form III) were obtained by evaporating a solution of Form I in chloroform, or by exposing Form I to the vapour of chloroform in a desiccator for a few days. Elementary analysis shows that Form III is represented by Cu(3-CH_3O-SAL·Ch)$_2$·2$CHCl_3$. The crystals of Form III may be kept in a tightly closed sample-tube without decomposition for at least a few weeks. When allowed to stand in the atmosphere, Form III is transformed into Form I, losing two molecules of chloroform, as confirmed by the weight-loss measurement.

The remarkable colour change on the adduct formation apparently indicates that some configurational change takes place in this process, and that Form III does not contain the planar copper(II) complex of the starting compound. Combination of the chloroform molecule with the copper(II) ion to form complexes with coordination number five or six seems to be unlikely, in view of the finding that the electronic absorption spectrum of Form III as well as that of Form I in chloroform are similar to those of their ethanol solutions, and also to the solid spectrum of Form II; all of them are typical of the distorted tetrahedral complexes. It may thus be presumed that Form III in the solid state consists of the distorted tetrahedral complex, and that the chloroform molecule is not involved in the bonding with the copper(II) ion. It may be remembered that the chloroform molecule was previously reported to function in a similar way in its adduct with *N*,*N*′-ethylenebis(salicylideneiminato)-copper(II).[5]

When bromoform was employed instead of chloroform, an adduct represented by Cu(3-CH_3O-SAL·Ch)$_2$·2$CHBr_3$ was obtained as red-brown crystals. Its properties are similar to the chloroform adduct, and it is considered to consist of the copper(II) complexes with a similar configuration.

Dimerization of Ethylene Catalyzed by σ-Arylnickel(II) Compounds

Ken-ichi MARUYA, Tsutomu MIZOROKI and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received July 31, 1970)

In a previous paper,[1] it was reported that an isotopic exchange between C_2H_4 and C_2D_4 is effectively catalyzed by bis(triphenylphosphine)nickel(II) halide in an aprotic solvent in the presence of molecular hydrogen without accompaning any hydrogenation or dimerization. The complex shows some catalytic activity for the ethylene dimerization when it is used together with boron trifluoride etherate. During the course of study dealing with the effect of ligand coordinated to nickel(II) atom, it has been found that the activity of the nickel(II) complex for the ethylene dimerization is highly increased by substituting one of the halogen ligands by a σ-aryl ligand such as 1-naphthyl, *o*-tolyl, *etc.* This communication reports a highly selective dimerization of ethylene catalyzed by bis(triphenylphosphine)σ-aryl nickel(II) bromide[2] in the presence of boron trifluoride etherate in benzene or methylene chloride.

Ethylene dimerization with this catalyst system took place almost quantitatively(95%) without any induction period at room temperature under atmospheric pressure. Only a trace amount of hexene was detected in the product. Co-dimerization of ethylene with propylene occurred to some extent, but no dimer of propylene was detected under these mild reaction conditions. Butadiene as well as triphenylphosphine strongly inhibited the ethylene dimerization. 1-Naphthyl ligand and triphenylphosphine seem to remain in the nickel complex during the reaction, because only small amounts of decomposed products of the complex such as naphthalene, 1,1′-dinaphthyl and triphenylphosphine were detected in the solution after the reaction. Bis(triphenylphosphine) *o*-tolyl nickel(II) bromide is more effective than the corresponding 1-naphthyl complex. The treatment of bis(triphenylphosphine) 1-naphthyl nickel(II) bromide with sodium tetraphenylborate ($1\text{-}C_{10}H_7Ni(P\phi_3)_2Br + NaB\phi_4 + s \rightarrow [1\text{-}C_{10}H_7Ni(P\phi_3)_2(s)]^+[B\phi_4]^- + NaBr$, $\phi = C_6H_5$, s=solvent)[3] results in a considerable decrease in catalytic activity for ethylene dimerization. This suggests that halogen ligand is important for the catalytic activity.

The experimental procedure is illustrated by the following ethylene dimerization. To a solution of bis(triphenylphosphine) 1-naphthyl nickel(II) bromide (1 mmol, 0.79 g) in dry methylene chloride (20 m*l*) under nitrogen in a 50 m*l*-flask was added boron trifluoride etherate (1 mmol, 0.125 g). The nitrogen gas in the flask had been evacuated before ethylene gas (64.5 m*l* at STP) was introduced at the temperature of liquid nitrogen. The flask was warmed up to 0°C and kept at that temperature for 1 hr with vigorous stirring. Subsequently all volatile materials (C_2H_4, C_4H_8 and solvent) were transferred into another 50 m*l*-flask by means of a liquid nitrogen trap. Their amounts were determined by gas chromatography. From the residual materials only trace amounts of naphthalene, 1,1′-dinaphthyl and triphenylphosphine were extracted by *n*-hexane. The results are shown in Table 1.

Structures of Lignans of *Magnolia fargesii*

Hiroshi KAKISAWA, Takenori KUSUMI,* Hong-Yen HSŪ and Yuh Pan CHEN**

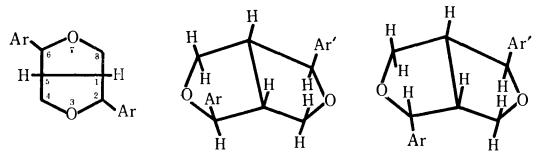
* *Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo*
** *Bristol Research Institute of Taiwan, Taipei, Taiwan*

(Received August 7, 1970)

Alcoholic extract of flower buds of *Magnolia fargesii* afforded four kinds of lignans besides some alkaloids. Two of the neutral compounds were known lignans, eudesmin (**1**), $C_{22}H_{26}O_6$, and lirioresinol-B dimethyl ether (**2**), $C_{24}H_{30}O_8$, while the remaining two were new lignans designated as magnolin and fargesin.

Magnolin, $C_{23}H_{28}O_7$, mp 97°C, ν^{KBr} 1590, 1520 cm^{-1}, $[\alpha]_D$ +55.7°, λ_{max} 231, 279 mμ, and fargesin, $C_{21}H_{22}O_6$, mp 139°C, ν^{KBr} 1605, 1590, 1505 cm^{-1}, λ_{max} 233, 284 mμ, have all their oxygen atoms in ether linkages because the IR spectra of both compounds did not show hydroxyl or carbonyl absorption. The NMR spectra (Table 1.) of both compounds are best interpreted on the basis of the skeleton of 2,6-diphenyl-3,7-dioxabicyclo[3.3.0]octane, and the structures (**3**) and (**4**) were assigned for magnolin and fargesin, respectively. These structures were supported by mass spectra.[1] The mass spectrum of magnolin (**3**) is composed of two series of fragmentation, one of which is the same as the spectrum of eudesmin (**1**), and the other lirioresinol-B dimethyl ether (**2**). Simple addition of the mass spectra of **1** and **2** led to a composite almost identical with the spectrum of magnolin. The mass spectrum of fargesin (**4**) was in a similar situation and in good agreement with the composite of the spectra of **1** and sesamin.

All six aliphatic protons attached to carbon atoms bearing the ethereal oxygens in the hydrofuran rings of magnolin appear at a lower field than δ 3.8 ppm in the NMR spectrum. Birch *et al.*[2] reported that *endo* aryl group bonded at C-2 of 3,7-dioxabicyclo[3.3.0]octane system is held very close to the *endo* hydrogen atom (8-H) on the opposite ring, which causes a high field shift (δ 3.1—3.5 ppm) of the hydrogen from the normal position (δ 3.8—4.0 ppm) by the anisotropic effect of the aryl group. These NMR features show that two aryl groups of magnolin are in the *exo* positions, and thus their stereochemistry is assigned to **3**. In contrast with magnolin, all aliphatic protons attached to the hydrofuran skelton of fargesin appeared in different positions and one of C_4-methylene protons is found at upfield (δ 3.25—3.45 ppm). Thus *endo*-C_4-hydrogen is within a shielding cone of the aryl group, which must be held at *endo* position of the opposite ring. These NMR properties are very similar to those of epieudesmin as shown in the table, and the stereochemistry of fargesin is assigned to **4**.



(**1**), (**2**) (**3**) (**4**)

[2.1.1]Metacyclophane[1)]

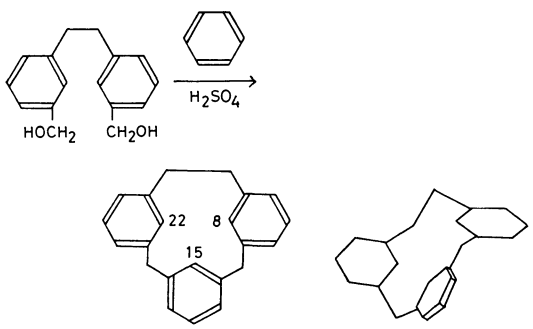
Takeo SATO, Meiko WAKABAYASHI and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received August 10, 1970)

Recently interest has been shown in the chemistry of multi-benzene cyclophanes.[2)] We wish to report the preparation and conformational studies of [2.1.1]metacyclophane. The compound was obtained *via* new cycloalkylation, in which a benzene molecule was incorporated in the cyclic system as a *m*-phenylene unit.

Slow addition of a benzene solution containing 3,3′-bis(hydroxymethyl)bibenzyl[3)] to concentrated sulfuric acid at room temperature in course of 20 hr produced a mixture of hydrocarbons from which 22.8% of bis-phenylation product, 3,3′-dibenzylbibenzyl, and a crystalline material having a formula $C_{22}H_{20}$ was isolated by column chromatography on Florisil (eluted by *n*-hexane-benzene).



I Ia

The C_{22} hydrocarbon was obtained as colorless needles, mp 130—132°C, in 17% yield. Found: C, 92.74; H, 7.14%. Calcd for $C_{22}H_{20}$: C, 92.21; H, 7.09%. Spectral data suggested a cyclic structure in which benzene was cycloalkylated by diol. It showed a parent peak at *m/e* 284 together with abundant $P-91$, $P-106$ and $P-119$ peaks. Convincing evidence for the suggested structure was obtained by NMR spectra, which showed singlets at δ 2.78 (ethylene) and 3.60 (methylene) and three groups of absorption for the arylprotons at δ 6.27 (2H), 6.49 (1H), and 6.90 (9H). The upfield shift of two-proton and one-proton aryl signals which can be assigned to $C_{8,22}$ and C_{15} protons, respectively, suggests a metacyclophane structure. They appeared as triplets with $J=1.74$ Hz (*m*-coupling) by irradiating the benzyl methylene signal at 3.60.

The upfield shift of inner aryl protons favors the stepped conformation Ia (C_2 symmetry) over a folded one (C_s symmetry), in which two benzene rings take an overlapping arrangement. This was also supported by the UV spectrum determined in *n*-hexane, which showed benzenoid bands at 250 (ε 726), 265 (787), 270 (626) and 274 mμ (537). The absorption curve is quite similar to the overlapping spectra of *m*-xylene and diphenylmethane.

Comparison of the UV spectrum of I with that of [2.2]metacyclophane[4)] reveals that anomalies associated with bent benzene structure and transannular electron interaction found in the latter compound no longer prevail, suggesting that the 13-membered ring would be quite free to undergo conformational changes. This was further confirmed by low temperature NMR spectroscopy, which showed that both the methylene and ethylene signals stayed singlets over a wide range of temperature. They showed slight broadening only at low temperatures, the half-height width being doubled at −100°C.

Attempts to obtain [1.1.1]metacyclophane by a similar reaction of bis(3-hydroxymethylphenyl)methane failed and gave only bis-phenylation product in 60% yield. Similarly the treatment of 1,2-bis(hydroxymethyl)benzene under the same conditions gave *o*-dibenzylbenzene in 64% yield.

Structure of Cobalt(III) Complexes of *d*-, *l*-, and *meso*-2,4-Pentanediaminetetraacetate

Fujio MIZUKAMI, Haruko ITO, Junnosuke FUJITA and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received August 21, 1970)

The conformation of a six-membered chelate ring of the tristrimethylenediaminecobalt(III) complex was first determined to be of chair form by X-ray diffraction by Y. Saito *et al.*[1] van Saun and Douglas, and Ogino *et al.*[2] synthesized cobalt(III) complex of trimethylenediaminetetraacetate ($trdta^{4-}$) and suggested that the six-membered chelate should have a twist form. We examined the influence of the methyl group on α-carbon atom of the trimethylene part upon the chelate structure, and found a stereospecific formation of 2,4-pentanediaminetetraacetatocobaltate(III) complex depending on the optical isomerism of 2,4-pentanediamine.

2,4-Pentanediamine was synthesized by the known method[3] and the racemic and meso forms were separated by utilizing the difference in solubility of their dihydrochlorides in 95% ethanol.*1 The amine was converted into 2,4-pentanediaminetetraacetic acid ($ptntaH_4$) by Weyh and Hamm's method.[4] A violet complex was formed by heating $Na_3[Co(NO_2)_6]$ and racemic $ptntaH_4$ in water at 60—70°C for 15 hr. The product was converted into diastereomers of d-$[Co(NO_2)_2en_2]^+$ salt (en= ethylenediamine) with $[\alpha]_D$ +887° and −696°. They were treated with potassium iodide to give $K[Co(ptnta)]\cdot H_2O$. Found: $(+)_D$ isomer, C, 34.40; H, 4.55; N, 6.31: $(-)_D$ isomer, C, 34.61; H, 4.53; N, 6.27%. Calcd for $C_{13}H_{20}CoKN_2O_9$: C, 34.98; H, 4.55; N, 6.28%. When *meso*-$ptntaH_4$ was used in place of racemic $ptntaH_4$ the violet complex was not formed, and only a blue complex H[CoCl(ptntaH)] was isolated crystalline on treatment with dilute hydrochloric acid. Found: C, 36.35; H, 5.58; N, 6.55%. Calcd for $C_{13}H_{20}ClCoN_2O_8$: C, 36.59; H, 4.72; N, 6.57%.

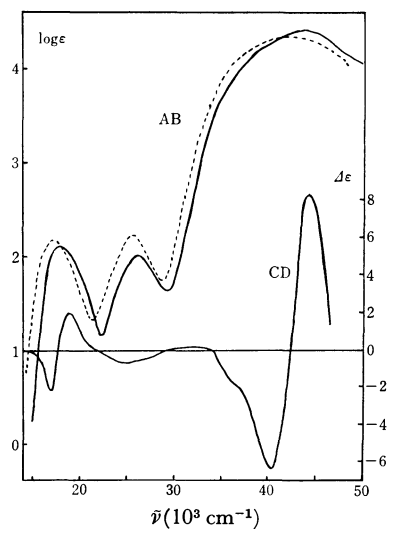

Fig. 1. AB and CD spectra of $(+)_D$-K[Co(RR-ptnta)]·H_2O in H_2O (——) and AB spectrum of H[CoCl(*meso*-ptntaH)] in dil. HCl (------).

The violet complex gives an absorption spectrum (AB) in water very similar to that of $[Co(trdta)]^-$ or $[Co(edta)]^-$. Its infrared spectrum shows no absorption of free carboxylate. Its PMR spectrum in D_2O gives only one methyl signal and two kinds of acetate methylene signal. The $(+)_D$ complex is assigned to be Δ, from comparison of its circular dichroism (CD) with that of Δ-$[Co(trdta)]^-$.[2] It is thus clear that the complex contains sexadentate $ptnta^{4-}$ ligand and the trimethylenediamine chelate takes a twist form. Since methyl groups should take an equatorial position in the chelate, the $ptnta^{4-}$ in the $(+)_D$ complex should have RR configuration.

The blue complex gives an absorption pattern similar to that of $[CoCl(edta)]^{2-}$ and the infrared absorption gives the peak of free carboxylate. The PMR spectrum gives two kinds of methyl signal, and the signals of acetate methylene are much more complicated than those of the violet complex. We consider that the ligand is quinquedentate in this blue complex. So far as the methyl groups orientate equatorially to the chelate ring, the trimethylenediamine ring should take the chair form and only three out of four acetate branches seem to be allowed to coordinate to cobalt(III).

Such a stereospecific formation of sexa- and quinquedentate complex from racemic and meso $ptnta^{4-}$ indicates that the steric regulation coming from the methyl group on the α-carbon atom is very strong in six-membered as well as in five-membered rings.

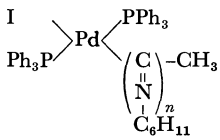
Five Co-ordination in Isocyanide Insertion Complexes of Pd(II)

Yasuhiro YAMAMOTO and Hiroshi YAMAZAKI

The Institute of Physical and Chemical Research, Yamatomachi, Saitama

(Received August 29, 1970)

We have already reported that the reaction of cyclohexyl isocyanide (**1**) with *trans*-Pd(PPh_3)$_2$I(CH_3) underwent the insertion of isocyanide molecules into a methyl-palladium σ-bond, affording imidoyl complexes.[1]



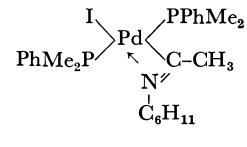
n=1 or 2

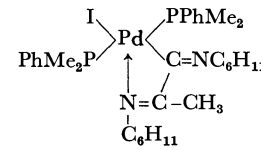
In our further studies of the insertion reaction of isocyanide,[2-4] we concluded that it had a five co-ordinate structure complexes to palladium through the lone-pair electrons of imino nitrogen atom; our conclusion was based on the NMR spectra of these types of complexes with dimethylphenylphosphine. We wish now to report on this subject.

The treatment of **1** with *trans*-Pd($PPhMe_2$)$_2$I(CH_3) in a 1 :1 or 2 : 1 molar ratio in benzene at 0°C underwent the single or double insertion of isocyanide into a methyl-palladium σ-bond, producing *trans*-Pd($PPhMe_2$)$_2$I[C(CH_3)=NC_6H_{11}] (**2**)[5] (as very pale yellow crystals, 59%, mp 169—172°C dec., $\nu_{C=N}$(KBr) 1627 cm^{-1}) and *trans*-Pd($PPhMe_2$)$_2$-I[CH_3(C=NC_6H_{11})$_2$] (**3**)[5] (as yellow crystals, 54%, mp 223—227°C dec., $\nu_{C=N}$(KBr) 1632 and 1583 cm^{-1}) respectively. The complex **3** was more stable than **2**.

In the NMR spectrum of **2** in C_6D_6 at 23°C, the methyl resonances of dimethylphenylphosphine ligands showed a well-defined 1 : 2 : 2 : 2 : 1 pattern. This may be considered to arise from two overlapping 1 : 2 : 1 patterns (8.47 and 8.35 τ), separated by 7.2 Hz, in which the triplet resonance suggests that the two phosphorus ligands were co-ordinated to a metal in mutual *trans*-positions.

The presence of two triplet signals indicates that the two methyl groups on the same phosphorus atom are magnetically nonequivalent, for there is no plane of symmetry resulting from the co-ordination of the imino nitrogen to the palladium atom.[6]





An elevation of the temperature might be expected to give the four co-ordinate complex by releasing the imino nitrogen. This would cause the two methyl proton resonances to be magnetically equivalent.

The P–CH_3 protons of **2** at 42°C appeared as two triplets (with the same coupling constant, $|^2J_{P,H}+{}^4J_{P,H}|$=6 Hz), and separated by 4.6 Hz. At 63°C and 81°C, the spectra showed 1 : 3 : 3 : 1 and 1 : 1 : 2 : 2 : 1 : 1 patterns, separated by 3 and 1 Hz, respectively, indicating two overlapping 1 : 2 : 1 patterns. At 85°C, the two P–CH_3 resonances converged to a triplet peak, indicating the absence of magnetic nonequivalence.

Analogous NMR behavior was observed in the complex **3**. In the spectrum of **3** in C_6D_6 at 23°C, the methyl proton resonances of the phosphorus ligands showed two triplets at 8.45 ($|^2J_{P,H}+{}^4J_{P,H}|$= 6.5 Hz) and 8.22 τ ($|^2J_{P,H}+{}^4J_{P,H}|$=6.5 Hz), indicating also the presence of magnetic nonequivalence. The magnitude of the chemical-shift difference of the two triplets due to the P–CH_3 resonances decreased with a rise in the temperature without changing their forms. The convergence of the two triplets to a triplet peak was ultimately observed at *ca.* 130°C, indicating that the co-ordination strength of **3** is higher than that of **2**. This indicates a parallel between the co-ordination strength and the difference in stability of the two iminoacyl complexes. Detailed studies are in progress.

4) Y. Yamamoto and H. Yamazaki, *J. Organometal. Chem.*, **24**, 717 (1970).

5) Both complexes gave satisfactory results in elementary analysis and molecular-weight determinations.

6) The triple-inserted complex, Pd(PPh_2Me)I[CH_3-(C=NC_6H_{11})$_3$], obtained from the reaction of *trans*-Pd-(PPh_2Me)$_2$I(CH_3) with **1** in a 1 : 3 molar ratio had a four-co-ordinated structure containimg the five-membered chelate co-ordinated to palladium through the terminal imino nitrogen atom; see Ref. 1. An analogous structure was noted in the nickel complexes; see S. Otsuka, A. Nakamura and K. Yoshida, *J. Amer. Chem. Soc.*, **91**, 7196 (1969).

Structure Analysis of *p*-Bromobenzoate of Sterigmatocystin by X-ray Diffraction Method

Nobuo TANAKA,[*1] Yukiteru KATSUBE, Yuichi HATSUDA,[*2] Takashi HAMASAKI[*2] and Masayoshi ISHIDA[*2]

Faculty of Engineering, Tottori University, 1-1, *Koyama-cho, Tottori*

(Received July 16, 1970)

Sterigmatocystin, a metabolite of Aspergillus versicolor (Vuillemin) Tiraboshi, is a natural product containing the dihydrofurobenzofuran system. The structure was postulated by means of spectrometry and various chemical methods.[1,2] In order to establish the structure, *p*-bromobenzoate of sterigmatocystin was investigated by X-ray diffraction method.

TABLE 1. CRYSTAL AND PHYSICAL DATA

Molecular weight:	$C_{25}H_{15}O_7Br$ 507.31
Melting point :	260°C
Monoclinic :	$a=13.01\pm0.04$ Å
	$b=9.03\pm0.03$ Å
	$c=8.93\pm0.03$ Å
	$\beta=102.5\pm0.5°$
Space group :	$P2_1$
Density (by flotation) :	1.640 g/cm³
Density (calculation) :	1.645 g/cm³
Two molecules per unit cell.	
Volume of the unit cell :	1023.8 Å³

The compound was obtained by the reaction between sterigmatocystin and *p*-bromobenzoylchloride. The crystal grown from acetone solution was light brown needles elongated along the *b* axis. The unit cell dimensions shown in Table 1 were obtained from NaCl-calibrated Weissenberg and rotation photographs about the *b* and c axes. Intensities of 1545 independent reflections were measured visually from equi-inclination Weissenberg photographs of 0—6 layers around the *b* axis.

The bromine atom was easily located as $x=-0.06$, $y=0.25$(arbitrary chosen) and $z=0.16$ from the Harker peak of a sharpened three-dimensional Patterson function. The nine atoms were assigned in the benzoyl group near the bromine atom, though the first Fourier map based on the bromine atom alone was confused by false symmetry. The whole structure of the molecule was revealed after five successive structure factor and Fourier synthesis calculations.

Refinement of the structural parameters was carried out by the block-diagonal least-squares method. The discrepancy factor was reduced to 0.168 after six cycles of the refinement with the isotropic thermal parameters. The average standard deviation of the bond length is 0.041 Å. The current three-dimensional electron density distribution viewed along the *b* axis is shown in Fig. 1. The structure of sterigmatocystin in this molecule is in agreement with that proposed by Bullock *et al.*[2]

Further refinement of the structure and determination of the absolute configuration will be published later.

A New Observation on the Polarized Absorption Spectra of TCNNQ Molecular Complexes

Yasumasa J. I'HAYA, Toru YUNOKI and Noboru SUZUKI

Department of Materials Science, The University of Electrocommunications, Chofu-shi, Tokyo

(Received July 22, 1970)

A current explanation for the origin of a second charge-transfer (CT) band which appears in some CT molecular complexes is that the second CT band is mainly associated with a charge transfer from the second highest occupied molecular orbital (HOMO) of a donor molecule to the lowest vacant molecular orbital (LVMO) of an acceptor molecule[1]. In this communication, we show a possibility of the charge transfer from the HOMO of donor to the *second* LVMO of acceptor in some TCNNQ (11, 11, 12, 12,-tetracyano-1,4,-naphthaquinodimethane)-polycyclic aromatic hydrocarbon complexes. A similar interpretation was first given by Iwata, Tanaka and Nagakura for the 1,2,4,5- tetracyanobenzene complexes[2].

We measured the polarized absorption spectra in the visible and ultraviolet regions at room temperature and 80°K for the molecular complexes which involve TCNNQ as an acceptor and anthracene (An), pyrene (Py), phenanthrene (Ph), 1,2-benzanthracene (Ba), chrysene (Ch), and triphenylene (Tp) as donors. The mole ratio of donor and acceptor was found to be 2:1 for TCNNQ-An, -Py, -Ph complexes (Group 1), while that for TCNNQ-Ba, -Ch, and -Tp complexes (Group 2) was 1:1. Two broad bands were observed in each polarized absorption spectrum of these complexes. In Group 1 complexes, the longer wavelength bands (14-19kK) are clearly polarized along the crystal elongated axes, and the shorter wavelength bands (19-23kK) are perpendicular to them. The two bands of Group 2 complexses, however, both have polarization components, though the dichroic ratios of the longer wavelength bands are two to five times larger than those of the shorter wavelength bands. These two bands are not local excitation bands but can be assigned to be the first and second CT bands, since the lowest transition of TCNNQ has an absorption maximum at 25kK and those of the donors appear at much shorter wavelength regions.

The wave numbers of the absorption maxima ($h\nu_{CT1}$ and $h\nu_{CT2}$) are plotted in Fig. 1 against the HOMO energy of donor. For the first CT bands, a straight line is obtained (Line I) as usual, so that

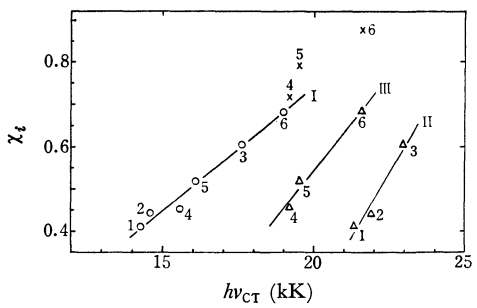

Fig. 1. Charge-transfer transition energies *vs* the Hueckel molecular orbital coefficients, χ_i, of the polycyclic aromatic donors. ○: 1st CT band, △: 2nd CT band; 1:An, 2:Py, 3:Ph, 4:Ba, 5:Ch, 6:Tp. Values of χ_i are taken from C. A. Coulson and A. Stereitwieser, Jr., Dictionary of π-Electron Calculations, W. H. Freeman and Co., San Francisco (1965).

these bands are undoubtedly associated with the charge transfer from the HOMO of donor to the LVMO of acceptor.

A plot of $h\nu_{CT2}$ *versus* the HOMO energy of donor produces two linear relationships, one for Group 1 complexes (Line II) and the other for Group 2 complexes (Line III). The charge transfer mechanism for the second CT bands may, therefore, be divided into two classes depending on the mole ratio of donor and acceptor. If we assume a charge transfer from the second HOMO of donor in Group 1 complexes, the magnitude of $h\nu_{CT2}$ should be in the order An>Py>Ph, which is inconsistent with the present observation. Thus it should be tentatively concluded, that the second CT bands of Group 1 complexes are associated mainly with the charge transfer from the HOMO of donor to the second LVMO of acceptor.

On the other hand, if we plot $h\nu_{CT2}$ of Group 2 complexes against the second HOMO energy of donor, we obtain the crosses in Fig. 1. Although the data deviate considerably from linearity, some relationship between $h\nu_{CT2}$ and the second HOMO energy of donor can be recognized. Therefore, we tentatively conclude that the second CT bands of Group 2 complexes are due to a mixed charge transfer mechanism, one from the HOMO of donor to the second LVMO of acceptor and the other from the second HOMO of donor to the LVMO of acceptor.

Photochemical Reactions of Nicotinic Acid in Aqueous and Ethanol Solutions

Fumikatsu TAKEUCHI, Takako FUJIMORI and Akira SUGIMORI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo

(Received August 4, 1970)

In a previous paper, photodecarboxylation of pyridinecarboxylic acids was reported.[1] The present paper deals with pH dependence of the photoreaction of nicotinic acid in aqueous and ethanol solutions.

Nicotinic acid was irradiated with a low pressure mercury lamp at room temperature in 5×10^{-4}M solution. The acidity of the solution was adjusted with acetate or phosphate buffer. Before irradiation nitrogen was bubbled to eliminate oxygen in the solution. Photo-products were separated by anion exchange chromatography (column; Dowex-1 formate, eluent; formic acid) and identified by elementary analysis, IR, NMR and comparison with authentic specimens synthesized.

Nicotinic acid shows manifold photoreactivity depending on solvent and acidity. In Scheme 1 are summarized photoreactions of nicotinic acid. In Fig. 1 is shown pH dependence of the photoreaction in aqueous solutions, together with pH dependence of λ_{max} of UV spectra of nicotinic acid.

The cationic form of nicotinic acid undergoes photo-hydroxylation at 2-position.[2] The anionic form is photoreactive in lower pH region to give 2-(3-pyridyl-)pyridine-5-carboxylic acid (decarboxylative bipyridyl formation), while this form is stable in alkaline solution.

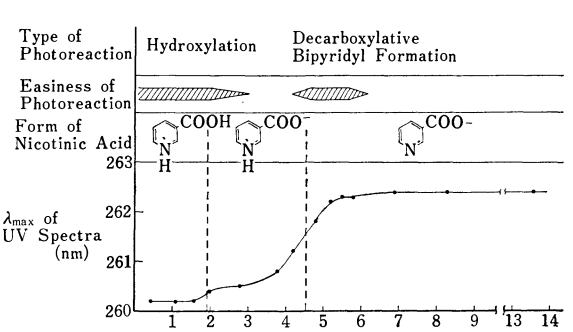

Fig. 1. pH dependence of the photoreaction and λ_{max} of nicotinic acid in aqueous solutions.

The photoreactivity of nicotinic acid in ethanol solutions differs from that in aqueous solutions. Nicotinic acid in ethanol undergoes photo-ethylation in acidic media and photo-decarboxylation in alkaline media. Since the photoreactions in ethanol were not affected by the addition of 1,3-pentadiene, the photoreactions in ethanol would proceed from excited singlet state.

Chemically Induced Nuclear Polarization in the Hydroxylamine Derivatives Obtained by Addition of 1-Cyano-1-methylethyl Radicals

Hiizu IWAMURA, Michiko IWAMURA, Masako TAMURA and Kengo SHIOMI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo
and
Department of Chemistry, Faculty of Science, Toho University, Narashino-shi, Chiba

(Received July 21, 1970)

We would like to report the observation of polarized NMR in the adducts I and II of 1-cyano-1-methylethyl radicals. When a solution of α,α'-azobisisobutyronitrile (AIBN) and excess nitrosobenzene in 1,1,2,2-tetrachloroethane/*o*-dichlorobenzene (1 : 1 v/v) was placed in an NMR probe which had been heated at 110°, AIBN decomposed with an approximate half-life of 89 sec as judged by exponential decay of its NMR absorption at 1.61 ppm.[1] At the same time an intense emission line was observed at 1.44 ppm. The amplitude reached its maximum in a negative sense at 40 sec after insertion of the sample tube, and decayed to the apparent zero in 80 sec.[2] By comparison with the authentic sample[3] it was found that the emission originated from one of the methyl signals of adduct I. Intensity of

$$\mathrm{Ph\text{-}N{=}O \xrightarrow{\cdot CMe_2CN} Ph\text{-}N(CMe_2CN)\text{-}O\cdot \xrightarrow{\cdot CMe_2CN} Ph\text{-}N(CMe_2CN)\text{-}O\text{-}CMe_2CN}$$

III I

the remaining methyl signal at 1.51 ppm, on the other hand, increased exponentially as expected for a normal growth of the chemical species as the reaction proceeds.

AIBN was similarly decomposed thermally in the presence of α,N-diphenylnitrone.[4] Adduct II shows four separate

$$\mathrm{Ph\text{-}CH{=}N(\rightarrow O)\text{-}Ph \xrightarrow{\cdot CMe_2CN} Ph\text{-}CH(CMe_2CN)\text{-}N(\text{-}O\cdot)\text{-}Ph} \quad \text{(IV)}$$

$$\mathrm{\xrightarrow{\cdot CMe_2CN} Ph\text{-}CH(CMe_2CN)\text{-}N(\text{-}OCMe_2CM)\text{-}Ph}$$

(II)

peaks (δ 1.19, 1.41, 1.70 and 1.88 ppm) of the methyl protons due to the presence of the asymmetric carbon atom in the molecule. Out of these four only a pair at 1.41 and 1.70 gave emission signals.[2]

It is reasonably assumed that the first addition of a 1-cyano-1-methylethyl radical would lead to more or less stable nitroxide radicals III and IV.[4,5] Thus the present findings that only half of the methyl groups in I and II showed emission can be considered to indicate that nuclear polarization which is developed by dipolar cross relaxation during the second step of the free radical addition is observable as emission signals.[6] It then follows that the methyl signals which appeared as emission should be assigned to the *O*-CMe_2CN of the hydroxylamine derivatives I and II.

This is the first example in which the polarized NMR signals have been applied to the assignment of the spectra. Conversely the method will find application for discussing the chronology of free radical addition when the assignment of the spectra is unambiguously available.

1) NMR measurements were carried out on a Japan Electron Optics 4H-100 spectrometer. The proton signal of the solvent tetrachloroethane was used as the lock signal and the chemical shifts are expressed relative to the internal TMS.

2) In addition to this emission two pairs of polarized NMR were always observed in the *C*-methyl region of the spectra due to isobutyronitrile and methacrylonitrile formed by disproportionation of the 1-cyano-1-methylethyl radicals. See H. Fischer and J. Bargon, *Accounts Chem. Res.*, **2**, 110 (1969), and H. Iwamura and M. Iwamura, *Tetrahedron Lett.*, **1970**, 3723.

6) The spin-lattice relaxation time was found to be 2.5 sec for all the four methyl signals of II.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3639—3643 (1970)

Redox Reactions on α-Ferric Oxide Electrode

Hiroshi YONEYAMA, Shiñichi HAMAMATSU and Hideo TAMURA

Department of Applied Chemistry,[*1] *Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka*

(Received August 18, 1969)

The redox reactions of $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$, Fe^{2+}/Fe^{3+}, and Ce^{3+}/Ce^{4+} systems on α-Fe_2O_3 electrodes containing different amounts of titanium were studied. The anodic current showed a tendency to be saturated in the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ and Fe^{2+}/Fe^{3+} systems. The forward direction of the current flow in these systems was the reverse of the case with the lithiated NiO electrode. On the other hand, the cathodic current flow was negligible and the redox potential was not observed for the Ce^{3+}/Ce^{4+} system. It was concluded that the reaction proceeds through electron transfer and that *I–V* curves are determined by the influence of the potential barrier formed on the electrode surface over which an electron transfers from the electrode into the electrolyte or in the reverse direction.

In a previous paper,[1] it was reported that redox reactions in the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$, Fe^{2+}/Fe^{3+}, and Ce^{3+}/Ce^{4+} systems on a lithiated NiO electrode which had a P-type conduction were affected by the electrical properties of the electrode and the electrode potential of the redox system. The *I-V* characteristics of these redox systems show directly how charge carriers in the electrode relate with the reaction system, for at least the reactions of the Fe^{2+}/Fe^{3+} and Ce^{3+}/Ce^{4+} systems proceed *via* only a solvent-reorganization process[2] without any formation of the adsorbed intermediate to cause a change in the surface property of the electrode. In this paper, we will study the redox reactions of these systems on a Ti-doped α-Fe_2O_3 electrode in order to clarify the relation between the charge carrier in the N-type 3*d* transition metal oxide electrode and the reaction systems. These studies will provide some information on the role of the oxide film on the electrode reaction; this film is often formed on the electrode during electrolysis.

Experimental

Electrode. The electrode was prepared and the effective area of the electrode was estimated by a method described previously.[3] The material in contact with α-Fe_2O_3 was platinum, for this material act as an ohmic contact and platinum is electrochemically inert even if the electrolyte penetrates into the electrode. The α-Fe_2O_3's used as electrodes had specific resistivities of 15, 30, 280, and 7500 Ω-cm.

Cell Equipment and Chemicals. The cell equipment and chemicals were the same as those reported previously.[1] The redox systems used in this study are also the same; they are shown in Table 1. All of the measurements were carried out at 25±1°C.

Table 1. Redox system studied

System	Medium
10 mM Ce^{3+} 10 mM Ce^{4+}	1N H_2SO_4
5 mM Fe^{2+}, 5 mM Fe^{3+}	0.1N H_2SO_4
5 mM $Fe(CN)_6^{4-}$, 5 mM $Fe(CN)_6^{3-}$	0.1N H_2SO_4

Results

The polarization curves of the α-Fe_2O_3 electrode in electrolytes containing the redox systems are

presented in Figs. 1, 2, and 3 for the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$, Fe^{2+}/Fe^{3+}, and Ce^{3+}/Ce^{4+} systems respectively. The cathodic reaction seems to proceed under an "activation controlled condition" in the former two redox systems, which have relatively low redox potentials,[4] while in the Ce^{3+}/Ce^{4+} system, which has a higher redox potential, a distinct reaction seems to occur in the case of the anodic polarization and the measured open circuit potential was below 0.6V *vs.* SCE.

To clarify the nature of the anodic current hindrance in the Fe^{2+}/Fe^{3+} system, the dependence of the concentration of Fe^{2+} on the anodic portion of the current was measured. An approximate proportionality was observed between the concentration of Fe^{2+} and its oxidation current, as Fig. 4 shows. Likewise, the effect of the concentrations of Ce^{3+}

and Ce^{4+} on the anodic current was investigated. The *I-V* curves of the α-Fe_2O_3 obtained in 1N H_2SO_4 were not changed by the addition of these ions, as Fig. 5 shows. This result caused us to doubt whether the anodic current shown in Fig. 3 directly showed the reaction current of the redox system itself. In order to elucidate this question, the quantity of Fe which had been produced by the anodic dissolution of the α-Fe_2O_3 electrode into the electrolyte during polarization for a known period and at fixed potential was analytically determined for the

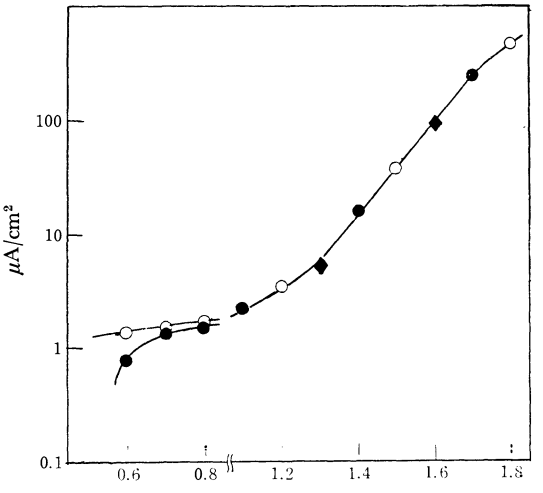

Fig. 5. *I-V* curves of α-Fe_2O_3 electrode in 1N H_2SO_4, 0.01M Ce^{3+}/1N H_2SO_4 and 0.01M Ce^{4+}/1N H_2SO_4. Data was obtained with 0.1 v step in each electrolyte, but only some of them are plotted in this figure. Noticeable difference was not detected for the above three electrolytes except for especially figured.

Table 2. Quantity of Fe in the electrolyte after polarization of electrode

Electrolyte	Potential V	Time of electrolysis hr	Quantity of electricity Q (coulomb)	Quantity of Fe g	Fe produced per unit coulomb g/Q
1N H_2SO_4	1.3	3	2.7×10^{-3}	4.5×10^{-4}	1.7×10^{-1}
	1.3	8.2	1.1×10^{-2}	2.2×10^{-4}	2.0×10^{-2}
5 mM Ce^{3+}, 5 mM	1.5	25.1	3.2×10^{-1}	9.3×10^{-5}	2.9×10^{-4}
Ce^{4+}/1N H_2SO_4	1.5	25.8	1.2×10^{-1}	19.7×10^{-4}	1.6×10^{-4}

case of 1N H_2SO_4 containing Ce^{3+}/Ce^{4+} and of 1N H_2SO_4 only. Table 2 indicates that the dissolution of the electrode was distinctly suppressed when the Ce^{3+}/Ce^{4+} was present. The current in Fig. 3, therefore, exhibits the reaction current of the redox system itself.

The apparent exchange current density, i_0, was obtained from the extrapolation of the Tafel region of the *I-V* curves on various electrodes to an open-circuit potential of each redox system, as measured with a Pt electrode, and was plotted against the conductivity of the electrodes for the $Fe(CN)_6^{4-}$/

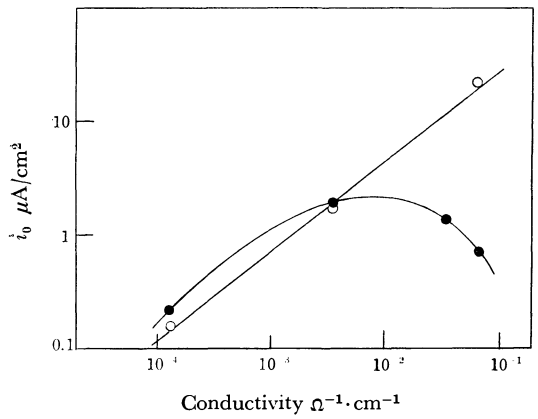

Fig. 6. Exchange current densities of $Fe(CN)_6^{4-}$/$Fe(CN)_6^{3-}$ and Fe^{2+}/Fe^{3+} systems as a function of the electrical conductivity of the electrodes.
—○— $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$, —●— Fe^{2+}/Fe^{3+}

$Fe(CN)_6^{3-}$ and Fe^{2+}/Fe^{3+} systems. Figure 6 shows a linear relationship between i_0 and the conductivity of the electrode for the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$. Such a relation has already been observed with the redox reactions on the lithiated NiO electrode,[2] though i_0 had its maximum value at the specified conductivity of the α-Fe_2O_3 electrode in the Fe^{2+}/Fe^{3+} system.

Discussion

The *I-V* curves of the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ and Fe^{2+}/Fe^{3+} systems were quite different from those on the lithiated NiO electrode,[1] where the cathodic current flow was hindered and where the anodic reaction proceeded under activation-controlled conditions. The suppression of the anodic current flow in these systems must occur as a result of either the delay of the supply of the charge carrier in the electrode[5-7] or the hindrance of the flow of the change carriers by the rectifying portion present in the electrolytic system. The former possibility is, however, obviated by the fact that the anodic current was proportional to the concentration of Fe^{2+}, as Fig. 4 shows. Therefore, the anodic current must be suppressed by the potential barrier.

The role of the potential barrier which might

exists at the Pt-α-Fe_2O_3 interface can be ignored, as was discussed previously.[3] Another possible potential barrier is the one formed on the electrode surface.[8] The electron density on the surface of the electrode must be poor in the potential shown in Fig. 4, since the flat-band potential is by far the lower.[3] Thus, the energy profile of the electrode/electrolyte interface can be pictured as is shown in Fig. 7(a), although the application of the band model to the energy structure of the 3*d* transition metal oxide may not necessarily be adequate.[9] In Fig. 7, the energy state of the redox electrolyte is also presented using a concept of the electron state which is fully anologous to that of the solid state.[10] In this figure, $E_{F,redox}$ and $E_{E,sc}$ represent the Fermi level of the redox electrolyte[10] and that of the semiconductor respectively. ϕ_0 is the potential drop in the space-charge layer formed on the semiconductor electrode when it is in equilibrium with the redox electrolyte, and η is the overpotential.

According to Fig. 7(a), no potential barrier exists to the hole transfer from the electrode into the electrolyte. The hole transfer in this direction is equivalent to the anodic current. Therefore, if the positive holes were abundant in the electrode, the anodic current would not be saturated at such a small value as 10—100 μA/cm^2. By combining this fact with the fact that there is no possibility of a delay in the supply of a charge carrier in the electrode, the possibility of the hole transfer mechanism in these reactions can be denied.

On the other hand, there will be a potential barrier for electron transfer in the electrode/electrolyte interface, as Fig. 7(a) shows. However, the height of the potential barrier for the electron transfer from the electrode into the electrolyte will decrease in proportion to the cathodic polarization, because much of the polarization potential will be applied to the surface of the electrode. Thus, the cathodic current resulting from the electron transfer from the electrode into the electrolyte will not be suffered to pass through this potential barrier. In the case of the reverse direction of the current flow, the electron must flow from the electrolyte into the electrode, and during this process the electron should jump over the potential barrier. The height of the potential barrier in this case would not be changed distinctly with the polarization[11] if the polarization voltage is almost entirely applied in the electrode surface region. Then the situation could resemble the rectifying junction formed on the metal *N*-type semiconductor interface. The anodic current would, therefore, be saturated with the anodic polarization.[12] Almost the same interpretations is applicable to the reaction of the $Fe(CN)_6^{4-}$/$Fe(CN)_6^{3-}$ system, because the redox potential of this system is near to that of the Fe^{2+}/Fe^{3+} system and the *I-V* curves of these two system resemble each other.

The situation is quite different in the Ce^{3+}/Ce^{4+} system (Fig. 7(b)). The charge carriers in the redox electrolyte will have a chance to come in contact with the unoccupied state of the electrode because of their high redox potentials. If the electron-transfer mechanism is also acceptable under these circumstances, the electron should jump over by far the higher potential barrier in the electrode surface and then flow into the electrolyte, although the height of this potential barrier decreases with an increase in the cathodic polarization.

Therefore, the reduction current necessarily decreases in this system compared with those in the Fe^{2+}/Fe^{3+} or the $Fe(CN)_6^{4-}$/$Fe(CN)_6^{3-}$ systems. The distinct reduction current which was observed below 0.6V may indicate that a distinct electron transfer over this barrier is possible below 0.6V (see Fig. 5). On the contrary, a distinct cathodic current would have been observed if the hole density had been rich enough in the electrodes. The almost negligible reduction current in the potential near the redox potential, that is, 1.3 $-$1.0V *vs.* SCE, suggests, however, that positive hole were scarce, if any existed at all. As has already been described, the distinct anodic current above 1.2V was not affected by the addition of Ce^{4+} or Ce^{3+}, although the dissolution of the electrode was suppressed by these ions. This finding suggests that

8) H. Gerischer, "Advances in Electrochemistry and Electrochemical Engineering," Vol. 1, ed. by P. Delahey and C. W. Tobias, Interscience Publishers, New York, N.Y. (1961), p. 151.

10) H. Gerischer, *Z. Physik. Chem. N.F.*, **26**, 223 (1960).

11) In the energy profile for the lithiated NiO/redox electrolyte interface presented previously (Ref. 1), a bending of the energy band of the electrode surface with the polarization was shown, but the energy difference between the electrode and the redox electrolyte during a steady-state polarization was not taken into consideration. However, an energy difference equivalent to the overvoltage will eventually exist between the redox electrolyte and the electrode. In this respect, the energy profile represented in the previous paper should be modified in such a manner that the Fermi level of the electrode is different from that of the redox electrolyte by an energy equivalent to the overvoltage. Accordingly, it should be possible to understand similarly the cathodic current of the redox system on the lithiated NiO electrode, presented previously, assuming that an almost constant potential difference is preserved between the redox electrolyte and the upper, or the lower energy state at the band edge of the electrode whether the electrode is polarized or not.

12) According to the Mott-Schottoky theory, the current, J, is related to applied voltage, V, as in the following formula when there is a rectifying junction between a metal and a semiconductor:

$$J=J_0[\exp(eV/kT)-1]$$

the current was restricted by a factor other than the concentration of ions in the electrolyte.

The hole transfer mechanism may, then be considered to be inadequate. Therefore, an electron transfer mechanism should be considered. The distinct current increase above 1.2V might be brought by the electron tunneling[13] through the barrier layer. Under a high anodic polarization, the redox electrolyte will meet the electron in the electrode through the narrower part of the potential barrier, though the width of the potential barrier increases with an increase in the potential.[14] Thus, the electron tunneling through the narrower part of the potential barrier becomes possible. The width of the barrier layer at the same polarization potential is narrower for a electrode with a low resistivity.[14] Therefore, the probability of the electron tunneling is larger for the electrode with a low resistivity at the same polarization potential.

According to the above discussion, i_0 is determined by the numbers of the charge carriers which jump over the potential barrier. Therefore, i_0 may be expected to be larger for the electrode with the lower resistivity. Nevertheless, the highest i_0 was observed in the Fe^{2+}/Fe^{3+} system. The Fe^{2+}/Fe^{3+} system is the simpler redox system and are not usually form the adsorbed intermediate. However, either the ferric of the ferrous ion, or the both, in the electrolyte might adsorb on the electrode surface, which has unshared electrons pointing into the electrolyte, since ferric and ferrous ions were also constituent ions of the electrode. The energy-barrier height formed in the electrode surface region is conceivably determined by the quantity of the adsorbed ions and the polarization potential. The electrode with a large Ti content is rich in nonstoichiometry. Therefore, if it is assumed that the adsorption of the ions in the electrolyte occurs most effectively on the nontoichiometric parts of the electrode surface,[15] the quantity of adsorbant will be large for the electrode with a large Ti content; then, the potential barrier height of this electrode will be changed distinctly. The i_0 in the Fe^{2+}/Fe^{3+} system was possibly determined by this effect as well as by the concentration of the charge carriers in the bulk of the electrode.

Among 3*d*-transition metal oxides, Ti-doped α-Fe_2O_3 and Li-doped NiO are usually accepted as typical "hopping-type" semiconductors, while TiO_2 shows a typical "drift-type" conduction. In the drift-type semiconductor electrodes, such as Ge, ZnO, and TiO_2, the electrochemical reaction is occasionally controlled by the behavior of the minority carriers.[16] As has been discussed above, however, it seems that only the majority carrier is conceivably concerned in the electrochemical reaction on the α-Fe_2O_3 electrode. This is also suggested in the case of the lithiated NiO electrode.[1] In this sense, the electrode of a hopping-type semiconductor may play a different role in the electrochemical reaction from a drift-type semiconductor.

Studies on the Effect of Some Anionic Detergents on the Stability of Emulsions Stabilised by Partially Flocculated Sols

S. P. JAIN and S. N. SRIVASTAVA

Chemical Laboratories, Agra College, Agra, India

(Received October 30, 1969)

A partially flocculated $Fe(OH)_3$ sol has been used as an emulsifying agent to stabilize toluene/water system. The electrophoretic mobilities of the emulsion thus obtained in the presence of different anionic detergents have been measured microelectrophoretically and from these values the zeta potentials have been calculated. At the charge reversal concentrations the adsorption and free energy constants were calculated. From the surface potential values the repulsion and attraction energies were evaluated which clearly showed that the flocculation occurrs in the secondary minima. The operating van der Waals constant A has been estimated by correlating the results of degree of aggregation obtained haemocytometrically with the theoretical values. It was found to be 1.05×10^{-12} erg. The values of interfacial tension have been reduced by the addition of these detergents which are directly connected with the chain length of the detergent and adsorption characteristics.

Adoorption and its relation with electrokinetic potential for various detergents has been studied by some workers.[1-6] Haydon[7] also studied the relationship between the electrokinetic potential and surface charge density for long chain alkyl sulphates. Levich and Kuzhetsov[8] observed the retardation effect of surface active agent on the movement of the drop in a liquid between the regions of high and low interfacial tensions. The coagulation kinetics of rutile in hydrocarbon solutions of Aerosol OT reported by McGown and Parfit[9] showed an excellent agreement with the DLVO theory over a wide range of zeta potential.

A study of literature reveals that detergents influence the stability of colloidal systems, as they get ionized and affect zeta potentials. In the case of emulsions stabilized by solid substances and specially by metal hydroxides, practically no quantitative measurement has been done on the stability in the presence of detergents. In the present work an attempt has been made to study quantitatively the stability of emulsions in the presence of anionic detergent especially in the light of DLVO[10-12] theory. Electrokinetic measurements have been used for the interaction between the droplets and haemocytometric device for flocculation studies.

Theoretical

According to Derjaguin and Kussakov,[13] the repulsion energy V_R between the two spherical particles for the system having $\kappa a \gg 1$ is given by

$$V_R = \frac{\varepsilon a \psi_0^2}{2} \ln (1+\exp(-\kappa H)) \qquad (1)$$

where ψ_0 is the surface potential (approximately equal to zeta potential for the present system), H is the distance of separation of the droplets and κ is the Debye-Hückel parameter equal to the reciprocal thickness of the double layer

$$\kappa = \frac{1}{d} = \left[\frac{4\pi e^2 \sum n_i z_i^2}{\varepsilon k T}\right]^{1/2} \quad (2)$$

where z is the valency of the ions of ith kind and n_i is the number of ions per m*l*.

The attraction energy V_A at intermediate distances where the force is partially retarded is given by Schenkel and Kitchener[14] as follows.

For $H > 150$ Å,

$$V_A = -\frac{Aa}{\pi}\left(\frac{2.45\lambda}{120H^2} - \frac{\lambda^2}{1045H^3} + \frac{\lambda^3}{5.62\times10^4 H^4}\right) \quad (3)$$

For $H > 150$ Å

$$V_A = -\frac{Aa}{12H}\left(\frac{\lambda}{\lambda+3.54\pi H}\right) \quad (4)$$

where λ, the wavelength of the intrinsic electronic oscillations of the atoms, is taken to be equal to 1000 Å.

The change in charge density caused by the addition of a small quantity of foreign ions which are adsorbed on emulsion particles will be given by the Stern equation[15,16]

$$\sigma_C = \frac{N_1 ze}{1 + \frac{55.6}{C}\exp\left(\frac{\Delta G}{kT}\right)} \quad (5)$$

where C is the molar concentration of the added detergent, N_1 the number of binding sites available per cm^2 and ΔG is the electrochemical free energy of adsorption per molecule. This can also be put in the form[17-19]

$$\Delta\sigma_C = \frac{K_1 C}{1+K_2 C} \quad (6)$$

which is similar to Langmuir adsorption isotherm.[20] K_1 and K_2 are called adsorption constants.

The relation between log C, ψ_δ (here $\psi_\delta = \xi$) and N_1 at the isoelectric points where $\kappa a \gg 1$ is given by the equations

$$\frac{1}{C} = K_2\left\{\left[\frac{4\pi e N_1 Z}{\xi'\varepsilon\kappa}\right] - 1\right\} \quad (7)$$

where C is the concentration of detergents at ($\xi = 0$) zero point of charge and ξ' is the initial zeta potential taken instead of ψ_δ, and assuming that only a single adsorbed layer was formed upto $\xi = 0$.

$$\left(\frac{d\xi}{d\log C}\right)_{\xi=0} = 2.303\xi'\left(\frac{\xi'\varepsilon\kappa}{4\pi e z N_1} - 1\right) \quad (8)$$

The chemical free energy of adsorption ΔG has been calculated by the equation[21]

$$-\Delta G = kT(\ln K_2 + \ln 55.6) \quad (9)$$

The degree of aggregation, *viz.*, the total number of particles associated with a given central particle can be determined with knowledge of the depth of the secondary minima by solving the following equation where the integration has been carried out graphically.

$$D = 4\pi a^3 n_0 \int s^2 \exp(-V/kT)\,ds \quad (10)$$

Experimental

A positively charged ferric hydroxide sol was prepared, dialyzed and partially flocculated by the addition of 0.15 mmol of potassium oxalate. To this sol toluene (5%, weight) was dispersed by shaking by hand and the emulsion was then well homogenized using a stainless steel homogenizer (C. W. Logemann Co. U.S.A.). After half an hour the creamed layer was removed and same emulsion was prepared under the same conditions.

In order to study the effect on stability the following detergents have been used: dibutyl ester of sodium sulphosuccinic acid, dioctyl ester of sodium sulphosuccinic acid, sodium salt of secondary alkyl sulphate containing 17 carbon atoms and sodium lauryl sulphate. All the detergents were obtained from BDH and used as they are. For the sake of convenience they have been represented by the BSS, OSS, SAS and SLS. The other chemicals and reagents used were of Analar grade.

Electrokinetic measurements were carried out by micro electrophoresis apparatus using a Northrup-Kunitz rectangular type cell in which the direct movement of the emulsion droplets was observed with a microscope for a definite distance under a suitable electric voltage which was measured by the VTVM across the two ends of the cell. An equiconducting solution of KCl was used in electrode vessels and the zeta potentials were calculated by means of the relation

$$z = \frac{4\pi n u}{\varepsilon} \quad (11)$$

the relaxation correction being neglected because of the large sized particle (radius 1.12 μ) (Fig. 1 and Fig. 2).

Results and Discussion

Effect of Anionic Surface Active Agents on Zeta Potential. The zeta potentials of the emulsions in the presence of different concentrations of surface active agents have been plotted against log molar concentrations in Fig. 3. In general, as the

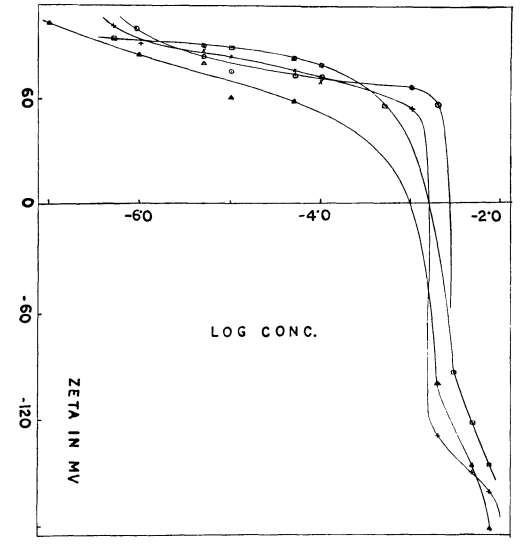

Fig. 3. Curves showing the variation of zeta with concentration for △ SLS, × OSS, ⊡ SAS and ⊙ BSS.

concentration of these detergents is increased in a low range the zeta potential decreases very slowly until a certain concentration is reached after which it gradually decreases to a certain fixed value of nearly 50 mV, with increasing gradient. Further increase in concentration gave visible flocculation where the measurements were not feasible because of agglomeration of a large number of solid particles on oil globules on account of small zeta value. On a further increase of concentration, reversal of charge took place and the zeta became increasingly negative.

Increase in zeta value in this range of concentration is very sharp. With a small change in concentration an appreciable increase in zeta took place which increases upto critical micelle concentration. Over this CMC there should be no further change theoretically. However, a decrease was observed only in one case with SLS. The decrease in zeta after CMC can be explained as follows. It is likely that during the mixing of concentrated solution of detergent to the system, conditions could occur in which the miceller solution of the detergent becomes submiceller. The breakdown of micelles to submicelles is a very fast reaction.[22] The time required during mixing of the detergent in to the system is of the same order as required for breaking down of the micelles, and mutual coagulation would have occurred between the micelles and the stabilized emulsion droplets resulting in an artificial decrease of stability.

The flocculating concentration at which zeta potential becomes zero was obtained from zeta-log C curves. From them the efficiency of reversing the charge or the extent of adsorption is in the order SLS>OSS>SAS>BSS, and their CMC are to be expected in the increasing order. Thus a higher concentration of SAS is required to reverse the charge than SLS. The charge reversal was not obtained with BSS though relatively high concentration of the order of 2.0×10^{-3} mol/l has been reached. This is presumably on account of a comparatively smaller chain length of the detergent. This order of their efficiencies is also confirmed by their structural formulae; SLS possesses a long chain of 12 carbon atoms, OSS and SAS possess of only eight carbon atoms while BSS has only 4 carbon atoms in its chain. Thus their efficiencies increase as carbon chain increases. The distinction between SAS and OSS is on the basis that OSS possesses a bigger head group than SAS.

Charge Density and Binding Parameters. The number of binding sites available per cm^2,

BSS	3.2×10^{2}	2.32	9793

N_1, binding parameters and charge density have been calculated with the help of the slope of zeta-log C curves and the concentration at which $\zeta=0$, and are represented in Table 1. The area occupied by each anionic surface active agent when all the sites are covered is also calculated. The value of free energy of adsorption ΔG which determines the strength of binding of these surface active ions are shown in Table 2.

From the table we see that the values of K_2 are in the order SLS>OSS>SAS>BSS, which gives the order of adsorption. This can also be seen from zeta-log$C$ curves, where the slope of the curves are found to increase with increasing chain length of the surface active agents, and a shift of the zero point of charge to higher concentration for a smaller chain length is also observed.

The nature of adsorption of these anionic surface active ions can be explained on the basis of the binding parameters. At a smaller concentration the surface active ions go to the positively charged surface of oil globule, probably the surface occupied by potential determining ions. The surface sites are essentially the same for different surface active agents, because the values of N_1 obtained for each detergent are reasonably consistent. However, it is clear that the maximum number of sites is greater than the surface excess of ferric ions since the sign of zeta is reversed. Thus, it seems reasonable to assume that at a certain concentration nearly 5×10^{-4} mol/l, the surface active ion may be adsorbed directly on the surface at the sites other than those occupied by potential determining ions. Uncertainty may arise due to a slight differences in the values of N_1.

The adsorption can also be explained by the consideration that the oil phase is in reversible equilibrium with the ions in the solution. When surface active agents are added, one particle of it is adsorbed on one potential determining ion site, and an additional potential determining ion is adsorbed and this process will continue until the system becomes irreversible. In this process with the adsorption of detergent on potential determining ions, the adsorption directly on the oil surface also occurs.

Interaction Energy Curves and Secondary Minimum Flocculation. The interaction energies of the double layer around the particles at the different concentrations of the detergents SLS, OSS, SAS and BSS have been calculated with respective values of the zeta potentials, and are tabulated in Table 3. The corresponding curves for the interaction energy *vs.* the distance between the two particles are plotted, the only representative figure

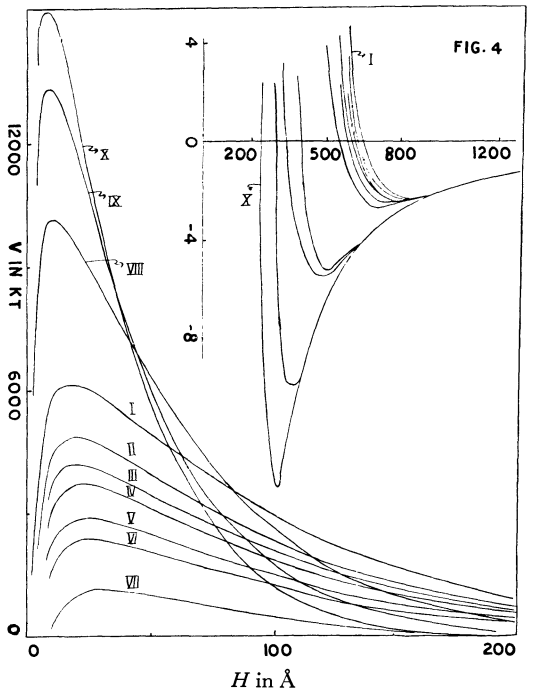

Fig. 4. Potential energy profiles and elaborated secondary minima for OSS at I, 5×10^{-7}, II 1×10^{-6}, III 5×10^{-6}, IV 1×10^{-5}, V 5×10^{-5}, VI 1×10^{-4}, VII 1×10^{-3}, VIII 2×10^{-3}, IX 5×10^{-3} and X 7.5×10^{-3} mol/*l*.

is shown in Fig. 4. The value of *A i. e.* van der Waals constant has been taken to be equal to 1.0×10^{-12} erg.

From the equations of interaction energies it can be seen that the value of V depends mainly on the factors ψ_δ, κ and a which change with concentrations of the detergent. The κa values remain almost the same nearly upto the concentration 1×10^{-4} mol/*l* in case of all the detergents, *i. e.* the ionic strength will not change much and hence practically no change in the value of interaction energies will be observed. Addition of the surfactants has an effect on ψ_δ or ξ. However, at higher concentrations both the factors κ a and ξ change and affect the value of V.

At smaller distances the values of interaction energies obtained are considerably high in all cases while at larger distances attraction prevails and secondary minima are obtained in which particles aggregate reversibly. The depth of secondary minima is nearly constant in the low range of concentrations and is equal to $2.5kT$ for all detergents. This is too shallow to trap the particles but at higher concentrations the depth increases upto 10—15kT which is reasonable for the occurrence of flocculation. These high energy values and the occurrence of the secondary minima may be due to large particle radius ($a=1.1$ μ).

The relation between the interparticle distance H_m at which the minimum energy occurs and Debye-Hückel parameter κ can be represented by the equation

$$H_m{}^2e^{-\kappa H_m} = 1.80\times10^{-9}\frac{v^2}{\kappa V^2}$$

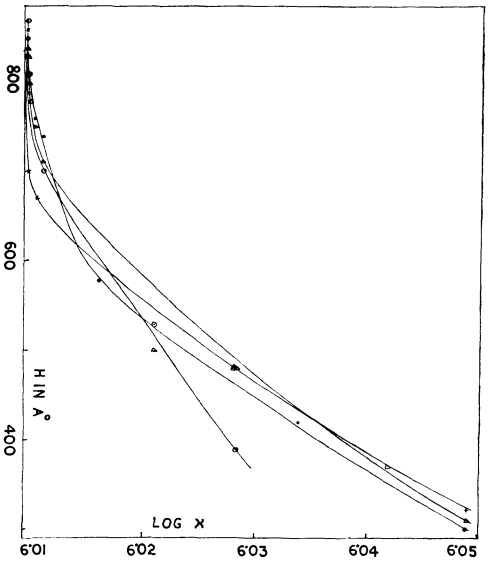

Fig. 5. Curves showing the depencence of κ Debye-Hückel parameter to H_m for × SLS, △ OSS, ● SAS and ⊙ BSS.

The effect of κ upon H_m separation of particles when they are reversibly flocculated in secondary minima is shown in Fig. 5. The distance H_m decreases with the increase in concentration of the detergents. This H_m distance is also directly proportional to the valency of the added ions which are uni valent. Thus the value of H_m is nearly the same at low range of concentration and is just linear, but it varies with κ at higher concentrations. The depth of the secondary minima also depends

on the value of the van der Waals constant A.

Concerning flocculation, the singlets and doublets as obtained haemocytometrically were plotted with respect to time at different concentrations of detergents, the representative plot being shown in Fig. 6. They are levelled off after certain time because of attainment of a temporary equilibrium between singlets and doublets. This confirms the occurrence of secondary minimum flocculation in the emulsion of large particles.

Determination of the van der Waals Attraction Constant. In order to determine the van der Waals constant, the value of degree of aggregation D is required which has been calculated by Eq. (10) with the help of depth of secondary minima at different values of the van der Waals constant. These values of D are plotted for the different values of A as shown in Fig. 7. The observed value of D has been determined haemocytometrically with the help of the equation

$$D = \frac{\text{number of singlets}}{\text{number of singlets} + \text{number of doublets}} \qquad (12)$$

The value of A corresponding to these values has been deduced from the graphs and given in Table 4. The mean value of A was found to be 1.0×10^{-12} erg which is reasonable for oil droplets coated by solid particles and agrees with the theoretical value calculated by physico optical data.[23]

Effect of Anionic Detergents on Interfacial Tension. The interfacial tension between oil phase and continuous phase were measured by an Agla micrometer syringe. The volume of a drop falling in oil phase was noted and the interfacial tension was calculated by the density difference of the two phases by equation

$$\nu = \frac{(d_2-d_1)v}{gr}f \qquad (13)$$

The interfacial tensions in presence of different

amounts of anionic detergents have been measured and the curves between interfacial tension and log molar concentration are given in Fig. 8. Th change in interfacial tension and the volume of each drop are reported for all the detergents in Table 5. The value of interfacial tension decreases which implies a positive adsorption as suggested by Gibbs adsorption equation. These anionic surface active ions are adsorbed at the surface of positively charged oil particles and cause instability with increase in concentration of the detergents. The decrease in interfacial tension is greater in the cases of SLS and OSS than in cases of SAS and BSS which indicates that the effect depends on the chain lengths of the detergents. This is also in accordance with electrokinetic results.

Thermal Decarboxylation of Nitrobenzoic Acids. I

D. S. MANIKYAM and E. V. SUNDARAM

Chemistry Department, Osmania University, Hyderabad, India

(Received November 12, 1969)

Thermal decarboxylation of *o*-, *m*- and *p*-nitro benzoic acids was studied in glycerol in the temperature range 210—250°C *m*- and *p*-Nitrobenzoic acids exhibited first order rate constants and in support of the proposed S_E1 mechanism, the isomers were also studied in aniline at 110—140°C. Pseudo-first order rate constants of the ortho isomer in glycerol suggested a change in mechanism from S_E1 to S_E2. The rate constants were influenced by boric acid or aniline added to glycerol as the result of a change in pH and confirmed thus the proposed S_E1 or S_E2 mechanisms. Activation energies, enthalpies and entropies of activation were obtained for the three isomers.

A survey of literature of several organic acids reveals that decarboxylation occurs either by unimolecular or bimolecular electrophilic substitutions, S_E1 or S_E2.[1] The S_E1 mechanism requires the loosening of R–C bond, and the substituents which diminish the electron density on the α-carbon atom facilitate this mechanism as in the cases of nitro acetic, nitro-isobutyric,[2] trihaloacetic[3] and cyano-acetic acids.[4]

The view that decarboxylation by S_E2 mechanism involves the attack of a proton or a protonated solvent on the α-carbon atom of the carboxyl group is supported by Schenkel and Schenkel-Rudin,[5] Hammick and coworkers[6] and Muhammad and Siddiqui.[7] A polyhydric alcohol glycerol was used as a solvent in the studies of decarboxylation of hydroxy benzoic and chlorobenzoic acids and 1-hydroxy-2-naphthoic acid.[8]

In view of the above studies, the decarboxylation of *o*-, *m*- and *p*-nitrobenzoic acids was carried out in the solvents glycerol and aniline in order to study their mechanisms.

Results and Discussion

***m*- and *p*-Nitrobenzoic Acids.** Decarboxylation of the *m*- and *p*-nitrobenzoic acids in the solvents glycerol and aniline is kinetically first order. The rates, being faster in the basic solvent aniline than in glycerol, suggest that these isomers follow the unimolecular S_E1 mechanism. The rate constants and the other thermodynamic parameters are shown in Table 1.

Substances such as aniline and boric acid added to glycerol alter the acidity of the medium and the rate constants, as in Table 2 (a) and (b), also exhibit a marked increase and decrease for the meta and para isomers respectively in support of the S_E1 mechanism. The stability of the two isomers in the acidic solvent, resorcinol is an additional support for the proposed mechanism.

The presence of a nitro group either in the meta or para position in benzoic acid, by withdrawing electrons, deactivates the ring and facilitates the C–C bond cleavage. Glycerol being a polyhydric alcohol ionizes the acids to a less extent than aniline.

A comparison of the rates, enthalpies and entropies of activation reveals that a more basic solvent aniline favours the S_E1 mechanism rather than a neutral solvent glycerol, and is in good agreement with the observation of Clark.[9a] In these solvents it has been visualised that the electrophilic carbon

atom of an undissociated acid apparently co-ordinates with an unshared pair of electrons on a nucleophilic atom of the polar solvent favouring the subsequent cleavage of the molecule into the products.[9b]

Since the rate determining step involves the decomposition of the transition state, the extent of formation of this state depends on the polarizability of the carboxyl carbon atom as well as on the nucelophilicity of the solvent. Therefore, it can be suggested that the greater the availability of the electrons on the neucleophilic atom of the solvent, the greater would be the probability of the formation of the activated state. Hence, in the activated state, the nucleophilic aniline interacts more readily than glycerol with the carbon atom of the carboxyl group resulting in high enthalpies and entropies of activation. However, as the accepting ability of the carbon atom of the carboxyl group does not change much in the two isomers, it is the basicity of the solvent that plays an important role in the formation of the transition stage. The rate constants, activation energies and other thermodynamic parameters are nearly the same in the weakly basic solvent glycerol comparable to their pK_a value. But in the highly basic solvent aniline, the effective electrophilicity developed on the α-carbon atom of the carboxyl group in the two isomers also plays a role and shows an increase in the thermodynamic parameters, similar to the change from glycerol to aniline.

o-Nitrobenzoic Acid. The kinetics of decarboxylation of *o*-nitrobenzoic acid in glycerol follows a different pattern from that of the other two isomers. The rate of ortho acid (Table 1) is small compared to its meta and para isomers and exhibit pseudo-first order rate constants. The rate constants also show an increase with added boric acid to glycerol as the result of a change in pH (Table 3).

It was also observed that the ortho isomer decarboxylates more easily in acidic solvent, resorcinol, and is stable in basic solvent, aniline, unlike the meta and para isomers. This exhibits a change in mechanism from S_E1 to S_E2 since the latter are acid-catalyzed.

It has been suggested that the geometry of the ortho-transition state of *o*-nitrobenzoate ion exhibits a dipolar interaction of the type as in Fig. 1, the stereochemistry of the transition state being suitable for the electrophilic substitution. This type of internal chelation[10] is mainly responsible for a change in mechanism and the decarboxylation proceeds in the anionic form.

$$k = [RCOO^-][H^+]$$

Fig. 1

Besides the chelation in the case of ortho isomer, deactivating influence of nitro group in ortho position will be less. This is due to the fact that the nitro group, which is in the same plane as the benzene in para isomer, deactivates the carbon atom mostly due to resonance interaction. However, in ortho position, because of steric effect, the nitro group is twisted out of the plane of benzene ring. Hence, the resonance inter-action will become less, and deactivating influence will be diminished compared to its para or meta isomer.

Experimental

The experimental procedure and the calculation of the rate constants were similar to the one adopted in 1-hydroxy-2-naphthoic acid.[8] The experiments were carried out with B.D.H. and analar samples of ortho, meta and para nitrobenzoic acids and the solvents glycerol and aniline were of pure quality, which did not emit any carbon dioxide when heated alone. In all the experiments, the final volume of carbon dioxide was calculated theoretically. The kinetics were followed in all cases, till 25—30% of acid was decarboxylated. The reactions were studied in the temperature range 200—250°C in glycerol and 110—135°C in anilline.

The authors wish to thank Professor N.V. Subbarao for his keen interest and one of the authors (D.S.) is grateful to the Government of India for the Award of a Research Training Scholarship.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3653—3657 (1970)

Mechanism of Hydrogenolysis. I. Effect of Methyl Substituent on the Demethylation Rate of Polymethylbenzenes

Akira AMANO, Masao UCHIYAMA and Yoshiki SATO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba-Aramaki, Sendai

and Hiroo TOMINAGA, Hiromichi ARAI and Taiseki KUNUGI

Department of Synthetic Chemistry, Faculty of Engineering, the University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received January 31, 1970)

Rates of demethylation of six different polymethylbenzenes have been measured, at 702°C and residence times ranging from 0.5 to 6.0 sec in the presence of five-fold in excess hydrogen, by using toluene as an internal reference. The rates per one equivalent methyl group were: 1.08 for *p*-xylene, 1.73 for *o*-xylene, 1.26 for 4-position of 1,2,4-trimethylbenzene, 1.87 for 2-position of 1,2,4-trimethylbenzene, 1.85 for 1-position of 1,2,4-trimethylbenzene, 1.20 for 1,3,5-trimethylbenzene, 2.22 for 1-position of 1,2,3-trimethylbenzene, 3.25 for 2-position of 1,2,3-trimethylbenzene, 1.5 for 5-position of 1,2,3,5-tetramethylbenzene, 2.1 for 1-position of 1,2,3,5-tetramethylbenzene, and 2.8 for 2-position of 1,2,3,5-tetramethylabenzene, all the figures being expressed against the standard value of 1.00 for toluene. The observed accelerating effect of neighboring methyl groups on the demethylation rates of crowded reactant molecules has been correlated with modified superdelocalizability in z direction for radical aromatic substitution. The latter values calculated by the extended Hückel molecular orbital method were: 0.4070, 0.4116, 0.4908, 0.4169, 0.4124, 0.4116, 0.4131, 0.4133, 0.4148, 0.4204, 0.4120, and 0.4029 (toluene) in the order given above. The general parallelism between the observed and the theoretical values may be taken as a support not only of the extention of the concept of superdelocalizability to radical aromatic substitution, but also of our mechanistic interpretation on the key reaction of hydrogenolyses.

Considerable number of kinetic investigations were reported on the thermal hydrogenolytic demethylation of toluene.[1] Observed rates of the hydrogenolysis, $C_6H_5CH_3+H_2\rightarrow C_6H_6+CH_4$, can best be summarized within the specified deviations by $-d(C_6H_5CH_3)/dt=10^{(11.0\pm1.0)-(55\pm5)/\theta}\ (C_6H_5CH_3)\cdot(H_2)^{0.5}$ mol/l·sec over strikingly wide ranges of both temperature and pressure. The following chain mechanism initially proposed by us[2] and later supported by Benson and Shaw,[3] gives reasonable accounts for the observed overall three-halves reaction order as well as the values of Arrhenius kinetic parameters.

$$C_6H_5CH_3 \rightleftarrows C_6H_5CH_2 + H$$

$$H + C_6H_5CH_3 \rightleftarrows H_2 + C_6H_5CH_2$$

$$H + C_6H_5CH_3 \xrightarrow{(a)} C_6H_6 + CH_3$$

$$CH_3 + C_6H_5CH_3 \rightleftarrows CH_4 + C_6H_5CH_2$$

In the above chain scheme, the propagation rate is effectively controlled by reaction (*a*). This reaction can be pictured as a perpendicular approach of hydrogen atom to ring carbon atom to which methyl group is attached. This is followed by elimination of methyl group to complete the reaction. Energetics of the concerted process, quoted by Benson and Shaw as abstraction-elimination reaction,[3] has been successfully treated in our following communication[4] in terms of total electron energies of postulated transition structures using extended Hückel molecular orbital calculations.

The rate measurements were also reported for

xylenes,[1b,5,6] 1,3,5-trimethylbenzene,[6] and 1,2,4-trimethylbenzene.[7] The reaction order was again found to be three-halves, indicating the validity of the same chain scheme proposed for toluene.[3] There is certain evidence,[5,7] however, that the specific rate of demethylation is affected by both number and position of methyl substituents of the reactant molecule. Thus, demethylation of the first methyl group of xylene and trimethylbenzenes was quite definitely easier than that of toluene. Unequal amounts of *o*-, *m*-, and *p*-xylenes were formed from 1,2,4-trimethylbenzene.

In the first part of the present work, effort has been made to evaluate quantitatively the ease with which any particular methyl group is substituted. Experiments are carried out for six different polymethylbenzenes at a fixed temperature of 702.1°C by an internal competitive reaction system. The latter technique assures a fair comparison of the demethylation rates. The value of demethylation rate constant for any given methyl group relative to that of toluene is then correlated with the relevant reactivity index for radical substitution.

Experimental

Commercial reagent grade polymethylbenzenes were used as received. Purities of the reagents as analyzed by gaschromatography were: benzene, >99.9 mol%; toluene, >99.9 mol%; *o*-xylene, 94.2 mol%; *m*-xylene, 97.3 mol%; *p*-xylene, >99.9 mol%; 1,2,3-trimethylbenzene, >99mol%; 1,2,4-trimethylbenzene, 99.7mol%; 1,3,5-trimethylbenzene, 99.8 mol%; 1,2,3,5-tetramethylbenzene, 96.6 mol%. Balancing impurities were consisted of hydrocarbons in the neighboring boiling ranges. Cylinder hydrogen of not less than 99.9 mol% purity was used after a conventional purification.

An all-glass flow apparatus was operated under an atmospheric pressure. Reactant polymethylbenzene was mixed with an adequate amount of toluene, and the mixture was introduced into the apparatus by using a glass syringe. The polymethylbenzene-toluene vapor was then carried into a reaction vessel along with a stream of hydrogen dried over magnesium perchlorate. Rate of hydrogenolysis of any given polymethylbenzene was thus evaluated in relation with that of toluene admixed as a standard reference. The use of the internal competitive reaction technique could afford a sufficiently reliable measure as to the reactivity ratios. In a few runs, where toluene was not a convenient reference because of an interference in the product analyses, 1,3,5-trimethylbenzene was used as a reference material.

The reaction vessel was made of a quartz tubing, 23 mm in inside diameter and 90 mm in length, and was equipped with a thermo-sheath placed along its central axis. The vessel was fitted in an electrically heated aluminum-bronze block furnace, the temperature of which was controlled electronically within ±0.5°C. Temperature profiles of the reaction vessel were determined, during each run while the reaction was taking place, by a movable Pt-Pt·Rh thermocouple in the sheath. Annular space of the vessel was filled with quartz tips, resulting in a free volume of about 10 ml. Reaction temperature and residence time were defined by the method described elsewhere.[8] The reaction was carried out at a fixed temperature of 702.1°C, hydrogen-hydrocarbon mole ratio of 5, and residence times ranging from 0.5 to 6.0 sec.

Condensable components of the products were collected in a train of cold traps immersed in liquid nitrogen, and were subjected to the conventional gaschromatographic analysis using dinonylphthalate (3 m) and polyethyleneglycol (3 m) packed columns.

Results

The gaseous products consisted mainly of methane and unreacted hydrogen with trace amounts of ethane, propane, propene, *etc.* The liquid products were compared of lower homologues of reactant polymethylbenzenes. Distributions of the products were in accord with those already reported for trimethylbenzenes.[6,7] The hydrogenolyses of polymethylbenzenes should therefore follow the general consecutive scheme: $C_6H_{6-n}(CH_3)_n+H_2\rightarrow C_6H_{7-n}(CH_3)_{n-1}+CH_4$. The relative rate of demethylation per one equivalent methyl group of polymethylbenzenes could thus be obtained directly from the composition of liquid products. The procedure assumes that the first order reaction with respect to polymethylbenzene takes place in an ideal plug flow reactor. It should be noted, however, that the deviations from the ideality do not produce substantial error in the values of reactivity ratio.

Demethylation rates of *o*-xylene and *p*-xylene were measured in relation with that of 1,3,5-trimethyl-

benzene by analyzing for toluene and *m*-xylene produced. The results obtained under varying conversion levels are listed in Table 1 and 2. In excellent agreement with previously reported values,[1b,5] *o*-Xylene is shown 1.6 times as reactive as *p*-xylene.

Demethylation rates of other polymethylbenzenes were measured using toluene as internal referance. The results are listed in Tables 3, 4 and 5. In these instances, either two or three structural isomers were initially formed depending on the number of unequivalent methyl groups in the reactant molecule. Thus, the liquid product from 1,2,4-trimethylbenzene at a conversion level of 2.73 mol% was composed of *o*-xylene (0.64 mol%), *m*-xylene (0.98 mol%), *p*-xylene (1.01 mol%), and toluene (0.10 mol%). The amount of toluene produced from the three xylene isomers by secondary reaction was then corrected based on the reported relative reactivity among these isomers, resulting in the initial isomer distribution of *o*-xylene (21.1 mol%), *m*-xylene (38.7 mol%), and *p*-xylene (40.2 mol%). The values of the initial distribution corrected by the method described above are listed in the second column of Tables 3, 4 and 5. Relative rate to produce any particular isomer was deduced from the overall relative rate and the initial distribution, giving proper consideration of statistical factor if necessary. Thus, for example, relative rate to produce *o*-xylene from 1,2,3-trimethylbenzene was obtained by dividing analytical value by statistical factor of two. The final values of the relative rate are listed in the last column of the tables. A check of the data can be made, for example, by comparing the overall relative rate of 4.98 given in Table 3 with the reported value of 5.0.[7]

Table 6 lists the results obtained for a mixed feed of toluene and 1,3,5-trimethylbenzene. Summarized in Table 7 are the relative rates of demethylation per one equivalent methyl group based on the averaged value of 3.59 given in Table 6. It should be emphasized at this point that the values of relative rates listed in Table 7 are essentially those for (*a*), and are free from other elementary reactions included in our mechanism.[2] This is, in fact, one of the advantages of the present experimental method.

Discussion

As has been shown by the foregoing experimental results, the rate of reaction *a* is affected by both number and position of methyl substituents in any given reactant molecule. In the word of classical organic chemistry, this is due obviously to a cummulative result of inductive and resonance effects. Such effects should modify electronically the reactivity of methylated carbon atoms in benzene ring toward hydrogen atom attack, reaction (*a*), which in turn controls the rate of the overall hydrogenolysis. Fukui, Yonezawa, and Nagata have successfully introduced an index termed superdelocalizability,[9] in their work calculated by the simple Hückel method, as a measure of the reactivity of aromatic compounds for substitution reactions.

We adopt in the present paper the concept put forward by Fukui *et al.* but using the extended Hückel method. The use of the latter method should be preferred in elucidating the electronic structures of polymethylbenzenes, since *sigma* and *pi* electrons can be treated without arbitrary parametrizations. The modified superdelocalizability radical substitution, $S_p(\mathrm{R})$, defined by the following equation is thus taken as reactivity index.

$$S_p(\mathrm{R}) = \sum_{i}^{\mathrm{occ}} \{(c_{p_i})^2/\lambda_i\} + \sum_{j}^{\mathrm{unocc}} \{(c_{p_j})^2/-\lambda_j\}$$

where $\lambda_i = -\varepsilon_i + \alpha_0$, and $\alpha_0 \fallingdotseq (\varepsilon_{\mathrm{ho}} + \varepsilon_{\mathrm{lv}})/2$. ε_i and c_{p_i} are eigen value and eigen vector of the *i*th molecular orbital, respectively. The validity of the approximation in estimating the value of α_0 can be tested for the case of toluene hydrogenolysis where the energy level of half-filled orbital of the activated complex was estimated as being −10.439 eV in our follwing paper.[4] This should be compared with −10.426 eV deduced from the energy level of the highest occupied orbital, $\varepsilon_{\mathrm{ho}}$, of −12.491 eV and that of the lowest unoccupied orbital, $\varepsilon_{\mathrm{lv}}$, of −8.361 eV for toluene both listed in Table 8.

Detail of the molecular orbital calculations by the extended Hückel method have been described.[4] The calculations are carried out for ten different polymethylbenzenes based on the following molecular geometries: coplanar skeletal structure;[10] C-(ring)-C(ring) distance, 1.40 Å; C(ring)-C(methyl) distance, 1.51 Å; C(ring)-H distance, 1.09 Å; C-(methyl)-H distance, 1.09 Å. It is further assumed

1,2,3,4-Tetramethylbenzene	—	—	2,3	0.4158	0.3058	0.5257	0.7754
1,2,3,5-Tetramethylbenzene	−12.0826	−8.0031	1,3	0.4204	0.2691	0.5717	0.7752
1,2,3,5-Tetramethylbenzene	—	—	2	0.4120	0.3417	0.4823	0.7719
1,2,3,5-Tetramethylbenzene	—	—	5	0.4148	0.2682	0.5613	0.7714

that the conformation of neighboring methyl groups is such that the separation between two hydrogen atoms should be maximum. Summarized in Table 8 are the values of the modified superdelocalizability in z-direction, namely perpendicular to ring plane, of ring carbons for radical substitution together with eigen values of the highest occupied and the lowest unoccupied orbitals. The values of the modified superdelocalizability for electrophilic and nucleophilic substitutions are also included in Table 8 for comparison.

The observed rates of demethylation per one equivalent methyl group of polymethylbenzenes relative to that of toluene have already been listed in Table 7. These values are plotted in Fig. 1 against the relevent values of modified superdelocalizability. Since the latter quantity should relate primary with the energetics of the critical reaction path, the observed relative rates are expressed by logarithmic scale in Fig. 1.

The linearity shown by empty circles in Fig. 1 serves as an evidence for the extension of Fukui's concept of superdelocalizability which has been largely confined within ionic substitutions.[9] Conversely, if it is assumed that the aromatic reactivity for radical substitution can be properly described by the value of $S_p(R)$, the linearity may be taken as a support of our mechanistic interpretation on the hydrogenolyses and hence the role of reaction (*a*) in the chain scheme.[2,4]

11) R. S. Mulliken, *J. Chem. Phys.*, **23**, 1833, 1841, 2338, 2343 (1955).

The values of atomic bond population[11] M[C(ring)-C(methyl)] have also been calculated by the extended Hückel method, and are listed in the last column of Table 8.

$$M[\mathrm{C(ring)-C(methyl)}] = \sum_p \sum_q N_{pq}$$

$$N_{pq} = 4 \sum C_{p_i} C_{q_i} S_{pq}$$

They exhibit no radical correlation what so ever with the observed reactivity ratios. This indicates that the reactivity for aromatic substitution is determined by the dynamic property of the ring carbon atom at whicn the substitution takes place, and not by the static property such as atomic bond population at the bond which is to be broken. The conclusion drawn here is in conformity with our following computational analysis[4] in which hydrogen atom attack has been reckoned as rate-determing step of reaction (*a*).

Deviation from the theory is, however, beyond any conceivable uncertainty for cases marked by filled circles in Fig. 1. They include 2-positions of 1,2,3-trimethylbenzene and 1,2,3,5-tetramethylbenzene where neighboring methyl groups have an effect toward higher reactivity than can be predicted by the theory. The following may possibly be the reasons for the present discrepancy. (1) Slight alternations in the planar conformation of these highly crowded homologues may lead to a significant effect on the values of $S_p(R)$. (2) Structure of transition-state for the hydrogen atom attack toward the 2-positions may be influenced by the presence of neighboring methyl groups.

Mechanism of Hydrogenolysis. II. A Molecular Orbitals Study of Hydrogenolysis of Toluene

Hiroo TOMINAGA, Hiromichi ARAI and Taiseki KUNUGI

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo

and Akira AMANO, Masao UCHIYAMA and Yoshiki SATO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba-Aramaki, Sendai

(Received January 31, 1970)

In hydrogenolysis of toluene to produce benzene and methane, atomic cracking process $H+C_6H_5CH_3 \rightarrow C_6H_6CH_3$ (*a*) or $H+C_6H_5CH_3 \rightarrow C_6H_5+CH_4$ (*b*) has been presumed as rate controlling in chain propagation step of the radical chain mechanism. These two alternative processes are compared on the energetics calculated by the extended Hückel M.O. method. The reaction (*a*), an addition of the attacking hydrogen atom to phenyl carbon atom adjacent to methyl group followed by an elimination of methyl radical in a concerted manner, is found to be the most likely pathway.

In the last decade a considerable number of kinetic investigations have been reported on the thermal hydrogenolytic demethylation of toluene.[1] The reaction can be expressed by the stoichiometry,

$$C_6H_5CH_3 + H_2 \longrightarrow C_6H_6 + CH_4,$$

and is sufficiently clean for rate measurements. The observed rates can be described within the specified deviations by

$$-d[C_6H_5CH_3]/dt = k[C_6H_5CH_3][H_2]^{1/2} \text{ mol}\cdot l^{-1}\cdot\text{sec}^{-1},$$
$$k = 10^{(11\pm1)-(55\pm5)/\theta},$$

where θ being $(2.303\,RT)$ in kcal mol^{-1}.

The values of Arrhenius kinetic parameters and the overall three-halves order were interpreted by these authors in terms of a free radical chain mechanism, which was subsequently supported by Benson and Shaw.[2b] The chain propagation step was controlled by the following *atomic cracking* process:[2a]

$$H + C_6H_5CH_3 \xrightarrow{(a)} C_6H_6 + CH_3, \text{ or}$$
$$H + C_6H_5CH_3 \xrightarrow{(b)} C_6H_5 + CH_4$$

The latter alternative was suggested by Silsby and Sawyer,[1a] and also by Burr, Meyer and Strong.[1c] However, exact mechanistic natures of the reactions have not hitherto been discussed in any detail. In the present paper a comparison will be made on the energetics between the two reactions; perpendicular approach of hydrogen atom to phenyl carbon atom to which methyl group is attached (reaction (*a*)) on one hand, and direct Walden inversion type hydrogen attack to methyl carbon atom (reaction (*b*)) on the other. The comparison is to be based on the total electron energy calculations of the postulated transition structures using the extended Hückel M.O. method. As will be discussed in the present paper, reaction (*a*) is the most likely pathway in hydrogenolytic demethylation. The *atomic cracking* is, therefore, an addition of hydrogen atom to phenyl carbon followed by an elimination of methyl radical in a concerted manner.

Molecular Orbitals Calculation

To investigate which one of the two alternative reaction mechanisms is operative, the changes in total electron energies of the transition structures along presumed reaction coordinates are calculated. An empirical molecular orbitals theory developed by Hoffmann,[3] that is, extended Hückel method is employed which has proved useful in discussing the hydrocarbon conformational problems such as barriers to internal rotation, geometric iso-

merism,[3] as well as electronic structure of transient species.[4]

The secular determinant, with the order of $(4n+m)$ for a molecule C_nH_m, of which atomic orbitals are $2s$, $2p_x$, $2p_y$, $2p_z$ for carbon and $1s$ for hydrogen, is solved using an electronic computor HITAC 5020 for eigen values ε_i and eigen vectors C_{pi} of the molecular orbitals. The complete secular determinant is treated, namely, all overlap integrals computed, and off diagonal E's retained. The Coulomb integrals H_{pp} are chosen as valence state ionization potentials of Pritchard and Skinner.[5] The reasonance integrals H_{pq} are approximated as

$$H_{pq} = 0.5K(H_{pp}+H_{qq})S_{pq},$$

where

$$K = 1.75,$$

after the original proposal by Hoffmann.[3] The effective nuclear charges of Slater orbitals are employed.[6] The ovelap integrals S_{pq} are calculated by Mulliken's procedure.[7] For radicals and transient species with odd number of electrons, the highest orbital is assumed to be half-occupied.

Reaction Co-ordinate and Conformation

The configuration of toluene molecule is presented in Fig. 1, where large open circles indicate carbon atom and small full circles hydrogen atom. The bond lengths and angles are found in chemical dictionary.

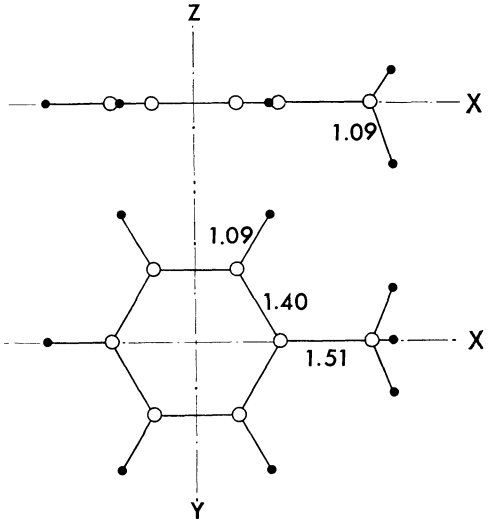

Fig. 1. Conformation of toluene.

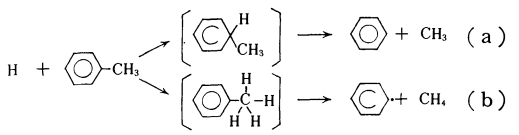
Reactions (*a*) and (*b*) are considered to proceed through the following transition states, respectively;



The former route denotes the approach of hydrogen atom to the phenyl carbon atom adjacent to methyl group in perpendicular direction to toluene ring plane. This forms the σ-complex with pseudo sp^3 hybrid structure, ending with the elimination of methyl radical to form benzene. While the latter signifies the approach of hydrogen atom to the methyl carbon atom in the horizontal direction along methyl - ring (C7-C1) axis. Through penta - valent carbon complex, this results in Walden type inversion to form phenyl radical and methane.

Perspective sketched for the two transient species are illustrated in Figs. 2 and 3, where H16 stands

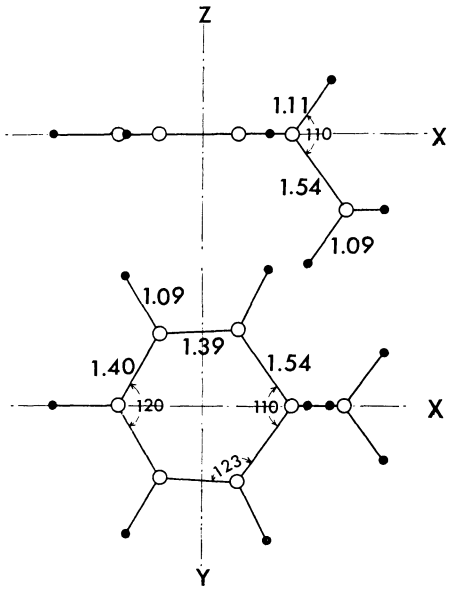
IX′[b]	1.09	5.0	70°32′	Benzene	Methane	−648.44

Remarks
a) Conformation of phenyl radical is taken as the same with that of benzene except one ring hydrogen lost. Refer to G. Porter and B. Ward.
b) Conformation of methane; CH bond length 1.09 Å with bond angle ∠HCH 109°28′.

for the attacking hydrogen atom, Cl the phenyl carbon atom adjacent to the methyl group, and C7 the carbon atom of the methyl group to be removed. The total electron energies of 24 transient species are calculated based on the conformational parameters listed in Tables 1 and 2. The distance between Cl and H16, or C7 and H16, is arbitrarily chosen as reaction co-ordinate. The calculation covers the range from 5 Å to 1.09 Å that is equivalent to the normal C–H bond length for benzene or methane. With the approach of H16, the bond length Cl-C7 correspondingly increases from the original 1.51 Å to 5 Å and the bond angles also change as are shown in the tables. In this course the C–H bond length of methyl group is assumed to remain constant at 1.09 Å with a sole exception of 1.08 Å for methyl radical.

The conformation of σ-complex, VI in Table 1, is presumed as is shown in Fig. 4 based on that of cyclohexadienyl radical proposed by Drago and



METHYL CYCLOHEXADIENYL RADICAL

Fig. 4. Conformation of methyl cyclohexadienyl radical.

Peterson.[8] As for the penta-valent carbon complexes, V′ and VI′ in Table 2, the bond distance C7-H16 (or C1-C7) is taken as 20% (or 10%) longer than that of methane (or of toluene) for V′, and *vice versa* for VI′. The conformation of methyl radical is taken as planar with C–H distances of 1.08 Å as is presented by Herzberg.[9] Phenyl radical is supposed to have the same conformation with that of benzene except that one hydrogen atom is lost. This is suggested by Porter and Ward.[10]

At a given reaction co-ordinate, namely at a given approach of the attacking hydrogen atom to carbon atom C1 or C7, effects of some changes in C1-C7 bond distance or bond angle are evaluated. Indicated are the lower total electron energies for the transient species with the longer bond distances between departing carbon atoms. The formation of these transient species with the lower energies, however, seems less favoured due to the less chance of hydrogen atom attack on one of the carbon atoms with the C1-C7 bond which is longer than in equilibrium and in vibration.

Results and Discussion

Indicated in Fig. 5 are the changes in total electron energies of the reacting systems with the two different ways of approach of attacking hydrogen

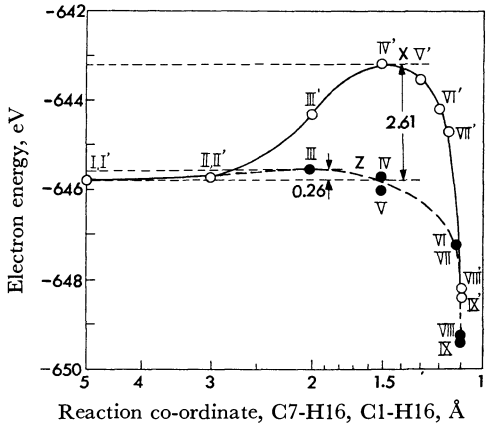


Fig. 5. Reaction co-ordinate energy diagram for reactions (a) and (b).

atom. It is clearly demonstrated that the approach to C1, the phenyl carbon atom, in parallel with z axis requires much less energy than the approach to C7, the methyl carbon atom, along x axis does. The energy barrier of the former reaction route, E_z, is calculated as 0.26 eV (*ca.* 6 kcal mol^{-1}) while that of the latter, E_x, is approximated as 2.61 eV (*ca.* 60 kcal mol^{-1}), 10 times larger than E_z. The value E_x=60 kcal mol^{-1} does not seem exceedingly large in view of the high activation energies that are generally associated with ionic Walden inversion reactions.

The value E_z=6 kcal mol^{-1}, on the other hand, is in surprisingly good agreement with the value of 5 kcal mol^{-1} predicted by these authors.[2a] They have evaluated the kinetic parameters of a number of possible elementary reactions involved in the thermal hydrogenolysis of toluene based on the bulk of kinetic and thermodynamic informations. More important elementary reactions are thus selected, and the following formulation is obtained to describe the main scheme of the hydrogenolysis:

$$C_6H_5CH_3 \underset{2}{\overset{1}{\rightleftharpoons}} C_6H_5CH_2 + H$$

$$H + C_6H_5CH_3 \underset{4}{\overset{3}{\rightleftharpoons}} H_2 + C_6H_5CH_2$$

$$H + C_6H_5CH_3 \xrightarrow{(a)} C_6H_6 + CH_3$$

$$CH_3 + H_2 \underset{6}{\overset{5}{\rightleftharpoons}} CH_4 + H$$

$$CH_3 + C_6H_5CH_3 \underset{8}{\overset{7}{\rightleftharpoons}} CH_4 + C_6H_5CH_2$$

The proposed mechanism is shown to be in conformity with hitherto observed kinetic behaviours of the reaction. Assuming steady-state approximation, the overall rate equation is given by the equation:

$$-d[C_6H_5CH_3]/dt \fallingdotseq k_a\left(\frac{k_1 \cdot k_4}{k_2 \cdot k_3}\right)^{1/2}[C_6H_5CH_3][H_2]^{1/2}$$

8) R. S. Drago and H. Peterson, Jr., *J. Amer. Chem. Soc.*, **89**, 3978 (1967).
9) G. Herzberg, *Proc. Roy. Soc.*, **262A**, 291 (1961).
10) G. Porter and B. Ward, *Proc. Chem. Soc.*, **1964**, 288.

Therefore the overall values of A-factor and activation energy can be expressed in terms of individual kinetic parameters by the following equations:

$$A \text{ overall} = A_a(A_1A_4/A_2A_3)^{1/2}$$
$$= A_a \cdot 10^{3.06}\ l^{1/2} \cdot \text{mol}^{-1/2} \cdot \text{sec}^{-1}$$
$$E \text{ overall} = E_a + \frac{1}{2}(E_1 - E_2 - E_3 + E_4)$$
$$= E_a + 51.6 \text{ kcal} \cdot \text{mol}^{-1}$$

The comparison of these theoretical values with the experimental ones would thus place the values of A_a and E_a as approximately 10^8 l mol^{-1} sec^{-1} and 5 kcal mol^{-1}, respectively. The value E_a coincides fairly well with the value E_z obtained in the present paper.

The calculated values of E_z=6 kcal mol^{-1} is also supported by some experiments. In the gamma radiolysis of propane, Kan Yang[11] observed the rate of formation of hydrogen is reduced by the presence of olefins or benzene. The effect of temperature on this inhibition indicates that it results from the hydrogen atom addition to olefins or benzene. The activation energy of 3.5 kcal mol^{-1} is obtained for benzene and can be compared to the value E_z=6 kcal mol^{-1}. Myran C. Sauer, Jr. and Barry Ward used the technique of pulsed radiolysis obtaining the rate constants at 25°C for the gas phase reaction of hydrogen atoms with benzene and toluene as 0.37×10^8 and 1.0×10^8 l mol^{-1} sec^{-1}, respectively.[12] The activation energy in the case of benzene is about 3 kcal mol^{-1}. Benzene and toluene was found to yield the cyclohexadienyl and methylcyclohexadienyl radicals, respectively, with absorption maxima at 302 and 307 mμ, respectively, in the gas phase. These experimental data are also in excellent agreement with the calculated kinetic parameters aforementioned.

This agreement might be rather fortuitous, because neither nuclear nor electronic repulsion is explicitly considered in the extended Hückel molecular orbitals calculation. Development of a more advanced molecular orbitals treatment and its application to this study is now in progress in this laboratory.

Conclusion

These considerations lead to the conclusion that the atomic cracking of toluene by hydrogen atom is a radical substitution proceeding through a methylcyclohexadienyl radical type σ-complex, to give benzene and methyl radical in a concerted manner. The validity of this conclusion may be further supported by the previous study[13] where the effect of methyl substitution on the hydrogenolytic demethylation of polymethylbenzenes has been discussed in terms of reactivity index deduced from molecular orbitals theory.

The Effect of Solvents on the Optical Rotation of Poly(propylene Oxide)

Yoshiyuki KUMATA, JUNJI FURUKAWA and Takayuki FUENO*1

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received March 28, 1970)

The change in the rotatory direction of optically active poly(propylene oxide) in different solvents has been discussed from the viewpoint of dielectric theory of solution. It has been pointed out that, in general, the shapes of the optical rotatory dispersion curves of polymers cannot directly be related to their conformation.

Price and Osgan[1] first noted that the optical rotation of poly(propylene oxide) measured at 589 mμ in chloroform and in benzene are of opposite sign. Tsunetsugu *et al.*[2] have suspected that this phenomenon might be due to a change in local polarizability of the asymmetric center effected by some weak complexation of polymer with solvent. Alternatively, Hirano *et al.*,[3] have interpreted this phenomenon as resulting from the formation of some helical component (gauche conformation) in chloroform solution.

According to the usual interpretation of optical rotatory dispersion, an optically active polymer having a helical conformation should exhibit an "anomalous" dispersion curve.[4] However, we have observed that the dispersion curves of poly(propylene oxide) prepared from optically active monomer are plain for all the solvents examined. In the present paper, we will reconsider the physical meaning of the anomalous dispersion, and show that the effect of solvents on the optical rotatory dispersion of poly(propylene oxide) might also be interpreted from a factor other than the conformational change of the polymer in different solvents.

Experimental

Optically active propylene oxide was polymerized by potassium hydroxide as a catalyst. The benzene solution of polymer was washed successively with dilute hydrochloric acid and water, and then freeze-dried. The molecular weight of the polymer obtained was determined by osmometry to be *ca.* 3200.

Measurements of the optical rotation of this polymer in various solvents were carried out at ambient temperature using a JASCO polarimeter Model ORD, UV-5. The concentration of polymer was fixed at 2.5 g/100 m*l*.

Results and Discussion

The specific rotation of poly(propylene oxide) at 589 mμ measured in various solvents is listed in Table 1. In any solvent used, the sample polymer gave a plain dispersion curve. Some typical curves are compared in Fig. 1, and the corresponding Moffitt-type plots (Eq. (1)) are shown in Fig. 2.

$$\frac{[M](\lambda^2-\lambda_0^2)}{\lambda_0^2} = a + \frac{b\lambda_0^2}{(\lambda^2-\lambda_0^2)} \qquad (1)$$

It may be seen in Fig. 2 that in all cases the values of $[M](\lambda^2-\lambda_0^2)/\lambda_0^2$ linearly decrease with increasing magnitudes of $\lambda_0^2/(\lambda^2-\lambda_0^2)$ and that no line crosses the zero line of $[M](\lambda^2-\lambda_0^2)/\lambda_0^2$ in the wavelength region of observation. This latter feature is in contrast to that encountered in the case of propylene oxide monomer, in which the quantity $[M](\lambda^2-\lambda_0^2)/\lambda_0^2$ becomes zero for some solvents (Fig. 3). In both Figs. 2 and 3, the values of λ_0 were chosen by the trial-and-error method so as to allow the best fit of observation to the Moffitt equation (1). The λ_0 values thus chosen are listed in Table 2.

It should be noted that the Moffitt equation (1) has proved to hold even in propylene oxide which has a rigid ring structure. Equation (1) was originally introduced as an approximation of Drude's two-term equation (2).[5]

$$[\alpha] = \frac{A}{\lambda^2-\lambda_1^2} - \frac{B}{\lambda^2-\lambda_2^2} \qquad (2)$$

The two-term equation of Drude has hitherto customarily been interpreted as equivalent to a summation of partial rotations originating from different

optical asymmetries of molecules. However, it is known that even the optical dispersions of several amino acids, which have only one asymmetric carbon, fit the two-term equation.[6] We thus feel it necessary to reconsider physical meanings underlying equations (1) and (2).

Let us briefly outline the fundamental logic necessary for understanding optical rotatory dis-

persion. Theoretical interpretation of the optical rotation owes much to Fresnel's equation

$$\alpha = \frac{\pi}{\lambda} x(n_R - n_L) \tag{3}$$

where α is the optical rotation expressed in the radian scale, x is the optical path length, and n_R and n_L are the refractive indexes of the right- and left-handed circular polarized lights, respectively. It is known that the refractive indexes themselves are subject to dispersion, as may be represented, for example, by the Ketteler-Helmholtz equation (4) or the Sellmeier equation (5).[7]

$$n^2 = a + \sum_m \frac{b_m}{\lambda^2 - \lambda_m^2} \tag{4}$$

$$n^2 = 1 + \sum_i \frac{A_i}{\lambda^2 - \lambda_i^2} \tag{5}$$

Quantum-mechanical treatments[8] of the refraction support the form of Eq. (4).

From Eqs. (3) and (5), coupled with suitable approximations, we may derive Drude's many-term equation[7]

$$[\alpha] = \sum_i \left(\frac{A_{iR}}{\lambda^2 - \lambda_{iR}^2} - \frac{A_{iL}}{\lambda^2 - \lambda_{iL}^2} \right) \tag{6}$$

In short, the optical rotatory dispersion can be interpreted as a difference in the refractive dispersions of the two polarized light beams. Hence, an "anomalous" dispersion that does not conform to Drude's one-term equation does not suggest that there exist more than one type of asymmetric center in the system under examination. This conclusion finds strong support in our previous demonstration that even monomeric R-propylene oxide, which has only asymmetric center, exhibits an anomalous dispersion.[9]

We now inquire why each term of Drude's equation should depend on solvent. According to the dielectric theory,[10] it is considered that, in a non-spherical cavity field which is surrounded by partially oriented solvent, both polarization and polarizability tensor of solute are transformed by change of solvent. This in turn will effect a change in the difference between the refractive indexes of the right- and left-handed circular polarized lights. The change will usually be very small but large enough to influence the optical rotation which may be calculated from equation (3). In the case of quartz,[7] for example, the difference in refractive indexes at 589 mμ is calculated from its optical

rotation ($[\alpha]_D=2170°$) to be 0.000071, so that the variation in the refractive index difference by 0.00001 should lead to a variation in $[\alpha]_D$ amounting to *ca.* 310°. In some cases, the influence of solvent on polarization and polarizability of solute may become complicated to cause a change even in the direction of optical rotation.

It is difficult to express the shape of cavity and the degree of orientation by numeral parameters. Thus we will examine the effects of solvent on the optical rotation only qualitatively in terms of some empirical polarity parameter of solvents.

In Fig. 4 are shown the relations of the rotivities of propylene oxide and poly(propylene oxide) with the solubility parameter of solvents. Here, a rotivity is described by the equation[11]

$$\text{rotivity} = \frac{[\alpha]_D}{n_D^2+2} \qquad (7)$$

According to Herbandson *et al.*, the solubility parameter is a kind of polarity parameter of solvents.[12]

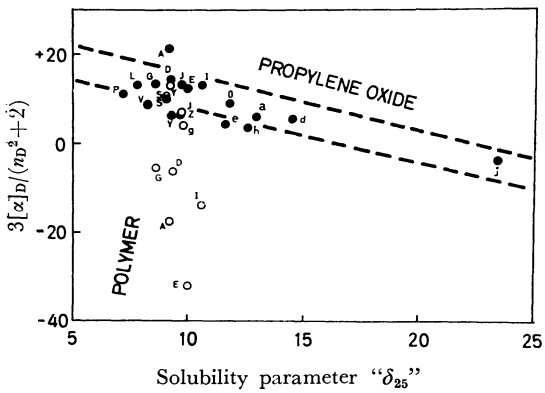

Fig. 4. Plots of the optical rotations of R-propylene oxide and its polymer measured in various solvents against the solubility parameter of the solvents. The symbols attached to the plots indicate the solvents listed in Table 1.

It may be seen in Fig. 4 that the rotivity of the monomer is dependent on the solubility parameter of solvents just in the same manner as it depended on various solvent polarity parameters.[9]

The rotivity of the polymer, on the other hand, appears not to be related with the solubility parameter in any simple manner. However, because the rotivities themselves of the monomer and polymer observed in various solvents are roughly correlated with each other as may be seen in Fig. 5. The polymer rotivity might increase with increasing solubility parameter of solvents, in contrast to the monomer rotivity.

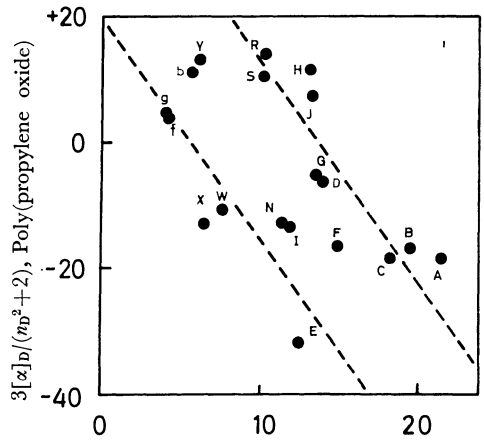

Fig. 5. The rotivity of polypropylene oxide *vs.* that of propylene oxide. The symbols attached to the plots indicate the solvents listed in Table 1.

In a solvent having a large solubility parameter, our polymer is hardly soluble and is aggregated. However, the variation of rotatory direction would not be due to the aggregated conformation, because even propylene oxide which has a rigid skeltal structure is apparently subject to variation in rotatory power in varying solvents. A similar situation is reported in isofenchon,[13] conformation of which is also difficult to change because of its rigid bicyclic ring structure.

Moreover, we found a poly(propylene oxide) film casted from the polymer melt to have a large negative rotation; the α_D value observed for a polymer film of 0.04 mm in thickness being $-1.5°$, a value which leads to a specific rotation of *ca.* $-2000°$. The specific rotation observed is far greater in magnitude than that reported by Hirano *et al.* for a film casted from solution. The different results are probably because our film was formed with polymer molecules highly oriented as in a liquid crystal.

In conclusion, the variation in the rotatory dispersion of poly(propylene oxide) with solvent can be interpreted, at least partially, as a result of the different variations of the refractive indexes toward the right- and left-handed circular polarized lights. The dispersions of the refractive indexes toward the two polarized light beams probably are influenced in a different way by the so-called cavity field which is induced by partially oriented polar solvents.

The authors are grateful to Mr. Ikuo Morino for assistance in the numerical analysis of the dispersion curves.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3667—3671 (1970)

Surface Activities of Nonionic Polymeric Surfactants

Masao NAKAMURA*1 and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received April 6, 1970)

The relationship between surface activity and molecular structure has been studied for the nonionic polymeric surfactants which have 2,3,4 or 6 branches of polypropylene glycol-polyethylene glycol (PPG-PEG) chain in their molecules. A linear relation, $1/\Delta\gamma = A + B \cdot x/y$ has been found to hold for each series, where $\Delta\gamma$ is the surface tension depression of surfactant solution of a given concentration from that of water, x/y is the molecular structure index, in which x is the weight percent of PEG group in a molecule and y is the molar weight of PPG part, and A and B are constatns. Constant A, being equal to 0.025 cm/dyn, is independent of the concentration and the number of PPG-PEG branches and corresponds to the reciprocal of surface tension lowering of an aqueous solution of infinitely large PPG polymer. Constant B decreases linearly with the logarithm of molar concentration, and increases with the number of branches. It also depends on the hydrophilic nature of the central group of molecule.

Recently, numerous nonionic surfactants have been prepared for various practical purposes, and the selection of surfactant has become much simpler by application of the HLB system proposed by Griffin.[1] Studies have been made on the relation between the HLB value and the molecular constitution of nonionic surfactants.[2] However, the relation between molecular structure and surface activity is not yet clear.

As regards nonionic surfactants, block copolymer (PPG-PEG) composed of polypropylene glycol (PPG) and polyethylene glycol (PEG) has recently attracted attention in relation to theoretical and practical problems. These surfactants are favorable for studying the relation between molecular structure and surface activity, because a slight difference in nature of the hydrophobic propylene glycol unit (PG) of the PPG group and the hydrophilic ethylene glycol unit (EG) of the PEG group makes a delicate control of surface activity possible by the change of degree of polymerization of PG and EG. In the present study we tried to obtain systematic information on the relation between surface activity and molecular structure for this type of polymer surfactants, from the study of surface tension lowering of the solution.

Experimental

Materials. PPG-PEG type of surfactants employed in the present study are of the following molecular structure:

"Pluronic" m, n (2-branch series)

$$HO(CH_2CH_2O)_{n/2}(\overset{\displaystyle CH_3}{\overset{|}{C}}HCH_2O)_m(CH_2CH_2O)_{n/2}H$$

"Trinic" m, n (3-branch series)

$$N{\equiv}[CH_2CH_2O(\overset{\displaystyle CH_3}{\overset{|}{C}}HCH_2O)_{m/3}(CH_2CH_2O)_{n/3}H]_3$$

"Tetronic" m, n (4-branch series)

$$\begin{array}{l}[H(OCH_2CH_2)_{n/4}(OCH_2\overset{\displaystyle CH_3}{\overset{|}{C}}H)_{m/4}]_2{=}NCH_2\\ \qquad\qquad\qquad\qquad\qquad\qquad\quad |\\ [H(OCH_2CH_2)_{n/4}(OCH_2\overset{\displaystyle CH_3}{\overset{|}{C}}H)_{m/4}]_2{=}NCH_2\end{array}$$

"Hexonic" m, n (6-branch series)

$$C_6H_8O_6[(\overset{\displaystyle CH_3}{\overset{|}{C}}HCH_2O)_{m/6}(CH_2CH_2O)_{n/6}H]_6$$

in which m and n are the average degrees of polymerization of PG and EG, respectively. The Pluronic and Tetronic series were obtained from Asahi Denka Industry Co., and the rest from Nihon Surfactant Industry Co. The Trinic, Tetronic and Hexonic series may be regarded as having 3, 4 and 6 branches of PPG-PEG chains of equal average length in respective molecules and the Pluronic series is conventionally seen to have two branches. The Hexonic series is the ether derivative of sorbitol. The surfactants investigated are listed in Table 1.

Polypropylene glycols, glycerine polyoxypropylene ethers and trimethylolpropane polyoxypropylene ethers of molecular weights ranging from 260 to 2500 were used as samples having no hydrophilic PEG group.

These samples were also obtained from Asahi Denka Industry Co.

In order to remove water and impurities having low boiling points, all the samples had been vacuum dried for about 48 hr until their weights became constant at room temperature. Solutions were prepared immediately after purification.

Aqueous solutions of 1×10^{-4}, 1×10^{-5} and 1×10^{-6} mol/l were made by dissolving the substances in water which had been obtained by refluxing a solution of $KMnO_4$ and NaOH in ion-exchanged water for about 15 hr in a borosilicate glass apparatus and then distilling.

Method. The equilibrium surface tension lowering from pure water was measured and taken as a parameter of surface activity. Since the surface tension of an aqueous surfactant solution of a concentration below the critical micelle concentration usually changes gradually over a long period after the surface is freshly formed,[3] a method should be adopted which allows a continuous measurement over a long period with minimum disturbance of the system under examination. For this purpose, a modified Wilhelmy plate method was used.[4]

The vessel containing the solution was a Petri-dish of 6.5 cm in diameter and 1.5 cm in depth, the edge of which was coated smoothly with paraffin for the purpose of bringing an aqueous surface level higher than the rim of the vessel and for avoiding contamination creeping in from the outer wall.

The solution was introduced into the vessel immediately after preparation. After about 1 hr a fresh surface was formed by sweeping off the surface of the solution in the vessel with a paraffin-coated glass barrier in order to keep the bulk aging effects constant. Surface tension was measured with time about 1 min after the sweep of the aqueous surface. Throughout the measurement, the temperature was controlled to 25.8 ± 0.2°C in an air thermostat, which also served to prevent evaporation.

Results and Discussion

It was confirmed that for all surfactant solutions the surface tension generally decreases with time and does not attain an equilibrium value even 120 min after the formation of a fresh surface, as illustrated by Tetronic 46, 20 in Fig. 1. Concerning

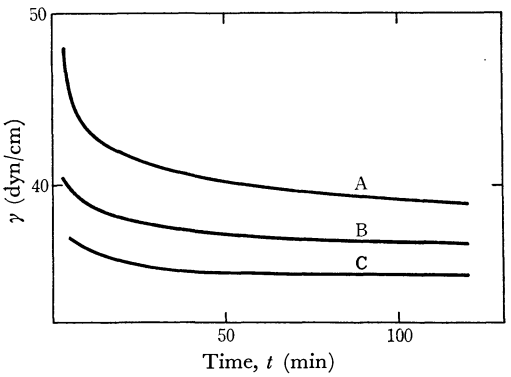

Fig. 1. Surface tension (γ) of the aqueous solutions of Tetronic 46, 20.
Concentration: A, 1×10^{-6}; B, 1×10^{-5}; C, 1×10^{-4} mol/l

the time dependence of surface tension of surfactant solution, some empirical relations have been reported: Lange[5] used the equation

$$\gamma = \gamma_0 - (\gamma_0-\gamma_\infty)/(b/t^{1/2}-1) \quad (1)$$

and Boutaric and Berthier[6]

$$\gamma = \gamma_\infty + (\gamma_0-\gamma_\infty)e^{-\alpha t}. \quad (2)$$

The present authors propose another equation of the following type

$$\gamma = \gamma_\infty + a/t - b/t^2. \quad (3)$$

In the above three equations, γ and γ_∞ are the surface tension of a solution at time t and at equilibrium respectively, γ_0 that of the solvent, and a, b and α are constants. To evaluate γ_∞, Eq. (3) is transformed into

$$t\cdot\frac{d\gamma}{dt} + 2\gamma = 2\gamma_\infty + a/t \quad (4)$$

and $t\cdot d\gamma/dt+2\gamma$ is plotted against $1/t$, $t\cdot d\gamma/dt$ being graphically obtained from the $\gamma-t$ plot. The extrapolated value of $t\cdot d\gamma/dt+2\gamma$ at $1/t=0$ gives $2\gamma_\infty$ as Fig. 2 shows. Table 1 shows γ_∞, the values thus obtained for the surfactants studied. The value $\Delta\gamma=\gamma_0-\gamma_\infty$ is taken as a measure of surface activity, where $\gamma_0=71.8$ dyn/cm is the surface tension of water at 25.8°C. A linear relationship is found to hold between the reciprocal of $\Delta\gamma$ for each concentration and the molecular structure index x/y, as

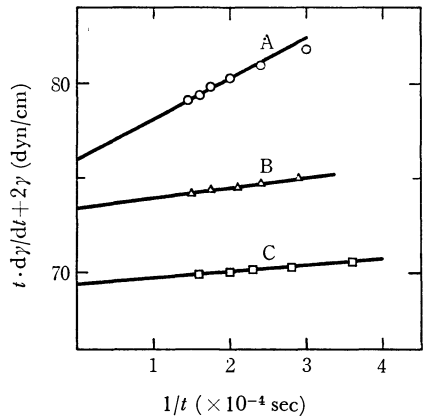

Fig. 2. $t\cdot d\gamma/dt+2\gamma$ *vs.* $1/t$ plot for Tetronic 46, 20.
Concentration: A, 1×10^{-6}; B, 1×10^{-5}; C, 1×10^{-4} mol/l

shown in Fig. 3, where x is the weight percent of hydrophilic PEG group in the molecule and y is the molar weight of PPG part. This plot is well expressed by

$$1/\Delta\gamma = A + B\cdot x/y, \quad (5)$$

where A and B are constants. In Fig. 3, plots scatter in the region of large values of $1/\Delta\gamma$ due to the small values of $\Delta\gamma$ observed. Constant A which is equal to 0.025 cm/dyn turned out to be independent of the concentration and the number of PPG-PEG branches. It depends only on the nature of hydrophobic group in a polymer chain, in this case PPG, as will be mentioned later. The value B was found to depend on both the concentration and the number of PPG-PEG branches.

Constant B, when compared at the same concentration, is indistinguishable with respect to 3- and 4-branch series, while the value for 2-branch series is slightly smaller than the value for 3- and 4-branch series. Further it was found that B decreases linearly with the logarithm of concentration C for 2-, 3- and 4-branch series as shown in Fig. 4. Thus we obtain the relations

$$B = -1.1\log C - 0.41 \quad (6)$$

for 2-branch series and

$$B = -1.3\log C - 0.45 \quad (7)$$

for 3- and 4-branch series, where C is expressed in mol/l. By substituting Eqs. (6) and (7) into Eq. (5), the surface tension lowering $\Delta\gamma$ can be expressed as a function of the structure index x/y and the concentration C for these series: The relation for 2-branch series is

$$1/\Delta\gamma = 0.025 - (1.1\log C + 0.41)x/y \quad (8)$$

and that for 3- and 4-branch series is

$$1/\Delta\gamma = 0.025 - (1.3\log C + 0.45)x/y \quad (9)$$

In these equations $\Delta\gamma$ can be taken as the measure of surface activity, at a given concentration C.

Concentration: (a), 1×10^{-4}; (b), 1×10^{-5}; (c), 1×10^{-6} mol/l

As to 6-branch series, since all samples employed are those of small values of the molecular structure index x/y, it is difficult to confirm the applicability of Eq. (5) and to obtain the exact values of constant B. But the value $1/\Delta\gamma$ is seen to approach 0.025 cm/dyn, the value of constant A in Eq. (5),with the decrease of x/y for the substance of this series.

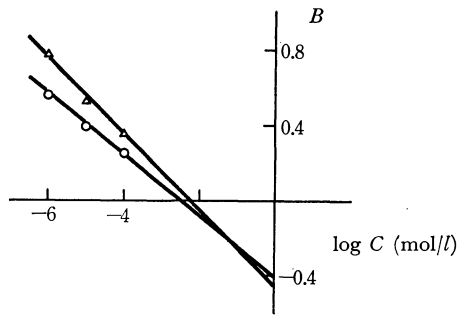

Fig. 4. Constant B *vs.* concentration C plot for Tetronic (4-branch), Trinic (3-branch) (both △) and Pluronic (2-branch) (○) series.

Constant A should correspond to $1/\Delta\gamma$ for a polymer having no hydrophilic PEG group or having PEG groups with hydrophobic PPG groups of infinitely high molecular weight. The surface activity of PPG is considered to depend on molecular weight, since the surface tension of aqueous PPG solution has been reported to depend on the molecular weight.[7] To study further details of the constants A and B, the surface tensions of polypropylene glycol (PPG) series, glycerine polyoxypropylene ether (GP) series, and trimethylolpropane polyoxypropylene ether (TP) series, as the samples having no PEG groups, were measured under the same conditions as for the above surfactants. The relation between the surface tension lowering $\Delta\gamma$ thus obtained and the molar weight y of PPG or PPG part of the molecule for each series is shown in Fig. 5. No distinction is seen between the surface activity of PPG

and TP series and the less surface activity of GP series, where the surface tension of GP is equal to that of the PPG or TP solution of the concentration, being about one tenth of the GP solution.

The fact that the GP series is less surface active than the TP series shows some other factors than those mentioned above affecting surface activity. It is evident that these two series differ only in the central group of their molecules. Therefore it may be presumed that the surface activity of polymeric surfactant is also affected by the nature of its central group to which polymer branches are attached. It is conceivable that glycerine is more hydrophilic than trimethylolpropane so that GP is less surface active then TP. The fact that the plots of PPG and TP series, differing in the number of branches, fall on the same curve suggests the effect of central groups on the surface activity. Thus, it may be concluded that the surface activity decreases with either the increase of branching or the degree of hydrophile of the central group.

It is seen in Fig. 5 that when the molecular weight increases towards infinity, the surface tension lowering is seen to approach a constant value (broken line in Fig. 5), 40 dyn/cm, for each curve; the value taken to be equal to $1/A$ in Eq. (5). This may indicate the constant A being independent of the value of x under the condition of $y=\infty$, and it can naturally be concluded that Eq. (5) can not be applied exactly if the value y is too small; a small value of y might give a larger value of A, as presumed from Fig. 5.

From the results of the above PPG polymers and their ethers it may be quite reasonable to consider that the difference of B in Eqs. (6) and (7) depends not only on the number of branches as was mentioned in the earlier section but also on the nature of the central groups. The fact that both the molecules of 3- and 4-branch series tend to ionize to a certain extent, while 2-branch series has no such ionizing nitrogen atom, can be taken at least as the cause of the difference in surface activity. The fact that 3- and 4-branch series show a similar surface activity (Eq. (9)) in spite of the difference in branching suggests a more hydrophobic nature of the central group of the latter series, since the increase in number of branches from 3 to 4 should be balanced with the stronger hydrophobic nature of the central group of the latter in order to keep the same surface activity.

In conclusion, the surface activities of the nonionic polymeric surfactants of PPG-PEG derivatives type depend upon the ratios of the amount of PPG to that of PEG groups, the molecular weights, the number of branches, and the nature of central group. Constant A in Eq. (5) depends only on the nature of hydrophobic group in polymer chain. In the present case it is the reciprocal of the surface tension lowering of the PPG polymer having a sufficiently large molecular weight. Constant B is in linear relationship with the logarithm of the surfactant concentration; it also depends upon the molecular structure of the surfactant, particularly the number of PPG-PEG branches and the hydrophilic nature of the central group to which they are attached.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3672—3679 (1970)

The Mechanism of the Reaction between Molecular Hydrogen and the Electron Donor-Acceptor Complexes (1:1 and 1:2) of Various Aromatic Hydrocarbons with Sodium*1

Masaru ICHIKAWA, Mitsuyuki SOMA, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 16, 1970)

The mechanism of the reaction between molecular hydrogen and the electron donor-acceptor complexes (A^-Na^+ and $A^{=}2Na^+$) of various aromatic hydrocarbons (A) with sodium were studied kinetically and spectroscopically. The relative activity of each electron donor-acceptor (EDA) complex for the hydrogen uptake was associated with its electronic properties, especially with the reduction potential of its anion. It was found that the hydrogen molecule reacts more readily with stronger electron-donating EDA complexes, whose anions have higher reduction potentials. It was also suggested that, on the hydrogen adsorption over the A^-Na^+ and $A^{=}2Na^+$ films (or in their solutions), the corresponding monohydroanion complexes (AH^-Na^+) and NaH were produced as follows:

$$2A^-Na^+ + H_2 = AH^-Na^+NaH + A$$
$$A^{=}2Na^+ + H_2 = AH^-Na^+ + NaH$$

The behavior of AH^-Na^+ was closely correlated with the localization energies of electrons in the anions of the aromatic hydrocarbons.

As has been demonstrated in previous papers, some catalytic reactions, such as the hydrogen exchange reaction of molecular hydrogen[1a] (or acetylene[1b]), the selective hydrogenation of unsaturated hydrocarbons[1c], and the isomerization of butenes[1d], take place readily at room temperature over the electron donor-acceptor (EDA) complexes of some aromatic compounds with strong donors, such as alkali metals, metallocenes, and phenothiazine.

The results obtained by electronic spectroscopy and ESR measurements suggest[2] that these EDA complexes studied are, in general, characterized by having their ionic salt between the anion radical or poly-valent anions of aromatic compounds (A) and the cation radical or cations of donor atoms or molecules (D), which are formed by the charge-transfer as follows:

$$mA + nD = mA^{n-} + nD^{m+} \quad (1)$$
$$n, m = 1 - 4.$$

In the solid state of the EDA complexes, their ion pairs come close to each other, resulting in strong electrostatic interactions.

Such stoichiometric EDA complexes are easily prepared, and various catalytic reactions proceed over their complex films[3a] or in solutions, for instance, for the 1 : 1 and 1 : 2 anthracene-sodium complexes.[3b]

In this investigation the stoichiometric EDA complexes of various aromatic hydrocarbons with sodium were prepared and the kinetics of the uptake of hydrogen was measured on their complex films and in their solutions. The behavior of the hydrogen

absorbed by the EDA complexes was also studied by means of UV, NMR, and ESR spectrometries.

Experimental

The stoichiometric EDA (1 : 1 and 1 : 2) complexes of aromatic hydrocarbons with sodium were prepared in a manner similar to that described previously.[3a,3b]

A dry tetrahydrofuran (THF) or dimethoxyethane (DME) was allowed to run into a reaction vessel, in which purified aromatic hydrocarbon (*ca.* 3×10^{-3} mol) and distilled sodium (in excess) had previously been placed. After the reaction vessel had then been shaken at room temperature for a long time, a deep-colored complex solution was obtained. The 1 : 1 complexes of anthracene, pyrene, perylene, tetracene, and 1,2-benzanthracene were prepared by controlling the reaction between each aromatic hydrocarbon and sodium. After the identification of their compositions by means of their electronic absorption spectra,[2] the complex solutions were introduced into the reaction cell through a glass filter.*2 The reaction-cell was equipped with a closed circulating system (the dead space of the reaction system was *ca.* 170 m*l*). The complex films were deposited on the glass wall or on silica wool by evaporating the solvent.

The complex films were evacuated further for a day at 90°C prior to the experiments. The complexes of weaker acceptors, such as biphenyl and naphthalene, were partly decomposed into their components by evacuation at 90°C, but other complex films of aromatic hydrocarbons with sodium were comparatively stable at higher temperatures, such as 120°C.

The uptake of hydrogen over the complex films and in solutions was determined by PVT measurements at a constant pressure or a constant volume.

The properties of the EDA complexes which adsorbed hydrogen were studied by the UV (HITACHI-spectrophotometer (EPS-2)), esr- (Varian Associates epr spectrometer), and NMR- (100 MHz high-resolution nmr-spectrometer (JEOL-JNR-4H100)) techniques.

Similar experiments were carried out for their complex solutions in THF or DME by introducing hydrogen.

Results and Discussion

I. The Kinetics of Hydrogen Adsorption over A^-Na^+ and $A^=2Na^+$ Films of Various Aromatic Hydrocarbons with Sodium. When hydrogen (10—35 cmHg) was applied to such complex films as biphenyl, naphthalene, pyrene, and phenanthrene with sodium (1 : 1) in the temperature range between 20 and 90°C, a small amount of hydrogen was adsorbed readily in the initial stage of the adsorption; further adsorption then proceeded slowly for several days, as is shown in Fig. 1, where the kinetics of hydrogen adsorption over the phenanthrene$^-$Na$^+$ complex film is presented. At temperatures higher than 60°C, a small amount of neutral acceptor molecules was separated from each

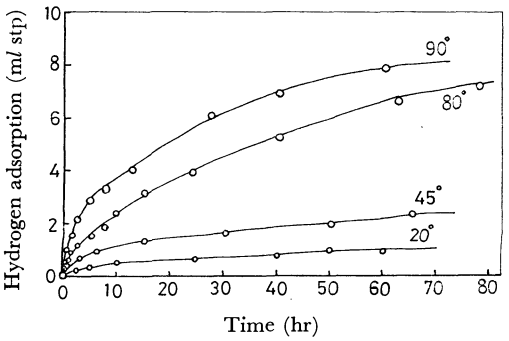

Fig. 1. The kinetics of the hydrogen adsorption over the phenanthrene$^-$Na$^+$ film (3×10^{-3} mol) at P_{H_2}=20 cmHg at the temperatures between 20 and 90°C.

complex film of these 1 : 1 complexes with the progress of the hydrogen adsorption in a manner similar to the case with anthracene$^-$Na$^+$.[4]

The slow adsorption of hydrogen in the later stage continued at higher temperatures and reached the saturation point. Judging from the total amount of hydrogen adsorbed at the saturation point, it may be suggested that the hydrogen uptake took place homogeneously throughout the A^-Na^+ films.

The desorption of hydrogen was very slow, even at higher temperatures such as 90°C; the complexes were partly restored by evacuation at 100°C for 20 hr, and a trace of a neutral molecule was also separated from the reaction systems.

When the phenanthrene$^-$Na$^+$ (3×10^{-3} mol) was deposited over a silica gel,*3 the surface area of which was estimated to be 60 m^2 by the BET method using nitrogen, the hydrogen uptake at the initial stage for the same amount of the complex increased

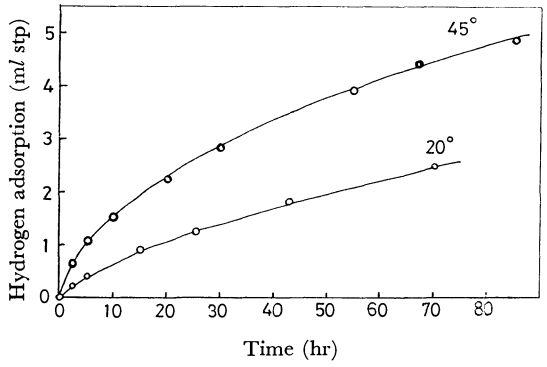

Fig. 2. The kinetics of the hydrogen adsorption on the THF solution of phenanthrene$^-$Na$^+$ (8×10^{-3} mol/50 m*l* of THF) at P_{H_2}=20 cmHg.

*2 The separation of the residual sodium metal was achieved by taking special cape.

4) S. Tanaka, S. Naito, M. Ichikawa, M. Soma, T. Onishi and K. Tamaru, *Trans. Faraday Soc.*, **66**, 976 (1970).

*3 The silica gel was evacuated at 400°C for 20 hr prior to use.

to several times that on the complex film deposited on the glass wall (the surface area was less than 1 m^2) under similar reaction conditions: $P_{H_2}=20$ cmHg, 65°C.

It was demonstrated that the uptake of hydrogen also occurred uniformly on a THF solution of the phenanthrene$^-$Na$^+$ complex, as is shown in Fig. 2, with simple first-order kinetics in the temperature range between 20 and 60°C.

It may, accordingly, be suggested that the slow adsorption in the later stage over the complex films is to be attributed to that hydrogen gas diffused with difficulty into the bulk from the surface of the complex films.

For the 1 : 2 complex films of anthracene,[4] pyrene, perylene, 1,2-benzanthracene, and tetracene with sodium, hydrogen was adsorbed at temperatures of 20 to 140°C with similar kinetics. Hydrogen was readily taken up in the initial stage, but thereafter was adsorbed rather slowly until saturation was reached. The hydrogen desorption from these 1 : 2 complex films took place slowly, but the complexes were restored completely by evacuation at 100°C for 20 hr without any appreciable decomposition of the complexes. It should be noted that only negligible amounts of the neutral molecules or other products were separated from these 1 : 2 complex films throughout the hydrogen adsorption.

The activation energies for the rate of the hydrogen uptake were measured over fresh 1 : 1 and 1 : 2 complex films of various aromatic hydrocarbons; the results are summarized in Table 1. The rates of hydrogen adsorption (V: m*l*/mol hr) listed were observed in the initial stage of the adsorption. The surface areas of all the complex films were found to be almost equal (less than 1 m^2) when the complexes were deposited on the glass wall of the vessel.

Table 1

Compelxes*	Amount of the complexes (mol)	V_{ads} (m*l*/mol hr) $P_{H_2}=20$ cmHg, 80°C	E** (kcal/mol)
Biphenyl$^-$Na$^+$	1.1×10^{-3}	1.8×10^{2}	10
Naphthalene$^-$Na$^+$	3×10^{-3}	3.2×10^{2}	10
Phenanthrene$^-$Na$^+$	3×10^{-3}	6.5×10^{2}	11
Anthracene$^-$Na$^+$	3.8×10^{-3}	1.0×10^{2}	15
Pyrene$^-$Na$^+$	4×10^{-3}	0.43×10^{2}	14
Anthracene$^=$2Na$^+$	5×10^{-3}	12×10^{2}	13
Pyrene$^=$2Na$^+$	4×10^{-3}	3.3×10^{2}	10
Perylene$^=$2Na$^+$	2×10^{-3}	0.38×10^{2}	14
Tetracene$^=$2Na$^+$	2×10^{-3}	0.14×10^{2}	17
Na	3×10^{-2}	negligible	—

* Each complex was deposited over the glass-wall of the reaction vessel (the surface area was less than 1 m^2). The complex formation was almost complete in a film at reaction conditions except the biphenyl$^-$Na$^+$, which exists less than 40%[2] of a given amount of biphenyl at an equilibruium in solution or in a film. The amount of the active biphenyl$^-$Na$^+$ complex was estimated from these consideration.

** The activation energies for the hydrogen adsorption were obtained from the Arrhenius' plots of the inititial rates of hydrogen adsorption (V_{ads}) at the temperatures between 20 and 90°C.

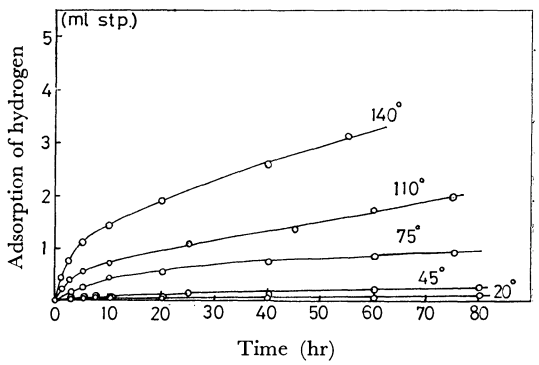

Fig. 3. The kinetics of hydrogen adsorption over the perylene$^=$2Na$^+$ film (1.0×10^{-3} mol, deposited on a silica gel (the surface area was *ca.* 46 m^2)) at $P_{H_2}=27$ cmHg. The dead volume of the reaction system was 168 m*l*.

II. Reactivities of Various EDA Complexes (A$^-$Na$^+$ and A$^=$2Na$^+$) for the Hydrogen Adsorption, and Their Electronic Properties. The rates of the hydrogen uptake were measured over the A$^-$Na$^+$ and A$^=$2Na$^+$ films (*ca.* 3×10^{-3} mol) of each of various aromatic hydrocarbons with sodium, which were deposited over silica gel (the surface area of which was *ca.* 60 m^2) by introducing hydrogen (26cmHg) at temperatures from 20 to 90°C. When the rates of hydrogen adsorption (V: m*l*/mol hr) were plotted against the reduction potentials of the mono- and di-anions of the corresponding aromatic hydrocarbons, a volcano-shape curve was obtained, as is shown in Fig. 4. Their reduction potentials ($-E'$ volt) have been obtained from the potentiometric measurements of Hoijtink and his coworkers'.[5]

5) J. Hoijtink, E. de Boer, P. H. van der Meij and W. P. Weijland, *Rec. Trav. Chim. Pays-Bas.*, **75**, 487 (1956).

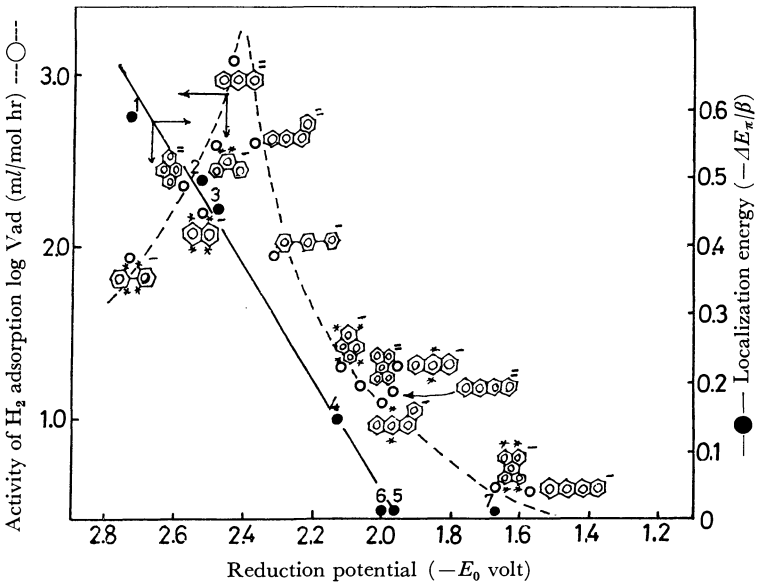

Fig. 4. The plots of the activities of hydrogen adsorption over various mono- and di-anion complex films with sodium against their reduction potentials ($-E_0$ volt), ---○---, and the plot of the localization energies of each acceptor molecules against the reduction potential of their mono-anions, —●—: 1) biphenyl 2) naphthalene 3) phenanthrene 4) pyrene 5) anthracene 6) 1,2-benzanthracene 7) perylene.
The asterisk (*) shows the position of the minimum localization energy in each of the anions of the corresponding aromatic hydrocarbons.

$$A + e \longrightarrow A^- \quad -E_1'$$
$$A^- + e \longrightarrow A^= \quad -E_2'$$

From these results it may be suggested that generally such EDA complexes which contain electron-donating anions with higher reduction potentials react readily with molecular hydrogen to cause a dissociative adsorption of hydrogen.

For the 1 : 1 and 1 : 2 complexes of pyrene, anthracene, 1,2-benzanthracene, perylene, and tetracene with sodium, each of these 1 : 2 complexes was about ten times as active as the corresponding 1 : 1 complex in the uptake of hydrogen. This can be reasonably understood in terms of the higher electron-donating properties of their di-negative ions than those of mono-anions.

It is also interesting to note in Fig. 4 that the activities of the EDA complexes with comparatively weak acceptors such as biphenyl, naphthalene, and phenanthrene, were lower in the hydrogen uptake that were expected from their reduction potentials. These acceptors have characteristically larger localization energies, as is presented in Fig. 4 to the right ordinate, where each localization energy has been calculated by the SCF MO method.[6] Accordingly, their lower activities for the hydrogen adsorption might be due to their difficulty in localizing an unpaired electron at the active position in the anions, in spite of their strong electron-donating properties.

A similar correlation was observed for the relative activities of the solutions of various complexes in connection with the reduction potentials of those anions. When hydrogen (10—45 cmHg) was introduced onto the 1:1 and 1:2 complex solutions (*ca.* 3

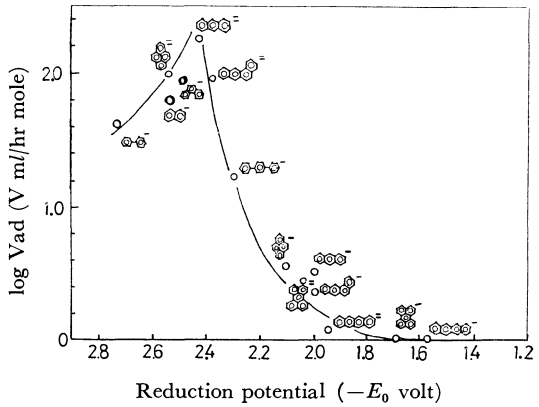

Fig. 5. The plot of the activities of the hydrogen-uptake onto the THF solution of various 1:1 and 1:2 complexes (*ca.* 3×10^{-3} mol/50 m*l* of THF) at 20°C and P_{H_2}=20 cm Hg against the reduction potentials of these anions.

6) G. Dallinga, A. A. V. Stuart, P. J. Smit and E. L. Mackor, *Z. Elektrochem.*, **61**, 1019 (1957).

$\times 10^{-3}$ mol) of biphenyl, naphthalene, phenanthrene, anthracene, 1,2-benzoanthracene, pyrene, perylene, and tetracene with sodium in THF or DME, a considerable amount of hydrogen was adsorbed in the temperature range between 20 and 45°C over 20-hr period. The relative amount of hydrogen uptake by each complex solution in THF at 20°C in 20 hr*4 is plotted in Fig. 5.

For the 1 : 1 complexes of biphenyl, naphthalene and phenanthrene with sodium, these THF solutions were gradually decolorized with the progress hydrogen adsorption, and a considerable amount of NaH was precipitated and almost completely converted in several days to a neutral molecule and dihydro-species.*5

III. The Behavior of Adsorbed Hydrogen over A^-Na^+ and $A^=2Na^+$ Films or Solutions. In order to study the change in the electronic properties of the EDA complexes in reactions with hydrogen, each of the A^-Na^+ and $A^=2Na^+$ films of various aromatic hydrocarbons with sodium was deposited*6 from their THF solutions onto the wall of a quartz cell by evaporating the solvent; hydrogen was then admitted onto their films at the reaction temperatures.

As is shown in Fig. 6a, when hydrogen (10—40 cmHg) was admitted onto the phenanthrene$^-Na^+$ complex films at temperatures from 20 to 90°C, the absorption peak at 620 mμ gradually decreased at 60°C for several hours and new, broad adsorption peaks appeared at 440 and 580 mμ. When the temperature was raised to 90°C, the new peak increased in intensity, while a small amount of neutral phenanthrene was separated. On the other hand, the phenanthrene$^-Na^+$ film, which adsorbed hydrogen sufficiently, was dissolved in THF in an NMR tube. An intense peak appeared at $t=8.73$ ppm in the NMR spectra; it was attributed to that of sodium hydride much as has previously been described.[4]

In addition, when hydrogen was admitted onto the phenanthrene$^-Na^+$ deposited on an ESR tube, the spin concentration of the complex film ($g=2.0036$) decreased markedly and became almost diamagnetic upon hydrogen adsorption at 60°C for several days.

It was also found that, by introducing hydrogen into the phenanthrene$^-Na^+$ solution of THF, a similar absorption spectra newly appeared in the temperature range between 20 and 45°C for several hours, as is shown in Fig. 6b. It should intensity gradually and that a small amount of sodium hydride was precipitated in the solution.

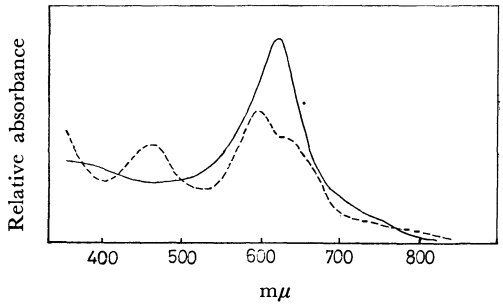

Fig. 6a. The change of the electronic spectra of the phenanthrene$^-Na^+$ film by the hydrogen adsorption. The solid line= that of the phenanthrene$^-Na^+$ film, and the dotted line= that after the hydrogen adsorption on the complex film at 60°C in 20 hr.

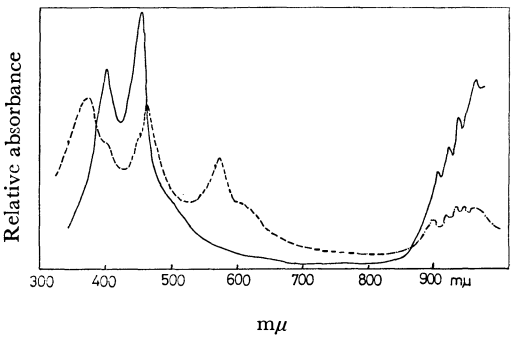

Fig. 6b. The electronic spectra of the THF solution of phenanthrene$^-Na^+$ (———) and after the uptake of the hydrogen at 20°C for 20 hr (--------).

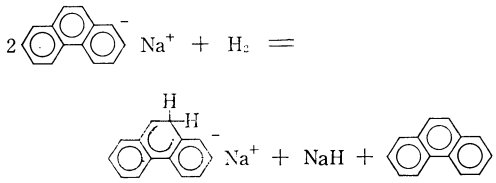
The peaks which newly appeared upon hydrogen adsorption were attributed to the 9-monohydrophenanthrenium anion complex by means of a comparison with those of the 9-monohydrophenanthrenium cation,[7b] as in the case of the 1 : 1 and 1 : 2 anthracene-sodium complexes.[4] These results suggest that hydrogen adsorption proceeded on the phenanthrene$^-Na^+$ film as well as in its solution as follows:

*4 The hydrogen adsorption proceeded in almost first-order kinetics in the initial stage, as is shown in Fig. 2.

*5 After a complete reaction with hydrogen, the THF solutions of these complexes were examined by NMR spectrometry at 20°C.

*6 The electronic absorption spectra of the complex films were comparatively broad and were considerably different from those of the corresponding complex solutions in THF or DME. This change in the spectra occurred reversibly; it is seemingly to be attributed to the formation of the anion dimer in a solid or condensed phase.

7) a) G. Dallinga, E. L. Mackor and A. A. V. Stuart, *Mol. Phys.*, **1**, 123 (1958); E. L. Mackor, G. Dallinga, J. H. Kruizinga and A. Hofstra, *Rec. Trav. Chim. Pays-Bas*, **75**, 836 (1956). b) N. H. Velthorst and G. J. Hoijtink, *J. Amer. Chem. Soc.*, **87**, 4529 (1965).



For the 1 : 1 and 1 : 2 complexes of other aromatic hydrocarbons, such as biphenyl, naphthalene, pyrene, anthracene, perylene, 1,2-benzanthracene, and tetracene with sodium, it was found similarly, in the UV, NMR and ESR measurements, that new and characteristic absorption spectra were observed after introducing hydrogen gas onto each of the complex films or THF solutions at temperatures of 20 and 90°C. The results are summarized in Table 2a for the hydrogen adsorption on the complex films and in Table 2b for that on the complex solutions. In Table 2a the positions of the absorption peaks newly appearing upon the hydrogen adsorption, the detection of sodium hydride, and the structures of the monohydroanion complexes (AH^-Na^+)*[7] in the hydrogen-adsorbed species are also presented. In Table 2b there are also the absorption peaks of the carbonium cations (AH^+) and the localization energies (L.E. $= -\Delta E\pi/\beta$) at each carbon atom in a given anion of aromatic hydrocarbons.

These results confirm that the adsorbed hydrogen was combined with the carbon atom of the mono- or di-anion at the position which has the lowest localization energy to form the corresponding monohydroanion complexes (AH^-Na^+), and that NaH was also formed simultaneously with the hydrogen adsorption.

Table 2a (film)

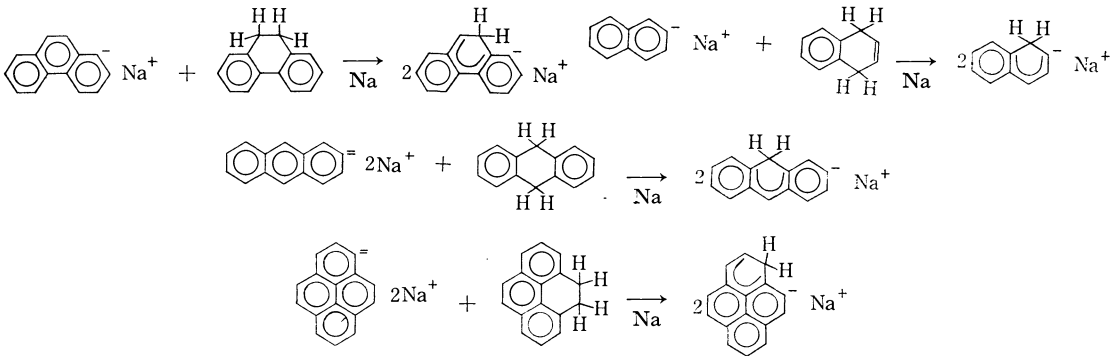
 $2Na^+$	540 (s)		460 (s)	1 0.37
 $2Na^+$	460 (s)	 Na^+	410 (s) 600 (s)	3 0.03 1 0.13

* The absorption peaks of the carbonium ions (AH^+) were obtained from the mixed solutions of a given aromatic hydrocarbon(A) and $HF+BF_4$ solution.[7a]

** Localization energy used has been calculated for the corresponding carbonium ions (AH^+): see Ref. 6.

It should be noted here that biphenyl$^-Na^+$ complex in the THF solution slowly changed to monohydro-anion by abstracting hydrogen from the solvent even in the absence of hydrogen gas.

In addition, AH^-Na^+ was also prepared independently by the following reactions in THF and the similar absorption peaks (AH^-Na^+) were observed in the resultant solutions.



It may also be suggested that the same monohydro-anion complex was produced in the hydrogen adsorption over the A^-Na^+ and $A^=2Na^+$ films and the solutions of pyrene, anthracene,[4] perylene, and 1,2-benzathracene with sodium.

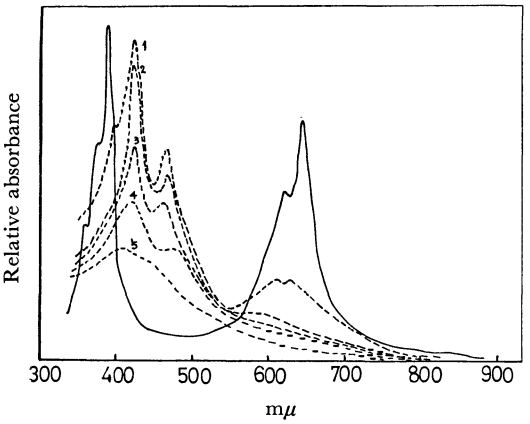


Fig. 7. The change of the electronic spectra of the biphenyl$^-Na^+$ solution in THF (———) after introducing H_2 at 20°C: (---------).
1) 10 min after 2) 20 min 3) 40 min 5) 200 min

For the biphenyl$^-Na^+$, it was found that no absorption peaks were newly observed upon introducing hydrogen on the complex film, even at higher temperatures. However, as is shown in Fig. 7, when hydrogen was admitted onto the THF solution at 20°C for several hrs, two new peaks appeared, at 425 and 490 mμ; these peaks may be attributed to the para- and ortho-monohydro-biphenyl anion respectively. These peaks decreased, however, at a considerable rate, and disappeared completely within several hrs, probably because to their decomposition, as follows:

$$AH^-Na^+ \longrightarrow A + NaH$$
$$2AH^-Na^+ \longrightarrow A + AH_2$$

For the tetracene$^=2Na^+$ complex, we found neither any appreciable change in the absorption spectra of the tetracene dianion nor the formation of sodium hydride upon the introduction of hydrogen in the temperature range between 20 and 120°C for several days. It was, however, demonstrated that a small and broad peak could be detected at 490 mμ*[8] after hydrogen treatment at 140°C for 10 days. It has previously been reported[8] that the proton complex of tetracene ($AH^+BF_4^-$) has an absorption peak at 448 mμ. The same absorption peak at 490 mμ could be observed in the slow reaction between tetracene$^=2Na^+$ and 9,10-dihydrotetracene at room temperature; this suggests that the new peak at 490 mμ can be attributed to the formation of the 9-monohydrotetracenium anion complex.

Therefore, these results suggest that a possible mechanism for the hydrogen activation by the A^-Na^+ and $A^=2Na^+$ is an electron transfer from mono- or di-anions to molecular hydrogen to form hydride and a hydrogen atom, which is then combined with each anion (A^-) to form the corresponding monohydro anion complexes (AH^-Na^+) as follows:

$$A^=2Na^+ + H_2 = A^-Na^+ + NaH + H$$
$$A^-Na^+ + H = AH^-Na^+ \qquad (1')$$
$$A^-Na^+ + H_2 = A + NaH + H$$
$$A^-Na^+ + H = AH^-Na^+ \qquad (2')$$

For the naphthalene$^-Na^+$ complex in the solution, a mechanism similar to (2′) has been proposed by Bank and his coworkers.[9] There has, however, been no crucial evidence to indicate a hydrogen atom in these reaction systems, probably because its life is too short for it to combine with radical anions (A^-).

*[8] When the film adsorbed hydrogen was dissolved in THF, a comparatively strong absorption peak appeared at 498 mμ.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3680—3684 (1970)

Evaluation of Softness from the Stability Constants of Metal-ion Complexes*1

Makoto Misono and Yasukazu Saito

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 23, 1970)

Utilizing the dual parameter equation we derived previously, we have evaluated quantitatively softness or class (b) character of metal ions on the basis of the original criteria of soft-hard classification, *viz.*, the stability of metal-ion complexes. Various softness parameters proposed so forth have been proved insufficient to describe softness quantitatively, although they are useful for a rough classification of metal ions into soft and hard acids. Discussion is also given concerning origin of softness, especially from the viewpoint of its closs correlation with the solvation effect.

The general idea of classifying acids and bases into class (a) and (b) (hard and soft) acids and bases has been proposed,[2] according to which hard acids prefer to coordinate with hard bases and soft acids with soft bases. This concept is based on the general trend in inorganic stability constants, that is, some acids (hard) form stable complexes in the sequence F>Cl>Br>I, while others in I>Br>Cl>F. This classification has been shown to be useful even in organic chemistry, although prediction remains qualitative, owing to the lack of quantitative scales for the acid or base strength.

Attempts were made to calculate the softness quantitatively from the fundamental properties of elements such as ionization potentials and ionic radii.[3-7] It has been claimed that a certain dual parameter scale is inevitably required in order to express the acid or base strength completely.[8,9]

The purpose of the present work is to determine the softness of metal ion on the basis of the original criteria for the soft-hard classification, utilizing the dual scale equation proposed before.[4] The most commonly used criterion for the soft-hard classification is the stability constants of halogeno-complexes. The concept of softness recently seems to be more or less subjective. The present attempt would make objective evaluation possible.

The dual parameter scale proposed by the authors is as follows.[4] One parameter X is closely related to "hardness" or the electronegativity, and another parameter Y to "softness." With these parameters, the log of stability constants of metal-ion complexes, log K,*2 is expressed well for hard-hard complexes and, to a lesser extent, for soft-soft complexes by the equation

$$\log K = \alpha X + \beta Y + \gamma \qquad (1)$$

where α and β are the dual basicity parameters of a ligand corresponding to X and Y, respectively, and γ is a constant determined for each ligand. The instability constants of hard-hard complexes are mainly determined by αX term and there is a good linear correlation between X and log K.[4] However, the correlation between Y and log K of soft-soft complexes was less satisfactory. It was, therefore, suggested that if one can adjust Y values, Eq. (1) will be much improved for stability constants.[4] Thus, we attempted to improve Y values using the dual parameter equation of the form of Eq. (1) and the regularities found among log K of halogeno-complexes of metal ions.

Results

Procedure for the Derivation of Softness Parameters, Y'. The stability constants of metal-

*2 The stability constant, K, is the equilibrium constant of $M^{n+}+mL \rightarrow ML_m^{n+}$. In the previous paper,[4] K was the equilibrium constant of the reverse reaction, that is, the instability constant. Therefore, log K in the present paper is equal to pK in the previous paper.

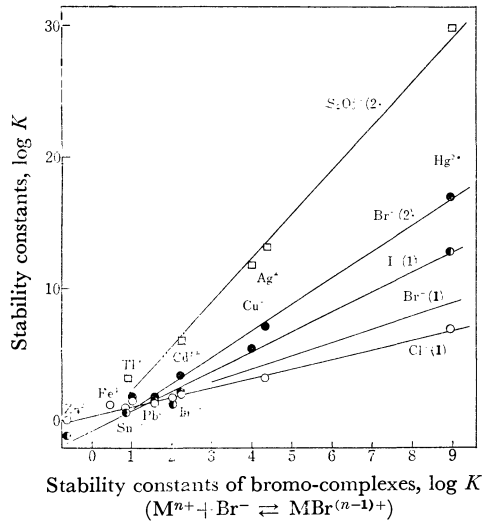

Fig. 1. Regularity among the stabilities of soft-soft complexes.
Log of stability constants of several soft ligand complexes are plotted against those of bromo-complexes. Numbers in parentheses indicate coordination numbers.

ion complexes with various soft ligands, log K, are plotted against those of bromo-complexes for several metal ions in Fig. 1. A fairly good regularity is found among these stability constants. In this figure two apparent trends should be noted: (i) soft metal ions have large log K values ($Hg^{2+}>Cd^{2+}>Zn^{2+}$), and (ii) soft ligands have steep slopes ($I^->Br^->Cl^-$). The trends are well interpreted with the softness sequences and are also expected from the βY term of Eq. (1), suggesting that this type of equation holds among these complexes.

Usefulness of a dual scale equation like Eq. (1) and the regularity in Fig. 1 demonstrated for these complexes prompted us to estimate the softness upon these bases. X values have already been proved to be satisfactory as the hardness parameter in Eq. (1). Thus, if one can choose such Y values that the equation gives satisfactorily the observed log K values, they may be considered to be good softness parameters. In order to avoid confusion, Y', α', β' and γ' will be used hereafter for the new parameters. Then the equation is written as

$$\log K = \alpha' X + \beta' Y' + \gamma' \qquad (2)$$

where X values are common to Eq. (1). From $\beta' Y'$ term which is obtained by the substraction of $\alpha' X + \gamma'$ from log K value, the softness of each metal ion can be estimated with the following procedure.

1) The log K of chloro-complexes is taken, to a first approximation, as Y' value respectively as follows: Hg^{2+}(7.2), Tl^{3+}(6.5), Ag^+(3.8), Cu^+(3.5), Cd^{2+}(2.1), In^{3+}(1.9), Fe^{3+}(1.6), Pb^{2+}(1.6), Sn^{2+}(1.6), Tl^+(1.2) and Zn^{2+}(1.0). Since there are linear correlations among the stability constants of halogeno-complexes (Fig. 1), the stability constants of any halogeno-complexes may be used as the basis for Y' values. Here, chloro-complexes are chosen, simply because a good number of reliable stability constants are available and they give Y' values whose magnitude is better to handle. When there is no experimental log K value of chloro-complex, estimation is made from log K of other halogeno-complexes, considering the regularity in Fig. 1.

2) By the method of least squares, α', β', and γ' are then calculated by Eq. (2) for several soft ligands, including different coordination numbers.

3) Improved Y' values are tentatively obtained from the slopes in log $K-\alpha' X-\gamma'$ *vs.* β' plots (Fig. 2).

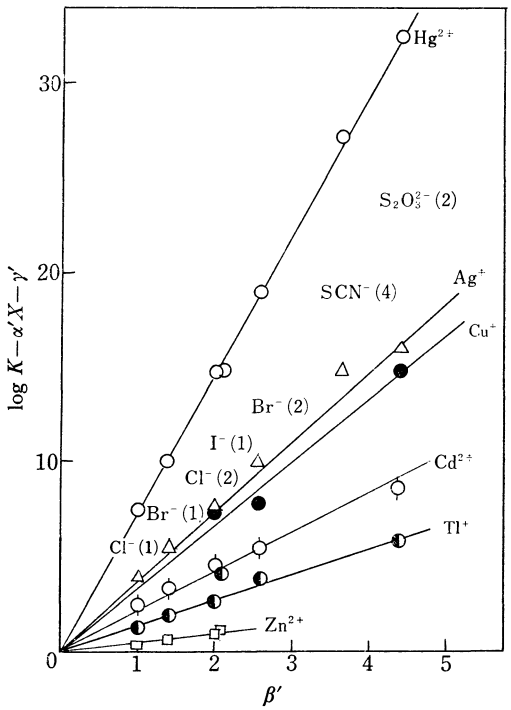

Fig. 2. log $K-\alpha' X-\gamma'$ *vs.* β' plot.

Repeating the above procedure one can get the most reasonable value of Y' for each metal ion. Iteration was not actually continued, since the agreement of the second Y' with the first ones was good enough. The final Y' values are Hg^{2+} (7.3), Tl^{3+} (6.0), Ag^+ (3.8), Cu^+ (3.3), Cd^{2+} (2.0), In^{3+} (1.8), Sn^{2+} (1.8), Pb^{2+} (1.6), Fe^{3+} (1.4), Tl^+ (1.3), and Zn^{2+} (0.7). Linearity of the plots in Fig. 2 is significantly improved compared to that in Fig. 1, which provides a good support for Y' as a good softness parameter which is based on the original criteria for the soft-hard classification. Additional Y' values are determined in a similar manner, using only log K of halogeno-complexes, as follows: Au^+ (10.9), Au^{3+} (9.4), Pt^{2+} (6.9), Pd^{2+} (5.6), Co^{2+} (1.2) Fe^{2+} (0.3) and Mn^{2+} (0.0). Although these values might be less reliable because of the limited number

a) The values on the left part of each row are those calculated by $\log K=\alpha' X+\beta' Y'+\gamma'$ and those on the right are the observed ones, which are the same as in the previous paper[4] except for some revision and supplements using data in Ref. 14. The values for $S_2O_3^{2-}$ are the overall instability constants of $M(S_2O_3)_2^{(n-4)+}$. Other values are of mono-coordinated complexes.

b) Since very few log K values have been reported for the complexes of less soft metal ions, such as Fe^{2+}, Co^{2+} and Cu^{2+}, Y' was estimated from $Y'=2.8Y-6.2$ which is found to hold approximately between Y and Y'. Y' was put to zero when $2.8Y-6.2$ became negative. This estimation seems sufficient for log K calculation, becuase $\beta' Y'$ term in Eq. (2) contributes little in these cases.

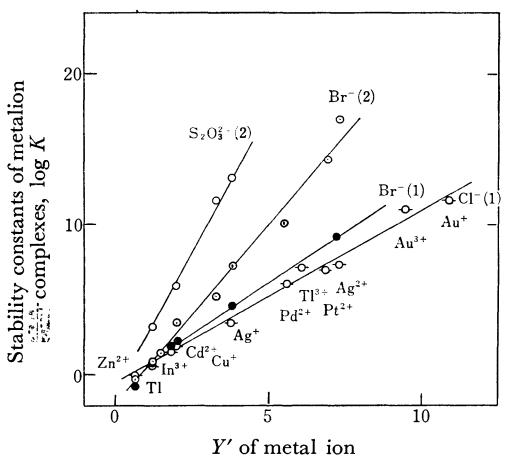

Fig. 3. Stability of metal-ion complex as a function of softness parameter, Y'.
Numbers in parentheses are the same as in Fig. 1.

of reported log K, satisfactory linear correlation of new parameters, Y', with log K values of soft-soft complexes is obtained as demonstrated in Fig. 3. This good correlation is comparable with that of X with log K of hard-hard complexes.[4] A part of the deviation from the straight line found in Fig. 3 may be due to the minor contribution from $\alpha' X$ term in Eq. (2). Some of the calculated log K values by Eq. (2) are given in Table 1 for several metal-ion complexes. The results for the complexes of ligands with considerable softness are given in this table. For hard ligand complexes, the agreement between the calculated and the observed log K values[4] was as good as the present one. Agreements between the calculated and the measured log K in this table are excellent as a whole. Remarkable improvements in agreement are observed especially for I^- and $S_2O_3^{2-}$($\beta'>1$). As for the magnitude of β there is little change; both β and β' follow the softness sequence and are linearly correlated with $n_{P.}$, the reactivity index of a nucleophile for the displacement reaction of Pt^{2+}-complex.[10]

Discussion

Comparison of Y′ with Other Softness Parameters. The proposed parameter Y' thus obtained semi-empirically on the basis of the original criteria for the soft-hard classification, may reasonably be considered as a quantitative expression of softness (see Figs. 1 and 2). It seems of interest to compare such various parameters proposed for the quantitative expression of softness of metal ion, as R(N),[3] R(W),[5] Y,[4] α/β[7] and $E_n^=$,[6] with the present parameter Y' and look into the physical meaning of softness. All of these parameters are useful as rough criteria for the soft-hard classification of metal ions, although a few exceptions are always inevitable.

However, it is apparent that the correlations are only qualitative. If one plots these parameters against Y', only fair correlations are obtained for $E_n^=$ and Y, and rather poor ones for R(N), R(W) and α/β. This means that the approximation used for the derivation of the parameters previously proposed are too simple for quantitative use.

Origin of Softness. The soft-hard classification is based on the fact that, reviewing inorganic stability constants in *aqueous* solution, metal ions fall into two distinct groups: those which form halogeno-complexes whose stability order is (i) F>Cl>Br>I, and (ii) I>Br>Cl>F. This situation, however, contrasts with that observed in the gas phase, where the sequence of molecular stability is always found to be MF_2>MCl_2>MBr_2>MI_2. This obviously demonstrates the importance of solvent effect, that is, the change in solvation state during the complex formation. Klopman[6] has recently derived his softness parameter as the difference between the bond energy and the desolvation energy accompanying complex formation. The bond energy consists of electrostatic and charge-transfer interaction energies. In his treatment, the extent of softness of metal ion depends on how much the bond energy overcomes the energy loss due to desolvation. We have previously discussed the bond energy of coordination and the soft-hard properties, dividing the total bond energy into electrostatic, σ-bond and π-bond energies.[4] In this treatment the heat of solvation was assumed to be proportional to the electronegativity X, since the bond energy of metal ion to aquo ligand is mainly correlated to the αX term.

The heat of complex formation, $M^{n+}+mL^- \rightarrow ML_m^{(n-m)+}$(L=F, Cl, Br and I) is equal to the difference between the heat of M-L bond formation and the desolvation energy. Since the latter is roughly equal, with opposite sign, to the solvation energies of M^{n+} and L^-, the stability sequence for a given metal ion, either F>Cl>Br>I or F<Cl<Br<I, may be determined by the change in M-L bond energy relative to that in solvation energy of L^- from F to I.

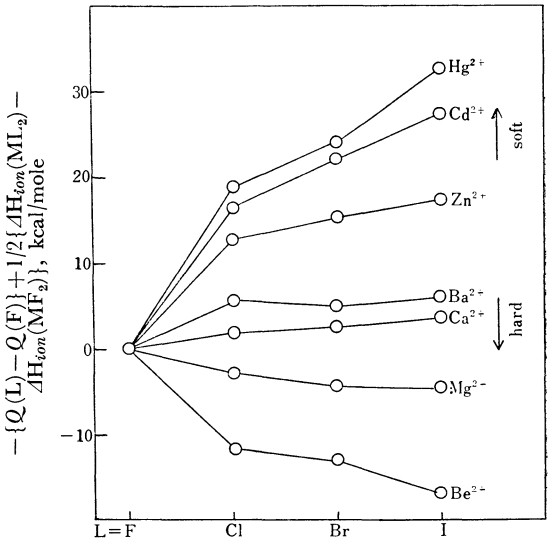

Fig. 4. The change in metal-halogen bond energy from F to I relative to the change in the heat of hydration of halide ion.
Q(L): Heat of hydration of halide ion (L^-).
Q(F): Heat of hydration of fluoride ion.
$\Delta H_{ion}(ML_2)$: Heat of reaction of M^{2+}(gas)+$2L^-$(gas)→ML_2(gas).

In Fig. 4, this situation is demonstrated for some metal ions. The coordinate represents the difference between the changes among halogens from F to I in M-L bond energies and those in solvation energies of L^- by refering to fluoride ion in both cases. In contrast to the M-L bond energy which is approximated by half of the heat of the reaction of $M^{2+}+2L^- \rightarrow ML_2$ in the gas phase, F>Cl>Br>I, the desolvation energy of L^- suggests a favorable order for the stable complex formation (F<Cl<Br<I). It may be stated, therefore, that the main factor to determine the stability sequence of metal-halogeno complexes is how much the decrease in M-L bond energy in F, Cl, Br, I series is compensated by the decrease in desolvation energy in the same series. Thus Hg^{2+} and Cd^{2+} are soft, because their M-L bond energies decrease more moderately than those of metal ions such as Be^{2+} and Ca^{2+}.

Roughly speaking, both the solvation energy and

	reported[c]	6.46	7.04	−3.0	−6.0	17.5	11.2	−9.0	3.6

a) The values of α', β' of $S_2O_3^{2-}$ are estimated as $\alpha'=0.06$ and $\beta'=2.50$ for mono-coordinated complexes, from those of dicoordinated ones considering the dependency of α' and β' of other ligands on the changes in the coordination number.
b) Taken from Ref. 11.
c) Taken from Ref. 8.

the σ-bond energy linearly depend on X,[4] probably the latter, to a lesser degree. As shown in Fig. 4, the more ionic the M-L bond, the more strongly the bond energy depends on X, resulting in a more negative slope in Fig. 4. In other words, an increase in covalency increases softness. The ability of π-bond formation (back donation) strongly favors the sequence I>Br>Cl>F. The reason why $E_n^{\neq}$ of Pd^{2+}, Pt^{2+} and Au^+ are lower than those expected from Y' may be explained by the fact that π-bonding was neglected in $E_n^{\neq}$ calculation. Thus, if the decrease in M-L bond energy from F to I of a certain metal ion becomes moderate, by the enhancement of covalency, especially of π-bonding in M-L bond, class (b) character or softness, increases.

Changes in softness may also occur by the solvent effect in the way pointed out by Williams and Hale.[5] Reduction of dielectric constant of solvent decreases the change in the solvation energy from F to I, so that the solvation becomes less important. As a consequence all cations revert to class (a) character as dielectric constants approach unity, that is, for example, in the gas phase.

Some Examples of Applications. The values of softness and hardness, (X, Y'), of CH_3Hg^+, CF_3Hg^+ and $C_3F_7Hg^+$ are calculated by Eq. (2) as (X=6.52, Y'=5.35), (6.79, 5.80) and (6.54, 5.89), respectively. These calculated log K values agree well with the reported ones (Table 2). Y' are large as expected, but it is to be noted that X values are also large. Belluco *et al.*[10] reported poor correlation of the log K of CH_3Hg^+ complexes with n_{Pt}. However, n_{Pt} correlates well with β[4] or β'. This discrepancy is understandable, if one takes into account the considerable hardness of CH_3Hg^+; n_{Pt} and β are determined by softness[4] while log K of CH_3Hg^+ complexes depends on both softness and hardness. The ability of mercuric ion to form strong σ-bond may partly account for the hardness, as σ-bond energy depends on X.[4]

The reactivity indices of a nucleophile in various displacement reactions on carbon, such as n,[11] E_n and H,[8] have been related to the present α' and β' by the formulas

$$n = 2.3\alpha' + 2.6\beta' \quad (3)$$

$$E_n = 0.9\alpha' + 1.0\beta' \quad (4)$$

$$H = 13.2\alpha' - 1.4\beta' \quad (5)$$

n and E_n are the nucleophilic constants (approximately, $n \propto E_n$) and H the basicity of a nucleophile (oxibase scale[12]). The values calculated by the above equations are in fair agreement with the reported values of n and E_n, but not with H (Table 3). Poor argeement for H may not be serious, because H is usually of little importance in the reactivity which depends mostly on n (or E_n). Equations (3) and (4) demonstrate that the reactivity of a nucleophile depends almost equally on hardness α' and softness β'. The ratio of these two coefficients, which gives the relative dependency of the reactivity on hardness to that on softness, is expected to vary from one type of reaction to another. In fact, in the case of the ligand displacement of Pt^{2+} complexes, the reactivity n_{Pt} is mainly controlled by softness.[4] The reactivities for the displacement reactions of CH_3I and CH_3Br by a nucleophile, n_{CH_3I} and n_{CH_3Br}, are determined by both hardness and softness, since they are proportional to E_n.[13]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3685—3688 (1970)

The Phase Transitions of the Anion Radical Salts Containing Mixed Cations; $[(C_6H_5)_3PCH_3]_{1-x}^{+}[(C_6H_5)_3AsCH_3]_x^{+}(TCNQ)_2^{-}$, $(0 \leq x \leq 1)$

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 27, 1970)

The phase transitions of the anion radical salts containing mixed cations represented by $[(C_6H_5)_3PCH_3]_{1-x}^{+}[(C_6H_5)_3AsCH_3]_x^{+}(TCNQ)_2^{-}$, $(0 \leq x \leq 1)$ were investigated. The transition temperature, T_c, and the magnitude of the heat, ΔH, of the transition were determined as a function of the composition parameter, x, by means of a differential scanning calorimeter. It was found that T_c increases, and ΔH decreases, monotonously with an increase in the value of x, and that the phase transition disappears with $x=1.00$. The mechanism of the phase transitions was discussed on the basis of the theory of triplet exciton-exciton interaction proposed by Chesnut. The theoretical values of the entropy changes of the transitions were found to be much less than those observed. In view of these results, it was concluded that the anomalies in the magnetic susceptibilities of these salts were induced by the change in the crystal structure.

There are a few ion-radical salts that are known to undergo phase transitions.[1-7] The phase transitions of such ion-radical salts are particularly interesting, because the anomalies in the magnetic susceptibilities are associated with the phase transitions.[1-6]

Much attention has been paid to the solid anion-radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ).[5,6,8-10] In the course of our study of these salts, we found that the ESR absorption intensity, which is proportional to the paramagnetic susceptibility, of the salt of methyltriphenylphosphonium, $[(C_6H_5)_3PCH_3]^{+}(TCNQ)_2^{-}$, increases abruptly at 40°C when the temperature is raised.[6] This discontinuity was also found in the electrical conductivity at that temperature.[6] This anomaly was ascribed to the phase transition of the crystal, as evidenced by the differential thermal analysis.[11] The methyltriphenylarsonium salt, $[(C_6H_5)_3AsCH_3]^{+}(TCNQ)_2^{-}$, exhibits electronic properties almost identical with those of the phosphonium salt; on the other hand, the arsonium salt is known to have no such anomaly. One can prepare the salts containing mixed cations, which may be expressed as $[(C_6H_5)_3PCH_3]_{1-x}^{+}[(C_6H_5)_3AsCH_3]_x^{+}(TCNQ)_2^{-}$, $(0 \leq x \leq 1)$.[5,8] Therefore, it seemed that it would be interesting to investigate the effect of the compositon upon the phase-transition phenomenon. The present investigation was performed by means of a differential scanning calorimeter (DSC).

An attempt has previously been made to explain the mechanism of the phase transitions of ion-radical salts in terms of the cooperative spin-exchange interaction.[12] Hence, the experimental results of our DSC measurements will be discussed in terms of such a theoretical consideration. In other words, we shall examine to what extent the spin-exchange interaction of these TCNQ anion radical salts contributes to the phase transition mechanism. Knowledge as to the effect of the chemical composition upon the phase transition is useful for this purpose.

The present study has already been reported in part in a short communication.[13]

Experimental

Materials. The preparation of TCNQ has been described by Acker and Hertler.[14] It was purified by recrystallization from acetonitrile. The anion-radical salts containing the mixed cations, $[(C_6H_5)_3PCH_3]_{1-x}^{+}[(C_6H_5)_3AsCH_3]_x^{+}(TCNQ)_2^{-}$, $(0 \leq x \leq 1)$, were synthesized according to the method of Melby *et al.*[8] The six salts were prepared with compositions of $x=0.00$,

Hexachloroethane (Wako Pure Chemical Industries, Ltd., GR grade) was used without further purification. Hexamethylbenzene (Eastman Kodak Co., white-label grade) was purified by recrystallization from ethanol.

Measurements. The DSC measurements were performed by means of a Rigakudenki Thermoflex apparatus. The rate of raising the temperature was 3.0°C/min. As a reference, powdered α-alumina was employed. The sample and the reference were packed and sealed, respectively, into aluminium vessels in order to prevent weight loss due to the sublimation. In DSC measurements, the peak area of the signal line should be proportional to the magnitude of the heat, ΔH, associated with the phase transition. Therefore, in order to determine the heat of transition, the integrated area of the peak of $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$ was compared with that of hexachloroethane or hexamethylbenzene. The phase transition of hexachloroethane is known to take place at 318.1°K with ΔH=0.613 kcal/mol and at 344.4°K with ΔH=1.965 kcal/mol,*1 and that of hexamethylbenzene, at 384.1°K with ΔH=0.42 kcal/mol.[15] In this technique, it was necessary to employ standard materials whose transition temperatures were close to those under investigation.

Results

In $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, where $0 \leq x \leq 1$, all the salts except for that with x=1.00 were found to show phase transitions. For instance, one of the DSC thermograms for $[(C_6H_5)_3PCH_3]_{0.80}^+[(C_6H_5)_3AsCH_3]_{0.20}^+(TCNQ)_2^-$ is reproduced in Fig. 1. These phase transitions were endothermic when the temperature was raised, and reversible when the temperature was lowered. The transition temperature, T_c, and the magnitude

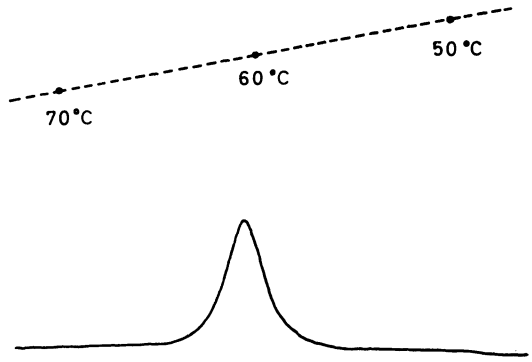

Fig. 1. One of the DSC thermograms for $[(C_6H_5)_3PCH_3]_{0.80}^+[(C_6H_5)_3AsCH_3]_{0.20}^+(TCNQ)_2^-$. The rate of raising temperature was 3.0°C/min.

of the heat, ΔH, associated with the phase transitions of these salts are listed in Table 1, together with the molecular weight, the sample weight used for this experiment, and the heat of transition of the specimen. On the basis of these results, the relations of T_c and of ΔH to the composition parameter, x, are illustrated in Fig. 2.

In the salt of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$, where x=0.00, the values of T_c=41.5°C and $\Delta H=4.5\times10^2$ cal/mol were obtained from these DSC measurements. These values were in agreement with the values, T_c=315.7°K and ΔH=487 cal/mol respectively, which were obtained from the heat-capacity measurement by Kosaki *et al.*[16]

As is shown in Fig. 2, it was found that, in the salts where $0<x<1$, T_c increases and the value of ΔH decreases, monotonously with an increase in the value of x, and that the phase transition

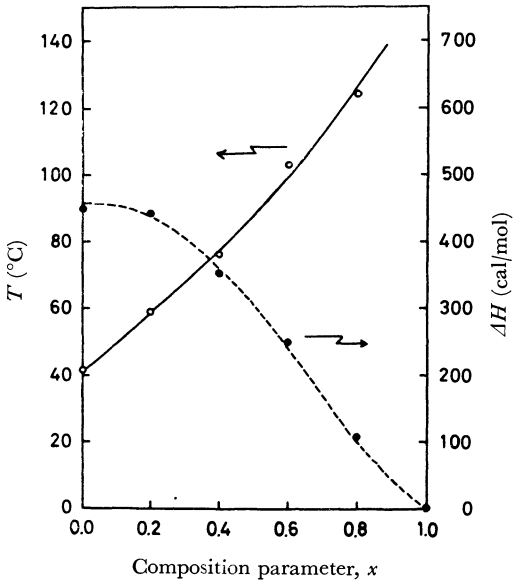

Fig. 2. The relations of the transition temperature, T_c, and of the magnitude of the heat, ΔH, associated with the phase transition, to the composition parameter, x, in $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$.

disappears at $x=1.00$. We can see that T_c is raised almost linearly as the value of x increases. On the other hand, the value of ΔH decreases slowly as the value of x increases in the region where $0 \leq x \leq 0.4$, while it decreases almost linearly as the value of x increases in the region where $0.4 \leq x \leq 1.0$. When $x \approx 1.00$, T_c may be extrapolated to about 160°C, although the value of ΔH tends towards zero.

Discussion

Triplet Exciton Interaction. These TCNQ anion-radical salts are composed of diamagnetic cations, TCNQ anion-radicals, and formally neutral TCNQ molecules. If the spins associated with the TCNQ anion-radicals did not interact, the magnetic susceptibility of these compounds would follow the Curie law. However, the magnetic susceptibility measurements have shown that this is not the case.[5] The extra electrons on the TCNQ molecules appear to be paired by an exchange interaction. These systems are known to contain a singlet ground state and a triplet exciton state. The TCNQ molecules are believed to be arranged in plate-like fashion in a unique crystal direction.[5,9]

In order to account for the occurrence of the phase transitions of these anion-radical salts, a simple phenomenological model has been proposed by Chesnut.[12] He showed that a certain type of order-disorder transition with respect to triplet excitation density does occur if one includes in the interaction a term which is quadratic in the triplet excitation density, ρ. In this case, the free energy, A, and the entropy, S, of the system for the N anions are represented by:

$$A = \frac{1}{2}N\left[\varepsilon_0\rho + \frac{1}{2}\varepsilon_1\rho^2 - kT\left\{\rho \ln g - \rho \ln \rho - (1-\rho)\ln(1-\rho)\right\}\right], \quad (1)$$

$$S = \frac{1}{2}Nk\left\{\rho \ln g - \rho \ln \rho - (1-\rho)\ln(1-\rho)\right\}, \quad (2)$$

where g is the multiplicity ($g=3$ for the triplet state), where ε_0 is the singlet-triplet energy separation, and where ε_1 is the interaction energy due to triplet exciton-exciton interaction.

The equilibrium value of ρ may be found by minimizing A with respect to ρ. The phase transition will take place at the temperature where two equally stable minima occur. In this case, the transition is of the first order. The spin entropy change will be:

$$\Delta S_{\text{spin}} = \frac{1}{2}R\Delta\rho \ln g, \quad (3)$$

where $\Delta\rho$ is the change in the triplet excitation density at the transition. $\Delta\rho$ can be calculated from the magnetic susceptibility data, since an abrupt change in the paramagnetic susceptibility at the transition temperature is due to the change in the triplet exciton population, $\Delta\rho$. Therefore, one can evaluate the magnitude of the spin entropy change by means of Eq. (3).

Comparison with Experimental Results. Kepler found a sharp discontinuity in the temperature variation of magnetic susceptibility in the crystals of $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, except for the salt with $x=1.00$.[5] At the temperature where the discontinuity occurred, there was an abrupt increase in the magnetic susceptibility in the higher temperature range. This critical temperature shifts to higher temperatures as the value of x increases. This relation is in good accordance with that obtained from the DSC measurements.

The values of $\Delta\rho$ were calculated from Kepler's susceptibility data. For example, in $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$, where $x=0.00$, $\Delta\rho=0.12$ is centered about the point where $\rho=0.37$. This leads, by Eq. (3), to; $\Delta S_{\text{spin}}=0.13$ cal/deg·mol. Similar calculations were made for the mixed crystals. Thus, the relation of ΔS_{spin} to x was found to be as shown in Fig. 3.

On the other hand, the observed entropy changes, ΔS_{obs}, at the transition were evaluated from the observed values of T_c and ΔH. The relation of ΔS_{obs} to x is also illustrated in Fig. 3.

As is shown in Fig. 3, it was found that the values of ΔS_{spin} were much less than those of ΔS_{obs} for all of the compounds. For example, in $[(C_6H_5)_3$-

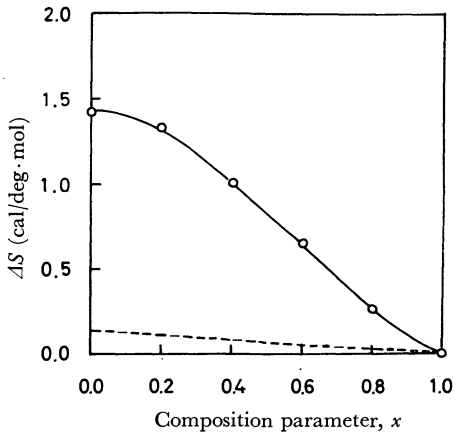

Fig. 3. The relation of the entropy change at the phase transition to the composition parameter, x, in $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, $(0 \leq x \leq 1)$. ΔS_{obs} (the solid line) represents the total entropy change estimated from the observed values of ΔH and T_c in Fig. 2. ΔS_{spin} (the dotted line) represents the spin entropy change calculated from the Chesnut's theory by Eq. (3).

$PCH_3]^+(TCNQ)_2^-$, $\Delta S_{spin}=0.13$ cal/deg·mol, while $\Delta S_{obs}=1.4$ cal/deg·mol. Therefore, the value of ΔS_{spin} is as small as 9.1% of that of ΔS_{obs}. Although the values of both ΔS_{spin} and ΔS_{obs} decrease with an increase in x, the ratio of ΔS_{spin} to ΔS_{obs} remains nearly constant in the mixed crystals.

Conclusion

The above-mentioned results clearly indicate that the total entropy change can not be understood solely by the spin-entropy change calculated from Chesnut's theory. This means that it is hopeless to consider only the spin system as the source of entropy creation at the transition. Therefore, one must also take into consideration the entropy change due to the change in the crystal structure. In this case, the magnitude of this entropy change reaches about 90% of the observed total entropy change. This kind of entropy change decreases as the percentage of the methyltriphenylarsonium cation of the salt increases. Since, in these TCNQ anion-radical salts, the crystal structure above the transition temperature is expected to be appreciably different from that below the transition temperature, it is desirable to study the difference in these crystal structures by X-ray analysis.*2 The anomalies in the magnetic susceptibilities of these anion-radical salts are probably induced by the change in the crystal structures.

*2 There are some other ion-radical salts that undergo phase transitions. It is well known that the phase transition of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (Würster's Blue) perchlorate, one of the stable cation-radical salts, takes place at 189°K. Elliot and Wolfsberg,[1] Duffy,[2] and Okumura[3] found a sharp decrease in the paramagnetic susceptibility below this transition temperature, where Würster's Blue cations are known to pair up to form dimers with a ground singlet state and an excited triplet state.[4] If Chesnut's theory is applied to this transition, Okumura's susceptibility data indicate that $\Delta\rho=0.087$ symmetrically about $\rho=0.643$. This leads by Eq. (3) to: $\Delta S_{spin}=0.095$ cal/deg·mol. This value is much less than the value, $\Delta S_{obs}=2.19\pm0.02$ cal/deg·mol, which was obtained from the heat-capacity measurements by Chihara *et al.*[7] They said that it was difficult to consider only the spin system as the source of entropy creation at the transition.[7] Again, in this salt, the rest of the entropy must then come from some structural changes. In fact, X-ray diffraction studies, cited by McConnell,[4] show that the transition is accompanied by a small structural change from the room-temperature orthorhombic phase to the low-temperature monoclinic phase. These results seem to be, in some respects, very similar to those for the present TCNQ anion-radical salts.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3689—3694 (1970)

An Electron Spin Resonance Study of the 5,12-Dihydrotetracene Radical Anion and Its Ion Pairs with Alkali Metal Cations

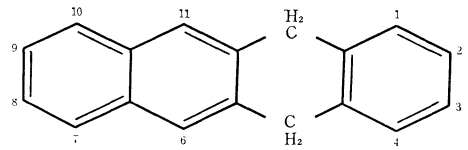
Masamoto IWAIZUMI and Taro ISOBE

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-nichome, Sendai

(Received May 27, 1970)

The 5,12-dihydrotetracene radical anion and its ion pairs with alkali-metal cations have been investigated by electron spin resonance (ESR). It has been found that the frequency of the inversion of the radical molecule is $\gg 10^8$ Hz and that the unpaired electron is distributed between the benzene and naphthalene rings. Such a distribution of the unpaired electron between the two conjugated systems is assumed to occur *via* a hyperconjugation mechanism. On the other hand, it was observed that the proton hyperfine splittings of the radical anion are appreciably affected by the association of an alkali-metal cation. In the case of the 5,12-dihydrotetracene-potassium ion-pair in THF, the hyperfine components of the methylene protons show an alternating line-width effect. On the basis of the observed effects of the alkali metal cations, a model of the ion-pair structure is proposed, and the alternating line-width effect is explained in terms of an intramolecular migration of the potassium ion from one side of the molecular plane to the other. The activation energy of this motion of the potassium ion has been estimated to be 3.1 ± 0.2 kcal.

In this paper we wish to report the results of an investigation of the 5,12-dihydrotetracene radical anion and of the ion pair formed between the 5,12-dihydrotetracene radical anion and alkali-metal cations. It is well known that the ESR technique provides us with interesting and important information on the spin distribution in free radicals.[1,2] It is also useful in providing information on the conformation of the molecules of free radicals, and some times allows measurements of the dynamic motions of the molecule, such as the conformational interconversion and the *cis-trans* conversion.[3-6] The 5,12-dihydrotetracene (I) treated here is an interesting molecule in that it can be considered as consisting of two conjugated systems, benzene and naphthalene rings, weakly coupled through two methylene bridges. By analogy with the 9,10-dihydroanthracene molecule, which is in a non-planar conformation,[7] it can also be considered that the conformation of the 5,12-dihydrotetracene radical anion is non-planar, which may therefore lead to an inversion process. It seemed interesting to investigate the spin distribution and the inversion process of such a molecule. In this paper we will show that the unpaired electron is distributed between the benzene and naphthalene rings by a weak coupling between the two rings, although a large portion of the spin densities exist on the naphthalene ring; the transfer of the unpaired electron between the two conjugated systems may be explained by the hyperconjugation effect of the methylene bridges. We will also show that the rate of inversion must be: $\gg 10^8$ Hz.



I

On the other hand, it has been observed that the proton hyperfine splitting constants of the 5,12-dihydrotetracene radical anion change appreciably upon the formation of the ion pair with an alkali-metal cation. For the case of the ion pair with the potassium ion in THF, the hyperfine splitting due to the methylene protons changes markedly with the temperature, and it shows an alternating line-width effect at high temperatures. It is shown that the observed effects of the cations can be explained by an ion-pair model where the alkali ion favors a situation above the naphthalene skeleton, and that

the alternating line-width effect may be attributed to the migration of the potassium ion form one side of the naphthalene ring to the other. Previously, de Boer *et al.*[8] proposed an ion-pair model for the pyracene-alkali metal ion-pair, which gave us the impression that the alkyl groups have a strong affinity to the alkali ion. However, in our studies of the ion-pairs of acenaphthene[9] and 9,10-dihydroanthracene radical anions[10] with alkali ions we pointed out that an electrostatic interaction model, which predicts the ion-pair structure where an alkali ion is situated at the position of the highest negative charge, is more reliable than de Boer's model. The present result supports our prediction. This is also one of the rare sources of information about the migration of the alkali ion form one side of a molecular plane to the other.

Experimental

The anion radical of the 5,12-dihydrotetracene was prepared by reduction with lithium, sodium, and potassium. The solvents used were 1,2-dimethoxyethane (DME), tetrahydrofuran (THF), and tetrahydropyran (THP). In DME and THF, three kinds of alkali metals were used as reducing agents, while in THP only potassium was used. The 5,12-dihydrotetracene used was obtained commercially (Tokyo Kasei, G. R.) and was purified by recrystallization from benzine. The ESR spectra were measured by a Hitachi X-band ESR spectrometer, model MES 4001, employing field modulation at 100 kHz. As the radical anion was unstable above room temperature, the radical anion was prepared and the ESR spectra were measured below room temperature. Low temperatures were obtained by letting cool nitrogen gas flow through a Dewar jacket leading through the sample cavity. The temperature was controlled by adjusting the flow rate of the cool nitrogen gas, and was checked with a copper constantan thermocouple placed just below the sample. The magnetic field was calibrated by a Hitachi field marker.

Results

Representative spectra obtained in the present experiment are shown in Figs. 1 to 4. The proton

Spectrum f) is a computer simulated spectrum for d) obtained using the Bloch's two jump model with $\tau = 1.7 \times 10^{-6}$ sec.*1 The magnetic field increases from right to left.

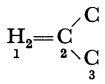
hyperfine splitting constants are listed in Table 1. For purposes of comparison, the hyperfine splitting constants of the *o*-xylene[11] and 2,3-dimethylnaphthalene[12] radical anions are collected, along with those of the 5,12-dihydrotetracene radical anion. All the splitting constants of the 5,12-dihydrotetracene radical anion were assigned on the basis of the Hückel molecular-orbital calculation, which is shown in Table 2, and by comparison with the hyperfine splitting constants of the *o*-xylene and 2,3-dimethylnaphthalene radical anions. In the molecular-orbital calculation, the hyperconjugation effect of the methylene bridges is included. The parameters used were as follows:

$$\delta\alpha_1 = -0.5\beta \quad \delta\alpha_2 = -0.1\beta \quad \delta\alpha_3 = -0.1\beta$$
$$\beta_{12} = 2.0\beta \quad \beta_{23} = 0.8\beta \quad \beta_{13} = 0.3\beta$$



Here, β_{13} was introduced since the methylene protons at the axial positions must be situated in close proximity to the π-orbital in the benzene and naphthalene rings if the molecule is non-planar. The inclusion of this parameter improved the agreement between the observed hyperfine splitting constants and the calculated ones. Table 2 also lists such results of the electrostatic perturbation calculation[13,14] on the effect of the alkali ion on the proton hyperfine splittings as relate to the following discussion.

The ESR spectra observed in DME with lithium, sodium, and potassium ions as counter ions show the same hyperfine structure, and no appreciable change with the alkali ions is observed (see Table 1). Although the line width broaden and the resolution of the spectra becomes worse with an increase in the temperature, there seems to be no large change in the hyperfine splitting constants with the temperature. It may be considered, therefore, that in DME the radical anion exists as a free anion or as an ion pair bound very loosely, for there is no marked effect of the cations on the ESR spectra. It may be noted here that, in these systems, the four methylene protons show a normal quintet splitting, although they must exist as axial and equatorial protons.

Table 2. Calculated ring proton hyperfine splitting constants*1 of 5,12-dihydrotetracene radical anion (gauss)

		Position (1,4)	(2,3)	(6,11)	(7,10)	(8,9)
Free-anion		0.110	0.040	4.018	5.018	1.812
Ion-pair*2	model A	0.049	0.040	3.577	5.027	1.923
	model B	8.160	1.944	0.302	0.119	0.071

*1 The splitting constants of the ring protons were calculated by $a_i = Q^H_{CH}\,\rho_i$ with $Q^H_{CH} = 27$ gauss.
*2 The calculations were carried out using McClelland method[13,14] with the alkali metal placed 4.0 Å above the center of the naphthalene ring (model A) and with that placed 4.0 Å above the center of the benzene ring (model B).

When THF or THP was used as a solvent, appreciable effects of the cation were observed on the hyperfine structure of the ESR spectra. The proton hyperfine splitting constants change with the cations, and when sodium is used as a reducing agent, an additional splitting arising from the sodium nucleus is observed. In THF, this sodium hyperfine splitting has a positive temperature coefficient and disappears below a temperature of about −50°C.

The effect of the cation on the proton hyperfine splittings is especially remarkable when the cation is a potassium ion in THF and in THP. The hyperfine splittings due to the protons at 1,4 and 2,3 positions are much smaller than those in the other systems, and that of the methylene protons splits into two sets of triplets. Moreover, in THF the methylene proton hyperfine splitting changes markedly with the temperature and the two sets of triplet splittings coalesce to a quintet splitting at a higher temperature, showing the effect of the alternating line width. In Fig. 3, four of the hyperfine lines with spin states, (1,1), (1,0), (0,1), and (0,0), are numbered from 1 to 4 respectively. Here the numbers in parentheses are the magnetic index numbers[15] for the two sets of methylene protons. One can see from the figure that, as the temperature increases, the 2 and 3 lines become broad and tend to coalesce to form the quintet splitting as a result of hyperfine interaction with the methylene protons.

Discussion

Spin Distribution and Inversional Motion of the 5,12-Dihydrotetracene Radical Anion. As Table 1 shows, the unpaired electron is dis-

15) J. H. Freed and G. K. Fraenkel, *J. Chem. Phys.*, **40**, 1815 (1964).

tributed between the naphthalene and benzene conjugated systems in the radical anion molecule. The distributions of the spin densities in the benzene and naphthalene rings are quite similar to those in the *o*-xylene and 2,3-dimethylnaphthalene radical anions respectively, although a large portion of the spin densities exist on the naphthalene ring. This implies that this molecule can be considered in terms of two weakly-coupled benzene and naphthalene rings. The coupling mechanism is presumably due to a hyperconjugation effect of the methylene bridges, as has also been suggested for the case of the 9,10-dihydroanthracene radical anion.[16] The molecular-orbital calculation for the hyperfine splitting constants including the hyperconjugation effect of the methylene bridges, given in Table 2, well predicts the observed spin distribution.

On the other hand, as was mentioned in the preceeding section, the methylene protons show the normal quintet splitting except when there is a strong perturbation due to the alkali metal cation, as in the case of the ion-pairs with a potassium ion in THF and in THP. From the fact that the conformation of the 9,10-dihydroanthracene is non-planar,[7] it seems reasonable to consider that the 5,12-dihydrotetracene also has a non-planar conformation, which would lead to an inversion process. The methylene protons which are in axial and equatorial positions can thus be expected to exchange their positions in the inversional process with each other. The equivalence of the methylene protons in the ESR spectrum implies that the rate of the inversional motion is $\gg 10^8$ Hz.

Ion-pair Formation and Structure of the Ion Pair. As was mentioned in the previous section, the hyperfine splitting constants change with the association of the alkali ion. The effect of the potassium ion observed in THF and in THP is especially remarkable. Such cation effects provide us with very useful information about the structure of the ion pair. In such a system as two-conjugated systems weakly coupled, the spin distribution between the two conjugated systems is considered to be sensitive to the association of a cation on either of the conjugated systems.[10] In the present case, it was observed that the association of the cation causes a migration of the unpaired electron density from the benzene ring to the naphthalene ring. This effect implies that the potassium ion may associate with the radical anion on the side of the naphthalene ring. The electrostatic perturbation calculations[13,14] were carried out in order to establish the effect of the cation. The results given in Table 2 are for two ion-pair models, one where the cation is placed 4.0 Å above the center of the naphthalene ring (model A) and the other where the cation is placed 4.0 Å above the center of the benzene ring (model B). As may be seen from Table 2, Model A well explains the observed effect of the migration of the unpaired electron density from the benzene ring to the naphthalene ring. It is also consistent with the electrostatic interaction model, since the electron density and, hence, the negative-charge density are at maxima on the naphthalene ring.

In this ion-pair model, the two different hyperfine splittings observed for the methylene protons are attributed to the hyperfine interaction with the methylene protons on the same side of the molecular plane as the potassium ion and with those at the reverse side. Therefore, the alternating line-width effect observed in the potassium-5,12-dihydrotetracenide ion-pair in THF can be explained by the exchange of the potassium ion between the two preferred positions, above and below the molecular plane.*2

The exchange reaction mentioned above can proceed by both *inter*- and *intra*-molecular processes, (1) and (2);

$$K^+ + A^-K^{*+} \rightleftarrows K^+A^- + K^{*+} \quad (1)$$

$$A^-K^+ \rightleftarrows K^+A^- \quad (2)$$

where A^- stands for the radical anion. In some cases of ESR studies of ion pairs, additional alkali-metal hyperfine splittings were very useful in getting information on the life time of the ion pairs and in deducing whether exchange reactions were *inter*-molecular or *intra*-molecular in nature.[8-10,17]

16) M. Iwaizumi, T. Isobe and J. R. Bolton, to be published.

*2 The alternating line width effect can be caused also by the inversional motion of the molecule. However in the present case we do not prefer a hypothesis that the observed alternating line width effect is related to the inversional motion of the molecule. If the ratio of axial to equatorial splitting constants follows from the angular dependence of the β proton splitting constants, $a_\beta^H = B\cos^2\theta$, it must be about 4.0.[6] However the observed ratios of the methylene proton splitting constants change with strength of association of the cation and have the values 1.287 for the potassium-5,12-dihydrotetracenide ion-pair in THF and 1.406 for that in THP. These ratios are rather close to the value observed in the methylene protons for the potassium-acenaphthenide ion-pair, 1.05. In the acenaphthene ion-pair system, two hyperfine splitting constants coming from the methylene protons were explained by the effect of the electrostatic force of the associated cation. In view of these facts it seems reasonable to attribute the present observation to the electrostatic effect of the associated cation on the proton splitting constants. It is considered that the rapid inversion process of the molecule still occur.

17) a) N. M. Atherton and A. E. Goggins, *Mol. Phys.*, **8**, 99 (1964). b) E. E. Gough and M. C. R. Symons, *Trans. Faraday Soc.*, **62**, 269 (1966). c) T. A. Claxton, W. M. Fox and M. C. R. Symons, *ibid.*, **63**, 2570 (1967). d) D. H. Chen, E. Warhurst and A. M. Wilde, *ibid.*, **63**, 2561 (1967). e) P. S. Gill and T. E. Gough, *Can. J. Chem.*, **45**, 2112 (1967). f) J. Gendell, *J. Chem. Phys.*, **46**, 4152 (1967). g) K. Nakamura, This Bulletin, **40**, 1019 (1967).

In the present system, however, the hyperfine splitting due to the cation was not observed. It is possible that the alkali metal hyperfine splitting is averaged to zero by a rapid *inter*-molecular exchange reactoin of the alkali ion, and in some cases rapid *inter*-molecular equilibria have been concluded from the absence of cation splittings in the ESR spectra of the ion-pair systems.[18] We consider, however, that the observed reaction is the *intra*-molecular process for the following reasons.

(1) No potassium hyperfine splitting was observed, even under slow exchange conditions, such as in the potassium-5,12-dihydrotetracenide in THP, where the methylene protons showed two definite sets of triplet splittings. This implies that the potassium splitting constants are essentially too small to be resolved and that the absence of the metal splitting constant is not due to the rapid *inter*-molecular exchange of the cation. Previously, Dodson and Reddoch[19] showed that, in the naphthalene-alkali metal ion-pair system, potassium hyperfine splittings are very small, or are not observed at all, because the contributions of the hyperfine interaction with the positive and negative signs cancel each other out, although stable ion pairs are formed. It is considered that the alkali metal couplings in the present system are in a situation similar to that of the naphthalene ion-pair system.

(2) The sodium 5,12-dihydrotetracenide ion pair in THF shows a well-resolved sodium hyperfine splitting above $-30°C$, from which the lifetime of the ion pair can be estimated to be $\gg 10^{-6}$ sec. In view of the fact that the potassium ion generally has a greater tendency to associate with anion radicals than does the sodium ion,[14,18,20,21] the lifetime of the potassium-5,12-dihydrotetracenide ion pair in THF may be considered to be $\gg 10^{-6}$ sec. On the other hand, the lifetime of the static conformation of the ion pair is estimated to be about 6×10^{-7} sec from the observed alternating line-width effect in the same temperature range.

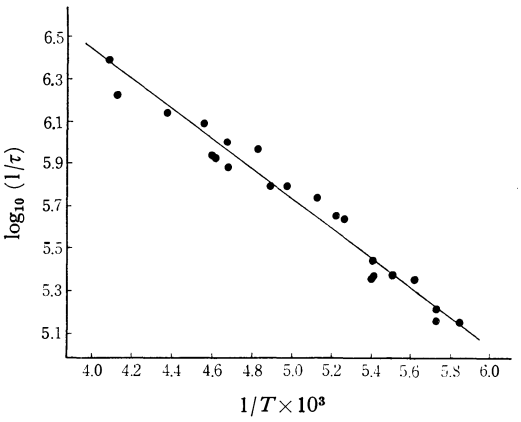

Fig. 5. Plot of $\log_{10} 1/\tau$ against $1/T\times 10^3$.

It may be concluded from these facts that the observed exchange reaction proceeds by the *intra*-molecular process. We computed spectra for different values of the lifetime of the ion-pair conformation, τ. Figure 5 shows the plot of the $\log_{10}(1/\tau)$ $(=\log_{10} k)$ thus estimated against $1/T$. Here k is the rate of the exchange reaction. As is expected from the Arrhenius equation,

$$k = 1/\tau = k_0 \exp(-E_A/RT) \qquad (3)$$

it shows a straight line. This gives a potential barrier to the migration of the potassium ion from one side of the molecular plane to the other; $E_A = 3.1\pm 0.2$ kcal/mol, and the frequency factor, $k_0, = 1.4\pm 0.5\times 10^9$ sec^{-1}.

On the other hand, one can see from Table 1 that effects of the cations on the proton hyperfine splittings vary with the cations. This implies that there may be slight differences in the equilibrium positions of the cations, but the ion-pair structure is not discussed in detail here. It may also be seen from the table that, in the case of the lithium or sodium-5,12-dihydrotetracenide in THF, the effects of the cations are smaller than in the case of the potassium-5,12-dihydrotetracenide in THF or in THP, suggesting that, in the former cases, the radical anion is in a more loosely bound ion-pair state.

The numerical calculations were carried out on the NEAC 2200 Model 500 computer at the Computer Center, Tohoku University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3695—3698 (1970)

Microwave Spectra of Vinylacetylene and Monodeutero Vinylacetylene in Ground and Excited Vibrational States

Chiaki HIROSE

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 22, 1970)

The microwave spectra of vinylacetylene, CH_2CHCCH, and monodeutero-vinylacetylene, CH_2CHCCD, have been observed in the ground state and several vibrational excited states. The vibration-rotation constants $\alpha_1^{(a)}$, $\alpha_1^{(b)}$, $\alpha_1^{(c)}$, $\alpha_2^{(a)}$, $\alpha_2^{(b)}$, and $\alpha_2^{(c)}$, have been obtained as 1 370, −18.32, −7.73, −907, −2.78, and −8.97 MHz for CH_2CHCCH, and 2 010, −16.66, −7.05, −1 640, −2.18 and −7.84 MHz for CH_2CHCCD, respectively, the error limits being ±50 MHz for $\alpha^{(a)}$'s and ±0.03 MHz for $\alpha^{(b)}$'s and $\alpha^{(c)}$'s. Electric dipole moments obtained are 0.223± 0.020 and 0.206±0.008 Debye for CH_2CHCCH and CH_2CHCCD, respectively, which are quite different from the values reported previously.

The present study was begun with the purpose of getting the rotational constants of normal- and monodeutero-vinylacetylene. The values obtained have been used by Fukuyama *et al.* in their research on the structure of a series of molecules with conjugated carbon-carbon multiple bonds.[1]

The study of vibration-rotation interactions of the molecule presents another interesting theme, since infrared spectroscopy gives relatively poor information, especially below 550 cm^{-1}, where three or five fundamentals, one overtone, and one combination-tone are known to exist,[2] and some perturbations on the energy levels are supposed to exist. The data on vibrational frequencies are listed in Table 1.*1 The author has investigated the rotational spectra in the above-mentioned vibrational states and found that strong resonances among the levels take place.

Table 1. Low-lying vibrational levels[a] (in cm^{-1})

Mode of vibration		CH_2C-HCCH	CH_2C-HCCD

b) Calculated by Abe.[2]
c) Sum of the corresponding fundamentals.

The electric dipole moment of the molecule has been reported by Sobolev *et al.* to be 0.43 Debye, which is obtained by analyzing the Stark effect of the transition $1_{0,1}\leftarrow 0_{0,0}$ on the assumption that $\mu_b=0$.[3] The author has tried to obtain the electric dipole moment without this assumption by analyzing transitions $J=1\leftarrow 0$ and $J=2\leftarrow 1$.

Experimental

Normal vinylacetylene, CH_2CHCCH, was supplied by Denki Kagaku Co. and was used without further purification. Impurities were checked using infrared and microwave spectra and believed to be less than 10%. Monodeutero-vinylacetylene, CH_2CHCCD, synthesized by reacting the normal species with D_2O, was contaminated with a few percent of normal vinylacetylene but was used without purification.

The rotational spectra were observed using a conventional microwave spectrometer with 110 kHz Stark modulation. Most lines were observed by cooling the waveguide cell with dry ice. The rotational transitions were assigned from the Stark effects of the lines. The relative intensities of the lines which had nearly the same Stark effect were the principal means for vibrational assignments.

Results

The transitions assigned are listed in Table 2. No b-type transition was observed in spite of a careful search. Because of this and a slight asymmetry of the molecule, it was impossible to obtain the exact value of the rotational constant A. Table 3 lists the derived constants B_0 and C_0 for the ground vibrational state and vibration-rotation constants $\alpha_i^{(b)}$ and $\alpha_i^{(c)}$ for ν_1 and ν_2 states. When the perturbation method is used, the value of A can be obtained from the deviation of the observed lines from the symmetric-top pattern through the value of $(B-C)^2/(A-(B+C)/2)$. The values of A_0, $\alpha_1^{(a)}$, and $\alpha_2^{(a)}$ thus obtained are listed also in Table 3.

Table 3. Derived molecular constants (in MHz)

	CH_2CHCCH	CH_2CHCCD
A_0	49 900 ±750	48 900 ±1600
B_0	4 744.66± 0.03	4 403.82± 0.08
C_0	4 329.68± 0.03	4 037.58± 0.08
$\alpha_1^{(a)}$	1 370 ± 50	2 010 ± 70
$\alpha_1^{(b)}$	−18.32± 0.03	−16.66± 0.05
$\alpha_1^{(c)}$	− 7.73± 0.03	− 7.05± 0.05
$\alpha_2^{(a)}$	−907 ± 50	−1 640 ± 50
$\alpha_2^{(b)}$	− 2.78± 0.03	− 2.18± 0.03
$\alpha_2^{(c)}$	− 8.97± 0.03	− 7.84± 0.03

Assignment of the rotational transitions in ν_3, ν_4, and ν_5 states was unsuccessful, because the Coriolis coupling between the states disturbs the spectra strongly in both CH_2CHCCH and CH_2CHCCD, and the $\nu_1+\nu_2$ state of the latter interacts with ν_4 and ν_5 through Fermi resonance. Further analysis and discussion on the problem will be given in a separate paper.

The Stark effects of the transitions $J=1\leftarrow0$ and $J=2\leftarrow1$ in the ground vibrational state were measured. From the results (Table 4), the electric dipole moments μ_a of the molecule were derived to be 0.223 ± 0.020 and 0.206 ± 0.008 Debye for normal and monodeutero-vinylacetylene, respectively. Analysis of the Stark effect revealed that μ_b is very small. Its value can not be determined accurately in spite of the fact that some of the transitions such as $3_{1,3}\leftarrow2_{1,2}$ $(M=0)$ have an appreciable dependence on μ_b^2.

As suggested by Morgan and Goldstein,[4] who observed five lines of the transitions $J=3\leftarrow2$ in the ground vibrational state of CH_2CHCCH, the effect of the centrifugal distortion is not negligible, and centrifugal distortion shifts of a few MHz is observed even in $J=3\leftarrow2$ transitions. However, because of the smallness of the molecular asymmetry and the failure to observe b-type transitions, it was not possible to determine the centrifugal distortion constants.

Discussion

Molecular Structure. The rotational constants observed in the present study were used by Fukuyama *et al.*[1] in combination with their electron-differaction data to determine the structure of the molecule.

Vibration-Rotation Constants. The rotational energy levels in an excited vibrational state are known to approximate a rigid rotor model when no vibrational state perturb the state,[5] and the rotational constants in the state v are expressed as B_v, which can be written in terms of α_v constants as

$$B_v^{(x)} = B_0^{(x)} - \alpha_v^{(x)} \qquad (1)$$

The $\alpha_v^{(x)}$ constants are the sum of two terms, one determined by the harmonic terms in the internal

He also expresses his thanks to Dr. Koichi Abe of the University of Tokyo for his information on vibrational spectra before publication and for his offer of the sample of C_4H_3D, to Professor Kozo Kuchitsu and Mr. Tsutomu Fukuyama of the University of Tokyo, and to Professor Robert F. Curl and Dr. Harold Jones of Rice University, who read through the manuscript and gave important suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3698—3705 (1970)

An ESR Study of an Al_2O_3-MoO_3-CoO Catalyst in a System with H_2 and Thio-β-naphthol

Hisashi UEDA and Naoyuki TODO

Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo

(Received June 3, 1970)

This work was planned in order to determine the reaction mechanism of the catalytic, direct desulfurization of organic sulfur compounds on the surface of Al_2O_3-MoO_3-CoO particles. The experimental method consists of quantitative ESR measurements, by means of which the paramagnetic species on the surface of Al_2O_3, Al_2O_3-MoO_3, and Al_2O_3-MoO_3-CoO in the presence and in the absence of H_2 and thio-β-naphthol were studied. As it is expected that, in an ideal and fast-reacting catalytic reaction system, no reaction intermediate can be found because it will be immediately converted to the final product, several artificial reaction systems were investigated in which either one of the reactants, catalyst components, or reaction conditions (*e. g.*, temperature) was deficient. In such deficient systems, the reaction cycle is cut off and some intermediates are expected to accumulate. The paramagnetic species observed were Co^{3+}, Mo^{5+}, thio-β-naphthol$^+$–O^{*2-} or RS^+H–O^{*2-}, and some species formed on the surface of Al_2O_3, in the temperature region of 20°C—200°C. Mo^{6+} is concluded to be the electron trap to facilitate the formation of RS^+H–O^{*2-}, Co^{3+} is concluded to oxidize the Mo^{5+} thus formed to Mo^{6+}, and Co^{2+} is concluded to reduce the R–S^+H_2–O^{*2-} species. The latter then decomposes to H_2S and R·.

The catalytic desulfurization of organic sulfur compounds contained in residual oil using an Al_2O_3-MoO_3-CoO catalyst (to be abbreviated as "AMC catalyst") has been considered to be one of the most promising techniques for lessening the atmospheric pollution. Though several works have been done on the mechanism of the catalysis,[1-4] most of the results obtained are not conclusive. There has been, for example, no clear-cut explanation of the role of each component of the catalyst. One of the present authors previously obtained some information on the nature of the paramagnetic species formed on the surface of various oxides by the ESR method;[5] he found that the results obtained in that work would be useful in analysing the desulfurization reaction with an AMC catalyst.

As organic compounds are processed with the catalyst, the organic reaction intermediates as well as the inorganic reaction intermediates must be determined. Since it is said that a considerable portion of the sulfur compounds in petroleum are

in the form of thiophenols and thioethers,[6] thio-β-naphthol (to be abbreviated as "TN") was chosen as the model compound to be added to the catalyst. The analysis of the catalytic reaction system consisting of TN, H_2, and the AMC catalyst has been carried out in the present work by a procedure based upon the results obtained in the previous paper.

The actual desulfurization reaction currently being engineered is at 400°C and at a hydrogen pressure of 200 atm. Industrial operation demands such conditions in order to get a reasonably fast reaction rate, thus securing a quick processing of the oil, mainly for economic reasons. In the present work, however, as the first and easiest possible approach to observe the actual reaction intermediates of the desulfurization reaction, a hydrogen pressure of lower than 1 atm and the highest observation temperature attainable with the attachment to our ESR equipment, 210°C, were used.

Experimental

The oxides and mixed oxides used in this study were all in the form of fine powder. Two different γ-alumina were used. One of them was prepared from aluminum isopropoxide (to be abbreviated as "Ai"), while the other was commercially-available (Shokubai Kasei Co., to be referred to as "Ac"). Al_2O_3-MoO_3 (the content of the latter being 5.44%; to be abbreviated as "AM") was prepared by precipitating ammonium molybdate on the surface of Ac, which was then oxidized in air. The AMC catalyst, consisting 91.38% of Al_2O_3, 5.44% of MoO_3, and 3.18% of CoO, was prepared by precipitating cobalt nitrate on the surface of AM, which was then oxidized in air. All of them were calcined at 500°C for one hour prior to use. The thio-β-naphthol was used after recrystallization. The H_2 used was 99.999% pure (Takachiho Co.) and was used at a pressure above 430 mmHg and at 20°C. Measurements of the ESR were made in the same way as in the previous paper,[5] except for the temperature of the measurements, which were here carried out in the temperature region between 20°C and 200°C. As quantitative ESR measurements are an essential part of this work, particular care had to be taken with them. Quartz tubes which gave almost no ESR signal in the D.C. magnetic field region of 300—5000 gauss and at *x*-band microwave frequencies, and which had almost identical dimensions, were used. As has been reported by Setaka *et al.*,[7] non-resonant microwave absorption by the specimen can affect the magnitude of the output of the microwave detector, which is due to the resonance absorption, even when the input power to the specimen is kept always constant. In the present specimens, all the samples have almost identical non-resonant absorptions, since all of them consist mostly of alumina (more than 90%). The resonant absorption is mostly due to the minor part of the sample components (less than 10%) existing on the surface. Therefore, the consideration of the non-resonant microwave absorption has been almost unnecessary in the present measurements. However, each of the intensities observed in the present work was calibrated by using the intensity of one of the lines from a Mn^{2+} (g=2.1401) sample which was placed inside the cavity, but not inside the sample section, which is inside a Dewar system. As this absorption line has a ralatively narrow line width compared to those of the absorption lines observed from the present specimens, a relatively slow sweeping rate of the magnetic field (0.16 gauss/sec) was necessary in order to record the intensity of this line accurately. The temperature variation of the sample also changes the non-resonant absorption of microwave. This, however, was the same value at 20°C and at 200°C under the present measuring conditions. The warming up of the 100 kHz lock-in amplifier was necessary to get a constant and stable amplification of the signal.

Results

As it is extremely difficult to measure ESR absorption under conditions identical with those actually employed in an engineering desulfurization reaction, it might be wise to start the research by examining the catalyst by conventional measurements. As will be discussed later, the quality of information obtained by conventional (meaning, at room temperature, and either in a vacuum or in atmospheric air) measurements are not as straightforward as might be expected. Figures 1a—1c illustrate the effects of the temperature of measurements, t_m, on the ESR intensities. In Fig. 1a, the intensity of the ESR line with g=1.9328 (for Mo^{5+}) of the sample consisting of AM and TN in a vacuum is shown. The sample which had not been subjected to any

thermal treatment before was measured at 20°C (point A_1), and then the t_m was elevated to as high as to 210°C (point A_2), after which the t_m was decreased to as much as to 20°C (point A_3). The A_3' point shows the value which is expected from the value for A_2 point by Curie's law. Figure 1b indicates the temperature variation in the intensity of the ESR line with $g=2.0036$ (for $TN^{+}-O^{*2-}$), for the specimen identical with that for Fig. 1a during one heating cycle. The B_1, B_2, B_3, and B_3' points correspond to A_1—A_3' in Fig. 1a. Figure 1c indicates the same quantity as does Fig. 1b for the specimen consisting of AMC, TN, and H_2. The C_1, C_2, C_3, and C_3' correspond to A_1—A_3' in Fig. 1a. These results indicate that the thermal history of the specimen, as well as the t_m value, strongly affects the concentration of these species on the surfaces of catalyst particles. In Fig. 2, the ESR spectra of

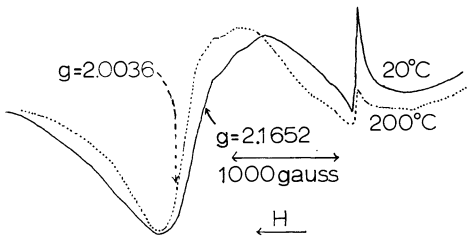

Fig. 2. ESR spectra of γ-alumina prepared from aluminum isopropoxide. Measurements were made at 20°C and at 200°C. Sample in vacuum.

alumina powder, Ai, are shown. The figure indicates that some unexplained paramagnetic species exist on the surface of the alumina specimen, which was supposed to be highly pure except for a small amount of organic contamination left when it was prepared from aluminum isopropoxide by decomposition. It is also shown that some new paramagnetic species are formed at higher temperatures, and that these species disappear when cooled to 20°C again. In Fig. 3, the ESR spectra of AM powder are shown. It will be seen that a new absorption appears at $g=2.1$ if the sample is observed at 200°C. In Fig. 4 the ESR spectra of AMC powder at 20°C are shown. In the spectra the broad absorption

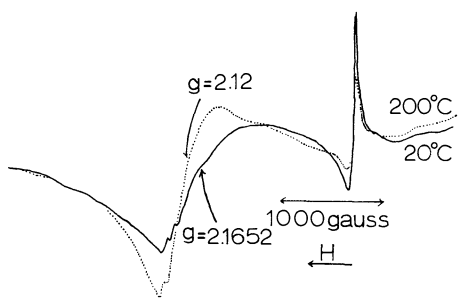

Fig. 3. ESR spectra of Al_2O_3-MoO_3. Measurements identical to Fig. 2.

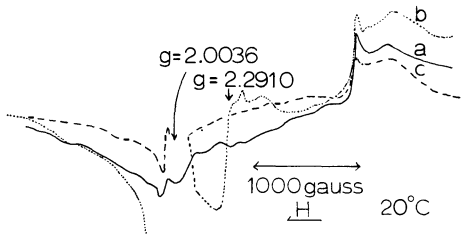

Fig. 4. ESR spectra of Al_2O_3-MoO_3-CoO with and without thio-β-naphthol at 20°C. a, with neither thionaphthol nor H_2. b, with thionaphtol and in vacuum. c, with thionaphthol in H_2.

with $g=2.1$—2.2 which was found in Ai and AM at 20°C, is not found at all, or it is relatively very weak. In Fig. 4b and 4c, the part of the spectra where the absorption of $R^{+}O^{*2-}$ is to be seen is not shown because the absorption in these parts is too strong to be shown together with the entire spectrum. It will be seen that the absorption with $g=2.2910$ appears if TN is added to the AMC powder in a vacuum, and that this species disappears when H_2 is introduced into the sample tube. In Fig. 5, the

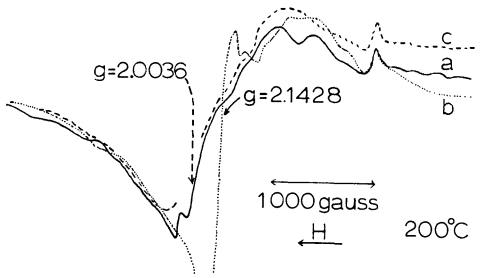

Fig. 5. ESR spectra of Al_2O_3-MoO_3-CoO with and without thio-β-naphthol at 200°C. a, b, and c are corresponding to those in Fig. 4.

ESR spectra of AMC powder at 200°C are shown. a, b, and c correspond to those values in Fig. 4. The broad absorption with $g=2.1$—2.2, which was found in Fig. 2 and Fig. 3, but which was not found in Fig. 4, again appears in this figure. The absorption with $g=2.2910$, previously found only in Fig. 4b, is again found in Fig. 5b with a somehow decreased g-factor of 2.1428. The temperature dependence of the g-factor for this line is shown in Fig. 6. In Fig. 7, the effects of N_2O and NH_3 on the intensities of the line, the g-factor of which is shown in Fig. 6, are shown. The solid curves indicate those in N_2O, while the dotted curves indicate those in NH_3. It will be seen that N_2O intensifies this line at higher temperatures, while NH_3 cancels it. The amplitudes of the curves have been calibrated with one of the Mn^{2+} absorption lines. In Tables 1—4, the relative ESR intensities of the lines with $g=$ 2.0036 and $g=1.9328$, observed with the catalyst components of x, y, and z at 20°C and at 200°C, are shown. The relative intensities for the line with

temperature-dependent g-factor have not been listed in the tables because of the irregular and temperature-dependent line shape.

Discussion

In the previous paper it was concluded that the species giving rise to the ESR absorption with $g=2.002$—2.004 was most properly written as R^+O^{*2-}, where R signifies the additive with a π-electron orbital and where O^{*2-} signifies some active surface oxygen anion at which the chemisorption of R takes place. The species for the ESR line with $g=1.9328$ has been concluded to be Mo^{5+}. The species for the ESR line, with a temperature-dependent g-factor as is shown in Fig. 6, has appeared in this study for the first time. It is most likely described to be Co^{3+} for the following reasons: (a) It is observed only in the specimen which has CoO as an oxide component. The unpaired electron may, therefore, be supposed to belong to the cobalt atom. (b) It is observed only when TN is added to the AMC powder. As TN forms TN^+–O^{*2-}, it may be concluded that the unknown species is a product of this reaction: $Co^{2+}+TN^+-O^{*2-}\rightarrow Co^{3+}+TN-O^{*2-}$. (c) It disappears if H_2 is introduced. (d) It disappears if NH_3 is introduced and the specimen is heated to above 100°C, but it is intensified if N_2O is added and the specimen is heated at above 100°C, as is shown in Fig. 7. As has previously been shown by one of the present authors,[5,8] NH_3 destroys a hole or an oxidized state, while N_2O eats a captured or solvated electron or an anion. The reactivity of this unknown species, as has been indicated above, is just like a hole. A hole formed in Co^{2+} should be a Co^{3+}. It can not be a free Co^{3+}; it would more properly be shown as $(Co-O_n)^{-(2n-3)}$ and so on, but in the present work the covalent bonds or molecular orbitals among the surface ions are neglected or are not discussed. For this reason, the "hole" found in some species which include at least a Co^{2+} ion is conveniently written as Co^{3+} in this paper. Therefore, it must be noted that the Co^{3+} postulated in this paper has not been obtained by the analysis of a single crystal spectrum, but has been concluded from the reactivity only; therefore, it must not be understood as having validity beyond the fact that it is a convenient nomenclature for a hole in a Co^{2+}. However, the fact that a surface species cannot be studied with a single crystal, or in an oriented state, and the fact that these surface species exhibit considerable anisotropy in their ESR spectra, both lead to the conclusion that an exact determination of the structures of these surface species by an analysis of the ESR spectra is impossible; therefore, the method employed in this report, reaching a conclusion after examining the reactivities of the species under investigation, is the only possible way to proceed.

Co^{3+}, $(3d)^6$, in an octahedral crystal field can be either paramagnetic or diamagnetic, depending on

8) H. Ueda, This Bulletin, **41**, 2578 (1968).

the strength of the field.[9,10] In the present AMC specimen, "Co^{3+}" must be formed from the Co^{2+} which is deposited on the surface of an Al_2O_3 particle, together with MoO_3; therefore, the crystal field surrounding "Co^{3+}" will not be a strong octahedral field, and will probably be of a C_{4v} or of C_{4d} symmetry. For this reason, paramagnetism can well be expected from the "Co^{3+}" in the present specimen. The temperature dependence of the g-factor in Fig. 6 would indicate a labile crystal field around this species; therefore, it is good evidence for rejecting the existence of a strong octahedral crystal field surrounding "Co^{3+}". A g-factor larger than 2.0 is to be expected from the $(3d)^6$ configuration. Generally speaking, the ESR spectrum from a d^6 ion in a symmetric crystal field is broadened or easily saturated, and is observed only at low temperatures and with a low microwave power. Only a few spectra, *e.g.*, that of Fe^{2+}, has been recorded. However, the effect of an asymmetric crystal field, such as that on a surface, on the ESR spectra of d^n metal ions has not been explored much; therefore, the experimental results obtained for "the ions in a symmetric crystal field or in a bulk state" are not always useful for analysing the spectra on the basis of the species on a surface.

It seems that cobalt affects the nature of the catalyst surface greatly. Evidence for this is the spectra in Fig. 4. The ESR absorption found in Fig. 2 and Fig. 3, which is due to some species on the alumina surface, has been almost totally cancelled by cobalt ions. The chemisorption of TN is greatly enhanced by cobalt ions. The datum No. 5, when compared to No. 3 in Table 1, shows that the ESR intensity at 20°C due to TN^+–O^{2-} is increased 15 times if cobalt ions are added to the surface of AM. These tendencies are not observed at 200°C; see the data No. 11 and No. 9, in Table 2, and B_1 and C_1 in the b and c of Fig. 1. These facts indicate that the cobalt ions are located on the catalyst surface so as to make it easy for foreign ligands to coordinate with them or to escape from them.

In the previous paper it has been established that Mo^{6+} ions act as electron acceptors on the surface, themselves being reduced to Mo^{5+}. By definition, the word "catalyst" signifies that, though it promotes a chemical reaction, there can be no overall change in the amount and structure of the catalyst itself during and after the reaction, if the circumstances are ideal. If so, it is quite hopeless to observe any reaction intermediate, at least on the side of the catalyst, if the catalytic reaction is proceeding in an ideal manner, except in a case where the catalyst itself is the intermediate. The accumulation of the intermediate is, then, to be expected only when some of the reaction components or some of the reaction conditions are lacking. The intensity of the ESR absorption is determined by the following formula:

$$\text{ESR intensity of a sample} = (x, y, z \text{ R and G})_{g,\, t_m}$$

if we ignore the history of the specimen. In this formula, x, y, and z are the oxide components (see Tables 1 to 4), R is an added compound such as TN, G is the gas added to the sample tube, and g is the g-factor of the line being measured. A sample have many absorption lines with varied g-factors and with different intensities. The effect of one of the variables, say, z_0, can be judged by comparing $(x, y, z=z_0, \text{R and G})_{g,\, t_m}$ with $(x, y, z=\text{O, R and G})_{g,\, t_m}$. For example, the datum No. 26 in Table 3 is for $x=91.38\%$ Al_2O_3, $y=5.44\%$ MoO_3, $z=3.18\%$ CoO, R=TN at the concentration of 0.2 mM/g of oxide, G=H_2 at 450 mmHg/20°C, $g=1.9328$ (the absorption by Mo^{5+}), and $t_m=200$°C, while the datum No. 23 is for the variables almost identical with those for the datum No. 26 except that no CoO was added to the system (accordingly, the value of $x=94.54\%$); in other words, $z=0$. The ratio of these two data, 6400/13349=0.48, can be accepted as indicating that Co^{2+} reduces the amount of Mo^{5+} at 200°C in the presence of H_2.

By similar arguments, it is possible to write the reaction cycle shown in Fig. 8. The equilibrium between charged species on the surface of oxide particles has been discussed in previous papers.[5,11] The process (1) in Fig. 8 has already been used to describe how "Mo^{6+} behaves as an electron trap in the formation of R^+O^{*2-} from RO^{*2-}." The process (2) is the reduction of Mo^{6+} by H_2, which is confirmed by comparing the datum No. 23, Table 4, with the datum No. 22. The process (3) can, in other words, be written as $Mo^{5+}+Co^{3+}\rightarrow Co^{2+}+Mo^{6+}$. Comparisons of the datum No. 25 with the datum No. 22, Table 4, and especially No. 19 with No. 15, Table 3, and No. 20 with No. 16, indicate that added cobalt oxide reduces the amount of Mo^{5+}. Such an effect of cobalt oxide can be explained only by the action of the Co^{3+} formed. Co^{3+} was observed only when TN was added in the absence of H_2 (see Fig. 4 and Fig. 5). Without H_2, the $H_2+Co^{3+}\rightarrow H^+ + H + Co^{2+}$ process does not occur, and so an observable amount of Co^{3+} is accumulated. It is also possible that, in a vacuum, the $Mo^{6+}+Co^{2+}\rightarrow Mo^{5+}+Co^{3+}$ equilibrium moves to the right, No. 25 and No. 26. The overall flow of electrons by the processes (1) and (3) can be seen in Table 1 and Table 3. The AM–TN system in a vacuum give the ESR intensity of 1500 at 20°C and for $g=2.0036$, the datum No. 3, which is increased to 22500 by the addition of cobalt to the above system, the datum No. 5. On the contrary, the AM–TN

system in a vacuum gives the ESR intensity of 9000 at 20°C and for $g=1.9328$, the datum No. 15, which is decreased to 570 by the addition of cobalt to the above system, the datum No. 19. The fact that, at lower temperatures, where the reactions of cobalt ions with H_2 and $RS^+O^{*2-}H$ are relatively slower, cobalt ions decrease the amount of Mo^{5+} and simultaneously increase the amount of TN^+–O^{*2-}, fits very well with the scheme. Though the electron-transfer reaction (5) can be postulated for the reason stated above, the products of the reaction (6) cannot be determined by the present results. As the species RS^+H–O^{*2-} has an unpaired electron, it is very likely that it will react with a hydrogen atom to yield RS^+H_2–O^{*2-}, which is then neutralized by the step (5) and decomposes to H_2S and R·. The R·, which may be $C_{10}H_7$· in the present case, will subsequently react with H_2 and/or with another R· to form some hydrocarbons.

The vast difference between the present conditions of ESR measurements, 200°C and 0.6 atm pressure of H_2, and the engineering conditions of the desulfurization reaction, 400°C and a 200 atm pressure of H_2, would lead one to suspect the suitability of the present ESR experiments for analyzing the reaction scheme in the engineering desulfurization. However, there is actually no reason to conclude that the reactions occurring under these two sets of conditions are contrary in nature, though the rates of reaction are enormously different. The present authors are planning to fill this gap by further studying this subject; the effect of the pre-treatments with H_2 and H_2S on ESR spectra is particularly interested.

In the engineering desulfurization, the oxide is pre-sulfurized. The actual desulfurization is, therefore, carried out by the sulfide catalyst. As the present ESR measurements are made with oxide powders, this difference must be considered. Since oxygen and sulfur belong to the same group in the periodic table of elements, the VIb group, and since both have the same number of *p*-electrons in the outermost shell, the species R^+O^{*2-} should have its sulfide version, R^+S^{*2-}, on the sulfide particles. Therefore, it is not likely that the difference between S^{2-} and O^{2-} essentially alters the reaction scheme on the surface of these particles. The fact, that, in the engineering operation, the pre-sulfurization is made with H_2 and the residual oil diluted with kerosene shows that desulfurization is actually going on with the oxide catalyst.

It may often happen that an intermediate or an intermediate-like species which is detected only after a lot of time and labor proves to be not the essential component of the reaction system under investigation, but one of the by-product of the reaction. The reaction cycle found, Fig. 8, might be one such off-route phenomenon. The first step of the reaction, the formation of the cation-like species, might be untrue; instead the formation of

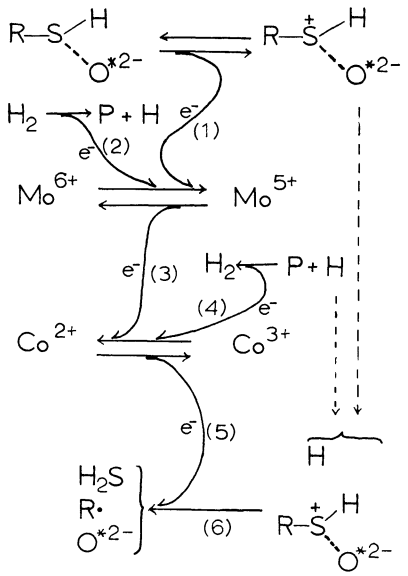

Fig. 8. The catalysis cycle of the desulfurization reaction of thio-β-naphthol with H_2 on the Al_2O_3-MoO_3-CoO catalyst particles. R signifies $C_{10}H_7$– group. S-O*2- signifies the chemisorbed state. About O*2-, see text and Ref. (5). P signifies a proton.

an anion might be the real first step. The discussion in the previous paper led to the conclusion that the formation of an anion is not likely on an oxide surface. The evidence of the succeding steps has already been discussed.

Another species which it might be necessary to consider as a component in the desulfurization cycle shown is Mo^{4+}. As Mo has the electronic configuration of (Krypton shell)$(4d)^5(5s)^1$, it can have four oxidation states, 3+, 4+, 5+, and 6+. Actually, MoS_2 is accumulated on the catalyst surface during desulfurization. Therefore, Mo^{5+}–Mo^{4+} might play some important role in the desulfurization cycle instead of Mo^{6+}–Mo^{5+}. The Mo^{4+} ion is paramagnetic in an octahedral crystal field, and it may or may not have paramagnetism in a field of lower symmetry.[10] In the present work, no ESR evidence for Mo^{4+} was found. This fact indicates that either the absence of the Mo^{4+} ions or the presence of the crystal field surrounding the Mo^{4+} ion, which makes the Mo^{4+} ion diamagnetic. However, the conclusions in the previous paper indicated the importance of Mo^{6+} as an electron trap on the surface of oxides. For this reason, it is unlikely that Mo^{4+} is an essential component of the catalysis cycle. If this is true, then it follows that the deactivation of the catalyst is due to the accumulation of Mo^{4+} on the catalyst surface.

Among the ingredients of the catalyst, the most important ingredient is alumina. The activity and the life of a catalyst is actually decided with it. In the reaction scheme (Fig. 8), this important role of

alumina appears in the form of O^{*2-}, indicating the active oxygen anion where the chemisorption occurs. The difference between a good alumina and a bad one lies not in the quality of their properties, but in the quantity of their properties; some quantitative measurement of the ESR absorption by the alumina surface might, therefore, be helpful in explaining the difference between good and bad carriers.

The authors thank Dr. K. Muramatsu for his cooperation in the preparation of the mixed-oxide catalysts. They also thank Dr. Y. Kotera for his encouragement in this work.

Phosphorus Nuclear Magnetic Resonance in Polyphosphates and Determination of Their Hydrolysis Rate Constants

Makoto KAWABE, Osamu OHASHI and Ichiro YAMAGUCHI

Department of Chemistry, Faculty of Science and Engineering, Sophia University, Tokyo

(Received June 4, 1970)

The phosphorus nuclear magnetic resonance spectra of several condensed phosphates (polyphosphates) were measured in aqueous solutions. The NMR spectra generally consist of three peaks which correspond to the phosphorus atoms at the end and middle of the molecular chain and in orthophosphoric acid which is the final product of the hydrolysis. The chemical shift and, for some phosphates, spin-spin coupling constants were obtained. Both depend on pH of the solution. The chemical shifts for the end and middle phosphorus atoms depend also on the chain length of the molecule. The hydrolysis process of the phosphates can be traced by the observation of the time dependence of spectral line intensities. From this observation the rate constant of the hydrolysis is obtained for several phosphates. The values are comparable with those obtained by other methods.

The chain of –P–O–P– in polyphosphoric acid or polyphosphates molecule has been known to degrade by hydrolysis in aqueous solutions.[1-11] The degradation results in shorter chain molecules and finally in orthophosphoric acid. The rate of the hydrolysis is very slow at ordinary temperature and in neutral aqueous solution. Some of the polyphosphates have long half-life up to several years under such conditions.[8,9]

Phosphorus nuclear magnetic resonance is a useful method for the study of phosphates and related compounds. Several papers on this subject appeared in the past decade.[11-16] The reported studies so far, however, concern with the phosphorus compounds in their "static" state. This work deals with the "dynamical" process of the phosphorus compounds by nuclear magnetic resonance, that is, the hydrolysis process of polyphosphoric acids and polyphosphates.

The slow rate process of hydrolysis of the compounds enables us to study it by observing the

increase or decrease of the intensity of phosphorus nuclear magnetic resonance signals as the hydrolysis process is going on. Rate constants were determined for several compounds from the data of the time dependence of the intensity, and assignment of the signals was made. The chemical shift and, in some cases, the magnitude of the spin-spin coupling constants were obtained.

Experimental

The compounds studied are shown in Table 1, with their structural formulas. Compounds Nos. 1,2,3,7,11 and 12 were commercial products, and Nos. 4,5,6,8,9 and 10 were synthesized.

Samples were dissolved in hydrochloric acid (0.5, 1, 3 and 6N), water, calcium chloride (3N) and sodium hydroxide (0.5, 1 and 12N). Concentration of the compounds was small because of their poor solubility. Saturated solutions (2—3 g in 10 ml) were used in most cases. The pH of solutions was measured with a pH meter.

Some compounds evolve a large amount of heat when dissolved and the temperature of the solutions is 90—110°C immediately after the dissolution. The temperature, however, decreases in several minutes to around 60°C. The effect of the heat evolution was taken into account for the analysis of data.

The NMR spectrometers used were Varian DP-60 and HR-60 operated at 15.1 MHz. The sample tube was 15 mm in outer diameter. The external reference for the chemical shift measurements was 85% orthophosphoric acid sealed in a glass tube 5 mm in outer diameter. The value of the chemical shift with respect to the orthophosphoric acid was determined by the usual sideband method. For the sample with fast rate of hydrolysis, the reference was the signal of orthophosphoric acid produced in the sample itself.

The relative amount of phosphorus atoms with different chemical environments in the course of hydrolysis was determined by measuring the height of the signals. Assignment of the signals to the phosphorus chemical species involved was made according to the fact that the phosphorus NMR signals of polyphosphates are classified into three groups.[11,13] They are signals M,E and O, and are the resonance lines of phosphorus atoms at the middle and end of -P-O-P- chain in a molecule and of the atom in orthophosphoric acid, respectively. In the spectrum, signal M appears at the highest field, signal E next and signal O at the lowest. The behavior of the signal intensity was in line with generally accepted hydrolysis process.[6-10] The spin-spin interaction splitting of the signal also supported the assignment.

Results and Discussion

NMR Spectrum. Polyphosphates in aqueous solution generally give three peaks which can be assigned to signals M (middle), E (end) and O

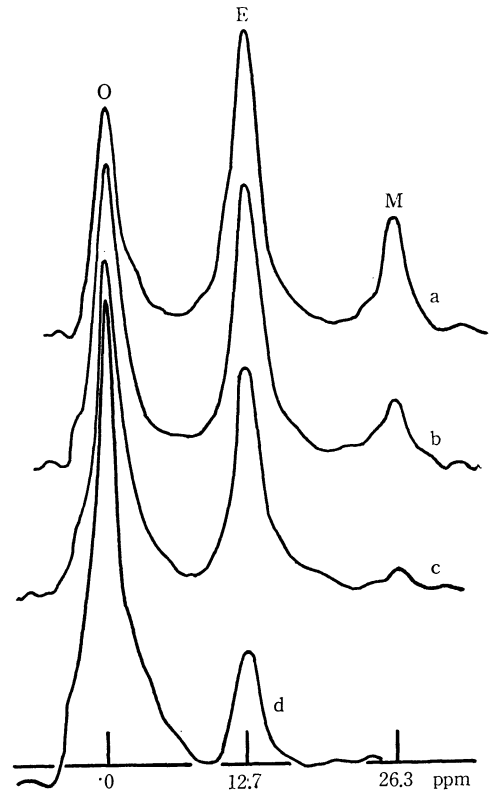

Fig. 1. NMR spectra of polyphosphoric acid in aqueous solution at different times after the dissolution of compounds. Spectra a, b, c and d correspond to 3, 9, 25 and 89 min, respectively.

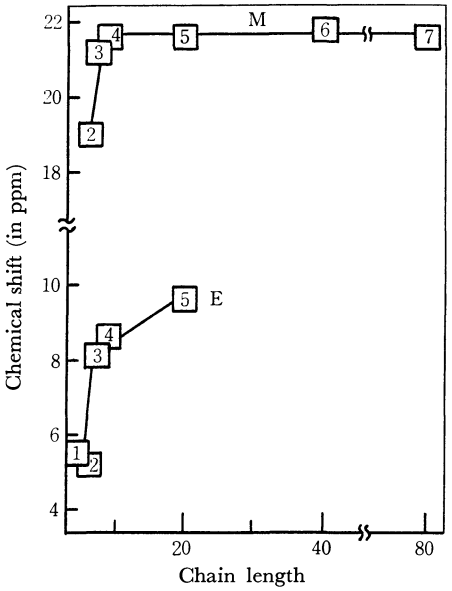

Fig. 2. Chemical shifts of M and E phosphorus atoms of the Na-phosphates with different chain length, refer to the phosphorus resonance in orthophosphoric acid. 1. Na-pyro-; 2. Na-tripoly-; 3. Na-tetrapoly-; 4. Na-hexapoly-; 5. Na-icosapoly; 6. Na-poly- ($\bar{n}$=40), 7. Na-poly- ($\bar{n}$=80), phosphates.

(ortho). A spectrum of polyphosphoric acid in aqueous solution is shown in Fig. 1 as a typical example. The time after dissolution is indicated. The heights of the signals vary with time. Each signal can be assigned unequivocally to M, E or O species. The chemical shifts for these species were measured.

Chemical Shift. The chemical shift of peaks M and E varies with the increase of the chain length of molecule as shown in Fig. 2. (The chemical shift of peak O referring to the external reference seems to be very small and can not be measured due to relatively poor resolution of the spectra.) The chemical shifts of species M and E increase for the compounds of short chain lengths up to n=6, where n is the number of phosphorus atoms in a chain of a molecule. In this range the chemical shift clearly depends on the chain length. However, the shifts for $n>6$ are almost constant. This suggests that in a long chain molecule most phosphorus nuclei are not much affected by their position in the molecule. The phosphorus nucleus at the boundary position between normal E and M species is expected to be sensitive to the change of position in a chain. However, for a long chain molecule the contribution of this kind of species to the whole signal intensity is very small, and its signal seems to lie at the skirt of signal M with very weak intensity and is not observed separately.

The chemical shift for compounds studied also depends on pH of the solution as shown in Fig. 3.

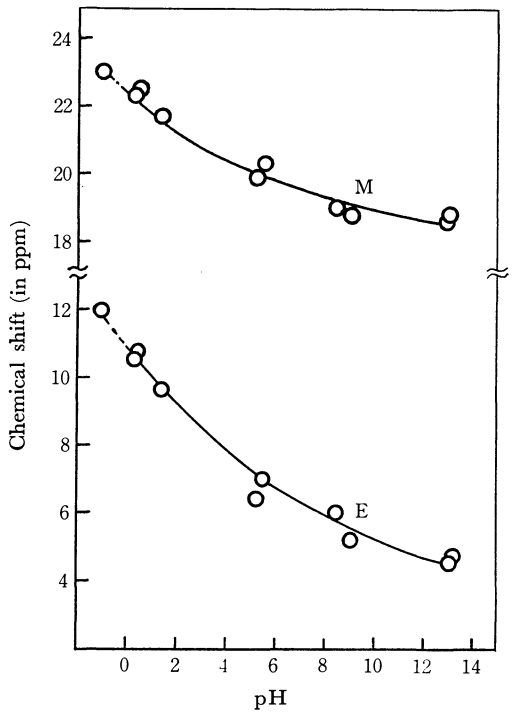

Fig. 3. pH Dependence of the chemical shift of Na-tripolyphosphate.

The signals do not cross (in the chemical shift scale) in the pH range observed. This shows that at any pH unique assignment of the signals can be made in the order of the field strength.

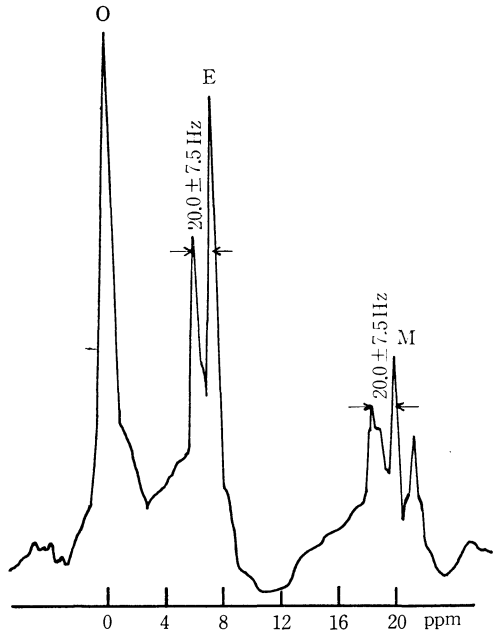

Fig. 4. Phosphorus NMR spectrum of Na-tripolyphosphate in 1N HCl solution.

Spin-spin Coupling. Sodium tripolyphosphate in solutions with pH 5, 9 and 13 gives spectra with splittings due to spin-spin coupling. This is the only case in which the spin-spin interaction splitting was observed. The splitting of the peaks are doublet and triplet as shown in Fig. 4. The magnitude of the splitting is around 20 Hz. This indicates that the coupling is between neighboring phosphorus atoms in the molecular chain.[13-15] The splitting gives a concrete assignment of the signals; the doublet at the low field side is due to species E and the triplet at the high field is due to species M.

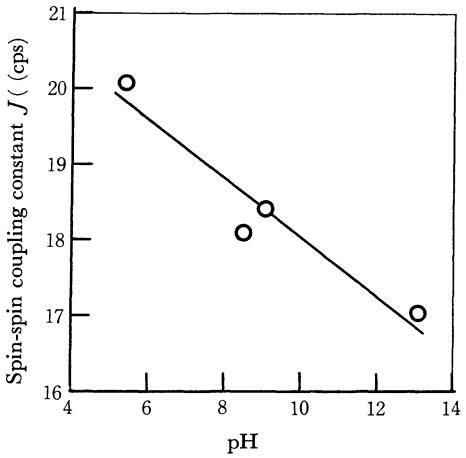

Fig. 5. pH Dependence of the spin-spin coupling constant of Na-tripolyphosphate.

The pH dependence of the coupling constant is evident for this compound as shown in Fig. 5. The coupling constant decreases from 20 to 17 Hz as pH increases from 4 to 13. This is in contrast to that by Crutchfield *et al.*[13]

Analysis of Hydrolysis. The time variation of the NMR signal height is plotted in Figs. 6 and 7. Apparent variations of the spectra are summarized in Table 2.

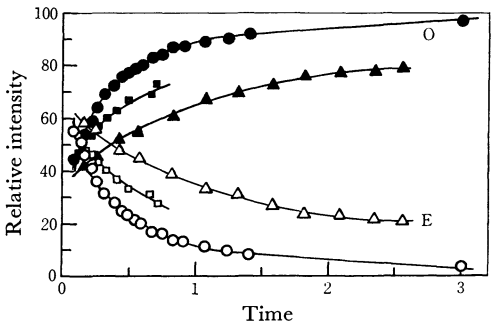

Fig. 6. Variation of the peak height (normalized to 100%) of phosphorus NMR spectral lines for species E and O in pyrophosphate molecules.

Na-Metaphosphate			
6N HCl	2 hr	I.I-D.[d]D.	80%
aq. (pH 5.7)	9 day	almost no	5%

I.: Intensity increasing; D.:Intensity decreasing.
a) disappeared in 15 min.
b) disappeared in 1 hr.
c) reached equilibrium in 1 hr.
d) initially increased then decreased.

Basic assumptions for the treatment of the time dependence of the NMR signal intensity are as follows:

i) Hydrolysis of polyphosphoric acid or polyphosphate produces shorter chain compounds. The final product in the process is orthophosphoric acid.

ii) The phosphorus NMR spectra of original compounds and intermediates of the hydrolysis process consist of three peaks due to species M, E and O.

iii) In the course of hydrolysis, the chain degradation proceeds as a first order reaction process[2-9], and the rate equation is

$$-\frac{d[\text{polyphosphate}]}{dt} = k[\text{polyphosphate}]$$

where k is the first order reaction rate constant.

iv) The peak height of the NMR signal is proportional to the amount of the phosphorus atoms in question.

Three unit degradation processes can be considered:

Process-1; the scission of E and M,

$$\text{-M-E} \longrightarrow \text{-E} + \text{O}.$$

Process-2; the scission of two M's,

$$\text{-M-M-} \longrightarrow \text{-E} + \text{-E}.$$

Process-3; the scission of two E's,

$$\text{E-E} \longrightarrow \text{O} + \text{O}.$$

If the original molecule is a linear chain, the initial numbers of the phosphorus species in a molecule are $(n-2)$ and 2 for M and E respectively, and if the molecule is in a ring form the number is n for M, where n is the number of phosphorus atoms in the original molecule. In the final stage of hydrolysis, the numbers of the species corresponding to one original molecule should be n for O and 0 for M and E when hydrolysis is completed. In principle, the relative amount of each species may be estimated at any intermediate stage of the degradation through processes 1, 2 and 3. For long chain molecules, however, there are many possibilities for the position of the chain scission in the degradation process. It is almost impossible to determine the relative amount of each species without knowing the rate of each degradation process. Thus, significant rate constants are obtained only for relatively simple systems such as pyrophosphate and tripolyphosphate.

Determination of the Rate Constant of Hydrolysis. *Pyrophosphoric Acid.* Pyrophosphoric acid has the simplest structure of the compounds studied. It undergoes hydrolysis to give orthophosphoric acid in one step by Process-3 as follows.

$$\text{P-O-P} \xrightarrow{k_3} 2\text{P}$$

Let us assume a first order reaction for the degradation. Then the rate of the hydrolysis is determined by the equation

$$\frac{dx}{dt} = k_3(a-x), \text{ or } \ln\frac{(a-x_1)}{(a-x_2)} = k_3(t_2-t_1),$$

where a is the initial quantity of the pyrophosphoric acid or the peak height of the NMR signal (species E). Therefore $(a-x_1)$ is the quantity at $t=t_1$ and k_3 is the rate constant (for Process-3).

Figure 8 shows the plot of $\ln[(a-x_1)/(a-x_2)]$ *vs.* (t_2-t_1) for pyrophosphoric acid. The plot gives a fairly straight line for a certain interval of time, and shows that the reaction is almost of the first order in the interval. The plot consists of two parts of straight lines. This is interpreted as follows: Phosphoric acid evolves a large amount of heat when dissolved in water. It is reasonable to consider that the heat accelerates the reaction and gives rise to a steeper slope at the first part of the plot leading to a large rate constant. After the lapse of ten to twenty minutes the temperature is lowered to room temperature, and the hydrolysis retarded. The straight line after a break can be assigned to the hydrolysis process at room temperature. Thus, the rate constant for the hydrolysis at room temperature, k_3, is obtained from the slope after the break point. (k_3' denotes the rate constant for the system immediately after dissolution.)

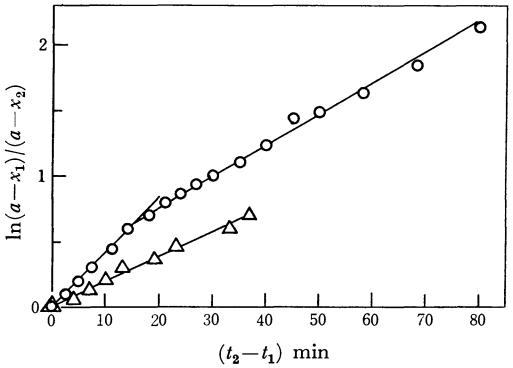

Fig. 8. Plot for the determination of the hydrolysis rate constant of pyrophosphoric acid.
○: 6N HCl solution; △: aqueous solution.

The obtained rate constants are shown in Table 3. The constant depends upon pH and ion concentration of the solution; k_3(6N HCl)$>k_3$(aq. soln.)$>k_3$(3N $CaCl_2$)$>k_3$(6N NaOH). This means that the hydrolysis process is accelerated by the H^+ ion. This is in line with results of several authors.[4-6,8-10] In $CaCl_2$ solution the rate constant is smaller than in aqueous solution. It seems that Ca^{2+} ion as well as pH of this solution affects the hydrolysis rate.[8-10,17]

Sodium Tripolyphosphate. Tripolyphosphate gives a spectrum with three peaks. Peaks M and E decreases their intensity with time, whereas peak O increases. This is shown in Fig. 7. Peak M diminishes in an hour in hydrochloric acid solution. Hydrolysis seems to reach equilibrium two hours after dissolution.

The hydrolysis of tripolyphosphate proceeds in the following pattern.

$$\text{P-O-P-O-P (tripoly-)} \xrightarrow{k_1} \text{P-O-P (pyro-)} + \text{P},$$
$$\xrightarrow{k_3} \text{P}.$$

The rate equations are as follows.

$$dx/dt = -k_1x \text{ or } x_2 = x_1\exp[-k_1(t_2-t_1)],$$

and $$dy/dt = -k_3y + k_1x \text{ or}$$

17) W. Wieker and E. Thilo, *Z. Anorg. Allg. Chem.*, **306**, 48 (1960).

$$y_2 = \frac{k_1 x_1}{k_1 - k_2}\{\exp[-k_3(t_2-t_1)] - \exp[-k_1(t_2-t_1)]\},$$

where x is the concentration of polyphosphate and y pyrophosphate, and their values are given by the peak heights as M and E−2M, respectively. The obtained results for the hydrochloric acid solution were $k_1=1.7\times10^{-2}$ min^{-1} and $k_3=0.8\times10^{-2}$ min^{-1}, and $k_1>k_3$. This relation of magnitudes of k's means that the amount of the primary product, pyrophosphate, in the solution increases at first because of slow rate of the second step degradation.

In aqueous solution of sodium tripolyphosphate, hydrolysis is very slow and the rate constant could not be determined although the observation was carried out for 24 hr. Hydrolysis is considerably slowed down in a solution with high pH value.

Polyphosphoric Acid. Both the structure of this compound and the mechanism of hydrolysis are not clear. It is difficult to determine the rate constant for the whole hydrolysis process. However, acceleration of the reaction due to the existence of H^+ ion is evident from comparison of the variation of the peak intensity for 6N HCl and aqueous solutions. Peak M disappeared within ten to several tens of minutes.

After the disappearence of peak M, only peak E can be traced. Analysis of the intensity of peak E for 6N HCl solution gives the rate constants $k_3'=5.36\times10^{-2}$ min^{-1} and $k_3=1.04\times10^{-2}$ min^{-1}. For aqueous solution there was no remarkable heat evolution and the rate constant $k_3=9.80\times10^{-3}$ min^{-1} was obtained. The values also show acceleration of the hydrolysis by H^+ ion.

Other Phosphates and Phosphoric Acids. Sodium metaphosphate and sodium pyrophosphate undergo hydrolysis in aqueous solution very slowly, but in 6N HCl solution they change to orthophosphoric acid in a day. It is concluded that the H^+ ion accelerates hydrolysis for the compounds studies.

The rate constants are summarized in Table 3. They are compared with those obtained by methods other than NMR.[1,7,9,18]

Table 3. Hydrolysis reaction rate constants (in min^{-1})

Compound	Solution	Rate constant
Pyrophosphoric acid	6N HCl	$k_3'=4.39\times10^{-2}$
		$k_3=2.50\times10^{-2}$
	aq.	$k_3=1.18\times10^{-2}$
	3N $CaCl_2$	$k_3'=9.80\times10^{-3}$
		$k_3=3.68\times10^{-3}$
	6N NaOH	$k_3'=1.65\times10^{-3}$
		$k_3=1.74\times10^{-4}$
Na-Tripolyphosphate	6N HCl	$k_1=1.7\times10^{-2}$
		$k_3=0.8\times10^{-2}$
Polyphosphoric acid	6N HCl	$k_3'=5.36\times10^{-2}$
		$k_3=1.04\times10^{-2}$
	aq.	$k_3=9.80\times10^{-3}$

k_1 : 1-st order rate constant for Process-1 at room temperature.
k_3 : 1-st order rate constant for Process-3 at room temperature.
k_3': 1-st order rate constant for Process-3 at the temperature of solution immediately after dissolution.

Conclusion

The chemical shifts of phosphorus NMR observed for polyphosphates appear to change with the chain length (so far it is short), the pH as well as the cation of the solution. The spin-spin coupling constant between phosphorus nuclei also depends on the pH of the solution.

The hydrolysis process of various kinds of phosphates was studied by NMR. The NMR gives clear information on the hydrolysis process from the observation of the signal intensities for the phosphorus species in molecules. For simple systems, this information gives the concentration of various molecular species in the course of the hydrolysis.

Analysis of the hydrolysis process with the intensity variation of the NMR signal is relatively simple when the structure of the molecule is known. The obtained values of the rate constant for the hydrolysis can be compared with those obtained by various methods other than NMR and thus the NMR method appears to be very useful.

The authors are greatly indebted to Professor M. Amagasa for the gift of samples. They also wish to thank Dr. O. Yamamoto, Government Research Institute; and Mr. N. Hayakawa, Japan Atomic Energy Research Institute, for use of their NMR instruments.

The Radiolysis of Liquid Nitrogen Containing Hydrocarbons. II. Acetonitrile Formation from the Solution of Ethylene

Takefumi Oka and Shin Sato

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 4, 1970)

The ^{60}Co γ-radiolysis of liquid nitrogen containing ethylene has been reinvestigated in order to elucidate the mechanism of the formation of nitrogenous products. When the conversion of ethylene was 10%, the G-values of hydrogen cyanide and acetonitrile were 0.21 ± 0.03 and 0.05 ± 0.01 respectively. The isotopic distributions in acetonitrile, *n*-butane, and acetylene were examined by using an equimolar mixture of C_2H_4 and C_2D_4 as the solute. From the analysis of these distributions, it has been concluded that acetonitrile is produced mainly from the reaction between nitrogen atoms and ethyl radicals.

Recently we have reported on our study of the radiolysis of liquid nitrogen containing small amounts of ethylene and propylene.[1] In the case of propylene, the only nitrogenous product observed was acetonitrile, most of which could be explained as resulting from the reaction between nitrogen atoms and propylene molecules. In the system of ethylene, however, the mechanism of the formation of the nitrogenous products, hydrogen cyanide and acetonitrile, could not be ascertained in the previous experiment. We have, therefore, reinvestigated the liquid nitrogen-ethylene system more thoroughly and have now been able to elucidate the mechanism of the formation of acetonitrile in some detail.

Experimental

Nitrogen gas of a high purity was purchased from the Nippon Sanso Co. Fully-deuterated ethylene C_2D_4 was synthesized from C_2D_2,[2] which had been synthesized from CaC_2 and D_2O. The nitric oxide, carbonyl sulfide, and ordinary ethylene were purchased from the Takachiho Chemical Industrial Co.

The samples were prepared and irradiated in the same manner as has been previously described.[1] For the determination of isotopic species, a mass-spectrometric analysis was made at a voltage near the appearance potential of the respective parent ions after separating the products with a gas chromatograph (a dioctyl phthalate column for acetonitrile and benzyl ether for acetylene and butane).

The rest of the procedure was similar to that previously described.[1]

Results

To assure the homogeneity of the reaction, the yields of hydrogen cyanide and acetonitrile were measured with various amounts of liquid nitrogen. The results are shown in Fig. 1. Obviously the yields are directly proportional to the amount of liquid nitrogen. This supports the assumption that the reactions take place in the bulk. In order to examine the effect of any impurity in liquid nitrogen, several experiments were carried out by using liquid nitrogen preirradiated in the presence of ethylene, but such treatment did not affect the G-values of the nitrogenous products.

Figure 2 shows the G-values of the main products

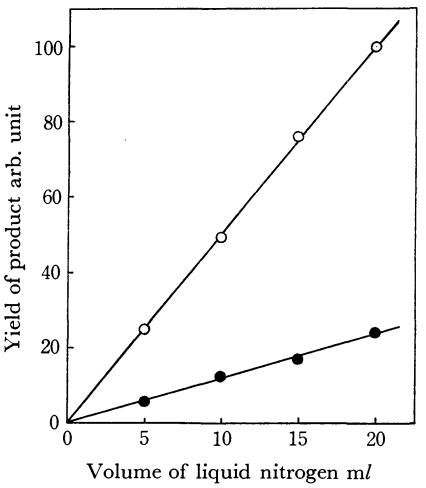

Fig. 1. Relative yields of hydrogen cyanide (○) and acetonitrile (●) as a function of the volume of liquid nitrogen. Ethylene concentration is 4×10^{-4} in mole fraction. Irradiation time is one hour.

2) Y. Hatano, S. Shida and S. Sato, *ibid.*, **41**, 1120 (1968).

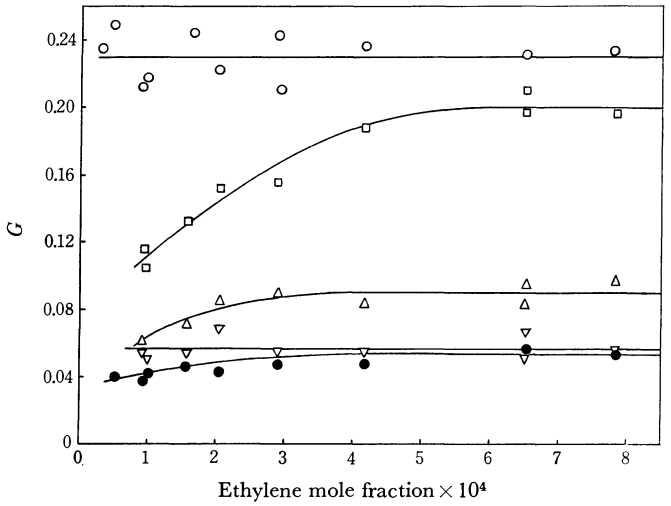

Fig. 2. *G*-values of hydrogen cyanide (○), ethane (□), acetylene × 1/10 (△), propane (▽) and acetonitrile (●) as a function of the concentration of ethylene. Volume of liquid nitrogen is 10 m*l* and irradiation time is one hour.

as a function of the concentration of ethylene. The products other than those shown in Fig. 2 were *n*-butene, 1-butane, and hexenes. A small amount of a paste-like material which may consist of more than two compounds was also formed. A part of it at least was yellow-colored and was soluble in methanol.

The *G*-values of ethane and acetylene decreased with a decrease in the concentration of ethylene. The *G*-value of acetonitrile also decreased slightly at the lower concentration. On the other hand, the *G*-values of hydrogen cyanide and propane were independent of the reactant concentration. The *G*-value of hydrogen cyanide was 0.21 ± 0.03.

In order to check whether the decrease in the *G*-values of ethane and acetylene at lower concentrations of ethylene is due to the high conversion or to the consumption of the primary products by the secondary reactions, the irradiation time dependence of the yields of the products was measured at two concentrations, 1×10^{-4} and 6.5×10^{-4} in mole fraction. The results are shown in Figs. 3, 4, and 5. At lower concentrations, the yields of acetylene, ethane, and propane deviated from a linear relationship at one hour and the reactant

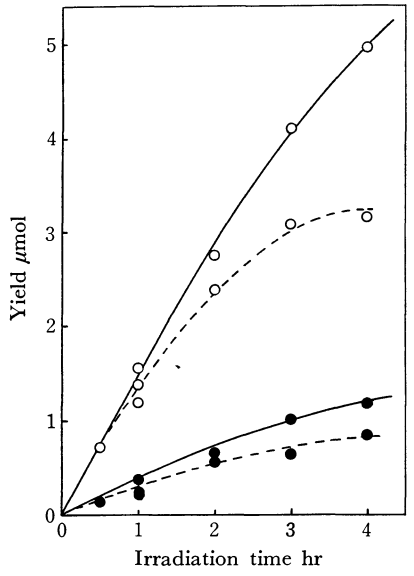

Fig. 3. Irradiation time dependence of the yields of hydrogen cyanide (○) and acetonitrile (●).
——, ethylene concentration is 6.5×10^{-4} in mole fraction.
------, 1.0×10^{-4} in mole fraction.

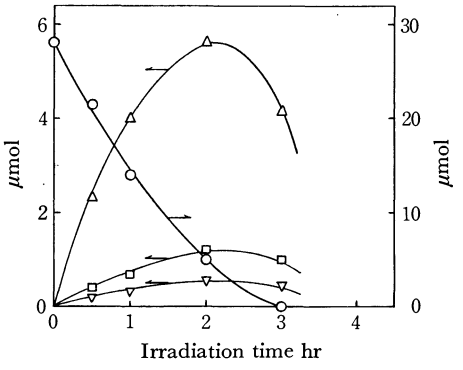

Fig. 4. Irradiation time dependence of the yields of acetylene (△), ethane (□) and propane (▽), and the amount of ethylene recovered (○). Initial ethylene concentration is 1.0×10^{-4} in mole fraction.

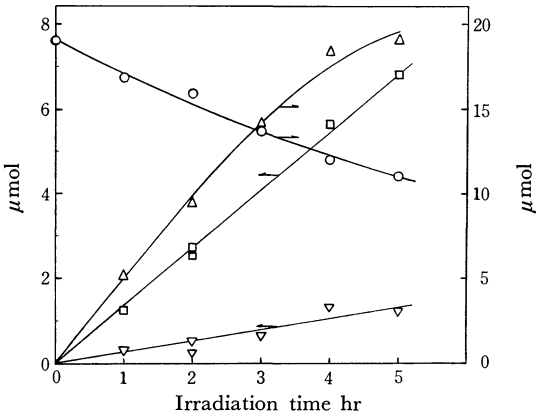

Fig. 5. Irradiation time dependence of the yields of acetylene (△), ethane (□) and propane (▽), and the amount of recovered ethylene × 1/10 (○). Initial ethylene concentration is 6.5×10^{-4} in mole fraction.

ethylene was almost completely consumed in three hours. At higher concentrations, the yields of all the products increased linearly up to about three hours and the conversion of ethylene in one hour was 10%. From these results, it may be concluded that the decrease in the *G*-values of ethane and acetylene at the lower concentrations of ethylene in Fig. 2 is not due to the high conversion.

Tables 1 and 2 show the isotopic distributions of acetonitrile, *n*-butane, and acetylene obtained when an equimolar mixture of C_2H_4 and C_2D_4, and pure C_2D_4 were used as the solutes. The isotopic distribution of hydrogen cyanide could not be obtained, because the H–D exchange reaction took place during the gas-chromatographic analysis. For example, the hydrogen cyanide obtained in Run No. 4 in Table 1 should be DCN, but the mass-spectrometric analysis showed HCN only.

For acetonitrile such an exchange occurred to only a negligible extent, as is shown in Table 1. In spite of the possibility of experimental error, it may be said that the *G*-value of DCN from the C_2D_4 solution is lower than that of HCN from the C_2H_4 solution. The isotopic distributions of *n*-butane and acetylene shown in Table 2 are averages of three measurements. These values will be discussed in detail later.

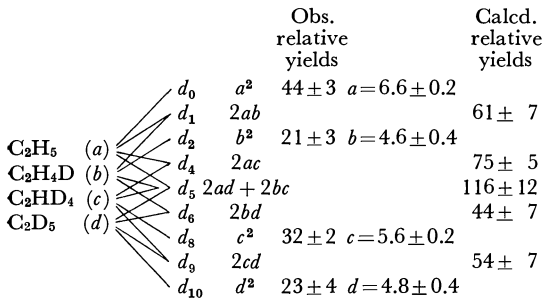
In Table 3, the effects of additives are summarized. Nitric oxide reduced the yields of all hydrocarbons except for acetylene to a large extent, and those of nitrogenous products to a certain extent. Carbonyl sulfide, which is now known as an electron scavenger in the condensed-phase radiolysis,[3] slightly reduced the yields of propane and *n*-butane.

Discussion

In a previous paper,[1] we have tentatively discussed the mechanism of the formation of nitrogenous products in the radiolysis of liquid nitrogen containing ethylene. We there suggested that the reaction between nitrogen atoms and ethyl radicals might be the only source of acetonitrile. Since the *n*-butane obtained in the present system is believed to be formed by the combination reaction of two ethyl radicals,[1] the isotopic distributions of *n*-butane and acetonitrile from solutions containing equimolar mixtures of C_2H_4 and C_2D_4 should have a certain relationship if the acetonitrile is

3) S. Hirokami, S. Shishido and S. Sato, *ibid.*, **43**, 973 (1970).



Scheme 1

produced by the reaction between nitrogen atoms and ethyl radicals.

The ethyl radicals formed by γ-irradiation in liquid nitrogen containing a mixture of C_2H_4 and C_2D_4 may be expected to be of four kinds, shown in the first column in the scheme 1 of calculation. Here, the *a*, *b*, *c*, and *d* in parentheses denote the relative concentrations. The relative amounts of isotopic *n*-butanes formed on the combination of ethyl radicals are those in the fourth column. Butane-d_3 and -d_7 are probably not formed; this is in agreement with the experimental data. Now, let us introduce from Table 2 the experimental values for a^2, b^2, c^2, and d^2; then we can calculate the relative yields of the isotopic ethyl radicals, *a*, *b*, *c*, and *d*. The results are shown in the sixth column. By using these values, we can calculate the relative yields of butane-d_1, -d_4, -d_5, -d_6, and -d_9. The calculated values can then be compared with those shown in Table 2. The agreement is satisfactory.

If acetonitrile is formed by the following reaction; Ethyl radical+N→Acetonitrile+2 Hydrogen atoms (1) the isotopic distribution of acetonitrile can be calculated by using the values for *a*, *b*, *c*, and *d*. However, in this calculation we need another assumption regarding the detachment of two hydrogen atoms in the reaction (1). We have calculated for two types of detachment:

1) Every hydrogen atom in an ethyl radical has an equal probability of detachment. On the basis of this assumption, the relative yields obtained for the isotopic distribution of acetonitrile are as follows:

d_0	d_1	d_2	d_3
100	33±5	40±4	83±11

These values are in good agreement with those shown in Table 1.

2) Two hydrogen atoms at the α position in ethyl radical preferentially detach in the reaction (1). In this case, the calculated results are as follows, far from the experimental data:

d_0	d_1	d_2	d_3
100	70±6	83±3	73±6

However, if a part of the acetonitrile is produced by such reactions as;

$$\text{Ethylene} + \text{N} \longrightarrow \text{Acetonitrile} + \text{Hydrogen atom} \quad (2)$$

and;

$$\text{Vinyl radical} + \text{N} \longrightarrow \text{Acetonitrile} \quad (3)$$

the relative yields of acetonitrile-d_0 and -d_3 will be increased and the isotopic distribution calculated will become consistent with the experimental data. The best-fit distribution was obtained by assuming that 65% of the acetonitrile is produced by the reaction (1) and the rest by the reaction (2) or (3) with the ratio of the isotope effect in the reaction (2) or (3) being 1 : 0.87 for $d_0 : d_3$. The obtained distribution is as follows:

d_0	d_1	d_2	d_3
100	36±3	44±2	80±3

Obviously, even when two α-positioned hydrogen atoms are detached in the reaction (1), it can be concluded the formation of acetonitrile is mainly due to the reaction (1), *i. e.*, the reaction of ethyl radicals and nitrogen atoms.

As is shown in Table 3, nitric oxide efficiently reduces the yields of ethane, propane, and *n*-butane. Since these hydrocarbon products are believed to be formed by the radical reactions, the above result indicated that nitric oxide is a radical scavenger, even at the temperature of liquid nitrogen. In the gas phase, nitric oxide is known as an effective scavenger for nitrogen atoms;[4]

$$\text{N} + \text{NO} \longrightarrow \text{N}_2 + \text{O} \quad (4)$$

The decrease in hydrogen cyanide and acetonitrile by the presence of nitric oxide is probably due to this reaction. However, if acetonitrile is formed solely by the reaction between nitrogen atoms and ethyl radicals, the presence of nitric oxide should reduce the yields of acetonitrile as much as that of *n*-butane, but acetonitrile was observed to the extent of G=0.015 even at the nitric oxide concentration, whereas the formation of *n*-butane was almost completely suppressed. This suggests that a part of the acetonitrile is produced by a process other than the reaction (1). In the preceding section, we have discussed two types of ethyl radical reactions producing acetonitrile; in the first, the hydrogen atom-detachment was indiscriminative, while in the second α-positioned hydrogen atoms were predominant in the detachment. Moreover, in the latter case a part of the acetonitrile formation has to be attributed to a process other than the reaction (1). If this is the reaction (2), the effect of nitric oxide on the formation of acetonitrile can be ex-

4) P. Harteck, R. R. Reeves and G. Mannella, *J. Chem. Phys.*, **29**, 608 (1958).

plained consistently.*1 A similar explanation may serve to explain the effect of nitric oxide on the formation of hydrogen cyanide; this product is formed by two processes, the one containing ethylene as the reactant, and the other containing methyl radicals, which are subject to the radical scavenging of nitric oxide:

$$C_2H_4 + N \longrightarrow HCN + CH_3 \quad (5)$$

$$CH_3 + N \longrightarrow HCN + 2H \quad (6)$$

Although the effect was small, the addition of COS reduced the yields of hydrocarbon products. Since COS is known to be an electron scavenger, even at the temperature of liquid nitrogen,[6] the participation of ionic species in the formation of propane and *n*-butane cannot be completely ruled out. However, the contribution of this type of reaction is obviously minor.

In the study of the argon-sensitized radiolysis of ethylene, Klassen found that $G(C_2H_2) \simeq G(C_2H_6) + G(n\text{-}C_4H_{10})$ and that $G(C_3H_8)$ is much smaller than $G(n\text{-}C_4H_{10})$.[7] The present system is similar to that of Klassen, the only difference being in the solvent, but the relative yields of the hydrocarbon products are quite different. For example, $G(C_2H_6)$ is much larger than $G(n\text{-}C_4H_{10})$ and $G(C_3H_8)$ is nearly equal to $G(n\text{-}C_4H_{10})$. These discrepancies may be explained by the reactions of radicals produced by the reactions (1), (2) and (5); that is, the following reactions become important in the present system:

$$H + C_2H_5 \longrightarrow C_2H_6$$

$$CH_3 + C_2H_5 \longrightarrow C_3H_8$$

$G(C_2H_2)$ is not affected by the presence of nitric oxide. The formation, therefore, can be explained by this reaction;

$$N_2^* + C_2H_4 \longrightarrow N_2 + C_2H_2 + H_2(\text{or } 2H),$$

which has already been discussed.[1]

*1 In the presence of nitric oxide, another source of acetonitrile is possible:[5] $C_2H_5 + NO \rightarrow C_2H_5NO \rightarrow CH_3CN + H_2O$. However, if this reaction should occur, the *G*-value of acetonitrile should be much larger than that observed.

An Infrared Spectroscopic Study of Hydrogen Bonding Interaction. Structural Studies of Proton-donating and -accepting Powers

Tsutomu KAGIYA, Yūzō SUMIDA and Toshihiro TACHI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 19, 1970)

The relationship between the proton-donating and proton-accepting powers and the structures of various proton donors and acceptors was studied in the liquid phase by means of an infrared spectrophotometer. The proton-donating powers of the donors were evaluated by means of the ratios of the O–H shifts of the donors (RO–H) to those of methanol in various proton acceptor solutions. The proton-accepting powers of the acceptors were evaluated by means of the division of the O–H shifts by the proton-donating powers of the donors used. The proton-donating powers increased with the decrease in the pK_a or the ionic RO–H bond dissociation energies and with the increase in the electron affinities of RO radicals, *i. e.*, *t*-butanol$<$methanol$\ll$trimethylsilanol$<$phenol$<$*p*-nitrophenol. In a homologous series, the proton-accepting powers increased with the decrease in the ionization potentials. In the case of the aromatic ethers with two proton accepting sites, two characteristic O–H vibrational bands were observed. The difference in the proton-accepting powers of the vinyl and ethyl compounds with the same substituent was observed, and the π-electron-mobility index, which was considered to be a measure of the energy level of the π-electrons of the vinyl group, was defined and discussed.

Since the hydrogen bond was first recognized, great attention has been paid to the physicochemical behavior of many types of polar compounds.[1] Enormous studies dealing with the intra- and intermolecular hydrogen bond have been made by many researchers from the theoretical and the experimental aspects; they were summarized by Pimentel *et al.*[2,3] However, the main studies in this field have been focused on the physical properties of liquid and crystal states, except for the gaseous adsorption on a solid.[4,5]

In our previous papers,[6–8] we have concluded that the shifts of the O–D or the C=O vibrational bands of monodeuteromethanol as a proton donor, or of acetophenone as a proton acceptor, in various liquid organic compounds can be regarded as a measure of the electron-donating powers, or of the electron-accepting powers, of compounds respectively.

The objective of the present spectroscopic work is to discuss quantitatively the relationship between the proton-donating and proton-accepting powers and the structures or the electronic natures of various proton donors and acceptors. Moreover, on the basis of the experimental results of the proton-accepting powers of the vinyl and ethyl compounds with the same substituent, the π-electron-mobility index, as a measure of the energy level of the π-electrons of the vinyl group, will be defined and discussed.

Experimental

Materials. Methanol, monodeuteromethanol, *t*-butanol, phenol, *p*-nitrophenol, and trimethylsilanol were used as the proton donors. All the compounds but trimethylsilanol were obtained commercially and were purified by distillation or recrystallization. The trimethylsilanol was synthesized by the method of Sommer.[9]

Apparatus and Method. A small quantity (0.03—0.08 mol/*l*) of the proton donor was added to 1.0 m*l* of the proton acceptor in a weighing bottle. After the

bottle had then been shaken for 10 min at room temperature (20±3°C), the mixture was used for the measurement of the infrared spectrum. All the spectral measurements were made in the O–H (or O–D) fundamental region, using a Japan Spectroscopic Co. Model DS-402G or DS-403G infrared spectrophotometer. The thickness of the KBr fixed cell used was 0.010 cm. The dependence of the concentration of the proton donor on the shift of the O–H (or O–D) band was negligible in this concentration range. The experimental error in the measured shifts of the O–H (or O–D) bands was not more than ±1.0 cm^{-1}.

Results and Discussion

Proton-donating Powers and Proton-accepting Powers. The positions of the unassociated hydroxyl fundamental vibrational bands of various proton donors involved in several proton acceptor solutions are summarized in Table 1. According to the definition of the electron-donating powers of compounds presented in a previous paper,[6] the relative differences in the O–H frequency shifts of the proton donors (RO–H) observed in the proton acceptor solutions from that in benzene were calculated:

$$\Delta\nu_{RO-H}(\text{proton acceptor}) = \nu_{RO-H}(\text{benzene}) - \nu_{RO-H}(\text{proton acceptor}) \quad (1)$$

Obviously, the magnitudes of the O–H frequency shifts are due to the relative strengths of the intermolecular interaction between the proton donors and the proton acceptors, *i. e.*, the proton-donating powers and the proton-accepting powers.

In order to evaluate quantitatively the proton-donating powers of proton donors with the use of the definition expressed by Eq. (1), the O–H frequency shifts of the proton donors in several acceptor solutions were plotted against those of methanol in the same solution. As is shown in Fig. 1, linear relations with different slopes were found between them. The slopes are obviously the characteristic values, depending only on the structures of the proton donors, not on those of the proton acceptors.

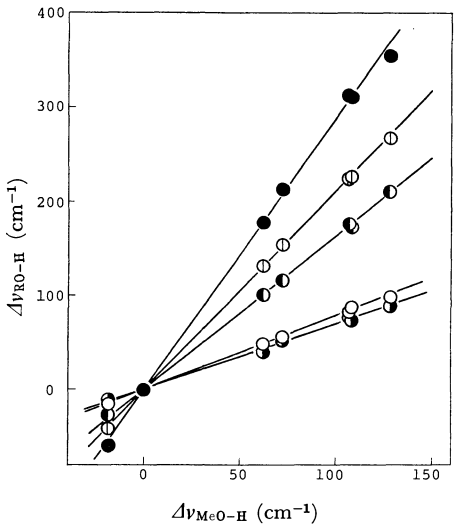

Fig. 1. O–H Frequency shifts of the proton donors in the typical proton acceptor solutions and O–H frequency shifts of methanol in the same solutions.
Proton donor: ◑, Monodeuteromethanol; ○, *t*-Butanol; ◐, Trimethylsilanol; ①, Phenol; ●, *p*-Nitrophenol

Therefore, we believe that the values of the (Φ_D) slopes, which represent the magnitudes of the O–H shifts of the proton donors relative to that of methanol as a standard proton donor, indicate a quantitative measure of the proton-donating powers:

$$\Phi_D = \frac{\Delta\nu_{RO-H}}{\Delta\nu_{MeO-H}} \quad (2)$$

On the basis of the same consideration, we defined the proton-accepting powers of proton acceptors (Φ_A), independent of the kind of proton donors, as the division of the O–H shifts of a certain proton donor in the proton-acceptor solutions by the Φ_D of the proton donor, as follows:

$$\Phi_A = \frac{\Delta\nu_{RO-H}(\text{proton acceptor})}{\Phi_D} \quad (3)$$

TABLE 2. COMPARISON OF PROTON-DONATING POWERS OF PROTON DONORS RO–H WITH RADICAL- AND IONIC-DISSOCIATION ENERGIES OF RO–H BONDS AND ELECTRON AFFINITIES OF RO RADICALS

Proton Donor RO–H	Φ_D	pK_a	D(RO–H) (kcal/mol)	D(RO$^-$–H$^+$)[a] (kcal/mol)	EA(RO)[b] (kcal/mol)
t-Butanol	0.79	19	105	325	56
Methanol	1.00	16	100	315	61
Trimethylsilanol	1.65	11	88[c]	295[c]	69
Phenol	2.13	10	84	290	70
p-Nitrophenol	2.92	7.1	75[c]	276[c]	75
Monodeuteromethanol	0.71	—	102	—	61

a) Values estimated by using $D(RO^-–H^+)=D(RO–H)+IP(H)-EA(RO)$.
b) Values estimated from the pK_a values. See Ref. 11.
c) Approximate values.

It is obvious from this definition (3) that the proton-accepting powers should be equal to the O–H frequency shifts of methanol as a standard proton donor.

Proton-donating Powers and the Structures of Proton Donors. The acid-dissociation constant (pK_a) of the proton donor in an aqueous solution corresponds to the free-energy change of the equilibrium reaction to form the hydrated proton and corresponding anion; therefore, the pK_a is a thermodynamic measure of the proton-donating powers. As Fig. 2 shows, the Φ_D increases with the decrease in the pK_a.[3,10] By using the pK_a values of the proton donors, the Φ_D value and then the O–H frequency shifts can be approximately predicted. The unknown values of pK_a can also be estimated from the frequency shifts.

In Table 2, the dissociation energies, D(RO–H), the ionic-dissociation energies, D(RO$^-$–H$^+$), of the RO–H bonds of the proton donors, and the electron affinities, EA(RO), of the RO radicals are listed. A correlation between the Φ_D and the ionic-dissociation energies of the RO–H bonds is illustrated in Fig. 3; the Φ_D becomes larger as the ionic-dissociation energy decreases. It can also be seen that, for the proton donors employed, the Φ_D increases with the increase in the electron affinity of the RO radical and the decrease in the dissociation energy of the

RO–H bond. However, although the dissociation energies of the C–H bonds are slightly smaller than those of the RO–H bonds, the hydrocarbons have little proton-donating properties. This is due to the smaller electron affinities (12~25 kcal/mol) of the hydrocarbon radicals, compared with those (55~75 kcal/mol) of the RO radicals. It may be concluded from these considerations that the proton-donating powers, Φ_D, are mainly affected by the electron affinities of the RO radicals rather than by the dissociation energies of the RO–H bonds.

Moreover, in order to examine the isotope effect on the proton-donating powers, we compared the shifts of methanol and monodeuteromethanol. As is shown in Table 2, the values of Φ_D should fall to about 0.7 times by deuteration; this agreed well with the theoretical prediction proposed by Coggeshall.[2)]

Proton-accepting Powers and the Structures of Proton Acceptors. When trimethylsilanol was used as a proton donor, the O–H vibrational bands were sharp and symmetrical in all of the proton

acceptor solutions except in case of the aromatic ether solutions. The experimental data are summarized in Table 3.

In the aromatic hydrocarbons, it is observed that the introduction of electron-withdrawing groups or of electron-relieving groups to the benzene rings results in a decrease or an increase in the proton-accepting powers. For the aromatic ethers, represented by anisole, two unassociated O–H vibrational bands were observed. It is known that one showing the larger shift and intensity is to be assigned to the hydrogen bond formed by the lone-pair electrons of ether oxygen, while the other, showing the smaller shift and intensity, is to be assigned to the bond formed by the benzene ring.*1

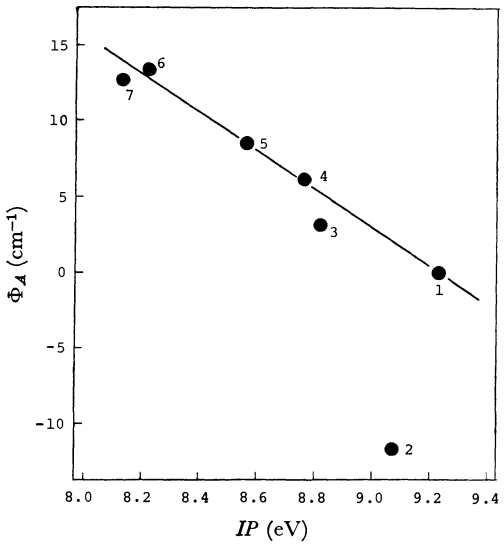

Fig. 4. Relation between the proton-accepting powers Φ_A and the ionization potentials of benzene derivatives.
Benzene derivative: 1, Benzene; 2, Chlorobenzene; 3, Toluene; 4, Ethylbenzene; 5, *m*-Xylene; 6, Anisole; 7, Phenetole

In order to determine a correlation between the proton-accepting powers, Φ_A, and the electronic natures of benzene derivatives, the Φ_A was plotted against the ionization potential. As is shown in Fig. 4, a linear relationship with a negative slope was observed between them. If the first ionization of the benzene derivatives is caused by the benzene ring, the results in Fig. 4 should indicate the intermolecular interaction between the silanol proton and the π-electrons on the benzene ring. Similarly, a straight line with a negative slope was also drawn between the Φ_A and the Hammett substituent constants (Fig. 5). This fact also supports the above consideration.

*1 Detailed descriptions on this phenomenon will be given in a subsequent paper.

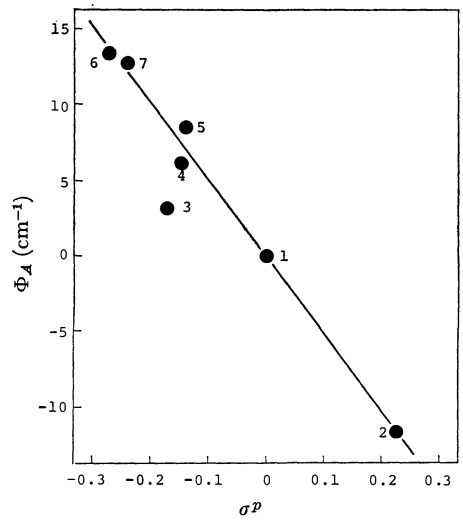

Fig. 5. Relation between the proton-accepting powers Φ_A and the Hammett substituent constants σ^p of benzene derivatives.
Benzene derivative: 1, Benzene; 2, Chlorobenzene; 3, Toluene; 4, Ethylbenzene; 5, *m*-Xylene; 6, Anisole; 7, Phenetole

On the other hand, it is of interest to ascertain information on the electronic state of the π-electrons, not only on the benzene ring, but also on the vinyl groups of vinyl compounds. From this point of view, the Φ_A values of a pair of the proton acceptors (CH_2=CHY and CH_3CH_2Y) with analogous chemical structures were compared as an example, methyl

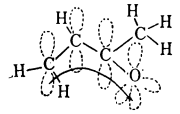
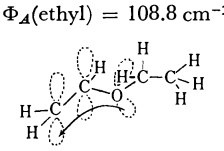
vinyl ketone and methyl ethyl ketone. It may be noted from this comparison that the Φ_A is markedly affected by the substitution of vinyl group for ethyl group bonding with the substituent group Y. In order to clarify the phenomena, we plotted the Φ_A of the vinyl compounds against that of the ethyl compounds, as is shown in Fig. 6; for convenience, we classified them into the following three types: (i) Φ_A(vinyl)$>\Phi_A$(ethyl), (ii) Φ_A(vinyl)$\simeq\Phi_A$(ethyl), and (iii) Φ_A(vinyl)$<\Phi_A$(ethyl). Since the introduction of a hetero atom to the proton-accepting molecule as an unsaturated hydrocarbon molecule results in an enhanced Φ_A, the hydrogen atom in a silanol molecule is considered to form a hydrogen bond more preferentially with the hetero atom than with the vinyl group. Therefore, the difference in the Φ_A values of the vinyl and ethyl compounds with the same substituent should indicate directly the difference in the electronic natures of the hetero atoms in the substituents. In other words, it can be said that the difference in the Φ_A indicated the π-electron drift between the vinyl group and the neighboring hetero atom.

Typical pairs of compounds belonging to the (i) and (iii) types are methyl vinyl ketone–methylethyl ketone and ethyl vinyl ether–diethyl ether respectively:

Methyl vinyl ketone
Φ_A(vinyl) = 112.0 cm^{-1}
Φ_A(ethyl) = 73.0 cm^{-1}



Ethyl vinyl ether
Φ_A(vinyl) = 51.7 cm^{-1}
Φ_A(ethyl) = 108.8 cm^{-1}



In methyl vinyl ketone, it can be considered that the π-electrons of the vinyl group migrate from the vinyl group to the carbonyl oxygen whose lone-pair electrons associate with the hydrogen atom in a silanol molecule, resulting in a lowering of the π-electron density of the vinyl group or in a lowering of the energy level of the π-electrons of the vinyl group. In the case of ethyl vinyl ether, it can be considered that the lone-pair electrons of an oxygen atom which have some π-characteristics transfer to the vinyl group and enhance the energy level of π-electrons of the vinyl group.

On the basis of the above qualitative consideration, we may defined the π-electron-mobility index (I_{em}), which represents the degree of the mobility of π-electrons of the vinyl group, as follows:

$$I_{em}=\frac{\Phi_A(\text{ethyl})-\Phi_A(\text{vinyl})}{\Phi_A(\text{ethyl})} \quad (4)$$

The I_{em} values are listed in Table 4.

In order to confirm this definition, we examined the relationships between the I_{em} and the other measures representing the energy level of π-electrons of the vinyl group (Table 4). It is obvious from Table 4 that the I_{em} values are in relation to the coefficients (λ_{ho}) of the highest occupied π-levels ($\varepsilon_{ho}=\alpha+\lambda_{ho}\beta$) rather than to those ($\eta_{lv}$) of the lowest vacant π-levels ($\varepsilon_{lv}=\alpha-\eta_{lv}\beta$) of vinyl compounds, as calculated by the method of the simple Hückel MO.[11]

It may also be seen in Table 4 that the I_{em} values are correlated with the average π-electron densities

11) T. Kagiya, Y. Sumida and T. Nakata, This Bulletin, **41**, 2239, 2247 (1968).

$(q_\alpha+q_\beta)/2$ of the vinyl groups, where q_α and q_β are, respectively, the π-electron densities of α-carbon and β-carbon; the larger the values of $(q_\alpha+q_\beta)/2$, the larger the I_{em} values. It may be concluded from these results that the I_{em} is a measure not only of the energy level of the highest occupied π-orbital of vinyl compound, but also of the average π-electron density of the vinyl group.

There is, however, no relationship between the I_{em} and the π-bond dissociation energies of the vinyl compounds, which depend upon the electronic nature of the vinyl group.[11,12] This means that the I_{em} indicates the degree of π-electron drift in the molecule, but not essentially the strength of the π-bond.

Moreover, in order to elucidate the resonance effect on the I_{em} values, we then plotted the I_{em} against the substituent constants, $(\sigma_R{}^p)$, due to the resonance effect. As is shown in Fig. 7, there exists a good correlation — the I_{em} becomes larger as the $\sigma_R{}^p$ decreases.

It seems reasonable to conclude from the above correlations that the I_{em} is a semi-quantitative measure of the various electronic properties of π-electrons of the vinyl groups.

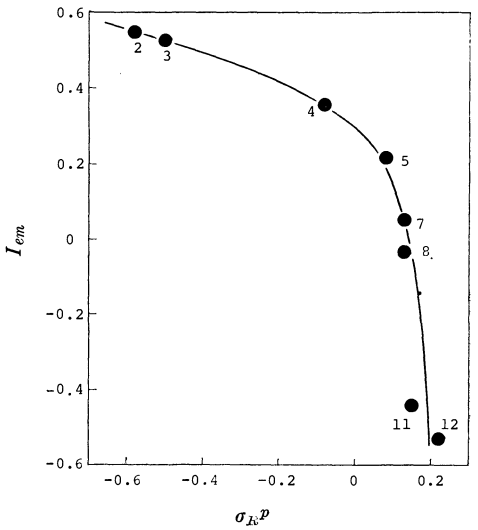


Fig. 7. Relation between the π-electron-mobility indexes I_{em} and the resonance substituent constants $\sigma_R{}^p$. The number of a point represents the number in Table 4.

The authors would like to express their gratitude to Mr. Takeshi Watanabe for his technical assistance.

Sound Velocity in Polyoxyethylene(6)laurylether Aqueous Solution

Otohiko NOMOTO*,** and Harumi ENDO*

* *Department of Applied Physics, Defense Academy, Yokosuka*
** *Kobayasi Institute of Physical Research, Kokubunji, Tokyo*

(Received June 20, 1970)

The sound velocity and density of polyoxyethylene(6)lauryether and its aqueous solutions are measured, and the adiabatic compressibility is computed from these results. The virtual sound velocity was calculated in ideal mixtures by using Kudriavtsev's formula, and above 33°C for ideal suspensions by the use of the equation of Urick and Ament for dispersed systems. Some deviations in the experimental velocity from the calculated value are ascribed to the interaction energy of mixing. This energy, or the heat of the hydration of a nonionic surfactant, is obtained as a function of the temperature. The diagrams of the density, sound velocity, and adiabatic compressibility *vs.* the temperature at various concentrations always exhibit a common crossing point, nearly at the cloud point. It may thus be concluded that the measurements of the sound velocity and density give a new method for determining the cloud point.

The dissolved state and the properties of ionic surfactants in aqueous solutions have been studied with ultrasonics by Yasunaga *et al.*[1,2] and by Shigehara,[3-5] but so far no study of the dissolved state and properties of nonionic surfactants in aqueous

solutions using ultrasonics has been reported.

In the present study, we adopted polyoxyethlene-(6)laurylether as the nonionic surfactant and measured its sound velocity in aqueous solutions.

The experimental data were compared with the results of the thermodynamical calculation of sound velocity using the Lennard-Jones potential. The heat of the hydration of the nonionic surfactant was estimated from deviation of the sound velocity from that of an ideal solution.

It is known that a nonionic surfactant in an aqueous solution suddenly turns cloudy white at a specified temperature called the cloud point (in our specimen, at 33°C). The curve of the difference in sound velocity between solvent and solution plotted against the temperature shows a sharp turn at nearly this temperature.

Solutions of a surfactant with a distribution of molecular weight exhibit a second transition temperature, the double cloud point (at 42°C for our specimen), above which two separated phases appear.

In the temperature range below 33°C, we computed the heat of hydration from the deviation of the experimental sound velocity from the ideal-solution sound velocity, as obtained by Kudriavtsev's formula.[6] In the 33—42°C temperature range, the present system becomes a dispersive system, or an emulsion. The sound velocity for emulsion or suspension is different from that of an ideal solution of the same composition, also in the absence of the heat of hydration. The ideal value of the sound velocity in this temperature range (33—42°C) was computed by Urick and Ament's formula;[7] we obtained the heat of hydration from the deviation of the experimental velocity from this ideal suspension value.

Experimental

Material. Polyoxyethylene(6)laurylether. The $C_{12}H_{25}O(C_2H_4O)_6H$ sample is a commercial product*1 and is used without further purification. The surfactant has its cloud point and double cloud point at 33°C and 42°C respectively.

Apparatus. The sound velocity is measured with a variable-path ultrasonic interferometer with a 1/1000 mm reading and a frequency of 5 MHz. The density measurements are made by means of an Ostwald-type pycnometer to an accuracy higher than 1 part in 10^4. The temperature-regulated water in a thermostat of ± 0.05°C is circulated in the mantle surrounding the cell by means of a circulation pump. The overall accuracy of velocity measurement is ± 0.3 m/sec.

Theoretical

The sound velocity in binary liquid mixtures has been thermodynamically calculated by Kudriavtsev.[6] It is assumed that, in an ideal mixture, the internal energy, E, and the volume, V, are additive;

$$E = x_1E_1 + (1-x_1)E_2 \tag{1}$$

$$V = x_1V_1 + (1-x_1)V_2 \tag{2}$$

where the suffixes 1 and 2 refer to the first and second components of the mixture respectively, and where x_1 is the mole fraction of the first component. By differentiating Eq. (1) twice with respect to the volume at a constant entropy, S, and noting that

$$\left(\frac{\partial^2 E}{\partial V^2}\right)_S = \frac{MC^2}{V^2} \tag{3}$$

where C is the sound velocity, and M, the molecular weight, we obtain this expression for the sound velocity in the mixture:

$$C^2 = x_1\frac{M_1}{\bar{M}}C_1^2 + (1-x_1)\frac{M_2}{\bar{M}}C_2^2 \tag{4}$$

Here, C_1 and C_2 are, respectively, the sound velocities in the first and second components, M_1 and M_2 are the molecular weights of the two components, and $\bar{M}$ is the average molecular weight:

$$\bar{M} = x_1M_1 + (1-x_1)M_2 \tag{5}$$

The Eq. (4) obtained by Kudriavtsev is only approximate, because the thermodynamic relation (3) gives the result more exactly:

$$MC^2 = \frac{E}{\chi'} \tag{6}$$

χ' is dependent on each liquid (and also somewhat on the temperature), as obtained by Nomoto,[8] though the range of χ' for various liquids is not very wide ($\chi' \fallingdotseq 0.2-0.3$). Therefore, we have, in place of Eq. (4), more exactly:

$$C^2 = x_1\frac{M_1}{\bar{M}}\frac{\chi}{\chi_1}C_1^2 + (1-x_1)\frac{M_2}{\bar{M}}\frac{\chi}{\chi_2}C_2^2 \tag{7}$$

Experimentally, however, Kudriavtsev's relation (4) is known to be quite valid for many liquid mixtures, and we use it below to represent the sound velocity in ideal mixtures.

Assuming the Lennard-Jones potential for the intermolecular potential of the liquids, we obtain:

$$\Phi(r) = \frac{A}{r^{12}} - \frac{B}{r^6} \tag{8}$$

Here, r is the intermolecular distance. The A and B quantities are functions of the temperature, but at a constant temperature they are constants

8) O. Nomoto, *J. Phys. Soc. Jap.*, **18**, 1526 (1963).

characteristic of the specified liquid. We can also write Eq. (8) in terms of the molar volume, V, as:

$$\Phi(V) = \frac{A_0}{V^4} - \frac{B_0}{V^2} \quad (9)$$

The deviation from ideal behavior expressed in Eq. (1) may be accounted for by taking into account the interaction energy of mixing ΔE_{12}:

$$E = x_1E_1 + (1-x_1)E_2 + \Delta E_{12} \quad (10)$$

If we assume that the internal energy of molecular interaction between the components of the mixture also obeys Eq. (9), then from Eq. (10) we can find:

$$C^2 = x_1\frac{M_1}{\bar{M}}C_1^2 + (1-x_1)\frac{M_2}{\bar{M}}C_2^2 + 2 \times 4\gamma\Delta E_0 \quad (11)$$

where γ is the ratio of the specific heats. If we use for ΔE_0 the heat of hydration, L (cal/solution 1 g), then we have, as the sound velocity in mixtures, the expression:

$$C^2 = x_1\frac{M_1}{\bar{M}}C_1^2 + (1-x_1)\frac{M_2}{\bar{M}}C_2^2 + 3.35 \times 10^8L \quad (12)$$

In the temperature range from the cloud point to the double cloud point, we have emulsions. Urick and Ament[7] obtained the propagation constant in a medium containing numerous small spherical particles. In our notations, their expression takes the form:

$$\left(\frac{C_2}{C_s}\right)^2 = \{1+\alpha(\beta_1-\beta_2)/\beta_2\}\{1+3\alpha\sigma/(2\sigma+3)\} \quad (13)$$

Here, C_2 and C_s are the sound velocities in the solvent water and in the dispersive system respectively. β_1 and β_2 are the adiabatic compressibilities of the surfactant and the solvent respectively, and $\sigma=(\rho_1-\rho_2)/\rho_2$, with ρ_1 and ρ_2 the densities of the surfactant and the solvent, and α, the volume fraction of the surfactant. We use Eq. (13) in place of Eq. (4) and use:

$$C^2 = C_s^2 + 3.35 \times 10^8L \quad (14)$$

to represent the deviation from an ideal emulsion in this temperature range.

Results and Discussion

We studied the behavior of sound velocity in dilute aqueous solutions of polyoxyethylene(6)-laurylether (a commercial product). The phase diagram of this purified surfactant + water system was previously studied by Balmbra *et al.*[9]

Figures 1—4 show the sound velocity as functions of the temperature for solutions with various concentrations of the nonionic surfactant. The experimental values and computations for ideal solutions by Eq. (4) and for an ideal emulsion by Eq. (12) are shown. The difference between the observed sound velocity and the ideal-solution (or -emulsion) velocity increases with an increase in the concentration. The emulsion velocity (C_s) is somewhat lower than the ideal solution velocity, though the difference is rather small.

As L represents the heat of hydration per gram of solution (p wt%), the heat of mixing L_M per mole of the solute becomes:

$$L_M = \frac{ML}{1000\left(\frac{p}{100}\right)} \text{ (kcal/mol)} \quad (15)$$

In the temperature range betweem the two cloud points, both the values of L_M, these calculated by using $C_{cal}=C_{ideal}$ and $=C_s$, are as shown in Table 1. Each datum is the average of four determinations. It may be seen in Table 1 that the calculated energies from an ideal solution and from a dispersive solution are nearly equal. As is also to be seen from Table 1, the mixing is exothermic at lower temperatures, but it becomes endothermic at higher temperatures. As regards the sound velocity, we can see from Figs. 1—4 that C_{exp} is higher than C_{ideal} in the lower temperature range, while $C_{exp}<C_{cal}$ in the higher temperature range. From Table 1, it is also to be seen that the value of energy found is comparable to the energy for the breakdown of the hydrogen bond (3.4 kcal/mol[10]) between water molecules. According to Chwala and Martina,[11] in an aqueous solution of ethylene oxide derivatives a hydrogen bridge is formed between the ether-like combined oxygen atom and the water molecule as is illustrated below:

$$-CH_2-O-CH_2-$$
$$\updownarrow$$
$$H-O-H$$

At temperatures above the cloud point, dehydration phenomena of the nonionic surfactant may be expected in forming the emulsions.

As the value of the heat of hydration decreases with an increase in the temperature, it may be inferred that the cloud point phenomenon does not take place abruptly at a specified temperature, but that the phase separation takes place gradually in the temperature range slightly below the cloud point. Our sample being a high polymer, it may have a distribution of molecular weights, and the gradual-phase separation may thus be attributed to the distribution of molecular weights. This makes it difficult to analyse the dissolved state and the properties of the solution. If we can get a substance with a narrow distribution of molecular weight by the method of solvent extraction, molecular distillation or particular synthesis, we may be able to clarify the relationship between the heat of hydration and the phase separation.

The energy set free in the form of heat is measurable by the calorimetric method, but we obtained the heat of hydration from the deviation of the sound velocity from that of an ideal mixture instead of by calorimetric study. From their calorimetric measurements, Racz and Orban[12] give an empirical

relation between the hydrophile lipophile balance (*HLB*) of a liquid nonionic surfactant and the heat of hydration (at the temperature of 20°C):

$$HLB = 0.42Q + 7.5 \qquad (16)$$

where Q=heat of hydration in cal/g surfactant. Using Eq. (16) for our specimen with HLB=9.6,[13] we obtain the energy of hydration, L_M, as 2.3 kcal/mol. Though the value of *HLB* in our specimen is in nearly the same range as that investigated by Racz and Orban, the samples are somewhat different in the two cases. The samples of Racz and Orban were Tweens.*2 Therefore it is not certain

whether this value of $L_M=2.3$ kcal/mol is sufficiently accurate. We may thus conclude that the acoustically-determined energy of hydration for the nonionic surfactant is nearly in agreement with the calorimetric measurements.

Figures 5—7 show the temperature dependence of the sound velocity(C), density(ρ), and the adiabatic compressibility(β), respectively, for polyoxyethylene(6)laurylether. As is to be seen in Fig. 5, ρ plotted against T becomes a straight line, while we see from Figs. 6 and 7 that the curves of $C(T)$ and $\beta(T)$ have somewhat different slopes in different temperature ranges.

Figures 8—10 show the values of ρ, c, and β as functions of T for various concentrations. It may be seen that all of these curves intersect at one temperature, independent of the concentration. This temperature is about 32°C and is to be identified as the cloud point.

It is to be noticed that the sound velocity, the density, and the adiabatic compressibility are all independent of the concentration at the cloud point. We obtain the "acoustical cloud point" 32—33°C from Fig. 9; it coincides with the visual cloud point (33°C) within the range of experimental error.

Figures 11 and 12 show the difference in sound velocity (ΔC) and adiabatic compressibility ($\Delta\beta$) between the solution and the solvent as functions of the temperature in solutions of various concentrations. Each curve consists of two linear segments, with a turn at nearly 32—33°C. This break point, independent of the concentration of the surfactant, may reasonably be ascribed to the cloud point. The slopes per unit of concentration of ΔC–T curves and $\Delta\beta$–T curves are nearly constant above and below the cloud point respectively.

Mr. Noriaki Ohba of Nippon Surfactant Industr. Inc. has kindly supplied the surfactant sample for us. We express our sincere thanks to him in this place.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3728—3740 (1970)

The γ-Radiolysis of Liquid *n*-Hexane. The Effects of Radical, Electron, and Positive-ion Scavengers

Kyoji SHINSAKA and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received June 23, 1970)

The effects of various additives, SF_6, NH_3, C_2H_5OH, N_2O, NO, SO_2, and C_2H_4, on the product yields in the γ-radiolysis of liquid *n*-hexane at room temperature have been investigated. The following conclusions have been drawn: (i) The added SO_2 acts mainly as a radical scavenger. (ii) The added NO shows not only the effect of radical scavenging, but also other effects. Therefore, it is inadequate to use NO as a simple radical scavenger. (iii) The C_7-C_{12} products are formed from a combination reaction of alkyl radicals, but not from an ion-molecule reaction. (iv) The formation of $C_6H_{13}^+$ ions by the direct action of radiation is suggested. (v) The *G*-value of ionization is evaluated to be 4.0. A brief discussion concerning the formation of N_2 in the presence of N_2O is also given.

One of the methods of investigating the radiation chemistry of liquid hydrocarbons is the scavenger technique. This method aims at elucidating the mechanism of radiolysis from the effect of additives, which react selectively with radicals or charged species produced by irradiation, on the yields of the radiolytic products. Product analysis, however, has usually been carried out on fragment products. Thus, in the case of alkane radiolysis, there have been only a few works in which the effects of scavengers for charged species on the product yields, including those of olefins and of dimeric paraffins, have been investigated. Consequently, there remain several unsolved problems even in the radiolysis of *n*-hexane, which has been widely investigated by many researchers[1-7] as a typical liquid paraffin. For

example, there are two views concerning the mechanism of the formation of dodecanes; one[1] attaches importance to the ion-molecule reaction, and the other,[4] to the combination reaction of hexyl radicals.

In order to clarify the problems, it appears suitable to investigate the effect of additives on the yields of products, including hexenes and dodecanes. The additive should be carefully selected in such a way that it scavenges selectively one reactive species. Thus, SF_6,[8] which is often used as an electron scavenger, and NH_3[9] and C_2H_5OH,[10] which are often used as proton scavengers, appear to be suitable in view of their physical and chemical properties. In order to investigate the radical processes, a pertinent radical scavenger is necessary. For this purpose, SO_2 is tentatively chosen in view of its physical and chemical properties, although there is a possibility that SO_2 scavenges an electron due to its electron affinity ($EA(SO_2)=ca.$ 1 eV[11]). SO_2 shows a much higher reactivity to alkyl radicals (the rate constant of addition to methyl radicals is $5.0\times10^6 M^{-1}$ sec^{-1} at 25°C[12]) than that of ethylene, which is known as an effective hydrogen atom scavenger,[13] a higher ionization potential (IP (SO_2)=12.34 eV[14]) than that of n-hexane (IP(n-hexane)=10.17 eV[15]), and a much higher solubility in n-hexane than that of oxygen, which has been often used as an effective radical scavenger. There are few cases, at most, in which SO_2 has been used as a radical scavenger; to the authors' knowledge, the only example seems to be the work by Henglein *et al.*[16] They regarded SO_2 as a radical scavenger on the basis of the fact that the G-values of the SO_2 absorbed in the radiolysis of various liquid hydrocarbons were nearly equal to the radical yields determined with DPPH or I_2.

In a previous work,[17] the present authors used N_2O and NO as an electron scavenger and a radical scavenger respectively. With regard to NO, however, it has been pointed out that this is apt to undergo a charge-transfer reaction[18] due to its ionization potential (IP(NO)=9.25 eV[14]) being lower than that of n-hexane, and that it is also apt to form ionic addition products.[19] As for N_2O, the relation of the N_2 yield to that of the electron is still unclear. Therefore, N_2O and NO are again used in order to obtain more information on their effects.

Experimental

Materials. Research-grade n-hexane obtained from the Phillips Petroleum Co. was purified for the analysis of the C_7–C_{12} products by passing it through silica-gel, soda-asbestos, and magnesium perchlorate columns, besides the usual purification of freeze-pump-thaw cycles, as has been described in a previous paper;[17] it was purified for the analysis of H_2 and C_1–C_6 products, and N_2 in the presence of N_2O, by only the usual freeze-pump-thaw cycles, for the H_2 yield from the radiolysis of n-hexane purified by the latter, more convenient way was the same as the result of the former purification. The purity of n-hexane was determined to be more than 99.98% by gas chromatography. The additives were all commercially obtained. SF_6 (minimum purity: 98.0%) obtained from the Matheson Co.; N_2O(99.9%), NH_3(99.5%), SO_2(98.0%), NO(99.9%), and C_2H_4-(99.8%) obtained from the Takachiho-shoji Co., and C_2H_5OH(99.5%) obtained from the Wako-junyaku-kogyo Co. were used after the usual degassing by freeze-pump-thaw cycles. For C_2H_5OH, a further purification to remove a trace of dissolved water was carried out by mixing the ethanol with powder cupric sulfate which was degassed and thoroughly dehydrated.

Sample Preparation and Irradiation. The samples were prepared in the way which has been described before[17] except that the amount of n-hexane used for the analysis of H_2, the C_1–C_6 products, and N_2 was 5 cc; it was measured by a pipet, degassed by the usual freeze-pump-thaw cycles, and led into a glass ampoule fitted with a break-off seal. The samples were irradiated at room temperature by a ^{60}Co γ-source either at a dose rate of 6.67×10^{19} eV/g·h to a total dose of 8.0×10^{20} eV/g for the analysis of the C_7–C_{12} products, or at a dose rate of 5.85×10^{19} eV/g·h to a total dose of 5.85×10^{19} eV/g for the analysis of the H_2 and C_1–C_6 products, and of N_2 in the presence of N_2O, unless otherwise specified. In estimating the dose rates, a $G(Fe^{3+})$ value of 8.2 in the Fricke dosimeter saturated with nitrogen was used with the electron-density correction.

Analysis. The analysis of noncondensable gases at −196°C was carried out in the same way as has been described in the previous paper.[17] The C_2–C_{12} products were analyzed gas chromatographically. For the analysis of the C_2–C_6 products, the residual liquid after the analysis of noncondensable gases was sealed in a new glass ampoule under a vacuum at −196°C. Immediately after breaking the seal of the ampoule, a fixed volume of the contents was injected, by means of a micro-syringe, into a gas chromatograph equipped with a flame ioniza-

tion detector. An 11-m column with 20% dimethylsulfolane on 60/80 mesh Neosorb NP was used at room temperature (*ca.* 20°C). This column could not resolve *trans*-2-hexene and *cis*-3-hexene so as to allow separate values to be quoted for their yields; therefore, the total yield of these products was determined. After the gas chromatogram of an irradiated sample had been obtained, the same operation was repeated with a reference sample which contained a known quantity of each product component in a fixed quantity of *n*-hexane (nearly as much as in the irradiated sample). The product yields were determined by comparing the peak area of a gas chromatogram of the irradiated sample with that of the reference sample. In this method there was a possibility that a part of the low-molecular-weight products, such as ethane, ethylene, propane, and propylene, escaped into the air during the period from the break of the ampoule to the injection of the sample into the gas chromatograph. This fear could, however, be excluded because the dose dependence of the yields of the fragment products obtained by this method was reasonable; that is, the yields of ethane and propane showed no dose dependence, while the yields of ethylene and propylene indicated the dose dependence that these yields decreased with an increase in the dose. In the presence of a large quantity of an additive which does not dissolve so much in *n*-hexane, the low-molecular-weight product yields obtained by the above method may be somewhat inferior in accuracy to the case without additives, because the time required from the break of the ampoule to the injection of the sample into a gas chromatograph is a little longer than in the case without additives. The C_7–C_{12} products were analyzed in almost the same manner as were the C_2–C_6 products after the irradiated ampoule, without having been submitted to the analysis of noncondensable gases, had been broken open. A 5-m column with 25% Silicone DC 550 on 60/80 mesh Shimalite was used at 130°C. Under these conditions, *iso*-peaks were normally obtained for each hydrocarbon product, one corresponding to the *n*-isomer, and the other, to branched-chain isomers. The *iso*-C_7 peak was not resolved from the tail of the *n*-hexane peak; therefore, the yield of *iso*-C_7 has not been included in the results. Similarly, the *n*-C_{11} peak was not resolved from the *iso*-C_{12} peak and the *iso*-C_{11} peak was not determined quantitatively because the *iso*-C_{11} peak overlapped with that of an impurity peak. These product yields, however, contribute little to the C_7–C_{12} product yields. The C_7–C_{12} products were identified by using authentic samples and by comparison with the results of Widmer *et al.*[3]

Additive Concentration. There seem to be no data showing the solubility of SF_6, N_2O, and NO in *n*-hexane. However, on the assumption that the solubilities of SF_6 and N_2O in *n*-hexane are similar to the case of *n*-heptane,[20,21] in which the solubilities of SF_6 and N_2O have been reported, more than 95% of the amount of added SF_6 and more than 97% of the amount of added N_2O, respectively, were calculated to dissolve in the liquid phase of *n*-hexane in view of the fact that the volume of the gas phase in an irradiated ampoule was less than one-tenth of the total inner volume. On the other hand, it was confirmed that it was easy to dissolve C_2H_5OH in *n*-hexane, and it has been shown that SO_2[22] dissolves very much in *n*-hexane and that C_2H_4[23] dissolves also to about the same degree of N_2O in *n*-heptane. All the concentrations of the additives were estimated by assuming that the additives dissolved completely in the liquid phase of *n*-hexane, for the solubilities of the additives in *n*-hexane would not differ very much from those in *n*-heptane. This assumption is adequate except for the case of the addition of NO, whose concentration in *n*-hexane was estimated to be a few tens of percent less than the value calculated from the assumption of complete dissolution in view of the solubility of NO[21] in cyclohexane.

Results

The results obtained regarding the dose dependence of the C_6–C_{12} product yields from the radiolysis of *n*-hexane are as follows. The hexene yields decrease with an increase in the dose, the degree of the decrease depending on the type of hexene isomer. The dose dependence of hexene yields is very conspicuous in 1-hexene and *trans*-2-hexene+*cis*-3-hexene,*1 and weak in *cis*-2-hexene and *trans*-3-hexene. The yields of the C_7–C_{12} products, however, show no dose dependence within doses up to 8.0×10^{20} eV/g. The difference between the dose dependence of the hexene yields and that of the C_7–C_{12} product yields will be briefly discussed later. The *G*-values of the products obtained at the total dose of 5.85×10^{19} eV/g and at room temperature are shown in Tables 1 and 2, along with the results of other previous investigations.[1,3,4] The *G*-values in this work, shown in these tables, may be regarded as almost the initial values in view of the dose dependence of the hexene yields; they agree well with the results given by Widmer *et al.*[3] except for somewhat larger differences in the cases of ethane, ethylene, and propane. The ratio of the total number of carbon atoms to that of the hydrogen atoms calculated, respectively, from the *G*-values in Tables 1 and 2 is 0.420; this agrees well with the ratio in an *n*-hexane molecule, *i. e.*, 0.429. The

*1 Since the seperate values of *trans*-2-hexene yield and *cis*-3-hexene yield could not be obtained, the total value of these product yields was represented using the plus sign, +. The *cis*-3-hexene yield was calculated to be 0.076—0.17 by using the ratio, $trans/cis=4\pm1.5$ given by Hardwick[4] in regard to 3-hexene, and by using the *trans*-3-hexene yield obtained in this work. Therefore, the total yield of *trans*-2-hexene and *cis*-3-hexene may be regarded almost as the yield of *trans*-2-hexene and the total yield is approximately represented as the *trans*-2-hexene yield in Table 1.

a) Obtained in this work. Irradiation with ^{60}Co γ-rays at 5.85×10^{19} eV/g at room temperature.
b) Obtained by Widmer *et al.*[3] Initial values. Irradiation with ^{60}Co γ-rays at 25°C.
c) Obtained by Hardwick.[4] $G(H_2)$, $G(C_6H_{12})$: initial values. The dose for other products is not clear. Electron irradiation at 25°C.
d) Obtained by Kevan *et al.*[1] $G(H_2)$ obtained at 1.24×10^{19} eV/g. *G*-values of the fragment products obtained at 16.2×10^{20} eV/g. $G(C_6H_{12})$ obtained at 10.2×10^{20} eV/g. Irradiation with ^{60}Co γ-rays at 20°C.
e) This value shows more exactly the total yield of *trans*-2-hexene and *cis*-3-hexene. See the text.

G-value of a net decomposition of *n*-hexane is defined by the following equations:

$$G_{no}(-n\text{-}C_6H_{14}) = \sum_{i=1}^{12} iG(C_i)/6 \qquad (A)$$

or

$$G_{no}(-n\text{-}C_6H_{14}) = \sum_{i=1}^{13} 2iG(H_{2i})/14 \qquad (B)$$

where $G_{no}(-n\text{-}C_6H_{14})$ indicates the *G*-value of the net decomposition of *n*-hexane, and where $G(C_i)$ and $G(H_{2i})$ indicate the *G*-values of the products, whose numbers of carbon atoms and hydrogen atoms are i and $2\times i$ respectively. The average, $G_{no}(-n\text{-}C_6H_{14})$, of the two values obtained by the use of Eq. (A) and Eq. (B) is calculated to be 7.30. The percentage of the decomposition of *n*-hexane is calculated to be 0.061% at the dose of 5.85×10^{19}

eV/g and 0.84% at the dose of 8×10^{20} eV/g by using this value, 7.30.

The effects of additives on the C_7–C_{12} products were investigated with samples irradiated up to a dose of 8×10^{20} eV/g. This dose is permissible in view of the finding that the C_7–C_{12} product yields showed no dose dependence in the absence of additives and that the C_{12} product yields also showed no dose dependence in the presence of 0.55M N_2O. Figure 1 shows the changes in the *G*-values of hydrogen and methane upon the addition of SO_2, togeth-

er with those in the case of the addition of C_2H_4. The change in the *G*-value of hydrogen in the presence of SO_2 is very similar to that obtained in the presence of C_2H_4. The changes in the *G*-value of methane are, however, very different for SO_2 and C_2H_4. The *G*-value of methane decreases drastically to about a half of the initial value at a low concentration of SO_2, and afterward comes to show almost no change. On the other hand, with the concentration of C_2H_4 the *G*-value of methane gradually decreases.

Figures 2(a) and 2(b) show the changes in the *G*-values of the other fragment products upon the addition of SO_2. The *G*-values of the saturated fragment products decrease to about a half of the initial value, or more, upon the addition of SO_2. The *G*-values of the unsaturated fragment products, however, show only a small decrease. Figure 2(c) shows the changes in the *G*-values of hexenes upon the addition of SO_2. The *G*-values of hexenes decrease to about a half of the initial value, or more. Figure 2(d) shows the changes in three kinds of C_{12} products as examples of the effect of the addition of SO_2; the *G*-values of all the C_{12} products decrease drastically, *e. g.*, to a value less than one-fiftieth of the initial value in 4-ethyl-5-methylnonane (4Et5MeC$_9$ for brevity), which shows the most conspicuous decrease, and to a value less than one-fourth of the

initial value even in n-dodecane (n-C_{12} for brevity), which shows the smallest decrease. Figure 3 shows the changes in the G-value of 5-methylnonane+4-ethyloctane ($5MeC_9+4EtC_8$ for brevity) as a typical example of the C_7–C_{10} products affected by the addition of SO_2, together with the results of other additives.

Upon the addition of SO_2, the G-values of all the C_7–C_{10} products decrease drastically, *i. e.*, to a value less than one-tenth of the initial value in the most conspicuous decrease and to a value less than one-fourth of the initial value even in the smallest decrease, except for the case of n-heptane, whose G-value is poorer in accuracy due to its inclusion in the tail of n-hexane. Furthermore, the G-values of all the C_7–C_{12} products continue to decrease gradually with an increase in the concentration of SO_2 after the initial sharp decrease. Figure 4(a) shows the changes in the G-values of H_2 and CH_4 upon the addition of SF_6. Figures 4(b) and 4(c) show the changes in the G-values of hexenes and do-

decanes respectively upon the addition of SF_6. As is shown in Figs. 3, 4(a), 4(b), and 4(c), the *G*-values of all the products decrease to about a half of the initial values, or less, upon the addition of SF_6 and come to show little change at higher concentrations of SF_6.

Figures 5(a) and 5(b) show the changes in the *G*-values of hexenes and dodecanes upon the addition of NH_3. Though the changes in the *G*-values of hexenes depend on the kind of hexene, the total *G*-value of hexenes in the presence of NH_3 is almost equal to that obtained in the absence of the additive. The *G*-values of the dodecanes increase more or less with the concentration of NH_3. A tendency similar to the changes in the product yields obtained upon the addition of NH_3 is also observed upon the addition of C_2H_5OH. Figure 6 shows the changes in the *G*-values of H_2, CH_4, and N_2 upon the addition of N_2O. Figures 7(a) and 7(b) show the

changes in the *G*-values of hexenes and dodecanes respectively upon the addition of N_2O. Though the changes in the *G*-values of hexenes are different, depending on the kind of hexene, the total yield of hexenes increases markedly with the concentration of N_2O. Figure 8 shows the changes in the *G*-values of hexenes upon the addition of NO. As has been stated before, the actual concentration of NO is estimated to be less than the value indicated in Fig. 8 because of the small solubility of NO. The decrease in hexene yields upon the addition of NO is much larger than that upon the addition of SO_2.

As is shown in the figures given above, the *G*-values of the products, with some exceptions, generally come to show little change at higher concentrations of the additives. The *G*-values obtained at sufficiently high concentrations of the additives are tabulated in Tables 3, 4, and 5, together with the data which have not been shown before.

Discussion

i) Effects of SF_6, NH_3, and SO_2. SF_6 is known to scavenge efficiently thermal electrons such as reaction (1):[25]

$$e^- + SF_6 \longrightarrow SF_6^- \quad (1)$$

On the other hand, SF_6 does not react with a methyl radical, even up to the temperature of 350°C.[26] Consequently, SF_6 added to *n*-hexane may safely be assumed to act as an electron scavenger, but not to react with radicals. Further, the possibility of a charge-transfer reaction from a parent *n*-hexane ion to SF_6 can be excluded because the ionization potential of SF_6 (IP=16.15 eV)[27] is much higher than that of *n*-hexane. SF_6^- can be assumed subsequently to undergo a neutralization reaction with a hydrocarbon ion; this reaction can also be assumed to be such a moderate reaction that it does not cause the decomposition of either ion because of a comparatively high electron affinity of SF_6 (EA=1.49 eV).[28] The major neutralization reaction is shown by reacion (2):

$$SF_6^- + n\text{-}C_6H_{14}^+ \longrightarrow SF_6 + n\text{-}C_6H_{14} \quad (2)$$

As for the effect of added NH_3, the proton-transfer reaction shown by reaction (3) and the subsequent neutralization reaction, (4), can be assumed for the following reasons.

$$n\text{-}C_6H_{14}^+ + NH_3 \longrightarrow C_6H_{13} + NH_4^+ \quad (3)$$

$$NH_4^+ + e^- \longrightarrow NH_3 + H \quad (4)$$

NH_3 has a high proton affinity (PA=8.78 eV).[29] On the other hand, the possibility of the reaction of NH_3 with a hydrogen atom can be excluded because the reaction is very slow ($H+NH_3 \xrightarrow{k} H_2+NH_2$; $k=2.2\times10^2 M^{-1}\,sec^{-1}$, 25°C).[30] Furthermore, the possibility of a charge-transfer reaction from a hydrocarbon ion to NH_3 may be also excluded because the ionization potential of NH_3 (IP=10.15 eV)[31] is almost equal to that of *n*-hexane (IP=10.17 eV)[15] and because the concentration of NH_3 is 9 mol% at most. The above assumptions concerning the effects of SF_6 and NH_3 are the same as those adopted in other works.[9,32-35]

As was stated in the introduction to this paper, the most likely effect of the added SO_2 is radical scavenging, although there is a possibility that SO_2 also scavenges an electron, as has been shown by Guarino *et al.*[36] They reported that the electron-scavenging efficiency of SO_2 was relatively high in the irradiated matrix of MTHF at −196°C. Their results, however, were obtained very different conditions from this work, so it is inappropriate to use

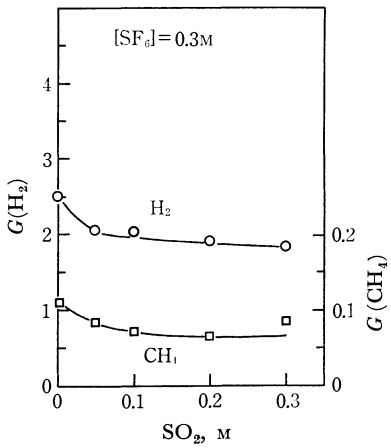

Fig. 9. Yields of H_2 and CH_4 as functions of SO_2 concentration in the presence of 0.3M of SF_6.

their results in the interpretation of the results of this work.

In order to estimate the effect of electron scavenging, the G-values of H_2 and CH_4 from the radiolysis of *n*-hexane in the presence of SO_2 were compared with those obtained in the coexistence of SO_2 and SF_6. The changes in the G-values of H_2 and CH_4 in the presence of 0.3M of SF_6 with the concentration of SO_2 are shown in Fig. 9. The G-value of H_2 at a sufficiently high concentration of SO_2 in Fig. 9 is 1.85, which is about one unit less than the case in which only SO_2 is added. The difference of one unit can not be explained if SO_2 also acts as an electron scavenger. On the other hand, in the coexistence of 0.3M SO_2 and 0.3M N_2O, the $G(N_2)$ value was determined to be 4.3, while in the presence of 0.3M N_2O only, $G(N_2)$ was 4.9. This small decrease in $G(N_2)$ due to the added SO_2 appears to indicate that the electron-scavenging effect of SO_2 is minor. The similarity in the changes in $G(H_2)$ between the addition of SO_2 and that of C_2H_4 supports the effect of radical scavenging of SO_2, because C_2H_4 in *n*-hexane can be regarded as an effective hydrogen-atom scavenger.[13] Consequently, the SO_2 added to *n*-hexane can be regarded mainly as a radical scavenger, and the decreases in the products upon the addition of SO_2 shown in the results may be considered to be brought about by the radical scavenging of SO_2. The sharp decrease in $G(CH_4)$ upon the addition of SO_2 in contrast with the result of the addition of C_2H_4 in Fig. 1 is considered to show that SO_2 is much more effective as a radical scavenger to the methyl radical than is C_2H_4. The C_7–C_{12} products appear to be almost exclusively formed from the combination reaction of alkyl radicals in view of the fact that the addition of SO_2 to *n*-hexane remarkably decreases the G-values of the C_7–C_{12} products to values ranging from one-fourth to one-fiftieth of the values obtained in the absence of the additives, as is shown in Tables 3 and 4.

The results shown in Tables 3 and 4, which were obtained when SF_6, NH_3 or SO_2 was separately added, can be explained qualitatively in terms of the effects of these additives, as has been mentioned before, assuming the following mechanism of *n*-hexane radiolysis:

$$n\text{-}C_6H_{14} \rightsquigarrow n\text{-}C_6H_{14}^+ + e^- \quad (5)$$

$$n\text{-}C_6H_{14} \rightsquigarrow n\text{-}C_6H_{14}^* \quad (6)$$

$$n\text{-}C_6H_{14}^+ + e^- \longrightarrow \begin{cases} C_6H_{13} + H & (7) \\ C_6H_{12} + H_2 & (8) \\ R_1H + R_2H & (9) \end{cases}$$

$$n\text{-}C_6H_{14}^* \longrightarrow \begin{cases} C_6H_{13} + H & (10) \\ C_6H_{12} + H_2 & (11) \\ R_1H + R_2H & (12) \end{cases}$$

$$H + n\text{-}C_6H_{14} \longrightarrow H_2 + C_6H_{13} \quad (13)$$

$$R_1H + R_2H \longrightarrow \begin{cases} R_1HH + R_2 & (14) \\ R_1 + R_2HH & (15) \\ R_1HHR_2 & (16) \end{cases}$$

$$R_1H + C_6H_{13} \longrightarrow \begin{cases} R_1HH + C_6H_{12} & (17) \\ R_1 + n\text{-}C_6H_{14} & (18) \\ R_1HC_6H_{13} & (19) \end{cases}$$

$$C_6H_{13} + C_6H_{13} \longrightarrow \begin{cases} C_6H_{12} + n\text{-}C_6H_{14} & (20) \\ C_{12}H_{26} & (21) \end{cases}$$

where reactions (5) and (6) are the ionization process and the direct-excitation process respectively, and where R_1H and R_2H represent fragment alkyl radicals other than hexyl radicals. Reactions (1) and (2) probably occur instead of reactions (7), (8) and (9) in the presence of SF_6 and cause the decreases in the product yields shown in Tables 3 and 4. On the other hand, reactions (3) and (4) probably occur instead of reactions (7), (8) and (9) in the presence of NH_3.

The results obtained upon the addition of NH_3 can be explained as follows. (i) The small increase in $G(H_2)$ from the value obtained without additives may correspond to the yield by which NH_3 replaces reaction (9) by reactions (3), (4) and (13). (ii) The result that the G-values of the fragment products (from C_1 to C_5) are nearly equal to the values obtained upon the addition of SF_6 may be because reaction (9) is interfered with, as in the case of SF_6. (iii) The result that the total G-value of hexenes is nearly equal to the value obtained in the absence of additives may be explained on the assumption that the decrease in the molecular yield of hexene by reaction (8) is nearly equal to the increase in the hexene yield by the disproportionation reaction (20). (iv) The results that the G-values of the C_7–C_{10} products are somewhat larger than those with SF_6, and that the G-values of dodecanes are somewhat larger than the values obtained in the absence of additives, may be because the increase of hexyl radicals in the presence of

NH_3 twice the yield by which the added NH_3 interferes with reactions (8) and (9).

ii) Dose Dependence of the Product Yields. The difference in the dose dependence between the yields of the hexenes and those of the dodecanes can be explained in the same way as Dewhurst[37] did in the case of cyclohexane. That is, when a hydrogen atom is added to a hexene molecule, as in reaction (22), the hexene yield decreases and the hexene scavenging the hydrogen atom becomes a hexyl radical:

$$C_6H_{12} + H \longrightarrow C_6H_{13} \quad (22)$$

Consequently, the yield of hexyl radicals would not change whether reaction (13) or reaction (22) occurs. On the other hand, the dodecanes are probably produced only by reaction (21). Therefore, the dodecane yields do not change with an increase in the dose, while the hexene yields decrease with such an increase.

iii) Effects of C_2H_5OH and NO. As is shown in Fig. 3 and Table 5, the *G*-values of the radiolysis products in the presence of C_2H_5OH are similar to the case of NH_3. Since the ionization potential of C_2H_5OH (IP=10.50 eV)[14] is a little higher than that of *n*-hexane (IP=10.17 eV),[15] the charge-transfer reaction, if any, from a parent *n*-hexane ion to C_2H_5OH can be ignored. As C_2H_5OH has a comparatively high proton affinity (PA=8.39 eV),[38] the proton-transfer reaction from a parent *n*-hexane ion to C_2H_5OH is most probable. On the other hand, the reaction of C_2H_5OH with electrons and radicals is probably unimportant under the present conditions in view of the reactivity of these reactive species and the concentration of C_2H_5OH. Therefore, the proton-scavenging effect of C_2H_5OH shown by Buchanan *et al.*[10] in the case of cyclohexane appears to have an effect similar to that of the addition of NH_3. The proton-scavenging reaction and the subsequent neutralization reaction are shown by the following schemes:

$$n\text{-}C_6H_{14}^+ + C_2H_5OH \longrightarrow C_6H_{13} + C_2H_5OH_2^+ \quad (23)$$

$$C_2H_5OH_2^+ + e^- \longrightarrow C_2H_5OH + H \quad (24)$$

The results with added NO are shown in Fig. 8 and Table 5. Since the *G*-values of hexenes in the presence of NO are much less than those with added SO_2, whose main effect is concluded to be radical scavenging, the added NO apparently undergoes reactions other than radical scavenging. Though the details of the effect other than radical scavenging can not be clarified in this work, it may be concluded that NO can not be used as a simple radical scavenger.

iv) Formation of the $C_6H_{13}^+$ Ion. The results obtained in the coexistence of SF_6 and NH_3 are shown in Tables 3 and 4. Since the results are somewhat singular, a re-examination of the radiolysis mechanism described in the previous section is necessary. The results show that, when SF_6 and NH_3 are both present, the total *G*-value of the hexenes increases more than one unit from the value obtained in the presence of SF_6 only, but that the other product yields are nearly equal to the values obtained in the presence of SF_6 only. In the coexistence of SF_6 and NH_3, it can be assumed that reactions (1) and (3) and the subsequent neutralization reaction (25) occur:

$$NH_4^+ + SF_6^- \longrightarrow NH_4F + SF_5 \quad (25)$$

The evidence for reaction (25) is as follows. The reaction (25) is calculated to be exothermic by *ca.* 7 eV. In the coexistence of SF_6 and NH_3, an insoluble product was found in *n*-hexane. The product dissolved easily in water, and the resultant aqueous solution showed the existence of F^- and NH_4^+ ions when alizarin complexone[39] and Nessler's reagent were used respectively. If, in the radiolysis mechanism of *n*-hexane assumed before, the SF_5 produced from reaction (25) caused the *G*-value of the total hexene to increase by 1.44, as is shown in Table 3, and if it simultaneously made the *G*-values of other products to remain almost at the values obtained by the addition of SF_6 only, the following two reactions, (26) and (27) would have also to be assumed and, further, all the hexyl radicals produced from reaction (3) would have to carry out these reactions:

$$SF_5 + C_6H_{13} \begin{cases} \nearrow SF_5H + C_6H_{12} & (26) \\ \searrow SF_5C_6H_{13} & (27) \end{cases}$$

However, it is unreasonable to consider that all the hexyl radicals produced from reaction (3) undergo only reaction (26) and (27), for reactions (20), (21), and (28) could also be considered.

$$SF_5 + SF_5 \longrightarrow S_2F_{10} \quad (28)$$

Consequently, the formation of the $C_6H_{13}^+$ ion during irradiation could be suggested as explaining the results obtained in the coexistence of NH_3 and SF_6. If the fragment ions had been produced according to the pattern of the mass-spectra of *n*-hexane[40] in such a large yield as to correspond to the required yield of $C_6H_{13}^+$ ions, the yield of fragment paraffin products would have been larger than that of the congruent fragment olefin products; *e. g.*, the yield of C_3H_8 would have been larger than that of C_3H_6 in the presence of a radical scavenger because of an H^--transfer reaction from *n*-hexane to a fragment ion. However, such a result could not be obtained, as is shown in Table 3 (column: SO_2). Therefore, H^--transfer reaction from *n*-

hexane to fragment ions, *e. g.*, the $C_3H_7^+$ ion, does not appear to play an important role in the formation of the $C_6H_{13}^+$ ion; the $C_6H_{13}^+$ ion can be thus tentatively assumed to be produced by the direct excitation shown by reaction (29):

$$n\text{-}C_6H_{14} \longrightarrow C_6H_{13}^+ + H + e^- \quad (29)$$

In the case of the addition of SF_6, an additional reaction, (30), may be assumed to occur besides reactions (1) and (2), and in the case of addition of NH_3, an additional reaction, (31), may be assumed to occur besides reactions (3) and (4). The SF_5 produced by reaction (25) probably undergoes reactions (26), (27) and (28).

$$C_6H_{13}^+ + SF_6^- \longrightarrow C_6H_{13} + SF_6 \quad (30)$$

$$C_6H_{13}^+ + NH_3 \longrightarrow C_6H_{12} + NH_4^+ \quad (31)$$

Assuming such a radiolysis mechanism including the existence of the $C_6H_{13}^+$ ion as has been described above, the increase in the hexene yield in the presence of both SF_6 and NH_3 from the value obtained in the presence of SF_6 only would be due to reactions (26) and (31), and the result that the *G*-values of all the products except for hexenes in the presence of both SF_6 and NH_3 are almost the same as in the case of the addition of SF_6 only is qualitatively explicable by the inferences that a part of the hexyl radicals produced by reaction (3) escapes reactions (26) and (27), and that the escaping amount is almost equal to the amount produced by reaction (30) in the presence of SF_6 only. As there seem to be no data on the reactivity of SF_5 except that Ingen *et al.*[41] have recently suggested that SF_5 does not abstract an H atom from cyclohexane, the *G*-value of the $C_6H_{13}^+$ ion can not be accurately estimated. However, it must be less than 1.26, which is the total hexene yield obtained in the presence of SO_2. Further investigation is necessary to confirm that the assumption of the existence of the $C_6H_{13}^+$ ion in the liquid phase is appropriate, for it seems to difficult for such a direct fragmentation as is shown by reaction (29) to occur in the gas phase.[40]

v) The *G*-value of Ionization. Considering the radiolysis mechanism and the effect of added SF_6 described before, the decrease in the *G*-value of the decomposition of *n*-hexane upon the addition of SF_6 from that obtained without additives can be approximately regarded as the *G*-value of the ionization of *n*-hexane in the liquid phase. The *G*-value of the decomposition of *n*-hexane can be obtained by adding the *G*-value of hexyl radicals which react with other radicals to give a *n*-hexane molecule by disproportionation to the *G*-value of the net decomposition of *n*-hexane. The *G*-value of net decomposition in the presence of SF_6 is obtained in the same manner, as is shown by Eqs. (A) and (B), except that the *G*-value obtained in the presence of SF_6 is used instead of that obtained without additives; this value was calculated to be 4.16 from Tables 3 and 4. The *G*-value of hexyl radicals which react with other radicals to give a *n*-hexane molecule by disproportionation is not included in the above *G*-value of the net decomposition; it can be approximately calculated by using the *G*-value of the total dodecanes and the ratio of k_d to k_c, k_d/k_c, where k_d and k_c indicate the average rate constants of the disproportionation reaction and the combination reaction between hexyl radicals respectively. To be exact, there are three kinds of hexyl radicals produced by irradiation, and the ratio of the rate constants of the disproportionation reaction to that of the combination reaction between these radicals seems to be dependent on the combination of these three kinds of radicals. In this work, however, the average rate constants, k_d and k_c, were used as approximate values. Considering the radiolysis mechanism and the effect of added SO_2 described above, the k_d/k_c ratio can be approximately expressed by the following equation, (C):

$$k_d/k_c = \{G_o(C_6H_{12}) - G_1(C_6H_{12}) - \Delta G\}/G_o(C_{12}H_{26}) \quad (C)$$

where $G_0(C_6H_{12})$ and $G_0(C_{12}H_{26})$ indicate the total hexene yield and the total dodecane yield in the absence of additives respectively, where $G_1(C_6H_{12})$ indicates the total hexene yield in the presence of SO_2, and where ΔG indicates the hexene yield formed by reaction (17) in the absence of additives. ΔG was calculated by using the radical yields obtained by Holroyd[42] and the *G*-values of the C_7-C_{10} products shown in Table 2 on the assumptions that the ratio of the rate constants of the disproportionation reactions, (17) and (18), to the combination reaction, (19), is 0.25 and that the rate constant of reaction (17) is equal to that of reaction (18). Thus, ΔG was calculated to be about 0.09. By substituting the values of $G_0(C_6H_{12})$, $G_0(C_{12}H_{26})$, and $G_1(C_6H_{12})$ shown in Tables 3 and 4, and ΔG for Eq. (C), k_d/k_c was estimated to be 1.33. Consequently, the decomposition yield in the presence of SF_6 was calculated to be 5.05 by adding the *G*-value of the disproportionation reaction of the hexyl radical, 0.89, to the *G*-value of the net decomposition, 4.16. On the other hand, the decomposition yield in the absence of additives was calculated to be 9.02 in the same manner. The difference, 3.97, can be regarded as the *G*-value by which the decomposition of *n*-hexane is suppressed by the added SF_6; it may also be regarded as approximately the *G*-value of the ionization of *n*-hexane in the liquid phase. This value is a little smaller than the value, 4.27, obtained by using the

41) J. W. F. van Ingen and W. A. Cramer, *J. Phys. Chem.*, **74**, 1134 (1970).

42) R. A. Holroyd, "Aspects of Hydrocarbon Radiolysis," ed. by T. Gäumann and J. Hoigné, Academic Press, New York, N. Y. (1968), p. 13.

W-value[43] of n-hexane in the gas phase, but it is close to the corresponding value, 3.9, obtained for liquid cyclohexane by Warman *et al.*[44]

vi) $G(N_2)$ in the Presence of N_2O. In the presence of N_2O, the following reaction, (32), which shows the electron - scavenging effect of N_2O, is well known[8,45,46] as one of the processes which bring about nitrogen:

$$e^- + N_2O \longrightarrow N_2 + O^- \qquad (32)$$

Though reaction (33) also produces nitrogen, this reaction may be ruled out because the rate constant of this reaction is relatively small, *i.e.*, $k = 1.2 \times 10^4 M^{-1}\ sec^{-1}$ at 150°C.[47]

$$H + N_2O \xrightarrow{k} HO + N_2 \qquad (33)$$

As another reaction producing nitrogen, Holroyd[48] has suggested the following reaction, (34), which includes the decomposition of N_2O by excitation transfer from the excited n-hexane to N_2O:

$$n\text{-}C_6H_{14}^* + N_2O \longrightarrow n\text{-}C_6H_{14} + N_2 + O \qquad (34)$$

Though the formation of nitrogen as a result of a subsequent reaction of O^- ion with N_2O can not be excluded completely, such a reaction to form nitrogen may tentatively be assumed to be negligible compared with the reaction of the O^- ion with n-hexane because the latter reaction seems to be quite fast (the rate constant of hydrogen - atom abstraction reaction from n-C_4H_{10} by the O^- ion has been reported to be $7.2 \times 10^{11} M^{-1}\ sec^{-1}$ in the gas phase).[49] By using the G-value of ionization obtained in the previous section, the $G(N_2)$ evolving from reaction (32) may be 3.97 at most. On the other hand, as may be seen in Fig. 6, $G(N_2)$ in the presence of N_2O shows little increase at a concentration of about 0.5M and the G-value at 0.5M of N_2O was 5.29. At least, the difference in these G-values, 1.32, may be attributed to a reaction other than reaction (32). Assuming that reaction (34) is responsible for this difference, and that the O^- ion and the oxygen atom produced by reactions (32) and (34) respectively subsequently undergo the following reactions, (35) to (39), water should be observed at the same G-value as that of nitrogen, and the decomposition yield of n-hexane in the presence of N_2O should increase by at least the G-value, 2.64, which is calculated to be twice as much as the G-value of reaction (34):

$$O^- + n\text{-}C_6H_{14} \longrightarrow OH^- + C_6H_{13} \qquad (35)$$

$$OH^- + n\text{-}C_6H_{14}^+ \longrightarrow H_2O + C_6H_{13} \qquad (36)$$

$$OH^- + C_6H_{13}^+ \longrightarrow H_2O + C_6H_{12} \qquad (37)$$

$$O + n\text{-}C_6H_{14} \longrightarrow OH + C_6H_{13} \qquad (38)$$

$$OH + n\text{-}C_6H_{14} \longrightarrow H_2O + C_6H_{13} \qquad (39)$$

Gäumann *et al.*[5,7] have reported that, in the same system as was studied in this work, *i.e.*, an n-hexane solution of N_2O, hexanol could not be observed as a product, but that water was observed in yield of 3.2 ± 0.8 at the N_2O concentration of 0.06M. This G-value of water is approximately equal to the G-value of nitrogen, 3.35, as may be seen in Fig. 6. This is not inconsistent with the reaction mechanism discussed above in terms of the yield of nitrogen. On the other hand, the decomposition yield of n-hexane in the presence of N_2O was calculated to be 11.28 by using the product yields shown in Tables 3 and 4 and the value of k_d/k_c in the manner described earlier. Since the decomposition yield of n-hexane in the absence of additives is 9.02, the difference in these values, 2.26, may be regarded as the G-value by which the decomposition of n-hexane is promoted by the addition of N_2O. This value is close to the value, 2.64, mentioned earlier. This result seems to support the reaction mechanism supposed earlier in regard to the yield of nitrogen. For the purpose of clarifying further the mechanism for producing nitrogen, however, it is necessary to measure more accurately the yields of water and other oxygenated products.

The authors wish to express their thanks to Dr. S. Sato, Dr. H. Yamazaki and Dr. Y. Hatano of this institute and Dr. T. Miyazaki of Nagoya University for their helpful suggestions. They also wish to thank Miss H. Yamaguchi for assistance in preparing the manuscript.

The Temperature Dependence of Hole Injection into Anthracene Crystals

Akihiko YAMAGISHI*1 and Mitsuyuki SOMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 29, 1970)

The temperature dependence of dark- and photo-currents was studied for the hole injection into anthracene crystals between 0 and 30°C. It was observed that the photocurrent or, as has been previously established, the electron-transfer rate from an excited anthracene crystal to an acceptor had a small temperature dependence, while the dark current or the electron-transfer rate from the crystal in its ground state to an acceptor had a definite value of activation energy. The observed small activation entropy for the dark reaction was interpreted in terms of Marcus' theory, and the small polarizability of the organic crystal was, accordingly, suggested to increase the probability of the electron transfer.

During the past few years, a considerable number of studies have been concerned with the electron-transfer reactions involving organic molecules. The hole injection into an organic crystal from electrodes is regarded as a reaction of this type. The saturation current which appears in a sufficiently high voltage region is associated with the rate of the electron-transfer process between the organic molecule (Ar) on the crystal surface and an organic or inorganic acceptor (M) in an electrode;

$$Ar + M \longrightarrow Ar^+ + M^- \qquad (1)$$

Although some pieces of evidence indicate that a qualitative interpretation of this reaction is possible on the basis of the "outersphere" type of reaction mechanism, no direct measurement has yet been performed to show that this process has an activation free energy such as is predicted by the theory.

This work is concerned with the temperature dependence of the saturation current and, for the most part, deals qualitatively with the factors influencing the rate of this process.*2

Several previous theoretical discussions have been presented, notably by Mehr.[1] Applying Marcus' theory,[2] he attempted to calculate the probability of the electron transfer from an organic crystal to an electron acceptor. His results demonstrated a qualitative agreement with the experimental results. It is, however, still open to question whether or not the theory is consistent with the temperature dependence and other features of the process.

In the present work, an attempt has been made to estimate the activation free energy and to examine the applicability of the Marcus theory.

Experimental

Single crystal platelets of zone-refined anthracene about 50 μ-thick were obtained by the sublimation technique. They were mounted with paraffin wax on the glass cell which is shown in Fig. 1. The back side of the cell, on which the negative potential was applied, contained an aqueous solution of the injecting species. The surface area of the anthracene crystal in contact with the solution was about 0.01 cm^2.

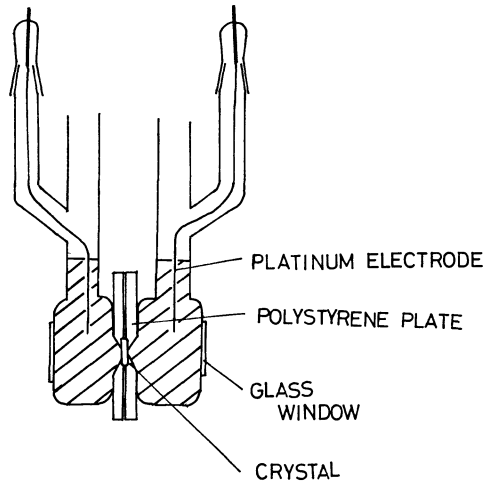

Fig. 1. Measuring cell.

2) R. A. Marcus, *J. Chem. Phys.*, **24**, 966 (1956); **38**, 1858 (1963).

When the dc photocurrent in the above arrangement was measured, the front side was illuminated by a tungsten lamp with a filter which had a maximum transmission at 401 nm and a half width of 11 nm.

The current was measured with a Kawaguchi-type, direct coupled ammeter, Model NA-12E.

The crystals of the other organic molecules were obtained in the following ways:

a) Tetracene was purified by repeated sublimation and was sublimed in a sealed tube under N_2 atmosphere to form single crystals.

b) Phenanthrene and *p*-terphenyl were zone-refined, and single crystals of them were obtained by the sublimation method.

The temperature of the cell was controlled by immersing it in a thermostated water bath.

Results

A. Photocurrents. Ethanol acted as a hole-injecting electrode for the illuminated anthracene crystal, and the various electron acceptors in the electrode were shown to enhance the hole-photocurrent.[3] Phthalonitrile (PN) dissolved in the ethanol electrode was found to enhance the photocurrent, as is shown in Fig. 2. It had previously been observed that tetrachlorophthalonitrile (TCPN) had a similar, but stronger, effect.[3] The increase in the current was proportional to the concentration of the acceptor in both cases. No absorption of light in this wavelength region was found by PN or TCPN. Therefore, the increase in the current is due to the reaction:

$$Ar^* + PN(\text{or TCPN}) \longrightarrow Ar^+ + PN^-(\text{or TCPN}^-)$$

where Ar* is an electronically-excited anthracene and where Ar^+ is an anthracene cation.

The temperature dependence of the photocurrents for the anthracene crystal with the ethanol electrode containing PN or TCPN was measured. The results are shown in Fig. 3 and Table 1. Table 1 gives the apparent activation energy and the magnitude of the saturation currents at room temperature. The difference in the apparent activation energy between PN and TCPN determined experimentally is 1.8 kcal/mol. On the other hand, from the value of the saturation current at room temperature, PN is calculated to have an activation energy about 2.1 kcal/mol larger than TCPN, assuming that they have the same activation entropy.

B. Dark Current. Most of the dark-injecting ions corroded the crystal surface because of their strong oxidizing power. Accordingly, the dark currents more or less decreased with the time.

$K_2Cr_2O_7$ in aqueous H_2SO_4 provided a rather stable dark current, which was kept constant for almost two hours. The results of the temperature dependence measurements of the saturation dark current for the electrode containing $K_2Cr_2O_7$ are shown in Table 2. It definitely confirms that

Table 2. The temperature dependence of the saturation current due to the hole injection by $K_2Cr_2O_7$ (3×10^{-3}M in 1.1NH_2SO_4) into anthracene crystal

Temperature, °C	Saturation current Amp/cm²	Apparent activation energy, kcal/mol
0.5	1.2×10^{-7}	11
12.2	2.4	11
22.0	4.7	12
33.0	9.4	—

the dark current has a constant activation energy over the measured temperature range, which was not necessarily the case for the photocurrent. An additional experiment, which examined the dependence of the saturation dark current on the concentration of $K_2Cr_2O_7$ and the proton, indicated that the saturation dark current follows the expression $i_d=k[HCrO_4^-][H^+]^2$, where k is a constant value and where $[HCrO_4^-]$ and $[H^+]$ are the concentrations of the $HCrO_4^-$ ion and the proton respectively.

In addition, when sulfuric acid was replaced by deuterated sulfuric acid, and the solvent, by heavy water, the current was found to increase by a factor of 3.3 or the kinetic isotope effect was $i_H/i_D=1/3.3$. These facts suggest that protons are involved in this electron-transfer reaction.

In the case of an aqueous solution of the Ce^{4+} ion, the dark current decreased rather rapidly with the time. The reproducible initial values, however, were obtained by washing the crystal surface with ethanol. The temperature dependence was obtained by this technique; the results are given in Fig. 4.

Since the current was proportional to the concentration of the Ce^{4+} ion and was almost independent of the concentration of H_2SO_4 in the range of 0.1—1.0M, it may be concluded that a one-step electron-transfer reaction takes place from the molecule at the crystal surface to the Ce^{4+} ion or, specifically, the $Ce(SO_4)_3^{2-}$ complex ion.[4]

Taking the collision frequency as 2×10^{24} cm^{-2} $sec^{-1}mol^{-1}$, the activation entropy and free energy

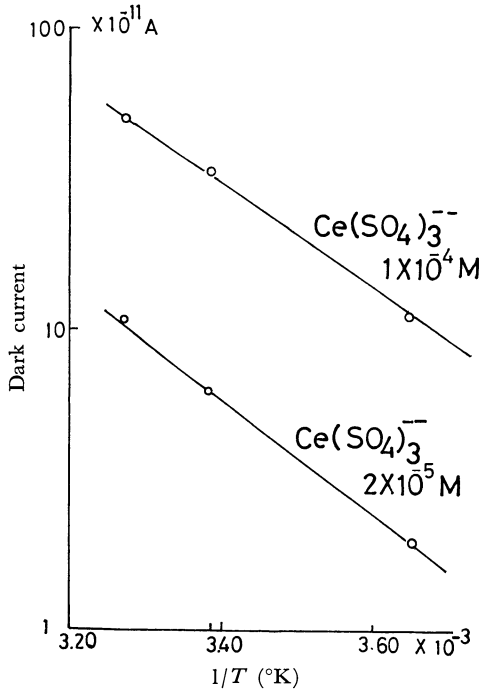

Fig. 4. Temperature dependence of dark currents in anthracene crystal.
Electrode arrangement: Water|Anthracene|Ce^{4+} in aqueous H_2SO_4

were calculated to be as shown in Table 3, in which the thermodynamic data for the isotopic exchange reaction of cerium ions[5] are given for comparison. It is demonstrasted that the activation entropy for the present reaction is considerably smaller than that for the homogeneous reaction. This feature will be discussed in the following section in terms of the Marcus theory.

The dark currents due to the hole injection by Ce^{4+} into various organic crystals were measured at room temperature. As is shown in Fig. 5, all the crystals exhibited current-voltage characteristics similar to those of anthracene. In Table 4, the saturation currents and the activation free

energies are given; the latter were calculated by assuming that the activation entropy is equal to that for anthracene.

Discussion

A. Activation Free Energy. By applying the Marcus theory to the present system, the free energy of activation for the electron-transfer reaction (1) at the surface of organic crystals is expressed as follows:

$$\Delta F^{\ddagger} = \frac{\lambda}{4}\left(1 + \frac{\Delta F^{0}}{\lambda}\right)^{2} \qquad (2)$$

where ΔF° denotes the standard free energy change in the reaction (1) and λ is the energy parameter relating to the orientation of solvent molecules in an activated state. When the reactants are approximated by charged conducting spheres, λ is expressed as:

$$\lambda = \frac{1}{2a_1}\left(\frac{1}{D_{op_1}} - \frac{1}{D_{s_1}}\right) + \frac{1}{2a_2}\left(\frac{1}{D_{op_2}} - \frac{1}{D_{s_2}}\right) - \frac{2}{r_1 + r_2}\left(\frac{1}{D_{op_1} + D_{op_2}} - \frac{1}{D_{s_1} + D_{s_2}}\right) + \frac{1}{4r_1}\left\{\frac{D_{op_1} - D_{op_2}}{D_{op_1}(D_{op_1} + D_{op_2})} - \frac{D_{s_1} - D_{s_2}}{D_{s_1}(D_{s_1} + D_{s_2})}\right\} + \frac{1}{4r_2}\left\{\frac{D_{op_2} - D_{op_1}}{D_{op_2}(D_{op_1} + D_{op_2})} - \frac{D_{s_2} - D_{s_1}}{D_{s_2}(D_{s_1} + D_{s_2})}\right\} \qquad (3)$$

where the 1 and 2 indices refer to the crystal and the electrode medium respectively; where D_{OP} and D_s are the optical and static dielectric constants; r, the distance between the center of a change and the boundary of the two phases, and a, the radius of a charged sphere. The last two terms in (3) arise from the interaction between a real charge and an image charge induced in each medium. It is evident that Eq. (3) gives the known formula for the electron-transfer reaction in the homogeneous phase when $D_1 = D_2$, and for the electrochemical case at metal electrodes when D_1 is infinite.

B. Photocurrent. In a previous paper,[3] it was concluded that the electron-transfer reaction from an excited anthracene at the surface of the crystal to TCPN is almost diffusion-controlled. The present low value of the activation energy for TCPN confirms this; it may be attributed to the diffusion process. The relatively large activation energy for PN may arise from the lower electron affinity. Table 5 gives a rough estimation of ΔF°, the free-energy change of the reaction for each acceptor. It shows that a change of about 0.5 eV in ΔF° caused a change of about 0.09 eV (Table 1) in the activation free energy. As this difference

TABLE 5. THE ESTIMATION OF THE FREE ENERGY CHANGE ΔF° FOR THE PHOTO HOLE INJECTION

Acceptor	Electron affinity (eV)	Solvation energy (eV)	ΔF°[a] (eV)
PN	1.1[b]	2.2[c]	−0.7
TCPN	1.6[d]	2.2[e]	−1.2

a) ΔF° = (ionization energy of anthracene crystal, 5.7 eV) − (electron affinity of acceptor + solvation energy + photon energy, 3.1 eV).

6) R. E. Merrifield and W. D. Phillips, *J. Amer. Chem. Soc.*, **80**, 2778 (1958).

may be attributed to the difference in ΔF^{*} expressed by Eq. (2), the required value of λ is about 1.4 eV. On the other hand, the theoretical estimate gives λ to be about 0.5 eV using Eq. (3), where the radius, a, for the acceptor is assumed to be 3.3 Å and that for anthracene to be 3.0 Å, those values being consistent with the experimental solvation energy in polar solvents[8] and with the polarization energy in the crystal[7] respectively. The experimental value of λ is considerably larger than the theoretical one. As the electron-transfer reaction can reasonably be described as an "outer-sphere" type,[9] this discrepancy cannot be attributed to the contribution of the reorganization in "inner-sphere" to λ, but must be attributed to some flaws in estimating ΔF° and λ, or in the theory itself.

C. Dark Current. According to the Marcus theory, the greater part of the free energy of activation in the electron-transfer process is to be attributed to the reorientation of solvent molecules in the activated state, in which they are not electrostatically in equilibrium. This brings about a largely negative activation entropy, since the solvent molecules lose many degrees of freedom in such a state.

The present system is considered to have half of its medium replaced by an anthracene crystal. Since anthracene crystals have a negligible orientational polarizability as compared with water, the observed low value of the activation entropy supports this prediction.

In order to put this interpretation into more quantitative form, we will below calculate for various cases, since λ determines the main part of the free energy of activation and, moreover, includes the contribution of the solvent molecules described above in terms of polarizability. The λ's were calculated in three cases: 1. the present system (Ce^{4+}/anthracene crystal), 2. the electron-transfer reaction from an anthracene molecule to Ce^{4+} in a water solvent, 3. the homogeneous reaction between Ce^{4+} and Ce^{3+}. The resulting λ's were 0.35 eV, 1.35 eV, and 0.66 eV respectively. These values are calculated from Eqs. (2) and (3), assuming that a_1 of an anthracene molecule is 3.5 Å, and the a_2 values of Ce^{4+} and Ce^{3+} ions, 6 Å. The assumed value of a_1 is obtained as the mean value of the required radius for the ion in polar solvents and in the crystal, while that of a_2 is obtained as a sum of the bond lengths and the van der Waals radius of an oxygen ion. The above results show that value for the (1) reaction is the smallest, or the presence of anthracene crystals lowers the ΔF^{*} because of its low polarizability; this finding is in qualitative agreement with the experimental observations shown in Table 3.

The results given in Table 4 show that the saturation current or electron-transfer rate increases as the ionization potential decreases. It should, however, be noted that the change in the activation free energy with the ionization energy is much smaller than that predicted by Eq. (2). In making this discrepancy clear, we calculated the activation free energy from Eq. (2), assuming each crystal have the same value λ (59 kcal/mol) as anthracene.

Mehr noticed[10] that, in the case of naphthalene crystals, the dark current for Ce^{4+} is much larger than predicted by Eq. (2). He attributed this to the formation of a charge-transfer complex between the naphthalene molecule and the Ce^{4+} ion. However, the present results suggest that the small dependence of the current on the ionization potential is not limited to naphthalene but is, rather, common to all crystals. This fact makes us doubt the applicability of Eq. (2). The real situation may be that, although λ determines the greater part of the activation free energy, ΔF^{*} dose not depend on λ and ΔF° in the way expressed by Eq. (2).

The authors are grateful to Professor Kenzi Tamaru for his constant encouragement and helpful discussions throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3746—3750 (1970)

The Relation between the Amounts of Chemisorbed and Physisorbed Water on Zinc Oxide

Tetsuo MORIMOTO and Mahiko NAGAO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received July 1, 1970)

In the system ZnO-H_2O, in which a jump appears in the adsorption isotherm, the relation between the amounts of chemisorbed and physisorbed water has been investigated, on the basis of the measurements of the water adsorption isotherms and the water content. The first adsorption isotherm of water was measured at 18°C on a sample degassed at 450°C. After degassing the sample again at 30°C, the second adsorption isotherm was obtained at the same temperature as before. The water content (V_h) on the surface of the sample was determined by the successive ignition-loss method. In the present system, the amount of water physisorbed in the first layer is composed of two parts: one (V_{p1}) is the amount adsorbed at lower vapor pressures, up to the beginning of the jump in the isotherm, and the other (V_{p2}), the amount adsorbed during the jump. The amount of water chemisorbed (V_c) during the adsorption process could be estimated as the difference between the monolayer capacities of the first and second isotherms, the total amount of chemisorbed water being the sum of V_h and V_c. The ratio of the total amount of physisorbed water ($V_{p1}+V_{p2}=V_p$), expressed in the number of water molecules per unit of area, to that of chemisorbed water (V_c+V_h), expressed in the number of hydroxyl groups per unit of area, was found to be about 1 : 1 in the first physisorption layer for all the samples tested, irrespective of their origin, while the ratio of V_{p1} to V_{p2} varied extensively with the origin of the samples.

The surface of most metal oxides adsorbs water molecules physically and chemically. In a previous paper,[1] it has been found in TiO_2 (rutile) and two kinds of α-Fe_2O_3 (hematite) that the ratio of the number of physisorbed water molecules in the monolayer to the number of surface hydroxyl groups (chemisorbed water) is about 1 : 2. The type of the water adsorption isotherms on these oxides was that of the polymolecular adsorption isotherm, whereas on zinc oxide the type of the isotherm has been found to be quite different from that on the other metal oxides:[2,3] the amount of water adsorbed increases remarkably in the relative pressure range of 0.2—0.3. No such phenomenon has been found in the other oxide-water systems; it was called the "hump" of the adsorption isotherm in previous papers.[2,3] The purpose of the present work is to ascertain the relation between the amounts of water physisorbed and chemisorbed on zinc oxide by analysing the adsorption isotherms, and to investigate the structure of the adsorption layer in this system.

Experimental

Materials. Three kinds of zinc oxide samples were used in the present work. One of them was the same sample as had been studied previously;[2-4] it was presented from Sakai Kagaku Co., being prepared by burning zinc metal in air (sample A). The second sample was made by the pyrolysis of zinc hydroxide in air, the latter being precipitated by mixing 0.37M ammonia water with a 0.34M zinc-nitrate solution. In the present procedure, the precipitate of zinc hydroxide was first washed sufficiently with distilled water, dried at 100°C, and then calcined at 500°C for 4 hr (sample B). The last sample was prepared from zinc oxalate precipitated by mixing 0.20M zinc-nitrate and 0.22M oxalic-acid solutions. This precipitate was treated in the same way as sample B, and was finally calcined at 500°C for 4 hr (sample C). From X-ray analysis, the sample B and C were found to be only pure zinc oxide, their crystallinity being to the same extent as that of the sample A.

Surface-area Measurement. The specific surface area of the ZnO samples was determined by applying the BET theory to the nitrogen adsorption data which had been obtained at the temperature of liquid nitrogen; the cross-sectional area of a nitrogen molecule was assumed to be 16.2 Å^2.

Water-adsorption Isotherm. The adsorption isotherms of water on the surfaces of ZnO samples were

determined volumetrically by using a usual adsorption apparatus equipped with an oil manometer. About a 10-m^2 sample was used in each measurement. Initially, the sample was degassed at 450°C under a reduced pressure of 10^{-5} Torr for 4 hr, and then the adsorption isotherm of water was measured at 18°C. After the first adsorption isotherm had been obtained, the sample was degassed at 30°C in order to remove only the physisorbed water;[2,5-8] the measurement of the second adsorption isotherm was then carried out at the same temperature as before. The adsorption equilibrium was attained within 30 min after each dose of water vapor. A preliminary experiment of desorption was done on each sample; it revealed no hysteresis, indicating that the samples used were nonporous.

Water-content Measurement. It has become clear that the surfaces of metal oxides placed in an atmosphere have water molecules adsorbed both physically and chemically. The physisorbed water can be removed *in vacuo* at relatively low temperatures, *i. e.*, even at room temperature, whereas the surface hydroxyl groups (chemisorbed water) can be removed only gradually at higher temperatures. The temperature at which the removal of the surface hydroxyl groups starts has been found to vary with the nature of the metal oxides, and to be about 200°C in the case of ZnO.[2] The amount of chemisorbed water, that is, the water content (V_h), on the surfaces of ZnO samples was determined by the successive ignition-loss method[1,9] using the same apparatus as that used for the water-adsorption measurement: the sample was heated at various temperatures *in vacuo*, and the gas evolved at every stage of the treatment was measured volumetrically.

When the ZnO sample was treated *in vacuo* at elevated temperatures, a small amount of a gas other than water vapor was found. The gas expelled was condensed in a vessel kept in liquid nitrogen, and was determined volumetrically in the measuring system after having been re-evaporated at room temperature. Next, when the gas was allowed to condense again at −72°C, a small part of the gas was found to remain uncondensed. When only the water vapor was present in the gas, however, this procedure did not leave a uncondensed gas phase. Mass spectroscopy showed that this uncondensed gas was, for the most part, composed of carbon dioxide. The values (V_h) given in Table 1 are the true water content; they do not include the amount of gas uncondensed at −72°C.

Results and Discussion

The first and second adsorption isotherms of water on ZnO at 18°C are given in Figs. 1, 2, and 3. The sample A shows a remarkable jump in its adsorption isotherm in the relative pressure range of 0.2—0.3, as has been observed in the previous works.[2,3] From Figs. 2 and 3 it is clear that, in the cases of the samples B and C, the jumps are considerably smaller than that of the sample A, though they all appear in the same pressure region. These results present important problems yet to be solved concerning the adsorption properties of the

system ZnO–H_2O: (1) a jump appears on the adsorption isotherm at relative pressures of 0.2—0.3, (2) the height of the jump depends on the origin of the samples, and (3) the relation between the amounts of physisorbed and chemisorbed water is unclear. The former two problems will be discussed in detail in subsequent papers. Here, mainly the last problem will be dealt with, using, for comparison, the data on the other oxides reported previously.[1]

As was reported in the previous paper, the amount of adsorbed water on metal oxide evacuated at an elevated temperature increases with a rise in the pretreatment temperature. Furthermore, it was found that the adsorption isotherms can be treated by the BET method; the plot of the resulting V_m values against the pretreatment temperature suggests the temperature at which the removal of the chemisorbed water starts.[2] In other words, on the surfaces of metal oxides degassed at elevated temperatures, the chemisorption and physisorption of water occur simultaneously, whereas only the physisorption occurs on the surfaces treated at room temperature.[2,5–8] A conventional application of the BET theory to the first adsorption isotherms of water on various kinds of metal oxides, including both physisorbed and chemisorbed water, has given the monolayer capacity.[5–8] Also, in the present system we can apply the BET theory to the initial part of the isotherms and thus obtain the monolayer capacity. Thus, the V_m value in Table 1 is the monolayer capacity calculated from the first adsorption isotherm, and the V_{p_1}, that calculated from the second one. As has been described above, the former should include the physisorbed and chemisorbed water, whereas the latter, only the physisorbed water. The difference between the values V_m and V_{p_1}, therefore, will indicate the amount of water chemisorbed during the adsorption process. V_c in Table 1 is this amount of chemisorbed water expressed in terms of the number of hydroxyl groups per 100 Å² of the surface, by taking into account the fact that one water molecule forms two hydroxyl groups. V_h is the surface water content, being the amount of the water chemisorbed on the surface just before the adsorption process. The sum of V_c and V_h is, therefore, the total amount of water chemisorbed after the adsorption process; this water may act as the sites for the physisorption of water molecules.

On the other hand, by applying the B-point method to the second adsorption isotherm, we can obtain the overall monolayer capacity of physisorption. This value is listed in the V_p column in Table 1. The V_p value may be considered to be composed of two parts: one is the initial part of the adsorption isotherm (V_{p_1}), as has been calculated above, while the other is the part of the jump, the latter being obtained by subtracting V_{p_1} from V_p. Thus, V_{p_2} is the second part of physisorption. In conclusion, the chemisorbed water layer is present as a substrate on which the water molecules are adsorbed physically. Here, we can estimate the relation between the numbers of the molecules present in the two layers up to the attainment of the B point.

This ratio is given in the last column of Table 1, in which the total amount of physisorbed water is

Table 1. The relation between the amounts of chemisorbed and physisorbed water on ZnO

Sample	Calcn. temp. (°C)	Surface area (m^2/g)	V_m (ml(S.T.P.)/m^2)	Physisorbed amount (H_2O molecules/100Å²)			Chemisorbed amount (OH groups/100Å²)			$V_p/(V_c+V_h)$ (H_2O/OH)
				V_{p_1}	V_{p_2}	V_p	V_c	V_h	V_c+V_h

expressed in H_2O molecules/100 Å^2, and that of the underlying chemisorbed water, in OH groups/100Å^2. It may be seen from Table 1 that the ratio is about 1 : 1 for every sample tested.

It is well known that the crystal of ZnO is of the same type as wurtzite. The numbers of the zinc atom on the (0001) and (10$\bar{1}$0) planes, both of which are known to have excellent cleavage,[10,11] can be estimated crystallographically to be 11 and 6/100 Å^2 respectively. If we assume that these two kinds of planes are equally present on the actual surfaces, and that a surface hydroxyl group is bonded to a zinc atom, the total amount of chemisorbed water will become to about 8.5 OH groups/100 Å^2; this figure agrees fairly well with the results in Table 1. Furthermore, the experimental results show that the water molecules are adsorbed on these surface hydroxyl groups in the ratio of 1:1. If the molecular area of water is assumed to be 10.8 Å^2, as usual, it is found that the number of water molecules of 7—8/100 Å^2 is suitable to be adsorbed as a monolayer. When we calculate the ratio of each physisorbed amount, V_{p_1} or V_{p_2}, to the total amount of chemisorbed water, they are very different from each other, depending on the origin of the samples. With the sample A, V_{p_1} is smaller than V_{p_2}, whereas the situation is quite the reverse with the samples B and C; the value of V_{p_2} is only 20% of the value of V_{p_1} in the case of the sample B and only 41% in the case of the sample C respectively, corresponding to the smaller jump in the isotherms with the two samples than with the sample A. Here it is noticeable that the larger the V_{p_1} value, the smaller the V_{p_2} value.

In the cases of α-Fe_2O_3 (hematite) and TiO_2 (rutile), which give the polymolecular adsorption isotherm of water, the ratio of the amounts of physisorbed to chemisorbed water has been found to be nearly 1 : 2, as has been reported previously.[1] In the present work, we could not prepare the sample of ZnO, which gives a usual polymolecular adsorption isotherm of water, though Egorov *et al.*[11] obtained a sample of ZnO in which the jump was not observed in the water adsorption isotherm. It can be seen from Fig. 4 that the second adsorption isotherms of the three samples agree fairly well with one another in the range of relative pressures higher than 0.3 (*i. e.*, above the "B-point"), but at lower relative pressures they are quite different, depending on the origin of the samples. The results show that V_{p_2} decreases when V_{p_1} increases, the sum of V_{p_1} and V_{p_2} keeping almost constant. From the features of the adsorption isotherms observed here, we can

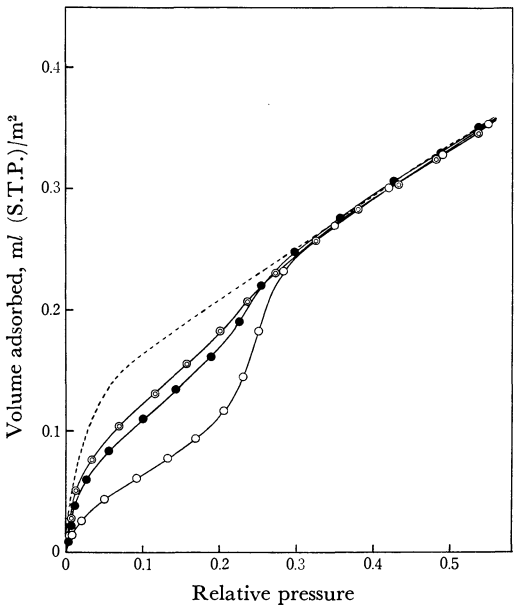

Fig. 4. Second adsorption isotherms of water at 18°C on ZnO samples: ○, sample A; ◎, sample B; ●, sample C; dotted line represents a hypothetical isotherm.

expect, as the limiting case, an adsorption isotherm in which the jump does not appear. The curve expressed by the dotted line in Fig. 4 shows this hypothetical isotherm, which is obtained by extrapolating the upper part of the real isotherms to the lower pressures. By applying the BET theory to this hypothetical isotherm, we can obtain the V_m value and calculate the other quantities as being similar to those obtained in the preceding paper.[1] The values thus obtained are given in the bottom row of Table 1. As a matter of fact, when the initial adsorption amount increases, the slope of the linear part of the adsorption isotherm after the attainment of the monolayer coverage often tends to fall. Therefore, the hypothetical isotherm may scarcely be realized unless all the features of the isotherm are changed. However, there is a great indication in Table 1 that if we prepare a sample of ZnO which does not reveal the jump in the water adsorption isotherm, we can expect the ratio of H_2O : OH to rise to 1 : 2.

ed the adsorption isotherms on systems containing a nonpolar adsorbent with homotattic surfaces and found that the nonpolar molecules adsorbed on such surfaces behave like a mobile film according to the two-dimensional van der Waals equation. Furthermore, when the pressure exceeds a limiting value, the film give rise to a two-dimensional phase transition, resulting in a sudden change to a close-packed state of the adsorbed molecules. Also, in the present system a similar circumstance may hold between the surfaces of the ZnO and the water molecules: the amount of water physisorbed on the homotattic layer of surface hydroxyl groups on ZnO is depressed initially, but increases steeply to the adsorption ratio of 1 : 1 (H_2O : OH) when the vapor pressure exceeds a certain value.

Usually, the surfaces of most metal oxides are considered to be inhomogeneous, and it has been reported that, on such surfaces, the adsorption of molecules first occurs on the highest energy sites and later on successively lower energy sites. Moreover, on such surfaces no jump in the adsorption isotherm appears and the stable ratio of H_2O : OH is 1 : 2 in the first layer of adsorption.[1] On the contrary, the present system shows depressed adsorption at lower pressures and a stable ratio of 1 : 1 (H_2O : OH). Also, this comparison makes it possible to predict that the surfaces of ZnO may be homotattic for the physisorption of water molecules. Further investigations will appear in the next paper.

Dielectric Absorption in Crystalline Pentachloronitrobenzene

Ariyuki AIHARA, Chikazu KITAZAWA and Akira NOHARA

Department of Materials Science, Denki-Tsushin University, Chofu, Tokyo

(Received July 2, 1970)

Dielectric measurements have been performed with pentachloronitrobenzene in polycrystalline state using a trans-former bridge, between 30 Hz and 1 MHz and in the temperature range 20—99°C. The substance shows distinct dielectric absorption in the frequency and temperature ranges, presumably due to molecular rotation in the solid state similar to that of pentachlorotoluene and 1,2,4-trimethyl-3,5,6-trichlorobenzene as has been found by Turney. The frequency factor and the energy of the barrier for the rotation are $\log A = 15.2$ (A in sec^{-1}) and $\Delta H = 16.1$ kcal/mol. A possible mechanism for the rotational transition of the molecule in the crystalline lattice has been discussed. The dipole moment of this substance in benzene solution has been measured, the result being $\mu = 2.33$ Debye.

Despite the fact that both pentachlorotoluene and 1,2,4-trimethyl-3,5,6-trichlorobenzene in crystalline state show anomalous dielectric dispersion at radio frequencies, without undergoing any phase transitions,[1] hexasubstituted benzenes with the nitro group as one of the substituents have been thought to show no molecular rotation in the solid state.[2] Of six hexasubstituted benzenes with one or two nitro groups among the substituents, only 1,2,3,4-tetramethyl-5,6-dinitrobenzene has been referred to by White, Biggs and Morgan[3] as a substance showing molecular rotation in the solid state.

Pentachloronitrobenzene, whose molecular shape and symmetry might be regarded as similar to that of pentachlorotoluene, is a substance left so far uninvestigated in relation to this problem. Thus, with a view that this substance may also exhibit molecular rotation in the crystalline state, a dielectric investigation on pentachloronitrobenzene has been performed. The result seems to confirm our view that the dielectric absorption should be due to rotational movement of the molecule.

In connection with this, the dipole moment of this molecule, too, has been measured in benzene solutions.

Experimental

Material. Commercial product was first recrystallized from ethanol several times and then purified by means of zone-refining. The sample was subjected to dielectric measurements as a disc of 4 cm in diameter

and 1.08 mm in thickness, which was shaped under the pressure of 3 ton/cm^2.

Apparatus. Measurements of dielectric permittivity and loss in the solid phase were performed with a transformer bridge*1 over the frequency range of 30 Hz to 1 MHz and at temperatures 20—99°C. The measuring cell consists of two circular plate electrodes and a guard ring, the diameters of the main electrode being 37 mm. The separation of the two electrodes can be adjusted so as to make close contact with the surface of samples.

The dipole moment of the substance in benzene solution was measured with a heterodyne double-beat permittivity measuring equipment (1 MHz).[4]

Results and Discussion

In view of the possible effect of cold working on dielectric loss factors, the sample was kept at a temperature some degrees below the melting point 151.0°C for several hours prior to the measurement. After repeating runs three times, observed values of ε' and ε'' were found to remain almost invariant.

The plot of ε' and ε'' as a function of frequency at several temperatures are shown in Fig. 1. We see that pentachloronitrobenzene exhibits distinct anomalous dispersions in the frequency and temperature ranges investigated, region of the dispersion making a gradual shift toward the higher frequency range with the rise of temperature.

The absorption curves are somewhat broader than the normal Debye absorption due presumably to the distribution of relaxation times, while the heights of the absorption curves, that is the intensity of maximum absorption, ε''_{max}, show a slight tendency to decrease with the rise of temperatures.

The Cole-Cole plots of ε' versus ε'' (Fig. 2) form arcs, the values of distribution parameters decreasing from $\beta=0.21$ at 20.0°C to 0.05 at 99.1°C. It is obvious that the absorption will become a real Debye type at higher temperatures. The values of static and optical permittivities, ε_0' and ε'_∞, have been determined from these diagrams as listed in Table 1.

Table 1. Experimental values of static permittivities (ε_0'), optical permittivities (ε'_∞), maximum loss factors (ε''_{max}), and distribution parameters (β)

Temp. °K	ε_0'	ε'_∞	$(\varepsilon_0'-\varepsilon'_\infty)$	$2\varepsilon''_{max}$	β
293.2	4.09	2.58	1.51	1.16	0.21
313.6	4.00	2.55	1.45	1.12	0.15
333.2	3.87	2.52	1.35	1.10	0.14
353.9	3.74	2.49	1.25	1.08	0.08
373.2	3.65	2.46	1.19	1.06	0.05

The dielectric dispersion $(\varepsilon_0'-\varepsilon'_\infty)$ which should be equal to $2\,\varepsilon''_{max}$ if the absorption follows the Debye mechanism, increases almost linearly with $1/T$, T being the temperature expressed in °K. A comparison of $(\varepsilon_0'-\varepsilon'_\infty)$ with $2\,\varepsilon''_{max}$ (experimental) is also shown in the table. Considering the rather broad feature of these absorptions, $(\varepsilon_0'-\varepsilon'_\infty)/2$ should be

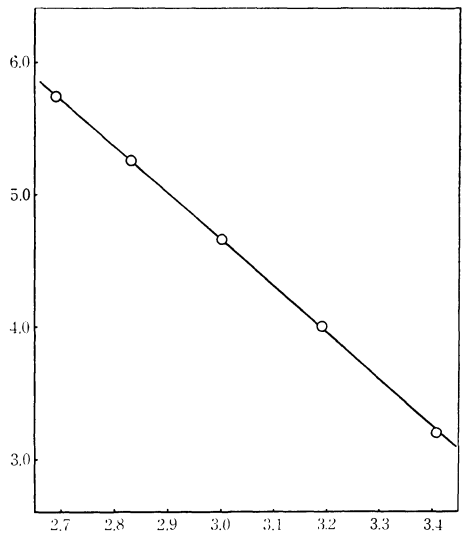

Fig. 3. Relation between $\log f_{max}$ and $1/T$.

TABLE 2. COMPARISON OF FREQUENCY FACTORS, ENERGY BARRIERS, AND OTHER ENERGY DATA

Substances	$\log A$ (A in sec^{-1})	ΔH kcal/mol	ΔS e.u.	$\Delta F^{20°}$ kcal/mol	ΔE_0 kcal/mol
$C_6Cl_5NO_2$	15.2	16.1	12.8	12.4	0
$C_6Cl_5CH_3$[1]	14.1	11.6	9.3	8.9	0
$C_6(CH_3)_3Cl_3$[1]	14.7	10.3	12.3	6.7	0

taken to stand for the intensity of maximum dielectric absorption.

The enthalpy of activation for the molecular rotation in the solid state ΔH as well as the frequency factor A have been calculated with the use of the equation[5,6]

$$f_{max} = A \exp(-\Delta H/\boldsymbol{R}T), \quad (1)$$

where f_{max} means the frequency at which the absorption becomes of maximum value, $\boldsymbol{R}$ is the gas constant and T is the absolute temperature;

$$\Delta H = 16.1 \text{ kcal/mol},$$
$$\log A = 15.2 \ (A \text{ in } sec^{-1}).$$

These values can be compared with those of pentachlorotoluene and 1,2,4-trimethyl-3,5,6-trichlorobenzene obtained by Turney[1] as shown in Table 2.

ΔE_0, the difference of energy in equilibrium positions between which the rotational transitions of the dipole might occur in the crystalline lattice, can be calculated according to the equation[6]

$$\varepsilon_0' - \varepsilon_\infty' = C/T\{1 + \cosh(\Delta E_0/\boldsymbol{R}T)\}, \quad (2)$$

where C is a constant. This expression approximates to

$$\varepsilon_0' - \varepsilon_\infty' = B \exp(-\Delta E_0/\boldsymbol{R}T)/T \quad (3)$$

when $\Delta E_0 \gg \boldsymbol{R}T$, B being a constant. If $\Delta E_0 \doteqdot 0$, we get a simple relation

$$\varepsilon_0' - \varepsilon_\infty' = C/2T, \quad (4)$$

that is, the magnitude of dielectric dispersion is inversely proportional to temperature. Conversely, we may safely conclude that the energy difference ΔE_0 must be almost zero when $(\varepsilon_0' - \varepsilon_\infty')$ increases with 1/T, as is the case with pentachloronitrobenzene.

An inspection of Table 2 leads to an interesting conclusion that despite a bulky substituent, $-NO_2$, instead of $-CH_3$, the molecule of pentachloronitrobenzene can perform a rotational transition in the solid state probably about an axis perpendicular to the molecular plane, as has been found with pentachlorotoluene by Turney,[1] but with a larger potential barrier as well as a larger entropy change for rotation. The difference of entropy between the stationary and transitional positions, ΔS, was calculated assuming $f_0/\pi = 10^{12}$ sec^{-1} [6] in the following relation between A and ΔS.

5) H. Fröhlich, "Theory of Dielectrics," Oxford Univ. Press, Oxford (1949), Section 11.

6) J. S. Dryden and R. J. Meakins, *Rev. Pure Appl. Chem.*, **7**, 15 (1957); R. J. Meakins, *Progress in Dielectrics*, **3**, 150 (1961).

$$A = f_0/\pi \cdot \exp(\Delta S/R), \quad (5)$$

where f_0 is the frequency of oscillation of the dipole about the equilibrium position. Due to this rather unfavorable assumption, no serious conclusion should be drawn from the larger value of ΔS, 12.8 cal/deg. mol, for pentachloronitrobenz enecompared with that of pentachlorotoluene, 9.3 cal/deg. mol,[1] although the difference suggests the more regular arrangement of molecules in the crystalline lattice in the case of pentachloronitrobenzene.

In relation to the mode of aggregation of molecules in crystalline state, Fröhlich's $B(T)$ function has also been examined.

$$B(T) = 4\pi N_0 \overline{\mathbf{mm}^*}/3k = (\varepsilon_0 - \varepsilon_\infty)(2\varepsilon_0 + \varepsilon_\infty)T/3\varepsilon_\infty \quad (6)$$

where $\overline{\mathbf{mm}^*}$ is the average value of the product $\mathbf{mm}^*$, $\mathbf{m}$ and $\mathbf{m}^*$ being a dipole moment and a moment polarized by the former, respectively, k is Boltzmann's constant and N_0 is the number of dipoles per unit volume. According to Fröhlich,[7] $B(T)$ should be constant independent of temperature, "if Onsager's equation holds, *i. e.*, if the dipole moment of a molecule can be considered as a constant, and if there are no short-range forces leading to mutual orientation of dipole." Actually the calculated values of $B(T)$ with pentachloronitrobenzene remain almost constant independent of the rise of temperature as shown in Table 3, suggesting that there is no particular preferential interaction between neighboring molecules, such as a pair formation. In Table 3 are also shown the values of dipole moment in the solid state calculated tentatively with the use of Onsager's equation which has been derived for the pure dipolar liquid:[8]

$$\varepsilon_0 - \varepsilon_\infty = 4\pi N_0 \mu^2 \varepsilon_0 (\varepsilon_\infty + 2)^2 / 9kT(2\varepsilon_0 + \varepsilon_\infty) \quad (7)$$

where ε_0, ε_∞, N_0, k and T have the same meanings as in (6), and μ is the dipole moment.

Table 3. Fröhlich's $B(T)$ function and the dipole moment in solid state

Temp. °C	$B(T)\times 10^{-2}$ deg.	μ Debye (solid phase)
20.0	3.88	1.18
40.4	4.01	1.19
60.0	3.98	1.20
80.7	3.94	1.21
99.1	3.95	—[a]

a) The μ value at 99.1°C was not calculated because of the lack of the density value: μ values at other temperatures were calculated using the density values, 1.959 (20.3°C), 1.954 (40.4°C), 1.949 (60.0°C), 1.944 (80.7°C), g/cc, measured with a pycnometer.

The dipole moment values in Table 3 are definitely lower than those in benzene solutions, 2.33 and 2.32 Debyes (28.8°C), obtained by following the usual Halverstadt-Kumler procedure and that of Guggenheim-Smith, respectively.

Experimental details of the measurement of dipole moment in benzene solutions are to be published elsewhere,[9] but some of the data are shown in Table 4.

The fact that the moment values, estimated for a molecule in the solid state, applying Onsager's equation, are far smaller than the actual value of the dipole moment in benzene solutions, offers clear evidence that the equilibrium positions for the dipole to perform rotational transitions in the crystalline lattice should be less than 180° apart instead of being located in completely opposite directions, *i. e.*, 180° separation.

Thus, the molecule of pentachloronitrobenzene in the crystalline state is supposed to perform rotational transitions between several equilibrium posi-

tions, equal in energy but separated from each other by potential barriers of different magnitude, which are most likely to become identical at temperatures higher than 100°C leading to a single relaxation time.

No mention has been made so far of the molecular structure of pentachloronitrobenzene. Problems to be solved in this connection are whether the molecule is distorted or not with respect to the C–Cl bonding, on the one hand, and how far twisted the nitro group is about the C–N bond, on the other.

This twisting of the nitro group may be inevitable for reducing the steric repulsion between oxygen and chlorine atoms on both ortho positions to the nitro group,[10] which in turn produces a possibility of the molecule existing as two isomeric conformations, with a nitro group twisted clockwise and with a group twisted anti-clockwise, and consequently, interconversion between the two isomers may happen through a potential barrier separating the two equilibrium orientations of the nitro group. It is probable, therefore, that the nitro group will acquire, on the average, almost axial symmetry around the C–N bond and hindrance against rotation of the molecule as a whole, in the crystalline lattice, will be fairly reduced.

In order to discuss the mechanism of dielectric absorption more precisely, details of molecular as well as crystal structure of this substance are necessary. A three-dimensional X-ray crystal structure analysis with pentachloronitrobenzene is now in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3754—3761 (1970)

Electronic Structure of Lone Pairs. V.*1 Thiothiophthene and 2,5-Dimethyl-dithiofurophthene

Hiroko YAMABE, Hiroshi KATO*2 and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 4, 1970)

The electronic structure and the electronic transition of thiothiophthene(I) and 2,5-dimethyl-dithiofurophthene(II) are calculated by the semi-empirical ASMO SCF method. The E_{AB} value, used instead of the bond order of the S···S bond of Compound I, and those of the S···S bond and the S···O interaction of Compound II are found to be −6.125 eV, −12.957 eV, and −0.740 eV respectively. These E_{AB} values are compared with that of the previously-obtained transannular interaction and the hydrogen bond of water dimers calculated by the same method. The properties of the electronic transition of these compounds are discussed. No separability of the π–$\pi^*(B_2)$-type and σ-$\sigma^*(B_2)$-type transitions of the Compound I is indicated. The orbital energy of the highest occupied MO of the Compound I is remarkably high, which corresponds well with the very small I_p value.

Once the structures of thiothiophthene (I of Fig. 1) and 2,5-dimethyl-dithiofurophthene (II of Fig. 1) had been determined correctly, using X-ray diffraction, and once the concept of the 'no-bond' resonance of thiothiophthene had been presented by Bezzi *et al.*[1–3] in 1958, various investigations of their properties were performed. Thiothiophthene has been prepared by different routes, and many derivatives*3 have been prepared, employing

the UV, IR, and NMR techniques.[4-12] Some reviews[13] of these compounds have been presented. According to Bezzi *et al.*[1-3] the two end sulfur atoms of thiothiophthene are equivalent, judging from the results of X-ray analysis.*4 The S–S bond length is 2.36 Å, greater than that of 2.00—2.10 Å in disulfides, but less than the sum of the van der Waals radii of 3.07 Å between two sulfur atoms.[13] The C–C bonds are all in the 1.37—1.38 Å range, the bond length of aromatic double bonds. This compound was considered to exhibit a 'no-bond' resonance,[1] which confers an aromatic character on the rings, this is in agreement with the properties of the substance[3] (see Fig. 2).

In Compound II[2,13], the S–S distance of 2.12 Å is the normal bond length, suggesting a contribution by structure IIa of Fig. 2. However, the S–O distance*5 of 2.41 Å is halfway between the normal S–O single bond length and the sum of the van der Waals radii of the sulfur and oxygen atoms.[13] This compound shows no lines of anormal shift for CO-CH_3 protons in its NMR[4,5] spectrum, and it lacks infrared carbonyl absorption.[6,12] The absence of a ketonic character can be accounted for by the polarized structure of IIb. Bezzi *et al.* established that the essential features characterizing thiothiophthene were present in Compound II, but to a small extent; therefore, the actual electronic distribution is best represented by the formula IIa in Fig. 2.

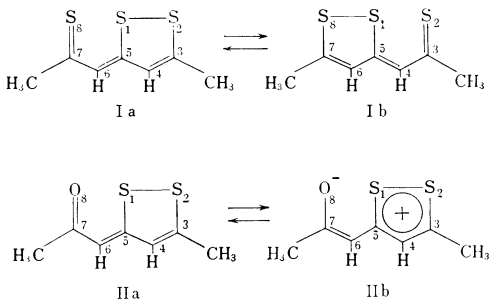

Fig. 2

As for the theoretical investigation of these molecules, a simple LCAO MO calculation of the electronic structure, including only the *p* orbitals, was carried out by Giacometti;[14] they mentioned that

the abnormal bond lengths can be interpreted. Later Maeda[13,15] reported that the S–S–C bond angles and the S–S bond lengths of Compound I can be understood by considering the system to be bicyclic and the central sulfur atom to be quadrivalent, judging from the *p–d* hybridization. Gleiter and Hoffmann[16] regarded the bonding in Compound I as an electron-rich, three-centered bond.[6] Very recently theoretical work on Compound I and its analogues has been reported by Johnstone *et al.*[17] They observed the I_p and UV spectra and made a semi-empirical SCF LCAO calculation of the π electron system. However, no MO calculation including all the valence σ and π electrons has yet been made, as far as we know.

Previously we investigated the electronic structure and the interaction of the lone pair of the sulfur atom of trimethylene disulfide, $(CH_2)_3S_2$,[18] which is a five-membered cyclic disulfide. It seemed that it would be interesting to know the interaction of the lone pair of the S···S···S system of Compound I and to compare it with the S–S system of trimethylene disulfide. Futhermore, compound I has a fused form of five-membered cyclic disulfides, and its electronic structure has been calculated before.[18] On the other hand, the S···S interaction of compound I and the S···O interaction of Compound II have the character of a transannular interaction. It seemed that there would be some value in obtaining the amount of such an interaction in terms of the bond order and in comparing it with the value obtained previously in our MO calculation of the transannular interaction.[19] This S···S···S interaction of Compound I is also interesting as a form of reaction intermediate.[20] Though the UV spectra of Compound I[7] and its analogues[8,9] have been observed, an interpretation of them based on MO calculations has been tried for only an electron system.[17]

Under these circumstances, we calculated the electronic structures of Compounds I and II by the semi-empirical ASMO SCF method,[21],*6 taking into account all the valence and electrons, but excluding the contribution of the *d* orbitals of the sulfur. The bond lengths and bond angles exployed here are shown in Fig. 1; they were taken from the work by Bezzi *et al.*,[1] but slightly modified.

Results and Discussion

Population Analysis of Thiothiophthene. In the present treatment, the following E_{AB} value[21] is used instead of the bond order:

$$E_{AB} = \sum_{r}^{\text{on A}} \sum_{s}^{\text{on B}} P_{rs}(H_{rs}+F_{rs})$$

where H_{rs} is the core resonance integral,[21] where F_{rs} is the Fock's operator, and where $\sum_{r}^{\text{on A}}$ denotes

the summation over all the valence AO's belonging to the A atom. The atomic density and the E_{AB} value of Compound I are shown in Fig. 3, and those of Compound II, in Fig. 4. The π bond orders of Compounds I and II are shown in Figs. 5 and 6 respectively. The atomic orbital (AO) density of Compound I is given in Table 1, and that of Compound II, in Table 2.

First we will discuss the electron density of thiothiophthene. From the value of the atomic density of Fig. 3, three sulfur atoms of Compound I polarize $\bar{S}$–$\bar{S}$–$\overset{+}{S}$. The AO densities of the p_z orbital of the S_1 and S_2 atoms, which constitute a MO of the π type with the p_z orbitals of the carbon atoms, are 1.866 and 1.789.*[7] In the limiting structure of Ia in Fig. 2, 5 electrons are offered formally to the π orbital from three sulfur atoms, namely, two lone pairs from the central sulfur S_1 atom and the S_2 atom, and a p_z electron from the S_8 atom. If this contribution of the S_2 and S_8 atoms is replaced mutually, a similar relation is seen in the structure I_b. The summation of the AO densities of the p_z AO of the three sulfur atoms, 5.444, nearly equals the above-mentioned value of 5. The excess electrons of 0.444 are drawn mainly from the electron of the carbon (see Table 1). Four electrons from the three sulfuratoms contribute formally to the S···S···S p_σ bond of I_a, namely two p_x electrons from the S_1 and S_2 atoms, and a lone pair (p_x) from the S_8 atom. The summation of the AO densities of the p_x AO's is 4.090; it agrees with the above value, 4.0. The AO densities of the p_x AO of the S_2 and S_8 atoms are both 1.588. This value is reasonable, because the offered electrons from the S_2 atom and S_8 atoms are formally 3.0. As the electron density of the p_y AO of the S_1 and S_2 atoms is considerably larger than 1.0, and as that of the C_3 or C_5 atom is smaller than 1.0, the electrons of the S–C p_σ bond can be said to depend much on the sulfur atom. Judging from the E_{AB} value between the S_1 and the S_2 atoms (−6.125 eV), the S···S bond is considerably weaker than the other bonds, while it should be much stronger than the usual transannular interaction.*[7] However, this interaction may be considered to be a sort of transannular interaction, in an extended sense, between the p_x orbital (a pseudo lone-pair orbital) of the S_2 atom and the central atom S_1. Otherwise, it can be regarded as a sort of intramolecular nucleophilic interaction of the p_x orbital of the S_2 to the S_1–S_8 bond. As will be shown later, in Table 5, the MO coefficient of $S_2(x)$ in HO and those of $S_1(x)$ and $S_8(x)$ in LV are large. On the other hand, in our previous calculation of trimethylene disulfide(five-membered ring), we found that the nucleophilic interaction takes place in the direction of the S–S bond. This type of interaction should play an important role in the formation of a nucleophilic intermediate,[20] such as RS–S–SR. The symmetric property of a molecule, such as compound I and RS–S–SR about the central S–C bond will stabilize this interaction to a great extent.

Population Analysis of 2,5-Dimethyl-dithiofurophthene. Next let us discuss the electron den-

sity of compound II, in which the symmetry of the S···S···S bond of the compound I is disturbed. Some electronic properties of the compound II which are different from those of I are observed in our calculation, but there are similarities as well. In view of the atomic density shown in Fig. 4, the O_8, S_1 and S_2 atoms can all be said to be electronegative, but the central sulfuratom, S_1 is most electron-poor, much like compound I. The AO densities of the p_z AO of the S_1 and the S_2 atoms are 1.905 and 1.920, which form a lone pair of the p type and which constitute a π MO with the other

TABLE 3. TRANSITION ENERGIES (eV) AND TRANSITION MOMENTS OF THIOTHIOPHTHENE

Transition	Type of transition	Transition energies			Transition moment M and its components			
		Calcd	Obsd[8]	Obsd (der)[8]	m	$m(x)$	$m(y)$	$m(z)$
2→2*	π-$\pi^*(B_2)$[a]	3.84	~2.38	~2.92	1.483	1.483	0.000	0.000
1→1*	σ-$\sigma^*(B_2)$[a]	4.26	~4.55	~6.02	2.069	2.069	0.000	0.000
3→2*	π-$\pi^*(A_1)$	5.40	—	—	0.936	0.000	0.936	0.000

Obsd(der): The observed value of phenyl derivative, which is estimated from the absorption spectra of Fig. 7 (Ref. 8).

a) The matrix element between these two transitions, π-$\pi^*(B_2)$ and σ-$\sigma^*(B_2)$, is large(−1.197 eV). This indicates a possibility of large mixing and no separability of the transitions of the two types. Including 2 excitations for B_2, 4 excitations for A_1 and 3 excitations for B_1, the CI calculation does not give better results. The exctitations with higher energies being included, the better results will be expected.

TABLE 4. TRANSITION ENERGIES (eV) AND TRANSITION MOMENTS OF 2,5-DIMETHYL-DITHIOFUROPHTHENE

Transition	Type of transition	Transition energies		Transition moment M and its components			
		Calcd	Obsd(der)[8]	m	$m(x)$	$m(y)$	$m(z)$
1→2*	π-$\pi^*(A')$[a]	4.15	~3.27	1.305	1.223	0.456	0.000
2→1*	σ-$\sigma^*(A')$[a]	4.88	~5.04	0.759	0.726	0.222	0.000
3→2*	π-$\pi^*(A')$	5.77	—	0.794	0.457	−0.649	0.000

Obsd(der): The observed value of phenyl derivative, which is estimated from the absorption spectra of Fig. 7 (Ref. 8).

a) The matrix element between these two transition, π-π^*(A′) and σ-σ^*(A′) is not so large (0.476 eV). After the CI calculations including seven (A′) excitations, the transition energies and transition moments of π-π^*(A′) and σ-σ^*(A′) transitions become as follows:

π-π^* 3.83 eV: m=0.778, $m(x)$=0.74782, $m(y)$=0.21326, $m(z)$=0.00000

σ-σ^* 5.02 eV: m=1.123, $m(x)$=0.93344, $m(y)$=0.44116, $m(z)$=0.00000

Transition energies considerably approach to the observed values, but the relative intensity become inverse to the observation in Fig. 7.

a) The orbital coefficients larger than 0.1 are shown in this table.

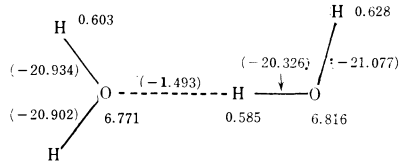
p_z AO's of the C atom and the O atom. From the value of the AO density, the p_x AO of the O atom can be considered to be a lone-pair orbital. The AO densities of the p_x AO's of the S_1 and S_2 atoms are approximately 1.0. This is different from the case of compound I (see Table 1). That is, the resonance between five-membered rings, as in compound I, can not be expected; rather, a nucleophilic interaction (a transannular interaction) between the lone pair of the O_8 atom and the S_1–S_2 bond of the five-membered cyclic disulfide is observed. The E_{AB} value between the S_1 and O_8 atoms in Fig. 4 confirms this. That is, the E_{AB} values of the $O_8\cdots S_1$ and $S_1\cdots S_2$ bonds are −0.740 eV and −12.957 eV respectively. The order of the $O_8\cdots S_1$ interaction seems to be that of a usual transannular interaction*[8,19]; it is ten times as small as the S···S interaction of compound I (Fig. 3). The S–S bond of Compound II is about two times as strong as the S···S interaction of Compound I and about one half as weak as a usual σ bond.

For comparison, an example of the hydrogen bond has been calculated by the same semi-empirical ASMO SCF method,[21] though only the relative value of the E_{AB} value will be discussed. The E_{AB} value corresponding to the hydrogen bond between the oxygen atom, O_I and the hydrogen atom, H_{II}, of the water dimer is found to be −1.493 eV.*[8] From these calculations, the S···O interaction of compound II seems to be weaker than, or approximately equal to, the hydrogen bond.*[9,10] This type and this order of interaction will be important in a catalytic interaction of a biochemical substance, as has been discussed in a previous paper.[19] Some examples may be seen in the literature.[22]

*[7] In the calculation of $(CH_2)_3S_2$, the atomic density of the lone-pair AO of the sulfur atom was almost 2.00 at the various dihedral angles (Ref. 18).

*[8] In our previous calculation of the electronic structure of several mesocycles with transannular interactions, this interaction was found to be −0.5 eV—−1.2 eV in terms of the E_{AB} value. In the extreme conformation, its value was −7.6 eV. However, this value is too large, for the conformation has been revealed as too extreme (Ref. 19).

*[9] The ∠HOH angle is taken as 105°, and a planar configuration of the dimers is adopted. The O–H bond length and the O···O distance are taken to be 0.96 Å and 2.76 Å respectively. The atomic densities and the E_{AB} values, denoted by the parentheses, are calculated to be as follows:



The E_{AB} value, −1.493 eV, of the hydrogen bond is slightly larger than that of the transannular interaction (*7); this is in accordance with the experimental trend. That is, the frequenncy shift of IR caused by the hydrogen bond is about 10 cm^{-1} several hundred cm^{-1}, while that of the transannular interaction reported is about 10 cm^{-1}~20 cm^{-1} (Ref. 19).

*[10] The E_{AB} value of the hydrogen bond varies over some range of values, depending on the kind of hydrogen bond, although only are example of a water dimer is calculated in the present work.

22) "Organic Sulfur Compounds," ed. by N. Kharasch, Pergamon Press (1961), Chap., 9 35, *etc.*; T. C. Bruice, *J. Amer. Chem. Soc.*, **81**, 5444 (1959); T. C. Bruice and B. Holmquist, *ibid.*, **89**, 4028 (1967).

π-Bond Orders. The main bond densities among the p_z orbitals (the π-bond orders) of compounds I and II are shown in Fig. 5 and 6. The π-bond order of the S···S bond of the compound I and those of the S–S bond and the S···O bond of the compound II are not very different. The π character of the C–O bond of Compound II, and conjugation with a π electron system from the C_7 atom to the C_9 atom, hexene, are seen. The S–C bond of the compound I has something of the nature of the single bond. The alternating π-bond order of the hexene is more flattened in the compound I, and the π-bond orders in the ring are averaged out, compared to the compound II.

Electronic Transitions. The calculated transition energies and transition moments are listed in Tables 3 and 4. The energy levels connected with these transitions and the main orbital coefficients are shown in Tables 5 and 6. The levels are numbered from the highest occupied level to the lower levels, and from the lowest unoccupied level, denoted by *, to the higher levels. In Table 6, the highest occupied MO and the next highest occupied MO of the compound II are, approximately, degenerated π and σ orbitals. The contribution of the p_x AO of the oxygen atom (denoted by $O(x)$), which is a lone-pair AO of the oxygen atom to this σ orbital is large. That is, this σ MO has the character of the lone-pair MO. In the π MO's and the π MO's of Table 5 and 6, the coefficients of the $S(z)$ AO's, which are lone-pair-type AO's of the sulfur atom, are comparatively large.

The highest occupied σ orbital of the compound I has a remarkably high energy (-8.926 eV).*11 Though there is a possibility that the inclusion of the $3d$ orbital of the sulfur atom stabilizes the S···S···S interaction, more or less, and lowers the enregy of this σ MO, the highest occupied MO of this compound seems to be higher than that of an ordinary molecule with lone pairs. This may correspond to the very small I_p (7.47 eV) of the Compound I.[17] In Table 5, the main contributions to this σ orbital of the Compound I are shown to be made by $S_1(s)$ AO and $S_2(s)$ AO, which is a pseudo lone-pair AO of the S_2 atom. That is, this orbital has the character of a lone-pair MO and of a S···S···S p_σ bond. Perhaps the reaction in termediate,[20] RS–S–SR, also
R
has such a high energy and becomes very reactive.

The UV spectrum of the Compound I (in cyclohexane and/or dioxane) has been reported,[7] but there is no data on the Compound II in the same solvent. In these calculations, there is an unexpected agreement of the absolute values of the calculated and the observed transition energies, as may be seen in Table 3. Therefore, as the experimental values of the UV spectrum, those of the phenyl derivatives in the same solvent (in acetic acid.[8]) are adopted in making a comparison of the electronic transitions of the Compounds I and II.

The spectra of these derivatives are shown in Fig. 7(Ic[8] and IIc),[8] together with that of the Compound I.[7] In Fig. 7, the spectra of I and Ic show typical electronic absorptions, with a strong peak in the ultraviolet region and a weaker peak in the visual region. That is, the strong peak of the Compound Ic at $\sim$210 mμ[8] and that of Compound I at 273 mμ[7] are characteristic of the S···S···S bond of the series[10] and are shifted, more or less, among them. Another property of these spectra[7,8,10] is that the oxygen compound, IIc, absorbs much more weakly in the ultraviolet region about 250 mμ, and more strongly in the visual region, but at a lower wave length than I and Ic. This feature is also seen in the UV spectra of other derivatives.[10] That is, the spectra of Fig. 7 conform closely to the pattern that is evidently characteristic of the series.[7,8,10]

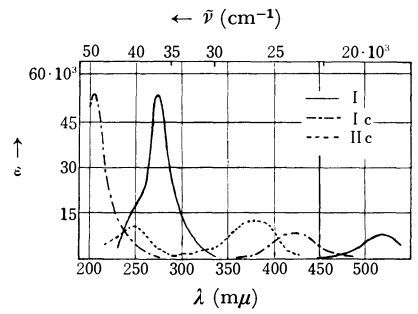


Fig. 7. UV spectra of  (Ic) (Ref. 8),  (IIc) (Ref. 8) and  (I) (Ref. 7).

In view of the calculated transition moment, the observed longer wavelength absorption of the Compound I (C_{2v}) may be said to correspond to π–π^* (B_2, 2→2*)-type transition, and the shorter one may be said to be a σ–σ^*(B_2, 1→1*)-type transition, as primary results. However, the matrix element between these π–π^* and σ–σ^* excitations is calculated to be large, -1.197 eV. This indicates the possibility of a large mixing and no separability of the transitions of the two types after the configuration interaction is calculated. Furthermore, the longer wavelength absorption of Compound II (C_{1h}) may correspond to the π–π^*(A', 1→2*)-type transition, and the shorter one may correspond to the σ–σ^*(A', 2→1*) type.*12 The agreement between

*11 No such high energy, higher than -9 eV, of the highest occupied level has ever before been found in our ASMO SCF calculations.

*12 Johnston *et al.* ascribed the absorption to the π–π^* transition only in their semi-empirical SCF LCAO calculation of the π electron system (Ref. 17).

the observed[8] and the calculated transition energies is not very good, but a relatively high intensity of the absorption in the 270(210)mμ region of the Compound I can be obtained in our calculations. This high intensity is caused mainly by the delocalized S···S···S interaction (σ bond character) of the Compound I, as has previously been mentioned. The relative position of the absorption in the visual region of I (Ic) and IIc (that is the fact that IIc absorbs at a lower wavelength), is correctly predicted in these calculations.

The previous semi-empirical ASMO SCF calculation[21] of the electron structure of the cyclic disulfides,[18] neglecting the contribution of *d* orbitals, predicted the main absorption maximum in the UV spectra well. In the present case, however, for quantitative discussions a consideration of the *d* orbitals and of the configuration interaction seems to be necessary.

The calculations were carried out on an HITAC 5020 computer at the Computation Center of the University of Tokyo.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3761—3765 (1970)

An ESR Study of Intermediates in γ-Irradiated Methylcyclohexane and Isobutane Containing Benzene

Terunobu WAKAYAMA, Tetsuo MIYAZAKI, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received July 6, 1970)

The present work was undertaken in order to examine intermediates from benzene and toluene in γ-irradiated glassy methylcyclohexane (MCH) and polycrystalline isobutane matrices at 77°K. The γ-irradiation of MCH containing low concentrations of benzene gave an ESR spectrum with a good hyperfine resolution, which can be ascribed to the benzene anion, while at higher concentrations of benzene it gave an ESR spectrum with a poor resolution, which is attributable to the benzene monomer and dimer anions. On the contrary, the γ-irradiation of polycrystalline isobutane containing benzene did not yield an ESR spectrum which can be attributed to the benzene anion. However, the γ-irradiation of a mixed glass of isobutane and 4 mol% MCH containing benzene gave an ESR spectrum which is attributable to the benzene anion. The yield of trapped electrons in this system was three times as large as that in pure γ-irradiated MCH. Such a difference in the results between glassy MCH and polycrystalline isobutane matrices gives evidence of a phase effect on the radiolysis of solid hydrocarbon.

In a previous paper,[1] we reported a study of radiation-induced intermediates from toluene in solid isobutane in which the electron spin resonance technique was used. The ESR spectrum observed consisted of five lines, with a splitting constant of 4.2 G; it was ascribed to the toluene anion. These results indicated that toluene has some electron scavenging ability in a hydrocarbon matrix at 77°K. However, γ-irradiated polycrystalline isobutane containing benzene did not give an ESR spectrum which is attributable to the benzene anion. Recently, it was found by optical absorption spectroscopy that a γ-irradiated glassy matrix of 3MP containing low concentrations of benzene yielded the benzene anion and cation, while at higher concentrations of benzene it yielded the dimer anion and cation.[2] We have investigated, by the ESR method, radiation-induced intermediates from benzene in glassy matrices of MCH and of isobutane- 4 mol% MCH, independently of the optical study referred to above. In this paper, we will report the ESR results on the reaction intermediates and will attempt to compare these results with the optical results.

Experimental

The isobutane, methylcyclohexane (MCH), and 3-methylpentane (3MP) were more than 99.9% pure. The gas-chromatographic analysis did not show any detectable impurities. These materials were used after degassing and distillation on a vacuum line. The

benzene and toluene (99.9%) were used after vacuum distillation. The nitrous oxide and sulfur hexafluoride were of a high purity, while the cyclohexene was 99.9% pure and was used after vacuum distillation.

The samples were irradiated with γ-rays from Co-60 at a dose rate of 4.2×10^5 rad/hr. The photobleaching of γ-irradiated samples was carried out at 77°K with light from an infrared or tungsten lamp.

The ESR measurements were made on a JES-3BX ESR spectrometer. The G-value of the benzene anions was determined by assuming G(radical)$=1.6$ for radicals produced in γ-irradiated 3MP at 77°K.[3]

Results and Discussion

A) Intermediates Produced at Lower Concentrations of Benzene.

When 0.05 mol% benzene in MCH glass is γ-irradiated at 77°K, a species is formed which displays an ESR spectrum with a good hyperfine resolution. This ESR spectrum consists of five lines whose splitting constant is 3.8 G, and it can be bleached by exposure to infrared light for a few minutes (Fig. 1(A)).

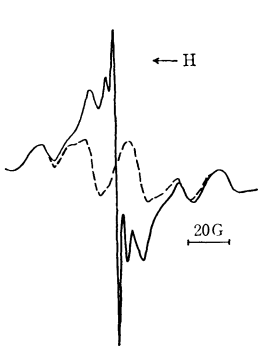

Fig. 1. A

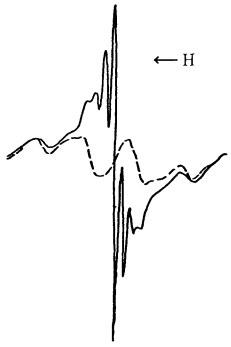

Fig. 1. B

A) ESR spectrum of γ-irradiated MCH containing 0.05 mol% benzene at 77°K.
——, after γ-irradiation.
------, after 5 min illumination with infrared light.
Dose, 1.7×10^5 rad.
B) ESR spectrum of γ-irradiated MCH containing 0.05 mol% benzene and 1.0 mol% cyclohexene at 77°K.
——, after γ-irradiation.
------, after 5 min illumination with infrared light.
Dose, 1.7×10^5 rad.

As the benzene concentration in MCH matrix is increased, the intensity of the five-line spectrum at first increases, and then reaches a plateau at 0.05 mol% benzene concentration (Fig. 2).

In order to determine whether the species produced in γ-irradiated MCH containing benzene is the benzene anion or the benzene cation, we used SF_6 and N_2O as electron scavengers, and cyclohexene as a cation scavenger. Since the hyperfine splitting constants for the benzene anion and cation have been reported to be 3.75[4] and 4.2 G[5] respectively, it is difficult to distinguish between the anion and the cation by their ESR spectra under our experimental conditions.

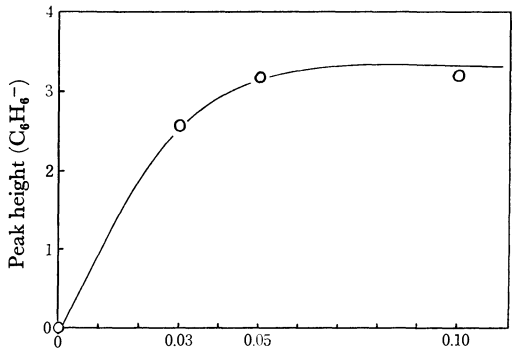

Fig. 2. Effect of benzene concentration in MCH glass on the yield of the benzene anion at 77°K.
Dose, 1.7×10^5 rad.

It is known that when olefin is added to hydrocarbon matrices, the yield of trapped electrons in γ-irradiated hydrocarbons increases.[6] Such a result was obtained for γ-irradiated MCH containing cyclohexene in the present study (Fig. 3). Cyclohexene may stabilize trapped electrons, since a charge transfer from MCH to cyclohexene would suppress cation-electron recombination by trapping the positive charge.

$$MCH \rightsquigarrow MCH^+ + e^- \quad (1)$$

$$MCH^+ + C_6H_{10} \longrightarrow MCH + C_6H_{10}^+ \quad (2)$$

When 0.05 mol% benzene in MCH glass containing 1.0 mol% cyclohexene as a cation scavenger is γ-irradiated at 77°K, a species is formed which displays an ESR spectrum with a good resolution (Fig. 1(B)). This spectrum consists of seven lines, and its splitting constant is 3.8 G. It can be bleached by exposure to infrared light for a few minutes.

γ-Irradiated MCH containing 0.07 mol% benzene and 0.07 mol% SF_6 displays a very different ESR spectrum from that of γ-irradiated MCH containing 0.07 mol% benzene and 0.4 mol% SF_6 (Fig. 4(A)). The former spectrum has a seven-line component with a hyperfine splitting constant of 3.8 G and is attributed to the benzene anion, while the latter does not have a seven-line component and indicates only MCH radicals. This result can be interpreted in terms of the following competitive reactions:

$$e^- + C_6H_6 \longrightarrow C_6H_6^- \quad (3)$$

$$e^- + SF_6 \longrightarrow SF_6^- \quad (4)$$

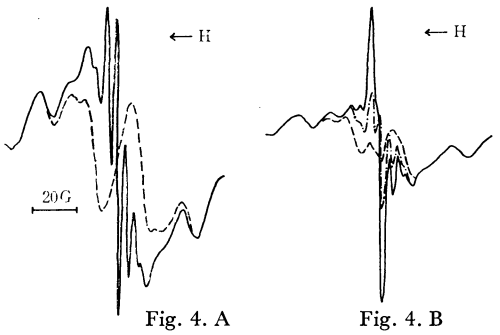

Fig. 4. A Fig. 4. B

A) ESR spectrum of γ-irradiated MCH containing 0.07 mol% benzene in the presence of SF_6 at 77°K.
——, 0.07 mol% SF_6.
------, 0.4 mol% SF_6.
B) ESR spectrum of γ-irradiated MCH containing 0.07 mol% benzene and 0.07 mol% N_2O at 77°K.
——, after γ-irradiation.
-·-·-, after 1 sec illumination with infrared light.
------, after 40 sec illumination with infrared light.
Dose, 1.7×10^5 rad.

Figure 4(B) shows the ESR spectrum, obtained after γ-irradiation, of MCH, containing 0.07 mol% benzene and 0.07 mol% N_2O, as an electron scavenger. The center line in the spectrum may be ascribed to the electron trapped near the N_2O superimposed on the spectrum of the benzene anion and the solvent radical. The narrow side lines are due to the benzene anion. The center line does not saturate so easily upon an increase in the microwave power as does the trapped electron in pure MCH. A similar result is obtained upon microwave saturation and the photobleaching of the trapped electron (ESR singlet with $\Delta H_{ms1}=4.1$ G) produced in MCH containing N_2O.[7] The ESR spectra obtained by illuminating the preceding sample with infrared light for 1 sec and for 40 sec are shown in Fig. 4(B). As can be seen in Fig. (4B), the spectrum of the trapped electron decreases remarkably in intensity upon illumination, while that of the benzene anion does not change very much. This result indicates that the trapped electron can be photobleached more efficiently than the benzene anion.

Thus, the seven-line spectrum may be attributed to the benzene anion, and the *G*-value of the benzene anion in MCH containing 0.05 mol% benzene and 1.0 mol% cyclohexene is 1.3. This value is in accordance with the *G*-value of the biphenyl anion in a γ-irradiated hydrocarbon containing biphenyl.[8] The results presented above indicate that benzene has some electron scavenging ability at low concentrations.

B) Intermediates Produced at Higher Concentrations of Benzene.

When 3MP glass, MCH glass, or isobutane-4 mol% MCH glass containing 5 mol% benzene is γ-irradiated at 77°K, a species is formed which displays an ESR spectrum with a poor resolution. This ESR spectrum has a hyperfine splitting constant of 3.8 G, and it can be bleached by exposure to infrared light for a few minutes (Fig. 5(A)). The formation of this species is suppressed by the presence of N_2O as an electron scavenger in 3MP. On the contrary, the species produced in MCH is not suppressed by the presence of 1 mol% N_2O or SF_6, and in this case the ESR spectrum can not be

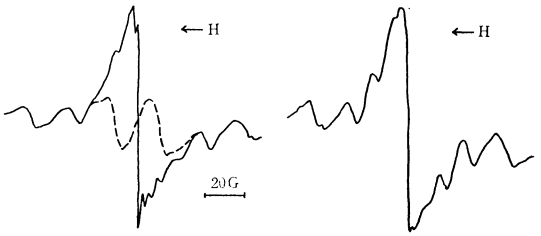

Fig. 5. A Fig. 5. B

A) ESR spectrum of γ-irradiated MCH containing 5 mol% benzene at 77°K.
——, after γ-irradiation.
------, after 5 min illumination with infrared light.
B) ESR spectrum of γ-irradiated MCH containing 5 mol% benzene and 1 mol% N_2O at 77°K.
Dose, 1.7×10^5 rad.

7) A similar effect of N_2O on the trapped electron in 3-methylhexane was reported by Yamazaki *et al.* at the 22nd Annual Meeting of the Chemical Society of Japan, 1969, Tokyo, Japan.

8) J. Lin, K. Tsuji and F. Williams, *J. Amer. Chem. Soc.*, **90**, 2766 (1968).

bleached by exposure to a tungsten light (Fig. 5(B)).

These results suggest that an anion is produced in γ-irradiated 3MP, MCH, and isobutane- 4 mol% MCH containing 5 mol% benzene, while the species produced in γ-irradiated MCH containing 5 mol% benzene and 1 mol% N_2O or SF_6, is a cation. Recently Ekstrom suggested, in an optical absorption study, that the species produced in γ-irradiated 3MP could be attributed to the benzene monomer anion and cation, or to the benzene dimer anion and cation, depending on the benzene concentration. We would also like to suggest that the ESR spectra obtained at higher concentrations of benzene in the hydrocarbons may be ascribed to the benzene monomer and dimer anions, while the species produced in γ-irradiated MCH containing 5 mol% benzene and 1 mol% electron scavengers may be ascribed to the benzene monomer and dimer cations. Our results indicate that the dimer anion is formed at benzene concentrations above about 1 mol%, a value which is in good agreement with the optical values.[2)]

TABLE 1. EFFECTS OF THE HYDROCARBON MATRIX ON THE FORMATION OF BENZENE AND TOLUENE ANIONS

	Benzene	Toluene
MCH	Benzene anion	No
Isobutane	No	Toluene anion
Isobutane- 4 mol% MCH	Benzene anion	Toluene anion

C) Effects of the Hydrocarbon Matrix on the Formation of Benzene and Toluene Anions.

Table 1 shows the anionic species produced in γ-irradiated hydrocarbon matrices (MCH, isobutane, and isobutane- 4 mol% MCH) containing 3 mol% benzeene or toluene at 77°K. The benzene anion is produced in a MCH matrix, but not in an isobutane matrix. On the contrary, the toluene anion is produced in an isobutane matrix, but in a MCH matrix. Both the benzene and toluene anions, however, can be produced in a mixture of isobutane- 4 mol% MCH.

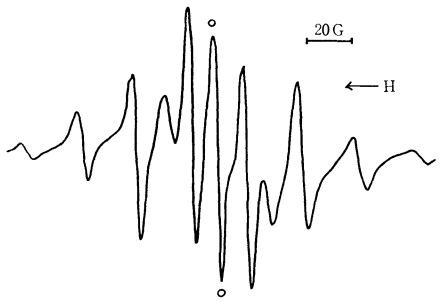

Fig. 6. ESR spectrum of γ-irradiated isobutane- 4 mol% MCH at 77°K. ○ represents a signal of the trapped electron.
Dose, 0.7×10^5 rad.

It is found by ESR measurements that the species produced in γ-irradiated pure isobutane, which is polycrystalline at 77°K, is the isobutyl radical, while the species produced in a γ-irradiated mixture of isobutane- 4 mol% MCH, which is glassy at 77°K, consists of the isobutyl and t-butyl radicals and trapped electrons (Fig. 6). The yield of t-butyl radicals in this system is much greater than that of isobutyl radicals, and the yield of trapped electrons in a γ-irradiated mixture matrix is three times as large as that in γ-irradiated pure MCH.

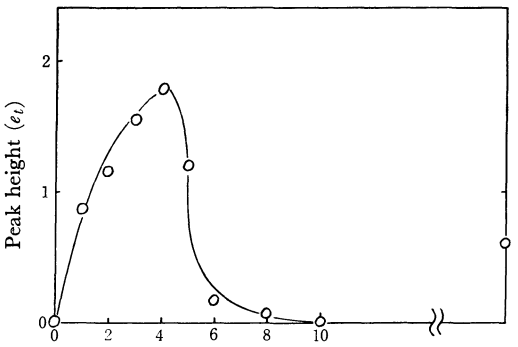

Fig. 7. Effect of MCH concentration in isobutane on the yield of the trapped electron at 77°K.
Dose, 0.7×10^5 rad.

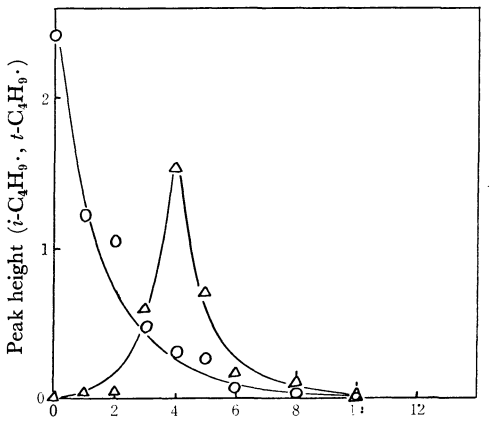

Fig. 8. Effect of MCH concentration in isobutane on the yields of the i-butyl radical and of the t-butyl radical at 77°K.
○, isobutyl radical. △, t-butyl radical.
Dose, 0.7×10^5 rad.

Figures 7 and 8 show the dependence of the yields of trapped radicals and electrons on the concentration of MCH. As the concentration of MCH in isobutane is increased, the yields of both t-butyl radicals and trapped electrons increase, while the yield of isobutyl radicals decreases. The yields of t-butyl radicals and trapped electrons decrease in the range of MCH concentrations above

4 mol%, where the matrix becomes so soft that the radicals and electrons are not trapped in the matrix. As the concentration of MCH increases, the matrix becomes glassy, so benzene and toluene dissolve easily in the matrix; both the benzene and toluene anions may be trapped in an isobutane-4 mol% MCH mixture.

Accordingly, the results presented above indicate that the viscosity of a matirx has an important influence upon the formation of trapped anions, cations, electrons, and radicals in the matrix.

The Interaction of Oxygen with Organic Molecules. III.[1] Electron Transfer between Oxygen and Aromatic Amines Studied by Flash Technique

Mitsufusa HORI,[2] Hiroyasu ITOI and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received July 6, 1970)

Flash photolysis of aniline derivatives in various solutions has been studied in oxygenated and deoxygenated conditions. Absorption spectra of the triplet states appeared in deoxygenated liquid paraffin solutions, but no transient absorption was observed in the oxygenated liquid paraffin solutions. Transient spectra, due to the cations of the anilines, were observed in deoxygenated ethanol solutions, but none in oxygenated ethanol. In highly polar solvents — acetonitrile, water, and formamide — either deoxygenated or oxygenated, the cation was observed. In the case of oxygenated solutions, the initial yield of the cation was found to be proportional to the intensity of the flash light, indicating that the ionization is a one-photon process. These results, together with the previous findings that the photo-ionization of organic molecules in solutions are caused by the two-step, biphotonic excitation processes strongly suggest that the charge transfer states are formed between the aromatics and the oxygen molecule, either by direct excitation or *via* the interaction of excited anilines and the ground state of oxygen, and the charge transfer states then lead to the solvated cations and anions in highly polar solvents. The decay of the ions have been found to follow the second order kinetics.

Oxygen molecule is known for its various special actions on the photochemical behaviors of organic molecules, such as quenching of phosphorescence and fluorescence, photo-oxidation, and enhancement of T←G transition (transition from the ground state to the lowest triplet state). It is also known that oxygen induces absorption spectra in ultraviolet or visible regions when dissolved in various organic solvents. The absorption has been attributed to a type of contact charge transfer absorption by Evans,[3] and Tsubomura and Mulliken.[4] This theory assumes the existence of charge transfer (CT) excited states between oxygen and organic molecules, where oxygen acts as the electron acceptor. Tsubomura and Mulliken explained the mechanism of enhanced intercombination between singlet and triplet states using this concept of CT states.

Although the assumption of these CT states is consistent with all known experimental observations, more evidence to verify the CT nature of the excited states is desirable. Measurement of the dipole moments of the excited states and other experiments to show the highly polar nature of the excited states are, however, very difficult in this case, because of the non-fluorescent nature of the CT states.

Some years ago, Leonhardt and Weller[5] showed that flash excitation of a solution of perylene and *N,N*-dimethylaniline in a polar solvent leads to the transient formation of perylene anion. They proposed that the perylene anion and the aniline cation were formed from a CT excited state where perylene acts as an acceptor and aniline a donor. We have

obtained similar results for other organic donor-acceptor systems and shown that such transient formation of ionic species after the CT interaction is a general phenomena.[6,7]

It should be pointed out here that the formation of a CT state may not be a prerequisite for the appearance of ionic species in polar solutions, because ionic species may be formed either by spontaneous ionization from a charge transfer state or by photo-ejection of electrons (which will be discussed later in this article) followed by capture of the electron by electron acceptors. We thought that it was important to study the photochemical behavior of oxygen and organic substances under flash illumination, and to find more detailed mechanism of the formation of transient ionic species.

In order to clarify the role of oxygen in photo-ionization processes involving aromatic donor molecules, it was necessary to study whether photo-ionization could occur in solutions containing only aromatic compounds and no oxygen. It has been well established that many aromatic hydrocarbons and amines are photo-ionized in solutions. In cases where the exciting radiation contains only near-ultraviolet or visible light, the photo-ionization in low temperature matrix occurs by the two-step excitation, *via* the lowest triplet states of the aromatics.[8] We have found that the two-step ionization takes place not only in non-polar matrix at low temperature but in fairly polar solutions like ethanol[7] at room temperature. The ionic species formed are no doubt stabilized to a great extent in polar solutions. However, we found the photon energy necessary for an effective production of ions to be only a few tenth electron volt smaller than the gas-phase ionization potential of the donor.

In the present work, particular emphasis was laid on the study of the difference in the photochemical behaviors of aromatics in oxygenated and deoxygenated polar solutions.

Potashnik *et al.* reported independently that a spontaneous ionization may occur from a charge transfer triplet state of an electron-donor-acceptor pair in a polar matrix.[9] They also studied the photo-ionization of *N,N,N',N'*,-tetramethyl-*p*-phenylenediamine (TMPD) at various oxygen concentrations[10] using a flash technique. Their main conclusion is that the photo-ionization in polar solutions is mainly a bi-photonic process *via* an intermediate whose nature is still not thoroughly understood, and the photo-ionization in less polar solutions is mostly a mono-photonic process due to the interaction of the triplet TMPD and oxidizing impurities.

Experimental

Materials. *N,N*-Dimethyl-*p*-anisidine was recrystallized from 60% ethanol and sublimed in a vacuum. *n*-Hexane was purified by passing through a silica-gel column. Acetonitrile was twice refluxed with phosphorous pentoxide for several hours, followed in each case by fractional distillation. Formamide was kept overnight with anhydrous sodium sulfate and distilled under 30 Torr at *ca.* 130°C. Water was passed through activated charcoal and ion-exchange resin columns. (Specific resistance: 10^6 ohm/cm). Liquid paraffin was purified by passing through a silica-gel column. All other materials used were purified by methods similar to those described in previous papers.

Methods. The concentrations of most of the solutions of aniline derivatives studied were made 0.3—0.5 $\times 10^{-3}$ mol/*l* so as to give optical densities of *ca.* 1 cm^{-1}. The solutions saturated with either one atmosphere oxygen or nitrogen were placed in a cylindrical silica cell, 1.4 cm in diameter and 20 cm in length. The apparatus used for the flash-spectroscopic measurements is mostly the same as that described in our earlier paper.[11] The light of the exciting flash lamps was filtered by an aqueous solution of cobaltous chloride (0.5 gr/c.c.) using a double-wall sample cell, and only the light in the range from 2800 to 3800 Å was passed in order to minimize the effect of scattered light from the exciting flash lamps.

Results

Oxygen-Saturated Solutions. The transient absorption spectra obtained by flash illumination of *N,N*-dimethylaniline (DMA) in acetonitrile solutions saturated with oxygen is shown in Fig. 1. Similar spectra were obtained for aqueous and formamide solutions. In the case of *n*-hexane, liquid paraffin, and ethanol as solvents, no transient spectra were obtained. In a previous paper, it was reported that the photolysis of DMA in low temperature matrices yields the DMA cation and the neutral radical, and a part of the visible spectrum was assigned as the absorption spectrum of the cation.[12] The transient spectra obtained in the present results agree well with this and the species formed is therefore identified to the DMA cation. This conclusion is supported by the fact that this transient spectrum is not found in solvents having relatively low dielectric constants, because unstable

ionic species like these are only sufficiently stabilized in very polar solvents such as acetonitrile (dielectric constant ε: 37.5), water (ε: 81), and formamide (ε: 109.5), and not in nonpolar solutions or even in ethanol (ε: 24.3). As a further evidence for the formation of DMA cation, we found that a momentary photoconductivity appeared by flash illumination of DMA in these highly polar solutions saturated with oxygen.[13] We also found a weak ESR signal by steady illumination of DMA in acetonitrile

saturated with 1 atmosphere oxygen. It is very interesting that we could not find the absorption spectrum of DMA cation by flash illumination of acetonitrile solutions of DMA saturated with oxygen at 8 Torr and at 20 Torr, discussion on which will be made later in this paper.

In the case of *N*,*N*-dimethyl-*p*-anisidine (DMAN), transient spectra have been observed in acetonitrile, water, and formamide, and not in liquid paraffin or ethanol. As an example, Fig. 2 shows the transient absorption spectrum obtained for the acetonitrile solution. It agrees with that obtained in our laboratory as a result of ultraviolet irradiation of DMAN in the low temperature matrix,[14] and is attributable to that of the cation of DMAN.

In an aqueous solution of DMA or DMAN, a transient band was obtained at 3400 or 4500 Å, respectively, which decayed much faster than the cation spectra. These bands might be assigned to *N*-methylaniline cation and *N*-methyl-*p*-methoxyaniline cation, respectively.

In the case of benzidine, transient absorption spectrum was obtained by flash illumination in ethanol, acetonitrile, water and formamide, and not in liquid paraffin. Absorption spectrum obtained for the case of an ethanol solution is shown in Fig. 3 together with that obtained by the photolysis of benzidine in a low temperature matrix. That the

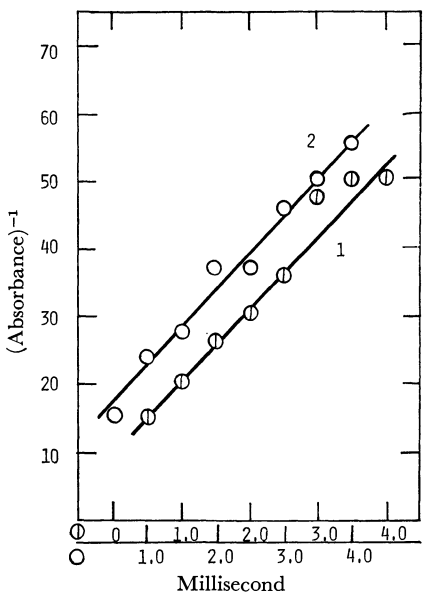

Fig. 4. Plot of reciplocal of absorbance of the cation formed by flash illumination of *N*,*N*-dimethylaniline in oxygenated acetonitrile against time.
1) At a flash with capacitors charged at 11.5 kV.
2) At a flash with capacitors charged at 11.0 kV.

14) K. Kimura, K. Yoshinaga and H. Tsubomura, *J. Phys. Chem.*, **71**, 4485 (1967).

spectrum appearing in the latter is due to the benzidine cation is concluded from the following: 1) The spectrum does not appear by irradiation in a nonpolar matrix. 2) When biphenyl is added in the matrix to be irradiated, the spectrum of biphenyl anion was observed. 3) Thermoluminescence was observed from the irradiated matrix. Agreement between the two spectra clearly shows that benzidine cation was produced by flash illumination of oxygenated benzidine solutions. The result that the cation is formed even in ethanol, contrary to results for DMA and DMAN, is probably related with the lower ionization potential of benzidine compared with the other two.

In the cases of DMA and DMAN in acetonitrile, water and formamide, the decay of the absorption due to the cation formed by flash illumination was found to be second order with respect to the concentration of the cation. As an example, the reciprocal of the absorbance of the cation produced from DMA plotted against time is shown in Fig. 4. By taking the molecular extinction coefficient of the cation at 4600 Å to be 1200,[12] the rate constant of the second order reaction is determined to be as shown in Table 1.

Table 1. Second order decay constants of the cations in various solvents, together with relative viscosities and dielectric constants of the solvents at room temperature

Solvent	Acetonitrile	Water	Formamide
Relative viscosity, centi-poise	0.345	1.00	3.764
Dielectric constant	37.5	80.0	109.0
The second-order decay constant, $10^8 M^{-1}\cdot sec^{-1}$, for *N,N*-dimethylaniline	2.4	0.2	0.7
The same for *N,N*-dimethyl-*p*-anisidine	6.8	7.4	3.0

By extrapolation to zero time, we could obtain the initial cation concentration produced by the flash. Intensity of the flash light can be changed by controlling the voltage applied to the condenser. It was confirmed that the profile of the flash light is fairly constant at all firings of the flash and, therefore, not only the integrated intensity but also the intensity at any stage of a flash is almost exactly proportional to the square of the voltage. Based on these results, the initial concentration of the cation produced was plotted against the flash light intensity. The results for DMA and DMAN are given in Fig. 5. As seen from the figure, the initial concentrations of the cations are proportional to the light intensity for both compounds. For aqueous and formamide solutions, the kinetic data are a little complicated by the formation of other species.

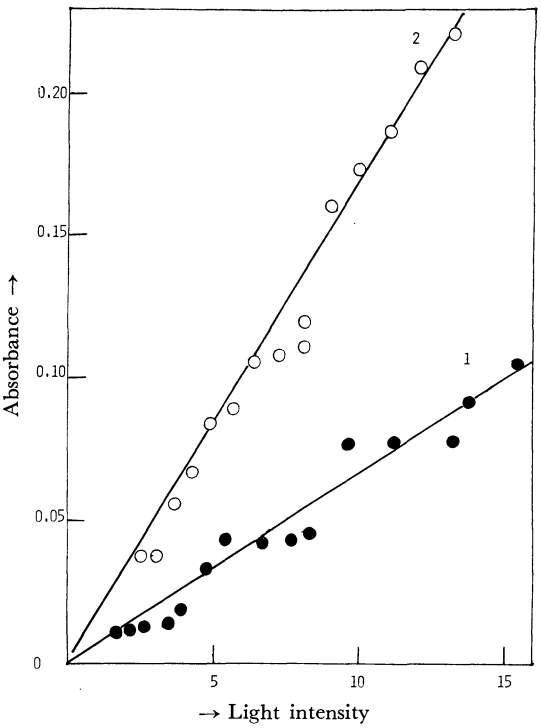

Fig. 5. Plot of initial concentration of the transient cation, in units of absorbance, formed in acetonitrile solutions saturated with oxygen against flash intensity.
1) *N,N*-dimethylaniline, 2) *N,N*-dimethyl-*p*-anisidine.

However, the results obtained show that the decay of the cation in these cases is of the second order and the initial concentration is proportional to the light intensity of the flash.

Deoxygenated Solutions. Flash photolyses of DMA and DMAN have been studied in carefully deoxygenated solutions.

The flash photolysis of DMA in deoxygenated liquid paraffin was studied by Land and Porter,[15] who assigned the spectrum with maxima at 3140 and 4000 Å tentatively to *N,N*-dimethylanilino radical. Kimura *et al.*[16] obtained a similar spectrum with maxima at 3400 and 4800 Å and a life time of the order of 100 μsec, and assigned it to the *T–T* transition. Later, the same authors found that the ultraviolet spectrum consists of two components: one probably due to *T–T* transition and another decaying much more slowly, We studied the flash photolysis of DMA and DMAN in carefully deoxygenated liquid paraffin again. The resulting spectra for DMA are shown in Fig. 6. The visible

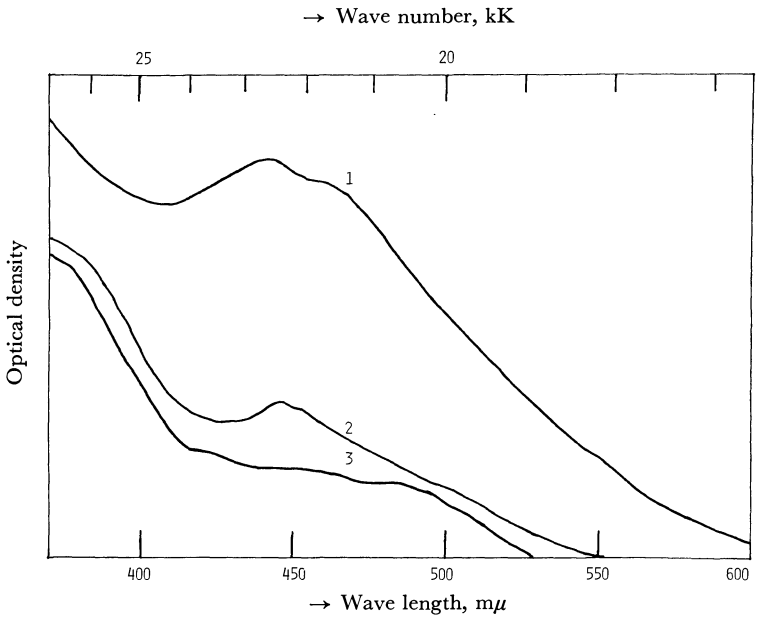

Fig. 6. Transient spectra obtained by flash illumination of *N,N*-dimethyl-aniline in deoxygenated liquid paraffin.
Delay time: 1) 8 μsec, 2) 80 μsec, 3) 270 μsec

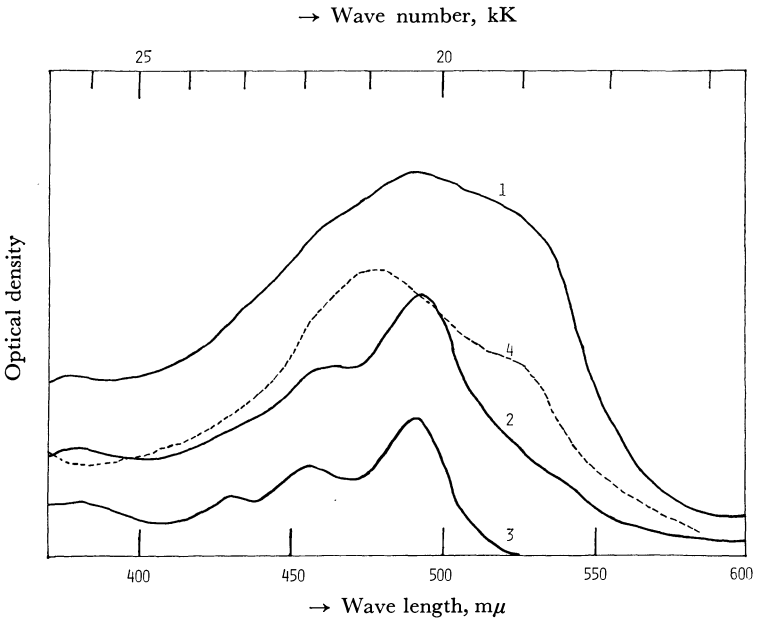

Fig. 7. Transient spectra obtained by flash illumination of *N,N*-dimethyl-*p*-anisidine in deoxygenated liquid paraffin.
Delay time: 1) 20 μsec, 2) 180 μsec, 3) 500 μsec, 4) *T-T* absorption spectrum measured in liquid paraffin at 77°K.

part of the spectrum decays exponentially with a life time of the order of 80 μsec, while most of the ultraviolet part remained after 80 μsec. These results confirm those obtained by Kimura *et al.* and show that the visible spectrum is the *T–T* absorption and most of the ultraviolet spectrum is probably due to *N*-methyl-anilino radical.

The spectra for DMAN also show that there are two components (Fig. 7): one, lying between 4500 and 5500 Å, decayed exponentially with a life time of 1.2 msec. and another, with peaks at 4290, 4500, and 4900 Å, remained for a long time. The yield

of the short-life component was found to be proportional to the flash light intensity, while that for the long-life component, although more difficult to analyse, is roughly proportional to the square of the light intensity. All these results are consistent with the assignment of the short-life component as a T–T band. That of the long-life component is uncertain. It does not agree in positions of the maxima with those of the DMAN cation nor those of *N,N*-dimethylamino-phenoxyl radical. One possible assignment is to *p*-methoxy-*N*-methylanilino radical.

The T–T spectrum of DMAN was also measured in an ethanol matrix and in a liquid paraffin matrix at 77°K using an apparatus constructed in our laboratory.[17] The result in Fig. 7 shows that the T–T spectrum lies in the same region as that of the fast decaying component of the transient spectrum.

The transient spectra obtained for various polar solutions of DMA and DMAN show complicated aspects. In ethanol and acetonitrile, transient spectra quite similar to those of the DMA and DMAN cations were obtained. The decay curves, however, showed in most cases that there are two components with different life times. The decay kinetics and the dependence of the yield of the transient species on the flash light intensity were difficult to determine exactly.

For aqueous solutions of DMAN, the transient spectrum obtained looks like that of the T–T transition. The spectrum, however, is found to have two components: the long-life component decays exponentially, with a life time of 23 min, and the short-life component also decays approximately in the first order with a life time of *ca.* 1 msec., and may be assigned to the T–T band. The long-life component is probably the cation band. Its initial absorbance, extrapolated to zero time, increases approximately proportional to the square of the flash light intensity. For the aqueous solution of DMA, the transient spectra can also be divided into T–T and cation components with life times of 80 μsec and 87 sec, respectively.

Flash photolysis of DMA and DMAN in formamide also showed transient spectra similar to those of the corresponding cations. The decay curves followed the second order kinetics, and the initial yields of the cations were found to be proportional to $I^{1.2}$—$I^{1.3}$.

Discussion

The transient species detected by the flash method are summarized in Table 2. It has been established that the anilines form their cations when flash-photolysed in highly polar solutions, irrespective of whether the solution is saturated with 1 atmosphere oxygen or deoxygenated. This is consistent with the result of our previous work that *N,N,N'N'*-tetramethyl-*p*-phenylenediamine (TMPD) forms its cation when flash-illuminated in deoxygenated ethanol.[7] As has been described earlier, it has been well established that TMPD ionizes from a higher triplet state by the two-step, biphotonic excitation.[7] The photolysis of aniline derivatives in organic matrices at 77°K were studied also in our laboratory.[12] It was concluded that they form the cation and the anilino-radical and the former yields more in polar matrices. The present results of flash photolysis in deoxygenated solutions seem

Table 2.* Transient species formed by flash excitation of aniline derivatives in solutions at room temperature

Solvent	*N,N*-Dimethylaniline		*N,N*-Dimethyl-*p*-anisidine

* O_2 means that the solution is saturated with oxygen at 1 atm. The species with life times indicated after them are found to decay in the first order. K_2 indicates the second order rate constant.

17) The details will be reported in a later paper.

to be consistent with the two-step photo-ionization mechanism, although quantitative analysis in the deoxygenated solutions is complicated by the formation of more than one species.

In previous papers,[7] we stated that TMPD is photoionized by flash photolysis in deoxygenated ethanol, but the presence of dissolved oxygen retards it to a great extent. In accordance with these findings, it has been found in the present work that DMA and DMAN do not form cations in oxygenated ethanol. The cation of DMA has been found to form in both deoxygenated and oxygenated acetonitrile, but not in acetonitrile saturated with oxygen at 8—20 Torr, as stated previously. This shows that the photo-ionization is retarded by a small amount of oxygen; this may be explained by taking into account the fact that oxygen quenches the lowest triplet states of the donor molecules very efficiently, so that the second step of the excitation hardly takes place.

The most important results obtained in the present work are that the aniline analogues form their cations in highly polar solutions saturated with 1 atmosphere oxygen, and the yields of the cations are proportional to the flash-light intensity. These results indicate that the cations are formed by the single-photon excitation from the ground states. The most plausible interpretation for this is that these cations are formed from the CT states, $D^+\cdots O_2^-$ by the interaction of the highly polar solvents.

$$D^+ \cdots O_2^- \longrightarrow D^+_{solv} + O_{2\,solv}^-$$

The CT states may be formed either by direct excitation from the ground states through the CT absorption, or by the interaction of the singlet excited states of the donor with oxygen in the ground state as follows:

$$^1D^* + O_2 \longrightarrow D^+ \cdots O_2^- \longrightarrow D^+_{solv} + O_{2\,solv}^-$$

As mentioned before, the cations are not detected in the acetonitrile solution of DMA containing a very small amount of oxygen, and this indicates that the excited triplet DMA is quenched by a very small amount of oxygen, because of its long lifetime. Consequently, it is concluded that the encounter of the triplet DMA in its lowest vibrational level and the oxygen molecule in the ground state does not lead to DMA cation even in highly polar solvents. The CT absorption of DMA$\cdots O_2$ extends far beyond the (0–0) band of phosphorescence spectrum (27 kK) of DMA, indicating that the triplet state (v=0) of DMA is higher in energy than the CT (v=0) level. The above result, therefore, seems to be explained by assuming that the process

$$D^+ \cdots A^- \rightsquigarrow D^+_{solv} + A^-_{solv}$$

should have an energy barrier as indicated in Fig. 8. In a highly polar solution, the charge transfer $D^+\cdots A^-$ state is thought to be stabilized by the solvation effect. The stabilization is the greater as the distance R_{DA} gets larger, possibly causing an energy maximum as indicated by the broken curve. In such a solution, the ground state D···A pair is excited to the charge transfer $D^+\cdots A^-$ state, not to the $D^+_{solv}\cdots A^-_{solv}$ state, in accordance with the Franck-Condon principle. It is conceivable, then, that only the excited DA pair, having energy higher than the maximum of the barrier, and accordingly larger intermolecular distance, will transfer to the $D^+_{solv}\cdots A^-_{solv}$ state.

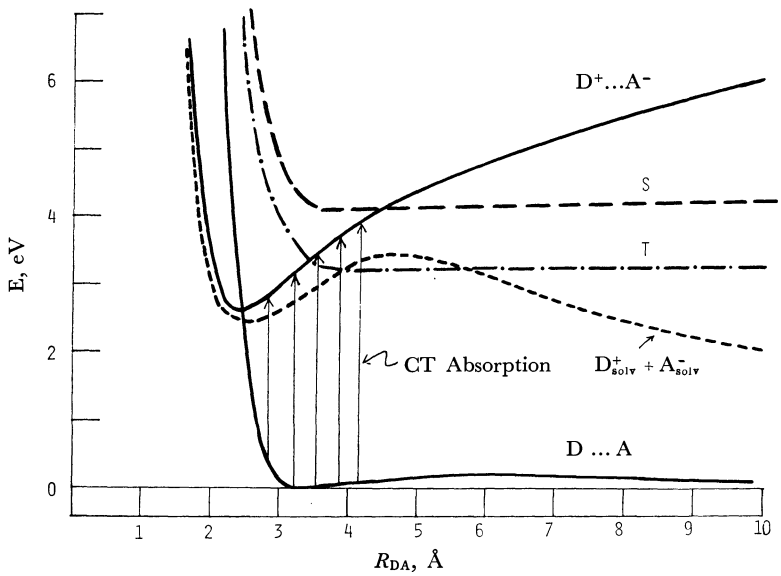

Fig. 8. Schematic diagram of the energy curves for the ground and various excited states of a donor-acceptor system.

Another mechanism, in which collison of oxygen with the donor in the singlet excited state leads to D^+_{solv} and $O_2^-{}_{solv}$ seems rather unlikely, because the short lifetime of the singlet excited donor and relatively low concentration of oxygen in the solution ($\sim$0.01 M) suggest that such a process is of minor importance.

The above interpretation of the experimental results assumes the formation of oxygen anion. In aqueous solutions it has been proved by pulse radiolysis of H_2O–O_2 system.[18] According to this and also to spectroscopic studies of the oxygen-doped alkali-halide crystals,[19] the oxygen anion has absorption spectrum lying in the region around 2400 Å. In our experimental conditions, therefore, it was impossible to detect the spectrum of oxygen anion even if it exists for a certain length of time. It is also very likely that the O_2^- anion reacts with the solvent rapidly, forming other types of anions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3773—3779 (1970)

Electron Spin-Spin Interaction and Methylene Bond Angles in the Quintet Ground State of *m*-Phenylene-dimethylene Radicals

Jiro HIGUCHI

Department of Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

(Received July 21, 1970)

The effect of the methylene bond angles on the electron spin-spin interaction has been semi-empirically investigated for the quintet ground states of the *m*-phenylene-dimethylene radicals, especially *m*-phenylene-bismethylene and *m*-phenylene-bisphenylmethylene. The D and E values calculated are compared with those observed, and the most probable structure, with a methylene bond angle near 140°, is estimated, as in the phenylmethylene radical.

Previously, the effect of the bond angle in the electron spin-spin interaction was semi-quantitatively investigated for the mono-methylene derivatives, especially the methylene and phenylmethylene radicals.[1] For these radicals, the spin Hamiltonian in the absence of the external magnetic field is expressed as:

$$\mathcal{H} = D\left[S_z^2 - \frac{1}{3}S(S+1)\right] + E[S_x^2 - S_y^2]. \quad (1)$$

In these derivatives, the value of $|E|/|D|$ can be used to determine the angle of the bent methylene carbon (–C–) bond by comparing the observed value with that calculated according to the following formulae:

$$D = \left(\frac{3e^2\hbar^2}{4m^2c^2}\right)\frac{2!(2S-2)!}{(2S)!}\sum_{i,j}\left\langle \phi_i(1)\phi_j(2) - \phi_j(1)\phi_i(2) \times \left| \frac{r_{12}^2 - 3z_{12}^2}{r_{12}^5} \right| \phi_i(1)\phi_j(2) \right\rangle \quad (2)$$

and:

$$E = \left(\frac{3e^2\hbar^2}{4m^2c^2}\right)\frac{2!(2S-2)!}{(2S)!}\sum_{i,j}\left\langle \phi_i(1)\phi_j(2) - \phi_j(1)\phi_i(2) \times \left| \frac{y_{12}^2 - x_{12}^2}{r_{12}^5} \right| \phi_i(1)\phi_j(2) \right\rangle \quad (3)$$

where the ϕ_i's are the unpaired orbitals. This approach is possible because of the facts that the σ-electron spin density is fairly close to unity at the –C– atom and the π-electron spin distribution is insensitive to the change in the –C– bond angle. As a result, the ratio of $|E|/|D|$ is mainly determined by the *s-p* hybridization of the unpaired σ orbital at the –C– atom. In these circumstances, the observed value of $|E|/|D|$ in phenyl derivatives can be explained by a –C– bond angle near 145°.[2]

Recently, electron spin resonance (ESR) absorption by quintet ground states of organic radicals has been reported for *m*-phenylene-bisphenylmethylene [*m*-$C_6H_4(CC_6H_5)_2$] in single crystals of benzophenone by Itoh[3] [$D/\boldsymbol{hc} = \pm 0.07137\ \mathrm{cm}^{-1}$, $E/\boldsymbol{hc} = \pm 0.01963\ \mathrm{cm}^{-1}$],[4] and for *m*-phenylene-bis-

methylene [m-$C_6H_4(CH)_2$] [$|D|/hc=0.0844$ cm^{-1}, $|E|/hc=0.0233$cm^{-1}], m-phenylene-bisphenylmethylene [$|D|/hc=0.0701$ cm^{-1}, $|E|/hc=0.020$ cm^{-1}], and m-phenylene-dinitrene [m-$C_6H_4N_2$] [$|D|/hc=0.156$ cm^{-1}, $|E|/hc=0.029$ cm^{-1}] in rigid solvents by Wasserman, Murray, Yager, Trozzolo, and Smolinsky.[5] These reports are the first demonstrations of quintet states in organic radicals. Although the possibility of higher molecular spin multiplets has already been discussed for these molecular species,[6-8] and the D and E values theoretically calculated by assuming the linear –C– bonds,[6,7] the effect of the bent –C– bonds has not yet been treated. In the present work, therefore, such an effect will be discussed for dimethylene derivatives with a quintet ground state, especially for m-$C_6H_4(CH)_2$ and m-$C_6H_4(CC_6H_5)_2$, the observed $|E|/|D|$ values of which are 0.276 and 0.275, respectively.

The treatment adopted here is just the same as in the previous papers.[1,6,7] That is, the one-center integrals were those calculated from the self-consistent field (SCF) atomic orbitals (AO's) of the carbon atom (the ^1D state) expanded by Löwdin.[9] The two-center integrals were approximately evaluated as follows: the $2s$ electron was replaced by a unit point charge at the nucleus, the $2p$ electron was two half-unit point charges located to give the same quadrupole moment, and the atomic dipole effect was added as a positive and a negative charge of

$$\int_0^\infty r^2 dr \int_0^{\pi/2} \sin\theta d\theta \int_0^{2\pi} \chi_{2s}\chi_{2p\sigma} d\phi$$

located to fit the atomic dipole moment. All the methylene bonds were assumed to be coplanar with the central phenylene group. All the C–C distances were taken as 1.393 Å as in the benzene molecule,[10] and the simple LCAO-MO's were used for the π-orbitals. The unpaired σ orbitals were assumed to be hybridized ones located at each –C– atom and directed along the bisector of the –C– bond angle. For the sake of simplicity, configuration interaction was disregarded.

Calculation and Results

In addition to the most important contribution of the n-π (σ-π) type, the spin-spin interaction in the m-phenylene-dimethylene radicals includes the π-π and the n-n types,[7] since the two σ and two π orbitals are occupied by unpaired electrons. As has previously been shown,[7] these two interactions should not be negligibly small compared with the n-π type and should be included in any semi-quantitative discussion of the zero-field splittings of these radicals. In the present paper, therefore, the D and E values [*cf.* Eqs. (2) and (3)] in m-$C_6H_4(CH)_2$ and m-$C_6H_4(CC_6H_5)_2$ radicals were calculated by including all the types of interaction. The coordinate system and the –C– bond angles were taken as shown in Fig. 1.

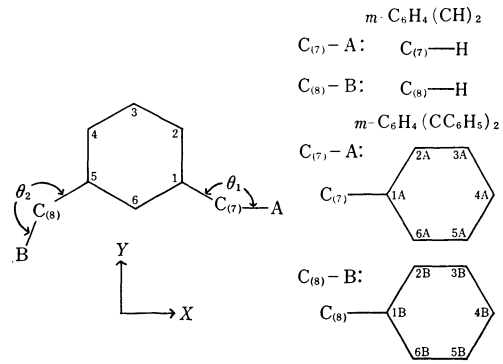

Fig. 1. Coordinate system (right-handed system) and the –C– bond angles in m-$C_6H_4(CX)_2$.

In the first instance, the m-$C_6H_4(CH)_2$ was taken as the simplest example of the ground-state quintet radicals on the assumption of the planar structure. The unpaired orbitals used were as follows:

$$\phi_1 = A_1\left[\chi_{2s7}\cot\frac{\theta_1}{2} + \left(1-\cot^2\frac{\theta_1}{2}\right)^{1/2} \times\left\{\chi_{2px7}\sin\left(\frac{\pi}{3}-\frac{\theta_1}{2}\right) - \chi_{2py7}\cos\left(\frac{\pi}{3}-\frac{\theta_1}{2}\right)\right\}\right] \quad (4)$$

$$\phi_2 = A_2\left[\chi_{2s8}\cot\frac{\theta_2}{2} - \left(1-\cot^2\frac{\theta_2}{2}\right)^{1/2} \times\left\{\chi_{2px8}\sin\left(\frac{\pi}{3}-\frac{\theta_2}{2}\right) + \chi_{2py8}\cos\left(\frac{\pi}{3}-\frac{\theta_2}{2}\right)\right\}\right] \quad (5)$$

$$\phi_3 = (3)^{-1/2}[-\chi_{2pz2}+\chi_{2pz7}+\chi_{2pz8}] \quad (6)$$

$$\phi_4 = (2)^{-1}[\chi_{2pz4}-\chi_{2pz6}+\chi_{2pz7}-\chi_{2pz8}] \quad (7)$$

where

$$A_i = \begin{cases} +1 & \left(\frac{\pi}{2}<\theta_i<\pi\right) \\ -1 & \left(\pi<\theta_i<\frac{3}{2}\pi\right) \end{cases} \quad (i=1,2). \quad (8)$$

The s-p hybridization in the ϕ_1 and ϕ_2 orbitals is determined by the –C– bond angles of θ_1 and θ_2, respectively, on the assumption that each bonding orbital of the –C– atom is equivalent and is directed along each bond. In the case of $\theta_1=\theta_2$, that is, when the radical belongs to the molecular symmetry of C_{2v}, the D and E values shown in Fig. 2 are

obtained. A similar calculation was carried out on the assumption that $\theta_1+\theta_2=360°$, that is, when the $-C_{(8)}-H_{(8)}$ coincides with the $-C_{(7)}-H_{(7)}$ by the rotation of 120° about the center of the phenylene ring. The results thus obtained are shown in Fig. 3. The other configurations are less probable in view of the equivalence in the methylene bonds. The ratio of E/D thus obtained is shown in Figs. 4 and 5, corresponding to the cases of $\theta_1=\theta_2$ and $\theta_1+\theta_2=360°$, respectively. As the observed value of $|E|/|D|$ is 0.276, one finds eight probable sets of the –C– bond angles, θ_1 and θ_2, where the calculated ratio coincides with the observed ratio, as given in Table 1.

Next, the m-$C_6H_4(CC_6H_5)_2$ radical was treated because it is the only species thus far observed in

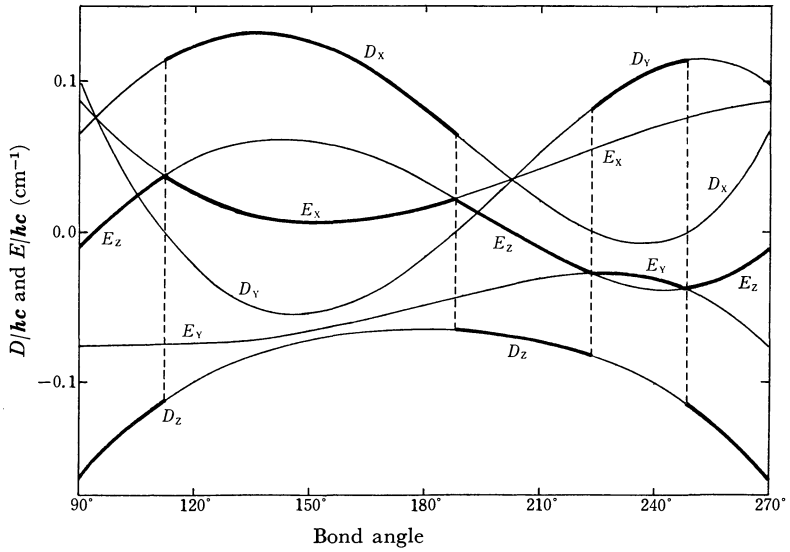

Fig. 2. D and E values of m-$C_6H_4(CH)_2$ in the case of $\theta_1=\theta_2$ (bold lines). The inferior letters, X, Y, and Z, on D and E imply that the set of axes (x, y, z) in Eqs. (2) and (3) should be taken the sets of directions, respectively, (Y, Z, X), (Z, X, Y), and (X, Y, Z) shown in Fig. 1.

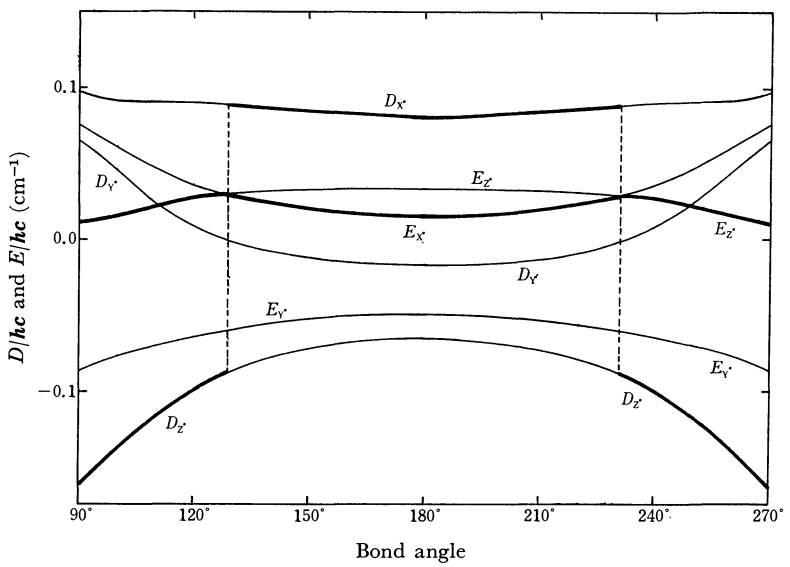

Fig. 3. D and E values of m-$C_6H_4(CH)_2$ in the case of $\theta_1+\theta_2=360°$ (bold lines). The inferior letters, X', Y', and Z', on D and E imply that the set of axes (x, y, z) in Eqs. (2) and (3) are close to the sets of directions, respectively, (Y, Z, X), (Z, X, Y), and (X, Y, Z) shown in Fig. 1. In this case, the deviations of the latter directions from the former axes are seen in the text.

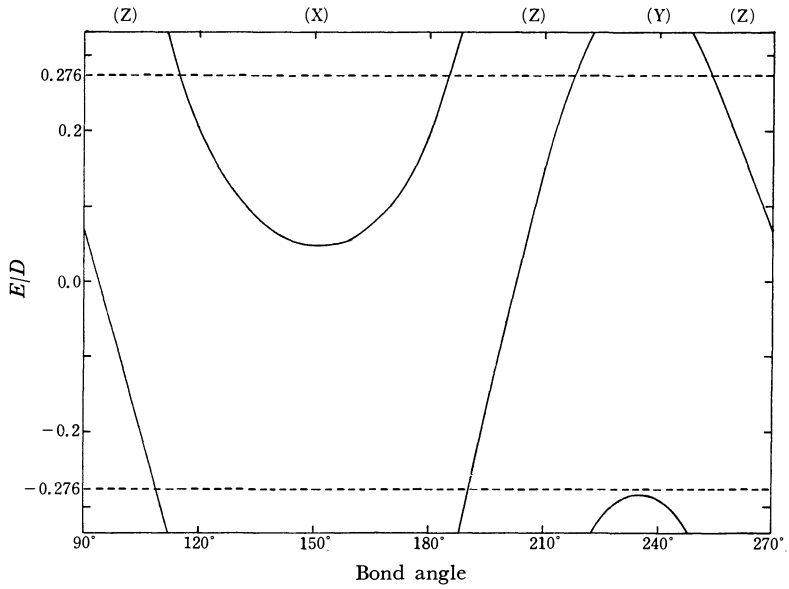

Fig. 4. The ratio of E/D of m-$C_6H_4(CH)_2$ in the case of $\theta_1=\theta_2$. The letters on the top of the figure indicate the directions of the z axis of the fine-structure tensor.

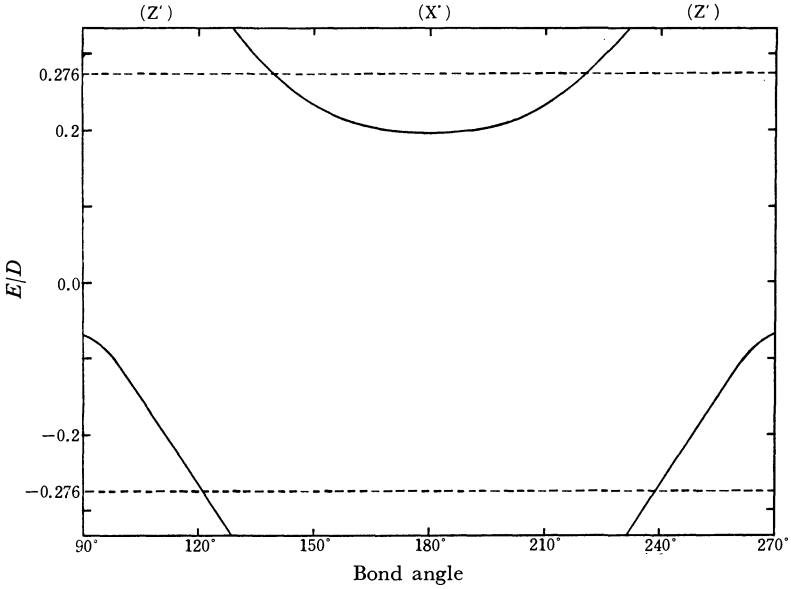

Fig. 5. The ratio of E/D of m-$C_6H_4(CH)_2$ in the case of $\theta_1+\theta_2=360°$. The letters on the top of the figure indicates the approximate directions of the z axis of the fine-structure tensor.

a single crystal. In this case, both the side phenyl groups were assumed to be either coplanar with, or perpendicular to, the central phenylene group. In the coplanar case, the treatment adopted was just the same as in the case of m-$C_6H_4(CH)_2$ except that the π orbitals used were as follows:

$$\phi_3^c = (18)^{-1/2}[-2\chi_{2pz2}+2\chi_{2pz7}+2\chi_{2pz8} -\chi_{2pz2A}+\chi_{2pz4A}-\chi_{2pz6A}-\chi_{2pz2B}+\chi_{2pz4B}-\chi_{2pz6B}] \quad (9)$$

and:

$$\phi_4^c = (22)^{-1/2}[2\chi_{2pz4}-2\chi_{2pz6}+2\chi_{2pz7}-2\chi_{2pz8} -\chi_{2pz2A}+\chi_{2pz4A}-\chi_{2pz6A}+\chi_{2pz2B}-\chi_{2pz4B}+\chi_{2pz6B}]. \quad (10)$$

In the perpendicular case, the following assumption was made: the unpaired orbitals parallel to the phenylene group are given by simple LCAO forms which are constructed from the zero-energy π-orbital

of phenylmethylene and the s-p hybridized orbital of the methylene carbon so as to give the –C– bond angle in question as follows:

$$\phi_3^{\mathrm{p}} = \left(7+\cot^2\frac{\theta_1}{2}\right)^{-1/2}\left[2\left(1+\cot^2\frac{\theta_1}{2}\right)^{1/2}\phi_1 + A_1\left(1-\cot^2\frac{\theta_1}{2}\right)^{1/2}\left\{(\chi_{2px2\mathrm{A}}-\chi_{2px4\mathrm{A}}+\chi_{2px6\mathrm{A}}) \times \sin\left(\frac{5}{6}\pi-\theta_1\right) - (\chi_{2py2\mathrm{A}}-\chi_{2py4\mathrm{A}}+\chi_{2py6\mathrm{A}}) \times \cos\left(\frac{5}{6}\pi-\theta_1\right)\right\}\right] \quad (11)$$

and:

$$\phi_3^{\mathrm{p}} = \left(7+\cot^2\frac{\theta_2}{2}\right)^{-1/2}\left[2\left(1+\cot^2\frac{\theta_2}{2}\right)^{1/2}\phi_2 - A_2\left(1-\cot^2\frac{\theta_2}{2}\right)^{1/2}\left\{(\chi_{2px2\mathrm{B}}-\chi_{2px4\mathrm{B}}+\chi_{2px6\mathrm{B}}) \times \sin\left(\frac{5}{6}\pi-\theta_2\right) + (\chi_{2py2\mathrm{B}}-\chi_{2py4\mathrm{B}}+\chi_{2py6\mathrm{B}}) \times \cos\left(\frac{5}{6}\pi-\theta_2\right)\right\}\right] \quad (12)$$

The calculation was performed in the two cases of the –C– bond angle of $\theta_1=\theta_2$ and $\theta_1+\theta_2=360°$, as in the m-$C_6H_4(CH)_2$ radical. The results thus obtained are quite similar to that obtained in the case of m-$C_6H_4(CH)_2$ shown in Figs. 4 and 5, and no significant differences can be found among these relative relationships. In each case, there are five sets of the –C– bond angles (θ_1 and θ_2), where the $|E|/|D|$ ratio calculated coincides with the observed value of 0.275 at larger –C– bond angles ($120°<\theta_1, \theta_2<240°$), as Table 1 shows.

For a structure with small –C– bond angles ($\theta_1, \theta_2<120°$, or $\theta_1, \theta_2>240°$), the ground state is not a quintet, since the orbitals,[11] $2^{-1/2}(\phi_1-\phi_2)$ and/or $2^{-1/2}(\phi_1+\phi_2)$, are doubly occupied because of the large energy difference between the ϕ_1 (or ϕ_2) and the ϕ_3 (or ϕ_4). As a result, such structures of these radicals, [I], [II], and [VI] in Table 1, are outside the scope of this discussion.

According to the recent experiment on m-C_6H_4-$(CC_6H_5)_2$ by Itoh,[4] the radical was oriented as a substituent for the two nearest neighboring molecules in a single crystal of benzophenone.[12] Taking

the orientation into consideration, the z axis of the fine-structure tensor does not appear to make a large angle (possibly within 30°) with the line $C_{(8)}$–$C_{(7)}$ (the X axis in Fig. 1). The experimental value of E/D is positive if the principal axes are chosen under the condition of $|D_x|<|D_y|<|D_z|$, as is usually done. These results appear to favor the cases [III] and [VIII] in Table 1. In these cases, the x axis of the fine-structure tensor lies close to the plane of the central phenylene group. It may be noted that these results show that the phenylene group of the radical may be oriented rather perpendicularly to the ab plane in the benzophenone single crystal.

Although the phenyl group is substituted for the hydrogen atom, the electronic property of the methylene bond is not significantly changed, and the relative angular dependence of the D and E is quite similar to that of the phenyl derivatives. As a result of this, one may reasonably assume that the directions of the principal axes of the fine-structure tensor for m-$C_6H_4(CH)_2$ do not much deviate from those of m-$C_6H_4(CC_6H_5)_2$ with respect to the central phenylene group. In that case, the permissible –C– bond angles are also restricted within the cases of [III] and [VIII] in Table 1. For reference, the calculated values of D and E in m-$C_6H_4(CH)_2$ and m-$C_6H_4(CC_6H_5)_2$ with the probably structures, [III] and [VIII], are given in Table 2.

Discussion

The present work includes several approximations, most of which are quite parallel to those of previous papers[1,6,7] and therefore need not be repeated here. As has been discussed already,[1] the approximations of the unpaired orbitals of ϕ_1 and ϕ_2, Eqs. (4) and (5), are not completely satisfactory, but they may be plausible for obtaining the trend of the D and E at larger –C– bond angles.[13] Although the unpaired orbitals of ϕ_1^p and ϕ_2^p, Eqs. (11) and (12), were also obtained so as to give the –C– bond angle in question, the use of these orbitals corresponds to the treatment that disregards the energy difference between the $2p$ and the s-p hybridized orbitals. In this case, the spin density at each –C– atom may be somewhat overestimated. However, the E/D ratio may not be significantly changed because both the D and E values are approximately proportional to the spin density at the –C– atom. Consequently, the approximation of the unpaired orbitals, ϕ_1^p and ϕ_2^p, may also be plausible in discussing the trend of the E/D ratio at larger –C– bond angles.

The contribution of the spin-orbit interaction is important in discussing the exact values of D and E.[14,15] Actually, the energy of this effect is predominatly due to the atomic term, while it is comparatively insensitive to the delocalization of unpaired electrons. In the case of the methylene radical, the E/D ratio is scarcely change if the D and E values of the spin-orbit interaction calculated by Glarum[14] are added to those of the spin-spin interaction.[1,6] In view of these facts, the present results may still be valid in a semi-quantitative sense.

In the case of $\theta_1+\theta_2=360°$ ($\theta_1<\theta_2$), the directions of the principal axes of the fine-structure tensor do not always coincide with those of the coordinate axes shown in Fig. 1. That is, one of the former axes which is perpendicular to the phenylene group (the y axis for $\theta_1 \geqq 129°$, or the

13) As discussed in the previous paper (Ref. 1), the use of the hybridized orbital for the unpaired orbital (*e. g.* ϕ_1 and ϕ_2) is plausible, since the coefficients of the $2s$ and $2p$ orbitals are fairly close to those of the SCF-LCAO-MO of the NH_2 radical [J. Higuchi, *J. Chem. Phys.*, **24**, 535 (1956).] at larger bond angles. Recently, Hoffmann *et al.* [R. Hoffmann, G. D. Zeiss and G. W. Van Dine, *J. Amer. Chem. Soc.*, **90**, 1485 (1968)] showed that the contributions (gross atomic population) of the $2s$ and $2p$ orbitals are somewhat different from those of the extended Hückel orbital of the phenylmethylene radical. However, it may be too hasty to deny the validity of the present approximation from only such a calculation, since the extended Hückel orbitals depend markedly on the selection of the parameters used and are not the best approximation of the SCF-LCAO-MO's.

15) S. J. Fogel and H. F. Hameka, *J. Chem. Phys.*, **42**, 132 (1965).

z axis for $\theta_1 < 129°$) is actually parallel to the Z axis of the latter system. However, the z axis ($\theta_1 \geq 129°$) or the x axis ($\theta_1 < 129°$) of the fine-structure tensor makes an angle of $90° - \theta_1/2$ counterclockwise with the line $C_{(8)}$–$C_{(7)}$ (the X axis in Fig. 1), if only the n-π interaction at each methylene carbon is taken into account. That is, the angle between the X axis and the z (or x) axis increases with decreasing the –C– bond angle. Actually, such an angle is rather large compared with that of the above one-center approximation, as can be seen in the last column [VIII] in Table 1. Apparently, this is due to the fact that other types of interaction occur in the ground-state quintet radicals.

There are many molecular species which are also expected to yield a multiplet ground state in ESR spectroscopy. Especially for the polyacene dimethylene derivatives, the π-electron distribution is fairly different from that of the present case and the spin densities at the two methylene carbons are not always equivalent. As a result, the angle between the z axis of the fine-structure tensor and the line with the two methylene carbons may be changed somewhat as compared with the cases of the radicals treated here.

It may be noted that, in the case of $\theta_1 \neq \theta_2$ and $\theta_1 + \theta_2 \neq 360°$, there are other possible sets of –C– bond angles where the calculated ratio of E/D coindcies with the observed value and where the z axis of the fine-structure tensor does not make a large angle with the X axis in Fig. 1. Such structures can be seen in configurations with intermediate –C– bond angles between the cases [III] and [VIII], such as $\theta_1 \simeq 160°$ and $\theta_2 \simeq 207°$. However, they may be less important for our present purposes except if a remarkable distortion of the radical in the host crystal were to occur.

The possible structure and the directions of the principal axes of the fine-structure tensor obtained in the present work do not always coincide with those estimated by Wasserman *et al.*[5] However, the details of their work are not clear in their report and comparison may be difficult because of their inclusion of some semi-empirical values.

For the triplet or quintet ground state of the methylene derivatives, the molecular structure has not been conclusively determined, since there seems to be no helpful experimental method except the magnetic resonance technique in the present situation. For the benzophenone molecule, the dihedral angle between the two phenyl groups is 56° in the single crystal.[16] This may suggest that the central phenylene group in m-$C_6H_4(CC_6H_5)_2$ makes some angles with the two planes of methylene bonds [$C_{(1)}$–$C_{(7)}$–$C_{(1A)}$ and $C_{(3)}$–$C_{(8)}$–$C_{(1B)}$] and also the z axis of the fine-structure tensor. The calculation of the diphenylmethylene[2] showed that the E/D value was almost insensitive to the change in the dihedral angle between the two phenyl groups, although it is concerned with only the small contribution of the interatomic spin-spin interaction. If only the n-π interaction at each methylene carbon is taken into account, the E/D ratio in m-$C_6H_4(CC_6H_5)_2$ is changed with an increase in the dihedral angle between the central phenylene and the two planes of the methylene bonds. For the permissible structures given in Table 2, however, the deviation from the planar configuration is small at the above dihedral angles between 0° and 30°.[17] Accordingly, the results obtained for the structures with coplanar –C– bonds may still be useful in discussing the –C– bond angle semi-quantitatively.

If the absolute sign of the D were to be determined by an experiment at a low temperature, one could still not choose between the cases [III] and [VIII] by the present procedure alone, since both the D values calculated are positive. However, it may be possible to obtain some information on the –C– bond angles if the ^{13}C hyperfine splittings of the methylene carbons are obtained. On the other hand, it might also be possible to estimate the probable structure if a detailed calculation of the electronic structure is carried out. Under these circumstances, the following speculation is possible. On the assumption that the –C– bond angles are not very different from the calculated value (146°) of the phenylmethylene,[2] the case [VIII] might be the more probable,[18] although there is still a possibility of the structure [III]. At any rate, the present procedure may, in general, be useful not only for obtaining information on the molecular structures of fairly large radicals with a multiplet ground state, especially their methylene bond angles, but also in estimating their orientation in the host single crystal when that cannot be determined experimentally.

The author wishes to thank Dr. K. Itoh for communicating his experimental results before publication and for his helpful discussion, and Dr. E. Wasserman for communicating his result before publication. Most of the numerical calculation were carried out on the HITAC 5020E at Computer Centre, The University of Tokyo.

17) In the benzophenone molecule, the dihedral angle between the plane of carbonyl bond [C–(C=O)–C] and the phenyl group is 30° and the above C–C–C bond angle is 122° (Ref. 16). As a result, the dihedral angle in the methylene derivatives is expected to be rather smaller than 30° because of the –C– bond angle larger than 122°.

18) A preliminary experimental result of 1,3,5-$C_6H_3(CC_6H_5)_3$ radical by Itoh [private communication] is also favorable to the present assumption.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3780—3789 (1970)

Far Infrared Transmission Spectra and Lattice Vibrations of $RbNiF_3$ and $CsNiF_3$

Kay KOHN*1 and Ichiro NAKAGAWA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received July 21, 1970)

The infrared absorption spectra of $RbNiF_3$ and $CsNiF_3$, both with a perovskite-like structure, have been measured in the region 500—50 cm^{-1} at room temperature and at liquid nitrogen temperature. The observed bands can be classified into three groups, corresponding to the three absorption bands in perovskite. These bands can reasonably be assigned on the basis of the crystal symmetry of the investigated compounds. A normal coordinate analysis of a crystal as a whole has been performed, where the interatomic force constants between the atom pairs within a distance of 3.5 Å are taken into account. It was shown that the normal coordinate treatment of the optically-active vibrations on the basis of a molecular dynamics model is useful for the interpretation of the lattice vibrations in these fluorides. The effects of the structural differences of the lattice vibrations are discussed.

In recent years several investigations of lattice vibrations in perovskite-type fluorides AMF_3 have been made, and the nature of the interatomic forces in these compounds is coming to be clear.[1-5] The observed infrared spectra were well interpreted on the basis of a valence force type potential for MF_6-octahedron and a central force type potential for the other atom pairs, A-F, F-F, and M-A.[5] This means that some covalent character is included in the M-F bond, even in the "ionic" crystal AMF_3.

Various compounds with the composition AMX_3, which have a crystal structure closely related to the perovskite structure, have been discovered, and the stability relations among these structures have been discussed.[6,7] All these compounds are com-

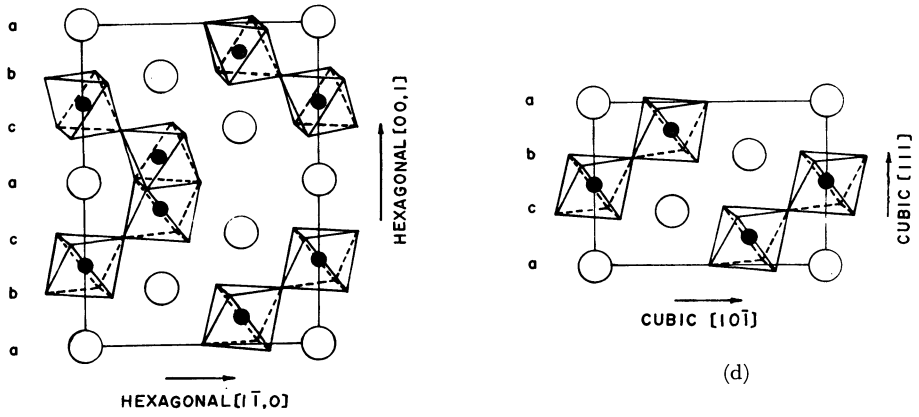

Fig. 1. Crystal structures of $RbNiF_3$ and $CsNiF_3$. All Ni (full circle) and Rb or Cs (open circle) ions on the hexagonal (1.1, 0) plane are illustrated. F ions are located on the octahedra around Ni ions. (a) $CsNiF_3$ 2L, (b) $CsNiF_3$ 9L, (c) $RbNiF_3$ 6L, (d) $RbNiF_3$ cubic.

posed of closely-packed layer lattice of larger cations, A, and anions, X, while smaller cations, M, are located at the octahedral interstices of the AX_3 lattice. The only difference between the several structures is in the stacking order of the closely-packed layers. If we denote the three different phases of such layers in a closely-packed structure as *a*, *b*, and *c*, an ordinary perovskite may be expressed as *abcabc*. The structures with the stacking sequences *ab* (2-layer type: 2L), *abcacb* (6-layer type: 6L), and *ababcbcac* (9-layer type: 9L) appear in fluorides, as is shown in Fig. 1.

The purpose of the present study is to investigate how these structural differences are reflected in the infrared spectra and to clarify the lattice vibrations in these "perovskite-like" compounds. Our aims are to establish the actual forms of vibrations, to test the validity of the pictures used for perovskites in a previous work by one of the present authors (I. N.) on these compounds, and, further, to establish the interrelations between the nature of the bonds and the stabilities of the various structures. For this purpose we have chosen to study two fluorides, $RbNiF_3$ and $CsNiF_3$. $RbNiF_3$ has a 6-layer structure (hexagonal $BaTiO_3$ structure) at ordinary pressure, and it is transformed into a cubic perovskite structure at 10 kbar.[6] $CsNiF_3$ has 2-layer structure at ordinary pressure, and it is transformed into a 9-layer structure at a few kbar.[8,9] Thus, we can compare different structures with the same composition.

We measured the far infrared transmission spectra at room temperature and at liquid nitrogen temperature. We also calculated the lattice vibrations on the same assumptions regarding interatomic forces as in the previous paper. The results show that the picture applied to perovskites is also valid in "perovskite-like" fluorides. The potential constants, which give calculated frequencies in good agreement with the observed, were also determined.

Experimental

Polycrystalline $RbNiF_3$ 6L and $CsNiF_3$ 2L were prepared from an intimate mixture of RbF and NiF_2 or CsF and NiF_2 by reaction at an elevated temperature. The reaction was made in a sealed-off platinum ampoule in order to prevent oxidation and evaporation. The high pressure phases, $RbNiF_3$ cubic and $CsNiF_3$ 9L, were supplied by Dr. Y. Syono of the Institute for Solid State Physics of the University of Tokyo. They were prepared from the corresponding low pressure phases using a tetrahedral anvil type, high pressure apparatus. These samples were dispersed in polyethylene sheets for use in the measurements.

A Hitachi FIS-I vacuum infrared spectrometer (500—50 cm^{-1}) was used. In the low-temperature measurements, samples were placed in direct contact with the metal conductor in the cryostat, and spectral measurements were made according to the procedure described in a previous paper.[5] The observed spectra are reproduced in Fig. 2.

Spectral measurements are limited to the transmittance, and throughout this study we regard the absorption frequencies obtained from the powder samples as ν's (resonance frequencies or minimum transmission frequencies as a thickness $d \to 0$). We checked the difference between the resonance frequencies obtained from the reflection data of a single crystal and those from the transmission data of a powder sample for a closely-related compound, MgF_2, for which both crystal and powder samples are available. This difference was found to be less than 5%, as will be shown in Appendix1.

Observed Spectra

The observed spectrum of $RbNiF_3$ cubic is similar to that of the isomorphous compound $KNiF_3$. It consists of three absorption bands, around 390 cm^{-1}, 270 cm^{-1}, and 140 cm^{-1}. It is clear that they correspond to the Ni-F stretching, F-Ni-F bending, and A-F stretching vibrations respectively. Many more bands appeared in the spectra of $RbNiF_3$ 6L and $CsNiF_3$ 9L. They can also be classified into three groups, the bands in the 350—420 cm^{-1} range, those in the 200—300 cm^{-1} range, and those below 200 cm^{-1}. It can easily be understood that these bands arise from the splitting of the above three bands in more complicated structures. The spectrum of $CsNiF_3$ 2L consists of four bands. The two bands at lower frequencies are considered to arise from the F-Ni-F bending and Cs-F stretching vibrations. However, the two at 420 cm^{-1} and 340 cm^{-1} are either too high or too low to be simply compared with the corresponding band of cubic perovskite.

With a lowering of the temperature almost all the bands become sharp, and a few split into several components. At the same time, they shift to higher frequencies. Among them, the bands around 400 cm^{-1} show the most remarkable shift.

Lattice Vibrations of "Perovskite-like" Fluorides

The crystal structures of $RbNiF_3$ 6L, $RbNiF_3$ cubic, $CsNiF_3$ 2L,[10] and $CsNiF_3$ 9L (Fig. 1) belong to the space groups $D_{6h}^4-P6_3/mmc$, O_h^1-Pm3m, $D_{6h}^4-P6_3/mmc$, and $D_{3d}^5-R\bar{3}m$, and the Bravais primitive cells of these compounds consist of 6, 1, 2, and 3 formula units respectively. The crystallographic data relevant to later discussions are summarized in Table 1. The numbers of optically-active lattice vibrational modes in the different species were determined by factor-group analysis.[11] The results are shown in Table 2.

The optically-active vibrational frequencies and the corresponding vibrational modes were calculated according to the method of Shimanouchi, Tsuboi, and Miyazawa.[12] First, we took a potential function:

$$U = \frac{1}{2}\sum_{i,j}K_i(\Delta r_{\text{Ni-F}}{}^i{}_j)^2 + \frac{1}{2}\sum_{i,j}H_i(\Delta\alpha_{\text{F-Ni-F}}{}^i{}_j)^2 + \frac{1}{2}\sum_{i,j}F_i(\Delta q_{\text{F-F}}{}^i{}_j)^2 + \frac{1}{2}\sum_{i,j}f_i(\Delta q_{\text{A-F}}{}^i{}_j)^2$$

Table 2. Result of factor group analysis for optically active lattice vibrations of $RbNiF_3$ and $CsNiF_3$

Space group	Compounds	Number of modes in each species
$D_{6h}^4-P6_3/mmc$	$RbNiF_3$ 6L	$5A_{1g}+1A_{1u}+2A_{2g}+6A_{2u}$ $+6B_{1g}+2B_{1u}+1B_{2g}$ $+6B_{2u}+8E_{1g}+8E_{1u}$ $+6E_{2g}+7E_{2u}$ IR active: A_{2u} and E_{1u} (acoustical modes: $1A_{2u}$ $+1E_u$)
O_h^1-Pm3m	$RbNiF_3$ cubic	$3F_{1u}+1F_{2u}$ IR active: F_{1u} (acoustical modes: $1F_{1u}$)
$D_{6h}^4-P6_3/mmc$	$CsNiF_3$ 2L	$1A_{1g}+1A_{2g}+2A_{2u}+2B_{1g}$ $+1B_{1u}+2B_{2u}+3E_{1g}$ $+3E_{1u}+1E_{2g}+2E_{2u}$ IR active: A_{2u} and E_{1u} (acoustical modes: $1A_{2u}$ $+1E_{1u}$)
D_{3d}^5-R3m	$CsNiF_3$ 9L	$4A_{1g}+2A_{1u}+1A_{2g}+7A_{2u}$ $+5E_g+9E_u$ IR active: A_{2u} and E_u (acoustical modes: $1A_{2u}$ $+1E_u$)

where K_i's and H_i's denote the Ni-F bond-stretching and F-Ni-F angle-bending force constants. The f_i's and F_i's represent the interactions between the A cations (Rb^+ or Cs^+) and the F^- ions, and those between F^- ions, respectively. The sum was taken over all kinds of internal coordinates, i, and all the internal coordinates, j, for each kind of i in a Bravais primitive cell. These potential is a generalization of the potential function described in the previous paper. That is, we assumed a valence force type potential for the NiF_6-octahedron, and a central force type potential for all the atom pairs, for which the nonbonded repulsions or the ionic interactions are expected to be considerable. In the present case, all the interactions between the atom pairs within a distance of 3.5 Å were taken into account.

The internal coordinates, in which the potential function is expressed, are transformed into Cartesian diplacement coordinates, and the potential function is expressed in terms of Cartesian displacement coordinates. The optically-active $\boldsymbol{F}$-matrix (potential energy matrix), $\boldsymbol{F}_{op}$, in terms of the optically-active Cartesian displacement coordinates, is set up; the secular equation,

$$|\boldsymbol{M}^{-1}\boldsymbol{F}_{x\,op}-\boldsymbol{E}\lambda|=0$$

where $\boldsymbol{M}$ is a diagonal mass matrix and $\boldsymbol{E}$ is an unit matrix, gives the eigenvalues and eigenvectors which correspond to the frequencies and the vibrational modes. The normal modes are described on the basis of the Cartesian symmetry coordinates listed in Appendix 2.

In the course of the calculation, the values of the atomic positions and interatomic distances were needed. They were calculated using the lattice parameters given in Table 1. Since precise crystal data were lacking for $RbNiF_3$ 6L and $CsNiF_3$ 9L, we used some parameter values of isomorphous

compounds, $CsMnF_3$ (6L type) and $BaRuO_3$ (9L type). They are given in parentheses in Table 1. This is justified since the corresponding parameter values in $CsMnF_3$[13] and hexagonal $BaTiO_3$,[15] both of which have a 6L-type structure, are quite the same.

The numerical calculations were carried out with a HITAC 5020E computer at the Computation Center of the University of Tokyo. Programs, AXSM and CART, set up in our laboratory were used.[16] The calculated frequencies of optically-active vibrations are listed in Table 3, together with the observed values. The values of the force constants are given in Table 4. All the force constants were determined in a consistent way, in the sense that the relation between the interatomic distances and force constants was taken as universal for all the fluorides in the present study as well as for perovskite $KNiF_3$ in the previous paper. The following points should be made:

1) The force constants K_i's and F_i's are assumed to be functions of the interatomic distances r_{Ni-F} and r_{F-F}, respectively, regardless of the composition or structure of the compound (see Figs. 3 and 4).

2) The force constants H_i's are taken to have a constant value of 0.30 mdyn·Å in all cases.

3) The force constants f_i's are assumed to be a linear function of the ratio of the actual bond length, r_{A-F}, to the sum of the ionic radii, $r_{A^+}+r_{F^-}$ (see Fig. 5).

TABLE 4(a). FORCE CONSTANTS K_i USED IN THE CALCULATION

Compound	Kind of bond	Bond length (Å)	K_i (mdyn/Å)
$RbNiF_3$ 6L	Ni 2-F 2	1.99	0.70

$CsNiF_3$ 2L	Cs 1 -F 1	3.33	0.03

Discussion of Results

The spectrum of $RbNiF_3$ cubic reveals a typical feature characteristic of a regular cubic perovskite structure. The three absorption bands observed correspond to the Ni-F stretching, F-Ni-F angle

bending, and Rb-F stretching modes respectively, all of which belong to the F_{1u} species. In contrast with this simple spectrum, those of $RbNiF_3$ 6L and $CsNiF_3$ 9L are much more complicated. However, they can be explained if we consider that a single band in perovskite splits into several components in more complicated structures. This situation may be clearly seen in the form of the calculated normal modes of vibrations. In Fig.6(a) we show the atomic displacements for the normal modes of the lattice vibrations of $RbNiF_3$ 6L as an example. This is based on the transformation matrix, $\boldsymbol{L}_x$, between the Cartesian coordinates, $\boldsymbol{X}$ and the normal coordinates $\boldsymbol{Q}$, defined as $\boldsymbol{X}=\boldsymbol{L}_x\boldsymbol{Q}$, $\boldsymbol{M}^{-1}\boldsymbol{F}_x\boldsymbol{L}_x=\boldsymbol{L}_x\boldsymbol{\Lambda}$. Here we will examine how the above splittings come about in the Ni-F stretching modes in $RbNiF_3$ 6L. In this phase Ni ions are still surrounded by six F^- ions, as in perovskite-type $RbNiF_3$. However, we can expect that a single band in $RbNiF_3$ cubic will split, since:

1) there are two different sites, (*a*) and (*f*), for Ni ions and the vibrational modes of these NiF_6-octahedra couple together to give two different frequencies;

2) these NiF_6-octahedra are not regular, unlike in perovskite, but are somewhat distorted in different ways (Table 5), and

Table 5. Distortion of NiF_6-octahedra in $RbNiF_3$ and $CsNiF_3$

Compound	Central Ni ion[a)]	Ni-F bond length (Å)	F-Ni-F bond angle
$RbNiF_3$ 6L	Ni 1	2.01	92.1°
	Ni 2	1.99	95.5°
		2.05	76.6°
$RbNiF_3$ cubic	Ni 1	2.04	90°
$CsNiF_3$ 2L	Ni 1	2.10	82.8°
$CsNiF_3$ 9L	Ni 1	2.10	86.2°
	Ni 2	2.08	84.7°
		2.13	95.3°

a) See Table 1.

3) some of the freedom of motion of the F^- ions is inhibited by the symmetry in infrared active vibrations, and the form of the vibrational modes of a single octahedron undergoes some change. It may clearly be seen in Fig. 6 that a simple vibrational mode in perovskite (Fig. 6b) is modified, and that some modes have a feature of the partially angle-bending type. This tendency is essentially the same for all the compounds studied here.

The reasonable agreement between the calculated and the observed frequencies suggests that our model is still applicable to these fluorides. However, we must remark on several points in this connection. First, there are some differences between the values of the force constants K_i's used in this paper and those determined for some perovskite-type fluorides

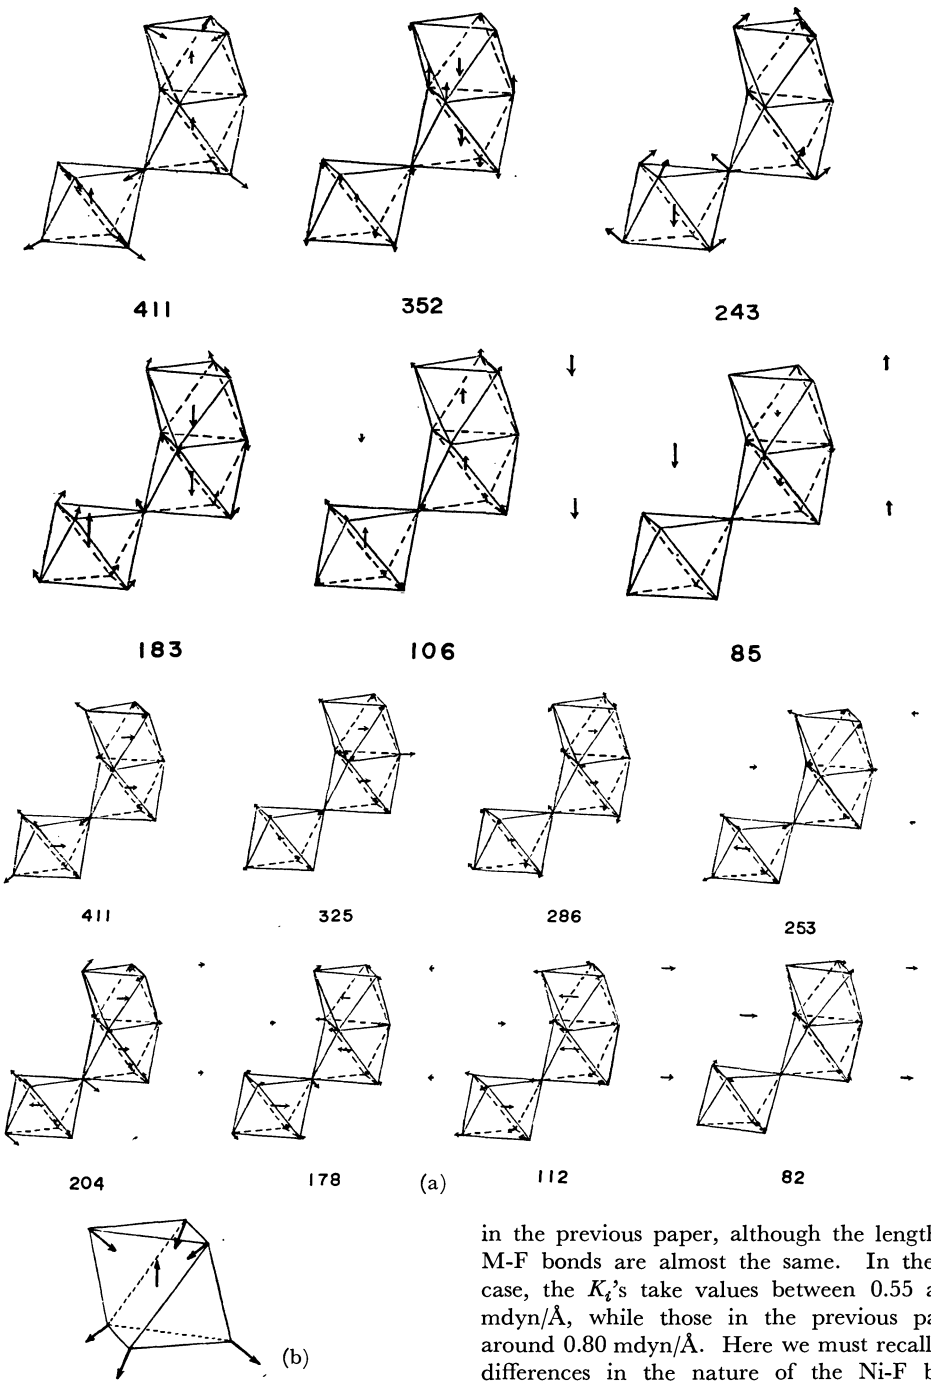

Fig. 6. (a) Displacements of ions for the lattice vibrational modes in $RbNiF_3$ 6L. Only a half of Bravais primitive cell is shown, since the displacements of other ions can be derived by considering inversion symmetry of the modes. The vibrational modes of A_{2u} and E_{1u} species are illustrated in upper and lower halves, respectively. (b) Displacements of ions in MF_6-octahedron for the Ni-F stretching vibrational mode in perovskite type fluoride.

in the previous paper, although the lengths of the M-F bonds are almost the same. In the present case, the K_i's take values between 0.55 and 0.70 mdyn/Å, while those in the previous paper are around 0.80 mdyn/Å. Here we must recall possible differences in the nature of the Ni-F bonds in these two cases. Some of the compounds in this study have a high pressure form, and the atoms are, so to speak, "squeezed together" in them. This will certainly cause a deviation of the force constants from their values in ordinary structures. In addition, there is some change in the covalent character in Ni-F bonds, as is suggested by the distortions of the NiF_6-octahedra. The distortion of NiF_6-octahedra are listed in Table 5. The

covalent character differs from one type of octahedron to another. Such factors are wholly neglected in our calculation, where the K_i's are taken as a function of the bond length only, and where the H_i's are assumed to be constant regardless of the actual bond angles. For instance, in $RbNiF_3$ 6L, the octahedron around the *f*-site Ni ions is much distorted. This suggests some modifications in some force constants, which results in the improvement in some of the calculated frequencies (352, 325, 286, 183, and 178 cm^{-1}). At present, however, we have no sound theoretical ground or empirical information sufficient to guide our estimation of the force constants in such cases. Thus, our simple model serves only as a useful starting point. The force constants, f_i's and F_i's, between nonbonded ions are more satisfactorily used.

As for $CsNiF_3$ 2L, we have some trouble in explaining the Ni-F stretching vibrations, since the calculated frequencies of the A_{2u} and E_{1u} species for this mode are almost the same, while we have two observed bands around 420 cm^{-1} and 340 cm^{-1}. An experimental check for isomorphous compounds is needed. A study about such compounds containing oxides and chlorides is now in progress.

The authors wish to express their thanks to Professor T. Shimanouchi of the University of Tokyo for his kind guidance and valuable discussions. Thanks are also due to Professor S. Akimoto and Dr Y. Syono of the Institute for Solid State Physics of the University of Tokyo for kindly supplying the samples of high pressure phases of $RbNiF_3$ and $CsNiF_3$.

Note Added in Proof.

Recently Dr D. Babel and Dr J. M. Longo have kindly informed us about their crystal data of $RbNiF_3$ 6-layer type (D. Babel: *Z. Anorg. Allgem. Chem.*, **369**, 117 (1969), R. J. Arnott and J. M. Longo: to be published in *J. Solid State Chem.*, **2**, (1970)). Their parameter values of ion sites are very close to those assumed in this paper.

Appendix 1. *Comparison of the Transmission Spectrum of Powdered Samples with the Reflection Spectrum of Single Crystals.*

The results of MgF_2 (uniaxial crystal: D_{4h}^{14}-*Pnnm*) are given in Fig. 7.

A transmission measurement of a MgF_2 powdered sample dispersed in a polyethylene sheet (*ca.* 1 mg/cm^2) was made by using a HITACHI EPI-L spectometer. A reflection measurement of the MgF_2 single crystal was made near a normal incidence on the *c*-plane, using HITACHI EPI-L and FIS-21 spectrometers with reflectance attachments. The optical constants were derived from the measured reflectivity, using the Kramers-Kronig relation.

The reflection spectrum and the real and imaginary parts of the infrared dielectric constant (ε' and ε'') are given in Fig. 7, where they are also compared with the transmission spectrum.

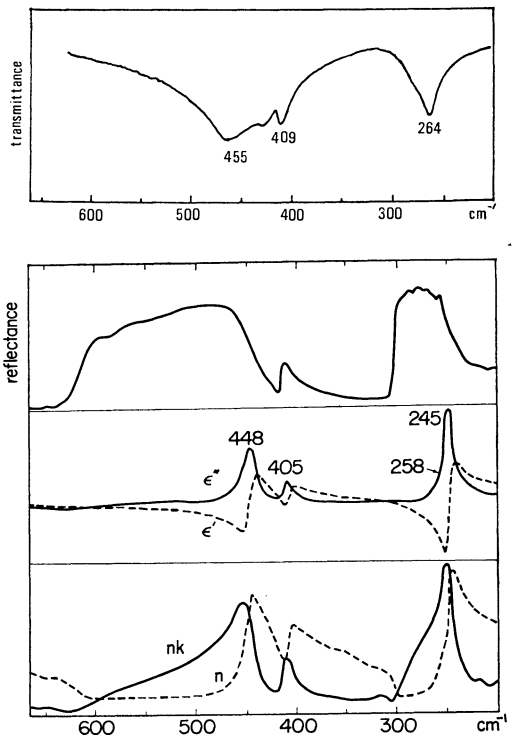

Fig. 7. Comparison of the transmission spectrum of powdered sample with the reflection spectrum of single crystal for MgF_2.

Appendix 2. *Cartesian Symmetry Coordinates of Infrared Active Vibrational Modes in "Perovskite-like" Compounds.*

The Cartesian symmetry coordinates of optically active vibrational modes in 2L, 6L, and 9L structures have been determined. The expressions for the infrared active vibrational modes are as follows:

1) $RbNiF_3$6L: Ions with the Cartesian coordinates given in the parenthesis are indexed as follows:

1 Ni 1; (0, 0, 0),
2 Ni 1; (0, 0, $c/2$),
3 Ni 2; ($-a/\sqrt{3}$, 0, w_1c),
4 Ni 2; ($-a/\sqrt{3}$, 0, $\overline{1/2-w_1c}$),
5 Ni 2; ($a/\sqrt{3}$, 0, $-w_1c$),
6 Ni 2; ($a/\sqrt{3}$, 0, $\overline{-1/2+w_1c}$),
7 F 1; $((\sqrt{3}/2)u_4a, (-3/2)u_4a, c/4)$,
8 F 1; $(-\sqrt{3}u_4a, 0, c/4)$,
9 F 1; $((\sqrt{3}/2)u_4a, (3/2)u_4a, c/4)$,
10 F 1; $(\sqrt{3}u_4a, 0, -c/4)$,
11 F 1; $((-\sqrt{3}/2)u_4a, (3/2)u_4a, -c/4)$,
12 F 1; $((-\sqrt{3}/2)u_4a, (-3/2)u_4a, -c/4)$,
13 F 2; $(-\sqrt{3}u_2a, 0, w_2c)$,
14 F 2; $((\sqrt{3}/2)u_2a, (-3/2)u_2a, w_2c)$,
15 F 2; $((\sqrt{3}/2)u_2a, (3/2)u_2a, w_2c)$,
16 F 2; $(-\sqrt{3}u_2a, 0, \overline{1/2-w_2c})$,
17 F 2; $((\sqrt{3}/2)u_2a, (-3/2)u_2a, \overline{1/2-w_2c})$,

18 F 2; $((\sqrt{3}/2)u_2a, (3/2)u_2a, 1/2-w_2c)$,
19 F 2; $(\sqrt{3}u_2a, 0, -w_2c)$,
20 F 2; $((-\sqrt{3}/2)u_2a, (3/2)u_2a, -w_2c)$,
21 F 2; $((-\sqrt{3}/2)u_2a, (-3/2)u_2a, -w_2c)$,
22 F 2; $(\sqrt{3}u_2a, 0, -1/2+w_2c)$,
23 F 2; $((-\sqrt{3}/2)u_2a, (3/2)u_2a, -1/2+w_2c)$,
24 F 2; $((-\sqrt{3}/2)u_2a, (-3/2)u_2a, -1/2+w_2c)$,
25 Rb 1; $(0, 0, c/4)$,
26 Rb 1; $(0, 0, -c/4)$,
27 Rb 2; $(a/\sqrt{3}, 0, w_3c)$,
28 Rb 2; $(a/\sqrt{3}, 0, 1/2-w_3c)$,
29 Rb 2; $(-a/\sqrt{3}, 0, -w_3c)$,
30 Rb 2; $(-a/\sqrt{3}, 0, -1/2+w_3c)$,

where u_i's and w_i's are parameter values (see Table 1). Then the Cartesian symmetry coordinates of A_{2u} and E_{1u} species are as follows.

(A_{2u})

Ni 1: $s_1=(1/\sqrt{2})\Delta(z_1+z_2)$,
Ni 2: $s_2=(1/\sqrt{4})\Delta(z_3+z_4+z_5+z_6)$,
Rb 1: $s_3=(1/\sqrt{2})\Delta(z_{25}+z_{26})$,
Rb 2: $s_4=(1/\sqrt{4})\Delta(z_{27}+z_{28}+z_{29}+z_{30})$,
F 1: $s_5=(1/\sqrt{6})\Delta(z_7+z_8+z_9+z_{10}+z_{11}+z_{12})$,
F 2: $s_6=(1/\sqrt{12})\Delta(z_{13}+z_{14}+z_{15}+z_{16}+z_{17}+z_{18}+z_{19}+z_{20}+z_{21}+z_{22}+z_{23}+z_{24})$,
F 2: $s_7=(1/\sqrt{12})\Delta\{(x_{13}+(-x_{14}+\sqrt{3}y_{14})/2+(-x_{15}-\sqrt{3}y_{15})/2-x_{16}-(-x_{17}+\sqrt{3}y_{17})/2-(-x_{18}-\sqrt{3}y_{18})/2+x_{19}+(-x_{20}+\sqrt{3}y_{20})/2+(-x_{21}-\sqrt{3}y_{21})/2-x_{22}-(-x_{23}+\sqrt{3}y_{23})/2-(-x_{24}-\sqrt{3}y_{24})/2),\}$

(E_{1u})

Ni 1: $s_1=(1/\sqrt{2})\Delta(x_1+x_2)$,
s_2=the same for y_i,
Ni 2: $s_3=(1/\sqrt{4})\Delta(x_3+x_4+x_5+x_6)$,
s_4=the same for y_i,
Rb 1: $s_5=(1/\sqrt{2})\Delta(x_{25}+x_{26})$,
s_6=the same for y_i,
Rb 2: $s_7=(1/\sqrt{4})\Delta(x_{27}+x_{28}+x_{29}+x_{30})$,
s_8=the same for y_i,
F 1: $s_9=(1/\sqrt{6})\Delta(x_7+x_8+x_9+x_{10}+x_{11}+x_{12})$,
s_{10}=the same for y_i,
F 1: $s_{11}=(1/\sqrt{6})\Delta\{(x_7+(-x_8-\sqrt{3}y_8)/2+(-x_9+\sqrt{3}y_9)/2+x_{10}+(-x_{11}-\sqrt{3}y_{11})/2+(-x_{12}+\sqrt{3}y_{12})/2)\}$,
F 1: $s_{12}=(1/\sqrt{6})\Delta\{(y_7+(\sqrt{3}x_8-y_8)/2+(-\sqrt{3}x_9-y_9)/2+y_{10}+(\sqrt{3}x_{11}-y_{11})/2+(-\sqrt{3}x_{12}-y_{12})/2)\}$,
F 2: $s_{13}=(1/\sqrt{12})(x_{13}+x_{14}+x_{15}+x_{16}+x_{17}+x_{18}+x_{19}+x_{20}+x_{21}+x_{22}+x_{23}+x_{24})$,
s_{14}=the same for y_i,
F 2: $s_{15}=(1/\sqrt{12})\Delta\{(x_{13}+(-x_{14}-\sqrt{3}y_{14})/2+(-x_{15}+\sqrt{3}y_{15})/2+x_{16}+(-x_{17}-\sqrt{3}y_{17})/2+(-x_{18}+\sqrt{3}y_{18})/2+x_{19}+(-x_{20}-\sqrt{3}y_{20})/2+(-x_{21}+\sqrt{3}y_{21})/2+x_{22}+(-x_{23}-\sqrt{3}y_{23})/2+(-x_{24}+\sqrt{3}y_{24})/2)\}$,
F 2: $s_{16}=(1/\sqrt{12})\Delta\{(y_{13}+(\sqrt{3}x_{14}-y_{14})/2+(-\sqrt{3}x_{15}-y_{15})/2+y_{16}+(\sqrt{3}x_{17}-y_{17})/2+(-\sqrt{3}x_{18}-y_{18})/2+y_{19}+(\sqrt{3}x_{20}-y_{20})/2+(-\sqrt{3}x_{21}-y_{21})/2+y_{22}+(\sqrt{3}x_{23}-y_{23})/2+(-\sqrt{3}x_{24}-y_{24})/2)\}$,
F 2: $s_{17}=(1/\sqrt{24})\Delta\{(2z_{13}-z_{14}-z_{15}-2z_{16}+z_{17}+z_{18}+2z_{19}-z_{20}-z_{21}-2z_{22}+z_{23}+z_{24})\}$,
$s_{18}=(1/\sqrt{8})\Delta\{(z_{14}-z_{15}-z_{17}+z_{18}+z_{20}-z_{21}-z_{23}+z_{24})\}$.

2) $CsNiF_3$ 2L: If ions are appropriately indexed, the Cartesian symmetry coordinates has the same expressions as those of $RbNiF_3$ 6L. Then in (A_{2u}), only s_1, s_3, and s_5 in $RbNiF_3$ 6L appear, and in (E_{1u}), only s_1, s_2, s_5, s_6, s_9, s_{10}, s_{11}, and s_{12} in $RbNiF_3$ 6L appear.

3) $CsNiF_3$ 9L: Ions with the Cartesian coordinates given in the parenthesis are indexed as follows:

1 Ni 1; $(0, 0, 0)$
2 Ni 2; $(0, 0, w_1c)$
3 Ni 2; $(0, 0, -w_1c)$
4 F 1; $(-a/2\sqrt{3}, 0, c/6)$
5 F 1; $(a/4\sqrt{3}, -a/4, c/6)$
6 F 1; $(a/4\sqrt{3}, a/4, c/6)$
7 F 2; $(\sqrt{3}u_2a, 0, w_2c)$
8 F 2; $((-\sqrt{3}/2)u_2a, (3/2)u_2a, w_2c)$
9 F 2; $((-\sqrt{3}/2)u_2a, (-3/2)u_2a, w_2c)$
10 F 2; $(-\sqrt{3}u_2a, 0, -w_2c)$
11 F 2; $((\sqrt{3}/2)u_2a, (-3/2)u_2a, -w_2c)$
12 F 2; $((\sqrt{3}/2)u_2a, (3/2)u_2a, -w_2c)$
13 Cs 1; $(\sqrt{3}a, 0, c/6)$
14 Cs 2; $(0, 0, w_3c)$
15 Cs 2; $(0, 0, -w_3c)$,

where u_i's and w_i's are parameter values (Table 1). Then the symmetry coordinates of A_{2u} and E_u species are as follows.

(A_{2u})

Ni 1: $s_1=\Delta z_1$,
Ni 2: $s_2=(1/\sqrt{2})\Delta(z_2+z_3)$,
Cs 1: $s_3=\Delta z_{13}$,
Cs 2: $s_4=(1/\sqrt{2})\Delta(z_{14}+z_{15})$,
F 1: $s_5=(1/\sqrt{3})\Delta(z_4+z_5+z_6)$,
F 1: $s_6=(1/\sqrt{3})\Delta\{(x_4+(-x_5+\sqrt{3}y_5)/2+(-x_6-\sqrt{3}y_6)/2)\}$,
F 2: $s_7=(1/\sqrt{6})\Delta(z_7+z_8+z_9+z_{10}+z_{11}+z_{12})$,
F 2: $s_8=(1/\sqrt{6})\Delta(x_7+(-x_8+\sqrt{3}y_8)/2+(-x_9-\sqrt{3}y_9)/2+x_{10}+(-x_{11}+\sqrt{3}y_{11})/2+(-x_{12}-\sqrt{3}y_{12})/2)$,

(E_u)

Ni 1: $s_1=\Delta x_1$, s_2=the same for y_i,

Ni 2: $s_3=(1/\sqrt{2})\Delta(x_2+x_3)$, $s_4=$the same for y_i,
Cs 1: $s_5=\Delta x_{13}$, $s_6=$the same for y_i,
Cs 2: $s_7=(1/\sqrt{2})\Delta(x_{14}+x_{15})$, $s_8=$the same for y_i,
F 1: $s_9=(1/\sqrt{3})\Delta(x_4+x_5+x_6)$,
$s_{10}=$the same for y_i,

F 1: $s_{14}=(1/\sqrt{2})\Delta(z_5-z_6)$,
F 2: $s_{15}=(1/\sqrt{6})\Delta(x_7+x_8+x_9+x_{10}+x_{11}+x_{12})$
$s_{16}=$the same for y_i,
F 2: $s_{17}=(1/\sqrt{6})\Delta\{(x_7+(-x_8-\sqrt{3}y_8)/2+(-x_9+\sqrt{3}y_9)/2+x_{10}+(-x_{11}-\sqrt{3}y_{11})/2+(-x_{12}+\sqrt{3}y_{12})/2)\}$,
F 2: $s_{18}=(1/\sqrt{6})\Delta\{(y_7+(\sqrt{3}x_8-y_8)/2+(-\sqrt{3}x_9-y_9)/2+y_{10}+(\sqrt{3}x_{11}-y_{11})/2+(-\sqrt{3}x_{12}-y_{12})/2)\}$,
F 2: $s_{19}=(1/\sqrt{12})\Delta(2z_7-z_8-z_9+2z_{10}-z_{11}-z_{12})$,
F 2: $s_{20}=(1/\sqrt{4})\Delta(z_8-z_9+z_{11}-z_{12})$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3789—3793 (1970)

The Preparation of Nitro-Carbonato and -Acetylacetonato Complexes of Cobalt(III) and Their IR and UV Spectra

Hiroyasu Ichikawa and Muraji Shibata

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received March 28, 1970)

Two new nitro complexes of cobalt(III), $K_2[Co(NO_2)_2CO_3acac]\cdot H_2O$ and $K_3[Co(NO_2)_4CO_3]\cdot H_2O$, have been prepared by the reaction of tricarbonatocobaltate(III) and the desired ligand. The 700—200 cm^{-1} region IR spectra for these complexes and the other related dinitro complexes have been measured, and the geometrical structures of these dinitro complexes have been determined as of the *cis*-form on the basis of the IR data. Furthermore, the absorption spectra of these nitro complexes have also been measured, and the stability of these complexes has been related to the spectral data.

We reported, in a previous paper, the preparation of a series of *cis*-dinitro complexes of cobalt(III), namely, $[Co(NO_2)_2(CO_3)_2]^{3-}$, $[Co(NO_2)_2CO_3ox]^{3-}$, and $[Co(NO_2)_2(ox)_2]^{3-}$.[1] In the present paper we will report the preparation of a new dinitro and a new tetranitro complex, namely, $K_2[Co(NO_2)_2CO_3acac]\cdot H_2O$ (acac=acetylacetonato ligand) and $K_3[Co(NO_2)_4CO_3]\cdot H_2O$. It has been found that the above carbonatoacetylacetonato complex is the most unstable of the five nitro complexes, including the previous three complexes. We will also report the 700—200 cm^{-1} region IR spectra for these complexes. On the basis of the data and some elemental knowledge of the group theory, the geometrical structures of the dinitro complexes are determined to be of the *cis*-form.

Furthermore, the frequency values of the nitro specific band of the complexes have been compared in terms of their stability in an aqueous solution.

Experimental

Preparation. 1) *Potassium Dinitrocarbonatoacetylacetonatocobaltate(III) Monohydrate*, $K_2[Co(NO_2)_2CO_3acac]\cdot H_2O$. Into a green solution of tricarbonatocobaltate(III) ($CoCl_2\cdot 6H_2O$ 10 g scale; 0.048 mol) prepared by the usual method,[2] 10 m*l* (0.10 mol) of acetylacetone were added, drop by drop. The mixture was then stirred under an iced condition for half an hour. After filtering the *tris*(acetylacetonato) complex and a residue out, 34 g (0.40 mol) of potassium nitrite were stirred into the filtrate under an iced condition. After a while, red needle-shaped crystals of the desired complex began to appear. The crystals were then washed thoroughly with benzene to remove the *tris*-(acetylacetonato) complex. The yield was about 6 g.

Found: C, 17.79; N, 6.68; H, 2.30%. Calcd for

1) H. Ichikawa and M. Shibata, This Bulletin, **42**, 2873 (1969).

2) M. Shibata, *Nippon Kagaku Zasshi*, **87**, 771 (1966).

$K_2[Co(NO_2)_2CO_3acac]\cdot H_2O$: C, 17.74; N, 6.90; H, 2.24%.

The complex decomposed very rapidly in an aqueous solution, giving a brown residue, but it kept stable in an aqueous solution in which potassium nitrite had been dissolved.

2) *Potassium Tetranitrocarbonatocobaltate(III) Monohydrate*, $K_3[Co(NO_2)_4CO_3]\cdot H_2O$. To a green solution of tricarbonatocobaltate(III) prepared on the same scale as 1), 26 g (0.30 mol) of potassium nitrite were added under cooling. The mixture was then stirred under an iced condition for an hour, after which 30 m*l* of 6N acetic acid were added, drop by drop. The mixed solution was further stirred for 3—4 hr to complete the reaction. Then, the resulting red solution was allowed to stand in a refrigerator overnight. After a small quantity of a precipitated material, $K_3[Co(NO_2)_6]$, had been filtered off, 50 m*l* of ethanol were added to the filtrate; the whole was then kept in a refrigerator for a day to precipitate orange, needleshaped crystals. The yield was about 7 g.

Found: C, 3.04; N, 12.46; H, 0.59%. Calcd for $K_3[Co(NO_2)_4CO_3]\cdot H_2O$: C, 2.74; N, 12.79; H, 0.46%.

When 100 m*l* of ethanol were added to the mother liquor and the mixture was allowed to stand in the cold, a mixture of tetranitrocarbonato- and dinitrodicarbonatocobaltate(III) was obtained.

Measurements. The infrared absorption spectra in the 700—200 cm^{-1} region were measured by the Nujol mull technique using a Hitachi EPI-L grating infrared spectrometer. The IR spectra in the 4000—700 cm^{-1} region and the visible and near-ultraviolet absorption spectra were measured with the same instruments as were used in a previous investigation.[1] In addition, an automatic recording spectrophotometer (JASCO Model UV-5) was used for the rapid measurement of the absorption spectrum of the carbonatoacetylacetonato complex.

Results and Discussion

Preparation and Measurement. As another reaction, we attempted partial replacement of the carbonato ligand in $[Co(NO_2)_2CO_3)_2]^{3-}$ with acetylacetonate, but the reaction gave a mixture of *trans*-$[Co(NO_2)_2(acac)_2]^-$ [3,4] and a brown, unknown material.

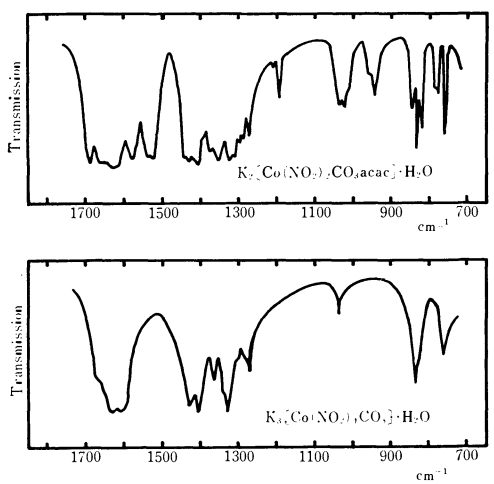

Fig. 1. Infrared absorption spectra of the *cis*-$K_2[Co(NO_2)_2CO_3acac]\cdot H_2O$ and $K_3[Co(NO_2)_4CO_3]\cdot H_2O$.

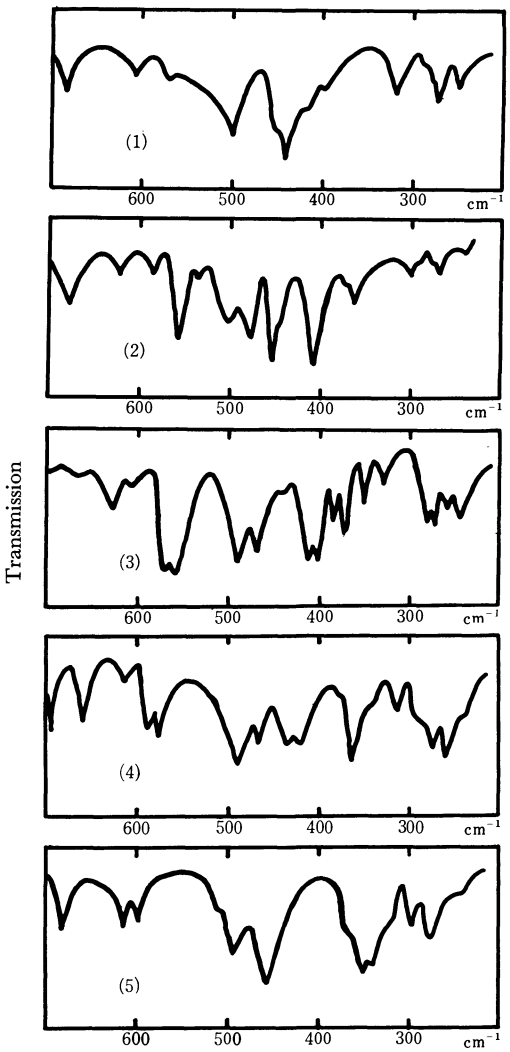

Fig. 2. Far-infrared absorption spectra of the nitro complexes of cobalt(III).
(1) $K_3[Co(NO_2)_2(CO_3)_2]\cdot H_2O$
(2) $K_3[Co(NO_2)_2CO_3ox]$
(3) $K_3[Co(NO_2)_2(ox)_2]\cdot H_2O$
(4) $K_2[Co(NO_2)_2CO_3acac]\cdot H_2O$
(5) $K_3[Co(NO_2)_4CO_3]\cdot H_2O$

The complexes were unstable in an aqueous solution. The measurement, therefore, of the absorption spectrum of the tetranitrocarbonato complex was carried out in a 0.10M potassium bicarbonate aqueous solution. The carbonatoacetylacetonato

complex rapidly changed from red to green in a potassium bicarbonate aqueous solution, but the green solution thus produced rapidly returned to the original red state on the addition of potassium nitrite, and the recovered solution was stable for a few hours at room temperature. This phenomenon seems to arise from the rapid substitution between CO_3^{2-} and NO_2^- ions. Therefore, a potassium nitrite aqueous solution in a high concentration was used as the solvent of the carbonatoacetylacetonato complex. However, because of the absorption of the nitrite ion itself, the absorption spectrum of the complex was measured only in the 700—400 mμ region, with a 0.50M potassium nitrite aqueous solution (Fig. 3, ------). The measurement in the 700—250 mμ region was carried out with a 0.10M aqueous solution (Fig. 3, ——).

IR Spectra. The IR spectra in the 4000—700 cm^{-1} region for the present complexes are shown in Fig. 1, while the numerical data are given in Tables 1 and 3. The 700—200 cm^{-1} region spectra of the present complexes and of related complexes are shown in Fig. 2, and the numerical data are given in Tables 2 and 3.

It is clear that the NO_2^- in the present complexes coordinates to a central atom through the N-atom, because of the absence of a nitrito characteristic band (sym. ν(NO)) at 1050 cm^{-1} [5,6] and a characteristic bridged nitrito band (asym. ν(NO)) near 1520 cm^{-1}.[7]

When we assume that the C_{2v} symmetry of a free nitrite ion is maintained in the complex, the number of infrared active modes becomes 6 for the M–NO_2. These 6 fundamentals were observed for all the complexes except the tetranitro complex in the range of 1450—400 cm^{-1} (Tables 1 and 2). For the tetranitro complex, 5 bands were observed.

In the previous paper,[1] we determined the geometrical structures of the dinitro complexes on the basis of the number of NO_2^- symmetrical stretching and bending vibrations. In this work, we expected that the IR spectra of these complexes in the far-infrared region (below 700 cm^{-1}) would afford more information about the structure, since the Co–NO_2 stretching and the wagging of the nitro group appear in this region. For example, *cis*-$[Co(NO_2)_2(NH_3)_4]^+$ has two bands, at 605 and 587 cm^{-1}, attributable to the NO_2^- wagging vibration, whereas *trans*-$[Co(NO_2)_2(NH_3)_4]^+$ has only one band, at 623 cm^{-1}.[7] In the case of the present complexes, one or two bands attributable to the NO_2^- wagging vibration were observed (Table 2).

From a group theoretical consideration, the *trans* dinitro complex was expected to have one IR active M–NO_2 stretching mode in a D_{4h} or D_{2h} symmetry, and the corresponding *cis* complex, to have two modes in a C_{2v} or C_2. For the present dinitro complexes, two bands attributable to the Co–NO_2 stretching vibration were observed. The assignment was tentatively achieved by the method of Nakagawa *et al.*[8] (Table 2). From this result, it may be concluded that these dinitro complexes belong to the *cis*-form.

The symmetry, D_{3h}, of the free carbonate ion is lowered to C_{2v} by chelation, and the complexed carbonate ion has 9 fundamentals. Among the 9 fundamentals, 7 in-plane modes belong to the A_1 and B_2 representations, and 2 out-of-plane modes belong to B_1. We observed at least 7 bands for the four nitro complexes in the 1700—340 cm^{-1} region. Their locations are shown in Tables 1 and 2.

In our previous paper,[1] we identified a broad and strong band in the 1700—1600 cm^{-1} region as asym. ν(C–O_I) (where O_I represents the oxygen atom coordinated to a central atom), according to the method of Gatehouse.[9] Fujita *et al*,[10] however, have identified the same band as ν(C–O_{II}) (where O_{II} represents the free oxygen atom). Judging from the fact that the C–O_{II} bond has a double-bond character in $[Co(NH_3)_4CO_3]^+$,[11] we will now regard the absorption band (1700—1600 cm^{-1}) as ν(C–O_{II}).

The band near 500 cm^{-1} may be assigned to the M–CO_3 asymmetrical stretching vibration (Table 2). In fact, the corresponding Co–CO_3 mode in the double complex $[Co(NH_3)_6]\cdot[Co(CO_3)_3]$ has been observed at 488 and 465 cm^{-1}.[10] In the case of *trans*-$[Co(NO_2)_2(acac)_2]^-$, no absorption band was observed near 500 cm^{-1}.

When C_{2v} symmetry is assumed for a chelated structure of an oxalate ion, there are 15 fundamentals.[12,13] The number of infrared active modes of M–C_2O_4 is 13 in C_{2v}. Of these fundamentals, 8 bands were observed in the 1750—450 cm^{-1} range. Their locations in the 1750—700 cm^{-1} range were shown previously,[1] while those in the 700—450 cm^{-1} range are shown in Table 2.

acetonate was attempted according to the references.[14-16] The data are given in Table 3.

Absorption Spectra. The absorption spectra in the solution are shown in Fig. 3, while the numerical data are listed in Table 4. The frequency values of the first absorption band for a number of dinitro complexes including the hexanitro complex are diagrammatically represented in Fig. 4. From this figure, it may be seen that the positions of the first absorption band shift according to the spectrochemical series.[17] We therefore calculated the position of the first absorption band of hexanitrocobaltate(III) by the following equation, based on "the rule of average environment"[18];

$$2/3(A) + 1/3(X) = (B)$$
$$(X) = 3(B) - 2(A)$$

where (A) and (B) are the positions of the first band for a $[CoA_6]$-type and a $[Co(NO_2)_2A_4]$-type complex respectively, and where (X) is the frequency value to be estimated. In the case of a $[Co(NO_2)_2$-(aa)(bb)]-type complex, (A) was taken as the mean value of a $[Co(aa)_3]$-type complex and a $[Co(bb)_3]$-type complex. The results are represented in Fig. 5. The positions, estimated from the mixed dinitro complexes with carbonato, oxalato, and acetylacetonato ligands, are at $70—73\times 10^{13}$ sec^{-1}. On the other hand, the positions estimated from the other dinitro-ammine-type complexes are at $75—78\times 10^{13}$ sec^{-1}. From these results, it may be said that the nitro-ligand field of the mixed dinitro complex with the *bis*(bidentate O–O)-type ligand is less weak than that of the mixed-dinitro complex with the ammine-type ligand. In fact, the aqueous solutions of the mixed dinitro complexes with the O–O type ligands are unstable, while the solutions of the dinitro-ammine type complexes are stable.

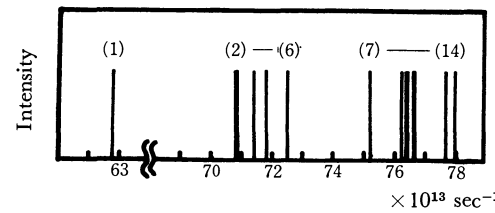

Fig. 5. The estimated position of first absorption band of hexanitrocobaltate(III).
(1) $[Co(NO_2)_6]^{3-}$
(2) $[Co(NO_2)_2(acac)_2]^-$
(3) $[Co(NO_2)_2CO_3acac]^{2-}$
(4) $[Co(NO_2)_2(CO_3)_2]^{3-}$
(5) $[Co(NO_2)_2CO_3ox]^{3-}$
(6) $[Co(NO_2)_2(ox)_2]^{3-}$
(7) $[Co(NO_2)_2(NH_3)_4]^+$
(8) $[Co(NO_2)_2ox\ en]^-$
(9) $[Co(NO_2)_2gly\ en]$
(10) α-$[Co(NO_2)_2ox(NH_3)_2]^-$
(11) $[Co(NO_2)_2(gly)_2]^-$
(12) α-$[Co(NO_2)_2CO_3(NH_3)_2]^-$
(13) $[Co(NO_2)_2en_2]^+$
(14) $[Co(NO_2)_2CO_3en]^-$

The maximum frequency of the nitro specific absorption band was found at *ca.* 80.8×10^{13} sec^{-1} for the carbonatoacetylacetonato complex and at 85.65×10^{13} sec^{-1} for the tetranitrocarbonato complex. The position for the former complex lies in the longest-wavelength side among the dinitro complexes (81.02 for $[Co(NO_2)_2(ox)_2]^{3-}$; 85.85 for $[Co(NO_2)_2CO_3ox]^{3-}$; 87.15 for $[Co(NO_2)_2(CO_3)_2]^{3-}$). It should be noted that the positions for the $[Co(NO_2)_2CO_3acac]^{2-}$, $[Co(NO_2)_2(ox)_2]^{3-}$, and $[Co(NO_2)_6]^{3-}$ complexes, which are unstable in an aqueous solution, are at lower frequencies than that (84.93×10^{13} sec^{-1}) for the free nitrite ion.

An Application of the Oxidation Reaction between Ammonia and Bromate, Permanganate or Dichromate for the Determination of Ammonia Nitrogen in the Kjeldahl Digests without Distillation

M. A. SIDDIQUI and M. K. BHATTY

Pakistan Council of Scientific & Industrial Research Laboratories, Lahore, Pakistan

and Muhammad ASHRAF

Department of Pharmacy, Punjab University, Lahore, Pakistan

(Received March 4, 1970)

Nitrogen in organic compounds, agricultural and animal products is converted into ammonium sulphate by Kjeldahl digestion. The ammonium sulphate is reacted quantitatively with hypobromite produced *in situ* by the addition of an excess of potassium bromate and bromide. The unutilized potassium bromate is determined iodometrically and the amount of ammonia nitrogen can be calculated from the consumed potassium bromate. Accurate results are also obtained when potassium bromate is replaced with potassium permanganate or dichromate for the determination of ammonia nitrogen in Kjeldahl digests. However, the present method is not applicable to the determination of ammonia nitrogen in undigested sample.

It has already been reported by various workers that the distillation step in the Kjeldahl method can be effectively replaced by a bromometric titration. Thus a hypobromite method,[1] employing brominating mixture and potassium tetraborate has been proposed. A similar method in which potassium tetraborate is replaced with an alkali has been applied to the determination of non-protein nitrogen in serum.[2] Recently such a method has been modified and used for the determination of organic nitrogen on both the micro as well as the semi micro scales.[3]

During the present investigations, it has been shown that potassium permanganate and potassium dichromate work as well as potassium bromate in the brominating mixture in this method. In addition, these oxidants have been shown to be successfully applicable to all types and scales of Kjeldahl nitrogen. Both potassium permanganate and potassium dichromate solutions are already employed as analytical reagents whose stability is, at any rate, better than that of hypobromite or even hypochlorite solutions prepared in the laboratory.

Potassium permanganate or dichromate and potassium bromide in the acidic medium generate bromine which on the addition of an alkali, can be coverted into hypobromite *in situ*. Although hypohalite solutions have been previously extensively used for the determination of nitrogen in organic compounds,[4] soil,[5] biological material and agricultural products,[6] yet they are not ordinarily stable. In the matter of stability, hypobromite solutions are hopelessly inferior to hypochlorite solutions.[7] Difficulties encountered in their preparation and application are known too well to be enumerated here. Such difficulties do not arise when bromate, permanganate or dichromate is used as oxidant in the presence of potassium bromide.

Experimental

Apparatus. A 500 m*l* round bottom flask, with B 19 neck fitted with a 15 cm tube attached to B 19 cone, is used for digestion on the macro scale. After digestion the cone is replaced with an *N*-shaped tube[3] having the following dimensions. Tube bore 1.8 cm, the B 19 cone limb 4 cm, the middle limb 16.5 cm, and stoppered (with B 19 joint) limb 14 cm long.

Reagents. Sulphuric acid (d, 1.84), G.R.; Potassium sulphate, G.R.; Mercuric sulphate, G.R.; Glucose, G.R.; Potassium bromate solution, 0.5 N Potassium permanganate solution, 0.5 N; Potassium dichro-

mate solution, 0.5 N; Sodium hydroxide solution, 60% W/V; Potassium iodide, G.R.; Hydrochloric or sulphuric acid, 10 N; Sodium thiosulphate solution, 0.25 N; Starch solution (aqueous), 1%.

Procedure. Weigh accurately 0.1 to 0.2 g of the organic sample (dried blood=0.1—0.2 g, cereal, tea leaves and meat=1 g, fresh vegetables=2 g, etc) into the flask. Add 5.6 g of the catalyst (5.0 g potassium sulphate and 0.6 g mercuric sulphate) and use 12 m*l* concentrated sulphuric acid for organic compounds and 15 m*l* for commercial materials. Add 1—2 g of glucose and 16 m*l* of sulphuric acid in case of compounds which require reduction prior to digestion. Digest the sample for 1—2 hr. Cool and dilute the digest by rinsing the cone with about 50 m*l* of distilled water. Place the flask in cold water and add 20 m*l* of the potassium bromate, permanganate or dichromate solution. Add 5 g of potassium bromide and immediately fit in the *N* tube containing 35 m*l* of sodium hydroxide solution. In the case of potassium dichromate, add 15 m*l* of sodium hydroxide solution into the *N* tube. Keep the tubes neck open and heat the flask at 70°C. Continue heating for 15 min. Cool the flask and add the remaining 20 m*l* of the sodium hydroxide solution into the tube and stopper it.

Transfer the alkali portion-wise from the *N* tube to the cold contents of the flask by tilting the system slightly. Shake the flask and allow it to stand for 10—15 min. Add 8 g of potassium iodide followed by 25 m*l* of 10 N hydrochloric or sulphuric acid through the *N* tube. Allow to stand for another 5 min, remove the *N* tube and titrate the liberated iodine with sodium thiosulphate solution, using starch solution as an indicator. Carry out a blank determination under similar conditions.

Calculation. 1 m*l* 0.1 N $KBrO_3$ or $KMnO_4$ or $K_2Cr_2O_7$=0.4667 mg. N_2

Discussion and Conclusion

Potassium bromate is a primary standard and advantages realised by its use in nitrogen determination on the micro and semi micro scales have already been listed.[3] Potassium permanganate and dichromate have been used for nitrogen determination for the first time. Their solutions when prepared and stored according to the established practice, can work as well as that of bromate.

The results (Table 1) show that the reagents are applicable to the determination of all those types of organic nitrogen which either as such or after reduction can be digested into ammonium sulphate. It has also been shown (Table 2) that these reagents in general and potassium bromate in particular can be employed with advantage for a variety of nitrogenous commercial materials.

Some difficulties are encountered when nitrogen is determined in the agricultural and animal products by the hypochlorite-arsenite method.[6] For example the neutralized digest in the case of tea leaves becomes reddish brown on the addition of sodium hypochlorite solution with the result that it becomes difficult to mark the end point. Similarly, for larger than 1 g of meat and 0.2 g of blood samples, a yellow precipitate appears after the addition of the hypochlorite. This colour changes to greyish black on the addition of sodium arsenite solution, thus making it difficult to mark the end point.

In the present method, involving the use of potassium bromate, however, the above mentioned difficulties do not arise. The method gives good results even if comparatively large amount of tea leaves, meat and blood samples are used for analysis. It further shows that the present method can also be applied to materials containing metals like iron. It has also been observed that the results are higher when digestion is incomplete. This is due to the fact that some bromine or even acidic potassium permanganate is consumed in the oxidation of the undigested organic matter. Therefore, the present method can not be applied to the determination of ammonia nitrogen in the undigested sample.

Our thanks are due to Mr. M. Aslam, Director, Pakistan Council of Scientific & Industrial Research, Laboratories, Lahore, Pakistan, for providing facilities to carry out this research work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3796—3800 (1970)

The Photometric Determination of Minute Amounts of Iodine in Silicate Rocks*1

Norinobu YONEHARA,*2 Minoru YOSHIDA and Iwaji IWASAKI*3

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 2, 1970)

A rapid and sensitive method for the determination of minute amounts of iodine in silicate rocks has been developed. A rock was fused with potassium hydroxide, and the cake was treated with water and sulfuric acid. The iodine in the solution was reduced to iodide by sodium sulfite, and was then oxidized to free iodine by sodium nitrite. The free iodine thus obtained was extracted with carbon tetrachloride and then back-extracted with a sodium hydroxide solution. The iodine in this aqueous layer was determined photometrically by a method based on the catalytic effect of iodine on the color-fading of ferric thiocyanate. By the proposed method, amounts of iodine as low as 0.007 μg in a 1-g sample of silicate rocks can be determined. Application to some igneous rock samples gave results with a relative standard deviation of less than 7.2%, except for very low concentrations.

Since von Fellenberg's classical work,[1] there have been almost no data on iodine in rocks. Recent determinations of iodine in meteorites by neutron-activation analysis suggest, however, that the iodine contents of rocks may be much smaller than those reported by von Fellenberg. Therefore, reliable data on iodine in rocks are desirable from the viewpoint of geochemistry. However, the determination of iodine in rocks requires an extremely sensitive method, for the iodine content in rocks is very low, particularly in igneous rocks.

Crouch[2] has developed a spectrophotometric method for determining the iodine in silicate rocks based on the starch-iodine reaction, but this method requires quite a large sample and a time-consuming procedure; there are also some problems still to investigate regarding the treatment of the residue resulting from the dissolution of rocks. The kinetic method,[3] followed by titration, is also not sensitive enough to analyse iodine in igneous rocks. Goles and Anders[4] have determined the iodine contents of some meteorites by neutron-activation analysis. Recently, Tajima and Akaiwa[5] have reported a method of determining the iodine in sedimentary rocks, also by neutron-activation analysis. These methods may be suitable in sensitivity, but their procedures are time-consuming and require considerable manipulation and special equipment.

Yonehara and others[6–8] have previously reported colorimetric methods for the determination of ultramicro amounts of iodine by utilizing its catalytic effect on the color-fading of ferric thiocyanate. According to these methods, 0.005 μg of iodine can be determined colorimetrically. Although the catalytic method is very sensitive, it is supposed that there are some difficulties in the separation of iodine from rocks because of the chemical complexity of silicate rocks and the very low content of iodine. After a rock had been decomposed by fusion, we tried to separate the iodine as follows. As the iodine in the solution obtained by dissolving the cake is presumably in a highly oxidized form, such as the iodate ion, iodate was first reduced to iodide by sodium sulfite. The iodide was then oxidized to free iodine by sodium nitrite. The free iodine was extracted with carbon tetrachloride, and then back-extracted with a sodium hydroxide solution. Finally the iodine in the aqueous layer was determined by the catalytic method.

According to a previous study,[9] the iodine content in igneous rocks seems to be less than 0.1 μg/g; therefore, a 0.5–1-g sample of silicate rocks is required for the application of the catalytic method to the determination of iodine in rocks. The treatment of the cake obtained by the fusion of a 1-g rock sample requires considerable amounts of water, causing the solution finally obtained to have an extremely low iodine concentration. That the behavior of very small amounts of iodine differs significantly from that of macro amounts of iodine[10,11] suggests the difficulty of achieving the quantitative separation of iodine in low concentrations such as that discussed above.

In the present work, we investigated whether the separation processes involving reduction, oxidation, extraction, and back-extraction could be performed quantitatively at very low concentrations and whether the catalytic method could be applied to the determination of iodine in silicate rocks. In addition, the catalytic method was modified so as to increase the sensitivity by changing the concentration of the reagents and the conditions of the reaction.

Experimental

Apparatus. A Hirama IIB photoelectric-colorimeter with a 460 filter (with maximum transmission at 460 mμ) and 10-mm cells were used to measure the absorbance.

The catalytic reaction was carried out at 60.00± 0.05°C, using a water bath with a Taiyo Thermo Unit.

Reagents. All the chemicals used were of a guaranteed reagent quality.

Redistilled water was used for the reagent preparation and throughout the procedures.

(Treatment of Rocks)

Potassium Hydroxide. The potassium hydroxide used for the fusion of rocks was a special-grade reagent; SV grade, obtained from the Tokyo Ôka Kôgyo Co., Ltd.

Sulfuric Acid Solution (1 : 1).

Sodium Sulfite Solution (about 5%).

Sodium Nitrite Solution (1.0M). Dissolve 6.90 g of sodium nitrite in water and dilute to 100 m*l*.

Sodium Hydroxide Solution (0.1N). Dissolve 2.0 g of sodium hydroxide in water and dilute to 500 m*l*.

(The Catalytic Reaction)

Ferric Ammonium Sulfate-Nitric Acid Solution. Dissolve 6 g of ferric ammonium sulfate in 100 m*l* of a 7.0N nitric acid solution.

Potassium Thiocyanate Solution (0.010M). Diluted from about a 0.1M potassium thiocyanate solution, as standardized by Volhard's method.

Sodium Nitrite Solution (0.014M). Dissolve 0.483 g of sodium nitrite in water and dilute to 500 m*l* in a volumetric flask.

Sodium Chloride Solution (20 g of Chloride per l). Dissolve 32.971 g of sodium chloride in water and dilute to exactly 1*l*.

Standard Iodide Solution. Prepare about a 0.1M potassium iodide solution and standardize by Volhard's method. Prepare the working solutions by diluting this solution adequately.

Standard Iodate Solution. Dissolve 0.847 g of potassium iodate in water and dilute to exactly 500 m*l* to give an iodine concentration of 1000 ppm. Prepare the working solutions by successive dilutions.

Procedure and Calibration Curve. Into a 30-m*l* nickel crucible, add 0.5—1 g of the powdered rock sample and the flux (potassium hydroxide, about six times the weight of the rock sample); heat first over a small flame, gradually raise the temperature to about 500°C, and then heat further for about 30 min. After cooling to room temperature, dissolve the cake with 15—20 m*l* of water and transfer all of the contents to a 50-m*l* centrifuge tube with a glass stopper. Crush the cake with a glass rod and stir the solution to dissolve the soluble material. After the solution has been centrifuged at about 3000 rpm for 5 min, transfer the supernatant liquid to a 50-m*l* glass beaker. Add a 1 : 1 sulfuric acid solution to neutralize the solution, and then add an excess of 1 m*l* of the acid. Then add 0.3 m*l* of a 5% sodium sulfite solution.

Into the centrifuge tube containing the residue, add 10 m*l* of water, 1—2 m*l* of the 1 : 1 sulfuric acid solution, and 0.1 m*l* of the 5% sodium sulfite solution, and shake vigorously to dissolve the residue. It is desirable to use just the amounts of sulfuric acid necessary to dissolve the residue present. Almost all of the precipitate can be dissolved by this procedure. Centrifuge again and pour the supernatant liquid into the same beaker. Wash the remaining residue three times with 2 or 3 m*l* of redistilled water and small portions of the 1 : 1 sulfuric acid, and pour all of the washings into the beaker. Keep the total volume of the 1 : 1 sulfuric acid used in washing at 1 m*l*. Transfer the solution thus obtained into a 100-m*l* separatory funnel and bring the volume of the solution to 60—80 m*l*. Then add 3.0 m*l* of a 1M sodium nitrite solution, mix thoroughly, add 10 m*l* of carbon tetrachloride, and shake the separatory funnel for 1 min. After the layers have

5 g KOH was used.
* obtained by following the procedure without fusion.
** obtained by the procedure.

been completely separated, transfer the carbon tetrachloride phase into a 50-m*l* separatory funnel.

When a large amount of the residue still remains, dissolve this residue with 60—80 m*l* of water, 2 m*l* of the 1 : 1 sulfuric acid solution, and 0.3 m*l* of the 5% sodium sulfite solution, and then determine the iodine in this solution separately. Add the value obtained to that of the supernatant liquid obtained above.

To the carbon tetrachloride phase thus obtained, add 8.0 m*l* of water, 1.0 m*l* of a 0.1N sodium hydroxide solution, and 1.0 m*l* of a sodium chloride solution (2.0% as chloride), shake the separatory funnel for 1 min, and allow the layers to separate. Then transfer the aqueous layer into a 20-m*l* glass tube with a glass stopper. The iodine in this aqueous phase is then determined by the following catalytic method.

To the solution in the glass tube, add 1.0 m*l* of a 0.014M sodium nitrite solution and 1.0 m*l* of a 0.010M potassium thiocyanate solution, and mix thoroughly. Place the glass tube in a water bath at 60°C for about 10 min. Start the reaction by adding 3.0 m*l* of a nitric acid solution of ferric ammonium sulfate (at the same temperature), and then replace the glass tube in the water bath. Exactly 18 min after the addition of the ferric ammonium sulfate solution, measure the absorbance of the solution at 460 mμ, using water as the reference.

The calibration curve shown in Fig. 1 was prepared by taking 0.0-, 2.0-, 4.0-, 6.0-, 8.0- and 10.0-m*l* aliquot of a 0.010 ppm standard iodate solution and 1—6 g of potassium hydroxide, and by then following the procedure described above without fusion. The variation in sensitivity and in absorbance values resulting from the use of different batches of reagents makes it necessary to check the calibration curve for each set of determinations.

Results and Discussion

The Treatment of Rocks. In order to determine the iodine in rocks, decomposition and separation procedures must be used. In the present work, the fusion with potassium hydroxide was adopted, because this fusion is made at a relatively low temperature and a specially-pure reagent is obtainable. The use of sodium hydroxide gave lower absorbances than those of potassium hydroxide.

When the cake was treated with water, iodine was distributed to both the aqueous phase and the residue. As the iodine in the residue could not be removed to the aqueous phase by washing, it was necessary to dissolve the residue with sulfuric acid and to combine the resultant solution with the aqueous phase obtained above.

Decomposition by hydrofluoric acid was not adaptable because of the volatilization of the iodine during the process.

The Contamination during the Fusion Process. In order to examine the possibility of contamination during a fusion process, absorbances were measured by following the above procedure, after a 5-g portion of potassium hydroxide had been fused in the absence of iodine. The values without fusion were also obtained. As the comparison of these values shows good agreement, as can be seen in Table 1, the contamination during the fusion process was found to be insignificant.

The Reduction of Iodate to Iodide. Several experiments were made to examine the reduction of iodate to iodide by using a 5% sodium sulfite solution. In order to obtain a tolerable reproducibility of the reduction of the minute amounts of iodate,

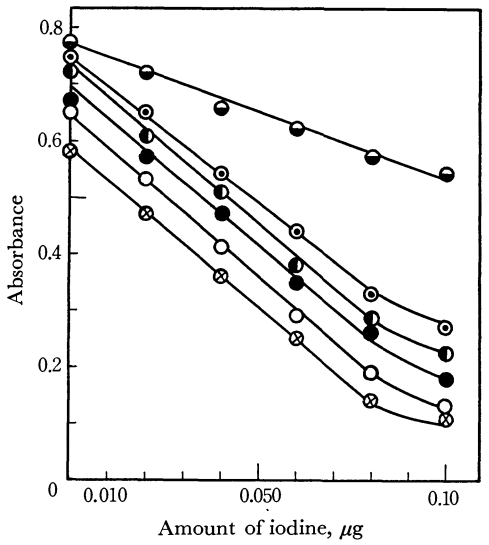

Fig. 2. Effect of amount of nitrite solution. (in the absence of KOH)
1M nitrite solution is used.
—◒— 0.1 m*l* —●— 2.0 m*l*
—⊙— 0.5 m*l* —○— 3.0 m*l*
—◐— 1.0 m*l* —⊗— 4.0 m*l*

less than 0.10 μg as iodine, it was necessary to keep the volume of the solution less than 50 m*l* at the reduction. As the reduction time, more than 15 min was required. No effect was observed on varying the volume of the sodium sulfite solution added.

The Oxidation of Iodide to Free Iodine. In measuring the effect of the amount of sodium nitrite on the oxidation of iodide, several experiments were made using a 1.0M sodium nitrite solution and the procedure featuring the absence of potassium hydroxide. The experimental results are shown in Fig. 2. The effect of the volume of the solution on the oxidation was examined; the same calibration curves were obtained on the volumes of 50, 60, and 80 m*l*.

The Use of Sulfuric Acid. In most cases of rock analysis, the rock samples are treated with hydrochloric acid. However, in this work, reduction, oxidation, extraction and back-extraction were not achieved quantitatively by using hydrochloric acid. Therefore, sulfuric acid was used. As can be seen in Fig. 3, the effect of the amount of sulfuric acid added is quite similar to that of sodium nitrite.

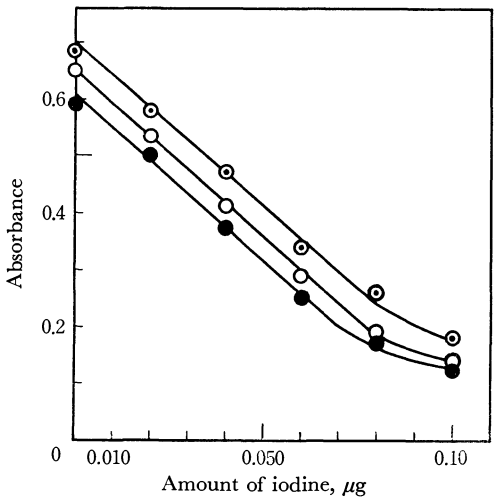

Fig. 3. Effect of amount of sulfuric acid. (in the absence of KOH)
1 : 1 sulfuric acid is used.
—⊙— 1.0 m*l* —○— 2.0 m*l*
—●— 3.0 m*l*

The Extraction and the Back-Extraction. In order to treat the cake obtained by the fusion of a 1-g rock sample, it is desirable to use 200 m*l* of water. The extraction of iodine from 200 m*l* of the solution was first attempted; however, the results obtained were not reproducible enough to determine the iodine. It was necessary to keep the volume of the solution within 80 m*l*. The reproducibility deteriorated slightly when the shaking time was less than 30 sec.

Ten milliliters of a sodium hydroxide solution convenient for the subsequent catalytic method were used. The use of a concentration of 0.005—0.1N gave the same recovery of iodine. The effect of the presence of chloride has been described in previous papers.[7,8]

The Effects of the Amounts of Potassium Hydroxide and Silicate. As considerable amounts of potassium ion and silicate ion are introduced into the solution by the fusion of silicate rocks, the effects of their amounts were examined. The experiments were made using 1–6 g of potassium hydroxide and the procedure without fusion. All of the values obtained fell just on the curve shown in Fig. 1. A 250—700-mg portion of silica was fused with 3 or 6 g of potassium hydroxide and a known amount of iodate was added; the same results were obtained. When the solution contains a considerable amount of the silicate ion, the precipitate of silica appears on neutralization. However, the presence of the precipitate in the solution does not disturb the subsequent procedure.

The Effect of Diverse Ions. To examine the effect of the substances commonly occurring in igneous rocks, several experiments were made in the presence of 0.06 and 0.04 μg of iodate and in its absence. The quantities of these substances studied may be the maximum content present in 1 g of common igneous rocks. There appears to be no significant effect of these substances, as is shown in Table 2.

The Determination of Iodine in Rocks. The iodine in several igneous rocks was determined by the present method; the results are shown in Table 3. The determinations were made by taking 1-g and 0.5-g samples; the results show good agreement

within the limits of experimental error of this method. Table 3 also shows the reproducibility of the method. Samples containing various amounts of iodine were analyzed in replicate by this method. The precision of this method was within 10% except for very low concentrations.

The Recovery of Known Amounts of Iodine. The method was also checked by adding known amounts of iodate to 1.0-g rock samples. The results, presented in Table 4, show the relative errors of the determination to be less than 6.6%. According to these results, it may be concluded that the loss of iodine during the fusion was insignificant and that no major source of interference was present in the rock samples analyzed.

This investigation was supported in part by a grant from the Kawakami Memorial Foundation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3801—3804 (1970)

The Crystal Structure of $(+)_{589}$-Dichlorobis(ethylenediamine)-cobalt(III) Chloride Monohydrate

Keiji MATSUMOTO, Shun'ichiro OOI and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received July 2, 1970)

The crystal structure of *cis*-$(+)_{589}$-$[CoCl_2en_2]Cl \cdot H_2O$ has been determined by the X-ray-diffraction method. The crystal is monoclinic with the cell constants: $a=12.07$, $b=11.52$, $c=8.33$ Å, and $\beta=96.9°$. The space group is $P2_1$, and $Z=4$. There are two crystallographically-independent complexes in the unit cell, but they have the same configuration and almost identical molecular dimensions. The absolute configuration of the complex cation is consistent with that proposed by McCaffery, Mason and Norman and should be denoted as $\Lambda(\delta\delta)$.

Several investigations have been made of the absolute configurations of optically-active *cis*-$[CoX_2en_2]$ or *cis*-$[Co\widehat{XX}en_2]$ complexes, making use of their Cotton effects or chemical interconversions.[1-7] Particularly, McCaffery, Mason and Norman[7] made a detailed study of the CD spectra in the first absorption-band region on the *cis*-series of bisdiamine complexes of cobalt(III) and established a definitive correlation between the major CD bands of these complexes and that of the thoroughly-examined $(+)_{589}$-$[Co\ en_3]^{3+}$;[8] they thus succeeded in making assignment of the absolute configurations to these bisdiamine cobalt(III) complexes.

We have been attempting to determine directly the absolute configurations of several metallic complexes by the X-ray method. We wish here to report on the results obtained for *cis*-$(+)_{589}$-$[CoCl_2en_2]Cl \cdot H_2O$.

Experimental

The racemic "violeo" compound was prepared by the method of Jörgensen and resolved into optical isomers by utilizing its reaction with ammonium (+)-α-bromocamphor-π-sulfonate.[9] The crude chloride obtained from the less soluble diastereoisomer yielded, upon crystallization from a saturated aqueous solution, needle-like, deep violet crystals of $(+)_{589}$-$[CoCl_2en_2]Cl \cdot H_2O$.

The unit cell dimensions were determined by the least-squares refinement of the *hk*0 and *h*0*l* reflection data recorded on Weissenberg photographs. The aluminum powder diffraction lines were superimposed on the films for calibration. The systematic absences were: 0*k*0 for *k*=odd. Hence, the space group could be either $P2_1$ or $P2_1/m$. However, the latter should be excluded, since the crystal contains only one form of the enantiomorphous isomers.

The crystal data are as follows:

monoclinic
space group $P2_1$
$a=12.07$ (0.008)Å
$b=11.52$ (0.007)
$c=8.33$ (0.005)
$\beta=96.9$ (0.2)°
$Z=4$ ($D_m=1.71$, $D_c=1.75$ g·cm^{-3})
$\mu=100.6$ cm^{-1} (for Ni$K\alpha$)

Weissenberg multiple-film photographs were taken for the 0—4 and 0—6 layers about the *c* and [101] axes respectively, with Ni$K\alpha$ radiation ($\lambda=1.6591$ Å). The relative intensities of 1159 independent reflections were measured visually, and the Lorenz, polarization, spot-shape,[10] and absorption corrections were applied. The specimen crystal used was a rod with the approximate dimensions of $0.12 \times 0.07 \times 1.0$ mm.

Determination of the Crystal Structure

Prior to the complete collection of the three-dimensional reflection data, *hk*0 and *h*0*l* data were obtained and the Patterson functions, $P(UV)$ and $P(UW)$, were calculated.*1 Since the unit cell

contains four formula units, there are eight heavy atoms (two cobalt and six chlorine atoms) in the asymmetric unit. $P(UW)$ was difficult to be solved because of the peculiar arrangement of the Patterson peaks. The coordinates of the two Co atoms and one Cl atom were found by an elaborate examination of $P(UV)$. These coordinates were used for a graphical derivation of the minimum function, on which we found seven additional heavy peaks (not including the above three atoms). Of these seven peaks, the five heaviest were assumed to be Cl-atoms. The remaining atoms were found on the electron-density map phased by the eight heavy atoms thus obtained. The z-coordinate of each atom was determined by the use of $P(UV)$ and the Fourier map, $\rho(xz)$. Subsequent refinement by the diagonal least-squares method reduced R to 0.14 for $hk0$ and to 0.19 for $h0l$.

Further refinement of the structure was made by the block-diagonal, least-squares method using the three-dimensional data. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[11] The real part of the anomalous dispersion correction was taken into account for Co.[12] The function minimized was $\sum w(|F_o|-|F_c|)^2$, and the following weighting scheme was employed:

$w = 0.5$ if $F_0 < F_{\min}$ $(= 5.0)$

$w = 1.0$ if $F_{\min} \leq F_0 \leq F_{\max}$ $(= 44.6)$

11) "International Tables for X-ray Crystallography," Vol. III, Kynoch Press, Birmingham (1962), p. 202.

12) R. W. Games, "The Optical Principles of the Diffraction of X-rays," G. Bell & Sons, London (1948), Appendix, p. 608.

$$w = F_{max}/F_0 \quad \text{if } F_0 > F_{max}$$

Three cycles of the refinement with isotropic thermal parameters reduced R to 0.150. At this stage, anisotropic temperature factors were introduced for the heavy atoms, and three further cycles of the least-squares calculation improved R to 0.109. The atomic parameter shifts in the last cycle of the refinement were less than their standard deviations. The final atomic coordinates, the temperature factors, and their e.s.d.'s are listed in Table 1.

In order to determine the absolute configuration of the complex ion, the $hk1$ and $hk2$ Weissenberg photographs were taken with Cu$K\alpha$ radiation.*2 The inequality relationships which were observed for some Bijvoet pairs of hkl and $h\bar{k}\bar{l}$ are shown in Table 2. In this table, the calculated intensities which were obtained by the use of the atomic coordinates shown in Table 1 are also listed. The values of $\Delta f'_{Co}$ and $\Delta f''_{Co}$ were taken from the International Tables for X-ray Crystallography.[11] A comparison of the observed inequalities with the calculated ones indicates that the atomic coordinates shown in Table 1 can give the absolute structure of the crystal.

Discussion

The crystal structure viewed along the b and c axes are shown in Figs. 1 and 2 respectively. The crystal is composed of $(+)_{589}$-$[CoCl_2en_2]^+$, Cl^-, and H_2O. Although, as has been stated previously, there are two crystallographically-independent complexes in an asymmetric unit, they have the same configuration and almost identical molecular dimensions, as is shown in Table 3. No significant differences are found in the corresponding bond lengths and angles. The absolute configuration of $(+)_{589}$-$[CoCl_2en_2]^+$ is illustrated in Fig. 3 (together with those of $(+)_{589}$-$[Co(CN)_2en_2]^+$ [13]) and $(+)_{589}$-$[Coen_3]^{3+}$,[8] which are given

$(+)_{589}$-$[CoCl_2en_2]^+$ $(+)_{589}$-$[Co(CN)_2en_2]^+$ $(+)_{589}$-$[Coen_3]^{3+}$

Fig. 3. The absolute configurations of $(+)_{589}$-$[CoCl_2en_2]^+$, $(+)_{589}$-$[Co(CN)_2en_2]^+$ and $(+)_{589}$-$[Coen_3]^{3+}$.

as references). This configuration is exactly in agreement with that proposed by Mason *et al.* and should be denoted as $\Lambda(\delta\delta)$, following the proposal of the IUPAC Commission.[14]

The conformation of the ethylenediamine molecules is of the "*lel-lel*" form in the present complex, whereas it is of the "*ob-ob*" form in $(+)_{589}$-$[Co(CN)_2en_2]Cl \cdot H_2O$[13] and of the "*ob-lel*" form in $(\pm)$-$[CoCl_2en_2]Cl \cdot H_2O$.[15]

On the basis of a conformational analysis of $[Coen_3]^{3+}$, Corey and Bailar predicted that the difference in the interaction energy between the three chelate rings would be 1.8 kcal/mole, the *lel-lel-lel* form being more stable, and the *ob-ob-ob* form, less stable.[16] This prediction was verified by the equilibrium study of $[Co(l\text{-pn})_3]^{3+}$ by Dwyer *et al.*[17] In the case of *cis*-$[CoX_2en_2]$, however, if the X's are spherical (as in Cl) or cylindrical (as in CN): (1) the potential energy between the X's and each of the chelate rings is indifferent to the arrangement of the en-molecule—*ob* or *lel*—, and (2) the energy between the two chelate rings is one-third of that in the tris-ethylenediamine complex.[15] In short, though the degree of the steric interaction in the complex increases in the order of: *lel-lel*$<$*ob-lel*$<$*ob-ob*, (the *lel-lel* form being accordingly the most stable, and the *ob-ob* form, the least stable), the potential energy differences between these forms are quite small. This enables, on some occasions, the chelate ring to take the less-favored *ob-lel*[15] or *ob-ob*[13] form. The combination of *ob* and *lel* in a complex must, of course, be affected by the surroundings of the cation.

The distances of the notable short contacts are shown in Figs. 1 and 2. The nitrogen atoms of the ethylenediamine molecules form rather weak hydrogen bonds. That is, the cations are not very tightly bound by their environments; this must be the reason why the rings are of the *lel-lel* form in the crystal.[18]

The average value of Co-Cl is 2.26 Å, a value which is comparable to 2.286 Å in $[CoCl(NH_3)_5]Cl_2$[19] and 2.26 Å (average) in $(\pm)$-$[CoCl_2en_2]Cl \cdot H_2O$.[14] $\angle$Cl–Co–Cl is 91.8°, a value in good agreement with the 91.6° found in the racemate.[14] The bond lengths and angles in the ethylenediamine molecules are not accurate enough to be discussed in detail.

A complete list of the observed and calculated structure factors is preserved by the Chemical Society of Japan.*3

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3805—3813 (1970)

The Ruthenium Complexes Formed by the Reactions of Nitrosylruthenium(III) with Tin(II) in Hydrochloric Acid Solution

Masao MUKAIDA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioicho, Chiyoda-ku, Tokyo

(Received July 4, 1970)

The complexes formed by the reactions of nitrosylruthenium(III) in hydrochloric acid solutions with tin(II) chloride were investigated. The following reaction products, $(Me_4N)_2[RuCl_3(SnCl_3)_2NO]$, [1]; $(Me_4N)_4[RuCl_6(SnCl_3)_2(NO)_2]\cdot H_2O$, [2]; $(Me_4N)_4[RuCl(SnCl_3)_5]$, [3] and $K_3[Ru_2Cl_8(H_2O)_2N]$, [4] were isolated as crystals and were characterized. On the basis of chemical and thermal analyses, and on the basis of observations of the magnetic properties, the conductivities, and the infrared spectra, it was concluded that complexes [1], [2], and [3] contain terminal or bridging nitrosyl groups and/or a coordinating $SnCl_3^-$ group, and that complex [4] contains a bridging nitrido group. The presence of the binuclear complex, "$K_3[Ru_2Cl_9(NO)_2]$," which has both the terminal and singly-bridged nitrosyl groups was also suggested. The relations among those complexes were discussed.

The polynuclear metal complexes bridged by carbonyl or nitrosyl groups have recently been studied. Few binuclear ruthenium complexes bridged by nitrosyl groups have been studied. Attention has also recently been focussed on the metal-metal bonds in metal complexes. Complexes of platinum metals with metal-tin bonds have been studied considerably.[1-5] However, nitrosylruthenium complexes with the coordinating $SnCl_3^-$ groups have not yet been reported on. In this study, the binuclear ruthenium complexes bridged by nitrosyl groups and the complexes with ruthenium-tin bonds were prepared by the reactions of nitrosylruthenium(III) with tin(II) in hydrochloric acid solutions. They are $(Me_4N)_2[RuCl_3(SnCl_3)_2(NO)]$ and $(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2]\cdot H_2O$. The complexes will be discussed on the basis of their properties. Two other complexes were also isolated from the reactions of nitrosylruthenium(III) with tin(II). One was $(Me_4N)_4[RuCl(SnCl_3)_5]$, which was identical with the complex prepared from ruthenium (III and IV) and tin(II) in a hydrochloric acid solution.[6] The other was $K_3[Ru_2Cl_8(H_2O)_2N]$, which had been mentioned by Brizard[7] and Charonnat[8] and which has recently been established by Cleare and Griffith[9] and by Ciechanowicz and Skapski.[10]

Nitrosylruthenium(III) is a fairly stable group when exposed to mild chemical reactions. It has been suggested that the reduction of nitrosylruthenium(III) compounds is clearly a field which should be more fully investigated.[11] It was thought that the complexes prepared in this study would give valuable information on the reaction of nitrosylruthenium(III) with tin(II) in hydrochloric acid solutions.

Experimental

Materials. Nitrosylruthenium(III) in a hydrochloric acid solution was prepared by the conventional method.[12] This solution was adjusted to contain 8 mg Ru/ml in 3M hydrochloric acid and was used as the starting solution for the syntheses of the complexes in this study. The ^{15}N-labeled nitrosylruthenium(III) in a hydrochloric acid solution was prepared by the method

reported by Miki,[13,14] it was used for the syntheses of the ^{15}N-substituted complexes. All the other reagents used were of an analytical grade.

Measurements. The infrared spectra were measured with Leitz 221(4000—400 cm^{-1}), JASCO DS-301 (4000—700 cm^{-1}), Hitachi EPI-L(700—200 cm^{-1}), and Hitachi FIS-1(500—40 cm^{-1}) IR spectrometers. The KBr disk, Nujol mull, HCB mull and polyethylene film techniques were used. The magnetic properties were measured by the Gouy method. An electromagnet was used at the maximum field strength of *ca.* 9 kG. The conductivities of the complexes were measured in nitromethane or distilled water at 30°C with a Yokogawa Universal Bridge, BV-Z-13A. The visible spectra were measured with a Hitachi-Perkin-Elmer 139 spectrometer. The differential thermal analyses were carried out with a Shimadzu DT-2B apparatus. The measurements were made at a heating rate of 10°C/min in an atmosphere. The powder X-ray diffraction data for finely-powdered samples were obtained with a Rigaku-Denki X-ray diffractometer 2001.

The ruthenium in the complexes was determined by the ruthenate method[15] after the samples had been ignited at a rather low temperature. The tin was determined as tin dioxide after tin(IV) cupferrate had been precipitated and had been ignited.[16] The chlorine was determined gravimetrically as silver chloride. The potassium and the tetramethyl ammonium ion were determined by the use of tetraphenyl borate. Elementary analyses were made by the Institute of Physical and Chemical Research, Japan.

Preparations of Complexes. $(Me_4N)_2[RuCl_3(SnCl_3)_2(NO)]$, Complex [1]. The starting solution (1.58 mmol Ru(III)NO in 20 m*l*) was evaporated to dryness on a water bath. The residue was dissolved in 30 m*l* of 4M hydrochloric acid, and then $SnCl_2 \cdot 2H_2O$ (1.5 g, 6.7 mmol) was added gradually. The solution was subsequently vigorously stirred about 20 min at room temperature (20—25°C). After the solution had been filtered, a $(Me_4N)Cl$ solution (500 mg/5 m*l* H_2O) was added to obtain orange needle crystals. The crystals were filtered, washed several times with ethanol and with ether, and dried *in vacuo*, giving 400 mg of the complex. The complex is slightly soluble in both nitromethane and DMF. Found: Ru, 11.87; Sn, 28.13; Cl, 37.91; (Me_4N), 17.92%. Calcd for $(Me_4N)_2[RuCl_3(SnCl_3)_2(NO)]$: Ru, 12.08; Sn, 28.40; Cl, 38.27; (Me_4N), 17.71%.

$(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2] \cdot H_2O$, Complex [2]. The starting solution (1.58 mmol Ru(III)NO in 20 m*l*) was evaporated to dryness on a water bath. The residue was dissolved in 16 m*l* of 3M hydrochloric acid, and $SnCl_2 \cdot 2H_2O$ (1.7 g, 7.6 mmol) was added. The solution was then stirred vigorously about 30 min at room temperature (20—25°C) and subsequently left to stand for 24—30 hr. After the solution had then been filtered, a $(Me_4N)Cl$ solution (0.5 g/10 m*l* H_2O) was added. After this solution had stood for a long period, black or dark brown crystals were separated out. The crystals were filtered, washed several times with water, ethanol, and dried *in vacuo*, giving 200 mg of the complex. The complex is insoluble in most organic solvents.

Found: Ru, 16.27; N, 6.58; Sn, 19.14; Cl, 34.41; (Me_4N), 24.26%. Calcd for $(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2] \cdot H_2O$: Ru, 16.31; N, 6.78; Sn, 19.16; Cl, 34.34; (Me_4N), 23.89%.

$(Me_4N)_4[RuCl(SnCl_3)_5]$, Complex [3]. *Method 1.* To the starting solution (1.58 mmol Ru(III)NO in 20 m*l*), 6M hydrochloric acid (60 m*l*) and $SnCl_2 \cdot 2H_2O$ (1.5 g, 6.7 mmol) were added. The mixed solution was then concentrated to about 20—30 m*l* by boiling it. Again, to the resulting solution, 3M hydrochloric acid (60 m*l*) and $SnCl_2 \cdot 2H_2O$ (0.5 g, 2.2 mmol) were added, and the solution was boiled for 10 min. After this solution had then been filtered, a $(Me_4N)Cl$ solution (1 g/10 m*l* H_2O) was added until crystals appeared. These orange-yellow crystals were separated out. The crystals were washed several times with an ethanol-hydrochloric acid mixture and with ether, and dried *in vacuo*, giving 300 mg of the complex. The complex is slightly soluble in both nitromethane and DMF.

Method 2. An alternative procedure for the preparation of this complex is as follows. The starting solution (1.58 mmol Ru(III)NO in 20 m*l*) was evaporated to dryness on a water bath. The residue was dissolved in 20 m*l* of 6M hydrochloric acid, and $SnCl_2 \cdot 2H_2O$ (1.7 g, 7.6 mmol) was added to the solution. The mixed solution was left to stand overnight at room temperature (20—25°C). After the solution had then been filtered, a $(Me_4N)Cl$ solution (1 g/10 ml H_2O) was added. An orange-yellow complex was thus obtained.

Found: Ru, 6.76; Sn, 38.80; Cl, 36.01; (Me_4N), 18.77%. Calcd for $(Me_4N)_4[RuCl(SnCl_3)_5]$: Ru, 6.48; Sn, 38.08; Cl, 36.45; (Me_4N), 18.99%.

$K_3[Ru_2Cl_8(H_2O)_2N]$, Complex [4]. This complex was prepared by the reduction of nitrosylruthenium(III) with tin(II) or with formaldehyde.

Procedure with Tin(II) Chloride. To the starting solution (1.58 mmol Ru(III)NO in 20 m*l*), potassium chloride (1 g) and $SnCl_2 \cdot 2H_2O$ (2.2 g, 9.8 mmol) were added. The mixture solution was completely evaporated to dryness on a water bath. The product was dissolved with a 3M hydrochloric acid solution (15—20 m*l*) and was then concentrated until crystals appeared. After the solution had then stood overnight, the reddish-brown crystals thus obtained were filtered and washed several times with water-ethanol and ether, and dried *in vacuo*, giving 100—150 mg of a crude product. A mixture of the crude product (250 mg), potassium chloride (0.5 g), and $SnCl_2 \cdot 2H_2O$ (2 g) was dissolved in 6M hydrochloric acid (30 m*l*) by heating, after which the solution was heated vigorously in a flask equipped with a reflux condenser for 2—4 hr. When the resulting solution was concentrated by evaporation, crystals were separated out. The reddish-brown crystals thus obtained were filtered, washed several times with a water-ethanol (1 : 1) mixture and with ether, and dried *in vacuo*, giving 30 mg of the complex. Recrystallization was made from 3M hydrochloric acid containing small amounts of potassium chloride. The complex is slightly soluble in water, but it is not soluble in any organic solvent.

Found: Ru, 30.25; N, 2.27; H, 0.81; Cl, 43.78; K, 17.50% (Ru, 30.18; N, 1.90; H, 0.73; Cl, 42.34;

Table 1. The complexes prepared from the reactions of Ru(III)NO with Sn(II) in hydrochloric acid solutions

	Formula	Color in solid state	Absorption maxima (mμ) (ε in parentheses)	
1,	$(Me_4N)_2[RuCl_3(SnCl_3)_2NO]$	orange	440 (9.0×10^2) 326 (1.8×10^4)	*1
2,	$(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2]\cdot H_2O$	black-dark brown	—	
3,	$(Me_4N)_4[RuCl(SnCl_3)_5]$	orange-yellow	444 (1.3×10^3) 293 (2.2×10^4)	*1
4,	$K_3[Ru_2Cl_8(H_2O)_2N]$	reddish brown	440 (1.1×10^2) sh 360 (5.0×10^2) sh	*2
5,	"$K_3[Ru_2Cl_9(NO)_2]$"	brown	—	

*1: in 3M hydrochloric acid solution, *2: in aqueous solution.

K, 17.38% for the crude product). Calcd for $K_3[Ru_2Cl_8(H_2O)_2N]$: Ru, 30.92; N, 2.14; H, 0.61; Cl, 43.47; K, 17.95%. The evaporation of a D_2O solution of the complex gave a deuterium-substituted complex as crystals.

Procedure with Formaldehyde. To the starting solution (1.58 mmol Ru(III)NO in 20 m*l*), enough potassium hydroxide was added to make the pH of the solution higher than 13. After the mixed solution had then been boiled vigorously for about 30 min, the solution gradually turned from brown to pale-violet, and finally to dark red. While a formalin solution (10 m*l*) was poured, drop by drop, into the solution, a gelatinous, brown precipitate was thrown down from the solution. The precipitate thus obtained was centrifuged and then washed several times with water. The precipitate was subsequently dissolved in a hydrochloric acid solution containing 0.3 g of potassium chloride, and the solution was concentrated by evaporation. After the solution had stood overnight, the reddish-brown crystals thus obtained were filtered, washed several times with a water-ethanol (1 : 1) mixture and with ether, and dried *in vacuo*, yielding 50 mg of a crude product.

Found: Ru, 30.31; N, 2.22; H, 0.71; Cl, 41.60; K, 17.58% for the crude product.

Results and Discussion

From the reactions between nitrosylruthenium(III) and tin(II) chloride under the various reaction conditions, two complexes were newly prepared and two complexes which had recently been reported were isolated. The analytical data were in good agreement with the calculated compositions. The complexes are summarized in Table 1, along with the absorption maxima in their visible and UV spectra. All the complexes are fairly stable in an atmosphere. However, exposure to sunlight changes complexes [1] and [3] from the original orange to dark gray. The conditions of preparing complexes [1] and [2] were rigid, and the methods of these preparations were specially examined.

The type of electrolyte in complex [1] was examined by the use of the conductivities in solutions according to the method reported by Feltham and Hayter.[17] The results shown in Table 2 indicate

17) R. D. Feltham and R. G. Hayter, *J. Chem. Soc.*, **1964**, 4587.

Table 2. Type of electrolyte as determined by conductivity measurements

Complex	Solvent	Λ_0 (ohm^{-1})	$\frac{\Lambda_0-\Lambda_e}{\sqrt{C}}$	Type of electrolyte
$(Me_4N)_2[RuCl_3(SnCl_3)_2NO]$	CH_3NO_2	156	660	2:1
$K_3[Ru_2Cl_8(H_2O)_2N]$	H_2O	214	321	3:1

temperature; 30°C, concentration range; 10^{-2}—10^{-3}M. In order to determine the type of electrolyte, the data on $(Me_4N)_2[RuCl_3(SnCl_3)_2NO]$ were compared with those on $[(C_6H_5)_4As]Cl$ and $[Co(phen)_3](ClO_4)_3$, and the data on $K_3(Ru_2Cl_8(H_2O)_2N]$ with those on $[Co(NH_3)_6]Cl_3$.

that complex [1] is an electrolyte of the 2 : 1 type and that no appreciable dissociations of the $SnCl_3^-$ group occur in nitromethane solutions.

On the differential thermal analysis of complex [2], a distinct endothermic peak at 100—130°C was found, accompanied by a relatively small endothermic peak at about 140°C (Fig. 1). A violent decomposition started at 200°C. Infrared spectroscopy suggested that the two endothermic peaks may be based on the dehydration of crystalline water and the structural change in the complex. The gravimetric determination of the crystalline water was impossible.

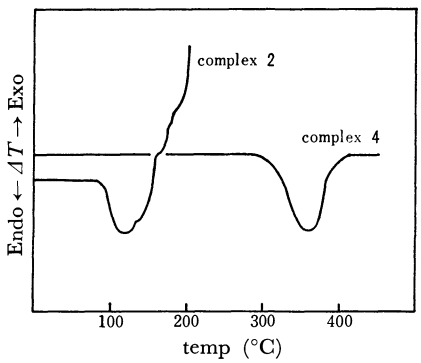

Fig. 1. DTA curves of $(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2]\cdot H_2O$, complex [2] and $K_3[Ru_2Cl_8(H_2O)_2N]$, complex [4].

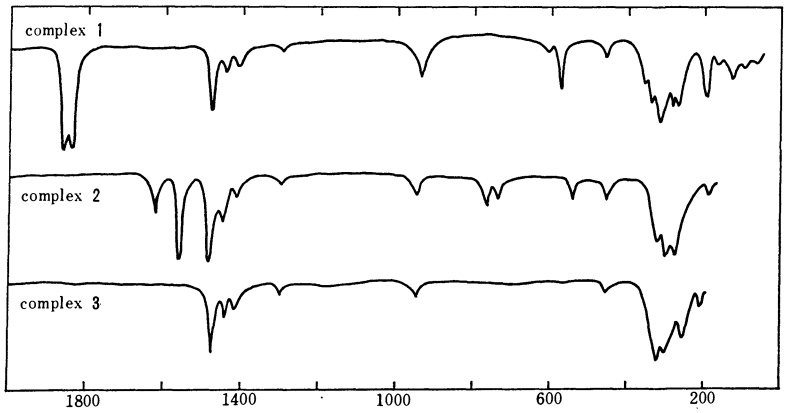

Fig. 2. Infrared spectra of $(Me_4N)_2[RuCl_3(SnCl_3)_2NO]$, complex [1], $(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2]\cdot H_2O$, complex [2] and $(Me_4N)_4[RuCl(SnCl_3)_5]$, complex [3].

Complex [3] was identical with a complex which has previously been prepared by the reaction of ruthenium (III and IV) with the tin(II) in a hydrochloric acid solution.[6]

Complex [4] was prepared by two methods similar to those described by Brizard;[7] the two methods yielded identical complexes. The complex is thought to be the same as that reported by Cleare and Griffith.[9] Complex [4] was shown to be an electrolyte of the 3 : 1 type by the conductivity measurements (Table 2), this supports the formula of complex [4]. A differential thermal analysis was made of complex [4] in order to determine the nature of water in the complex. The DTA curve obtained is shown in Fig. 1. The endothermic peak at about 300—380°C is thought to be caused by the dehydration of the coordinating waters from the complex, because the weight loss (5.66%) at 380°C corresponds to the two molecules of water in the complex and the dehydration temperature observed is considerably higher than the general dehydration temperature for water of crystallization.

The structures of the complexes will be discussed on the basis of the infrared spectra and the diamagnetisms.

Infrared Spectra. As Figs. 2 and 3 and Tables 3 and 4 show, complexes [1], [2], [3] and [4] display quite different spectra, indicating that their structures are also different.

In general, terminal nitrosyl groups in metal complexes are characterized by absorption bands due to the NO stretching vibration. The NO stretching absorptions of complex [1], $(Me_4N)_2[RuCl_3(SnCl_3)_2NO]$, were easily identified, because the NaCl region is free from ligand absorptions except for the absorptions due to the nitrosyl group. Thus, the strong bands at 1865 cm^{-1} and 1842 cm^{-1} can be assigned to the NO stretching frequencies,

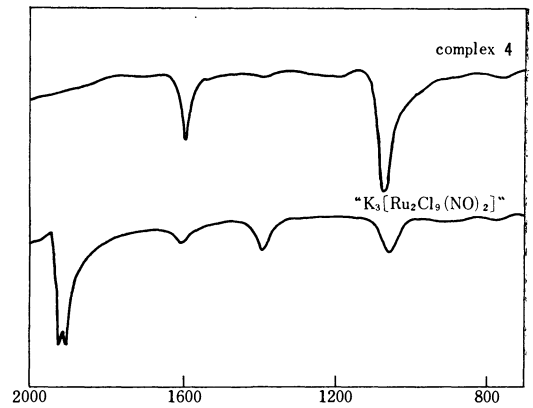

Fig. 3. Typical infrared spectra of $K_3[Ru_2Cl_8(H_2O)_2N]$, complex [4] and "$K_3[Ru_2Cl_9(NO)_2]$."

which are close to those for $K_2[RuCl_5NO]$.[18-20] The remaining two bands in the region about 600—550 cm^{-1} of complex [1] must be attributed to the Ru–NO bending and the Ru–NO stretching frequencies. If a linear Ru–N–O arrangement is assumed, there are three possible isomers of complex [1], one *trans* (C_{2v}) and two *cis* (C_s), with respect to the $SnCl_3^-$ ligands. However, the stereochemistry of complex [1] was not determined by the symmetry treatment and the observation of the infrared absorption bands. Since the NO and the $SnCl_3^-$ ion have strong *trans* effects, so that the *trans* positions of the NO and $SnCl_3^-$ groups may be expected to

be labile,[21,22] a stable structure of complex [1] can be presumed to be *cis* with respect to any two of the $SnCl_3^-$ and NO groups. However, it has been stated, with regard to the isomerism of the $[PtCl_2(SnCl_3)_2]^{2-}$ ion, that the *cis* isomer is more stable thermodynamically, while the *trans* isomer is favoured kinetically.[3]

The features of the spectra of complex [2], $(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2]\cdot H_2O$, were markedly different from those of complex [1]. No absorption band was observed in the region of 1700—1900 cm^{-1}, where the bands due to the stretching vibrations of the terminal nitrosyl group in nitrosylruthenium complexes had previously been reported. However, a strong absorption band appeared at 1566 cm^{-1}. Since absorption bands due to the stretching vibrations of the bridging nitrosyl group in metal complexes have been found in the region of 1550—1300 cm^{-1},[23-25] the band at 1566

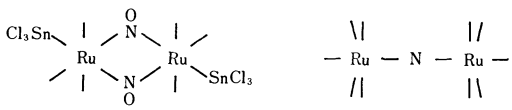
cm^{-1} can be assigned to the stretching vibration of the bridging nitrosyl group in complex [2]. The infrared investigation of the bridging nitrosyl groups has not yet dealt with the absorption bands in the lower frequency region. However, three absorption bands were observed, at 769, 747, and 543 cm^{-1}, in complex [2], instead of the two bands due to the skeletal vibrations of the Ru–NO(terminal) group. If the binuclear skeleton shown in Fig. 4, which has a center of symmetry, is assumed for complex [2], there should be three bands, due to Ru–N stretching, RuNO in-plane bending, and RuNO out-of-plane bending vibrations. The three absorption bands observed in the lower region can thus be explained. These three bands and the bands at 1566 cm^{-1} were shifted by the ^{15}N-substitution. The skeletal structure of complex [2] as shown in Fig. 4 is suggested on the basis of its



complex [2] complex [4]

Fig. 4. Proposed skeletal structures for $(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2]\cdot H_2O$, complex [2] and $K_3[Ru_2Cl_8(H_2O)_2N]$, complex [4].

infrared absorptions. The dimeric nature thus presumed could not be confirmed by molecular weight and electroconductivity measurements, because of its low solubility with regard to organic solvents. However, when complex [2] was heated at about 150°C, the infrared absorption due to the stretching vibration of the bridging nitrosyl group disappeared and that of the terminal nitrosyl group appeared. This observation suggests a bridge cleavage on the heating of complex [2] and supports its dimer structure.

The infrared spectra of complex [3], $(Me_4N)_4[RuCl(SnCl_3)_5]$, differ greatly from those of complexes [1] and [2]. No absorption bands due to the NO group were found in complex [3]. This confirms that complex [3] does not contain a nitrosyl group.

One of the most interesting investigations was the examination of the Ru–Sn bond in complexes [1], [2] and [3]. The absorption bands due to Ru–Cl stretching and Sn–Cl stretching vibrations have previously been reported.[19, 26–28] A direct comparison of the far infrared spectra of complexes [1], [2] and [3] shows that the bands in the region of 360—250 cm^{-1} must be ascribed to metal-halogen vibrations. In order to make tentative assignments of the remaining bands, it was assumed that the bands observed in the region lower than about 160 cm^{-1} are to be attributed to lattice vibrations in these complexes. Consequently, the strong bands at about 200 cm^{-1} were assigned to the Ru–Sn stretching vibration: 200 cm^{-1} for complex [1], 190 cm^{-1} for complex [2],*1 and 212 cm^{-1} for complex [3]. These assignments are in agreement with those of the absorptions due to metal-tin vibrations in the other metal-tin complexes.[29,30] Thus, it was demonstrated that ruthenium-tin bonds are present in complexes [1], [2], and [3].

Very recently, Cleare and Griffith have reported the preparation of a bridging nitrido complex, $K_3[Ru_2Cl_8(H_2O)_2N]$ (complex [4]), by the Brizard method.[7]

An X-ray diffraction study of this binuclear complex has indicated that the ruthenium atoms, which lie in mirror planes, have a distorted octahedral coordination with water molecules *trans* to the nitrogen.[10] The main features of the infrared spectra of complex [4] in this study were similar to those reported by Cleare and Griffith. Complex [4] displays five absorption bands, at 3360, 1611, 1082, ~600, and 543 cm^{-1}, over the range of 4000—400 cm^{-1}. The band at 1082 cm^{-1} was often accompanied by a shoulder peak at 1045 cm^{-1}. A very weak broad band at about 1410 cm^{-1} was often found. In order to distinguish the bands due to coordinating water from those connected with the nitrogen atom, isotopic substitutions on hydrogen and nitrogen atoms were carried out. The bands at 3360, 1611, and 600 cm^{-1} shifted to at 2450, 1190, and ~450 cm^{-1} respectively in the deuterated complex. Thus, these three bands were assigned to the OH stretching and H_2O bending (scissoring and wagging) vibrations.[28] On ^{15}N-substitution the two remaining bands, at 1082 and 543 cm^{-1}, shifted to the lower-frequency side. It has been reported that a metal complex such as $[Os_2N(NH_3)_8Br_2]Br_3$, which has a bridging nitrido group, is characterized by a strong absorption band in the 1100 cm^{-1} region.[31] On the basis of the structure of complex [4] (Fig. 4), which has been determined by X-ray study,[10] the bands at 1082 and 543 cm^{-1} can be assigned to the asymmetric stretching and bending frequencies respectively of the linear Ru–N–Ru skeleton. On the ^{15}N-isotopic substitution, these bands shifted to 1047 and 528

cm^{-1} respectively. These band shifts observed were in good agreement with the calculated ones, 34 and 17 cm^{-1}, which were estimated for the linear three-body model of Ru–N–Ru with the Ru–N distance of 1.718 A.[10] This agreement for the 1082 cm^{-1} band was shown also by Cleare and Griffith.[9]

When the crude product obtained in preparing complex [4] was not heated with Sn(II) in 6M hydrochloric acid, it usually exhibited a broad band at 1409 cm^{-1} with a medium intensity. The repeated recrystallization of the crude product gradually reduced the intensity of the absorption band at 1409 cm^{-1}, but it could not remove the band completely. This absorption band shifted slightly from 1409 to 1403 cm^{-1} on ^{15}N-substitution. The crude product showed identical features in its ^{15}N-substitution for the 1082 and 543 cm^{-1} bands, in its electronic spectra, and in its X-ray powder pattern with that of the purified complex, except that the band at 1409 cm^{-1} was present in the crude product.

It may be suggested that a complex with a singly-bridging nitrosyl group such as $K_3[Ru_2Cl_8(H_2O)_2NO]$ is present in the crude product of complex [4] and that the absorption band at 1409 cm^{-1} is due to the stretching vibration of the singly-bridging nitrosyl group. The disappearance of the absorption band of the crude product of complex [4] on the digestion in 6M hydrochloric acid may be caused by the rupture of the N–O bond in the bridging nitrosyl group and the formation of a bridging nitrido structure. On the other hand, it is also probable that the impurity in the crude product of complex [4] is a material which gives an infrared band only at 1409 cm^{-1}. The present study can not distinguish these possibilities. The impurity in the crude product of complex [4] will be discussed again later in connection with our other findings.

Complex [4] was dehydrated at 400°C under a nitrogen atmosphere, as has been described above. The infrared spectra of the complex heated exhibited two sharp bands at 1592 and 1063 cm^{-1} instead of the three bands at 3360, 1611, and 1082 cm^{-1} usually found in complex [4]. The corresponding two bands were observed at 1594 and 1031 cm^{-1} in the ^{15}N-substituted complex. The recrystallization of the complex dehydrated with a hydrochloric acid solution containing potassium chloride yielded the original complex [4]. These observation suggest a fairly stable skeletal structure of complex [4]. The appearance of the band at 1592 cm^{-1} in the dehydrated complex remained an unsolved problem. A proper assignement of the band at 1592 cm^{-1} was not made, though this infrared region is expected to be that for the stretching vibration of the bridging nitrosyl group. The other band, at 1063 cm^{-1}, is thought to correspond to the band at 1082 cm^{-1} in complex [4]; it may be suggested that the RuNRu skeleton is present in the dehydrated complex.

The preparation of the binuclear complex which has both terminal and singly-bridging nitrosyl groups was attempted. Preparation: to the starting material (0.79 mmol Ru(III)NO in 10 m*l*), 3M hydrochloric acid (20m*l*), potassium chloride (0.5 g), and $SnCl_2 \cdot 2H_2O$ (0.5 g, 2.2 mmol) were added. The mixed solution, in a porcelain dish, was then heated on a water bath for about 30 min. After the solution had subsequently stood for about a week, reddish-brown crystals were obtained. The composition of these crystals compared fairly well with the formula of $K_3[Ru_2Cl_9(NO)_2]$.

Found: Ru, 29.28; N, 3.61; Cl, 44.34; K, 17.38; Sn, 0.15%. Calcd for $K_3[Ru_2Cl_9(NO)_2]$: Ru, 28.91; N, 4.01; Cl, 45.76; K, 16.79%.

The nitrogen content determined was always less than the calculated value. There remains some uncertainty as to the purity of this product. The solubility of this product was much less than that of $K_2[RuCl_5NO]$, but greater than that of complex [4]. However, the recrystallization from hydrochloric acid solutions was not succesful, and it was

Relative intensities were estimated by comparing the hight of the peak. Less intensity lines are omitted.

observed that the recrystallization brought the decomposition to $[RuCl_5NO]^{2-}$ and/or the crude product of complex [4].

The infrared spectra of this product exhibited its major absorption bands at 3360, 1913, 1903, 1610, 1405, and 1082 cm^{-1} over the 4000—400 cm^{-1} range (Table 5) and are thought to involve absorption bands corresponding to those of complex [4]. The relative intensities of these absorption bands sometimes varied with the samples, and the intensity of the band at 1405 cm^{-1} decreased with an increase in the intensities of the bands at 3360, 1610, and 1082 cm^{-1}. However, the band at 1405 cm^{-1} was a sharp and symmetric band. This band may correspond to the band of the crude product of complex [4] at 1409 cm^{-1}.

The bands at 1913, 1903, and 1082 cm^{-1} are thought to be due to the terminal NO group and the asymmetric stretching vibration of the Ru–N–Ru group respectively. The four bands at 1913, 1903, 1405, and 1082 cm^{-1} shifted on ^{15}N-substitution, as is shown in Table 5. The bands at 3360 and 1610 cm^{-1} may be caused by the coordinating waters of complex [4], an impurity in this product. These observations, along with the chemical properties, indicate that the "$K_3[Ru_2Cl_9(NO)_2]$" complex, with a singly-bridging and a terminal nitrosyl group, may exist and that the sharp absorption bands observed at 1405 cm^{-1} may be due to the stretching vibration of the singly-bridging nitrosyl group in the complex, although the sample used in this infrared study was not pure enough. The X-ray powder patterns of the "$K_3[Ru_2Cl_9(NO)_2]$", $K_2[RuCl_5NO]$ complex and of complex [4] were compared (Table 6); it was thus shown that "$K_3[Ru_2Cl_9(NO)_2]$" is not a mixture of $K_2[RuCl_5NO]$ and complex [4].

When the final filtrate in the preparation of "$K_3[Ru_2Cl_9(NO)_2]$" was allowed to stand for a long time, red crystals were rarely obtained. The infrared spectra of this material exhibited only a strong band at 1408 cm^{-1} in the NaCl region and one at 1400 cm^{-1} for the ^{15}N-substituted material. Though this material is expected to have an interesting structure, the details on this particular crystals have not yet been clarified. However, these findings seem to support the idea that the crude product of complex [4] contains an impurity which gives an infrared band only at 1409 cm^{-1}.

Diamagnetisms. All the complexes prepared were diamagnetic. It is clear that $(Me_4N)_2[RuCl_3(SnCl_3)_2NO]$ (complex [1]) and $(Me_4N)_4[RuCl(SnCl_3)_5]$ (complex [3]) are diamagnetic. The oxidation state of the RuNO group in complex [1] is III, while that of ruthenium in complex [3] is II.

The diamagnetisms of $(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2]\cdot H_2O$ (complex [2]) will be explained on the basis of the skeletal structure, shown in Fig. 4. Complex [2] involves the skeletal group of $Ru_2(NO)_2$, the oxidaton state of which is IV. The formal oxidation states of the ruthenium atoms and nitrosyl groups may be designated as follows: (i) both ruthenium atoms with II, and both bridging nitrosyl groups with zero, or (ii) both ruthenium atoms with III, and both the bridging nitrosyl groups with -1. The diamagnetism of this com-

plex may be satisfactorily understood on the basis of the resonating four-member ring system, which accommodates two electrons of two nitrosyl groups in the case of (i), or those of two ruthenium atoms in the case of (ii), to make the spins of the two electrons paired. The diamagnetism of the binuclear manganese complex has similarly been explained by a four member-ring bridged with two nitrosyl groups.[23] Direct Ru(III)-Ru(III) interaction may also be possible in the case of (ii). Thus, the skeletal structure proposed can explain both the infrared spectra and the diamagnetism of complex [2].

The diamagnetism of $K_3[Ru_2Cl_8(H_2O)_2N]$ has been explained by assuming that the spin-pairing of $4d_{xz}$ and $4d_{yz}$ ruthenium orbitals takes place *via* the $2p_\pi$ nitrogen orbital.[9]

Reactions of Nitrosylruthenium(III) with Tin(II). The reactions of nitrosylruthenium(III) with tin(II) in hydrochloric acid solutions were quite complicated. The isolation of the reaction products is thought to give qualitative information on the reactions, although the isolation depends on the formation of complex ions, the solubilities of the salts of the complex ions formed, and the equilibria which involve the complex ions. The observed relations of these complexes are summarized in Fig. 5. The reactions of nitrosylruthenium(III) in this study may be divided into two broad classes: the coordinations of $SnCl_3^-$ on the ruthenium atom and the changes in the nitrosylruthenium(III) group. The differences in the conditions of preparing complexes [1], [2], and [3] indicate that the donation of $SnCl_3^-$ groups to the ruthenium atom of the nitrosylruthenium(III) group occurs first of all, and that the RuNO group then undergoes dimerization to form a binuclear skeleton bridged doubly by two nitrosyl groups; finally, the elimination of nitrosyl group occurs.

The reaction of $(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2]\cdot H_2O$ with tin(II) chloride in the presence of potassium chloride in a hydrochloric acid solution yields a large amount of $[RuCl(SnCl_3)_5]^{4-}$ and a very small amount of $K_3[Ru_2Cl_8(H_2O)_2N]$ (complex [4]).

A consideration of the conditions for preparing "$K_3[Ru_2Cl_9(NO)_2]$", and $K_3[Ru_2Cl_8(H_2O)_2N]$ suggests that the formation of the skeletal structures becomes easier in the order of: Ru(N)Ru<Ru(NO)Ru<Ru(NO)Ru(NO) (easiest), if $K_3[Ru_2Cl_8(H_2O)_2(NO)]$ is assumed to be present in the crude product of complex [4].

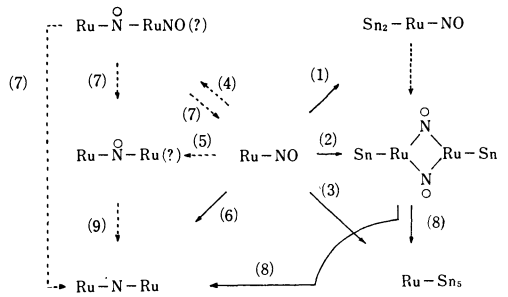

Fig. 5. Reactions of Ru(III)NO with Sn(II). (Only skeletons are cited.) (1)—(6): preparation routes, (7): decomposition of "$K_3[Ru_2Cl_9(NO)_2]$" in hydrochloric acid, (8): reaction of $(Me_4N)_4[Ru_2Cl_6(SnCl_3)_2(NO)_2]\cdot H_2O$ with Sn(II) and (9): reaction of the crude product of $K_3[Ru_2Cl_8(H_2O)_2N]$ with Sn(II).

When nitrosylruthenium(III) and tin(II) (in the mole ratio of 1 : 0.8) were concentrated with potassium chloride under gentle warming, dipotassium pentachloronitrosylruthenate(III) was obtained. On the other hand, nitrosylruthenium(III) can be changed to ruthenium(II) by the method described in the preparation of complex [3].

The author wishes to express his thanks to Professor Hisateru Okuno of St' Paul's(Rikkyo) University for his suggestion that the chemistry of ruthenium would be an interesting subject of study, and to Assistant Professor Ichiro Nakagawa of the Tokyo University, Dr. Eiichi Miki and Dr. Hiroshi Saito of St' Paul's(Rikkyo) University for their valuable suggestions concerning the infrared study. Thanks are also due to Professor Tatsujiro Ishimori of St' Paul's(Rikkyo) University and Assistant Professor Terunosuke Nomura of Sophia University for their continuing interest and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3814—3819 (1970)

A Study of Electronic Spectra of Square Planar Copper(II) and Nickel(II) Complexes by Circular Dichroism*1

Yuzo NISHIDA and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received July 6, 1970)

Using optically active 1,2-propylenediamine we have synthesized several ligands to form square planar Cu(II) and Ni(II) complexes with optical activity. The CD(circular dichroism) and AB (absorption) spectra of these compounds were measured. The broad absorption bands were resolved in the CD spectra into each component due to a *d-d* transition, to which a specific *d-d* transition was assigned. It was found that in these compounds the change in the central atom from Cu(II) to Ni(II) dose not alter the main feature of CD and AB spectra. This seems to be the general rule for the planar Cu(II) and Ni(II) complexes.

The ligand field theory predicts that three spin-allowed *d–d* transitions may be observed in the electronic spectra of square planar copper(II) and nickel(II) complexes. However, the three d–d bands are usually superposed and are observed as one broad band, sometimes with shoulders. Thus our attempt to assign the absorption bands to each electronic transition was accompanied with considerable difficulty.

Recently, Smith[1,2] has developed an elegant approach for the estimation of energy levels of tetragonal copper(II) complexes, making use of Hathaway and his coworkers' detailed experimental data.[3,4] According to Smith, the order of energy levels of $Cu(NH_3)_4X_2$ and Cu en_2X_2, (X=SCN^-, NO_2^-, $CuCl_2^-$, and other various anions) is $d_{x^2-y^2} > d_{z^2} > d_{xy} > d_{xz}$, d_{yz}, but in planar $CuCl_4^{2-}$ the order of d_{xy} and d_{z^2} is reversed. This implies that more detailed studies are necessary for the elucidation of the electronic spectra of copper(II) complexes. As for the electronic spectra of square planar nickel(II) complexes, information is still insufficient.[5]

We have prepared numerous square planar copper(II) and nickel(II) complexes of the $[MN_4]$ and $[MN_2O_2]$ types containing optically active ligands, and tried to obtain more information on the energy states of these complexes by taking advantage of CD spectra which give much more resolved spectra than the AB spectra for superposed bands. In addition, we could obtain some information of the configuration and the conformation of the complexes by CD spectra.

Experimental

The absorption and circular dichroism spectra were obtained by a Jasco ORD-UV/5 optical rotatory dispersion recorder with a CD attachment at room temperature. Optically active (−)D-propylenediamine (abbreviated as (−)pn) was obtained by the method of Dwyer *et al.*[6] These complexes may be classified into the following four types.

A. Complexes with optically active propylenediamine. $[Cu(-)pn_2](ClO_4)_2$, and $[Ni(-)pn_2](ClO_4)_2$ were obtained from metal perchlorate and (−)D-propylenediamine in methanol solution.

B. Complexes with optically active Schiff bases resulted from salicylaldehyde or its derivatives and (−)D-propylenediamine, such as sal(−)pnH_2, naphal(−)pnH_2, 7-mesal(−)pnH_2. (For abbreviation, see Table 2). Each of these complexes was obtained from metal acetate and schiff base, which was obtained from the mixture of salicylaldehyde or its derivatives and (−)D-propylenediamine.

C. Complexes with optically active schiff bases from acetylacetone or benzoylacetone and (−)D-propylenediamine, such as acac(−)pnH_2, bzac(−)pnH_2, (see Table 2). These complexes were obtained from a mixture of metal chloride, schiff base and sodium carbonate in water-methanol mixture.

D. Complexes with the mad(−)pnH_2, oxad(−)-pnH_2, sad(−)pnH_4, which were obtained from the condensation reaction between diethylmalonate, diethyloxalate or methyl salicylate and (−)-propylenediamine. Metal complexes were prepared by a method

similar to the Ojima's method.[7,8] Since the nickel complex of sad(−)pnH$_4$ did not crystallize, the solution was purified by eluting on alumina and the ion-exchange resin, Amberlite CG 120. The solution thus obtained was immediately used for optical measurements. The obtained spectrum agreed well with that of the ethylenediamine homologue, indicating that [Ni sad(−)pn]$^{2-}$ was formed in the solution.

Results and Discussion

Copper Complexes. It is believed that bis(propylenediamine)copper(II) ion has a nearly tatragonal configuration in methanol solution as in the case of bis(ethylenediamine)copper(II) ion. As is seen in Fig. 3, CD spectrum of Cu(−)pn$_2$(ClO$_4$)$_2$ shows a small band at 15.2 kK. besides the main broad band at 19.7 kK. Gillard[9] assigned the main band to the $d_{xz},d_{yz}\rightarrow d_{x^2-y^2}$ transition and the small bond at 15.2 kK to the $d_{xy}\rightarrow d_{x^2-y^2}$ transition. The band due to the $d_{z^2}\rightarrow d_{x^2-y^2}$ transition was assumed to be located at the region of much lower wave-number (*cf.* Fig. 2). However, from the Gaussian analysis of electronic spectra, measured at room temperature and at the temperature of liquid nitrogen, of the crystals of bis(ethylenediamine)copper(II) salts with different anion, Hathaway *et al.* found three bands in the visible region. They assigned the bands which were found at 20.3—17.9 kK, 18.0—16.2 kK and 16.8—12.2 kK to the transitions $d_{xz},d_{yz}\rightarrow d_{x^2-y^2}$, $d_{xy}\rightarrow d_{x^2-y^2}$, and $d_{z^2}\rightarrow d_{x^2-y^2}$, respectively. The result of Smith's calculation agreed satisfactorily with the experimental values on the same assignment. The band at 15.2 kK of Cu(−)pn$_2^{2+}$ was clearly resolved in our CD measurement, which should correspond to the band of the lowest wave-number in Cu en$_2^{2+}$, and is assigned to the $d_{z^2}\rightarrow d_{x^2-y^2}$ transition. Further support for this assignment will be seen in the following discussion.

In the solvent of stronger donating ability, such as pyridine, the coordination or semi-coordination of the solvent molecule to the copper ion along the

tetragonal axis would become stronger, and d_{z^2} orbital of the copper ion suffers the most profound effect among the *d*-orbitals (Fig. 2). As a result of this effect, the band due to the $d_{z^2} \rightarrow d_{x^2-y^2}$ transition will show the largest red shift among the *d–d* bands. In fact, as seen in Fig. 3, in the CD and absorption spectra of $Cu(-)pn_2(ClO_4)_2$ in pyridine solution, the red shift of the main peak is only about 1 kK in either AB or CD spectrum compared with that in methanol solution. On the other hand, the CD band, which was observed at 15.2 kK in methanol solution and was assigned to the $d_{z^2} \rightarrow d_{x^2-y^2}$ transition, disappeared in pyridine solution, and a shoulder appeared at 12 kK in the absorption spectrum, suggesting that this band shifted from 15.2 kK to 12 kK.

The CD and AB spectra of [Cu mag(−)pn] are shown in Fig. 4. In this complex two of four coordinated nitrogen atoms are anions of amide nitrogen which has lost a proton. It is accepted that in such a $[CuN_4]$ type complex as involving anion nitrogen in coordination, the coordination bonds in the tetragonal plane is much stronger than those of the complex coordinated by four neutral nitrogen atoms, and the axial coordination becomes very weak.[7,8] As a result of this effect, the d_{z^2} orbital will be stabilized and the $d_{z^2} \rightarrow d_{x^2-y^2}$ band will shift to the higher wave-number. This is the reversal of the spectral change from a methanol solution to a pyridine solution. In fact, only one broad band was observed in either AB or CD spectrum of [Cu mad(−)pn] in the visible region. This is understandable in view of the blue shift of the $d_{z^2} \rightarrow d_{x^2-y^2}$ band to the region of the main band.

The Resemblance of CD Spectra of Planar Cu(II) and Ni(II) complexes. It is readily ob-

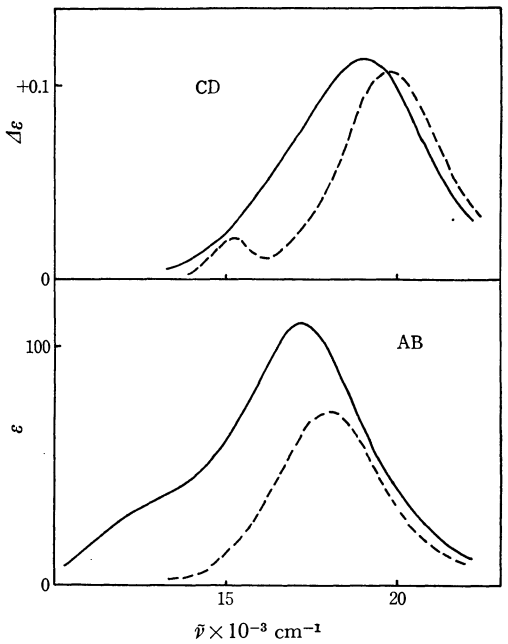

Fig. 3. AB and CD spectra of $[Cu(-)pn_2](ClO_4)_2$.
------ in methanol —— in pyridine

served that the CD and AB spectra of [Cu mad(−)-pn] resemble those of the nickel(II) complex of the same ligand as seen in Fig. 4. In the Cu(II) and Ni(II) complexes of sad(−)pn, which are shown in Fig. 5, the three components of the *d–d* bands are clearly resolved in CD spectra of both complexes. Resemblance of the two spectra is rather surprising, and the three bands may be assigned from the lower wave-number side to $d_{z^2} \rightarrow d_{x^2-y^2}$, $d_{xy} \rightarrow d_{x^2-y^2}$, and $d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}$ in each complex.

The spectra of [Cu acac(−)pn], [Cu sal(−)pn] and [Cu 7-mesal(−)pn] in chloroform are shown in Fig. 6. Judging from the absorption intensity, the bands above 23 kK would not be due to the d–d transition but could be attributed to the origin in the ligand electron. Though the three complexes all belong to the square planar *cis*-$[CuN_2O_2]$ type, the CD spectrum of [Cu sal(−)pn] associated with d–d transision entirely differs from those of the other two complexes, as is obvious from Fig. 6. Downing and Urbach,[10] and the present authors[11] independently reached the same conclusion that this fact may be rationalized in terms of the conformational preference of the central chelate ring resulting from the steric requirements of the ligands.

The nickel(II) complexes of acac(−)pnH_2, sal-(−)pnH_2 and 7-mesal(−)pnH_2 are expected to have a square planar configuration from the electronic spectra and a structure of homologous ethylenediamine derivatives. Each of the CD spectra of the nickel complexes bears a close resemblance to that of the corresponding copper complex, suggesting that the conformations of the bridging propane-1,2 diamine group are similar to each other in the nickel

and copper complexes of the same ligand (Figs. 6 and 7).

The close resemblance of CD spectra of the planar copper(II) and nickel(II) complexes of the same ligand is too obvious to be considered accidental. In fact, this tendency was observed not only in the above complexes but in the spectra of Ni(II) and Cu(II) complexes of every ligand studied in the present work (Fig. 8). Further, from literature we investigated we have always found such resemblance in CD spectra for each pair of nickel and copper complexes of the same ligand.[12–14] Thus, this appears to be the general rule.

The *d*-orbitals split under the ligand field of square planar coordination as shown in Fig. 2. If interelectronic interaction is neglected, there is no significant difference between planar Cu(II) and Ni(II) complexes. Actually, however, the energy states of nickel(II) complexes are largely dependent on interelectronic repulsion, even if the spin-orbit-coupling is neglected. Accordingly, the energies for some lower singlet states of a planar nickel(II) complex are expressed as

$$^1A_{1g}: E_0 = F_0 + 4F_2 + 36F_4$$
$$^1B_{1g}: E_1 = \delta_1 + F_0 + 21F_4$$
$$^1A_{2g}: E_2 = \delta_2 + F_0 + 4F_2 + F_4$$
$$^1E_g: E_3 = \delta_3 + F_0 + F_2 + 16F_4$$

Following Ballhausen and Liehr,[15] we assume $F_2 = 10F_4 = 1$ kK,

13) G. K. Bryce and F. R. N. Gurd, *J. Boil. Chem.*, **241**, 1439 (1969).

14) K. M. Wellman, S. Bogdansky, C. R. Hare and M. Mathiesm, *Inorg. Chem.*, **8**, 1025 (1969).

$$\Delta E_1 = \delta_1 - 4F_2 - 15F_4 = \delta_1 - 5.5\ \text{kK}$$
$$\Delta E_2 = E_2 - E_0 = \delta_2 - 35F_4 = \delta_2 - 3.5\ \text{kK}$$
$$\Delta E_3 = E_3 - E_0 = \delta_3 - 3F_2 - 20F_4 = \delta_3 - 5.0\ \text{kK}$$

and

$$\Delta E_{12} = E_2 - E_1 = \delta_2 - \delta_1 + 4F_2 - 20F_4 = \delta_2 - \delta_1 + 2.0\ \text{kK}$$
$$\Delta E_{23} = E_3 - E_2 = \delta_3 - \delta_2 + 3F_2 + 15F_4 = \delta_3 - \delta_2 - 0.5\ \text{kK}$$

From the above result, the effect due to the interelectronic repulsion is comparable to the observed band separations 2.5—3.0 kK, but is not large enough to change the order of energy levels $E_1 < E_2 < E_3$. Therefore, the same pattern can be expected with the same ligands. However, it is to be noted that the resemblance is close, at least in the examples cited above, and is considered to be more than that expected from the above discussion. An explanation for this tendency is still in question at present.[16]

The reason for the planar Ni(II) and Cu(II) complexes giving similar CD spectra for bands whose origins are the transitions between the same combination of *d*-orbitals is given as follows. According to Condon,[17] the rotational strength R_{ab} associated with the electronic transition from the state, a, to the state, b, is determined by

$$R_{ab} = \text{Im}\langle(a)|\mathbf{P}|(b)\rangle\langle(b)|\mathbf{M}|(a)\rangle$$

where Im denotes the imaginary part of the scalar product of these moments; (a) and (b) stand for the wave functions of the ground and the excited states, and **P** and **M** are the electric and magnetic dipole moment-oparators. In the case of a multi-electron system, (a) and (b) are to be expressed by the Slater determinants. However, since **P** and **M** are one-electron operators, $\langle(a)|\mathbf{P}|(b)\rangle$ and $\langle(b)|\mathbf{M}|(a)\rangle$ are reduced to the simple formulas, $\langle a'|\mathbf{P}|b'\rangle$ and $\langle b'|\mathbf{M}|a'\rangle$, where a' and b' represent the wave functions of simple orbitals between which an electron transfers. Thus, it has been verified that rotational strengths of Ni(II) and Cu(II) complexes of the same ligand may be expressed by the same formula for the transitions between the same combination of *d*-orbitals.

The authors would like to express their thanks to Mr. Masaaki Narimatsu for help in the experiment.

15) C. J. Ballhausen and A. D. Liehr, *J. Amer. Chem. Soc.*, **81**, 538 (1958).

16) The energies due to the interaction with upper $^1A'_{1g}$ and $^1B'_{1g}$ states were found to be less than 0.2 kK which is negligible in the present discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3819—3823 (1970)

Stereoselectivity in Mixed Tris-Type Cobalt(III) Complexes with Glycine and L-Aspartic Acid*1

Kiyoshi KAWASAKI, Junko YOSHII and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received July 9, 1970)

The reaction of the carbonatobis(glycinato)cobaltate(III) with L-aspartate in the presence of active charcoal led to the stereoselective formation of tris(glycinato-L-aspartato) complexes. By means of ion-exchange chromatography and fractional precipitation, four optically-active complexes, *mer*-Λ- and *fac*-Λ-$[Co(gly)_{3-n}(L\text{-}asp)_n]^{n-}$ ($n=1,2$), have been isolated, and they have been characterized by means of their absorption and circular dichroism spectra. Furthermore, the percent compositions of the geometrical isomers for the complexes ($n=1,2,3$) in the reaction mixture and also of Λ- (or Δ-) isomers for each geometrical isomer have been estimated using the spectral data. A marked stereoselectivity (>90%) has been found in the *fac*-Δ-isomers, while an appreciable selectivity (*ca.* 70%) has been found for the *mer* isomers. These stereoselectivities have been explained in terms of an enhanced stability through hydrogen bonding between the β-carboxylate group in the coodinated L-aspartate and the amino group in the adjacent ligand.

When optically-active ligands are combined with metal ions to make a source of dissymmetry at the central metal, the resulting diastereoisomers are usually unequal in amount. This stereoselectivity has been known for such asymmetric ligands as 1,2-diamines and amino acids. In the case of diamine

*1 Presented at the 19th Symposium on Coordination Chemistry, Sendai, September, 1969.

complexes, the stereoselectivity has been attributed to the interactions of the puckered chelate rings with each other.[1] On the other hand, in the case of aminoacidato complexes two factors have been considered in connection with the selectivity. One factor comes from the presence of bulky substituents in the ligands; the absence of the *mer*-*Λ*-isomer of the tris(L-prolinato)cobalt(III) complex can thus be explained.[2] The other factor is due to the interaction of the polar substituents in the aminoacidato ligand with the other polar site of the adjacent ligand. The stereoselective formation of *Λ*-(+)-$[Co(en)_2(L\text{-glut})]^+$ relative to the *Δ*-isomer, for example, has thus been interpreted.[3],*2 Indeed, an X-ray analysis of the *Λ*-isomer has shown the existence of hydrogen bonding between the *γ*-carboxylate group of the L-glutamate and the amino group of the ethylenediamine chelate.[3,4]

Previously, we reported the preparation of tris-type cobalt(III) complexes with different kinds of amino acids (*i. e.*, glycine, L- or D-alanine, and L-valine).[5] In the present work, the preparation of tris-type mixed complexes with glycinato and L-aspartato ligands was attempted in order to investigate the stereoselective effect of the coordinated L-aspartate ion on the complex formation.

In the course of this study, we succeeded in the spontaneous resolution of the potassium carbonatobis(glycinato)cobaltate(III) which had been used in the above preparation as the starting material.

Experimental

Preparations. Crystals (6.4 g, 0.02 mol) of potassium carbonatobis(glycinato)cobaltate(III) prepared by a previously-described method[5] were dissolved in 100 m*l* of water, and the 5.4 g of L-aspartic acid (0.04 mol) and 2.4 g of potassium hydroxide (0.04 mol) were added to the solution. After adding 2 g of active charcoal, the solution was stirred at 40—50°C for an hour; the color of the solution was thus changed from violet to red-violet. After the removal of the active charcoal and a small amount of a precipitated material by filtration, the solution was adjusted to a pH of about 6 with 6N acetic acid. A portion of this solution was added to an ion-exchange column (diameter, 3.5 cm; height of resin, 30 cm) containing 100—200 mesh Dowex 1×8 resin in chloride form. When the column was swept with water, the *mer* and *fac* isomers of the tris(glycinato) complex were eluted. Then, the column was treated with a 0.1M aqueous solution of calcium chloride at the rate of about 0.3 m*l*/min. After prolonged elution, six bands were separated; they were alternately violet and red in color. Each band was collected in fractions, and the absorption and circular dichroism spectra were measured with each fraction. Strong Cotton-effect peaks were observed, with a negative sign for the red bands and a positive one for the violet bands, in the first absorption-band region. This suggests that the stereoselective formation of either *Λ* or *Δ* isomers has occurred in these complexes. The fractions are conveniently labeled as E-1, E-2, ·····, up to E-6, according to the order of elution. The chromatographic separation was repeated a number of times in order to store up the same fractions. The stored solutions were concentrated to small volumes under reduced pressure. When ethanol was added to the concentrate, the calcium salt of the desired complex was precipitated as a crude material. This was dissolved in a little water, and then the solution was acidified with 6N hydrochloric acid. After a while, the complex precipitated as the hydrogen compound in place of the calcium salt. Recrystallization was performed by dissolving the compound in slightly alkaline water and by then acidifying it with diluted hydrochloric acid. This recrystallization procedure was repeated several times until the resulting complex showed no change in the intensity of its CD peak.

Formation Ratios. Since only one diastereomer could be isolated for each geometrical isomer, we conveniently assumed that the *Λ* and *Δ* isomers of a complex have the same ε and $\Delta\varepsilon$ values, but with the opposite sign, in their first absorption-band region. On the basis of this assumption, the relative concentrations of the six fractions and the formation ratios of the *Λ* and *Δ* isomers were determined spectrophotometrically using the ε and $\Delta\varepsilon$ values of the crystallized complexes. In order to ascertain the effect of the reaction time upon the formation ratios, we employed 5-hour and 10-hour reactions in addition to the usual one-hour reaction.

Spontaneous Resolution. When a supersaturated aqueous solution of potassium carbonatobis(glycinato)-cobaltate(III) was left to stand at room temperature, big crystals (*ca.* 4 mm^2) were separated out. Observing these crystals under a microscope, we were able to select two forms of the crystals which could not be superimposed. The aqueous solution of each piece of these forms gave an $\Delta\varepsilon$ value of the same magnitude, but with the opposite sign (*i. e.*, $\Delta\varepsilon_{max}=\pm 3.2$ in the first band region).

Measurements. The absorption spectra were measured with a Hitachi Perkin-Elmer Model 139 UV-VIS spectrophotometer, while the circular dichroism spectra were recorded on a JASCO Model ORD/UV-5 spectrophotometer with a CD attachment, using 60% perchloric acid as the solvent. The proton magnetic resonance spectra in deuterium oxide were recorded on a JEOL Model C-60H spectrometer, using tetramethylsilane as the internal reference.

Results and Discussion

Preparation. In a previous paper,[5] we reported that the reaction of the carbonatobis(glycinato) complex with L-valine gave the bis(glycinato)L-

valinato complex predominantly. In this work, however, the reaction of the bis(glycinato) complex with L-aspartate gave at the same time a series of complexes represented by the general formula of $[Co(gly)_{3-n}(L\text{-}asp)_n]^{n-}$ (n=0,1,2,3). Such a reaction may be the result of the presence of active charcoal in the system.

Characterization of the Complexes. The results of the elemental analyses of the isolated complexes are summarized in Table 1. From the results and the elution order, it is considered that the complexes obtained from the E-1 and E-2 bands are geometrical isomers of bis(glycinato)L-aspartatocobaltate(III), and that the complexes from E-3 and E-4 are those of glycinatobis(L-aspartato)cobaltate(III). Figure 1 shows the absorption spectra of the bis(glycinato) complex from E-1 and E-2. Since the bis(aspartato) complexes have spectra similar to those of the bis(glycinato) complexes, their spectra are omitted. The absorption spectrum of the violet complex obtained from E-1 (and E-3) showed a splitting of the first absorption band, whereas the red complex from E-2 (and E-4) showed no splitting. From these features in the spectra, the geometrical structures of the violet and red complexes could be identified as the *mer* and *fac* forms respectively.[6] The numerical data on the spectra are given in Table 1.

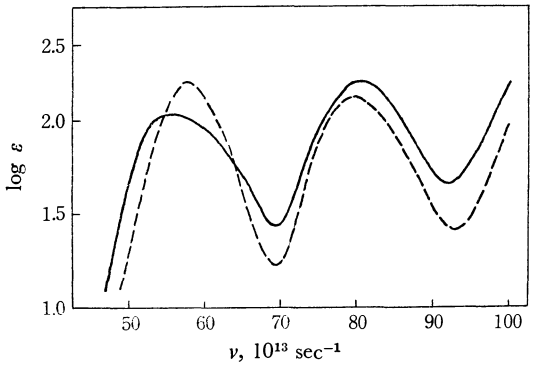

Fig. 1. Absorption spectra of [Co(gly)$_2$ L-aspH]·H_2O.
——: *mer*(from E-1) ------: *fac*(from E-2)

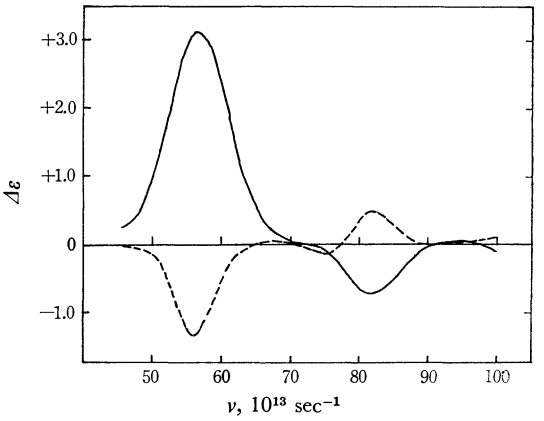

Fig. 2. CD spectra of [Co(gly)$_2$ L-aspH]·H_2O.
——: *mer* ------: *fac*

The CD spectra for the bis(glycinato) complexes are shown in Fig. 2. The spectra are similar in shape to those of the known tris(L-aminoacidato) complexes.[7] It is well known that the absolute configuration for a *fac* isomer of the tris(aminoacidato) complex can be related to that for the tris(ethylenediamine) cobalt(III) complex,[8] whereas the configuration of the corresponding *mer* isomer can be related to that for *mer*-tris(L-alaninato)-cobalt(III).[9] On this basis, the present *fac* isomer, exhibiting a dominant negative peak in the first-absorption-band region, should be identified as the *Δ* isomer, and the *mer* isomer with a dominant positive peak, as the *Λ* isomer.

For the tris-type complex containing two kinds

of aminoacidato ligands, four geometrical isomers are possible. One of them is the *fac* form, while the other three isomers belong to the *mer* form. It was experimentally found that the eluted solution of the E-3 band contains at least two geometrical-*mer* isomers; when the dominant CD peak was measured for successively-collected fractions of the band, the intensity and sign changed as follows; $+76 \rightarrow +54 \rightarrow +24 \rightarrow +4 \rightarrow -8 \rightarrow +2 \rightarrow +20$ (where the values are given by an arbitrary scale).

For all the complexes isolated, powdered crystals were obtained. On crystallization, the *mer* complexes precipitated as voluminous materials. The Λ isomers of the *mer* form were less soluble than the corresponding Δ isomers, which were not isolated because of their high solubility. On the the other hand, *fac*-Δ complexes precipitated readily, and they were less soluble in the bis(glycinato) complex, and more soluble in the bis(aspartato) complex, than the corresponding Λ isomers, which were not isolated because of their minute quantities.

Stereoselectivity. From the experiments on the formation ratios, we estimated the percent compositions of the *mer* and *fac* isomers and also the percent compositions of the Λ (or Δ) isomer predominantly formed for each geometrical isomer. The results are given in Tables 2 and 3. Since it is assumed that the ε and $|\Delta\varepsilon|$ values for a *mer* or a *fac* complex are the same with both the Λ and Δ isomers, — since, that is, the vicinal effects of the L-aspartate ion are disregarded, the results obtained are not very exact, but they do seem to be useful for estimating the stereoselectivity. For the tris(L-aspartato) complexes, the results were obtained from the data previously reported.[10]

The stereoselective formation of one diastereoisomer was markedly found in the *fac*-Δ isomers of the bis(glycianato), bis(L-aspartato), and tris-(L-aspartato) complexes. That is, the percent compositions of the isomers exceeded 90% in most cases. On the other hand, the selective formation for the *mer* isomers was appreciably found in their Λ isomers; the percent compositions of the Λ isomers ranged from 61% to 77% for a 1-hour reaction.

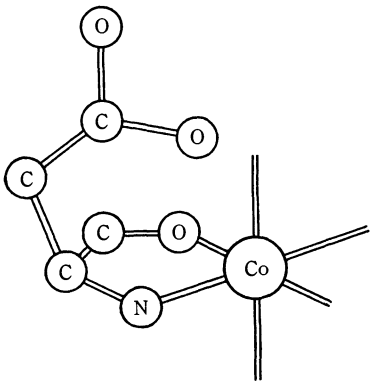

Fig. 3. The molecular model of coordinated L-aspartate.

When the molecular model for the chelation of a L-aspartate ion as a bidentate ligand is constructed, the β-carboxylate group of the aspartato ligand can be directed to the adjacent site of coordination, as is shown in Fig. 3. If the site is occupied by an amino group of the another aminoacidate ion, the β-carboxylate group is likely to interact with the amino group through hydrogen bonding in a manner similar to that found in the Λ(+)-L-glutamatobis(ethylenediamine)cobalt (III) complex.[3,4] If the site is occupied with a carboxylate group of the second ligand, both of the carboxylate groups will repel each other. The *fac*-Δ isomers have the possibility of such hydrogen bonding equal to the number of the chelated aspartato ligand. On the other hand, the *fac*-Λ isomers produce only the repulsion structures. Thus, the highly stereoselective formation of the *fac*-Δ isomers can be attributed to the possibility of such a hydrogen bonding. In the *mer*-bis(aspartato) complexes, the hydrogen bonding is possible for the both the Δ and Λ isomers, but the Λ isomer is favoured in the number of the possible hydrogen bonding. In this way, the preferential formation of the *mer*-Λ complex can be explained.

As may be seen in Table 2, the reaction time has an effect on the amounts of the products; one hour's reaction gives about 32% of the bis(glycinato) complex and about 16% of the tris(aspartato) complex in addition to 52% of the main product, while ten hour's reaction gives about 23% of the bis-(glycinato) and 25% of the tris(aspartato) complex. Such an increase in the tris(aspartato) complex

10) M. Shibata, H. Nishikawa and K. Hosaka, This Bulletin, **40**, 236 (1967).

with the reaction time can also be explained as the stereoselective effect of the L-aspartato ligand through the number of the possible hydrogen bonding.

However, in the bis- or tris(aspartato) complex the reason why the *fac* form is formed in an amount greater than that of the *mer* form cannot be explained by the possible hydrogen bonding, for its number is the same for both forms and, conversely, the *mer* form has more possible isomers than the *fac* form. The reason is suggested by the fact that, in the bis(glycinato) complex, the *mer* form is present in a greater amount than the *fac* form. As is well known, the *mer*-*Λ*-tris(L-prolinato)cobalt(III) isomer cannot exist because of the collision of the substituents with a cyclic structure.[2] Such a collision has also been observed in the *mer*-*Λ*-tris(L-leucinato) complex by means of the PMR spectrum.[2] For similar reasons, the complexes containing more than two aspartate ions appear to be more stable in the *fac*-*Λ* form, where the mutual repulsion in *β*-carboxyl groups is almost negligible. In the *mer* form, this repulsion is fairly large, especially in the *Λ* isomers. In our laboratory, concurrently with this study, the mixed complexes with L-aspartic acid and alanine were investigated. In these complexes, the *fac*/*mer* ratios were larger than in the present case, because of the addition of a methyl group; it must be noted that even in the complex containing one aspartate ion the *fac* form is more stable than the *mer* form.

Spontaneous Resolution. As far as we know, three examples have been reported of the spontaneous resolution of cobalt(III) complexes.[11] They are $K_3[Co(C_2O_4)_3]\cdot 3H_2O$, $[CoC_2O_4(en)_2]Cl\cdot 4H_2O$, and K[Co(trimethylenediaminetetraacetato)]$\cdot 2H_2O$. We are now able to show another example with $K[CoCO_3(gly)_2]\cdot 2H_2O$.*3 For this complex, three geometrical isomers, namely, *trans*(N), C_2-*cis*(N), and C_1-*cis*(N), are possible. However, the circular dichroism spectrum of the complex concerned (Fig. 4) was similar, in shape, to that of the known C_1-*cis*(N)$[CoC_2O_4(gly)_2]^-$;[12] moreover, the PMR spectrum of the present complex showed a pattern similar to that of the C_1-*cis*(N) oxalato complex, namely, two resonance lines due to the CH_2 group at 3.35, 3.51 ppm. Therefore, we can identify the present complex as the C_1-*cis*(N) isomer.[13]

(Received November 17, 1969)

Potassium iron carbonylate, $KHFe(CO)_4$, reacted with ethyl acrylate, crotonate, 3-butenoate, styrene, and α-olefins at 40—70°C under an atmosphere of carbon monoxide. Methylmalonate was selectively obtained from the acrylate by treatment of the reaction mixture with an alcoholic iodine and hydrogen chloride solutions. Dipotassium iron carbonylate, $K_2Fe(CO)_4$, reacted with β-bromopropionate to give mainly methylmalonate. Isomerization of β-ethoxycarbonylpropionyliron carbonylate to the α-isomer occurred readily in contrast to isomerization of acylcobalt carbonyl. Both crotonate and 3-butenoate gave ethylmalonate as a major product and methylsuccinate and glutarate as minor ones. The results suggest that α-ethoxycarbonylbutyliron carbonylate is more predominant than the corresponding β- and γ-isomers in equilibrium state. This is in striking contrast to the case of acylcobalt carbonyl. Styrene yielded two isomeric aldehydes, α- and β-phenylpropionaldehydes. Ethyl caproate and enanthate were obtained from 1-pentene and 1-hexene, respectively in poor yield.

Some of the present authors demonstrated that cobalt hydrocarbonyl reacted with ethyl acrylate to give, selectively, α-ethoxycarbonylpropionylcobalt carbonyl which readily isomerized to β-isomer.[1] Styrene also reacted similarly with cobalt hydrocarbonyl. In the present work, carbonylation of olefins with iron carbonylate and the isomerization of the intermediate alkyl- or acyliron complexes were investigated in detail. The effect of the functional groups on the isomerization was examined in order to estimate the reaction mechanism. The difference of reactivity between the iron and cobalt complexes was clarified.

Experimental

Preparation of Potassium Iron Carbonylate, $KHFe(CO)_4$ and $K_2Fe(CO)_4$. An alcoholic solution of potassium iron carbonylate was prepared by Krumholz's method.[2] A 200 m*l* three-necked flask, fitted with a 50 m*l* dropping funnel, a gas inlet and a rubber stopple, was connected with a 500 m*l* gas buret and the atmosphere was then replaced with dry carbon monoxide.

A 1N alcoholic potassium hydroxide solution (33 m*l* or 44 m*l*) and iron pentacarbonyl (1.5 m*l*, 11 mmol) were syringed into the flask and then stirred for a few hours at room temperature to give a brown solution of potassium iron carbonylate.

Materials. Ethyl acrylate, ethyl crotonate, styrene, 1-pentene, 1-hexene, ethyl α- and β-bromopropionates, β-phenylpropionate, diethyl methylmalonate, diethyl succinate, ethyl caproate, and ethyl enanthate were commercial reagents. Iron pentacarbonyl was obtained from the Strem Chemicals Inc., bp 102°C. Diethyl ethylmalonate, diethyl methylsuccinate, and diethyl glutarate were prepared by the usual esterification of the corresponding carboxylic acids. Ethyl 3-butenoate was obtained from allyl cyanide[3] (bp 118—119°C, lit, 119°C). α-Phenylpropionaldehyde was obtained from acetophenone.[4] Starting materials were distilled before use and purity was checked by gas chromatography.

Reaction Procedures. To a solution of potassium iron carbonylate prepared as described above, olefin (33 mmol) or alkyl halide (22 mmol) was added with a syringe. The mixture was then stirred vigorously at 25—65°C under an atmosphere of carbon monoxide. After a certain reaction time, a 7N alcoholic hydrogen chloride solution (5—7 m*l*) and 50 m*l* of a saturated benzene solution of iodine were added dropwise into the reacting mixtures at room temperature; stirring was continued until gas evolution ceased. Sodium thiosulfate (5 g) was then applied to remove excess

iodine. After 50 ml of water was added to the solution, the reaction products were extracted three times with 50 ml of benzene and dried over anhydrous magnesium sulfate overnight. The solution was concentrated to about 5% weight by distillation and then subjected to analysis.

Analytical Procedures. The reaction products were gas-chromatographed with a Shimadzu Model GC-3AH on a column, 3 m long, 3 mm in diameter, filled with Apiezon L or Carbowax on cerite at 150—180°C and at the carrier-gas (hydrogen) flow rate of 70 ml/min. Isomeric esters and aldehydes were confirmed and determined by direct comparison with authentic samples. The infrared spectra were measured with a Nippon Bunko Model DS-301 spectrophotometer on NaCl cells.

Results and Discussion

Reaction of $KHFe(CO)_4$ with Ethyl Acrylate. Results are summarized in Table 1. As shown

Table 1. Reaction of ethyl acrylate with potassium iron carbonylate, $KHFe(CO)_4$

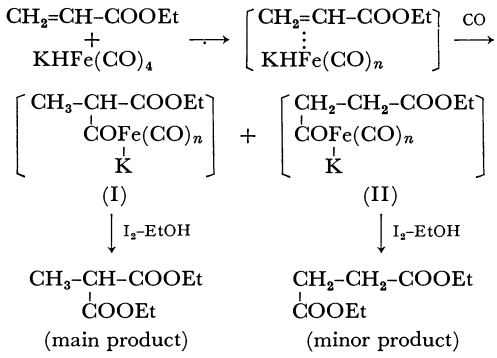
a) $KHFe(CO)_4$: 11 mmol (EtOH solution), Ethyl acrylate: 33 mmol
b) mol/mol $KHFe(CO)_4$
c) *iso*-Ester: Diethyl methylmalonate, *n*-Ester: Diethyl succinate
d) Methyl acrylate was used instead of ethyl acrylate.

in Scheme 1, ethyl acrylate reacted with potassium iron tetracarbonylate to give two isomeric diesters upon treatment with an alcoholic iodine and hydrogen chloride solutions. These diesters can be derived from the corresponding acyliron complexes, *i. e.*, α- and β-ethoxycarbonylpropionyliron carbonylates (I) and (II), as was proved in the case of acylcobalt carbonyls.[5] Diethyl methylmalonate was afforded as the main product and diethyl succinate as a minor one. Carbonylation of ethyl acrylate took place at temperatures above 25°C and an almost quantitative yield of esters was obtained for 1—1.5 hr at 60°C (Expts. 7 and 8). The consumption of potassium iron carbonylate was estimated by means of carbon monoxide absorption as in the case of cobalt hydrocarbonyl.[1] The absorption volume, however, was not always proportional to the yield of esters. The intermediate acyliron complexes seemed to decompose with a prolonged reaction time. The yield of the derived esters decreased in these cases (Expts. 3—7).



Scheme 1

At 25—40°C methylmalonate only was obtained, while at higher temperatures a small amount of succinate was also obtained (Expts. 3—9). The distribution of the esters was scarcely affected by reaction time and temperature. This implies that the potassium iron carbonylate gives selectively α-ethoxycarbonylpropionyliron carbonyl (I) in the same way as cobalt hydrocarbonyl,[1] but the branched acyliron complex (I) is not converted to the β-isomer (II) so readily as the corresponding acylcobalt complex. From these results, we see that the isomerization of the acyliron complexes is apparently different from that of two acylcobalt complexes between which the equilibrium lies well toward the side of the β-isomer. The following experiments were carried out in order to examine the equilibrium of isomerization.

Reaction of Dipotassium Iron Carbonylate, $K_2Fe(CO)_4$, with Ethyl α- and β-Bromopropionates. Results are shown in Table 2 and Scheme 2. The reaction of α- or β-bromopropionate with dipotassium iron carbonylate was carried out at 30—50°C under an atmosphere of carbon monoxide. The usual treatment resulted in the formation of two isomeric esters, diethyl methylmalonate and diethyl succinate in both reactions.

It is interesting that methylmalonate was predominantly obtained from the reaction of ethyl β-bromopropionate, while the same product was given from ethyl α-bromopropionate at 30—50°C (Expts. 10—17). The percentage of isomerization of the intermediate complexes (I and II) was estimated by the distribution of the derived esters. In the case of α-bromopropionate, the percentage of isomerization to the β-complex (II) was only

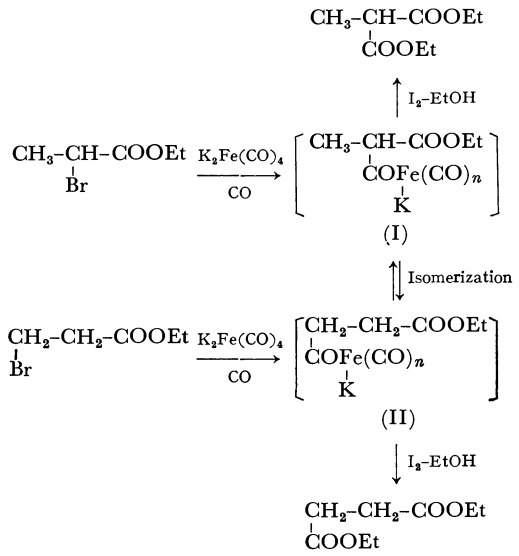
c) Diethyl succinate and diethyl methylmalonate, mol/mol $K_2Fe(CO)_4$
d) In the case of α-bromopropionate: Diethyl succinate/Total Esters × 100
In the case of β-bromopropionate: Diethyl methylmalonate/Total Esters × 100
e) The reaction was carried out in two stages, first at 30°C for 15 hr and then at 50°C for 2 hr.



Scheme 2

2—6%, whereas in the case of β-bromopropionate the percentage of isomerization to the α-complex (I) amounted to 95% (Expts. 13—17). Accordingly, isomerization of the straight-chained complex (II) to the branched complex (I), occurs more readily than the reverse isomerization and the equilibrium between these complexes lies far to the side of the branched isomer. Ethyl acrylate was not afforded under the conditions employed and therefore dehydrobromination of α- and β-bromopropionates would not occur in the reaction system.

Reaction of Ethyl Crotonate and Ethyl 3-Butenoate with Potassium Iron Carbonylate, $KHFe(CO)_4$. Results are shown in Table 3. The reactions of ethyl crotonate and its homolog were carried out to confirm a similar isomerization. Ethyl crotonate was carbonylated with potassium iron carbonylate to afford mainly diethyl ethylmalonate (A) and other isomers, diethyl methylsuccinate (B) and diethyl glutarate (C) as by-products (Expts. 18—25). Ethyl 3-butenoate gave the same products as in the case of ethyl crotonate and the distribution of products was similar in both reactions (Expts. 26 and 27). As shown in Scheme 3, isomers (A, B and C) may be derived from the corresponding α-, β- and γ-ethoxycarbonylacyliron carbonylate (III, IV and V), respectively.

The distribution of isomers shown in Table 3 implies that the intermediates, iron complexes (III, IV and V), were isomerized to each other at 60—70°C, and that the equilibrium was favorable to α-isomer (III). The results are consistent with those of the reaction of the ethyl acrylate or the alkyl halides with respect to isomer equilibrium.

Reaction of Potassium Iron Carbonylate with Styrene. Results are summarized in Table 4 and Scheme 4. Styrene reacted with potassium iron carbonylate to give two isomeric aldehydes, α- and β-phenylpropionaldehydes, instead of expected esters, α- and β-phenylpropionates. Tollen's reagent test for the products was positive. The infrared spectra had bands at 1725, 2708, 2800 cm^{-1}, characteristic of aldehydes. They were identified with those of authentic samples. The carbonylation of styrene occurred at 40—65°C, and the yield of aldehydes was not more than 50% in all runs. The poor yield seems to be partly due to instability of the intermediate complexes. These aldehydes may be readily formed with reduction of the α- and β-phenylpropionyliron carbonyls (VI and VII) as shown in Scheme 4. The mechanism is supported by the fact that *n*-propyl iodide reacted with the iron carbonylate to give *n*-butyraldehyde in good

yield.[6]

The distribution of β-phenylpropionaldehyde was already attained to 11—13% in the initial stage of the reaction, while in the case of ethyl acrylate or ethyl crotonate, the corresponding β-isomer was not observed initially. The discrepancy may be explained as follows. Potassium iron carbonylate attacked both the α- and β-carbons of styrene, whereas it carbonylated selectively the α-carbon of ethyl acrylate in the early stage.

In general, the distribution of acylmetal carbonyl isomers was affected by the following two factors: (1) the direction of addition of metal carbonylate to a carbon-carbon double bond and (2) the isomerization of intermediate alkyl- or acylmetal carbonyls.[1] The latter factor affected particularly the distribution of products in the case of ethyl acrylate and its homologs.

The reactions of dipotassium iron carbonylate with α- and β-bromoethylbenzenes were carried

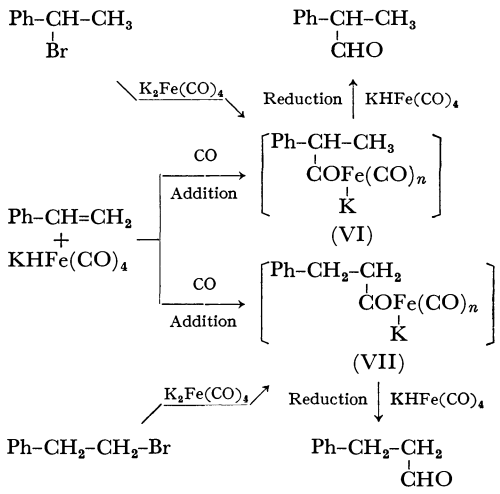
out to examine the isomerization of α- and β-phenylpropionyliron complexes (VI and VII). The results are summarized in Table 5. Such an isomerization as from VI to VII or from VII to VI was scarcely observed. Thus it seems that the distribution of aldehydes corresponds to the direction of the addition of iron carbonylate to styrene. α-Phenylpropionaldehyde should be derived from α-phenylpropionyliron carbonylate alone as well as in the case of β-phenylpropionaldehyde (Scheme 4).

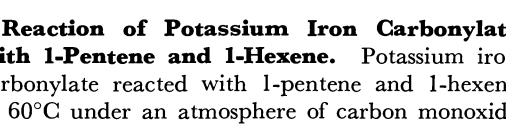


Scheme 4

Reaction of Potassium Iron Carbonylate with 1-Pentene and 1-Hexene. Potassium iron carbonylate reacted with 1-pentene and 1-hexene at 60°C under an atmosphere of carbon monoxide as shown in Table 6. Ethyl enanthate was obtained as a carbonylation product of 1-hexene. The yield of ester was invariably low under various conditions. Most of 1-hexene was readily reduced into *n*-hexane in the reaction system. Similarly 1-pentene was carbonylated with the iron carbonylate to give ethyl caproate in a yield less than 1%, whereas in the case of cobalt hydrocarbonyl, ethly caproate and ethyl α-methylvalerate were obtained in good yield under milder conditions.[7]

At room temperature carbonylation of α-olefin with potassium iron carbonylate could not occur. At higher temperatures, the α-olefin may be readily reduced into *n*-paraffin instead of carbonylation.

Discussion of Acyliron Carbonyls. The reaction of ethyl acrylate was followed by infrared spectra in order to prove the participation of acyliron carbonyls as reaction intermediates. After ethyl acrylate had been carbonylated and the complex formed neutralized with dilute alcoholic hydrogen chloride solution, excess acrylate and solvent were evaporated to dryness at 0°C in a high vacuum. The iron complex was extracted with cold benzene under carbon monoxide atmosphere to give a dark red solution and subjected to analysis immediately. The infrared spectrum in benzene contained coordinated carbonyl bands at 2118(w), 2005(vs) and 1967(s) cm^{-1}, an ester carbonyl band at 1742(s) cm^{-1}, the acyliron carbonyl bands at 1678(m) and 1710(m) cm^{-1}. The sample was then treated with an alcoholic iodine solution. The vapor phase chromatogram showed the presence of 97% of diethyl methylmalonate and 3% of diethyl succinate. Ethyl acrylate and its polymer were not detected by infrared spectra and chromatography. Thus the acyliron carbonyls (I′, II′) are suggested to be intermediate complexes in this reaction.



Triphenylphosphine complexes of acyliron carbonylates were scarcely obtained in the usual way on account of the cleavage to iron carbonyl triphenylphosphine, $Fe(CO)_4PPh_3$. Our suggestion of acyl-

iron complexes is strongly supported. Heck and Breslow[8] showed the infrared spectrum of the mixture of α- and β-methoxycarbonylpropionylcobalt tricarbonyl triphenylphosphines, which contained carbonyl bands at 1740(vs) and 1670(m) cm^{-1}. We have elucidated the fact that the α-methoxycarbonylpropionylcobalt complex had bands at 1743(m) and 1706(s) cm^{-1}, while the β-isomer had bands at 1745(s) and 1675(s) cm^{-1} assigned to an ester and acylcobalt carbonyls, respectively. On the other hand, maleyliron tetracarbonyl has a doublet in the 1665 cm^{-1} region due to the absorption of the ketonic groups of the organic ligands.[9] The spectrum of ethoxymalonyliron dicarbonyl(nitrosyl)triphenylphosphine contains acyl and ester bands at 1689 and 1754 cm^{-1}, which are similar to the bands observed in the case of acyliron complex (I').[10]

The results are summarized as follows. Potassium iron carbonylate reacted with unsaturated carboxylic esters and styrene to give carbonylated products under an atmosphere of carbon monoxide at 40—65°C. On the other hand, α-olefin was scarcely carbonylated under these conditions. Cobalt hydrocarbonyl reacted readily with various acrylates and styrene to give the branched-chain complexes mainly at 0°C for several hours.[1]

β-Ethoxycarbonylpropionyliron carbonyl was easily isomerized to the α-isomer and the reverse isomerization hardly occured, whereas α-ethoxycarbonylpropionylcobalt carbonyl completely isomerized to the β-isomer in a few hours at 25°C.[1] It is concluded that the isomeric equilibrium of acyliron complexes lies well towards the side of the α-isomer, in contrast to that of acylcobalt complexes. The isomerization of acyliron complexes was greatly affected by the functional groups in the olefins and alkyl halides. For example, ethoxycarbonylpropionyliron carbonyl was easily isomerized, while phenylpropionyliron carbonyl was scarcely isomerized. The electronic effect of the ethoxycarbonyl group[11] as well as the isomeric equilibrium of acyliron complexes promotes the isomerization of the iron complexes.

Absolute Structure of Acacic Acid*[1]

I. P. VARSHNEY*[2] and K. M. SHAMSUDDIN*[3]

Department of Chemistry, Aligarh Muslim University, Aligarh, India

(Received March 14, 1969)

Acacic acid, a pentacyclic triterpenic acid, is present as a saponin in various members of the family Leguminosae, but the highest yield is obtained from the pods of *Acacia concinna* DC. On the basis of degradative studies, transformations, IR, UV, NMR, mass spectrography, and ORD, and CD studies its absolute stereochemistry and structure have been fixed as 3β, 16β, 21β-trihydroxy-18β-olean-12-en-28-oic acid and that in the acetate the rings E and D are in *boat* and *quasi-boat* forms, respectively, with D/E rings *cis* fused.

Acacia concinna DC. commonly known as 'Shikakai' in Hindi is a member of the family Leguminosae, sub-family Mimosacaea. It is a common bush. It grows in tropical jungles, and especially in the southern part of India. The pods are extensively used as a detergent and are preferred to soap by people taking an oil bath.[1] In India the washing of women's hair with the powder of the pods of Acacia concinna is very prevalent as it is said to increase the length of the hair. It is a rich source of saponin which on hydrolysis yields an acid sapogenin (acacic acid).

No work seems to have been done on the saponin and sapogenin contents of this plant except for some works on the standardization of the conditions for commercial isolation of crude saponin.[2] Recently in these laboratories the seeds of this plant were studied and found to contain a new triterpenic acid, acacic acid,[3] which has been isolated from the seeds and bark of Acacia intsia.[3-5] Acacic acid has also been isolated from the seeds of Albizzia spitulata[6] and Albizzia odoratissima.[7] On preliminary studies the pods of Acacia concinna have been found to contain the saponin of acacic acid. Acacic acid was found to be a trihydroxymonocarboxylic acid belonging either to the α-amyrin group or to the tetracyclic triterpene group.[5,8] Later Varshney[9,10] on biogenetic grounds suggested 3,16, 21-trihydroxyolean-12-en-28-oic acid (I) structure for this acid.

Well powdered pods of *Acacia concinna* DC. obtained from Kerala (South India) were extracted exhaustively with ethanol. Removal of the solvent yielded a dark brown coloured semisolid residue, which was treated in the usual manner[10] to yield a fairly pure sample of the saponin. The saponin was then dissolved in a large amount of water and hydrolyzed with sulphuric acid (10%). All attempts to crystallize the saponin failed, and it was subjected to further purification by potassium salt formation. On acidification with hydrochloric acid the alkaline solution of the potassium salt precipitated the acid genin. It was then acetylated with pyridine and acetic anhydride in the cold. The acetate (II) on cyrstallization from methanol gave fine colourless needles mp 235—36°C. It showed a positive tetranitromethane test for a carbon-carbon double bond. It was found to be identical with acacic acid diacetate lactone by mixed m.p. and superimposable infrared spectra.[3,5] The infrared spectrum of diacetate lactone (Fig. 1) showed bands of acetate and γ-lactone at 8.05 μ and 5.6 μ. The

mass spectrum of the compound showed its molecular weight as 554 corresponding to the formula $C_{34}H_{50}O_6$. The general fragmentation pattern was that associated with triterpenes.

The acetate on deacetylation gave colourless needles of the free genin (I) mp 278—282°C. The genin on methylation with diazomethane gave a methyl ester (III) as colourless needles mp 224—225°C. Acetylation of the methyl ester (III) gave diacetate methyl ester (VI) as colourless needles mp 203—205°C. All these compounds gave yellow colour with tetranitromethane. All these evidences and analytical results showed that acacic acid is a trihydroxy-monocarboxylic acid with molecular formula $C_{30}H_{48}O_5$ corresponding to pentacyclic triterpenes.

The relationship of acacic acid to β-amyrin group was fixed by the facile formation of a saturated bromolactone*4(IV) mp 259—262°C, by the action of bromine on acacic acid in acetic acid. Formation of a bromolactone[11] not only indicated an olean type skeleton, but also fixed the position of the carboxyl group at C-28 and the double bond between carbon 12—13.

The infrared spectrum of acacic acid methyl ester in pyridine (Fig. 2), taken under prescribed conditions,[12] through the courtesy of Prof. R. Tschesche, showed only two absorptions at 1380 and 1355 cm^{-1} in region 'A' and three absorptions at 1330, 1300 and 1267 cm^{-1} in region 'B' which clearly indicated its relation to the β-amyrin group.

Furthermore, the relation of acacic acid to the β-amyrin group was fixed by the formation of the (di)acetate methyl ester of the hydrolysis product of sapogenin B of Styphnodendron coriaceum[13] (Proceric acid[14]) (VIII) from acacic acid (I). Acacic acid (I) on methylation with diazomethane gives a methyl ester (III) which on acetylation with acetic anhydride and pyridine in the cold yielded a (di)acetate methyl ester (VI) leaving one of the hydroxyl groups free. This hydroxy acetate methyl ester (VI) on dehydration with phosphorous oxychloride in pyridine gave a diene (VII) (*cf.* Varshney *et al.*,[15] echinocystic acid diene), which gives a very deep colour with tetranitromethane. Diene (VII) on hydrogenation with Adams' platinum yielded a product (VIII) which has been identified as proceric acid (di) acetate methyl ester[14] (diacetate methyl ester of the hydrolysis product of sapogenin B of Styphnodendron coriaceum[13]).

The formation of a diacetate lactone (28→21) (II) by acetylation of acacic acid (I) suggested that one of the hydroxyl groups should be situated at a position γ- to the carboxyl group, *i.e.* at C–15, 19 or 21. The above conversion of acacic acid into a compound of known structure confirmed that the position of the hydroxyl group is 21.

This conversion of acacic acid (I) to a compound of known structure (VIII) established not only the relation of acacic acid to the β-amyrin group but also established that one of the hydroxyl groups in acacic acid (I) is located at C–3, another at C–21, and the carboxyl at C–28.

The formation of the diacetate methyl ester (VI) instead of the expected triacetate on acetylation of the methyl ester paralleling the formation of a monoacetate of methyl echinocystate[15] suggested the possible location of the third hydroxyl group at a position β- to the carboxyl group (*i.e.* on C-16 or C-22), the methylation of which hinders the formation of acetate derivatives.

Methyl ester (III) on periodic oxidation was recovered unchanged, indicating the absence of a 1,2-diol system in the compound. Similarly the methyl ester failed to form an isopropylidene derivative, which while confirming the above observation also indicated the absence of a *cis*-1, 3-diol system (*cf.* Tomentosic acid[16]), thus eliminating the adjacent position (*i.e.* C-22) for the third hydroxyl group, leaving only position C-16 for the third hydroxyl group.

Acacic acid diacetate lactone (II) undergoes hydrogenation at atmospheric pressure in the presence of Adams, catalyst, yielding a saturated compound (V), contrary to the normal behaviour of the members belonging to the β-amyrin group. This abnormal behaviour can only be explained on the basis of some conformational or stereochemical arrangements differing from those accepted. This also suggests the possibility of the location of one hydroxyl group in a γ-position to the carboxyl group (*i.e.* position 21). The diacetate lactone (II) on partial hydrolysis with potassium carbonate in methyl alcohol gave a product mp 307—320°C which could not be characterised. The diacetate lactone (II) on hydrolysis with methanolic hydrochloric acid (10%) gave colourless needles of hydroxy lactone (IX) mp 252—

*4 The purity of the bromolactone (IV) is doubtful but the product obtained does not show any unsaturation with tetranitromethane, indicating that the double bond has been removed by lactone formation.

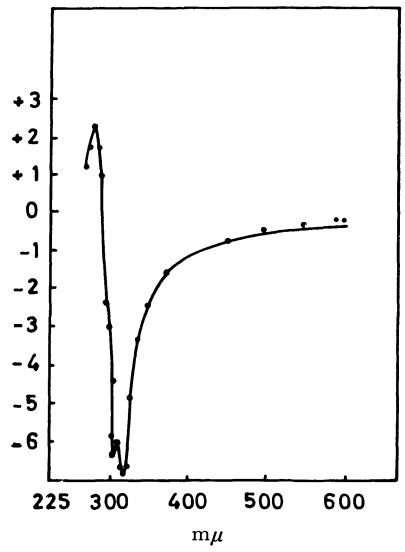

Fig. 3

254°C, which was confirmed by its reacetylation to diacetate lactone (II). Pyrolysis of acacic acid (I) also resulted in the formation of the same dihydroxy lactone (IX). The ORD curve (Fig. 3) of the diketo lactone (XI) formed by the oxidation of dihydroxy lactone (IX) with chromic acid in the cold shows a strong negative multiple Cotton effect, closely resembling that of *nor*-echinocystenolone acetate.[17] This shows that the stereochemical arrangement in acacic acid is iden-

tical with that of *nor*-echiyocystenolone acetate (D-E *cis* fusion). Thus DE *cis* ring junction was assigned to acacic acid. A *trans* fusion should be expected to give a positive Cotton effect. The CD curve (Fig. 4) also supported this finding.

Ketone (XI) on Wolff-Kishner reduction gave colourless needles mp 183—188°C (XII) a *nor*-compound by decarboxylation of the β-keto acid formed under the reaction conditions. This compound on acetylation gave an acetate mp 210—216°C (XIII). The infrared spectrum of compound (XII) showed a strong band in the hydroxyl region. The analytical results correspond to the formula $C_{29}H_{48}O$, and thus this compound should have the structure (XII) on the basis of the scheme outlined.

Earlier, the product (XII) mistakenly thought to be 28 -*nor*-β-amyrin (XVII) according to the scheme shown below (XIV—XVII) as no depression in mp took place when the compound (XII) was mixed with an authentic sample of *nor*-β-amyrin (XVII).[18] But later infrared studies showed that this compound was different from 28-*nor*-β-amyrin. This led to the complete revision of the scheme (XIV—IX—XII). More extensive study of compound (IX) was done through IR, NMR, and mass spectrometry to give structure (IX).

It may be pointed out that compound (XII) and 28-*nor*-β-amyrin (XVII) have given the same R_f values on TLC, and have the same elemental composition. However there is a large difference in the IR spectra of the two compounds.

The formation of *nor*-compound (XII) starting with C-30 ketone (XI) definitely indicated that the ketone was a β-ketolactone, as only this hypothesis can explain the decarboxylation during Wolff-Kishner reduction due to the formation of a β-keto acid under the alkaline conditions of the reaction. All evidences fixed the position of the third hydroxyl group to be C-16. The formation of the acetate methyl ester of the sapogenin B of Styphnodendron coriaceum coupled with other evidences discussed above fixed the structure of acacic acid as 3,16,21-trihydroxyolean-12-en-28-oic acid (I) leaving the question of stereochemistry and conformation undecided.

The NMR spectra of acacic acid diacetate lactone(II) (Fig. 5) showed signals corresponding to the lactonic proton at 4.2 ppm as a doublet. This is quite in agreement with the structure formulated, for the dihedral angle between the hydrogen at C-21 and one of the hydrogens at C-22 is about 90° which leads to a doublet rather than the triplet normally obtained by splitting the vicinal hydrogens. The acetoxyl proton on C-3 appears in the form of quadruplet centered at 4.5 ppm; $J_1=9$ Hz and $J_2=2$ Hz which indicates that the hydrogen is α- and the hydroxyl β-oriented.

The other acetoxyl proton at C-16 appears in the form of a quadruplet centered at 5.0 ppm; $J_1=12$ Hz and $J_2=5$ Hz also indicating a β-orientation for the hydroxyl group at C-16.

The hydroxyl group on C-21, on the basis of lactone formation, can be designated as β. The α-hydroxyl group will not form a lactone with the β-carboxyl group at C-28.

Therefore acacic acid(I) is 3β,16β,21β-trihydroxy-18β-olean-12-en-28-oic acid.

The NMR spectra of compound (IX)(Fig. 6) showed signals corresponding to vinyl proton at 5.38 ppm as a triplet characteristic of the proton of the β-amyrin group. One proton appearing at 4.2 ppm as a doublet should be a lactonic proton (CH–O–C=O). Two hydroxyl protons appeared at 1.53 ppm as singlets.

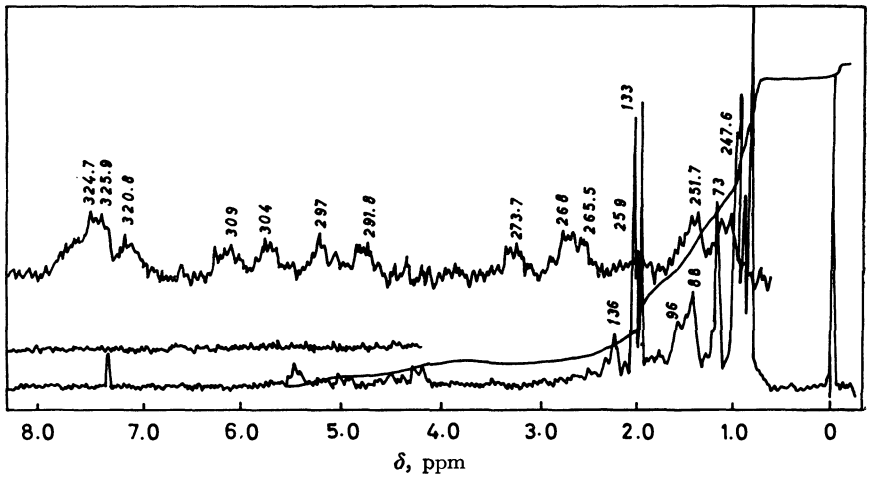

Fig. 5

18) I. P. Varshney and K. M. Shamsuddin, *Tetrahedron Lett.*, **1964**, 2055.

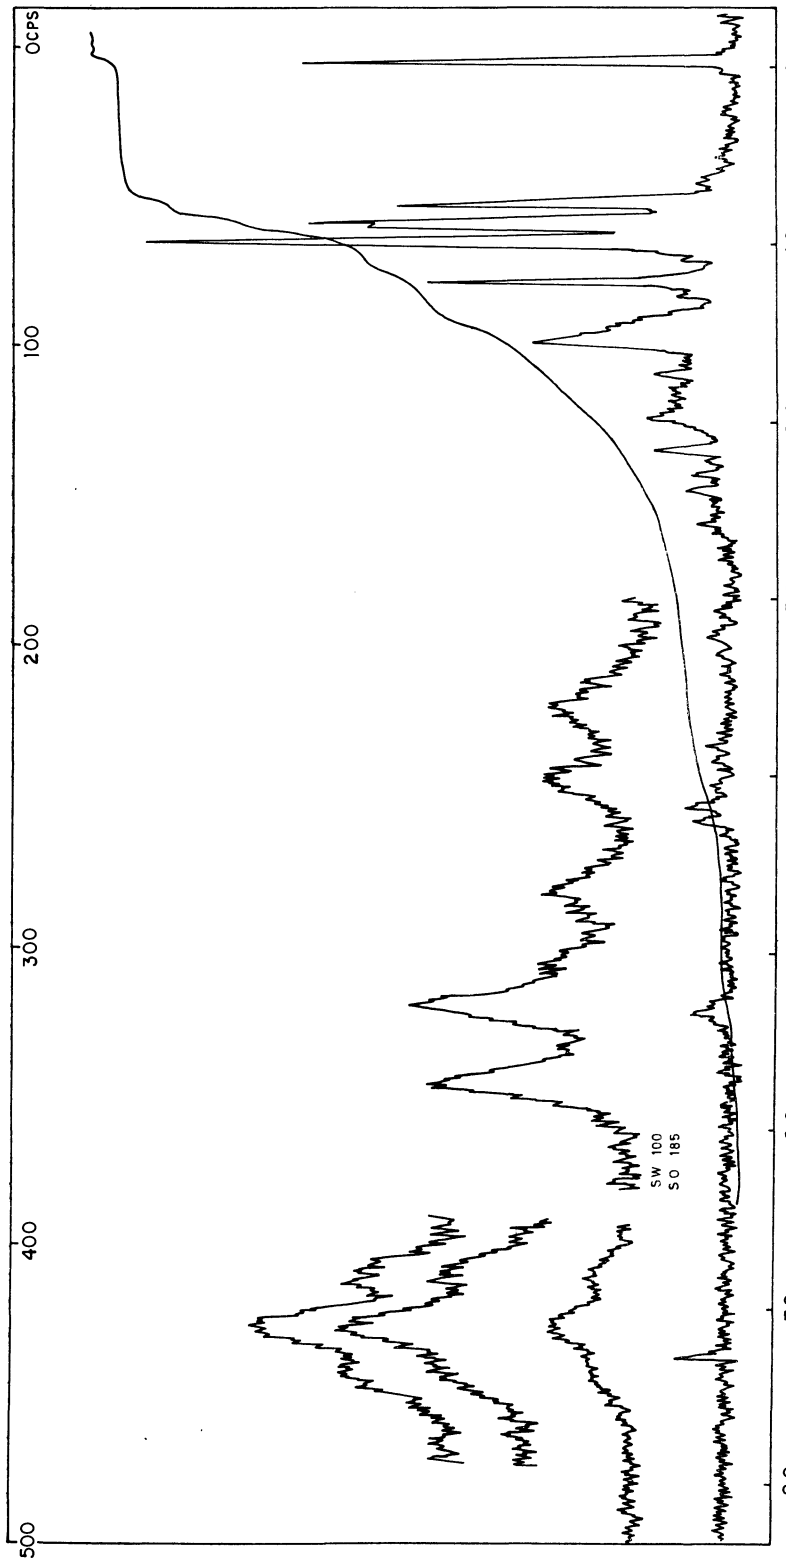

Fig. 6

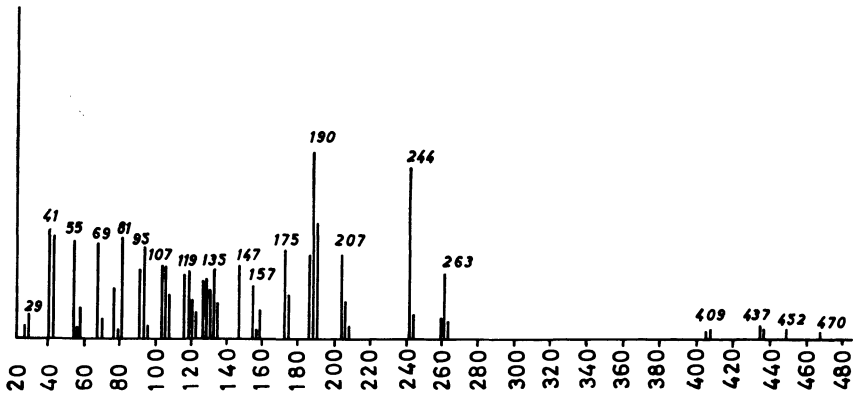

Fig. 7

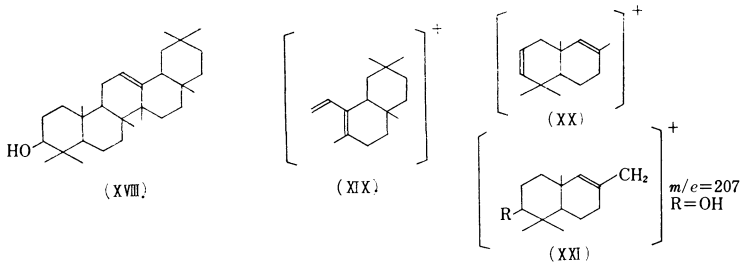
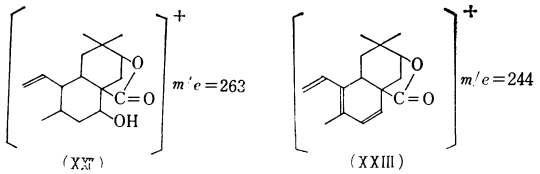


The mass spectrum (Fig. 7) of (IX) had the M^+ peak at 470 which is in definite agreement with the proposed structure, $C_{30}H_{46}O_4$. There is a peak at *m/e* 452 arising out of the loss of one molecule of water. In the triterpenes Δ^{12}-compounds (XVIII) undergo predominantly retro-Diels-Alder reaction leading to fragments (XIX) and (XX) while the rings A and B lead to the fragments (XXI).[19]

Thus the peaks at *m/e* 263 and 244 are due to fragments (XXII) and (XXIII) which correspond to fragment (XIX). The other peak at *m/e* 207 is due to fragment (XXI; R–OH). The peak at *m/e* 175 can be attributed to the *m/e* 190 fragment minus a methyl group.



The oxidation of dihydroxy lactone (IX) with pyridine-chromium trioxide complex, gave a product (XI) mp 338—342°C. It gave a yellow colour with tetranitromethane and formed a semicarbazone mp 278—282°C.

The NMR spectrum (Fig. 8) of compound (XI) shows signals of a proton at 4.2 ppm, as a doublet which is due to the lactonic proton as in the case of (IX) (Fig. 6). The spectrum also shows the presence of the vinylic proton at 5.8 ppm.

The mass spectrum (Fig. 9) of this compound also confirms this postulation. It has M^+ peak at 466 which is in entire agreement with the formula $C_{30}H_{42}O_4$ for the diketolactone. The peak at *m/e* 451 should correspond to M-15, due to the loss of a methyl group. The peak at *m/e* 260 is due to the normal fragmentation procedure and corresponds to the 'a' type fragment[13] represented in this case by (XXV), as in the case of sapogenin B of Stryphnodendron coriaceum (XXIV) which has also a lactone function between the carboxyl at C-28 and the hydroxyl at C-21 leading to fragment (XXVII). This compound also gives rise to fragment (XXVI) corresponding to *m/e* 215.

There is a peak at *m/e* 480 which has been assumed to be due to a small quantity of the triketo product (X) formed by allylic oxidation of the dihydroxy lactone (IX) and whose molecular formula is $C_{30}H_{40}O_5$. The presence of traces of the triketo product (X) was detected by thin layer chromatography. A weak peak at *m/e* 315 in the mass spectrum can be attributed to the fragment (XXVIII) arising out of the 11-keto compound (X).

Usually pentacyclic triterpenes of the β-amyrin group have rings A-B, B-C, and C-D *trans* and D-E *cis* fused, with an all chair conformation.

Fig. 8

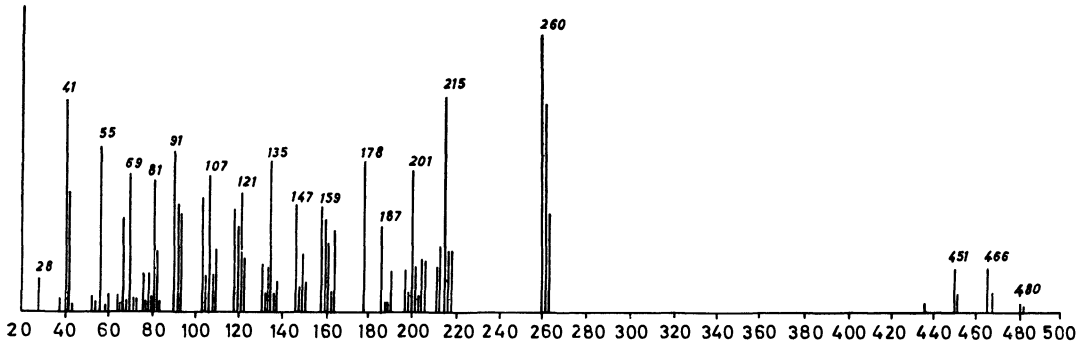

Fig. 9

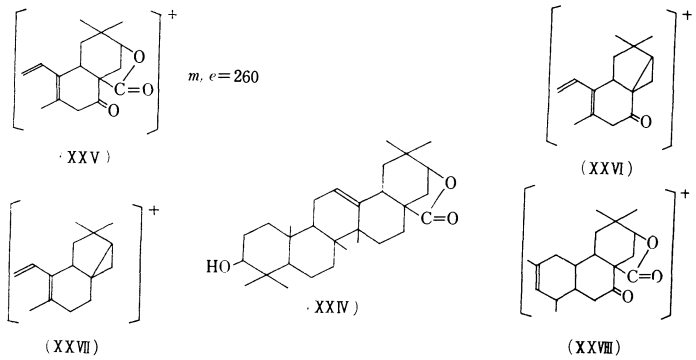

Easy hydrogenation of the diacetate lactone(II) of acacic acid is contrary to the properties of β-amyrin group which cannot be hydrogenated under normal conditions,[11,13] and therefore indicates that some subtle conformational difference exists in this compound. These instances are parallel to the behaviour of sapogenin B of Stryphnodendron coriaceum,[13] and can be explained on the basis that ring E exists in boat form and consequently ring D in a *quasi-boat* form.[13] The proximity of the C-21 hydroxyl and the C-28 carboxyl groups which tends to make the lactonisation easy can be seen by the study of a molecular model of acacic acid. Such a lactonisation could also be possible with a *trans* D-E fusion but this possibility is eliminated on the basis of the ORD (Fig. 3) and circular dichroism (Fig. 4) curves of the diketolactone(XI) which strongly resemble that of *nor*-echinocystenolone acetate.[17] The latter has a ring D-E *cis* fusion, and this resemblance indicates identical stereochemical arrangement around ring D in both the compounds. Thus D-E ring junction is *cis* in case of acacic acid(I). As this assignment made by Djerassi *et al.*[17] is accepted for *nor*-echinocystenolone, acacic acid(I) has an 18β-H configuration, except for the improbable event of an erroneous assignment of configuration to *nor*-echinocystenolone.[17] This would not change the conclusions regarding the stereochemistry except as regards configuration at C-18, in acacic acid.

While acacic acid(I) itself could exist in all chair conformation, this is impossible for the 28—21 lactone(II) of this series. A study of models shows that such a lactone can be easily formed provided ring E is constrained into a boat form. Ring D in the lactone can then adopt several conformations, but one of them, a twist form, appears to minimize all interactions effectively. In this conformation the 16β bond is *quasi*-equatorial and the geometrical relationship between the 16α-H and the 15-CH_2 group is such that the observed coupling constants are explained.

Therefore acacic acid can now be represented as 3β,16β,21β-trihydroxy-18β-olean-12-en-28-oic acid, and in its diacetate lactone (28—21), the rings E and D are in *boat* and *quasi-boat* forms respectively (XXIX).

Experimental*5

Extraction of Saponin. The pods of *Acacia concinna* DC. (900 g) obtained from Kerala (South India) broken into small pieces were exhaustively extracted with ethanol under reflux and solvent recovered. This left a dark brown syrupy residue which was successively treated with ether, petroleum ether, carbon tetrachloride, chloroform, and acetone. The mass left over was dissolved in a small quantity of alcohol, and saponin was precipitated by addition to a large quantity of ether/acetone. This process was repeated several times followed by treatment with activated charcoal to give a fairly pure specimen of saponin (28 g).

Hydrolysis of Saponin. Saponin (10 g) was dissolved in a large volume of water and heated with sulphuric acid (10%) on a water bath for an hour followed by refluxing for another hour. Sapogenin was filtered, and dried (7.5 g).

Purification of Sapogenin. Crude sapogenin (7.5 g) was refluxed with alcoholic potassium hydroxide (10%; 600 cc) for one hour and the volume reduced to half. The solution was then diluted with water (2 *l*) and extracted with ether. The aqueous layer was then acidified with hydrochloric acid and the precipitated acid genin filtered, washed and dried (3.2 g).

Diacetate Lactone (II). Genin (5 g) was acetylated in the usual manner by heating with acetic anhydride and pyridine. The product was crystallized from methanol mp 235—236°C. It gave a positive colour with tetranitromethane. Genin was acetylated by refluxing with acetic anhydride and sodium acetate as well as with acetic anhydride and pyridine in the cold gave the same product mp 235—236°C. It showed no depression in mp when mixed with an authentic sample of acacic acid diacetate lactone obtained from Acacia intsia bark.

Acacic Acid (I). Acetate (II) was refluxed with alcoholic potassium hydroxide (300 cc; 10%) for two hours and the volume reduced to half. The solution was poured into excess of water and acidified with hydrochloric acid which precipitated genin. The precipitated sapogenin was filtered, washed and crystallized from a large volume of methanol mp 278—282°C. It gave yellow colour with tetranitromethane. Mixed mp with authentic sample of acacic acid obtained from Acacia intsia bark showed no depression.

Bromolactone (IV). A suspension of acacic acid (I) (500 mg) in acetic acid (50 cc) containing anhydrous sodium acetate (2 g) was stirred during addition of bromine (1 cc) in acetic acid (25 cc) for an hour and the contents diluted with water. The product was extracted with ether and the water extract washed with sodium thiosulphate, sodium bicarbonate and water. Recovery of ether furnished the bromolactone which was crystallized from methanol, mp 259—262°C (*cf.* *4). It gave no colour with tetranitromethane.

Methyl Ester(III). Acacic acid (I) was treated with an excess of ethereal solution of diazomethane and the reaction mixture was kept overnight at room temperature. The product isolated by the evaporation of ether was crystallized from methanol mp 224—225°C. It gave a yellow colour with tetranitromethane. Mixed mp with an authentic sample was undepressed.

Methyl Ester Diacetate (VI). The methyl ester (1 g) (III) was acetylated with acetic anhydride (100 cc) and pyridine (100 cc) in the cold in the usual manner. It was crystallized from methanol as needles mp 203—205°C. It gave positive colour with tetranitromethane. Mixed mp with authentic sample was undepressed.

Found, C, 71.46, 71.36; H; 9.64, 9.50%. Calcd for $C_{35}H_{54}O_7$: C, 71.64; H, 9.28%.

Periodic Oxidation of Methyl Ester (III). The methyl ester (III) (500 mg) was dissolved in ethanol (95%; 30 cc) and treated with a solution of sodium periodate (150 mg) in sulphuric acid (6 cc). The mixture was kept at room temperature for 18 hours and then poured into excess of water. The precipitate was filtered, washed and crystallized from methanol as colourless needles mp 223—224°C. The mixed mp with the starting material was undepressed.

Isopropylidene Derivative of Methyl Ester. The methyl ester (III) (500 mg) in dry acetone (25 cc) was treated with a drop of concd. hydrochloric acid. It did not give any precipitate. The solvent was then removed and the product left over was crystallized from methanol mp 223—224°C. The mixed mp with the starting material showed no depression.

Dehydration of VI. The diacetate methyl ester (VI) (300 mg) was refluxed with pyridine (10 cc) and phosphorous oxychloride (2 cc) for 5 hr. It was then diluted with ice cold water. The product was extracted with ether, and the ethereal extracts washed with water. Evaporation of ether and crystallization from methanol furnished compound (VII) mp 280—282°C. It gave a deep yellow colour with tetranitromethane.

Found: C, 73.54, 73.78; H, 9.65, 9.19%. Calcd for $C_{35}H_{52}O_6$: C, 73.91; H, 9.22%.

Hydrogenation of VII. The dehydration product (VII) (200 mg) was dissolved in acetic acid (50 cc) and hydrogenated at atmospheric pressure and room temperature in the presence of Adams' catalyst. The product was crystallized from methanol as colourless shining needles mp 266—270°C. It still gave positive reaction with tetranitromethane.

Found: C, 72.88, 72.76; H, 9.24, 9.15%. Calcd for $C_{35}H_{54}O_6$: C, 73.64; H, 9.54%.

Hydrogenation of II. The diacetate lactone (II) (100 mg) was hydrogenated in acetic acid (20 cc) in the presence of Adams' catalyst at room temperature and pressure. It was crystallized from methanol in the form of colourless plates mp 280—285°C (V). It did not give any colour with tetranitromethane.

Found: C, 72.73, 72.50; H, 9.78, 9.90%. Calcd for $C_{34}H_{52}O_6$: C, 73.34; H, 9.41%.

Partial Hydrolysis of II. The diacetate lactone (II) (500 mg) was refluxed with methanol (50 cc) containing hydrochloric acid (10 cc) for two hours and the product worked out in the usual manner. It was crystallized from methanol as colourless crystals mp 252—254°C (IX). It gave a yellow colour with tetra-

*5 All the melting points recorded in this paper have been taken on Koflers hot microscopical melting point apparatus and are corrected. NMR spectra have been taken on varian A-60 and CD on Roussel Jouan Dichrograph. IR spectra have been recorded on Perkin-Elmer models 137, 21, 221 and Beckman IR5A.

nitromethane.

Acetylation of IX. The partial hydrolysis product (IX) (200 mg) was acetylated in the cold with pyridine (10 cc) and acetic anhydride (10 cc) in the usual manner and crystallized from methanol mp 234—236°C. Mixed mp with diacetate lactone (II) showed no depression.

Pyrolysis of I. Acacic acid (I) (150 mg) was taken in a pyrex tube and heated in an oil bath at 290—300°C for 25 min. The melt obtained was extracted and crystallized from methanol 252—254°C. It gave no depression on mixed melting with dihydroxy lactone (IX).

Oxidation of IX. A solution of dihydroxy lactone (IX) (200 mg) in pyridine (5 cc) was added to a suspension of chromium trioxide pyridine complex prepared from chromium trioxide (300 mg) and pyridine (8 cc) and the mixture kept at room temperature for 24 hours after which it was poured into crushed ice. The product worked out in the usual manner was crystallized from methanol-chloroform mixture mp 338—342°C (XI). It gave yellow colour with tetranitromethane. This product formed a semicarbazone mp 278—282°C.

Thin layer chromatography of the ketone using cyclohexane; ethylacetate system showed two spots, one major and one minor, the latter with a faster running rate. The product was purified by preparative thin layer chromatography and the pure ketone (XI) used for NMR measurements. Mass spectrometry was carried out with untreated product which clearly showed the impurity.

Wolff-Kishner Reduction of XI. Ketone (XI) (100 mg) was dissolved in diethylene glycol (20 cc) containing metallic sodium (400 mg) and to it was added hydrazine hydrate (100%). Then the reaction mixture boiled at 180°C. It was refluxed at this temperature for 18 hours after which hydrazine hydrate was evaporated till the solution boiled at 210°C. Refluxing was continued for another 24 hr and the reaction mixture worked out in the usual manner. No acidic product could be isolated, and the neutral product was crystallized from methanol-ethyl acetate mixture; mp 183—188°C (XII). It gave a positive colour with tetranitromethane.

Found: C, 84.20; H, 11.73%. Calcd for $C_{29}H_{48}O$: C, 84.40; H, 11.73%.

Acetylation of XII. The reduction product (XII) (60 mg) was acetylated with pyridine and acetic anhydride in the usual manner. The acetate was crystallized from ethyl acetate methanol mixture; mp 210—216°C (XIII). It gave positive colour with tetranitromethane.

The authors are thankful to Professor R.E. Beyler for the material help given by him during his stay at Strasbourg. Thanks are due to Professor G. Ourisson, Professor R. Tschesche, Professor C. Djerassi, Dr. G. Snatzke, and Dr. A. J. Shannon for their help in IR, NMR, ORD, CD, and mass spectrometry. Thanks are also due to the Council of Scientific and Industrial Research, New Delhi for the award of a Junior Research fellowship to one of the authors (K.M.S.) and to Dr. B. Tursch for comparing our sample with acetate methyl ester of the hydrolysis product of sapogenin B of Stryphnodendron coriaceum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3841—3845 (1970)

Kinetics of the Chromic Acid Oxidation of Glycollic and Benzilic Acids

Kalyan K. SENGUPTA, A. K. CHATTERJEE and S. P. MOULIK

Department of Physical Chemistry, Jadavpur University, Calcutta-32, India

(Received December 15, 1969)

The kinetics of chromic acid oxidation of glycollic and benzilic acids have been studied. Catalysis by H^+ ions has been noticed in both cases of oxidation. The results show that the logarithm of the rate constants increases with increase in the proportion of acetic acid in the mixture. Ionic strength decreases the rate of oxidation. Pyridine catalyzes the oxidation of glycollic acid whereas the catalysis in the case of benzilic acid is negligible. The energy of activation and entropy of activation have been calculated. Both kinetics and spectrophotometric results indicate the formation of intermediate chromium(VI)-hydroxycarboxylate complex in each case. The complex finally decomposes to give reaction products. Glycollic acid initially produces glyoxylic acid which subsequently gives formic acid whereas benzilic acid is oxidized to benzophenone.

Oxidation of a variety of organic compounds by chromic acid has been extensively studied. Bakore *et al.* have studied the oxidation of a number of α-hydroxy acids[1] *viz.*, lactic, malic and mandelic acids (all of them having C–H bond in the α-carbon atom) and explained the mechanism on the basis of the Kwart-Francis scheme,[2] which is a minor variation of the well known Westheimer's[3] mechanism. In the previous case[2] proton is removed intramolecularly instead of by an external base. However, no kinetic data for the oxidation of glycollic acid with chromic acid are known which may also be explained in the light of the above mechanisms. On the other hand, for benzilic acid having no C–H linkage in the molecule, the Kwart-Francis mechanism as well as Westheimer[3] type of mechanism (applicable in the case of chromic acid oxidation of isopropyl alcohol) could not be operative. Westheimer[3] considered that the oxidation of alcohols by chromic acid involves reversible formation of a chromate ester which slowly decomposes by a process catalyzed by bases. Presumably, the oxidation of benzilic acid may be explained on the basis of rupture of C–C bond[4] which is the other possible alternative. With this idea, we report in this communication, the chromic acid oxidation of two α-hydroxy acids, *viz.*, glycollic and benzilic acids.

Experimental

Potassium dichromate (G. R., Merck), glycollic acid (Riedel, Germany) and benzilic acid (Pure, E. Merck) were used without further purification. Manganous sulphate used was of 'Anala R' grade. 60% perchloric acid (E. Merck) was used. Sodium perchlorate was prepared by the neutralization of perchloric acid with sodium hydroxide. Neutralized benzilic acid solution was used. All other reagents were chemically pure. Details of kinetic measurements have been described elsewhere.[5] All experiments were carried out at 35°C unless otherwise mentioned. Spectral measurements were carried out with a Beckman DB. model spectrophotometer.

Results

The stoichiometry of the reactions were determined by allowing reaction mixtures, containing a large excess of dichromate ion, to stand for 48 hrs at 30°C. The unreacted oxidant was then estimated by the usual procedure.[5] The reactions may be represented by the following equations.

$$6CH_2(OH)COOH + 4Cr_2O_7^{2-} + 32H^+ \rightarrow 6HCOOH + 8Cr^{3+} + 22H_2O + 6CO_2$$

Found: 0.63 mol of the oxidant per mol of the substrate.

$$3(C_6H_5)_2C(OH)COOH + Cr_2O_7^{2-} + 8H^+ \rightarrow 3(C_6H_5)_2CO + 2Cr^{3+} + 7H_2O + 3CO_2$$

Found: 0.31 mol of the oxidant per mol of the substrate. The products of the reactions were formic acid and benzophenone respectively which were confirmed by the usual tests. Formic acid was tested by the chromotropic acid reaction and benzophenone was tested by the preparation of a 2,4-dinitrophenyl hydrazine derivative.

In both cases of oxidation a 8 min period of

TABLE 1. EFFECT OF OXIDANT ON THE REACTION RATE
(a) [Glycollic Acid]$=3.00\times10^{-2}$ M, $\mu=0.22$, pH$=0.69$
(b) [Benzilic Acid]$=8.3\times10^{-3}$ M, $\mu=0.14$, pH$=0.90$

	a		b	
No.	[Cr(VI)]$\times10^{3}$ M	$k_a\times10^{3}$(sec^{-1})	[Cr(VI)]$\times10^{3}$ M	$k_b\times10^{3}$(sec^{-1})
1	5.0	3.53	1.38	1.34
2	6.6	3.22	2.07	1.21
3	8.3	2.88	2.77	0.89
4	10.0	2.57	3.47	0.63

disturbance was observed. This disturbance is possibly due to some side reactions which progressively slow down as the complex formation approaches completion. A good first order reaction kinetics was found to occur after this period. Table 1 summarizes the values of rate constants at various initial concentrations of chromic acid. It is seen that the rates decreased with the increase of initial concentration of chromic acid.

To study the effect of [α-hydroxy group]$_0$ on k, a series of runs were made holding all the initial parameters constant. Increase in the concentration of α-hydroxy acids increased the rate of oxidation. The data on the effect of α-hydroxy acids on the rate of oxidation is shown in Fig. 1. The plots of $1/k$ against 1/[substrate] cut y-axis indicating the formation of an intermediate compound in both cases of oxidation. The spectrophotometric results also support the contention.

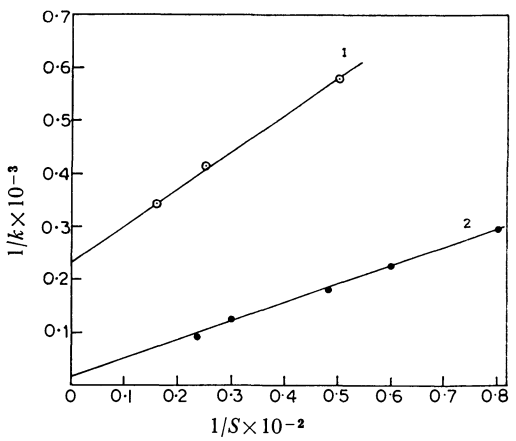

Fig. 1. Influence of substrate on the rate constant.

1. [Cr(VI)]$=3.30\times10^{-3}$ M
2. [Cr(VI)]$=1.38\times10^{-3}$ M

The experimental curves of Fig. 2 are physical evidences for complexation between chromium(VI) and hydroxy acids used. The spectra reported here were all taken after immediate mixing of the components. The strength of the dichromate solution was of the same order as used in the kinetic study. The change in the nature of the optical density/wavelength trend in the region 410—450 mμ of chromium(VI) (Curve 1), when ligands were added (Curves 2 and 3), seems to be due to new compound (complex) formation. A shift in the position of the shoulder towards longer wavelength from glycollate to benzilate was also noticed. The new nature of chromium(VI)-hydroxylate spectra cannot be due to change of pH. The effect of pH on the absorption spectra of dichromate solution is presented in curves 4, 5 and 6. Addition of glycollate and benzilate both changed (increased) the pH of the dechromate solution. The nature of both the curves (2 and 3), though similar to each other, differs from that of dichromate solutions having different acidities (curves 4, 5 and 6). All these observations support the

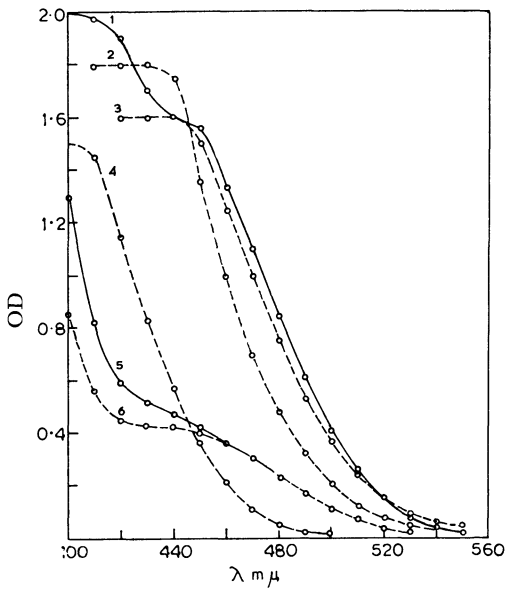

Fig. 2. Absorption spectra of chromium(VI) and its complexes.

1. [Cr(VI)] in water$=3.3\times10^{-3}$ M
2. [Cr(VI)]$=3.3\times10^{-3}$ M, [Na-glycollate]$=0.48$ M
3. [Cr(VI)]$=3.3\times10^{-3}$ M, [Na-benzilate]$=0.48$ M
4. [Cr(VI)] in water$=1\times10^{-3}$ M at pH 12.3
5. [Cr(VI)] in water$=1\times10^{-3}$ M at pH 4.53
6. [Cr(VI)] in water$=1\times10^{-3}$ M at pH 1.70

formation of chromium (VI)-hydroxycarboxylate complex upon immediate mixing.

The rate studies were made at various hydrogen ion concentrations. The acid dependence was studied, in a series of runs at fixed [substrate]$_0$ and [Cr(VI)]$_0$, by varying perchloric acid concentration but keeping the ionic strength constant by the addition of sodium perchlorate. The rates increased with the increase in hydrogen ion concentration. The plots between log k against pH is linear in each case (Fig. 3).

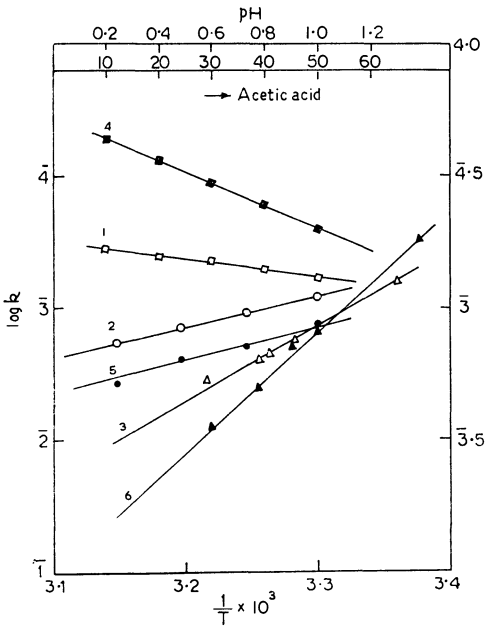

Fig. 3. Effect of solvent, temperature and pH on the rate constants.

1. [Cr(VI)]=3.33×10^{-3} M, [Glycollic acid]=2.50×10^{-2} M, pH=1.30, μ=0.06, Temp. 35°C
2. [Cr(VI)]=4.15×10^{-3} M, [Glycollic acid]=2.50×10^{-2} M, pH=0.22, μ=0.61
3. [Cr(VI)]=4.15×10^{-3} M, [Glycollic acid]=2.50×10^{-2} M
4. [Cr(VI)]=1.66×10^{-3} M, [Benzilic acid]=1.00×10^{-2} M, pH=1.0, μ=0.115, Temp. 35°C
5. [Cr(VI)]=1.38×10^{-3} M, [Benzilic acid]=8.3×10^{-2} M, pH=0.90, μ=0.14
6. [Cr(VI)]=1.38×10^{-3} M, [Benzilic acid]=8.3×10^{-2} M

The rates were also studied at different solvent composition of the reaction mixture. The solvent composition was varied by the addition of acetic acid. Figure 3 shows that the rate constant increases with increase in the proportion of acetic acid in the mixture. This is in agreement with previous observation.[5]

The results of the effect of pyridine on the rates of oxidations have been presented in Table 2. The base catalysis has been studied at constant [H$^+$] with varying [free base]. Since pyridine removes hydrogen ions, the effective hydrogen ion concentration in the presence of pyridine would correspond to {[H$^+$]–[Py]}. If pyridine catalyzes oxidation,[1] the value of $k/\{[H^+]-[Py]\}$ increases with increase in the concentration of pyridine. The value would decrease if pyridine inhibits the reaction and would be constant if pyridine has no effect on the rate of oxidation. Westheimer[3] has shown that the addition of a base like pyridine catalyzes the oxidation of isopropyl alcohol by chromic acid, but this was later shown to be incorrect.[6] At present there is no evidence[6] for the involvement of an external base in the rate controlling steps nor is there good evidence against such a process. We have also observed catalyzing behaviour of pyridine in the case of glycollic acid oxidation and slight retarding effect in the case of benzilic acid.

The influence of temperature was studied under identical conditions of [α-hydroxy acid]$_0$ and [Cr(VI)]$_0$. The Arrhenius plots of log k against $1/T$ gave straight lines (Fig. 3). The energies of activation were calculated to be 11.9 and 11.6 kcal/mol for glycollic and benzilic acids, respectively. The values of $-\Delta S^{\neq}$ were found to be 34.9 (e.u.) in each case. It is interesting that the values of energy and entropy of activation were found to be 12.86 kcal/mol and 34.6 (e.u.), respectively, in

Table 2. Effect of pyridine on the rate of oxidation

the chromic acid oxidation of isopropyl alcohol.[7] Such close values suggest that the same mechanism may be operative for the rate controlling step of the reactions of α-hydroxy acids with chromic acid.

The effect of changing ionic strength was also examined (Table 3). The ionic strength was varied by the addition of sodium perchlorate. The changes in ionic strength of the medium had a definite retarding influence. This is in agreement with the observations made by Wiberg and Mill.[8] The results in Table 1 show that the rate of reaction is not directly proportional to chromium(VI) concentration because of the following monomer-dimer equilibrium which is a function of ionic strength,

$$2HCrO_4^- \rightleftharpoons Cr_2O_7^{2-} + H_2O$$

Wiberg and Mill[8] have shown that increase in ionic strength will favour the formation of a divalent ion, which have a higher ion pair association constants than a univalent ion. This will shift the equilibrium towards dichromate ion as the ionic strength is increased, and the rate of reaction would correspondingly decrease.

The rate constants of the reactions of some α-hydroxy acids by chromium(VI) were also studied under comparable conditions of $[\alpha\text{-hydroxy acids}]_0$, $[\text{chromium(VI)}]_0$, pH and ionic strength. The concentrations of α-hydroxy acids and chromium (VI) used were 2.5×10^{-2} M and 2.70×10^{-3} M, respectively. Ionic strength and pH of each solution were maintained constant at 0.17 and 0.78, respectively. The rates increased with the increase in the substitution of hydrogen atom of the glycollic acid successively by phenyl nucleus. The values of 'k' in the cases of glycollic, mandelic and benzilic acids were found to be 0.767×10^{-3}, 0.921×10^{-3} and 4.07×10^{-3} (sec^{-1}), respectively. A comparison of the dissociation constants of glycollic, mandelic and benzilic acids show that the rates increased with the increase of dissociation constants which are 1.5×10^{-4}, 4.3×10^{-4} and 9.2×10^{-4}, respectively at 25°C. It will be difficult to interpret these data with rate constants, since the course of the reaction is mainly governed by two factors: (1) tendency of complex formation, (2) disproportionation of the complex to give products of the reaction. In the case of benzilic acid, the molecule appears to be sterically hindered due to the presence of two phenyl nucleus and the rate of the reaction with benzilic acid is expected to be the slowest. However, it seems very likely that benzilic acid molecule possibly violates the principle of steric hindrance, since due to the presence of two phenyl groups both hydroxyl and carboxyl groups are brought nearer, thereby facilitating the formation of the complex with chromic acid. Since hydroxyl and carboxyl groups are under strain, the benzilate chromate complex is expected to be most unstable in the series and hence its decomposition is fastest. In a similar way, glycollate chromate complex is more stable than benzilate chromate complex. This is possibly the reason why the rates follow the order $k_{\text{benzilate}}>k_{\text{mandelate}}>k_{\text{glycollate}}$.

Discussion

Kinetics and spectrophotometric results indicate that both glycollic and benzilic acids react with chromic acid to form an intermediate compound. They finally decompose slowly to give reaction products. Glycollic acid initially produces glyoxylic acid which subsequently is oxidized to formic acid. The other alternative would have been the oxidation of glyoxylic acid to oxalic acid, which on the way, might get oxidized to carbon dioxide. Since formic acid is one of the products of oxidation, it seems very unlikely that the reaction involves oxidation of glyoxylic acid to oxalic acid. Determination of stoichiometry also supports the above argument. Therefore, decarboxylation probably occurs as a part of the oxidation step. However, it has been shown recently during the oxidation of glyoxylic acid[9] by chromic acid, that decarboxylation of the molecule takes place followed by the oxidation of the hydrated formaldehyde molecule to afford formic acid. A few experiments were carried out using both glyoxylic acid with chromic acid and glycollic acid with chromic acid under comparable conditions. The rate constants were found to be 1.345×10^{-2} (sec^{-1}) and 1.072×10^{-3} (sec^{-1}), indicating the reaction is faster for glyoxylic acid. Again the activation energy in the case of the oxidation of glyoxylic acid by chromic acid

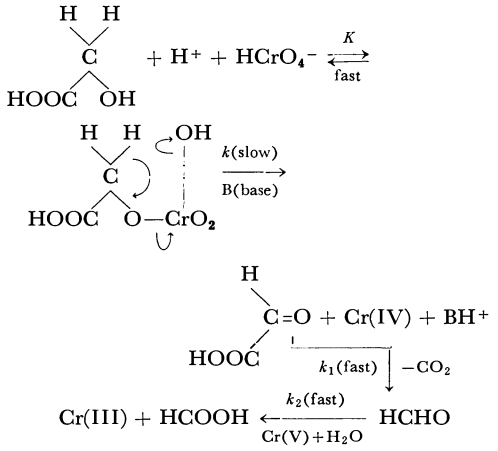
8) K. B. Wiberg and T. Mill, *J. Amer. Chem. Soc.*, **80**, 3022 (1958).

9) K. K. Sen Gupta and S. D. Bhattacharya, *Z. Phys. Chem.* (Leipzig), **240**, 279 (1969).

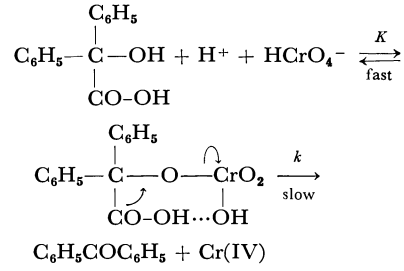
was found to be 5.5 kcal/mol as against 12.8 kcal/mol in the case of glycollic acid. This also supports that $k_{\text{glyoxylic}} > k_{\text{glycollic}}$.

On the basis of the above evidences, the reaction between glycollic acid and chromic acid may be explained in the following manner:



Scheme 1

The absence of C–H bond in benzilic acid suggests that the Westheimer type of mechanism is applicable in the other case. Moreover, the Kwart-Francis scheme in which proton is removed intramolecularly may also not be operative. In the case of benzilic acid, catalysis by pyridine has not been observed. Therefore, it may be proposed that the oxidation leads directly to the formation of a ketone and carbon dioxide by way of a chromate ester:



Scheme 2

In connection with the oxidation of pinacol by chromic acid, Chang and Westheimer have shown that an energy of 18.0 kcal/mol is needed during the rupture of a C–C bond. But in our case the value has been calculated to be 12.8 kcal/mol. This suggests that chromic acid possibly forms a more stable complex with symmetrical pinacol molecule than with benzilic acid.

It is clear that the first stage of the reaction involves a two electron transfer leading to chromium(IV), which is converted to chromium(V), either by reacting rapidly with chromium(VI) or chromium(IV) rapidly undergoing disproportionation to give chromium(V). The decreased rate of reaction on addition of Mn^{2+} ions suggests that intermediate valence states of chromium were formed.

Kinetic Studies of the Triethylenediamine-catalyzed Hydrolysis of 1,3-Diphenylurea in Dioxane

Yoshiaki Furuya,* Kazuo Itoho** and Sakiko Fukutaka**

* *Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto*

** *Daiichi College of Pharmaceutical Sciences, Fukuoka*

(Received March 26, 1970)

The rate of the hydrolysis of 1,3-diphenylurea (abbreviated as DPU) in dioxane in the presence of triethylenediamine (TED) was followed by ultraviolet spectrophotometry. The rate of the reaction satisfied the following equation:

$$v = \{k_2 - k_{3h}[H_2O]\}[DPU][H_2O] + \{k_{4uh}[H_2O] - k_{3u}\}[DPU]^2[H_2O] + \{k_{3c} - k_{4ch}[H_2O]\}[TED][DPU][H_2O] + \{k_{5cuh}[H_2O] - k_{4cu}\} \times [TED][DPU]^2[H_2O].$$

A probable mechanism which involves a nucleophilic attack of the lone pair of the O-atom of water and of the N-atom of TED on the carbonyl C-atom of DPU, passing through an ion pair of quaternary ammonium salt, is discussed.

In the kinetic studies of the TED-catalyzed transamidation of 1,3-diphenylurea with *n*-butylamine in dioxane which have been previously reported,[1] both non- and the TED-catalyzed hydrolyses were found. In the present paper, a probable mechanism of the hydrolysis, passing through an ion pair of quaternary ammonium salt, will be discussed.

Experimental

Materials. The 1,3-diphenylurea, the triethylenediamine, and the dioxane used as the reaction solvent were purified in a mannr similar to that described previously.[1]

Ultraviolet Spectrophotometry and Chemical Analyses. The absorption maxima of DPU and aniline were 255 and 234 mμ, while the minima were 227 and 214 mμ respectively. The absorption of TED is negligible at these wavelengths. Mixtures of DPU, aniline, and TED in known concentrations (corresponding to 0, 20, 40, 60, 80, and 100% conversion) were prepared at 90°C; plots of the extinction difference, $(E_{255}-E_{230})$ *vs.* $(E_{255}-E_{277})$, gave a straight line, and the cnoversions calculated from the values of $(E_{255}-E_{230})$ at 0 and 100% conversion agreed well with the conversions calculated from the mixtures within a 1% error.

Reaction-product Criterion. Aniline liberated from DPU in a reaction mixture was detected by paper chromatography in the manner described in a previous paper.[2]

A Typical Run for the Rate Measurements. A solution of 0.07 m*l* of 0.5M water in dioxane was added to a solution of 27.93 m*l* of 0.0143M DPU in dioxane; a solution of 12.00 m*l* of 0.05M TED in dioxane was poured into the solution of DPU in order to start the reaction after the three solutions had attained temperature equibrium at 90°C. Aliquots (0.2 m*l*, each) were pipetted out at appropriate intervals of time, and each one was diluted with methanol to a 2×10^{-5}M initial concentration of the reactant. The conversion was calculated graphically from the values of $(E_{255}-E_{230})$, and the value of the second-order rate constant, k_{2obs}, was calculated.

Determination of the Water. The water concentration in the reaction medium was determined by the Karl Fischer method.

Measurement of the Order of Self-association of DPU by the Cryoscopic Method. The order of the self-association of DPU in dioxane was measured by the cryoscopic method on solutions containing water ranging in concentration from 2×10^{-2} to 5×10^{-2}M.[3]

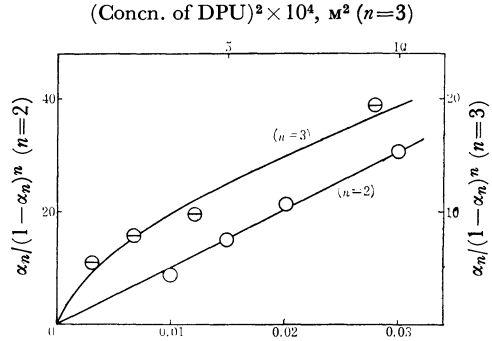

Fig. 1. Determination of the order of the self-association of DPU in dioxane.
Concn. of water: 0.02—0.05M

1) Y. Furuya, K. Itoho and H. Miyagi, This Bulletin, **42**, 2348 (1969).

2) Y. Furuya and K. Itoho, *Chem. & Ind.* (London), **1967**, 359.

It became evident that DPU existed in the dimer form, as is shown in Fig. 1.

However, DPU exists in the monomer form when the dioxane solution contains *n*-butylamine in the range from 1×10^{-2} to 5×10^{-2}M. Thus, the molecular weight of DPU gave the values of the monomer form, as is shown in Table 1.

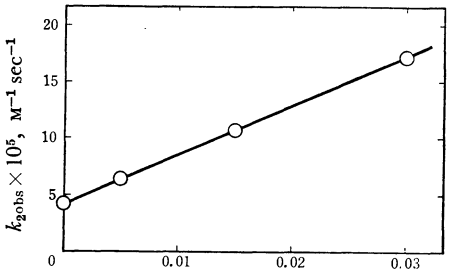
Table 1. The values of the molecular weight of DPU in dioxane containing *n*-butylamine

Concn. of *n*-butylamine (M)	Molecular weight of DPU	
	Obsd*	Calcd
0.01	223.95	212.25
0.015	209.95	212.25
0.02	213.29	212.25
0.03	216.73	212.25

* They were obtained by cryoscopic method.

Results and Discussion

The reaction followed the second-order kinetics with DPU and H_2O. The plots of the observed second-order rate constant *vs.* the concentration of TED gave a straight line which does not pass through the point of origin, as is shown in Fig. 2.



Initial concn. of TED, M

Fig. 2. The plots of k_{2obs} *vs.* the concentration of TED for the TED-catalyzed hydrolysis of DPU in dioxane at 90°C.
Initial concn. of DPU: 0.01M
Initial concn. of water: 0.02M

Therefore, the observed second-order rate constant is given by the following equation:

$$k_{2obs} = k_2'' + k_{3c}''[TED]. \quad (1)$$

The plots of k_2'' and k_{3c}'' *vs.* the concentration of DPU gave straight lines which have minus signs, as is shown in Figs. 3 and 4.

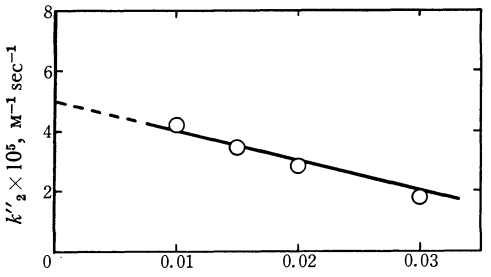
Thus, the rate constants, k_2'' and k_{3c}'', can be expressed by the following equations:

$$k_2'' = k_2' - k_{3u}'[DPU] \quad (2)$$

and

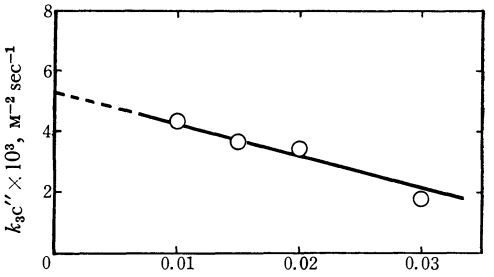
$$k_{3c}'' = k_{3c}' - k_{4cu}'[DPU]. \quad (3)$$

Moreover, k_2', k_{3u}', k_{3c}', and k_{4cu}' are variables for the concentration of water, as is illustrated in Figs. 5, 6, 7, and 8. Therefore, the following relationships are given:



Initial concn. of DPU, M

Fig. 3. The plots of k_2'' *vs.* the concentration of DPU for the TED-catalyzed hydrolysis of DPU in dioxane at 90°C.
Initial Concn. of water: 0.02M



Initial concn. of DPU, M

Fig. 4. The plots of k_{3c}'' *vs.* the concentration of DPU for the TED-catalyzed hydrolysis of DPU in dioxane at 90°C.
Initial concn. of water: 0.02M

$$k_{2z}' = k_2 - k_{3h}[H_2O]$$
$$-k_{3u}' = -k_{3u} + k_{4uh}[H_2O]$$

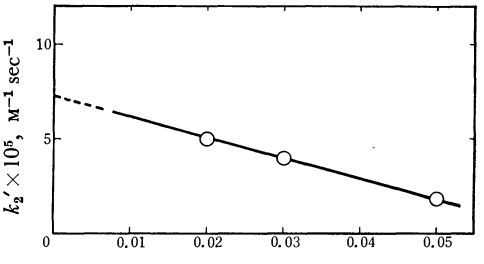
and

$$k_{3c}' = k_{3c} - k_{4ch}[H_2O]$$
$$-k_{4cu}' = -k_{4cu} + k_{5cuh}[H_2O].$$

Consequently, the total kinetics may be given by the following equation:

$$v = \{k_2-k_{3h}[H_2O]\}[DPU][H_2O] + \{k_{4uh}[H_2O]-k_{3u}\}[DPU]^2[H_2O] + \{k_{3c}-k_{4ch}[H_2O]\}[TED][DPU][H_2O] + \{k_{5cuh}[H_2O]-k_{4cu}\}[TED][DPU]^2[H_2O] \quad (4)$$

The values of $k_2\times10^5M^{-1}$ sec^{-1}, $-k_{3h}\times10^3M^{-2}$ sec^{-1}, $k_{4uh}\times10^2M^{-3}$ sec^{-1}, $-k_{3u}\times10^3M^{-2}$ sec^{-1}, $k_{3c}\times10^3M^{-2}$



Concn. of H_2O, M

Fig. 5. The plots of k_2' *vs.* the concentration of water for the TED-catalyzed hydrolysis of DPU in dioxane at 90°C.

3) Cf. T. Tonomura, K. Okamoto, T. Fujishima and H. Yamamura, *Nippon Kagaku Zasshi*, **88**, 707 (1967).

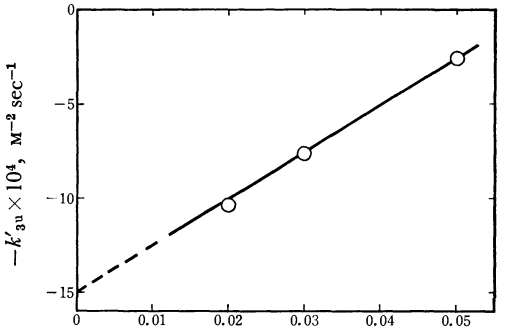


Fig. 6. The plots of $-k'_{3u}$ *vs.* the concentration of water for the TED-catalyzed hydrolysis of DPU in dioxane at 90°C.

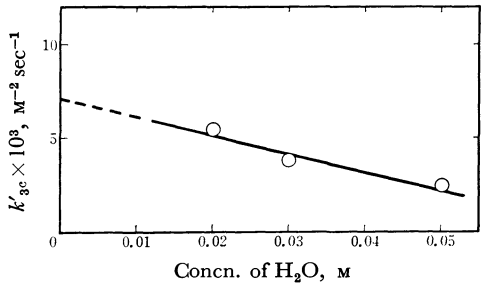

Fig. 7. The plots of k'_{3c} *vs.* the concentration of water for the TED-catalyzed hydrolysis of DPU in dioxane at 90°C.

sec^{-1}, $-k_{4ch} \times 10^2$M^{-3} sec^{-1}, k_{5cuh}M^{-4} sec^{-1}, and $-k_{4cu} \times 10^{-3}$ sec^{-1} were 7.28, −1.12, 2.49, −1.50, 7.10, −9.82, 2.39, and −1.54 respectively. The values of the rates of steps (5a) and (9) in non-catalyzed reactions and/or of steps (8c) and (10) in the TED-catalyzed hydrolyses are both comparable under these concentration conditions.

Here, four terms of both the non- and the TED-

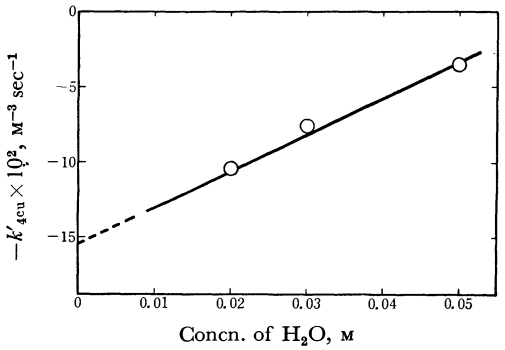

Fig. 8. The plots of $-k'_{4cu}$ *vs.* the concentration of water for the TED-catalyzed hydrolysis of DPU in dioxane at 90°C.

catalyzed hydrolyses of DPU contain the second-order terms with the concentration of DPU, though each term in the non- and the TED-catalyzed hydrolyses in the presence of *n*-butylamine contains only the first-order term with the concentration of DPU, as has been described in a previous paper.[1] The reasons for this are evident in view of the measurements of the order of the self-association of DPU in dioxanes containing water only and/or containing also *n*-butylamine, as has been described above.

As has been described in a previous paper,[1] the conductivity of the couple (DPU+TED) (10.87×10^{-6} Ω^{-1} cm^{-1}) is larger than the sum of the conductivities of the components (8.20×10^{-6} Ω^{-1} cm^{-1}); in that couple, the existence of quaternary ammonium salt was detected by Wagner's and Dragendorff's reagents.

From these findings, the following probable mechanism, one which involves a nucleophilic attack by the lone pairs of the N-atom of TED and the O-atom of water on the carbonyl C-atom of DPU, may be suggested:

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3849—3852 (1970)

The Chemical Modification of Biopolymers. III. The Introduction of SH Groups into Taka-amylase A

Shuichi SUZUKI, Yutaka HACHIMORI and Ryuichi MATOBA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received May 2, 1970)

The enzymic activity of Taka-amylase A on amylose, as measured by the blue-value method, increased to 180% of the original when one mole of mercaptosuccinyl group was introduced into one mole of the enzyme. Similar results were obtained for the activity measured by the Semogyi-Nelson method; the introduction of one or two mercaptosuccinyl groups raised the activity to 130—140% of that of the native enzyme. Even after the attachment of six mercaptosuccinyl groups per mole, the activity was 120% of the original. However, the enzymic activity was not elevated, but was lowered, by succinylation. When the sulfhydryl groups of the mercaptosuccinyl groups were blocked with *p*-chloromercurybenzoate or iodoacetamide, the enzyme was inhibited. These results suggest that the sulfhydryl groups of mercaptosuccinyl residues play an important role in increasing the enzymic activity.

Recently, Hartman and Wold[1] reported that the activity of bovine pancreatic Ribonuclease A (EC 2.7.7.16) treated with dimethyladipimidate was elevate to 160% of that of the natural material.

1) F. C. Hartman and F. Wold, *Biochemistry*, **6**, 2439 (1967).

Ikenaka[2] reported that phenylazobenzoyl-Taka-amylase had an activity on α-phenylmaltoside 2.5 times higher than that of the natural material, while its activity on amylose was diminished.

The introduction of sulfhydryl groups into proteins has been attempted by many investigators. Klotz[3] found that *S*-acetylmercaptosuccinic anhydride reacted selectively with free amino groups under mild conditions.

This paper will report on the preparation of mercaptosuccinyl Taka-amylase A (EC 3.2.1.1.) and their properties.

Experimental

Materials. The Taka-amylase A was prepared from Taka-diastase of the Sankyo Co., Ltd., by the method of Akabori *et al.*[4] The protein concentration was estimated by spectrophotometry, with an extinction coefficient, $E^{1\%}_{1cm}$, of 22.1 at 278.5 mμ,[5] or by the method of Lowry.[6] The *S*-acetylmercaptosuccinic anhydride was synthesized by adding thioacetic acid to maleic anhydride according to the method of Holmberg and Schjånberg,[7] it was recrystallized from benzene (melting point 76—77°C). The amylose was purchased from the Nagase Sangyo Co.

Preparation of the Modified Taka-amylase A. Mercaptosuccinyl and succinyl Taka-amylase were prepared as follows. One m*l* of a protein solution (3.6×10^{-4}M) was added to 6 m*l* of a 0.2M phosphate buffer, pH 8.0. One m*l* of *S*-acetylmercaptosuccinic anhydride or succinic anhydride (3.6×10^{-3}M to 1.8×10^{-1}M) in dioxane was then added to the buffered protein solution. After 30 min, 3 m*l* of a 0.33M hydroxylamine solution in a 0.2M phosphate buffer (pH 7.5) was added in order to remove the acetyl groups which blocked the sulfhydryl groups. The mixture was left to stand for 10 min at 20°C, and then dialyzed against distilled water for 24 hr at 20°C. The extent of mercaptosuccinylation was estimated by determining the sulfhydryl groups spectrophotometrically at 255 mμ by mercaptide formation using *p*-CMB, according to the method of Boyer.[8] The extent of succinylation was estimated by the decrease in the amino groups, using the method of Matsushima *et al.*[9]

Activity Measurement. The hydrolytic activity of the natural and modified Taka-amylase A was measured by the decrease in the absorbance at 700 mμ due to iodine-amylose complex formation (the blue-value method[10]) and by the increase in reducing groups (the Somogyi-Nelson method[11,12]). The digestion was conducted at 37°C for 30 min at pH 5.5.

Results and Discussion

Determination of mercaptosuccinyl Groups. *p*-Chloromercuribenzoate reacted with mercaptosuccinic acid stoichiometrically, the molar extinction coefficient of the product at 255 mμ was 5.8×10^3 at pH 4.6 in a 0.2M acetate buffer. The mercaptosuccinyl groups in protein were estimated by means of this coefficient after the *p*-chloromercuribenzoate had been reacted at 25°C for 24 hr.

The number of mercaptosuccinyl groups introduced per mole of the enzyme reached a constant value after 20 to 60 minutes' incubation (Fig. 1).

Table 1. Folin test for *O*-succinylation of protein tyrosine[13]

The results are given in the ratio of optical densities (O.D.) at 750 mμ measured at pH 8.0 and at pH 11.0.

Moles introduced SH per mole enzyme	O.D. pH 8.0/O.D. pH 11.0		
	After 3h	24h	48h
8	0.98	0.95	0.95
4	0.98	0.96	0.99

concentration of *S*-acetylmercaptosuccinic anhydride, it was six when a 500-fold excess mole was applied.

O-Mercaptosuccinylation of Tyrosyl Residues. The extent of the acylation of tyrosyl residues in this enzyme was estimated by the Folin phenol reagent test.[13]

The buffered solutions of the modified enzyme with four and eight moles of mercaptosuccinyl groups per mole were adjusted to pH 8 and 11 respectively. After 3, 24, and 48 hrs incubation at 25°C, the Folin phenol reagent was added to the solutions and they measured for absorbancy at 750 mμ. The results are summarized in Table 1. It may be concluded that the *O*-esterification of the tyrosyl residues occurred to only a slight extent, if at all, during the mercaptosuccinylation reaction.

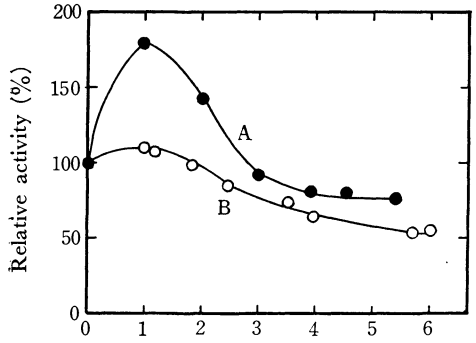

Fig. 3. The activities of native and modified Taka-amylase A on amylose measured by the blue value method. The modified enzymes mercaptosuccinylated at 2°C (Curve A, closed circle), and at 25°C (Curve B, open circle) were used.

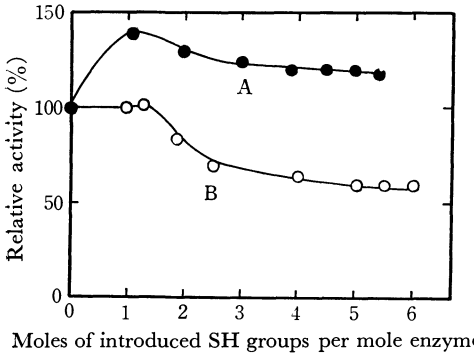

Fig. 4. The activities of native and modified Taka-amylase A on amylose measured by the Somogyi-Nelson method. The modified enzymes mercaptosuccinylated at 2°C (Curve A, closed circle) and at 25°C (Curve B, open circle) were used.

13) G. L. Miller, *ibid.*, **146**, 339 (1942).

Enzymic Activities of Mercaptosuccinyl Takaamylase A. The pH optimum of either the natural or the modified enzyme was around pH 5.5. The following experiments were, therefore, performed at this pH value. The results are shown in Figs. 3 and 4. When one mole of the mercaptosuccinyl group was introduced per mole of the enzyme at 2°C, the activity on amylose, measured by the blue-value method (Curve A in Fig. 3), increased to 180% of that of the natural material. The activities of the modified enzymes with more than three mercaptosuccinyl groups were, however, lower than that of the natural material. Similar results were obtained for the activity measured by the Somogyi-Nelson method (Curve A in Fig. 4); when one mercaptosuccinyl group was attached to the enzyme at 2°C, the activity was 140% of that of the natural

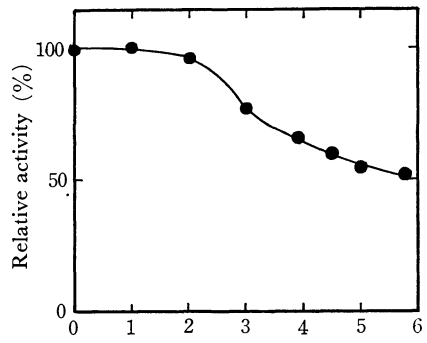

Fig. 5. The activities of native and succinyl Taka-amylase A on amylose measured by the Somogyi-Nelson method.

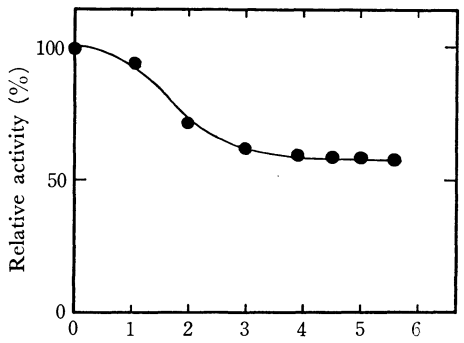

Fig. 6. The activities of native and succinyl Taka-amylase A on amylose measured by the blue value method.

material and 120% of the original activity was retained even after the attachement of six mercaptosuccinyl groups per mole of the enzyme. However, when the modification was made at 25°C, both activities of the modified enzymes decreased in proportion to the number of the mercaptosuccinyl residues introduced into the enzyme (Curves B in Figs. 3 and 4).

The difference between the activities of the modified enzymes prepared at 2°C and 25°C may be due to the difference in the mercaptosuccinylated sites.

Role of the Sulfhydyl Introduced into the Enzyme. The Activity of Succinyl Taka-amylase A. Succinyl Taka-amylase A was prepared has been described in the "Experimental" section, and its activity was compared with that of mercaptosuccinyl Taka-amylase A.

The optimum pH of the succinyl Taka-amylase A was the same as that of the natural enzyme. The activities of the modified enzymes prepared at 2°C were measured by the Somogyi-Nelson method and the blue-value method, and were then plotted against the numbers of succinyl groups introduced into the enzyme. These results are shown in Figs. 5 and 6. No enhancement of the activity was observed on succinylation by either method, in contrast to the case of mercaptosuccinylation.

Effect of the SH Reagents on the Activity of the Mercaptosuccinyl Taka-amylase A. One m*l* of iodoacetamide or *p*-CMB (1.44×10^{-7}M to 3.6×10^{-6}M) solution in a 0.2M phosphate buffer at pH 8.0 was added to 1m*l* of a natural or mercaptosuccinilated enzyme solution (7.2×10^{-9}M). After 4 hr, treatment at 25°C, the mixture was diluted and tested for the enzyme activity by the blue-value method at pH 5.5. The results are shown in Figs. 7 and 8.

The activity of the native enzyme on amylose was not affected by the addition of iodoacetamide (Curve B in Fig. 7), but that of the modified enzyme, which was elevated 1.8 times as compared with

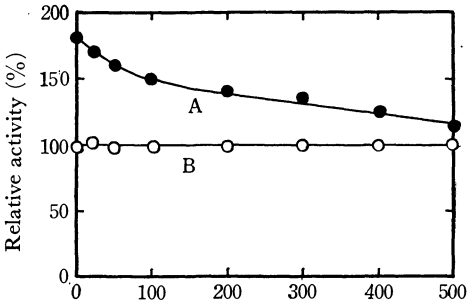

Fig. 7. The inhibition of native (Curve B, open circle) and modified Taka-amylase A (Curve A, closed circle) by iodoacetamide.

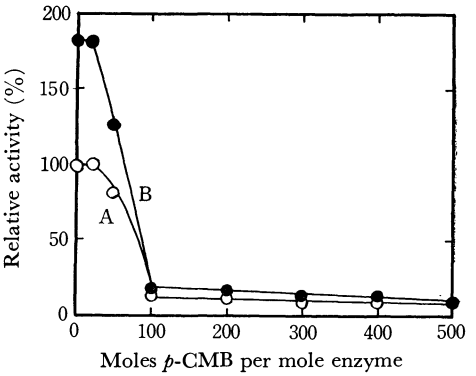

Fig. 8. The inhibition of native (Curve B, open circle) and modified Taka-amylaseA (Curve A, closed circle) by *p*-CMB.

that of the natural enzyme, was appreciably inhibited and approached that of the natural enzyme A in Fig. 7). On the contrary, *p*-CMB inhibited both modified and natural enzymes, as is shown in Fig. 8.

These results suggested that the sulfhydryl group of the mercaptosuccinyl residue plays an important role in the enhancement of the enzymic activity.

and Shoyu Kobayashi

Institute of Molecular Biology, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received May 4, 1970)

A copolymer consisting 95.8% of L-proline and 4.2% of *O*-benzyl-L-tyrosine was transformed in conformation from Form I to Form II as the propanol content changed from 100% to 74%. In Form I, the copolymer took a rod-like structure like that of poly-L-proline Form I, and the *O*-benzyl -L-tyrosyl residue moved independently of the molecular motion of the copolymer. On the other hand, the copolymer became flexible in Form II and the components associated with each other, forming an amorphous aggregation, when the propanol content decreased further, below the transition point. The hydrophobic interaction between the *O*-benzyl-L-tyrosyl side chain and the prolyl residue was the main factor which made the components of the copolymer associate with each other and form an amorphous aggregation. This was verified by a fluorescence study of the *O*-benzyl-L-tyrosyl residue.

Poly-L-proline exists in two forms, Form I and Form II, the structure of which have been elucidated by X-ray crystallography.[1-3] Form I forms, in the solid state, a right-handed helix with a translation of 1.90 Å and a rotation around the helix axis of 108° per proline residue, which the relationship between two successive C_α atoms around an amide bond is *cis*.[3] It has been shown by various investigators that Form I in solution maintains this structure and that its molecular shape is rod-like as a whole.[4] Form II possesses, in the solid state, a left-handed helical conformation with a translation of 3.12 Å and a rotation around the helix axis of 120° per proline residue, and the relationship between two successive C_α atoms around an amide bond is *trans*.[1,2] In solution, however, it has been shown that the polymer in Form II possesses a certain degree of flexibility.[4,5] The interconversion from Form I to Form II is induced by changing the solvent composition from unsubstituted aliphatic alcohol to aliphatic acid or water; this transformation is reversible.[5] The two conformations are very stable even when the temperature is changed.[5] On the other hand, *O*-benzyl-L-tyrosine is an amino acid forming α-helical polypeptide.[6]

We were interested in obtaining information about the states of fluorescent amino - acid side chains in polypeptides and proteins, and also about their secondary or higher structure, by a fluorescence study. One of the available methods was the method of fluorescence polarization measurements which was developed by Weber[7] and which has been applied to many proteins and polypeptides. For instance, Gill *et al.*[8] studied the helix-coil transition of polypeptide using this method. We planned to apply this method to the copolymer containing L-proline and *O*-benzyl-L-tyrosine. To avoid energy transfer between an excited chromophore and a non-excited one, which would complicate the analysis of fluorescence polarization, we used a sample with only a small amount of *O*-benzyl-L-tyrosine (4.2%). Since L-proline and *O*-benzyl-L-tyrosine were amino acids forming different polypeptide conformations, we first investigated the overall shape of the copolymer. In the course of our investigation we found a new fact, that the

components of the copolymer in Form II associated with each other and formed an amorphous aggregation. The hydrophobic interaction between the *O*-benzyl-L-tyrosyl side chain and the L-prolyl residue was the main factor which made the copolymer components associate with each other. This was verified by a fluorescence study of the *O*-benzyl-L-tyrosyl residue of the copolymer.

Experimental

The random copolymer of L-proline and *O*-benzyl-L-tyrosine was obtained by copolymerizing L-prolyl-*N*-carboxyanhydride (L-prolyl-NCA)[9] and *O*-benzyl-L-tyrosyl-NCA[9] in pyridine,[10] the molar ratio of L-prolyl-NCA to *O*-benzyl-L-tyrosyl-NCA being 21 : 1. The insoluble parts which appeared in the course of the polymerization were removed, and from the soluble parts the desired polymer was obtained by precipitation with ether. The precipitant was dissolved in acetic acid, and any insoluble parts which contained the *O*-benzyl-L-tyrosine rich polymer were removed. Then the polymer was reprecipitated with ether and dried under a vacuum. The molar ratio of the L-prolyl residue to the *O*-benzyl-L-tyrosyl residue of the copolymer was 22.6 : 1 (the molar content of *O*-benzyl-L-tyrosine was 4.2%). The average degree of polymerization, n, was determined as $n=72$ by the titration of the free carboxyl group with sodium methoxide in *n*-propanol, using a thymol blue indicator.

The vacuum-dried polymer was dissolved in *n*-propanol. The solution was then left overnight, and a portion was diluted by *n*-propanol and water to give a solution of the required solvent ratio. The final concentration was adjusted to 0.395 g/100 cc for solutions of various solvent ratios. These solutions were then used for measurements of the optical rotatory dispersion (ORD), the viscosity, the ultraviolet (UV) absorption, and the electric birefringence. The concentration of the solutions for the fluorescence measurements was 0.0152 g/100 cc.

The ORD was measured with a JASCO ORD/UV 5 apparatus made by the Japan Spectroscopic Co., Ltd., using a 1-cm cell; the UV absorption spectra with a Carl Zeiss spectrophotometer PMQ II, using a 1-cm cell, and the fluorescence spectra, with a Hitachi Fluorescence Spectrophotometer MPF-2A. The values of polarization,[11] p, were calculated at the 305-mμ emission peak of the *O*-benzyl-L-tyrosine fluorescence spectra with an excitation light of 282 mμ. The relative viscosities were measured in an Ostwald-type viscometer. The flowtime of the water at 25°C was 60 sec. The electric birefringence was measured using the optical method of O'Konski and Zimm[12] according to the usual procedure[13] at 20—23°C.

Results

Two weeks were necessary to obtain a constant value of specific rotation at 300 mμ and at room temperature. The equilibrium values thus obtained are shown in Fig. 1(a). After the equilibrium was

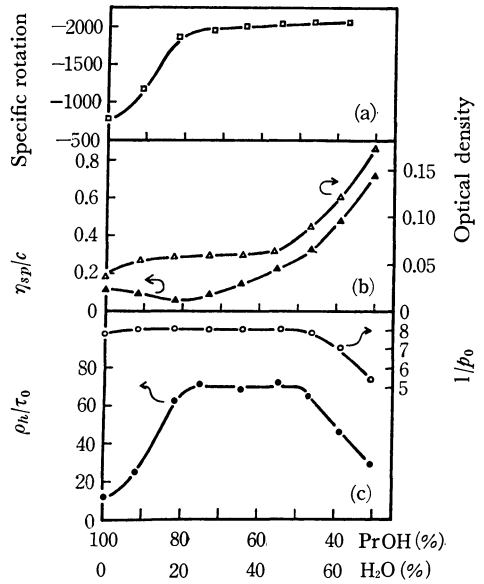

Fig. 1. Variations of specific rotation at 300 mμ (□), optical density at 500 mμ (△), η_{sp}/c (▲), $1/p_0$ (○) and ρ_h/τ_0 for $T/\eta_0=30000$ (●) with solvent composition.

attained, the specific rotation did not change even when the temperature was raised to 56°C. As may be seen in Fig. 1(a), a rapid change in the specific rotation from −615 to −1952 was observed in the range of the propanol content from 100 to 74%, and the rotation was almost unchanged below 74%. This behaviour shows that the copolymer is transformed in conformation from one to another as the solvent composition changes from 100% propanol to 74%. We here call the conformation in 100% propanol "Form I", and that in 74% or less propanol content, "Form II", following the studies of poly-L-proline.[4]

A positive electric birefringence was observed in the range from 100 to 83% of propanol, but it disappeared below 74%. In 100% propanol, a rotational relaxation time of 0.20 μsec was obtained at 20°C. It was suggested from the decay of the birefringence that the distribution of the molecular size was fairly narrow (see Fig. 2).[14]

On the other hand, the reduced viscosity, η_{sp}/c

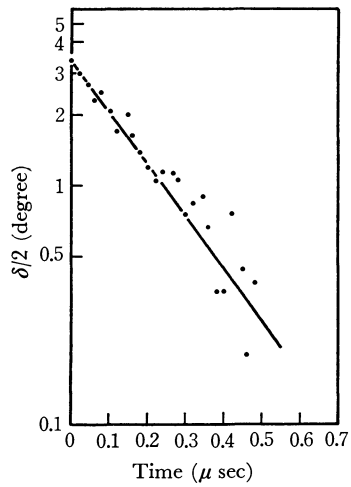

Fig. 2. Decay of electric birefringence of the copolymer in 100% propanol at 20°C.

(c=0.395 g/100 cc), in the same solvent system had its minimum at 83% propanol and rapidly increased below 50% propanol. The optical density at 500 mμ rapidly increased when the propanol content became less than 55% (Fig. 1(b)). Although we observed a small amount of precipitation in 30% propanol, we did not observe any precipitation above that.

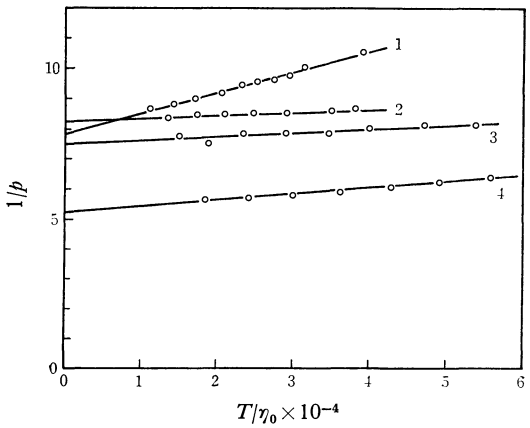

Fig. 3. Plots of reciprocal of polarization, $1/p$, against T/η_0 (degrees Kelvin per centipoise) for the copolymer in 100% propanol (1), 74% propanol (2), 38% propanol (3) and 30% propanol (4).

As may be seen in Fig. 3, linear plots of the reciprocal polarization, $1/p$, against T/η_0 were obtained, where p is the degree of the polarization of light emitted at a right angle to the direction of the excitation and where η_0 is the viscosity of the solvent. Therefore, we can calculate the value of ρ_h/τ_0 according to the Perrin equation:[15]

$$\left(\frac{1}{p}-\frac{1}{3}\right)=\left(\frac{1}{p_0}-\frac{1}{3}\right)\left(1+\frac{3\tau_0}{\rho_h}\right), \quad (1)$$

where τ_0 is the life time of the excited state of O-benzyl-L-tyrosine and where ρ_h is the harmonic mean of the two principal relaxation times of the rotation of the ellipsoidal molecule. The value of ρ_h/τ_0 increased at first as the propanol content decreased from 100% to 83%, stayed constant until 50%, and then decreased below a 50% propanol content (see Fig. 1(c)). The $1/p_0$ values stayed constant in the range from 100 to 50% of propanol, and then decreased below 50%.

Discussion

Assuming that the copolymer takes a rod-like structure in 100% propanol, we can obtain information about the molecular dimensions. We calculated the axial ratio, P, from the viscosity data alone, using the equation of Simha:[16]

$$[\eta]=\frac{\bar{v}\nu}{100} \quad (2)$$

where $\bar{v}$ is the partial specific volume and where ν is the well-known shape factor. We adopted the value of $\bar{v}$=0.758 cm³/g which was found for poly-L-proline.[17] An axial ratio of 8.5 was found for $[\eta]$=0.0868. The expected value of P, as calculated for the rod-like particle possessing the Traub and Shmueli configuration,[3] is 7.6 for n=72. The inconsistency of these two figures is reasonable, because the former assumes an ellipsoidal shape, and the latter, a rod-like one; therefore the value calculated by Eq. (2) may be expected to be larger than the latter.

On the other hand, we can calculate P from the rotational relaxation time, τ_{rot}, if the polymer length is known, by using the equation of Broersma:[18]

$$\frac{1}{6\tau_{rot}}=\frac{3kT}{8\pi\eta_0 a^3}\left[\ln 2P-1.57+7\left(\frac{1}{\ln 2P}-0.28\right)^2\right], \quad (3)$$

where η_0 is the viscosity of the solvent and where $2a$ is the polymer length. If we assume, based on n=72, a rod-like molecule with a length of 137 Å, Eq. (3) leads to P=7.8, which agrees well with the expected value of P=7.6. Therefore, it is confirmed that the copolymer in 100% propanol takes the same rod-like shape as poly-L-proline in Form I. This fact shows that the incorporation of a small amount of O-benzyl-L-tyrosine (4.2%) into poly-L-proline does not destroy the structure of Form I.

On the other hand, when the copolymer was transformed to Form II the electric birefringence disappeared. If the copolymer took a rod-like

shape possessing the Cowan-McGavin configuration[1] (Form II), the electric birefringence should be observed beyond the transition point between Form I and II. Therefore, judging from the absence of the electric birefringence below 74% of propanol, the copolymer should be very flexible in this range. The reduced viscosity had a minimum value at 83% propanol, and increased rapidly below 50%. Even if the copolymer took the structure, Form II, of poly-L-proline, we could not expect a value of reduced viscosity larger than 0.24, judging from Simha's equation[16] and assuming a value of $P=14.4$. The value of the reduced viscosity should actually be smaller than this, since the copolymer chain is flexible rather than stiff and rod-like. Nevertheless, the observed values were larger than this value in the range of low propanol content. The optical density at 500 mμ, where the copolymer should not show any optical absorption, increased below 55%. All these observations suggest that, when the copolymer was transformed from Form I to Form II, the rod-like structure collapsed and the polymer chain became flexible, and that when the propanol content decreased further beyond the transition point between Form I and Form II, the flexible components of the polymer associated with each other, forming an amorphous aggregation which did not contribute to the electric birefringence.

Although poly-L-proline in Form II had a certain degree of flexibility,[4,19] its components have not been reported to associate with each other or to form an aggregation in water at room temperature. In higher temperatures (above 55°C), poly-L-proline in water takes a crystalline phase,[20] but in this discussion we can ignore this phase separation because all our experiments except for the fluorescence study were performed at room temperature, while the fluorescence study was performed using dilute solutions. Therefore, it is very interesting that the copolymer with only a small amount of *O*-benzyl-L-tyrosine (4.2%) became flexible and formed an amorphous aggregation which made solutions very viscous without causing any precipitation when transformed from Form I to Form II in these solvent systems.

It has been shown that the hydrophobic bond is one of the main factors which maintain the secondary or higher structure of polypeptides and proteins.[21] A hydrophobic interaction should exist between the benzyl or tyrosyl group and the prolyl residue. Although this interaction may be absent in 100% propanol, it may be a main factor in making the copolymer components associate with each other and form an amorphous aggregation in the range of low propanol content. This inference was verified by the following fluorescence study of the *O*-benzyl-L-tyrosyl residue.

From the value of ρ_h/τ_0, we can study the motion of the *O*-benzyl-L-tyrosyl residue.[22] For this purpose, it is necessary to know the value of τ_0, which is proportional to the quantum yield of the fluorescent molecule.[23] Since there were insufficient data about the lifetime of the *O*-benzyl-L-tyrosine, we adopted L-tyrosine as a reference. Therefore, it should be noted that the following calculation gives merely a rough estimation of the lifetime of the *O*-benzyl-L-tyrosyl residue in the copolymer. The ratio of the relative quantum yield of the *O*-benzyl-L-tyrosine of the copolymer in 100% propanol to that of L-tyrosine in water (pH 7.0) was obtained as 0.05. The lifetime of the excited state of L-tyrosine in water (pH 7.0) was 2.6 nsec.[24] From these values, $\tau_0=1.3\times10^{-10}$ sec was obtained for the *O*-benzyl-L-tyrosyl residue of the copolymer in 100% propanol, giving a value of $\rho_h=3.0\times10^{-9}$ sec at 20°C. On the other hand, the mean harmonic of the principal relaxation times of the ellipsoidal copolymer, whose volume and axial ratio were 3.48×10^{-20} cm^3 and 8.5 respectively, was 1.3×10^{-7} sec at 20°C in 100% propanol. This value is larger than ρ_h, so it may be concluded that the *O*-benzyl-L-tyrosyl residue moves independently of the molecular motion of the copolymer in Form I.

This fact showed that the hydrophobic interaction between *O*-benzyl-L-tyrosyl residue and prolyl residue did not exist in 100% propanol. It has been reported that alcohols break the hydrophobic bond.[25] In this case also, *n*-propanol might break the hydrophobic interaction between the *O*-benzyl-L-tyrosine side chain and the prolyl residue by covering the side chain with *n*-propanol; the aliphatic groups of *n*-propanol came in contact with the *O*-benzyl-L-tyrosine side chain, and the OH groups were arranged outside. Therefore, it was understandable why the intermolecular association was not observed and the *O*-benzyl-L-tyrosyl residue moved independently of the molecular motion of the copolymer in 100% propanol.

When the propanol content changed from 100% to 80%, the copolymer was transformed in conformation from Form I to Form II, and the ρ_h/τ_0 value increased according to the conformational change. The value was then almost unchanged

over the range from 80% to 50% propanol. We can calculate the ρ_h value by the same procedure as has been described above. In 80% propanol, $\tau_0=0.98\times10^{-10}$ sec and $\rho_h=1.4\times10^{-8}$ sec at 20°C. On the other hand, we have no equation for determining the rotational relaxation time, ρ, of a flexible polymer, so we here calculate the ρ value for a sphere with the same volume as the rod-like poly-L-proline Form II (Cowan-McGavin's configuration), with $n=72$, by means of this equation:

$$\rho = \frac{3\eta_0 v}{kT}$$

where v is the volume of the sphere. We obtain $\rho=8.4\times10^{-8}$ sec for the sphere in 80% propanol at 20°C.

This value is not very different from the ρ_h value. Therefore, it is sure that the hydrophobic interaction between the O-benzyl-L-tyrosine side chain and the prolyl residue begins to occur when the propanol content decreases beyond the transition point between Form I and Form II, and that then the motion of the O-benzyl-L-tyrosyl residue is suppressed. Although this hydrophobic interaction may exist between intramolecular residues, it may also exist between intermolecular residues. Judging from the behaviour of the reduced viscosity and the value of ρ_h/τ_0 beyond the transition point from Form I to Form II, it is reasonable to conclude that intermolecular hydrophobic interaction between the O-benzyl-L-tyrosine side chain and the prolyl residue is a main factor in making the components of the copolymer associate with each other and form an amorphous aggregation.

The suppression of the motion of the O-benzyl-L-tyrosine side chain by the hydrophobic interaction was observed more clearly in 100% water. The value of p in 100% water was much larger than that in the mixed solvents, and it increased as the temperature was raised to 45°C, as may be seen in Fig. 4. This increment can be explained

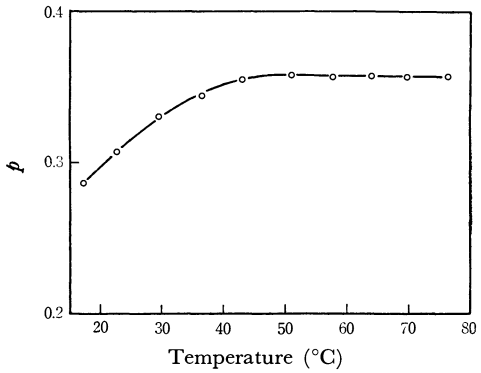

Fig. 4. Plot of polarization, p, against temperature for the copolymer in 100% water.

in terms of the general nature of the hydrophobic interaction.[21] Because of the positive ΔH value and the negative ΔF value, the hydrophobic interaction is more strengthened as the temperature is raised. The value of p decreased slowly above 45°C. This decrease may reveal a thermal rotational Brownian motion by a part of the polymer chain in which the side chain of the O-benzyl-L-tyrosine is fixed by the hydrophobic interaction.

In the propanol-content range from 50% to 30%, where the intermolecular associations became dominant and an amorphous aggregation is formed, the apparent decrease in ρ_h/τ_0 and $1/p_0$ was obvious. One possible interpretation was that the distance between the O-benzyl-L-tyrosyl residues was decreased because of the large amount of intermolecular associations and because energy transfer between the chromophores began to occur; this energy transfer might obviously decrease the value of ρ_h/τ_0.

The authors wish to thank Professor F. Oosawa and the members of his laboratory for their helpful advice and discussions in the course of this investigation. We also wish to thank Mr. M. Yura for his help in synthesizing the sample.

Hydrolysis of Dipeptides with Metal Oxides

Shinnichiro Suzuki and Ken-ichi Watanabe

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received May 14, 1970)

The hydrolysis of three dipeptides, Gly-Gly, Gly-L-Leu, and Gly-L-Phe, with metal oxide catalysts was studied. In most cases, the hydrolysis occurred in the pH range 5—6 accompanied by the formation of metal complexes of amino acids and dipeptides. Copper oxide, nickel oxide, cobalt oxide (III), and alumina have more catalytic activity than copper powder, cuprous oxide, commercial nickel oxide (II), and silica gel. Alumina and silica gel gave no metal complex. It is assumed that the hydrolysis proceeds by means of the formation of an active metal complex of dipeptide or by means of activation on the surface of the catalyst. The order of reactivity of the dipeptides was: Gly-Gly>Gly-L-Leu, Gly-L-Phe.

It has previously been reported[1] that 2-cyanopyridine and pyridine-2-carboxamide are easily hydrolyzed with nickel or copper oxide as a catalyst and that they afford chelate compounds of the acid with nickel or copper. This hydrolysis proceeds when they are refluxed in water without acid or alkali. On the other hand, 3 or 4-cyanopyridine is not hydrolyzed under the same reaction conditions. It is interesting to note that metal catalysts such as nickel or copper have no catalytic activity in this hydrolysis.

To develop this idea, thereupon, we attempted the hydrolysis of some dipeptides with metal oxides in the same manner. It has thus been found that the hydrolysis of dipeptides affords metal chelates of amino acids, along with metal complexes of the dipeptides. It is of interest that the hydrolysis of peptides thus takes place without acid or alkali. It has already been established that specific chelate catalysts,[2,3] an ion-exchange resin[4] or a copper (II) ion[5] can be effectively used for the hydrolysis. The reaction mechanism, especially in relation with metal ion catalyzed hydrolysis, will be discussed.

Results

Hydrolysis of Dipeptides with Metal Oxides. The dipeptides used were glycylglycine (Gly-Gly), glycyl-L-leucine (Gly-L-Leu), and glycyl-L-phenylalanine (Gly-L-Phe). The catalysts used were copper oxide, cuprous oxide, copper powder, nickel oxide-(A) (black), nickel oxide(B) (olive green, II), cobalt oxide (III), aluminum oxide (alumina), and silica gel. Copper powder, cuprous oxide, nickel oxide-(B), and silica gel showed very low activity for the hydrolysis of dipeptides. In general, hydrolysis started in the pH range 5—6. Soon after the reactions with copper oxide, nickel oxide(A), and cobalt oxide catalysts started, the reaction mixture colored, and the coloration was thereafter enhanced gradually. When copper powder, cuprous oxide, and nickel oxide(B) were used, the coloration was very slow. It is obvious that the dipeptides draw out the metal ions from the metal oxides and afford the water soluble metal complexes. The UV spectra of the reaction mixture after thirty minutes refluxing are shown in Table 1. As for the complex of Gly-Gly with copper, it is accordance with the data by Nakahara[6] (λ_{max} 643 mμ, logε=1.92).

Table 1. UV spectra of dipeptide complexes (after 30 min refluxing)

Dipeptide	Catalyst	Color	λ_{max} (mμ)
Gly-Gly	copper oxide	blue	643

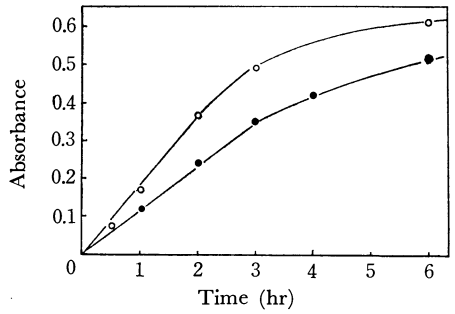

Fig. 1. Formation of dipeptide complexes: dipeptide 0.0023 mol, copper oxide 1.01 g, water 40 m*l*; ○ Gly-Gly, ● Gly-L-Leu. After the sample was diluted to five times with water, the absorbance was measured at 643 mμ for Gly-Gly and at 638 mμ for Gly-L-Leu.

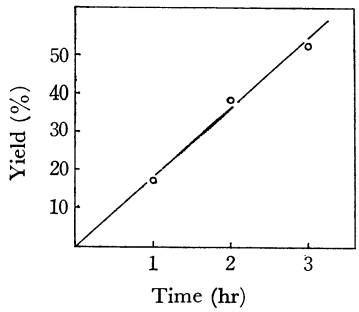

Fig. 2. The yield of Gly-Gly-Cu complex. The yield was calculated on the basis of UV spectrum of Gly-Gly-Cu complex prepared. The amount of glycine hydrolyzed at 3 hr was regarded as negligible.

In an earlier step of the reaction, the reaction solution was treated with ion-exchange resin (Dowex 50×2H type), in order to remove the metal ion, and was then analyzed by paper chromatography. The formation of complexes in the reaction with copper oxide is shown in Fig. 1 and Fig. 2. It is assumed that the formation of the Gly-Gly-Cu complex is *ca.* 50% after 3 hr reaction.

When the refluxing was continued longer than 3 hr, hydrolysis proceeded further in most cases. However, amino acids also formed complexes with metal ions, and usually no free acids were found in the reaction mixtures. The general profiles of the hydrolysis of three dipeptides with various catalysts are shown in Table 2. The pH values in the reactions are also shown in the table. On the whole, the hydrolysis proceeded in the pH range

a) pH: S=starting point, E=end point (21 hr refluxing)
b) The relative intensities of the spots on the chromatograms are represented thus: ···=no spot; tr.= trace, just visible; + to +++, increasing intensity of visible spots.
+: The amount of glycine was examined as 2—5% of the glycylglycine.

5—6 and the pH values increased more or less in the 21 hr reaction.

Since the hydrolysis of dipeptides hardly ever occurs without catalysts in this pH range,[5] it is evident that these metal oxides have a catalytic effect on the hydrolysis. It has been observed that the reactivity of the hydrolysis is dependent upon both the kinds of dipeptides and the kinds of catalysts, and that nickel oxide(A) turns a greenish gray and copper oxide turns brown in part, while the other metal oxides do not change color. Among the metal oxides, alumina is an especially active catalysts. In this case, free amino acid was obtained by the hydrolysis, but no aluminum complex of dipeptide was detected in the reaction mixture. The test was carried out with Gly-Gly (0.3 g) and alumina (1 g) in water (pH 6.3). After refluxing for 6 hr, the catalyst was filtered out and the filtrate was analyzed by the xylenol orange method.[7]

Hydrolysis of Dipeptide Complex. As has been mentioned above, it is apparent that both the formation of dipeptide complexes and the hydrolysis of dipeptides occur during the refluxing with the transition metal oxides. If the hydrolysis could proceed through the complex formation, it may be assumed that the sole dipeptide complex formed is hydrolyzed without catalysts and that it then affords the complexes of amino acids.

In order to examine this assumption, Gly-Gly was refluxed with copper oxide for 45 min, after which the catalyst was filtered out. It was then found by paper chromatography that no free glycine or glycine-Cu complex was present in the blue filtrate. On the other hand, the filtrate (pH 5.7, λ_{max} 643 mμ) was further refluxed and a few samples of it were taken out to be analyzed by paper chromatography. As is shown in Table 3, the hydrolysis of the Gly-Gly-Cu complex took place to give the glycine complex, and free glycine was detected in the solution refluxed for 21 hr. On the other hand, when the Gly-Gly-Cu complex[6] prepared beforehand was refluxed with water under about the same reaction conditions.*1 It gave about the same results (Table 3).

TABLE 3. HYDROLYSIS OF DIPEPTIDE CHELATE

	pH[a]		Gly, time (hr)			
	S	E	1	3	9	21

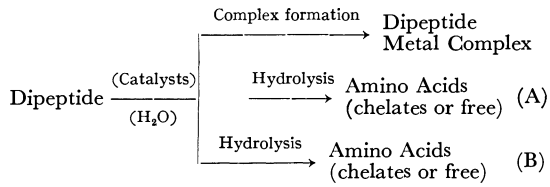
Discussion

As was expected, copper oxide, nickel oxide(A)*2, and cobalt oxide are effective for the hydrolysis of the peptide bond as well as for the specific hydrolysis of 2-cyanopyridine. These transition metal oxides form metal complexes with dipeptides. As a result of our studies, two routes might be proposed for this hydrolysis:



Route A is a mechanism in which metal complexes participate in the hydrolysis of peptides as the ligands; it is supported by the results of the experiment without heterogeneous catalysts (Table 3). In this mechanism, the metal oxides serve only as donors of metal ions to form complexes with dipeptides. As for the hydrolysis shown in Table 3, the concentration of the Gly-Gly-Cu complex is very low; therefore, the reaction velocity may be very slow in comparison with the hydrolysis in the presence of metal oxides. Grant[5] reported the hydrolysis of Gly-Gly with the Cu^{2+} ion in the pH range 3.5—6.0, in which Cu-Gly-Gly^+ type of active complex was assumed to participate in the reaction. In the case of our studies, it is also presumed that an analogous type of species might participate in the hydrolysis of Route A.

Route B is a mechanism which is regarded as a heterogeneous catalytic reaction on the solid surface. It is assumed that the amide bond of dipeptide is activated by the adsorption on the catalysts and that the nucleophilic attack of water may occur. Amino acids, the hydrolysis products, then may draw out the metal ions from the catalysts to form the chelates. When alumina or silica gel was used as the catalyst, free amino acids were obtained without forming any chelate. This is also evidence of direct catalytic hydrolysis. When copper powder, cuprous oxide, or nickel oxide(B) was used as the catalyst, the formation of metal complexes with dipeptides was extremely slow, and the hydrolysis proceeded very slowly, too. Route B might also be possible in the case of hydrolysis with transition metal oxides. It can be inferred, however, that the main route is A rather than B in the reactions with copper oxide, nickel oxide(A), and cobalt oxide.

As is shown in Table 2, the reactivity of dipeptide is in the order: Gly-Gly>Gly-L-Leu, Gly-L-Phe.

*2 In our previous paper,[1] NiO in Tables 1 and 2 should be corrected to nickel oxide (black), which is mentioned as nickel oxide(A) in the present paper.

The relatively low reactivity of Gly-L-Leu and Gly-L-Phe may be due to the steric effect of bulky groups in the α-position of the carboxyl group. This effect has also been pointed out in the case of hydrolysis with acid[8] or ion-exchange resin.[4]

Experimental

Materials. The glycylglycine, glycyl-L-leucine, and glycyl-L-phenylalanine were obtained from the Institute for Protein Research, Osaka University. They were examined by paper chromatography and were proved to be free from extraneous ninhydrin-reacting materials. Commercial copper powder, copper oxide (II), nickel oxide (II) (olive green, called nickel oxide(B) in this paper), cobalt oxide (III), alumina (Aluminum Oxide Woelm Neutral, Germany), and silica gel (300 mesh) were washed with distilled water and were then used as catalysts. The nickel oxide(A) (black) was prepared by the careful decomposition of nickel carbonate at 250—300°C and was then washed with ditstilled water. The cuprous oxide was prepared by the controlled reduction of a complex of copper sulfate and Rochelle salt with glucose.

The Hydrolysis of Dipeptides. 0.0023 mol of dipeptide and 1.0 g of a catalyst were refluxed in 40 m*l* of water. During the refluxing, 0.8 m*l* samples of the reaction mixture were taken out after 1, 3, 9 and 21 hr. Each fraction was filtered to remove a small amount of suspended catalysts, after which filtrate was treated with ion-exchange resin (Dowex 50×2H type) in a column (1 cm in diameter). Then, 1.4% ammonia solution as the eluent was passed through the column. Thus, metal ions were removed from the complexes and a solution containing free amino acid and dipeptide was obtained as the eluent. This was then evaporated *in vacuo* to *ca.* 0.3 m*l* for the analysis. In some cases, the cobalt ions of the complexes were precipitated as sulfide with hydrogen sulfide; the filtrate was then also treated as has been described above. In these processes, no hydrolysis of dipeptides took place.

Analysis of Amino Acids and Dipeptides. The analyses of hydrolyzed amino acids and of unchanged dipeptides were carried out by paper chromatography. Toyo filter paper No. 51 and *n*-butanol - ethanol - water (5 : 5 : 3) as the eluent were used. About a 5-μ*l* portion of the sample solution was spotted, and the chromatograms were run for from 12 to 24 hr. Amino acids and dipeptides were developed with a ninhydrin solution and by warming in an air oven at 95°C for 5 min. The results of the analysis (R_f value and coloration) are shown below.

	Gly-Gly	Gly	Gly-L-Leu	Leu	Gly-L-Phe	Phe
R_f	0.07	0.14	0.33	0.54	0.34	0.48
Color	Yellow	Violet	Yellow	Pink	Yellow	Pink

The authors wish to express their thanks to Professor Kazuo Hata and Professor Michio Kobayashi for their kind advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3861—3865 (1970)

Polyamino-Zucker. V.[1,2] Modellreaktionen zur Aminierung cyclischer Nitrodiole

Toshio NAKAGAWA,*† Tohru SAKAKIBARA* und Frieder W. LICHTENTHALER**

* *Department of Chemistry, Tokyo Institute of Technology, Ō-okayama, Meguro-ku, Tokyo*

** *Institut für Organische Chemie, Technische Hochschule Darmstadt, 61 Darmstadt, B.R.D.*

(Eingegangen am 13. Mai, 1970)

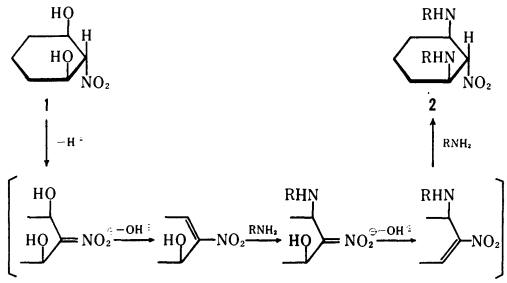
On treatment of 1r,3c-diacetoxy-2t-nitrocyclohexane (**3**) or its 1,3-dimesyloxy analogue **4** with primary amines or ammonia, nitrodiamines (**5**—**11**) are obtained *via* an elimination-addition mechanism. Similar aminations of 1r-methyl-1-nitrocyclohexane-2c,6c-diol (**15**) or its di-*O*-acetate **16** give *C*-methyl branched nitrodiamines (**12**—**14**), which are also formed by reaction of glutaraldehyde with nitromethane and amines. Structures and conformations of the products obtained were deduced from IR and NMR data.

Glutardialdehyd und *cis*-1,3-Dioxolan-2,4-dialdehyd lassen sich mit Nitromethan und Benzylamin in 60 bzw. 53% Ausbeute zu Nitro-bisbenzylamino-Verbindungen cyclisieren, deren Hydrierung auf einfache Weise vicinale Triamine wie 1,2,3-Triaminocyclohexan und 2,3,4-Triaminoidosan zugäng-

*† Dem Andenken von Prof. Dr. Tetsuo Sato gewidmet.

lich macht[3–5]). Die Dialdehyd-Komponente dieser im Sinne einer Bisaminoalkylierung von Nitromethan verlaufenden Cyclisierungsreaktion ist jedoch nicht beliebig variierbar. *o*-Phthaldialdehyd, sowie die aus α- bzw. β-Methyl-D-glucosid und Uridin bzw. Glucosyl-theophyllin durch Perjodoxidation entstehenden Dialdehyde liefern bei analogen Umsetzungen komplexe Gemische, in denen sich dünnschicht chromatographisch bis zu acht Produkte nachweisen lassen. Ähnliche Schwierigkeiten werden bei stufenweiser Durchführung dieser Reaktion, d.h. bei Umsetzung der diesen Dialdehyden entsprechenden Nitromethan-Cyclisierungs produkte[6]) mit Benzylamin oder Ammoniak beobachtet.

Nur im Falle des 2t-Nitrocyclohexan-1r, 3c-diols (**1**)[7]) läßt sich bislang eine zweifache Aminierung glatt vollziehen; mit stark basischen primären oder sekundären Aminen entstehen Nitrodiamine des Types **2** in Ausbeuten über 70%.[3]) Mechanistisch läßt sich der Übergang **1**→**2** einerseits durch basenkatalysierte Ringöffnung im Sinne einer "Retro-Nitromethan-Addition" und anschließender Recyclisierung der aus Aldehyd und Amin gebildete Aminale interpretieren. Da jedoch das Nitromethin-Proton gegenüber dem der OH-Gruppe acider ist, erscheint ein Eliminierungs-Additions-Mechanismus, der hier zweimal, d.h. nach beiden Seiten hin, durchlaufen wird, wahrscheinlicher,[8]) in dem der geschwindigkeitsbestimmende Schritt die Eliminierung der OH-Gruppen sein dürfte. Ihre Überführung in bessere Abgangsgruppen, durch Acylierung oder Sulfonierung erreichbar, sollte unter schonenderen Bedingungen und möglicherweise einheitlicher zu den im Hinblick auf die Synthese von Polyamino-zuckern und -cycliten erwünschten Nitrodiaminen führen—im Hinblick auf die glatt verlaufenden Aminierungen von β-Acetoxy-nitro-Verbindungen mit aromatischen Aminen[11,12]) und mit Ammoniak[11,13–17]) nicht ohne Analogie.



Aus diesen Überlegungen heraus wurden Modellversuche zur Diaminierung von 1r, 3c-Diacetoxy-2t-nitrocyclohexan (**3**) und des 1,3-Dimesyloxy-Derivates (**4**) unternommen, über die wir im folgenden berichten. Sie bildeten die Grundlage zu den inzwischen bereits durchgeführten Synthesen von Triaminoinositen[18,19]), Triaminozuckern[19–21]) und Triaminozucker-Nucleosiden.[22])

Ergebnisse und Diskussion

1. Darstellung cyclischer Nitrodiamine. Während die Umsetzung des Nitrodiols (**1**) mit Anilin nur durch Zusatz von Alkali erreicht werden kann und zu einem Gemisch führt, aus dem das *all-trans*-Isomere(**5**) in mäßiger Ausbeute (16%)

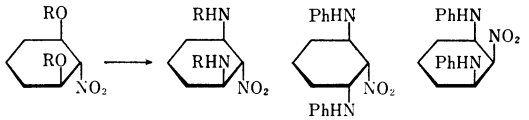
abtrennbar ist,[3] reicht zur Diaminierung des Nitrodiacetates(**3**) die Basizität des Anilins aus. Im entstehenden Isomerengemisch ist **5** jedoch nur in Spuren nachweisbar;[23] es besteht zu etwa gleichen Teilen aus dem *chiro*- (**10**) bzw. *cis*-Isomeren (**11**), die durch fraktionierte Kristallisation getrennt werden können. Damit sind nunmehr alle der theoretisch möglichen Isomere zugänglich.

Unter sehr milden Bedingungen (2 Stdn., 25°C in Chloroform) verlaufen auch die Umsetzungen von **3** oder **4** mit Benzylamin bzw. Cyclohexylamin. Die entsprechenden Nitrodiamine, **6** bzw. **7** entstehen, wie die Ausbeuten(<70%) zeigen, mit hoher Stereoselektivität.



3 R=Ac
4 R=Ms

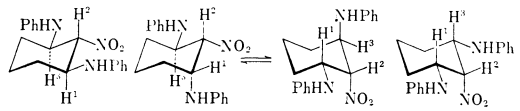
5 R=Ph
6 R=$PhCH_2$
7 R=C_6H_{11}
8 R=H
9 R=Ac

10 **11**

Auch Ammoniak läßt sich als Amin-Komponente einsetzen. So wird **3** sowohl durch Behandeln mit flüssigem Ammoniak, oder unter Bedingungen, wie sie bereits zur Aminierung von β-Acetoxy-nitro-Verbindungen herangezogen wurden—NH_3 in Dioxan,[14,15] Methanol[16] oder Tetrahydrofuran[17]—glatt in das entsprechende Nitrodiamin (**8**) übergeführt, das auf Grund seiner Instabilität[24] zweckmäßigerweise *N*-acetyliert wird. Die Ausbeuten an 1r, 3c-Diacetamino-2t-nitrocyclohexan (**9**) liegen am günstigsten bei Verwendung von Tetrahydrofuran (70%)[25] und wäßrigem Dioxan(74%).

2. Konfigurationsermittlung. Die *all-trans*-Konfiguration (1r,2t,3c)[7] der Verbindungen **5**—**9** geht in eindeutiger Weise aus dem Aufspalutungsmodus des für H^2(CH–NO_2) in $CDCl_3$ erhaltenen Signals hervor. Es wird allen Fällen als ein 1 : 2 : 1-Triplett erhalten—dies beweist bereits die sterische Identität der beiden benachbarten Protonen—mit einer Kopplungskonstante von $J_{1,2}=J_{2,3}\sim 10$ Hz, was die jeweils axiale Orientierung der Ringprotonen an C-1 bis C-3 indiziert.

Entsprechend lassen sich die Konformationen für **10** und **11** bestimmen. Das *cis*-Isomere (**11**) zeigt bei 4.58 τ ein 1.5 Hz-Triplett, das gegenüber dem für **5** erhaltenen (*vgl.* Tabelle) um 1.1 ppm nach niedrigerem Feld verschoben ist, und folglich[26] auf das Vorliegen eines äquatorialen H^2, bzw. einer axialen Nitrogruppe in **11** hinweist. Die für das Nitromethin-Proton in **10** beobachtete Aufspaltung von 2 und 6 Hz ließe sich auf Grund der für eine *Jaa*-Kopplung in Konformation **10a** zu kleinen Werte (z.B. 10 Hz in **5**) mit einer *a,e,e*-Anordnung der Ringwasserstoffe H^1–H^3(**10b**) in Einklang bringen; die chemische Verschiebung des Signals (5.08 τ), die in der Mitte zwischen den für **5** und **11** erhaltenen liegt (*vgl.* Tabelle) weist jedoch eher auf einen schnellen Übergang der beiden Alternativ-Konformationen **10a**⇌**10b** hin.



5 **10a** **10b** **11**

Bemerkenswert sind die Unterschiede, die diese Nitrodiamine in der Lage der NH-Valenzschwingung im Kristall(KBr) aufweisen. Sie wird bei den *trans*-Verbindungen **5**—**7** um 3340 cm^{-1} erhalten, ist bei dem *cis*-Isomeren (**11**) nach höheren Frequenzen (3400 cm^{-1}) verschoben, während bei chiraler Anordung der Substituenten (**10**) beide Banden (*vgl.* Tabelle) auftreten. Diese Abhängigkeit der NH-Streckfrequenz im Kristall von der molekularen Geometrie ist auf intermolekulare Wasserstoffbrückenbindungen zurückzuführen, da diese Unterschiede in Lösung (0.013—0.06 molar, in Chloroform, *vgl.* Tabelle) nicht beobachtet werden. Inwieweit diese Befunde generell zur Konfigurationsermittlung cyclischer Nitrodiamine herangezogen werden können, muß weiteren Untersuchungen vorbehalten bleiben.

Tabelle 1. NMR ($CDCl_3$)- und IR-Daten der isomeren 1,3-Dianilino-2-nitrocyclohexane

Verbindungen (Konfig.)	Lage (τ) und Aufsplatung für H^2(Hz)	NH-Absorptionsbande(cm^{-1})		
		KBr	in $CHCl_3$ 20 mg/ccm	in $CHCl_3$ 4 mg/ccm
5 (*all-trans*)	5.68 *t*(10)	3340	3410	3405
10 (*chiro*)	5.08 *q*(2 und 6)	3340 3410	3430	3420
11 (*all-cis*)	4.58 *t*(1.5)	3400	3425	3420

3. *C*-Methyl-verzweigte Nitrodiamine. Analog zur cyclisierenden Bisaminoalkylierung von Nitromethan[3] lassen sich bei Verwendung von Nitroäthan als Methylenkomponente *C*-Methyl-

23) Dünnschichtchromatographie auf Wako-Gel B5 (*Wako Pure Chemical Industries, Ltd., Japan*), mit Tetrachlorkohlenstoff-Äthylacetat (5 : 1) als Laufmittel; Sichtbarmachung durch Joddampf.

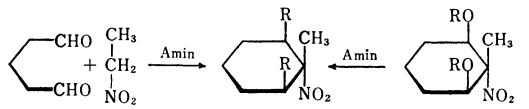
verzweigte Nitrodiamine darstellen. So liefert die Umsetzung von Glutardialdehyd mit Nitroäthan und Benzylamin im Molverhältnis 1 : 2 : 4 1r-Methyl-1-nitro-2c,6c-bisbenzylaminocyclohexan(**12**) in 56% Ausbeute, mit sekundären Aminen wie Piperidin und Morpholin entsprechend die Nitrodiamine **13** und **14**.



12 R = $PhCH_2NH$ **15** R = H

13 R =  **16** R = Ac

14 R = 
Dieselben Produkte lassen sich aber auch—und in besseren Ausbeuten—durch Umsetzung des Glutardialdehyd-Nitroäthan-Cyclisierungsproduktes **15** oder dessen Di-*O*-acetats (**16**) mit den entsprechenden Aminen gewinnen. Dieser Verlauf überrascht insofern, als diese Reaktionen nicht über einen Eliminierungs-Additions-Mechanismus, wie er für die Diaminierungen von **1**, **3** und **4** formuliert wurde, ablaufen können. In Ermangelung eines Nitromethin-Protons im Nitrodiol **15**—**16** wird unter den Reaktionsbedingungen primär ent-*O*-acetyliert dürfte hier durch die Base ein OH-Proton abstrahiert weden, wodurch Ringöffnung im Sinne einer "Retro-Nitroäthan-Cyclisierung" eintreten kann mit nachfolgender Recyclisierung der aus Aldehyd und Amin gebildeten Zwischenprodukte.

Beschreibung der Versuche

Die Schmelzpunkte wurden in Kapillarröhrchen bestimmt und sind nicht korrigiert. Die IR-Spektren wurden mit einem Hitachi-Perkin-Elmer 225 Gerät, die NMR-Spektren mit dem Jeolco 100 MHz-Gerät aufgenommen (in ppm, τ-Skala).

1r,3c-Dimesyloxy-2t-nitrocyclohexan (**4**). Zu 4.2 g (26 mMol) 2t-Nitrocyclohexandiol-(1r,3c) (**1**)[3,27] in 50 m*l* Toluol wurde unter Eiskühlung und Rühren ein Gemisch von 6.5 g (57 mMol) Methansulfochlorid und 4.5 m*l* Pyridin in 20 m*l* Benzol zugetropft und danach 5 Stdn. gerührt. Nach Abdampfen des Lösungsmittels i. Vak. und Versetzen des Rückstandes mit Wasser wurde der gebildete Niederschlag abgesaugt und aus Methanol umkristallisiert: 650 mg (8%) farblose Nadeln vom Schmp. 166—167°C. IR (KBr): 1565 (NO_2); 1345, 1180 cm^{-1} (SO_2); NMR ($CDCl_3$): τ 5.35 (1H-*t* mit $J_{1,2}=J_{2,3}=9.5$ Hz, $CHNO_2$); 7.01 (6H-*s*, $2CH_3SO_2$).

1r,3c-Bis benzylamino-2t-nitrocyclohexan (**6**). *a) Aus 1r,3c-Diacetyloxy-2t-nitrocyclohexan* (**3**). Zu 2.45 g (10 mMol) **3**[27] in 10 m*l* alkohol-freiem Chloroform wurden 5.5 m*l* (5 Moläquiv.) Benzylamin gegeben und 2 Stdn. bei Raumtemperatur stehengelassen, wobei sich ein Niederschlag (Benzylamin-Hydroacetat) absetzte. Das Reaktionsgemisch wurde i. Vak. eingedampft, der Rückstand mit 5 m*l* Methanol versetzt und Wasser bis zur beginnenden Trübung zugegeben. Nach Stehenlassen über Nacht im Kühlschrank wurde der Niederschlag abgesaugt, zweimal mit wäßrigem Methanol (1 : 1) und dann gut mit Wasser gewaschen. Nach Umkristallisation aus Methanol: 2.7 g (79%) farblose Nadeln; Schmp. 90—91°C (Lit.[2,3] 90—91°C). IR- und NMR-Spektren waren mit dem aus **1** mit Benzylamin dargestellten Produkt[3] identisch.

b) Aus 1r,3c-Dimesyloxy-2t-nitrocyclohexan (**4**). Eine Lösung von 0.32 g (1 mMol) **4** in 10 m*l* alkohol-freiem Chloroform wurde mit 0.6 m*l* (5 mMol) Benzylamin versetzt, nach Stehenlassen über Nacht bei Raumtemperatur zweimal mit Wasser gewaschen, die organische phase über Na_2SO_4 getrocknet und i. Vak. eingedampft. Umkristallisation aus Methanol ergab 0.24 g (70%) **6**.

1r,3c-Bis-cyclohexylamino-2t-nitrocyclohexan (**7**). 2.45 g (10 mMol) **3** in 10 m*l* Chloroform wurden mit 5.5 m*l* (5 Moläquiv.) Cyclohexylamin versetzt und 2 Stdn. bei Raumtemperatur stehengelassen. Die Aufarbeitung erfolgte analog der Umsetzung von **2** mit Benzylamin (*s. oben*): 2.3 g (71%); Schmp. 118—120°C (Lit.[3]: 119—120°C). Das IR-Spektrum war mit dem aus **1** dargestellten Produkt[4] identisch.

1r,3c-Diacetamino-2t-nitrocyclohexan (**9**). In eine Lösung von 2.45 g (10 mMol) **3**[27] in 100 m*l* Dioxan wurde bei 40°C 5 Stdn. trockenes Ammoniak-Gas eingeleitet, sodann zur Entfernung noch gelösten Ammoniaks i. Vak. auf *ca.* 50 m*l* konzentriert,[28] unter Eiskühlung mit Acetanhydrid (8 m*l*) versetzt und über Nacht bei Raumtemperatur stehengelassen. Der entstandenne Niederschlag wurde abgesaugt und zusammen mit der aus der Mutterlauge durch Eindampfen zur Trockene und Behandeln mit Wasser gewonnenen zweiten Fraktion umkristallisiert (Methanol/Wasser): 1.81 g (74%) feiner Nadeln; Schmp. 294—296°C (Zers.) nach Sublimation um 245°C. NMR (DMSO-d_6): τ 1.91 (2H-*d* mit J= 9 Hz, NH); 5.58 (1H-*t* mit $J_{12}=J_{23}=9.5$ Hz, H^2); 5.86 (2H-*m* H^1 und H^3), 8.26 (6H-*s*, *N*Ac).

Gef.: C, 49.29; H, 7.13; N, 17.24%. Ber. für $C_{10}H_{17}N_3O_4$: C, 49.37; H, 7.04; N, 17.28%.

Umsetzungen von **3** in NH_3/Methanol (3 Stdn., 25°C), in flüssigem NH_3 (2 Stdn., −40°C) lieferte nach analoger Aufarbeitung **9** in 40—50% Ausbeute.

DL-*1r,3c-Dianilino-2c-nitrocyclohexan* (**11**) und *1r,3t-Dianilino-2c-nitrocyclohexan* (**10**). 9.8 g (40 mMol) **3**, in 18 m*l* (0.2 Mol) frisch dest. Anilin gelöst, wurden mit 50 m*l* absol. Methanol versetzt und 5 Tage bei Raumtemperatur stehengelassen. Nach Absaugen des gebildeten Niederschlags, der neben Spuren **5** (R_f=0.22[23]) etwa gleich Mengen an **10** und **11** (R_f=0.54 bzw. 0.64[23]) enthielt, wurde fraktioniert. Umkristallisation aus 500 m*l* Methanol lieferte eine Kristallfraktion (**11**), Eindampfen der Mutterlauge zur Hälfte und Stehenlassen über Nacht eine zweite, aus Nadelbüscheln (**11**) und Prismen (**10**) bestehend, die beim Absaugen bleicht manuell getrennt werden konnten.

Die **10** bzw. **11** enthaltenden Fraktionen wurden jeweils zweimal aus Methanol umkristallisiert: 2.5 g

* *Department of Chemistry, Tokyo Institute of Technology, Ō-okayama, Meguro-ku, Tokyo*

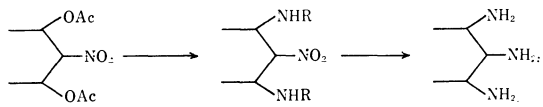
** *Institut für Organische Chemie, Technische Hochschule Darmstadt, 61 Darmstadt, BRD*

(Eingegangen am 13. Mai, 1970)

A facile synthesis of methyl and phenyl glycoside derivatives of 2,3,4-triamino-2,3,4-trideoxy-β-D-glucopyranose is described, involving as the integral part the diamination with benzylamine or ammonia of 2,4,6-tri-*O*-acetyl-3-deoxy-3-nitro-hexosides of *gluco*- and *galacto*-configuration.

Obwohl bislang keine Kohlenhydrate mit mehr als zwei Aminofunktionen in der Natur aufgefunden wurden, hat sich der Chemie von Polyamino-zuckern und -cycliten in den letzten Jahren beachtliches Interesse zugewandt[2-8] Die vorwiegend benutzte Methode zur Einführung der Amino-Gruppen war hierbei die bei der Synthese von Mono- und Diamino-zuckern bewährte Solvolyse von Sulfonester-Gruppierungen durch Natriumazid mit anschließender Reduktion der Azido-Verbindungen.[2-5] Andere Verfahren[6-8] kamen dagegen nur sporadisch zur Anwendung; sie waren entweder präparativ zu aufwendig, oder konnten nur Synthese speziller Verbindungen, wie, z.B. *cis*-Inosatriamin-1,3,5 durch Hydrierung von Triaminophloroglucin[6] herangezogen werden.

Aus der Fortführung unserer Arbeiten zur cyclisierenden Bisaminoalkylierug von Nitromethan[7,9] sowie zur Diaminierung cyclischer Nitrodiole[9] hatte sich ergeben, daß bei Verwendung von Nitrodi-*O*-acetaten (**1**) auch mit Ammoniak als Amin-Komponente eine glatte Diaminierung zu Verbindung des Typs **2** (R=H bzw. Ac) erreicht werden kann,[1] deren Hydrierung vicinale Triamine (**3**) liefert. Durch Übertragung dieses Syntheseprinzips (**1**→**2**→**3**) auf Polyacetate von Nitrozuckern, durch Nitromethan-Cyclisierung von Zuckerdialdehyden leicht zugänglich,[10] eröffnete sich ein einfacher, generell gangbarer Syntheseweg in die Reihe der Triaminozucker und Inosatriamine, worüber wir im folgenden—zunächst an Hand der Synthese von 2,3,4-Triamino-2,3,4-tridesoxy-glucosiden[11]—berichten.



1 **2** **3**

Ergebnisse und Diskussion

Bei Diaminierung von Methyl-2,4,6-tri-*O*-acetyl-3-desoxy-3-nitro-β-D-glucopyranosid (**4**) oder dem entsprechenden Derivat mit galacto-Konfiguration (**5**) können theoretisch acht Isomere gebildet werden. Da diese Reaktion jedoch über einen Eliminierungs-Addition-Mechanismus verlaufen dürfte,[1] ist zu erwarten, daß die Isomeren-Verteilung im entste-

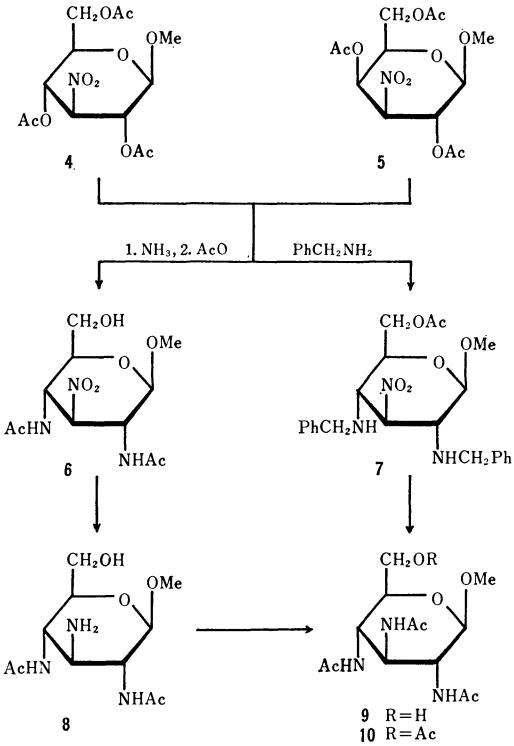
henden Nitrodiamin-Gemisch nur vom sterischen Verlauf der Ammoniak-Addition an die intermediär gebildeten Nitroolefine bestimmt wird, nicht dagegen von der sterischen Anordnung der funktionellen Gruppen im Nitro-diacetat-Vorläufer. Des weiteren sollte diese Umsetzung im Hinblick auf die bevorzugte äquatoriale Addition von Nucleophilen an Methyl-4,6-*O*-benzyliden-2,3-didesoxy-β-D-erythro-hex-2-enosid[12] mit hoher Stereoselektivität verlaufen, und zwar zugunsten der Bildung des Isomeren mit all-äquatorialer Orientierung der Substituenten.

Die experimentelle Befunde bestätigen diese Folgerungen. Bei Umsetzungen von Methyl-2,4,6-tri-*O*-acetyl-3-desoxy-3-nitro-β-D-glucopyranosid (**4**) oder der entsprechenden *galacto*-Verbindung (**5**) mit Ammoniak in Methanol und anschließender *N*-Acetylierung läßt sich Methyl-2,4-diacetamino-2,3,4-tridesoxy-β-D-glucopyranosid (**6**) in 53 bzw. 47% Ausbeute isolieren. Analoge Umsetzungen von **4** und **5** in flüssigem Ammoniak liefern dagegen niedrigere Ausbeuten (25—30%) an **6**. Bei Verwendung von Benzylamin als Amin-Komponente läßt sich die Diaminierung von **4** oder **5** unter Bedingungen durchführen (3 Stdn. in Chloroform bei 25°C), die keine gleichzeitige Ent-*O*-acetylierung der *C*-6-Acetoxy-Gruppe bewirken. Man erhält Methyl-6-*O*-acetyl-2,4-bisbenzylamino-2,3,4-tridesoxy-3-nitro-β-D-glucopyranosid (**7**) in Ausbeuten bis zu 35%.

Die Hydrierung der Nitro-Gruppen in **6** und **7** bereitet keine Schwierigkeiten. Mit 5—10% Palladium/Tierkohle/Wasserstoff entstehen aus **6** das Di-*N*-acetat **8**, als Hydroacetat charakterisiert, aus **7** infolge gleichzeitiger Hydrogenolyse der Benzyl-Reste ein Triamin, aus dem durch Acetylierung—ebenso wie aus **8**—das Tetraacetat des Methyl-2,3,4-triamino-2,3,4-tridesoxy-β-D-glucosids (**10**) erhalten wird.

In analoger Weise lassen sich 1-Phenyl-Derivate (**14**—**16**) darstellen, die aufgrund ihrer Überführbarkeit in 1,6-Anhydrozucker[13] Interesse besitzen. Ausgehend von Phenyl-β-D-glucopyranosid (**11**) wurde hierbei durch Perjodat-Oxidation und anschließenden Nitromethan-Cyclisierung primär Phenyl-3-desoxy-3-nitro-β-D-glucopyranosid (**12**) dar-



gestellt und dann mit Acetanhydrid/BF_3 in das Tri-*O*-acetat (**13**) übergeführt. Die Diaminierung von **13** mit Benzylamin lieferte in 59% Ausbeute die entsprechende Nitro-bisbenzylamino-Verbindung (**15**), während Umsetzung mit Ammoniak/Methanol und anschließende *N*-Acetylierung das Nitro-di-*N*-acetat **14** (44%) ergab. Beide konnten durch Hydrierung und Acetylierung in Phenyl-2,3,4-triacetamino-2,3,4-tridesoxy-β-D-glucopyranosid (**16**) übergeführt werden.

Die *gluco*-Konfiguration der Verbindungen **7**—**10** und **12**—**16** ließ sich eindeutig aus NMR-spektroskopischen Daten (*vgl.* Tabelle) ableiten. Für das anomere Proton (H^1) wird jeweils ein Dublett mit $J_{1,2}$=8—9 Hz erhalten, für das Nitro-methin-Proton (H^3) 1 : 2 : 1-Triplett mit $J_{2,3}=J_{3,4}$=10—11 Hz, was das Vorliegen axialer Ring-CH, bzw. äqua-

Beschreibung der Versuche

Die Schmelzpunkte wurden in Kapillarröhrchen bestimmt und nicht korrigiert. Die IR-Spektren wurden mit dem Perkin-Elmer-125 Gerät, die NMR-Spektren mit Varian-A60- bzw. Jeolco JNM-4H-100-Geräten (in ppm, τ-Skala) aufgenommen. Zur Dünnschichtchromatographie diente Kieselgel PF_{254} der *Fa. E. Merck AG, Darmstadt*; Schichtdicke 0.2 mm; Laufmittel: Essigester-Äthanol-Wasser 15 : 2 : 1.

Methyl-2,4-diacetamino-2,3,4-tridesoxy-3-nitro-β-D-glucopyranosid (**6**). In eine Lösung von 4.2 g (14 mMol) **4**[16] in 500 m*l* Methanol wurde unter Eiskühlung und Rühren 2 Stdn. ein schwacher Ammoniakstrom eingeleitet und danach noch 1 Stde. stehengelassen. Der nach Abziehen des Lösungsmittels i. Vak. und Nachdampfen mit Methanol (100 m*l*) verbleibende Sirup wurde in 250 m*l* Methanol aufgenommen, mit 20 m*l* Acetanhydrid versetzt und über Nacht bei Raumtemperatur stehengelassen. Nach Eindampfen i. Vak. und mehrmaligen Nachdampfen mit Äthanol ließ man aus Äthanol kristallisieren. Umkristallisation aus Äthanol ergab 2.2 g (53%) farbloser Kristalle vom Schmp. 285°C (Zers.) und $[\alpha]_D^{22}$ −9.3° (*c* 0.4, Methanol); IR (KBr): 3545 (OH), 3270 (NH), 1660 (Amid I), 1555—1545 (Amid II, NO_2), 1375 cm^{-1}(NO_2).

Gef.: C, 43.48; H, 6.24; N, 13.48%. Ber. für $C_{11}H_{19}N_3O_7$: C, 43.27; H, 6.27; N, 13.76%.

Umsetzung von **5** mit Ammoniak unter gleichen Bedingungen lieferte **6** in 47% Ausbeute. Bei Aminierung von **4** bzw. **5** mit flussigem Ammoniak (8 Stdn., −40°C) und anschließender *N*-Acetylierung liegen die Ausbeuten an **6** tiefer (25—30%).

Methyl-6-O-acetyl-2,4-bisbenzylamino-2,3,4-tridesoxy-3-nitro-β-D-glucopyranosid (**7**). 3.5 g (10 mMol) **4** in 20 m*l* Chloroform wurden unter Rühren mit 7 m*l* Benzylamin versetzt und 3 Stdn. bei Raumtemperatur stehengelassen. Nach Abziehen des Chloroforms i. Vak. wurde in 5 m*l* Methanol aufgenommen, mit Wasser bis zur beginnenden Trübung versetzt und der ausgeschiedene Niederschlag nach 12-stdgm. Stehen im Kühlschrank abgesaugt. Waschen mit Methanol/Wasser (1 : 1) und Wasser lieferte nach Umkristallisation aus Äthanol/Petroläther 1.5 g (35%) farbloser Nadeln; Schmp. 138—139°C (Zers.), $[\alpha]_D^{20}$ +18° (*c* 1.5, Chloroform); IR (KBr): 3300 (NH), 1735 (OAc), 1560 und 1370 cm^{-1} (NO_2). NMR ($CDCl_3$): τ 5.49 (1H-*t*, J=10 Hz, H^3), 5.82 (1H-*d*, J=8 Hz, H^1), 7.96 (3H-*s*, *O*Ac).

Gef.: C, 62.53; H, 6.51; N, 9.40%. Ber. für $C_{23}H_{29}N_3O_6$: C, 62.29; H, 6.59; N, 9.48%.

Die analoge Umsetzung von **5** mit Benzylamin ergab **7** in 20% Ausbeute.

Methyl-2,4-diacetamino-3-amino-2,3,4-tridesoxy-β-D-glucopyranosid Hydroacetat (**8**-HOAc). 850 mg (2.8 mMol) **6** in 50 m*l* Methanol wurden zu einer vorhydrierten Suspension von 600 mg 10% Palladium/Tierkohle in 50 m*l* Methanol gegeben und die stöchiometrische Menge Eisessig zugesetzt. Nach *ca.* 1 Stde. fiel ein weißer Niederschlag aus, der durch Zusatz von 60 m*l* Wasser wieder in Lösung gebracht wurde. Nach 24 Stdn. war der berechnete Wasserstoff aufgenommen. Die Lösung wurde filtriert, und das Lösungsmittel abgezogen. Dabei schieden sich 830 mg des Hydroacetats als weiße Kristalle ab, Zers.-P.: ab 240°C, $[\alpha]_D^{22}$ −14.2° (*c* 1, Wasser).

Gef.: C, 46.10; H, 7.35; N, 12.31%. Ber. für $C_{13}H_{25}N_3O_7$: C, 46.56; H, 7.51; N, 12.53%.

Methyl-2,3,4-triacetamino-2,3,4-tridesoxy-β-D-glucopyranosid (**9**). 950 mg (3.1 mMol) **8**-Hydroacetat wurden in 25 m*l* Methanol unter Rühren und Eiskühlung mit 1.2 m*l* Acetanhydrid versetzt. Nach 30 Min. bildete sich eine klare Lösung, aus der beim Stehen im Kühlschrank (4°C) Kristalle ausfielen. Das Lösungsmittel wurde abgezogen, mehrmals mit Äthanol nachgedampft und aus Äthanol mit wenig Wasser umkristallisiert: 825 mg (87%) weiße Kristalle, Zers.-P. 315°C,

b) Durch Hydrierung und Acetylierung von **7**. 2.2 g (5 mMol) **7** wurden in 50 m*l* Methanol und 3 m*l* Eisessig gelöst, und zu einer vorhydrierten Suspension von 500 mg Palladium/Tierkohle gegeben und die Hydrierung fortgesetzt, bis die berechnete Menge Wasserstoff aufgenommen war (2 Tage). Die Lösung wurde filtriert, mit Ammoniak neutralisiert, das Lösungsmittel abgezogen und mit 10 m*l* Äthanol nachgedampft. Der Rückstand wurde unter Eiskühlung und Rühren mit 6 m*l* Pyridin und 4 m*l* Acetanhydrid versetzt, über Nacht bei Raumtemperatur stehengelassen, die Lösungsmittel abgezogen, dreimal mit Äthanol/Toluol (1 : 1) nachgedampft und aus Äthanol umkristallisiert; 1.1 g (61%) farblose Nadeln, die mit der nach a) gewonnenen Substanz völlig übereinstimmten.

Phenyl-3-desoxy-3-nitro-β-D-glucopyranosid **(12).** Zu einer Lösung von 42.8 g (0.2 Mol) Natriummetaperjodat in 500 m*l* Wasser wurde innerhalb 10 Min. unter Eiskühlung und Rühren ein Gemisch von 29.2 g (0.1 Mol) Phenyl-β-D-glucopyranosid-dihydrat (**11**)[17] und 8.4 g Natriumhydrogencarbonat in mehreren Anteilen zugegeben. Nach 6 Stdn. wurde mit 400 m*l* Methanol versetzt, ein gebildeter Niederschlag abfiltriert und das Filtrat bei 40°C i. Vak. zur Trockne eingedampft. Der Rückstand wurde mit 60 m*l* Äthanol und 30 m*l* Äther versetzt, wieder filtriert und erneut eingedampft. Nach nochmaliger Wiederholung dieser Operation erhielt man einen klaren Sirup, der in 60 m*l* Methanol gelöst und mit 8 m*l* Nitromethan und dann tropfenweise mit 10 m*l* 2N Natriummethylat unter Eiskühlung und Rühren versetzt wurde. Nach Stehen über Nacht bei Raumtemperatur wurde das kristalline Produkt (10.4 g) abgesaugt. Aus der Mutterlauge wurde nach Neutralisierung mit Kationenaustauscher (H^+-Form) und Eindampfen auf ein Viertel des Volumens weitere 3.3 g erhalten. Das gesamte Rohprodukt wurde aus Äthanol/Petroläther umkristallisiert: 12.8 g (45%) farblose Kristalle, Zers.-P. 215—216°C, $[\alpha]_D^{20}$ −27.8° (*c* 0.85, Dioxan); IR (KBr): 3200, 3350, 3470 (OH), 1560, 1370 cm^{-1} (NO_2); NMR (DMSO-d_6): 4.88 (1H-*d*, J=8 Hz, H^1), 5.30 τ (1H-*t*, J=10 Hz, H^3).

Ester-Urethane Interchange Reaction

Hajime SUZUKI

Katata Research Institute, Toyobo Co., Ltd., Honkatata, Otsu

(Received June 1, 1970)

The ester-urethane interchange reaction has been studied by means of gas chromatography and NMR. The interchange reaction between low-molecular-weight ester and urethane was confirmed by the gas chromatography. Alternating copolyester-urethane was prepared by reacting bis-(hydroxyethyl)terephthalate with hexamethylene diisocyanate in anisole. When the polymer is melted at 190°C in the presence of sulfuric acid as a catalyst, the ester-urethane interchange reaction in alternating copolyester-urethane proceeds and causes a more random arrangement of the segments. This was proved by high-resolution nuclear magnetic resonance spectroscopy. An ethylene glycol residue adjacent to terephthalate on both sides, to diisocyanate on both sides, and to terephthalate and diiosyanate could be identified at 4.93, 4.48, and 4.71 ppm respectively in trifluoroacetic acid.

It is well known that condensation copolymers can be obtained by the following three general methods. One method is polycondensation with different kinds of monomer mixtures. The second is a so-called step-by-step polymerization with several kinds of monomer mixtures. Polyurethane elastomers are usually prepared by this method.[1] The third is an interchange reaction with different kinds of homopolymer mixtures. Copolyesters[2] and copolyamides[3] are easily prepared by this method. Usually, copolyester-urethane can be synthesized by the first and second methods. Recently, polyurethane was obtained by the urethane interchange reaction of dimethyl butane-1,4-dicarbamate with glycol;[4] however, no report has appeared describing the synthesis of copolyester-urethane by the interchange reaction. Therefore, this paper will describe the possibility of the synthesis of random copolyester-urethane from alternating copolyester-urethane by the ester-urethane interchange reaction.

The interchange reaction between low-molecular-weight urethane and an ester was studied as a model for the polymer by the aid of gas chromatography. The interchange reaction in polymer may be investigated by the following two methods; (1) an ester-urethane interchange reaction between the homopolyester and homopolyurethane and (2) an ester-urethane interchange reaction in the alternating copolyester-urethane. The melting points of polyethylene terephthalate, polyethylene hexamethylenecarbamate, and alternating copolyester-urethane prepared from hexamethylene diisocyanate and bis(hydroxyethyl)terephthalate are 256, 178, and 179°C respectively. Therefore, the transesterification reaction can be carried out at a lower temperature by using the alternating copolyester-urethane. In this work, the interchange reaction between ester groups and urethane groups in the polymer was studied through a transesterification reaction in the alternating copolyester-urethane, and was confirmed by NMR spectroscopy.

Experimental

Materials. Ethyl benzoate, *n*-butyl benzoate, *n*-butyl *n*-butyrate, and ethyl *n*-butyrate were fractionally distilled twice. *n*-Butyl phenylcarbamate, ethyl phenylcarbamate, ethyl *n*-propylcarbamate, and *n*-butyl propylcarbamate were prepared by reacting the corresponding isocyanates with alcohols. These structures were confirmed by elementary analysis and by a study of their NMR spectra; the gas chromatographs of these compounds showed them to be pure substances.

Interchange Reaction between Low-molecular-weight Urethane and Ester. Interchange reactions were carried out in sealed ampoules at 190°C for 43 hr. The products obtained by the interchange reaction were confirmed by comparing their retention times on gas chromatography with those of authentic samples. The gas chromatography was performed with a Yanagimoto gas chromatograph, model G8, with 15 ml/min of helium, using a 1.5-m column containing silicon DC-550 at 200°C.

Interchange Reaction in Molten Copolyester-urethane. Copolyester-urethane was prepared by reacting bis(hydroxyethyl)terephthalate with hexamethylene diisocyanate in anisole. The ester-urethane interchange reaction in the copolyester-urethane was carried out at 190°C in a stream of nitrogen, and new sequence units in the copolyester-urethane were confirmed by a

study of the NMR spectra. The NMR spectra were obtained with a Varian A-60 spectrometer operating at 60 MHz. The solutions containing 15% (w/v) polymers and tetramethylsilane as an external reference in trifluoroacetic acid were run at room temperature.

The viscosity measurements of polymers obtained by interchange reactions were carried out in an Ubbelohde viscometer at 30±0.03°C.

Results and Discussion

Confirmation of Interchange Reaction between Low-molecular-weight Urethane and an Ester. The interchange reaction was carried out in a sealed ampoule at 190°C for 43 hr in the presence of 0.05% sulfuric acid as the catalyst. Figure 1. (A)—(F) shows the results of the gas-

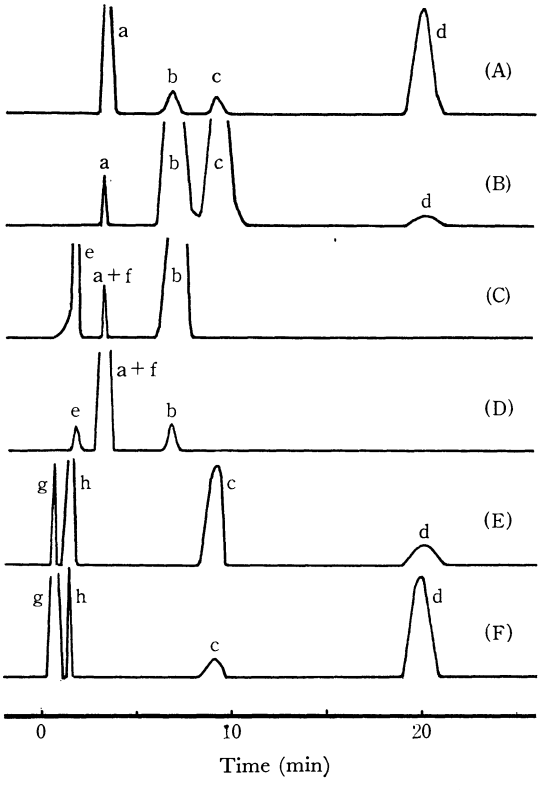

Fig. 1. Gas chromatograms of reaction mixtures. a, Ethyl benzoate; b, *n*-Butyl benzoate; c, Ethyl phenylcarbamate, d, *n*-Butyl phenylcarbamate; e, Ethyl *n*-propylcarbamate; f, *n*-Butyl *n*-propylcarbamate; g, Ethyl *n*-butyrate h, *n*-Butyl *n*-butyrate

chromatographic analysis of reaction mixtures of low-molecular-weight urethane and an ester. The peaks were identified by means of the retention data of pure substances. When the interchange reactions were carried out without sulfuric acid as the catalyst but otherwise under the same conditions as above, no new peak could be observed.

There have been a number of reports concerning the thermal dissociation of urethane.[5-7] These reactions can be shown by the following equations:

$$RNCO + R'NHCOOR'' \longrightarrow RNHCOOR'' + R'NCO \quad (1)$$

$$ROH + R'NHCOOR'' \longrightarrow R'NHCOOR + R''OH \quad (2)$$

$$RCOOH + R'NHCOOR'' \longrightarrow R'NHCOR + CO_2 + R''OH \quad (3)$$

It has been reported that ester interchange and interchange reaction between as ester and alcohol proceed easily. Judging from these reports, the first step in an interchange reaction between urethane and ester groups is probably the thermal dissociation of a urethane group, as is shown in Eq. (4). Therefore, the following reaction scheme may hold in the reaction between ester and urethane groups:

$$R_1COOR_2 + R_3NHCOOR_4 \rightleftarrows R_1COOR_2 + R_3NCO + R_4OH \quad (4)$$

$$R_1COOR_2 + R_3NCO + R_4OH \rightleftarrows \begin{pmatrix} R_1COOR_2 \\ \vdots \\ O-H \\ | \\ R_4 \end{pmatrix} + R_3NCO \quad (5)$$

$$\begin{pmatrix} R_1COOR_2 \\ \vdots \\ O-H \\ | \\ R_4 \end{pmatrix} + R_3NCO \rightleftarrows R_1COOR_4 + R_3NCO + R_2OH \quad (6)$$

$$R_1COOR_4 + R_3NCO + R_2OH \rightleftarrows R_1COOR_4 + R_3NHCOOR_2 \quad (7)$$

Confirmation of Interchange Reaction in Molten Copolyester-urethane. Recently, Miyake[4] synthesized polyurethane by the carbamate exchange reaction shown in the following scheme:

$$CH_3OCONH(CH_2)_4NHCOOCH_3 \xrightarrow[-CH_3OH]{+HO(CH_2)_nOH} [(CH_2)_nOCONH(CH_2)_4NHCOO]_m \quad (8)$$

The first step in the reaction may be assumed to proceed as is shown in Eq. (4). If the ester-urethane interchange reaction in copolyester-urethane proceeds, random copolyester-urethane may be prepared from the homopolyester and homopolyurethane as is shown in Eq. (9) or from alternating copolyester-urethane as is shown in Eq. (10):

$$(-T-G-)_n + (-I-G-)_m \longrightarrow [\{T-G\}_p\{I-G\}_q]_l \quad (9)$$

$$[\{T-G\}\{I-G\}]_l \longrightarrow [\{T-G\}_p\{I-G\}_q]_l \quad (10)$$

where T=OC CO, G=OCH_2CH_2O, and I=CO-$NH(CH_2)_6NHCO$

The present work has been concerned with the application of nuclear magnetic resonance spectroscopy to the analysis of alternating copolyester-urethane that has been heated for various lengths of time.

In the first step of the reaction, the polymer has the T-G-I unit only. The ethylene glycol residue in the T-G-I unit was confirmed at 4.71 ppm. When the interchange reaction proceeds, new two kinds of ethylene glycol residues (–G–), one of which is adjacent to terephthalate (T) an both sides, T-G-T, and the other of which is adjacent to diisocyanate (I) an both sides, I-G-I, may be produced. The glycol residues could be confirmed at 4.93 and 4.48 ppm respectively by comparing the proton signal of the ethylene groups in polyethylene terephthalate and polyurethane prepared from ethylene glycol and hexamethylene diisocyanate. These assignments of the proton signals were reported in a previous paper.[8] If these three signals are confirmed in molten copolyester-urethane, the thermal interchange reaction between an ester and urethane in the polymer can be confirmed.

The interchange reaction was carried out at 190°C without a catalyst or in the presence of 0.2% sulfuric acid as the catalyst, and the intrinsic viscosities and NMR spectra of the polymers were measured. Figure 2 shows the results of the NMR spectra. When there was no catalyst in the copolymer, the T-G-T and I-G-I signals at 4.93 and 4.48 ppm could not be confirmed after 43 hrs reaction. On the other hand, when there was sulfuric acid as a catalyst in the copolymer, the T-G-T and I-G-I signals could be confirmed. The signal at 4.85 ppm is due to the hydroxyethyl end group produced by molecular scission due to the catalyst. Table 1 shows the proportions of the intensities of the four signals due to T-G-T, I-G-I, T-G-I and hydroxyethyl group, and the intrinsic viscosity.

Table 1. Molar fraction of the four structural units and intrinsic viscosity after the interchange reaction

Reaction time (hr)	T-G-T	I-G-I	T-G-I	Hydroxyethyl group	[η]
0	0.00	0.00	1.00	0.00	0.618
2	0.02	0.00	0.94	0.04	0.379
4	0.08	0.00	0.86	0.06	0.331
6	0.14	0.05	0.75	0.06	0.419
10	0.21	0.10	0.62	0.07	0.466
20	0.27	0.10	0.56	0.07	0.504

The molar fraction of the hydroxyethyl end group is related to the number-average molecular weight. Therefore, the decrease in intrinsic viscosity for the first 4 hours may correspond to the decrease in the number-average molecular weight. Although the molar fraction of the hydroxyethyl group is kept approximately constant after heating for 6 hrs, the intrinsic viscosity gradually increases. Since the number-average molecular weight remains constant, the increase in intrinsic viscosity after 6 hrs may be assumed to correspond to the change in sequence distribution.

Synthesis of Corticotropin Peptides. XII. The Effect of Amino-terminal Substitution in the Corticotropin 1-18 Peptide

Ken INOUYE, Kunio WATANABE, Keiko NAMBA and Hideo OTSUKA

Biochemistry Division, Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received June 11,1970)

The synthesis and biological properties are described of an octadecapeptide amide, α-aminoisobutyryl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine amide, corresponding to the first eighteen amino acid residues of corticotropin (ACTH) except for the amino terminal residue. The amino-terminal decapeptide as intermediate is built up from a tripeptide (positions 1—3) and a heptapeptide (4—10), where a benzyloxycarbonyl and a benzyl ester groups are used for protection of the terminal α-amino group and the γ-carboxyl group of 5-glutamic acid, respectively. These protecting groups are removed in the final step with hydrogen fluoride. The new method is successfully applied to the corresponding 1-β-alanine octadecapeptide amide, which has been synthesized previously by a different procedure. Adrenal-stimulating properties of the 1-α-aminoisobutyric acid peptide are compared with those of the 1-β-alanine peptide to show that the former peptide is more active than the latter when assayed by the adrenal-ascorbic acid depletion and the *in vivo* steroidogenesis methods. The lipotropic activity of the new peptide is also shown to be more prolonged than that of the 1-β-alanine peptide.

In 1965 we reported the synthesis of octadecapeptides, ACTH(1-18)-OH(Ia) and ACTH(1-18)-NH_2 (Ib), corresponding to the first eighteen amino acid residues of corticotropin (ACTH).[1] The amide analog (Ib) was also described by Ramachandran *et al.*[2] and Bajusz and Medzihradszky,[3] independently. Later the synthesis of the 1-glycine analog of Ib, [1-glycine]-ACTH(1-18)-NH_2 (Ic) was reported from this laboratory.[4] From synthetic and biological data on corticotropin peptides, including those of our own work, which have been compiled over the past decade[5] we have learned that the aminoterminal eighteen residues fulfill the minimal requirements for eliciting hig hadrenal-stimulating activity. The corresponding peptides Ia, Ib and Ic were, however, still found to be much less active than the native hormone, especially when they were administered for assays by subcutaneous or intramuscular routes.[1,6] This is probably associated with the fact that these peptides are inactivated very rapidly in the tissues, compared with the native hormone. In an effort to find out the mechanism of inactivation we have tried to improve the biological properties of octadecapeptide Ib by partially modifying its structure.

We synthesized [1-β-alanine]-ACTH(1-18)-NH_2 (Id) and found that the amino-terminal substitution by β-alanine caused not only remarkable enhancement but also prolonged duration of action of the adrenal-stimulating and the lipotropic activities over the corresponding 1-serine and 1-glycine peptides.[6,7] This finding offered evidence to support the view that the marked increase in biological

activities, which was reported by Boissonnas *et al.*[9] and by Kappeler *et al.*[10] to occur when the amino-terminal L-serine of corticotropin peptides was replaced by D-amino acids, is a consequence of the decreased susceptibility of peptides toward the action of intracellular aminopeptidase. Geiger *et al.*[11] have also reported that [1-β-alanine]-ACTH(1-23)-NH_2 possesses a high potency over the 1-L-serine analog. The present communication will describe the synthesis of an octadecapeptide amide, α-aminoisobutyryl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine amide, [Ibu[1]]-ACTH(1-18)-NH_2 (Ie),[12] corresponding to the first eighteen amino acid residues of corticotropin except that the amino terminal serine in the native hormone has been replaced by α-aminoisobutyric acid.

α-Aminoisobutyric acid (α-methylalanine) has no hydrogen atom on the α-carbon and therefore belongs to the type of amino acids which forms peptide bonds resisting the action of aminopeptidase. If the current view is right, the amino-terminal substitution by α-aminoisobutyric acid in a corticotropin peptide should result in a remarkable improvement in its biological activities, to the same extent as that produced by D-amino acids[9,10] or β-alanine.[6,11] The present synthesis was undertaken to examine this point and to provide more evidence for the view.

In the present work a new procedure was applied to the synthesis of the decapeptide intermediate corresponding to positions 1—10 of Ie. The procedure is outlined in Fig. 1. A benzyloxycarbonyl group and a benzyl ester group were used to protect the amino group of position 1 and the γ-carboxyl group of glutamic acid residue at position 5, respectively. Formation of the decapeptide was performed by coupling of the tripeptide azide (positions 1—3) with the heptapeptide (4—10) which was synthesized stepwise from the glycine at position 10 *via* a free pentapeptide H-His-Phe-Arg-Trp-Gly-OH (VI)[13] as an intermediate. This procedure eliminates the possibility of partial oxidation by nitrous acid of methionine that may occur when the hydrazide of a methionine containing peptide is subjected to azide formation prior to coupling reaction. Because of the presence of benzyloxycarbonyl and benzyl ester groups the final step to generate the free octadecapeptide amide (Ie) was hydrogen fluoride treatment,[14] by which all the protecting groups were removed very smoothly. The procedure was also applied to the synthesis of 1-β-alanine peptide (Id), which has been prepared before by a different procedure,[6] in order to provide a proof of its utility.

Synthesis of [Ibu[1]]-Octadecapeptide Amide (Ie). The acylation of α-aminoisobutyric acid with benzyl chloroformate proceeded smoothly under the ordinary conditions to give Z-Ibu-OH (II) in moderate yield, whereas acylation with *t*-butyl azidoformate gave the desired Boc-Ibu-OH in a yield of only 9%, even when the reaction was continued for over a week in the presence of excess azidoformate. This is probably due to the presence of the additional α-methyl group, which will reduce the reactivity of α-amino group sterically. Attempts to prepare the Ibu-Tyr-Ser sequence were made by two different procedures. There was no difficulty in coupling compound II with tyrosine methyl ester by the DCC method. The resulting dipeptide ester was readily converted into the hydrazide Z-Ibu-Tyr-$NHNH_2$. In the subsequent steps, however, the products could not be characterized as the

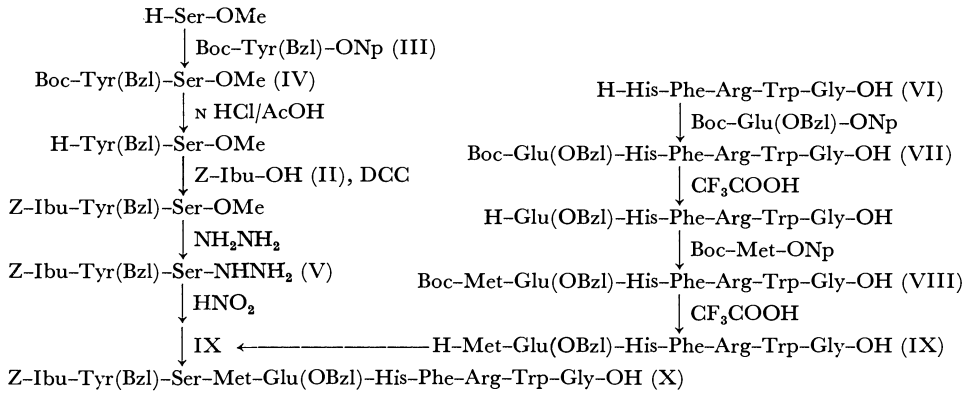

Fig. 1. Synthetic procedure of decapeptide intermediate X[12]

desired compounds, Z-Ibu-Tyr-Ser-OMe and its hydrazide. There must have been some complication in the azide coupling reaction. On the other hand, Boc-Tyr(Bzl)-ONp (III) was allowed to react with serine methyl ester to yield Boc-Tyr(Bzl)-Ser-OMe (IV). Compound II was then coupled by the DCC method with a crystalline dipeptide ester, derived from IV with N hydrogen chloride in acetic acid, to give a tripeptide Z-Ibu-Tyr(Bzl)-Ser-OMe, which was converted into the corresponding hydrazide (V).

A pentapeptide H-His-Phe-Arg-Trp-Gly-OH (VI), which was derived from Z-His-Phe-Arg-(NO_2)-Trp-Gly-OH[6] or from Z-His-Phe-Arg(Tos)-Trp-Gly-OH[13] by hydrogen fluoride treatment,[14] was acylated with Boc-Glu(OBzl)-ONp in the absence of added amine. The reaction was fairly complete in 24 hr. The product VII, isolated in 80% yield, was treated with trifluoroacetic acid and the resulting amino-free hexapeptide trifluoroacetate was then coupled with Boc-Met-ONp in the presence of triethylamine to obtain a heptapeptide Boc-Met-Glu(OBzl)-His-Phe-Arg-Trp-Gly-OH (VIII). Removal of the Boc group from VIII yielded the N^{α}-free heptapeptide (IX) as the key intermediate in the present synthesis of both Ie and Id. Coupling of IX with the azide derived from V gave the decapeptide derivative Z-Ibu-Tyr(Bzl)-Ser-Met-Glu(OBzl)-His-Phe-Arg-Trp-Gly-OH (X). Compound X was then converted into the dihydrochloride by lyophilization from acetic acid containing a small excess of hydrogen chloride, followed by esterification with *N*-hydroxysuccinimide by the carbodiimide method.[15] The active ester of X, which was isolated, was allowed to react with a partially protected octapeptide, H-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-NH_2,[16] in the presence of triethylamine to yield a protected octadecapeptide Z-Ibu-Tyr(Bzl)-Ser-Met-Glu(OBzl)-His-Phe-Arg-Trp-Gly-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-NH_2 (XI). The crude XI was, without purification, subjected to treatment with hydrogen fluoride[14] in the presence of anisole and methionine as radical scavengers. The crude deblocked octadecapeptide (Ie), obtained in the form of hydrofluoride, was treated with an anion exchange resin (acetate) to be converted into the acetate form, which was then chromatographed, for purification, on a column of carboxymethyl cellulose using an ammonium acetate buffer with a linear concentration gradient. After repeated chromatography, peptide Ie was obtained in pure form. The over-all yield of Ie for the final coupling, deblocking and purification steps was 50%. The product behaved as a single component in thin-layer chromatography and in paper electrophoresis. Quantitative amino acid analysis[17] showed that an acid hydrolysate of the product contained the individual amino acids in the ratios expected by theory with the exception of tryptophan. The tryptophan-tyrosine ratio of intact Ie was determined spectrophotometrically to be unity.

Synthesis of [β-Ala[1]]-Octadecapeptide Amide (Id). A synthesis of this octadecapeptide amide has been reported already in the preceding paper,[6] in which the terminal amino group was protected with a *t*-butyloxycarbonyl group and the γ-carboxyl group of the glutamic acid residue at position 5 by the formation of the *t*-butyl ester and the first decapeptide sequence was made up of tetrapeptide (positions 1—4) and hexapeptide (5—10). An alternative synthesis developed in the present work is summarized in Fig. 2. The amino-terminal tripeptide sequence was synthesized in the form of Z-β-Ala-Tyr-Ser-OMe (XIV) *via* Z-β-Ala-Tyr-$NHNH_2$ (XIII) as an intermediate. The tripeptide azide, derived from XV, was allowed to react with heptapeptide (IX) to give a decapeptide Z-

Fig. 2. Synthetic procedure of decapeptide intermediate XVI[12]

β-Ala-Tyr-Ser-Met-Glu(OBzl)-His-Phe-Arg-Trp-Gly-OH (XVI) in pure form in 62% yield. Compound XVI was then esterified with *N*-hydroxysuccinimide in the usual manner and the active ester was made react with the octapeptide H-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-NH_2.[16] The resulting crude preparation of protected octadecapeptide Z-β-Ala-Tyr-Ser-Met-Glu(OBzl)-His-Phe-Arg-Trp-Gly-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-NH_2 (XVII) was, without purification, deblocked with hydrogen fluoride to liberate peptide Id. The crude Id was then purified by chromatography on a column of carboxymethyl cellulose. These procedures, the final coupling, deblocking and purification steps, were carried out in a manner almost the same as that used in the synthesis of Ie. The over-all yield of Id thus obtained was 45%. The product was found to be homogeneous in thin-layer chromatography and in paper electrophoresis. The quantitative amino acid analysis[17] showed that an acid hydrolysate of the product contained the individual amino acids in the ratios expected by theory with the exception of tryptophan. The tryptophan-tyrosine ratio of intact Id was determined spectrophotometrically to be unity.[18] Optical rotation and chromatographic behaviors of the present preparation of Id were identical with those of a previous preparation obtained by a different synthetic procedure.[6]

Biological Properties of the Octadecapeptide Amides. Adrenal-stimulating activities of Ibu[1]-octadecapeptide amide (Ie) were compared with those of the present and previous preparations of β-Ala[1]-analog (Id) by six different assay procedures: 1) adrenal-ascorbic acid depletion,[19] 2) *in vitro* steroidogenesis,[20] 3) *in vivo* steroidogenesis in adrenal cannulation,[21] 4) *in vivo* steroidogenesis in dexamethasone-pentobarbital-blocked mouse,[22] 5) *in vivo* steroidogenesis in peripheral blood (intravenous administration), and 6) *in vivo* steroidogenesis in peripheral blood (intramuscular administration). The results are summarized in Table 1, in which the data on Gly[1]-analog (Ic)[4,6] are included for comparison. As is seen in Table 1, there is no significant difference in potency between the present preparation and the previous preparation of Id, proving their identity. This also proves the usefulness and safety of the new synthetic procedure, by which both peptides Id and Ie were prepared. The data in Table 1 clearly demonstrate that Ibu[1]-peptide (Ie) is endowed with a very high adrenal-stimulating activity and its potency appears to be more than twice that of β-Ala[1]-peptide (Id), when assayed by the adrenal-ascorbic acid depletion method and by the *in vivo* steroidogenesis methods. In addition, it is to be noted that the activity of Ie, estimated by the 11-hydroxycorticosteroid (11-OHCS) level in rat peripheral blood, is unchanged regardless of whether the peptide is administered intravenously or intramuscularly. In Ic and Id, however, the potency ratio of intramuscular *vs.* intravenous administration is 1/5 and 1/2, respectively. Tanaka has estimated the half-lives of a native corticotropin and the synthetic peptides Ic, Id, and Ie with the *in vitro* lipotropic activity[23] as a parameter. The results are shown in Table 2.[24] When the synthetic peptides are incubated in plasma, their half-lives are all the same, indicating that the inactivation of peptides in plasma is little associated with the action of aminopeptidase. On the other hand, when incubated with muscle fragments, the inactivation rate largely depends on the nature of the amino-terminal residue of peptides; Ibu[1]-peptide (Ie) can remain active rather longer than β-Ala[1]-peptide (Id). This may be correlated with the above observation that the intramuscular *vs.* intravenous potency ratio of Ie is larger than that of Id. In the preceding paper we described that β-Ala[1]-peptide (Id) was remarkably more potent, with a longer action in adrenal-stimulating activity than the corresponding Ser[1]-peptide (Ib) or Gly[1]-

b) A peptide sample was injected intravenously into vena cava inferior and blood samples, collected from abdominal aorta in appropriate time intervals and acidified, were assayed for the *in vitro* lipotropic activity.[23)]
c) A sample was dissolved in the fresh plasma from anesthetized rat or in the Krebs-Ringer bicarbonate buffer containing thigh muscle slices of rat, bovine serum albumin and glucose. These mixtures were then incubated at 37°C and the aliquots taken from the mixtures in appropriate time intervals were assayed for the *in vitro* lipotropic activity.[23)]

peptide (Ic).[6)] The present results show that Ibu^1-peptide (Ie) also exceeds Ic greatly in the biological activity, exhibiting a similarity to Id. Since α-aminoisobutyric acid amide and β-alanine amide are equally known not to be cleaved by hog kidney leucine aminopeptidase,[25)] this similarity is not surprising, and it provides additional support for the view that the marked increase in biological activities as a main effect of the amino-terminal substitution is a consequence of the decreased susceptibility of peptide toward aminopeptidase action. However, peptide Ie still differs from peptide Id as seen in Tables 1 and 2, indicating that α-aminoisobutyric acid is preferred to β-alanine as the amino-terminal residue of corticotropin peptide, probably because of some favorable effects of the α-amino group in the former amino acid. Geiger *et al.*[26)] reported that removal of 1-glycine residue from [Gly^1]-ACTH(1-23)-tricosapeptide amide caused a 50% loss of activity. This finding would suggest a significant importance for activity of the distance separating the terminal amino group and the center of active site of the peptide. In Ibu^1-peptide (Ie) the amino-terminal amino group occupies the place where it sits in a native corticotropin, whereas the corresponding group in β-Ala^1-peptide (Id) is located one methylene unit away from the regular position. In addition, it is to be noted that the amino group of α-aminoisobutyric acid will have a pK value close to those of ordinary α-amino acids (*e. g.* serine 9.15) rather than that of β-alanine (10.19).[27)] These properties would affect a specific binding of the peptide to its receptor site and the tighter binding may, in turn, serve to further stabilize the peptide; peptide Ie thus could be more potent and have a longer action than Id. One of other possibilities which explain the difference between Id and Ie is the participation of an enzyme which can act on β-alanine peptides specifically. Because of the occurrence of β-alanine peptides, such as carnosine and anserine, in animal tissues, it is not unreasonable to assume the presence of such enzyme.

It has been shown that the amino-terminal substitution by unusual amino acids, such as β-alanine and α-aminoisobutyric acid, in a corticotropin pep-

tide improves its biological properties greatly in both enhancement of potency and prolongation of action. As is apparent in Table 2, however, the amino-terminal substitution improves the stability of peptide in tissues, but not the stability in blood, indicating that the inactivation of peptide in blood may be associated with the action of some endopeptidase, but not with an aminopeptidase action. The presence of such an endopeptidase is known.[28] A further improvement in allowing the short-chain peptide to come closer to a native corticotropin should be achieved by reducing the susceptibility of peptide toward the endopeptidase action without a considerable loss of activity. The synthesis of [β-Ala^1, Orn^{15}]-ACTH(1-18)-NH_2 may be one solution.[29] This new peptide possesses a moderate adrenal-stimulating activity and shows an excellent prolongation of action; the half-life in plasma is longer than that of the native hormone (76 min, see Table 2 for comparison).

Experimental

All melting points were uncorrected.

Benzyloxycarbonyl-α-aminoisobutyric Acid (II). To a solution of α-aminoisobutyric acid (5.16 g, 0.05 mol) and anhydrous sodium carbonate (5.30 g, 0.05 mol) in N sodium hydroxide (50 m*l*) was added benzyl chloroformate (9.39 g, 0.055 mol) at 0°C and the mixture was stirred for 3 hr. The reaction mixture was washed with ether to remove the excess reagent and acidified with 6N hydrochloric acid, followed by extraction with ethyl acetate. The organic extracts were combined, dried over sodium sulfate and evaporated *in vacuo* to give a crystalline residue, which was recrystallized from ethyl acetate - petroleum ether; yield 8.75 g (73%), mp 69—70°C. Lit,[30] mp 78°C.

Found: C, 61.04; H, 6.36; N, 6.07%. Calcd for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37; N, 5.90%.

***t*-Butyloxycarbonyl-α-aminoisobutyric Acid.** To a solution of α-aminoisobutyric acid (4.75 g, 0.046 mol) and sodium bicarbonate (4.25 g, 0.05 mol) in N sodium hydroxide (46 m*l*) and dioxane (30 m*l*) was added dropwise a dioxane solution of *t*-butyl azidoformate (7.25 g, 0.05 mol) and the mixture was stirred at 45—50°C for 5 days. An additional quantity of *t*-butyl azidoformate (6.6 g, 0.046 mol) and N sodium hydroxide (46 m*l*) was introduced and the mixture was stirred for 2 days at the same temperature and then concentrated *in vacuo* to remove most of the organic solvent. The concentrate was chilled and acidified with ice-cold 4N hydrochloric acid to pH 3, followed by extraction with ethyl acetate. The organic solution was dried over sodium sulfate and evaporated. The resulting crystals were recrystallized from ether; yield 0.81 g (8.7%), mp 119—120°C.

Found: C, 53.64; H, 8.39; N, 7.19%. Calcd for $C_9H_{17}NO_4$: C, 53.19; H, 8.43; N, 6.89%.

Benzyloxycarbonyl-α-aminoisobutyryl-tyrosine Hydrazide. Compound II (1.54 g, 6.5 mmol) and tyrosine methyl ester (free base, 1.27 g, 6.5 mmol) were dissolved in acetonitrile and to this solution was added *N,N'*-dicyclohexylcarbodiimide (DCC, 1.34 g, 6.5 mmol) at 0°C with acetonitrile as solvent. The mixture was kept at 4°C overnight. *N,N'*-dicyclohexylurea (DCU) which formed was filtered off and the filtrate was evaporated *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed with N hydrochloric acid and 5% sodium bicarbonate, dried over sodium sulfate and evaporated *in vacuo* to give the dipeptide ester as a sirupy residue. The residue was dissolved in ethanol (15 m*l*) and hydrazine hydrate (0.8 m*l*) was added. After the reaction mixture had been kept at room temperature for 2 days, water was added to separate the desired dipeptide hydrazide as crystals; yield 2.35 g (87%), mp 160—162°C. Recrystallization from aqueous ethanol yielded the pure material in a recovery of 92%; mp 164—165°C, $[\alpha]_D^{27}$ $-31.4\pm0.7°$ (*c* 1.078, methanol).

Found: C, 60.95; H, 6.41; N, 13.31%. Calcd for $C_{21}H_{26}N_4O_5$: C, 60.86; H, 6.32; N, 13.52%.

***t*-Butyloxycarbonyl-*O*-benzyl-tyrosine *p*-Nitrophenyl Ester (III).** To a solution of *t*-butyloxycarbonyl-*O*-benzyl-tyrosine (2.97 g, 8 mmol)[31] and *p*-nitrophenol (1.12 g, 8 mmol) in ethyl acetate was added an ethyl acetate solution of DCC (1.65 g, 8 mmol) at 0°C and the mixture was kept at 4°C for 3 hr. The DCU which formed was removed by filtration and the filtrate was evaporated *in vacuo*. The resulting solid residue was suspended in hot ethanol and the crystals were filtered off after refrigeration, washed with cold ethanol and dried *in vacuo* to give the desired active ester; yield 3.39 g (86%), mp 140—141°C, $[\alpha]_D^{22}$ $-0.3\pm0.4°$ (*c* 0.983, ethyl acetate).

Found: C, 65.93; H, 5.73; N, 5.67%. Calcd for $C_{27}H_{28}N_2O_7$: C, 65.84; H, 5.73; N, 5.69%'

***t*-Butyloxycarbonyl-*O*-benzyl-tyrosyl-serine Methyl Ester (IV).** To an ice-cold solution of serine methyl ester hydrochloride (1.03 g, 6.6 mmol) in dimethylformamide (DMF, 8 m*l*) was added triethylamine (0.92 m*l*, 6.6 mmol) and the amine hydrochloride which formed was filtered off. ADMF solution of III (2.96 g, 6.0 mmol) was added to the filtrate and the mixture was kept at 4°C for 2 days. After the solvent had been removed by evaporation *in vacuo* at a bath temperature of 45—50°C, the residue was dissolved in ethyl acetate and the solution was washed successively with ice-cold N hydrochloric acid, water, 2N aqueous ammonia and water, dried over sodium sulfate and evaporated *in vacuo*. The resulting gelatinous mass was precipitated from ethyl acetate - petroleum ether. Reprecipitation from methanol-water afforded the pure dipeptide; yield 2.75 g (97%), mp 73—77°C, $[\alpha]_D^{22}$ $+7.7\pm0.5°$ (*c* 1.046, methanol).

Found: C, 63.36; H, 6.97; N, 5.71.% Calcd for $C_{25}H_{32}N_2O_7$: C, 63.54; H, 6.83; N, 5.93%.

Benzyloxycarbonyl-α-aminoisobutyryl-*O*-benzyl-tyrosyl-serine Hydrazide (V). Compound IV (2.08 g,

4.4 mmol) was dissolved in N hydrogen chloride in acetic acid (20 ml) and the mixture was allowed to stand at room temperature for 30 min. Evaporation of the solvent left an oily residue which solidified upon treatment with ether. The solid which was filtered off was dissolved in a mixture of water (6 ml) and dichloromethane (20 ml), and to this was added ice-cold 50% potassium carbonate (6 ml). The mixture was shaken well and the organic phase was separated, dried over sodium sulfate and evaporated *in vacuo*. The crystalline *O*-benzyl-tyrosyl-serine methyl ester (free base) thus obtained was dissolved in acetonitrile along with compound II (1.04 g, 4.4 mmol) and to this solution was introduced an acetonitrile solution of DCC (0.91 g, 4.4 mmol) at 0°C. The mixture was kept at 4°C overnight. The DCU which formed was filtered off and the filtrate was evaporated *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed successively with N hydrochloric acid, water and 5% sodium bicarbonate, dried over sodium sulfate and evaporated *in vacuo*, yielding the crude tripeptide ester which showed on a thin-layer chromatogram (in ethyl acetate) the presence of a smaller amount of an additional component. The crude ester was then dissolved in ethanol (20 ml) and hydrazine hydrate (1.0 ml, 20 mmol) was added. The reaction mixture was allowed to stand at room temperature for 2 days, followed by evaporation *in vacuo*. The residue was dissolved in ethyl acetate and the solution was washed with water and dried quickly over sodium sulfate. The precipitates which separated on standing were filtered off, washed with cold ethyl acetate and ether and dried *in vacuo* to give the desired hydrazide; yield 1.91 g (72%). Reprecipitation from ethanol gave the pure material in a recovery of 80%, mp 151—153°C, $[\alpha]_D^{22}$ $-2.2\pm0.4°$ (*c* 1.062, glacial acetic acid).

Found: C, 62.98; H, 6.31; N, 11.81%. Calcd for $C_{31}H_{37}N_5O_7$: C, 62.93; H, 6.30; N, 11.84%.

Benzyloxycarbonyl-β-alanyl-tyrosine Methyl Ester (XII). To a solution of benzyloxycarbonyl-β-alanine (8.9 g, 0.04 mol)[32] and tyrosine methyl ester (free base, 7.8 g, 0.04 mol) in acetonitrile was added a dichloromethane solution of DCC (8.3 g, 0.04 mol) at 0°C and the mixture was kept at 4°C overnight. After removal of DCU by filtration the filtrate was evaporated *in vacuo*. The resulting residue was dissolved in ethyl acetate and the solution was washed with N hydrochloric acid and 5% sodium bicarbonate, dried over sodium sulfate and evaporated *in vacuo* to yield a sirupy residue which crystallized from ethyl acetate - ether. After recrystallization from the same solvent the product amounted to 13.2 g (83%); mp 114—116°C, $[\alpha]_D^{27}$ $+6.2\pm0.4°$ (*c* 1.040, methanol).

Found: C, 62.94; H, 6.06; N, 6.85%. Calcd for $C_{21}H_{24}N_2O_6$: C, 62.99; H, 6.04; N, 6.93%.

Benzyloxycarbonyl-β-alanyl-tyrosine Hydrazide (XIII). Compound XII (4.81 g, 0.012 mol) was dissolved in ethanol (50 ml) and hydrazine hydrate (2.9 ml, 0.06 mol) was added. The mixture was allowed to stand at room temperature for a few hours and kept at 4°C overnight. The crystalline hydrazide which separated was filtered off, washed with cold ethanol and dried *in vacuo*; yield 4.72 g (98%). After treatment with hot ethanol the mp was 225—228°C; $[\alpha]_D^{26}$ $+3.9\pm0.4°$ (*c* 1.032, 50% acetic acid).

Found: C, 60.09; H, 6.16; N, 13.97%. Calcd for $C_{20}H_{24}N_4O_5$: C, 59.99; H, 6.04; N, 13.99%.

Benzyloxycarbonyl-β-alanyl-tyrosyl-serine Methyl Ester (XIV). Compound XIII (2.40 g, 6 mmol) was dissolved in DMF (7 ml) and N hydrochloric acid (15 ml) was added. The solution was chilled in ice and to this was added ice-cold 2M sodium nitrite (3. 6ml). After the mixture had been kept at 0°C for 4 min, the azide which separated was extracted with ice-cold ethyl acetate (25 ml×2). The organic extracts were combined, washed with ice-cold 5% sodium bicarbonate, dried over sodium sulfate. The resulting solution was added to a mixture of serine methyl ester hydrochloride (0.93 g, 6 mmol) and triethylamine (0.84 ml, 6 mmol) in 90% tetrahydrofuran (20 ml) and the mixture was stirred at 4°C for 48 hr. The gelationous precipitates which had separated were filtered off, washed with cold ethyl acetate and with water and dried *in vacuo*; yield 1.58 g (54%). After treatment with hot methanol the mp was 195—196°C; $[\alpha]_D^{26}$ $+2.1\pm0.4°$ (*c* 1.091, methanol).

Found: C, 59.29; H, 6.08; N, 8.63%. Calcd for $C_{24}H_{29}N_3O_8$: C, 59.13; H, 6.00; N, 8.62%.

Benzyloxycarbonyl-β-alanyl-tyrosyl-serine Hydrazide (XV). To a solution of compound XIV (1.46 g, 3 mmol) in DMF (5 ml) was added hydrazine hydrate (0.73 ml, 15 mmol) and the mixture was kept at 4°C for 24 hr. The hydrazide had separated as crystals. After addition of ethanol (10 ml) the crystals were filtered off, washed with ethanol and dried *in vacuo* (1.40 g). Treatment with hot ethanol gave the pure hydrazide; yield 1.32 g (90%), mp 220—224°C decomp, $[\alpha]_D^{25}$ $+15.7\pm0.5°$ (*c* 1.042, glacial acetic acid).

Found: C, 56.35; H, 6.04; N, 14.57%. Calcd for $C_{23}H_{29}N_5O_7$: C, 56.66; H, 6.00; N, 14.37%.

***t*-Butyloxycarbonyl-γ-benzyl-glutamic Acid Dicyclohexylamine Salt.** Glutamic acid γ-benzyl ester (9.5 g, 0.04 mol)[33] and sodium bicarbonate (12.5 g) were suspended in water (100 ml) and dioxane (80 ml) and to this was added *t*-butyl azidoformate (8.6 g, 0.06 mol) with dioxane (20 ml). The mixture was stirred at 45—50°C for 2 days, followed by concentration *in vacuo* to remove most of the dioxane. The concentrated solution was then acidified to pH 3—4 with ice-cold 4N hydrochloric acid at 0°C and the product was extracted with ice-cold ethyl acetate. The organic solution was washed with ice-cold N hydrochloric acid and water, dried over sodium sulfate and evaporated *in vacuo* to give an oily residue. The residue was dissolved in ether (50 ml) and dicyclohexylamine (7.3 g, 0.04 mol) was added. Crystalline precipitates which had separated upon standing at 4°C overnight were filtered off, washed with ether and dried *in vacuo*; yield 16.7 g (81%). After recrystallization from ethyl acetate the product showed mp 140—142°C, $[\alpha]_D^{27}$ $+13.3\pm0.5°$ (*c* 1.024, methanol). Lit,[34] mp 138—139°C, $[\alpha]_D^{25}$ $+11.9°$ (*c* 1, methanol).

Found: C, 67.03; H, 9.02; N, 5.68%. Calcd for $C_{17}H_{23}NO_6 \cdot C_{12}H_{23}N$: C, 67.15; H, 8.94; N, 5.40%.

***t*-Butyloxycarbonyl-γ-benzyl-glutamic Acid *p*-Nitrophenyl Ester.** *t*-Butyloxycarbonyl-γ-benzyl-glutamic acid dicyclohexylamine salt (9.0 g, 17.4 mmol) was shaken with Dowex 50W×8 (H^+ form, wet vol 18 cc) in 60% ethanol for 30 min. After the resin had been removed by filtration the filtrate was evaporated *in vacuo*. The residue was dissolved in ether and the solution was dried over sodium sulfate and evaporated *in vacuo* to afford the free acid quantitatively. This was dissolved in ethyl acetate together with *p*-nitrophenol (2.4 g, 17.4 mmol) and to this solution was added DCC (3.6 g, 17.4 mmol) at 0°C. The reaction mixture was kept at 4°C overnight. After removal of DCU by filtration the filtrate was evaporated *in vacuo* to give a residue which crystallized from ethanol. Recrystallization from the same solvent gave the active ester in a pure form; yield 7.0 g (88%), mp 118—119°C, $[\alpha]_D^{28}$ −33.1±0.7° (*c* 1.082, methanol). Lit,[35] mp 120—121°C, $[\alpha]_D^{25}$ −32.7° (*c* 1, methanol).

Found: C, 60.38; H, 5.80; N, 6.29%. Calcd for $C_{23}H_{26}N_2O_8$: C, 60.26; H, 5.72; N, 6.11%.

***t*-Butyloxycarbonyl-methionine Dicyclohexylamine Salt.** To a mixture of methionine (3.0 g, 0.02 mol) and sodium bicarbonate (3.8 g) in water-dioxane (1 : 1 by vol, 60 m*l*) was added *t*-butyl azidoformate (4.3 g, 0.03 mol) and the mixture was stirred at 45°C for 48 hr. The reaction mixture was worked up in the usual manner. The resulting acyl-methionine (oil, 4.3 g) was dissolved in ether and dicyclohexylamine (3.1 g, 0.017 mol) was added. The crystals were collected by filtration, washed with ether and dried *in vacuo*; yield 6.7 g (78%). A sample was recrystallized from ethyl acetate in a recovery of 92%; mp 141°C, $[\alpha]_D^{20}$ −18.2±0.9° (*c* 0.648, methanol).

Found: C, 61.56; H, 9.99; N, 6.68%. Calcd for $C_{10}H_{19}NO_4S \cdot C_{12}H_{23}N$: C, 61.36; H, 9.83; N, 6.51%.

***t*-Butyloxycarbonyl-methionine *p*-Nitrophenyl Ester.** *t*-Butyloxycarbonyl-methionine dicyclohexylamine salt (10.8 g, 0.025 mol) was treated with Dowex 50W×8 (H^+ form) in the same manner as above. The resulting oily acid and *p*-nitrophenol (3.5 g, 0.025 mol) were dissolved in ethyl acetate and to this was added an ethyl acetate solution of DCC (5.2 g, 0.025 mol) at 0°C. The mixture was allowed to stand at 4°C overnight. The DCU was filtered off and the filtrate was evaporated *in vacuo* to give a residue, which crystallized from ethanol. After recrystallization from ethanol the active ester was obtained in 84% yield; wt 7.8 g, mp 96—97°C, $[\alpha]_D^{27}$ −48.3±0.9° (*c* 1.020, methanol).

Found: C, 52.05; H, 5.97; N, 7.68%. Calcd for $C_{16}H_{22}N_2O_6S$: C, 51.88; H, 5.99; N, 7.56%.

***t*-Butyloxycarbonyl-γ-benzyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine (VII).** To a solution of histidyl-phenylalanyl-arginyl-tryptophyl-glycine monoacetate (VI, 1.20 g, 1.5 mmol)[36] in 50% DMF (10 m*l*) were added *t*-butyloxycarbonyl-γ-benzyl-glutamic acid *p*-nitrophenyl ester (1.03 g, 2.25 mmol) and DMF (25 m*l*), and the mixture was kept at 4°C for 3 days. The resulting solution was added dropwise into a mixture of ethyl acetate - ether (1 : 1 by volume, 200 m*l*) and the precipitates which formed were filtered off, washed with ethyl acetate and ether and dried *in vacuo* (1.86 g). These precipitates were redissolved in 50% acetic acid (*ca.* 10 m*l*) and ethanol (*ca.* 100 m*l*) was added. The resulting precipitates were collected and lyophilized from acetic acid; yield 1.37 g (89%), $[\alpha]_D^{22}$ −23.9±0.6° (*c* 1.020, 50% acetic acid).

Found: C, 56.40; H, 6.22; N, 15.40; CH_3CO; 3.25%. Calcd for $C_{51}H_{64}N_{12}O_{11} \cdot CH_3COOH \cdot 3H_2O$: C, 56.07; H, 6.57; N, 14.81; CH_3CO, 3.79%.

***t*-Butyloxycarbonyl-methionyl-γ-benzyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine (VIII).** Compound VII (1.26 g, 1.1 mmol) was dissolved in trifluoroacetic acid (6 m*l*) and the mixture was kept at room temperature for 30 min and then chilled in an ice bath. Addition of ether afforded the partially deblocked hexapeptide as precipitates (1.34 g). These precipitates were dissolved in DMF (10 m*l*) and to this solution were added triethylamine (0.46 m*l*, 3.3 mmol) and *t*-butyloxycarbonyl-methionine *p*-nitrophenyl ester (0.74 g, 2 mmol). The mixture was allowed to stand at 4°C for 24 hr and then introduced into an ice-cold mixture of ethyl acetate - ether (1:4 by volume, 250 m*l*). The resulting precipitates were filtered off, washed with ether and dried *in vacuo* (1.56 g). To this product was added ethanol (15 m*l*) and the suspension was heated to boiling point and then chilled. The precipitates were collected, washed with cold ethanol and ether and lyophilized from acetic acid; yield 1.16 g (88%), $[\alpha]_D^{22}$ −18.5±0.5° (*c* 1.072, DMF).

Found: C, 54.51; H, 6.16; N, 13.94%. Calcd for $C_{56}H_{73}N_{13}O_{12}S \cdot CH_3COOH \cdot 2H_2O$: C, 54.23; H, 6.67; N, 14.18%.

Benzyloxycarbonyl-α-aminoisobutyryl-*O*-benzyl-tyrosyl-seryl-methionyl-γ-benzyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine (X). Compound VIII (0.50 g, 0.4 mmol) was dissolved in trifluoroacetic acid (3 m*l*) containing one drop of water and the mixture was allowed to stand at room temperature for 30 min. The resulting heptapeptide trifluoroacetate (IX) was precipitated by the addition of ether. The precipitates collected by filtration were washed thoroughly with ether and dried *in vacuo*.

A mixture of V (0.47 g, 0.8 mmol), N hydrochloric acid (2 m*l*) and DMF (2 m*l*) was chilled in an ice bath and to this was added dropwise ice-cold 2M sodium nitrite (0.44 m*l*). The mixture was stirred at 0°C for 4 min and then extracted with ice-cold ethyl acetate. The organic extracts were combined, washed with ice-cold sodium bicarbonate and dried over sodium sulfate. The resulting solution was mixed with a solution of IX, obtained above, and triethylamine (0.25 m*l*, 1.6 mmol) in DMF (10 m*l*). The mixture was concentrated *in vacuo* at a bath temperature of 20°C until it became almost clear, and then kept at 4°C for 24 hr. Most of the solvent was removed by evaporation *in vacuo* at a bath temperature of 45°C. The precipitates which formed upon addition of ether were reprecipitated from methanol - ethanol (1 : 1 by vol); yield 0.96 g (82%), $[\alpha]_D^{24}$ −30.1±1.4° (*c* 0.515, DMF). Thin-layer chromatography:[38] R_f=0.44 (BAW), 0.68 (BAPW) and

Found: C, 57.31; H, 5.82; N, 12.33%. Calcd for $C_{82}H_{98}N_{16}O_{17}S \cdot 2CH_3COOH \cdot 4H_2O$: C, 57.26; H, 6.37; N, 12.42%.

Benzyloxycarbonyl-β-alanyl-tyrosyl-seryl-methionyl-γ-benzyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine (XVI). A mixture of XV (0.86 g, 1.75 mmol), N hydrochloric acid (4 ml) and DMF (5 ml) was chilled in an ice bath and to this was added dropwise ice-cold 2M sodium nitrite (0.96 ml). The mixture was stirred at 0°C for 4 min, after which ice-cold DMF (10 ml) was introduced to dissolve the azide, which had separated, followed by addition of triethylamine (0.56 ml, 4.0 mmol). The resulting solution was added to an ice-cold solution of IX (derived from 1.09 g, 0.88 mmol, of VIII by treatment with trifluoroacetic acid) and triethylamine (0.49 ml, 3.5 mmol) in DMF (20 ml) and the mixture was allowed to stand at 0°C for 24 hr. After addition of acetic acid (1 ml) the solvent was removed by evaporation *in vacuo* at a bath temperature of 45°C to afford a sirupy residue. To this was then added ethanol (20 ml) and gelatinous precipitates were filtered off, washed thoroughly with ethanol, ethyl acetate and with ether and dried *in vacuo* (0.88 g). The filtrate and washes were combined and evaporated *in vacuo*. The residue was dissolved in ethyl acetate and insoluble precipitates were filtered off. These precipitates were heated with ethanol to boiling point and filtered off after refrigeration (0.27 g). The total yield amounted to 1.15 g (78%). The precipitates combined were boiled in ethanol for several minutes and collected by filtration in 80% recovery; $[\alpha]_D^{22}$ $-18.5 \pm 0.5°$ (*c* 1.067, DMF). Thin-layer chromatography: R_f=0.75 (BAPW). Paper chromatography: R_f=0.8 (BAW).

Found: C, 55.71; H, 6.06; N, 13.34%. Calcd for $C_{74}H_{90}N_{16}O_{17}S \cdot 2CH_3COOH \cdot 3H_2O$: C, 55.70; H, 6.23; N, 13.33%.

α-Aminoisobutyryl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine Amide, [Ibu¹]-ACTH(1-18)-NH₂ (Ie). To a solution of X (0.32 g, 0.18 mmol) in acetic acid was added N hydrogen chloride in acetic acid (0.4 ml) and the mixture was immediately lyophilized and dried over sodium hydroxide pellets *in vacuo*. The decapeptide hydrochloride thus obtained was dissolved in DMF (3ml) together with *N*-hydroxysuccinimide (0.083 g, 0.72 mmol) and to this was added a solution of DCC (0.15 g, 0.72 mmol) in DMF (2 ml). The mixture was allowed to stand at 4°C overnight. The DCU which had separated was filtered off and the filtrate was introduced into ice-cold ethyl acetate - ether (1 : 1 by vol, 100 ml) The resulting precipitates were filtered off, washed with ethyl acetate and ether and dried *in vacuo* to yield the decapeptide active ester (0.36 g).

The triacetate of N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine amide (derived from 0.12 mmol of the corresponding N^{α}-benzyloxycarbonyl derivative by catalytic hydrogenolysis)[16] was dissolved in DMF (2 ml) and triethylamine (0.18 ml) was added. This solution was mixed with a DMF solution of the active ester obtained above and the mixture (total volume, 4 ml) was kept at 4°C for 48 hr. The reaction mixture was then introduced into ice-cold ethyl acetate (100 ml) and the precipitates which separated were filtered off, washed with ethyl acetate and ether, lyophilized from acetic acid and dried over sodium hydroxide pellets *in vacuo*, affording the crude protected octadecapeptide (0.56 g).

The protected peptide obtained above was put into a reaction vessel (made of fluorinated polyethylene) with methionine (0.1 g) and anisole (0.5 ml), and hydrogen fluoride was introduced into the vessel placed in a dry ice-acetone bath. The mixture (*ca.* 10 ml) was stirred at 0°C for 90 min, followed by evaporation *in vacuo* to give a sirupy residue, which was dissolved in ice-cold water. The solution was washed with ethyl acetate and then passed through a column (1.7×12 cm) of Amberlite CG-400 (acetate form); the column was washed with portions of water. The aqueous solutions combined were concentrated to *ca.* 20 ml *in vacuo* and lyophilized. The crude deblocked peptide thus obtained (0.65 g) was subjected, for purification, to chromatography on a column (2.7×27 cm) of carboxymethyl (CM) celullose (Serva, 0.56 meq/g) using an ammonium acetate buffer (pH 6.8, 2000 ml) with a linear concentration gradient from 0.02 to 0.6M. Ten-ml fractions were collected and their absorptivity at 280 mμ was recorded. The fractions corresponding to a main peak (tubes 156—180) and its shoulder (tubes 181—200) were collected separately and the bulk of the solvent was removed by evaporation *in vacuo* at a bath temperature of 50—55°C. The residues were lyophilized to constant weights to give 189 mg (F-I) and 76 mg (F-II) of colorless powder from the former fractions and from the latter, respectively. F-I (189 mg) was rechromatographed on a CM cellulose column (2.2×25 cm) in the same manner as above and the pure peptide (137 mg, F-I-1) was obtained from a single peak. A small shoulder of the peak afforded F-I-2 (37 mg). F-II (76 mg) and F-I-2 (37 mg) were combined and the chromatography was repeated twice to obtain 29 mg of the pure peptide. Total yield of the octadecapeptide amide (Ie) thus obtained amounted to 166 mg (50%, as calculated on the basis of the amount of octapeptide used in the final coupling step); $[\alpha]_D^{23}$ $-58.4 \pm 1.9°$ (*c* 0.514, 0.1N acetic acid). $\lambda_{max}^{0.1N\ HCl}$=279 mμ ($E_{1cm}^{1\%}$=25.1), $\lambda_{shoulder}^{0.1N\ HCl}$=288 mμ ($E_{1cm}^{1\%}$=19.7); $\lambda_{max}^{0.1N\ NaOH}$= 281 mμ ($E_{1cm}^{1\%}$=25.2), 288 mμ ($E_{1cm}^{1\%}$=24.4). The peptide behaved as a single component to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (PtI_6'') reagents in thin-layer chromatography (BAPW as solvent) and in paper electrophoresis (600 V/36 cm, in 2N acetic acid). Amino acid ratios in acid hydrolysate (6N HCl, 105°C, 40 hr):[17] Ser 0.83, Glu 1.00, Pro 1.07, Gly 2.10, Ibu 0.99, Val 1.00, Met 1.02, Tyr 0.97, Phe 1.04, Lys 3.17, His 0.92, Arg 2.90. The Trp/Tyr ratio in intact Ie was determined spectrophotometrically to be 1.12.[18]

β-Alanyl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine Amide, [β-Ala¹]-ACTH(1-18)-NH₂ (Id). Compound XVI (0.32 g, 0.18 mmol) was converted into the corresponding active ester hydrochloride by the same procedure as that described above in the preparation of Ibu¹-decapeptide active ester. A solution of the active ester in DMF (3 ml) was mixed with a solution of N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine amide triacetate (derived from 0.15 mmol of the corresponding N^{α}-benzyloxycarbonyl derivative)[16] and triethylamine (0.2 ml) in DMF (2 ml) and the mixture

was allowed to stand at 4°C for 4 days. The reaction mixture was then introduced into ice-cold ethyl acetate (100 m*l*) and the precipitates which formed were collected by filtration, washed with ethyl acetate and ether, lyophilized and dried over sodium hydroxide pellets *in vacuo*. The crude product (0.59 g) was dissolved in liquid hydrogen fluoride together with methionine (0.1 g) and anisole (0.5 m*l*) and the mixture (*ca.* 10 m*l*) was stirred at 0°C for 60 min, followed by evaporation *in vacuo*. A sirupy residue was dissolved in water and the solution was washed with ethyl acetate, treated with Amberlite CG-400 (acetate) and lyophilized, as described above, to yield the crude deblocked octadecapeptide amide (0.65 g). The crude product was subjected to chromatography on a column (2.6×23 cm) of CM cellulose (Serva, 0.56 meq/g) using an ammonium acetate buffer (pH 6.8, 2100 m*l*) with a linear concentration gradient of 0.02—0.6M. The fractions (10 m*l*/tube) corresponding to the main peak (tubes 151—190) and its shoulder (tubes 191—210) were collected separately. Removal of the bulk of the solvent, followed by lyophilization, yielded F-I (168 mg) and F-II (80 mg) from the peak and from its shoulder, respectively. F-I was rechromatographed on a CM cellulose column (2.2× 22 cm) in the same manner as above to give pure peptide (122 mg, F-I-1) and a less purified fraction (25 mg, F-I-2). F-II (80 mg) and F-I-2 (25 mg) were combined and rechromatographed to obtain an additional quantity of pure peptide (65 mg). Total yield of the octadecapeptide amide (Id) thus obtained amounted to 187 mg (45%, as calculated on the basis of the amount of octapeptide used in the final coupling step); $[\alpha]_D^{28}$ $-58.3\pm1.9°$ (*c* 0.527, 0.1N acetic acid). Lit,[6] $[\alpha]_D^{27}$ $-54.0\pm1.8°$ (*c* 0.515, 0.1N acetic acid). $\lambda_{max}^{0.1N\ HCl}$= 279 m$\mu$ ($E_{1\%}^{1cm}$=23.9), $\lambda_{shoulder}^{0.1N\ HCl}$=288 m$\mu$ ($E_{1cm}^{1\%}$=17.6), $\lambda_{max}^{0.1N\ NaOH}$=281 m$\mu$ ($E_{1cm}^{1\%}$=24.3), 288 mμ ($E_{1cm}^{1\%}$=23.8). The peptide behaved as a single component to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (PtI_6'') reagents in thin-layer chromatography (BAPW as solvent) and in paper electrophoresis (600 V/36 cm, in 2N acetic acid). Amino acid ratios in acid hydrolysate (6N HCl, 105°C, 40 hr):[17] Ser 0.89, Glu 1.03, Pro 1.09, Gly 2.11, Val 1.00, Met 1.02, Tyr 1.09, Phe 1.07, β-Ala 1.08, Lys 2.91, His 0.92, Arg 2.71. The Trp/Tyr ratio in intact Id was 1.03 as determined spectrophotometrically.[18]

Grateful acknowledgement is made to Dr. Akira Tanaka and staff for performing biological assays, Dr. Mitsuo Ebata and staff for amino acid analysis, Dr. Kaoru Kuriyama and staff for optical rotation measurements, and members of our microanalysis laboratory for elemental microanalysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3882—3886 (1970)

Tri(hetero) substituted Carbonium Ions. VI. An Anomalous Reaction of 2-Methylthio-1,3-dithiolanylium Ion with *N,N*-Dimethyldithiocarbamate Anion*1

Takeshi NAKAI and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo

(Received June 15, 1970)

The reaction of 2-methylthio-1,3-dithiolanylium ion (III) with *N,N*-dimethyldithiocarbamate anion ($^-$SN) has been studied with a view toward demonstrating the ambident character of the cation III. It was found that (i) the reaction afforded *S*-β-(*N,N*-dimethyldithiocarbamyl)ethyl-S′-methyltrithiocarbonate (IV; normal) together with ethylene bis(*N,N*-dimethyldithiocarbamate) (V; abnormal); (ii) methylthioxanthate anion ($^-$SS) was formed in the reaction; (iii) the formation of the abnormal product (V) was more favorable and this could not be ascribed to the attack of $^-$SN on the normal product (IV). The ambident reactivity of cation III has been compared with that of closely related cations, tris(methylthio)carbonium ion and 2-methylamino-1,3-dithiolanylium ion (Ia). It was also found that the reaction of Ia with ethylthioxanthate anion ($^-$SS′) afforded the *S*′-ethyl analog of IV (normal) together with a small amount of abnormal V. The mechanism for the formation of the abnormal product (V) both from III and $^-$SN and from Ia and $^-$SS′ has been suggested.

In previous papers[1-5] we reported that various dithiocarbamidium ions including 2-dialkylamino-

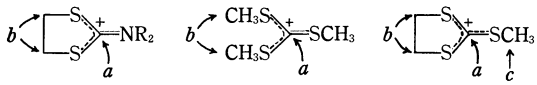
1,3-dithiolanylium ions (I) are ambident electrophiles capable of undergoing reactions with nucleophiles at two sites *a* and *b* in formula (I). Recently Tucker and Roof reported a similar behavior of tris(methylthio)carbonium ion (II).[6] However, little information on the ambident behavior of a cyclic analog of II, 2-methylthio-1,3-dithiolanylium ion (III), has can be found in literature, although reactions at the central carbon atom (site *a*) of III have been reported.[7]



I II III

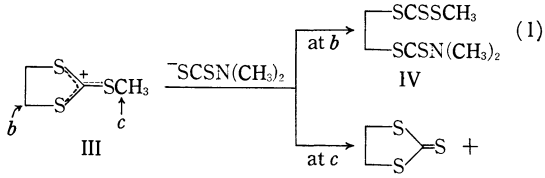
The purpose of this work is to demonstrate that cation III is also capable of undergoing electrophilic reactions at sites *b* or *c*. It has been established with some exceptions that cation I directs the attack of polarizable or bulky nucleophiles to site *b* and the attack of basic nucleophiles to site *a*.[2] Thus the reaction of III with *N,N*-dimethyldithiocarbamate anion, ranked as one of the most polarizable nucleophiles,[8] has been studied in detail.

In this paper anomalous results on the reaction of III with the dithiocarbamate anion are presented and the electrophilic reactivity of III is compared with that of closely related carbonium ions I and II.

Results

Isolation of Cation III as Perchlorate. Recently Gompper and Kutter[7] reported the formation of the methyl sulfate salt of III from the reaction of ethylene trithiocarbonate with dimethyl sulfate. However, the salt was not isolated. In this study, cation III was isolated as perchlorate (IIIa) in 72% yield by treatment of the methyl sulfate salt with an aqueous solution of sodium perchlorate. Recrystallization of the perchlorate from acetone gave colorless needles melting at 101—102°C. The NMR spectrum of IIIa showed two singlet signals at δ 3.21(CH_3S) and 4.37 ppm (CH_2S).

Reactions of 2-Methylthio-1,3-dithiolanylium Ion with *N,N*-Dimethyldithiocarbamate Anion. If we assume that III reacts with the dithiocarbamate anion in the same manner as cation I,[1,2] the reaction can be expected to yield *S*-β-(*N,N*-dimethyldithiocarbamyl)ethyl-*S'*-methyltrithiocarbonate(IV) as the sole product (Eq. (1)). There is another possibility that III and the dithiocarbamate anion would afford ethylene trithiocarbonate and methyl dithiocarbamate (Eq. (2)), if III behaves in the same manner as 2-methylthio-3-methyl-4,5-dihydrothiazolium ion.[9]



(1)

(2)

Thus the reaction of IIIa with sodium *N,N*-dimethyldithiocarbamate (abbreviated as NaSN) was carried out under various conditions. It was found that the reaction of III with NaSN gave ethylene bis(*N,N*-dimethyldithiocarbamate) (V) as a major product together with a very small amount of expected product IV. Bis(dithiocarbamate) V was identified by comparison of the IR and UV spectra with those of the authentic sample. Identification of product IV will be described below.

Table 1 shows yields of the unexpected product (V) under various conditions indicating that the yield of V increases either with reaction time or with an increase in the amount of NaSN employed. As a matter of course the formation of unexpected V must be accompanied by the elimination of thioxanthate moiety ($SCSSCH_3$) (abbreviated as SS) from cation III.

Table 1. Reaction of IIIa with NaSN

Run	IIIa mmol	NaSN mmol	DMF ml	Temp. °C	Time hr	Bis (dithiocarbamate) (V), Yield,[a] %
1	10	10	20	55	4	26
2	20	20	25	60	7	52
3	10	20	25	60	6	69
4	10	28	25	40	6	71

a) Based on IIIa

In order to prove occurrence of the elimination of the thioxanthate moiety, the UV spectrum of an aqueous solution of the resulting mixture was measured (Fig. 1). Comparison of this spectrum with that of NaSN and sodium ethylthioxanthate (NaSS') suggested that the aqueous solution contained both methylthioxanthate and unreacted dithiocarbamate anions.

9) T. Nakai, K. Hiratani and M. Okawara, the 19th Symposium on Organic Reaction Mechanisms, Yamagata, October, 1968; This Bulletin, to be published.

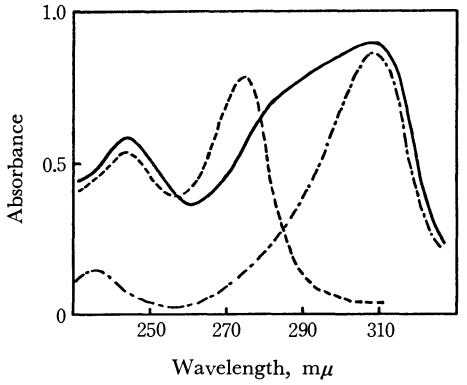

Fig. 1. UV spectra of the resulting aqueous solution (———), sodium *N,N*-dimethyldithiocarbamate (--------; ε_{max} (281 mμ) 12200) and sodium ethylthioxanthate (-·-·-·-; ε_{max} (335 mμ) 9300) in water.

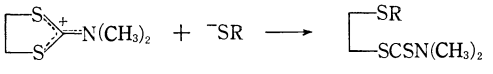
The molar ratio of $^-$SS to $^-$SN remaining in the aqueous solution was calculated from absorbances at 281 and 335 mμ on the assumption that the molar extinction coefficient (ε) of $^-$SS is the same as that of $^-$SS′. It was found in the case of Run 3 that the molar ratio was 0.90 and, hence, 7.5 mmol of $^-$SN remained unreacted since the molar amount of $^-$SS eliminated should be the same as that of bis(dithiocarbamate) (V) formed (Table 2). The finding indicates that most of reacted $^-$SN is distributed in the unexpected product (V).

Table 2. The Distribution of SN Moiety (Run 3)

Before the reaction $^-$SN (mmol)	After the reaction (mmol)		
	V	Unreacted $^-$SN	($^-$SS)
20.0	13.8±2.0	7.5±1.0	(6.9±1.0)

Reaction of 2-Dimethylamino-1,3-dithiolanylium Ion with Ethylthioxanthate Anion. As has been shown,[1,2] 2-dimethylamino-1,3-dithiolanylium ion (Ia) reacts with sulfur nucleophiles to give the open-chain products (VI).



Ia VI

R=Et, Ar, CNR_2' (S)

In view of the separate preparation of the *S′*-ethyl analog (IV′) of the minor product (IV) obtained above, the reaction of the cation Ia with sodium ethylthioxanthate (NaSS′) was carried out. However, contrany to our expectation, it was found that Ia and $^-$SS′ gave an abnormal product, bis(dithiocarbamate) (V), in low yields along with the normal product (IV′) as the main product.

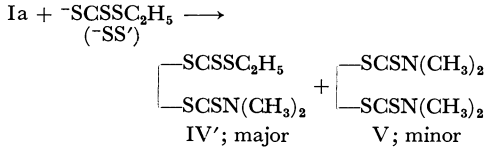


Table 3. Reactions of Ia with NaSS′

Ia mmol	NaSS′ mmol	DMF ml	Temp. °C	Time hr	Yields[a] (%) of products	
					IV′	V
20.0	30.0	25	70	6	37.0	5.5
50.0	50.0	40	60	6	22.0	0.7

a) Based on Ia

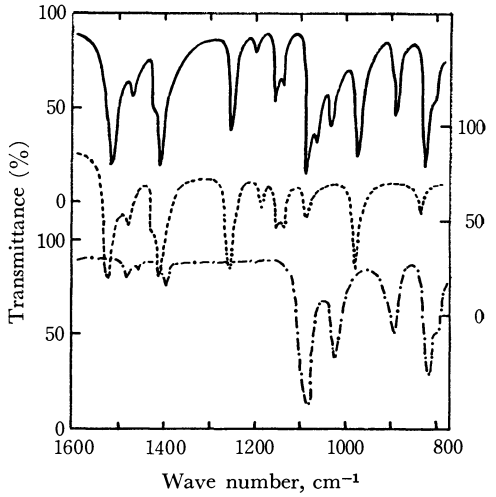

Fig. 2. IR spectra of product IV′ (neat; ———), bis(dithiocarbamate) V (KBr disk; --------) and *S,S′*-diethyltrithiocarbonate (neat; -·-·-·-).

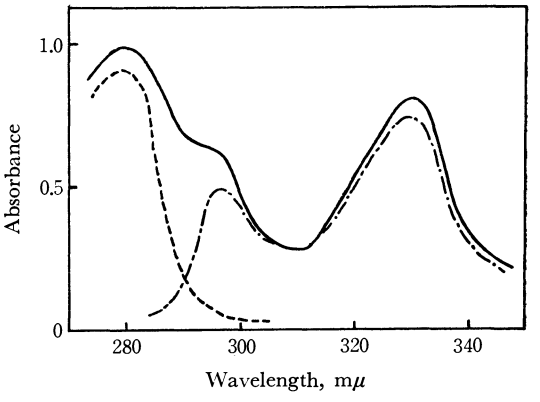

Fig. 3. UV spectra of product IV′ (———), *S*-ethyl *N,N*-dimethyldithiocarbamate (--------) and *S,S′*-diethyltrithiocarbonate (-·-·-·-) in ethanol.

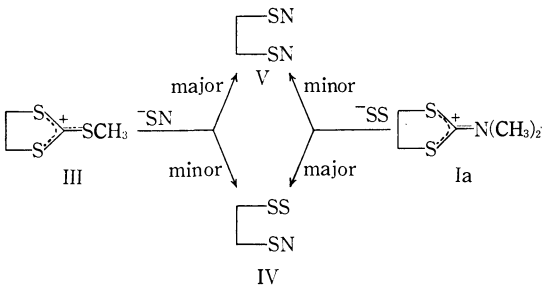
Product IV′ (a yellowish liquid) was purified by means of column chromatography on alumina and

identified by IR and UV spectra, which are shown in Figs. 2 and 3 together with those of related compounds. It is apparent from these spectra that the product IV′ has both –S–CS–N< and –S–CS–S– moieties. The IR and UV spectra of the minor product (IV) obtained from III and $^{-}$SN were essentially identical with those of IV′.

Discussion

The Ambident Character of Cation III. The above results are summarized in the following scheme.



[SN=SCSN(CH$_3$)$_2$; SS=SCSSR′ (R′=CH$_3$ or C$_2$H$_5$)]

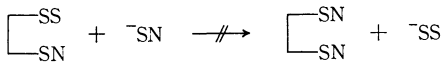
The normal product (IV) from III and $^{-}$SN is best explained as the result of the attack of $^{-}$SN on the *S*-methylene carbon atom (site *b*) of III presumably through the S_N2-like mechanism which has been accepted for the reactions of Ia with sulfur nucleophiles.[1,3] The combined results of the present work and that by Gompper and Kutter[7] reveal that cation III is an ambident electrophile with reactive sites at the central carbon (sp^2) and the *S*-methylene carbon (sp^3) atoms, although the mechanism of the formation of V remains unsettled.

The following evidence indicates that the *S*-methylene carbon atom of III is less reactive than that of Ia. Ia reacts with *p*-tolylmercaptide ion at 60°C giving VI (R=*p*-CH$_3$C$_6$H$_4$) in 77% yield,[2] while III does not react with the mercaptide ion under the same conditions. The smaller reactivity of III seems surprising because it would be more destabilized than Ia since the 2-SMe group in III is less electron-donating than the 2-NMe group in Ia.

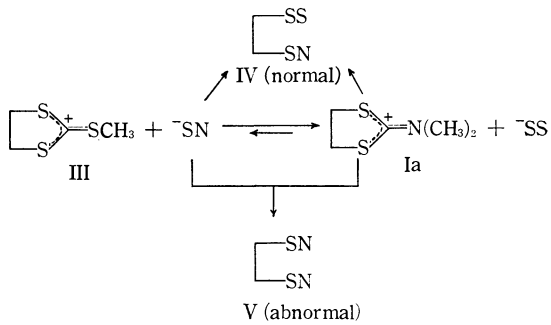
Let us compare the electrophilic reactivities of cation III and its open-chain analog, tris(methylthio)carbonium ion (II). It has been established that the five membered cation Ia is more stabilized than its open-chain analog of Ia.[3,4] By analogy, it is believed that III is more stabilized (less electrophilic) than open-chain II. The following evidence indicates smaller reactivity of III; as decribed above, III does not react with $^{-}$SC$_6$H$_4$CH$_3$ at any sites under given conditions, whereas II is capable of undergoing reaction with a less nucleophilic mercaptide ion ($^{-}$SCH$_3$) at the central carbon atom (site *a*) to afford tetrakis(methylthio)methane.[6]

On the Mechanism of Formation of the Abnormal Product (V). Let us consider the mechanism of the formation of the abnormal product from III and $^{-}$SN. Another formation of V from Ia and $^{-}$SS′ would take place by the subsequent reaction of $^{-}$SN eliminated from Ia with another molecule of Ia.

Controlled experiments demonstrated that neither *S,S*′-dimethyltrithiocarbonate nor trithiocarbonate IV′ reacted with $^{-}$SN at all. The result undoubtedly eliminated the possibility that the formation of the abnormal product (V) took place by the attack $^{-}$SN on the normal product (IV). This also indicates that the formation of V is competition with the formation of IV in both cases.



Thus, in order to explain the results, we have assumed the following scheme involving a direct interconversion between III and Ia.



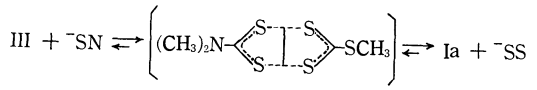
In the above scheme it has been established that (i) the *S*-methylene carbon atom of Ia is more electrophilic than that of III; (ii) $^{-}$SN is much more nucleophilic than $^{-}$SS;[9] (iii) Ia reacts preferentially with $^{-}$SN to afford bis(dithiocarbamate) V. From the scheme, the abnormal product (V) from III and $^{-}$SN is best explained as the result of an initial transformation of III with $^{-}$SN into Ia which then preferentially reacts with another molecule of $^{-}$SN, finally yielding V. Similarly V from Ia and $^{-}$SS′ is explained as the result of capturing $^{-}$SN formed *via* the interconversion process with another molecule of Ia.

The scheme may also account for both favorable formation of abnormal V from III and $^{-}$SN and favorable formation of normal IV′ from Ia and $^{-}$SS′; the more reactive cation Ia directs the attack of $^{-}$SS preferentially to the formation of IV, whereas the less reactive cation III reacts with $^{-}$SN preferentially to give cation Ia, finally yielding V.

As a result, in the absence of data to the contrary, it seems reasonable to assume the above scheme

for the formation of V and for the elimination of $^{-}$SS from III with $^{-}$SN.

Finally, the problem concerning the mechanism of the interconversion: III+$^{-}$SN⇆Ia+$^{-}$SS, still remains. Although the accurate mechanism of the interconversion process is not elucidated as yet, the following two-centered substitution might be assumed as a possible mechanism. However, its confirmation needs further studies.



Experimental

Melting points are uncorrected. The IR and UV spectra were recorded with Hitachi EPI-S2 and EPS-2 spectrometers, respectively. The NMR spectrum of perchlorate IIIa was obtained on a Varian Associate A-60 spectrometer in a $(CD_3)_2SO$ solution using tetramethylsilane as an internal standard.

Materials. *Sodium N,N-dimethyldithiocarbamate.* A commercial product was washed with chloroform before use.

Sodium ethylthioxanthate was prepared, from sodium ethylmercaptide and carbon disulfide according to Barltrop *et al.*[10]

2-Dimethylamino-1,3-dithiolanylium perchlorate (Ia) was prepared by the method[2] given previously. mp 179—180°C (acetone).

Ethylene trithiocarbonate. A commercial product was purified by recrystallization before use.

Preparation of 2-Methylthio-1,3-dithiolanylium Perchlorate (IIIa). Ethylene trithiocarbonate (27.2 g, 0.02 mol) was dissolved in 25.2 g (0.02 mol) of dimethyl sulfate. When the mixture was heated to 50°C a vigorous exothermic reaction occurred. The reaction temperature was kept below 90°C. After the exothermic reaction ceased, the mixture was further stirred at 95°C for 30 min. On cooling the mixture was poured into 200 m*l* of a saturated aqueous solution of sodium perchlorate giving 35.8 g (72%) of pale yellowish precipitates. The precipitates were washed with ether and recrystallized from acetone giving colorless needles: mp 101—102°C.

Found: C, 18.84; H, 2.93%. Calcd for $C_4H_7ClO_4S_3$: C, 19.16; H, 2.82%.

Reactions of 2-Methylthio-1,3-dithiolanylium Perchlorate (IIIa) with Sodium *N,N*-Dimethyldithiocarbamate (NaSN). A typical run is as follows. Carbonium salt IIIa (2.50 g, 0.02 mol) and NaSN (3.60 g, 0.02 mol) were dissolved in 20 m*l* of DMF. The mixture was stirred at 60°C for 6 hr, then poured into 150 m*l* of cold water giving precipitates of ethylene bis(*N,N*-dimethyldithiocarbamate) (V). The precipitates were filtered and washed with ether: mp 188—189°C (DMF) (188—190°C[11]).

The IR spectrum of the product was in agreement with that of the authentic sample.

The filtrate was extracted with ether. The ethereal layer was dried over anhydrous sodium sulfate and the solvent evaporated under reduced pressure giving a small amount of a yellowish oil of *S*-β-(*N,N*-dimethyldithiocarbamyl)ethyl-*S'*-methyltrithiocarbonate (IV). The IR and UV spectra of the oily residue were essentially identical with those of *S*-β-(*N,N*-dimethyldithiocarbamyl)ethyl-*S'*-ethyltrithiocarbonate (IV') described below.

The UV spectrum of the aqueous layer was measured (Fig. 1) indicating that the aqueous solution contained both thioxanthate and dithiocarbamate anions.

Reactions of 2-Dimethylamino-1,3-dithiolanylium Perchlorate(Ia) with Sodium Ethylthioxanthate (NaSS'). A typical run is as follows. Carbonium salt Ia (12.5 g, 0.05 mol) and NaSS' (8.0 g, 0.05 mol) were dissolved in 40 m*l* of DMF. The reaction mixture was stirred at 60°C for 6 hr. The mixture was poured into 300 m*l* of cold water giving 0.31 g of precipitates of V: mp 188—189°C (DMF) (188—190°C[11]). The IR spectrum of the product was identical with that of the authentic sample.

The filtrate was extracted with ether. Work-up gave 5.8 g of yellowish oil of *S*-β-(*N,N*-dimethyldithiocarbamyl)ethyl-*S'*-ethyltrithiocarbonate (IV'). Distillation of the oil *in vacuo* was unsuccessful. Thus the oil was purified by means of column chromatography on alumina: n_D (25°C) 1.6605.

Found: N, 4.79%. Calcd for $C_8H_{15}NS_5$: N, 4.91%.

The IR and UV spectra of the oily product are shown in Figs. 2 and 3, respectively.

The authors are greateful to Sanshin Chem. Ind. Co., Ltd., for the gift of ethylene trithiocarbonate and to Sankyo Co., Ltd., for measurement of the NMR spectrum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3887—3891 (1970)

The Reaction of β-Nitroalcohols and Reactive Aldehydes*1

Juji YOSHIMURA, Takao IIDA and Masuo FUNABASHI

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received June 23, 1970)

Condensation of acyclic or cyclic β-nitroalcohols with aldehydes was examined. In the case of non-protected 1-deoxy-1-*C*-nitro-D-glycitols and benzaldehyde, products caused by aldehyde-exchange reaction were obtained. However, the reaction of 2-methoxy-1-nitropentane or non-protected 2-nitrocyclohexanol and reactive aldehydes (formaldehyde, acetaldehyde and *n*-butyl glyoxylate) in the presence of sodium hydrogencarbonate gave the corresponding condensation products.

It is well known that nitromethane undergoes condensation with equimolar amount of aldehydes or dialdehydes in the presence of an alkaline catalyst to give acyclic β-nitroalcohols or cyclic β,β′-dihydroxynitro derivatives.[1,2] However, the possibility of further condensation of the products with a second aldehyde has not been clarified. Successful condensation of nitroethanol with aldehydes[3,4] or dialdehyde[5] seems to be attributed to the high reactivity of formaldehyde, because nitroethanol is an equimolar condensation product of nitromethane and formaldehyde, and three moles of the latter can be condensed with the former as an exception.[6]

Another important factor in such a condensation is the relative stability of *aci*-nitro salts of a starting material, the expected product, nitromethane, and the condensation product between nitromethane and a second aldehyde, because nitromethane condensation is a kind of reversible reaction. Moreover, the condensation product between a cyclic β-nitroalcohol and a second aldehyde is a tertiary nitro derivative which cannot form an *aci*-nitro salt. Thus the use of a strong alkali as a catalyst is undesirable.

In this paper, the reactions of acyclic or cyclic β-nitroalcohols with aldehydes are described.

Results and Discussion

At first 1-deoxy-1-*C*-nitroglycitol was used as an acyclic β-nitroalcohol without protection of the hydroxyl group. The reaction of 2,3-*O*-isopropylidene-D-glycerinaldehyde[7] and nitromethane in the presence of triethylamine at room temperature gave a mixture of 1-deoxy-3,4-*O*-isopropylidene-1-*C*-nitro-D-*threo*- and -*erythro*-tetritol (**1**) in 60% yield as a distilled sirup. Only when the reaction period was shorter than 12 hr, the isomer which was deduced from the rotational value to have *threo* configuration[8,9] was obtained as crystals. Moreover, 1-deoxy-3,4;5,6-di-*O*-isopropylidene-1-*C*-nitro-D-glucitol (**2**) and -D-mannitol (**3**) were newly synthesized by acetonation of the corresponding glycitols.[10] 1-Acetamido-1-deoxy-D-glucitol (**4**) and D-mannitol (**5**) were also derived from the same compounds by hydrogenation and *N*-acetylation. The position of isopropylidene groups in **2** and **3** was proved by the fact that both compounds and their mixture obtained by the condensation of 2,3 ; 4,5-di-*O*-isopropylidene-*aldehydo*-D-arabinose[11] with nitromethane were converted into the same α,β-unsaturated-nitro compound by acetylation and elimination.[12]

Treatment of **1** with benzaldehyde in the presence of sodium methoxide gave an intractable sirup,

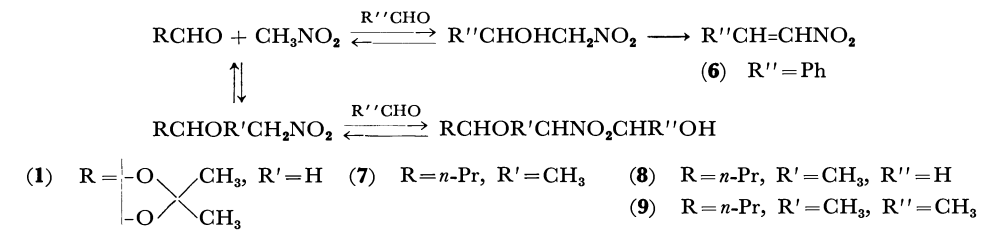

Scheme 1

from which only β-nitrostyrene (**6**) was isolated as crystals. A similar condensation of **3** with benzaldehyde also gave a sirup. In order to identify the products, the sirup was hydrogenated, hydrolyzed, *N*-acetylated and then examined by paper chromatography. The chromatogram showed three main spots, two of which were identified by comparison with authentic samples to be **5** and β-acetamido-α-phenylethanol.[13] An attempted separation of the third compound by a magnesol-celite column was unsuccessful. However, the presence of D-arabinitol was ascertained. This indicates that an aldehyde-exchange reaction occurred as shown in Scheme 1.

In order to prevent such a reverse nitromethane condensation, it was deduced that the protection of the hydroxyl group of an acyclic β-nitroalcohol is necessary, and as mild an alkaline condition as possible should be used. For instance, Magerlein[14] reported recently the successful condensation of methyl 6-deoxy-6-nitro-1-thio-α-D-galactopyranoside with acetaldehyde in a total synthesis of lincomycin, in which the hydroxyl group is protected by the pyranoside ring formation. As a simple model compound to prove the above deduction, 2-methoxy-1-nitropentane (**7**) was prepared by the reaction of 1-nitro-1-pentene[12] and sodium methoxide in absolute methanol at 0—7°C. As expected, condensation of **7** with formaldehyde or acetaldehyde in the presence of sodium hydrogencarbonate at room temperature for a week gave the corresponding product (**8** and **9**) in 26 and 38% yield, respectively. When sodium hydroxide was used as a catalyst in the case of formaldehyde, a small amount of olefinic byproducts were detected in the NMR spectrum of distilled **8**, in which two doublets (τ 3.52 and 4.24, J=1.3 Hz) and one triplet (τ 2.86, J=3.7 Hz) indicated the presence of the corresponding 1-olefin and 2-olefin, respectively. Because the absorption of a conjugated nitro group (ν_{max} 1520 cm^{-1}) was observed in the IR spectrum of undistilled **8**, it is concluded that a strong alkaline condition induced the elimination of water or methanol. The condensation product between **7** and *n*-butyl glyoxylate could not be purely isolated. However, it was isolated as methyl

3-amino-2-hydroxy-4-methoxyheptanoate hydrochloride (**10**) by hydrogenation, esterification, and column-chromatography in 6% yield.

On cyclic β-nitroalcohols, Lichtenthaler and Leinert[5] reported that the condensation of glutardialdehyde and nitroethanol afforded 2-hydroxymethyl-*r*-2-nitrocyclohexan-*t*-1,*t*-3-diol. However, it decomposes to *r*-2-nitrocyclohexan-*t*-1,*t*-3-diol with liberation of formaldehyde in higher pH regions, and the reverse reaction did not take place. Instead of nitroethanol, ethyl nitroacetate was reported as an reactive nitro compound in a similar cyclisation.[15] Recently, Sakai described that the condensation of glutardialdehyde and α-methoxy-β-nitropropionic acid in the presence of sodium hydroxide gave a lactone of the aimed compound (7%) and the corresponding unsaturated

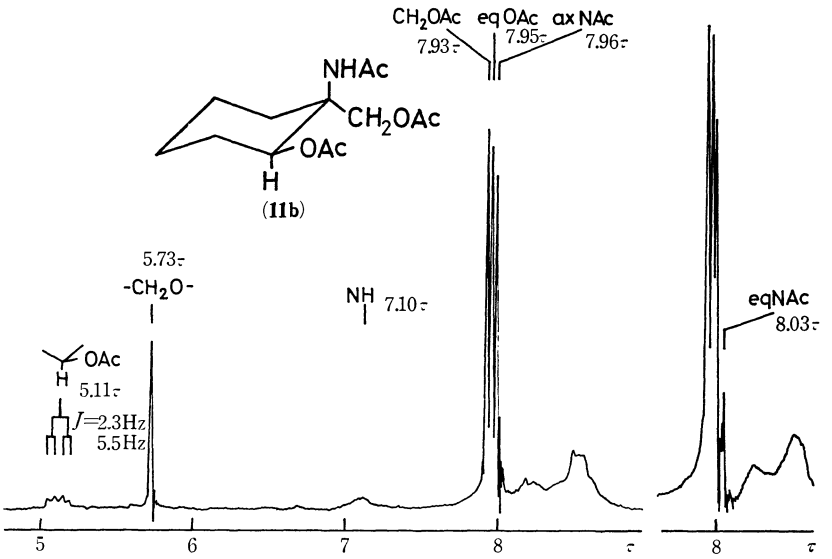

Fig. 1. NMR spectrum of **11b** and a mixture of **11a** and **11b** ($CDCl_3$, 100 MHz).

lactone (13%) in which the nitro group was eliminated.[16] In our experiments, 2-nitrocyclohexanol[17] and formaldehyde were treated under the same conditions as mentioned before, and the sirupy product was directly hydrogenated, acetylated and distilled to give the corresponding triacetate (**11**) in a total yield of 65%. The NMR spectrum of **11** indicated the presence of acetoxymethyl group (τ 7.93), equatorial-acetoxy group (τ 7.95), axial-acetamido group (τ 7.96) and equatorial-acetamido group (τ 8.03) as characteristic signals.[18] Because of the low intensity of the latter, it was deduced that **11** is a mixture of *r*-1-acetamido-*t*-2-acetoxy-1-acetoxymethylcyclohexane (**11a**) and its *c*-2-isomer (**11b**), and the latter is the main product. In fact, crystalline **11b** was obtained by standing for two months as shown in Fig. 1. Similarly, the condensation product of 2-nitrocyclohexanol with *n*-butyl glyoxylate was isolated as methyl α-(1-amino-2-hydroxycyclohexyl)glycolate hydrochloride (**12**) in a total yield of 12%, by hydrogenation, esterification and column-chromatography. However, the configuration of isomers in **12** could not be analyzed.

From these results, it is concluded that acyclic β-nitroalcohols in which the hydroxyl group is protected by ether-linkage and cyclic β-nitroalcohols without protection are successfully condensed with reactive aldehydes such as formaldehyde, acetaldehyde and glyoxylic acid in a weak alkaline condition.

Experimental

The solutions were evaporated under diminished pressure at a bath temperature not exceeding 45°C. All melting points are uncorrected. Optical rotations were measured in a 0.5-dm tube with a Carl Zeiss Photoelectric Precision Polarimeter. The NMR spectra were taken in deuteriochloroform with a JNM-4H-100 MHz Spectrometer, using tetramethylsilane as an internal standard.

1-Deoxy-3,4-*O*-isopropylidene-1-*C*-nitro-D-*threo*-and-*erythro*-tetritol (1). A solution of 2,3-*O*-isopropylidene-D-glycerinaldehyde[7] (14 g, 110 mmol), nitromethane (20 m*l*, 370 mmol) and triethylamine (10 m*l*, 73 mmol) in ethanol (40 m*l*) was allowed to stand for two days at room temperature, and then concentrated to give a sirup (21 g) which was distilled at 103—104°C/0.05 mmHg. Yield, 60% (12 g); $[\alpha]_D^{23}$ +9.5° (*c* 0.16, ethanol); IR (cm^{-1}) : 3430 (OH), 1540 and 1370 (NO_2).

Found: C, 43.22; H, 7.20; N, 7.25%. Calcd for $C_7H_{13}NO_5$: C, 43.97; H, 6.85; N, 7.33%.

When the reaction period was shorter than 12 hr, a part of the distilled product crystallized gradually. After recrystallisation from ether-petroleum ether it showed mp 58–59°C, $[\alpha]_D^{23}$ +17.6° (*c* 1.0, ethanol), and the analytical values consisted with the theoretical. The configuration of this isomer was deduced to be *threo* from the rotational value.[8,9]

1-Deoxy-3,4 ; 5,6-di-*O*-isopropylidene-1-*C*-nitro-D-glucitol (2). A solution of 1-deoxy-1-*C*-nitro-D-glucitol[10] (4 g, 19 mmol) and concentrated sulfuric acid (1.44 g) in acetone (90 m*l*) was allowed to stand overnight at room temperature, poured into aqueous sodium hydrogencarbonate (3 g), and extracted with chloroform. The extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to give a sirup which was distilled at bp 131—133°C/0.03—0.04 mmHg. Yield, 3.2 g (60%), $[\alpha]_D^{23}$ +2.7°

(*c* 2.58, ethanol).

Found: C, 49.62; H, 7.31; N, 4.87%. Calcd for $C_{12}H_{21}NO_7$: C, 49.47; H, 7.27; N, 4.81%.

1-Deoxy-3,4;5,6-di-*O*-isopropylidene-1-*C*-nitro-D-mannitol (3). Treatment of 1-deoxy-1-*C*-nitro-D-mannitol[10] in just the same manner as above gave the corresponding product in 65% yield. Bp 126—128°C/0.02—0.03 mmHg, $[\alpha]_D^{23}$ +15.3° (*c* 1.13, ethanol).

Found: C, 49.73; H, 7.64; N, 5.02%. Calcd for $C_{12}H_{21}NO_7$: C, 49.47; H, 7.27; N, 4.81%.

Treatment of 2,3;4,5-di-*O*-isopropylidene-*aldehydo*-D-arabinose with nitromethane in the same manner as in the case of **1** gave a mixture of **2** and **3** in 65% yield (Found: C, 49.25; H, 7.24; N, 4.63%). Bp 130—132°C/0.03—0.04 mmHg, $[\alpha]_D^{23}$ +11.8° (*c* 1.10, ethanol). Conversion of this sirup, **2** and **3** to the corresponding same nitroolefine by the usual method[12] gave a sirup which could not be distilled. However, the consumption of bromine in chloroform by these sirups indicated that **2** and **3** have a free hydroxyl group at C-2 position.

1-Acetamido-1-deoxy-D-glucitol (4). A solution of 1-deoxy-1-*C*-nitro-D-glucitol[10] (3 g, 14.2 mmol) in absolute ethanol (60 m*l*) was shaken with hydrogen in the presence of 10% of palladium-charcoal (2 g) until the hydrogen uptake ceased, and then filtered. Acetic anhydride (3 g, 30 mmol) was added to the filtrate, which was concentrated after the reaction mixture had been allowed to stand for several hr at room temperature. The residue was crystallized from ethanol to give the product in 82% (2.8 g) yield. Mp 124—125°C, $[\alpha]_D^{23}$ −19.4° (*c* 1.03, methanol).

Found: C, 43.05; H, 7.80; N, 6.31%. Calcd for $C_8H_{17}NO_6$: C, 43.04; H, 7.68; N, 6.28%.

1-Acetamido-1-deoxy-D-mannitol (5). 1-Deoxy-1-*C*-nitro-D-mannitol was treated in just the same manner as above to give **5** in 75% yield. Mp 149—150°C, $[\alpha]_D^{23}$ −15.5° (*c* 1.10, methanol).

Found: C, 42.98; H, 7.62; N, 6.30%. Calcd for $C_8H_{17}NO_6$: C, 43.04; H, 7.68; N, 6.28%.

Reaction of 1 or 3 with benzaldehyde. To an ice-cooled solution of **1** (10.3 g, 51.8 mmol), benzaldehyde (6 g, 56.5 mmol) in methanol (20 m*l*) was added a solution of metal sodium (1.19 g), in methanol (20 m*l*), and allowed to stand overnight at room temperature. The reaction mixture was neutralized with 2 N hydrochloric acid (26 m*l*) and concentrated. The resulting sirup was redissolved in ethanol, filtered, and evaporated. Distillation of a part of the sirup was unsuccessful. An attempt to fractionate the sirup from ethanol-petroleum ether gave 0.8 g of β-nitrostyrene as crystals (mp 56—57°C, lit,[19] 57—58°C), but other products could not be identified even by paper chromatography.

A solution of **3** (6 g, 20.6 mmol), benzaldehyde (3 g, 28 mmol) and triethylamine (0.8 m*l*) in methanol (10 m*l*) was allowed to stand at room temperature until the mutarotation ceased (about 12 hr), and concentrated to dryness. The sirup obtained was hydrogenated in absolute ethanol in the presence of palladium-charcoal, hydrolyzed with 2N-hydrochloric acid, and then *N*-acetylated. The sirupy product showed three main spots; R_f=0.21, 0.62 and 0.84, on paper chromatography, using ethyl acetate-pyridine-water (12 : 5 : 4 in volume) as a developer and potassium permanganate as a detecting reagent. Of the spots, the first and the third were identified by comparison with authentic samples to be **5** and β-acetamido-α-phenylethanol,[13] respectively. An attempted column-chromatographic separation of the other compound, using magnesol-celite (1 : 1 in weight) as a carrier and petroleum ether-benzene, ethanol-benzene, ethanol-methanol in turn as effluents, resulted in the compounds eluating in the order of larger R_f value, though the pure compound could not be isolated. Rechromatography of an enriched part of the desired compound showed a similar result, except that D-arabinitol (R_f= 0.40) was ascertained.

2-Methoxy-1-nitropentane (7). To a solution of metal sodium (4.8 g, 208 mmol) in absolute methanol (100 m*l*) was added 1-nitro-1-pentene[12] (23 g, 200 mmol) slowly at 0—7°C, because of exothermic reaction. After being stirred for one hr at 10°C, the reaction mixture was poured into 50% acetic acid under cooling, and extracted with chloroform. The extract was dried over anhydrous sodium sulfate, and evaporated. Distillation of the residual sirup gave the main fraction which boils at 83—85°C/13 mmHg, as colorless liquid in 75% yield. IR (cm^{-1}): 1548 and 1380 (NO_2), 1099 (C–O–C).

Found: C, 48.99; H, 9.12; N, 9.35%. Calcd for $C_6H_{13}NO_3$: C, 48.69; H, 8.90; N, 9.52%.

3-Methoxy-2-nitrohexan-1-ol (8). A solution of **7** (3.0 g, 20 mmol), formaldehyde (1.6 g of 37% aqueous solution, 20 mmol) and sodium hydrogencarbonate (1.6 g, 20 mmol) in 50% methanol was allowed to stand at room temperature for a week, neutralized with IR-120 ion-exchanger, and evaporated. Distillation of the residual sirup at 98—99°C/2 mmHg gave 1.4 g (38%) of colorless liquid. IR (cm^{-1}): 3410 (OH), 1541 and 1375 (NO_2), 1090 (C–O–C).

Found: C, 47.70; H, 8.54; N, 7.69%. Calcd for $C_7H_{15}NO_4$: C, 47.44; H, 8.53; N, 7.91%.

4-Methoxy-3-nitroheptan-2-ol (9). Acetaldehyde (3.3 g, of 80% aqueous solution, 60 mmol) and **7** (3.0 g, 20 mmol) was treated by the same procedure as mentioned above, and a fraction which boils at 118—121°C/11 mmHg was obtained in 26.2% yield. IR (cm^{-1}): 1545 and 1379 (NO_2).

Found: C, 50.41; H, 8.80; N, 7.33%. Calcd for $C_8H_{17}NO_4$: C, 50.25; H, 8.95; N, 7.33%.

Methyl 3-Amino-2-hydroxy-4-methoxyheptanoate Hydrochloride (10). Treatment of **7** (3.0 g, 20 mmol), *n*-butyl glyoxylate (2.6 g, 20 mmol) and sodium hydrogen carbonate (2.5 g, 30 mmol) in 50% methanol (30 m*l*) by the same method as above gave crude 2-hydroxy-4-methoxy-3-nitroheptanoic acid in 70% yield. For the sake of identification, the sirup was hydrogenated in methanol in the presence of Raney nickel at 40°C under 90 kg/cm², and the filtrate was concentrated after removal of the catalyst. The remaining sirup in 2N sodium hydroxide (10 m*l*) was extracted with ether, acidified with hydrochloric acid, and concentrated. The residual sirup in methanol was filtered, and concentrated. The operation was repeated twice. The sirup was then chromatographed on a silicagel column (1.6 × 35 cm) using benzene-methanol (8 : 2 v/v) solution as an eluent. Fractions No. 3—4 in each 20 m*l* fractionation contained the

methyl ester hydrochloride in the total yield of 6%. IR (cm^{-1}): 1740 (CO), 1625 (NH).

Found: C, 44.84; H, 6.98; N, 5.59%. Calcd for $C_9H_{19}NO_4Cl$: C, 44.73; H, 8.34; N, 5.80%.

Condensation of 2-Nitrocyclohexanol with Formaldehyde. A solution of 2-nitrocyclohexanol[17] (3.0 g, 20 mmol), formaldehyde (5.0 g of 37% aqueous solution, 60 mmol) and sodium hydrogencarbonate (4.0 g, 50 mmol) in 50% methanol (60 ml) was allowed to stand for a week at room temperature, neutralized with 2N hydrochloric acid, and concentrated. The resulting sirup in methanol was filtered, and the filtrate was evaporated. The operation was repeated twice. The sirup (3.9 g) obtained was hydrogenated in the presence of Raney nickel at 40°C under 110 kg/cm^2, and then the aminodialcohol obtained (3.2 g) was acetylated by the usual manner. The resulting triacetate was distilled at 149°C/0.1 mmHg. Yield, 3.5 g (65%). IR (cm^{-1}): 1740 and 1650 (CO), 1540 (NH), 1244 (C-O-C).

Found: C, 57.46; H, 7.95; N, 5.33%. Calcd for $C_{13}H_{21}NO_5$: C, 57.55; H, 7.80; N, 5.16%.

The main component of the triacetate; *r*-1-acetamido-*c*-2-acetoxy-1-acetoxymethylcyclohexane **(11b)**, crystallized on standing for two months showed mp 91—92°C, and the analytical values were consistent with the theoretical.

Condensation of 2-Nitrocyclohexanol with *n*-Butyl Glyoxylate. A solution of 2-nitrocyclohexanol (4.1 g, 28 mmol), *n*-butyl glyoxylate (5.2 g, 40 mmol) and sodium hydrogencarbonate (4.2 g, 50 mmol) in 50% methanol (50 m*l*) was allowed to stand for a week at room temperature, neutralized with 2N hydrochloric acid, and then extracted with chloroform. The extract was dried over anhydrous sodium sulfate and concentrated to give a sirup (5.3 g). The sirup was hydrogenated in methanol in the presence of Raney nickel at 40°C under 120 kg/cm^2 for 5 hr. The reaction mixture was filtered, and the filtrate was evaporated. The sirup obtained was dissolved in 20 m*l* of alkaline water (0.8 g of sodium hydroxide), and extracted with ether. The water layer was acidified with hydrochloric acid, and concentrated. Extraction of the residue with methanol gave the hydrochloride in 60% (3.0 g) overall yields. The paper chromatogram of the hydrochloride, using *n*-butanol - acetic acid - water (4 : 1 : 5 in volume) as a developer and ninhydrine as a detecting reagent, showed two violet spots; R_f=0.48 and 0.43. Fractionation on silicagel column (1.6×35 cm) using benzene-methanol (8 : 2 v/v) gave pure methyl α-(1-amino-2-hydroxycyclohexyl)glycolate hydrochlride (**12**) in 12% yield as a sirup. IR (cm^{-1}) : 1749 (CO), 1630 (NH).

Found: C, 45.10; H, 8.77; N, 5.97%. Calcd for $C_9H_{18}NO_4Cl$: C, 45.85; H, 7.69; N, 5.94%.

The authors wish to express their thanks to Mr. Sadao Ishige for his help in experiments, to Mr. Kiyofumi Fukukawa for measurements of NMR spectra, and to members of the Laboratory of Organic Analysis for elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3891—3894 (1970)

Steric Effects of Alkyl Substituents upon the Opening of the Lactone Ring of Coumaran-2,3-diones

Teruo MATSUURA, Masao KAWAI and Yasuo BUTSUGAN*1

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 24, 1970)

The stability of the lactone rings of alkyl substituted coumaran-2,3-diones against hydrolysis and alcoholysis is greatly affected by the positions of alkyl substituents. From UV spectral studies it was suggested that methyl substitutions at positions adjacent to the lactone ring contribute to stability for steric reasons.

Physalin A, the bitter principle of *Physalis Alkekengi var. Francheti*, was hydrogenated affording tetrahydrophysalin A,[1] which gave a yellow crystalline compound Ia ($C_{12}H_{12}O_3$) as a pyrolysis product. From the IR (KBr: 1820, 1730, 1635 and 1595 cm^{-1}) and the NMR ($CDCl_3$): 1.25 (t, J=8 Hz, 3H) 2.23 (s, 3H), 2.25 (s, 3H), 2.72 (q, J=8 Hz, 2H) and 6.89 (s, 1H)) spectra of Ia its structure was assumed to be 6-ethyl-4,7-dimethylcoumaran-2,3-dione, synthesized according to the scheme shown in Fig. 1.

The UV spectra of Ia in aprotic solvents as well as in acetic acid and in *t*-butyl alcohol (Fig. 2a) showed an absorption maximum at about 310 mμ (in dioxane 307, chloroform 317, carbon tetrachloride 308, acetic acid 314, *t*-butyl alcohol 314 mμ; ε 10000—11000) with a weak shoulder at about 370 mμ (ε *ca.* 2000). The UV absorption of Ia in dioxane-water (1 : 1) as well as in ethanol-

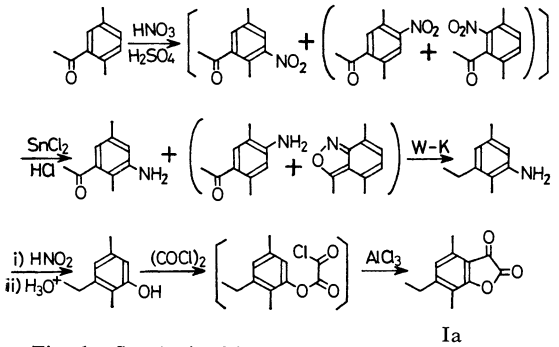

Fig. 1. Synthesis of 6-ethyl-4,7-dimethylcoumaran-2,3-dione (Ia).

water (1 : 1) (Fig. 2b) showed two maxima at 278 mμ (ε 14000) and 340 mμ (ε 3500) and the spectrum was similar to that of *o*-hydroxyphenylglyoxylic acid (IIb) (λ_{max}^{EtOH} 258 mμ, ε 14000; 330 mμ, ε 4000), suggesting that the lactone ring of Ia is opened in such media. The UV spectrum of Ia in ethanol (λ_{max} 280 mμ, ε 11000; λ_{sh} 320 mμ, ε 4200; λ_{sh} 360 mμ, ε 2400) (Fig. 2c) differs from the above spectra and does not resemble any of the spectra of III, IV and V, which were prepared in order to estimate the absorptions of the possible species formed from Ia in ethanol, VI, VII and VIII, respectively. The spectrum of Ia in ethanol can be explained as due to the absorption of the mixture of the open and the closed ring species (IIa + Ia) in the ratio 5 : 2, as shown by dotted and broken lines in Fig. 2c. Attempts to isolate 4-ethyl-2-hydroxy-3,6-dimethylglyoxylic acid (IIa) or its ester were unsuccessful.

Although it has been reported that 4,6- and 4,7-dimethylcoumaran-2,3-diones (If and Ie) are recovered on acidification from their alkaline solution and the corresponding open ring species (IIf and IIe) are not obtained,[2] unsubstituted coumaran-2,3-dione (Ib) and its 5,6- and 5,7-dimethyl derivatives (Id and Ic) were unstable against moisture to give *o*-hydroxyphenylglyoxylic acid derivatives, IIb, IId and IIc, respectively. This suggests that the stability of the lactone rings of alkyl substituted coumaran-2,3-diones against hydrolysis or alcoholysis is greatly affected by the positions of the alkyl substituents.

The UV spectra of five dimethyl and two trimethyl derivatives of Ib were measured in various solvents and the extents of the opening of the lactone rings were estimated from the spectra, as

Table 1. Extents of ring opening of coumaran-2,3-diones (I) estimated from UV spectra

summarized in Table 1. The lactone ring of each compound is more stable in the order *t*-amyl alcohol>*s*-butyl alcohol>*i*-propyl alcohol>98% ethanol. The extent of alcoholysis is smaller in the more sterically hindered alcohol.

The stability of the lactone ring against hydrolysis and alcoholysis are in the order; Id<Ic<If<Ig<Ie<Ih (≒ Ia)<Ii. The order can be explained in terms of steric effects of alkyl substituents of the benzene ring of I upon the stability of the lactone ring in the equilibrium (I + ROH⇌II). Methyl groups adjacent to the lactone ring (R_1 and R_4) make the lactone ring

stable and the effect is in the order $R_1>R_4$. The buttressing effects of R_2 and R_3 were observed; *i.e.* the stability of the lactone ring is in the order Ig>If, and also Ih and Ii>Ie.

Experimental

Melting points were uncorrected. IR spectra were measured for KBr discs.

Synthesis of 6-Ethyl-4,7-dimethylcoumaran-2,3-dione (Ia). According to the procedure of Buu-Hoï *et al.*[3] 2,5-dimethylacetophenone (63 g) was nitrated and then reduced with $SnCl_2$–HCl. After the usual treatment, the crude product (35 g) was shown by gas chromatography (Apiezone) to be a mixture of 3-amino-2,5-dimethylacetophenone, 4-amino-2,5-dimethylacetophenone and 3,4,7-trimethylanthranil in the ratio 8 : 7 : 3. The mixture was vacuum-fractionated and then purified by fractional crystallization (methanol). 3-Amino-2,5-dimethylacetophenone—colorless oil (3 g), bp 158°C/12 mmHg (lit,[3] 158°C/12 mmHg). 4-Amino-2,5-dimethylacetophenone—colorless prisms (1 g), mp 159—160°C (lit,[3] 157°C). 3,4,7-Trimethylanthranil—colorless prisms (4 g), mp 55—56°C, bp 140°C/12mm Hg. IR: 1630, 1580, 1555, 1230, 1085, 895, 840 cm^{-1}. NMR ($CDCl_3$) : δ 2.47(s, 6H), 2.87(s, 3H), 6.52(d, J= 7Hz, 1H), 6.83(d, J=7Hz, 1H) (Found: C, 74.3; H, 6.8; N, 8.6%).

3-Ethyl-2,5-dimethylaniline. 3-Amino-2,5-dimethylacetophenone (2.7 g) was reduced according to the Huang-Minlon method to give 3-ethyl-2,5-dimethylaniline (1.5 g) as a colorless oil. *N*-Acetyl derivative—colorless needles, mp 129—130°C (from aqueous methanol) (Found: C, 75.1; H, 9.0; N, 7.2%).

3-Ethyl-2,5-dimethylphenol. 3-Ethyl-2,5-dimethylaniline (1.15 g) in aqueous HCl was diazotized with $NaNO_2$ (555 mg) and the diazonium salt was decomposed in hot 70% H_2SO_4 (120°C). After the usual treatment, sublimation of the product gave 3-ethyl-2,5-dimethylphenol (350 mg) as colorless needles, mp 70—72°C (lit,[4] 71—72°C).

6-Ethyl-4,7-dimethylcoumaran-2,3-dione (Ia). The solution of 3-ethyl-2,5-dimethylphenol (200 mg) in ether (5 ml) was added to the mixture of oxalyl chloride (1 g) and ether (5 ml). After 48 hr the mixture was evaporated and the resulting oil (3-ethyl-2,5-dimethylphenyloxalyl chloride) was dissolved in CS_2 (5 ml). The solution was added to the suspension of $AlCl_3$ (1.9 g) in CS_2 (15 ml). After 24 hr water (50 ml) was added and the reaction mixture was extracted with ether. Sublimation of the extract (140°C/12 mmHg) gave 6-ethyl-4,7-dimethylcoumaran-2,3-dione (170 mg) as yellow needles, the IR spectrum of which was identical with that of Ia obtained from natural product.[1] Mp 154°C (from ether-light petroleum) and mixed mp 153—154°C.

Found: C, 70.5; H, 6.0%. Calcd for $C_{12}H_{12}O_3$: C, 70.6; H, 5.9%.

2-Hydroxy-3,4,6-trimethylphenylglycolic Acid (V). 4,6,7-Trimethylcoumaran-2,3-dione (Ih) (300 mg) in ethanol (40 ml) was hydrogenated at room

temperature and atmospheric pressure over 10% Pd-charcoal for 18 hr. The reaction mixture was treated as usual and the resulting colorless solid was dissolved in hot aq. solution of NaOH (90°C). On acidification with aq. HCl 2-hydroxy-3,4,6-trimethylphenylglycolic acid (V) (140 mg) was obtained as colorless needles, mp 148—151°C (from acetone-benzene). IR: 3350, 1745, 1210, 1095 cm^{-1}. UV (ethanol): λ_{max} 283 mμ (ε 2400). NMR (DMSO-d_6): δ 2.00 (s, 3H), 2.12 (s, 3H), 2.23 (s, 3H), 5.38 (s, 1H), 4.48 (s, 1H).

Found: 62.7; H, 6.8%. Calcd for $C_{11}H_{14}O_4$: C, 62.6; H, 6.7%.

3-Hydroxy-4,6,7-trimethylcoumaran-2-one (III). Sublimation of V gave 3-hydroxy-4,6,7-trimethylcoumaran-2-one as colorless needles, mp 121—126°C (from benzene-light petroleum). IR: 3320, 1815, 1640, 1600 cm^{-1}. UV (dioxane): λ_{max} 282 mμ (ε 1600). NMR ($CDCl_3$): δ 2.19 (s, 3H), 2.30 (s, 3H), 2.38 (s, 3H), 5.36 (s, 1H), 6.82 (s, 1H).

4,6,7-Trimethylcoumaran-3-one (IV). This compound was prepared according to Smith and Boyack[5], mp 89—91°C. UV (ethanol): λ_{max} 266 mμ (ε 13000), 330 mμ (ε 4600).

Synthesis of Alkyl Substituted Coumaran-2,3-diones (I). Dimethyl- and trimethyl-coumaran-2,3-diones were prepared from the corresponding dimethyl- and trimethyl-phenols according to the general procedure based on the method of Stollé and Knebei[2].

General procedure. The solution of alkyl phenol (1.0 g) in ether (10 m*l*) was added to the solution of oxalyl chloride (1.3 g) in ether (10 m*l*). After standing for 48 hr the solvent and the excess oxalyl chloride were distilled off and the residual oil was dissolved in CS_2 (25 m*l*). $AlCl_3$ (3.0 g) was added to the solution and after a week ice-water (30 g) was added. The reaction mixture was extracted with ether or chloroform to give alkyl substituted coumaran-2,3-dione (I), which was purified by sublimation and/or recrystallization.

5,7-*Dimethylcoumaran*-2,3-*dione (Ic)*. From 2,4-dimethylphenol (1 g) Ic (1.15 g) was obtained, mp 147—148°C (sublimation). IR: 1825, 1735, 1615, 1490 cm^{-1}. On standing in an open container Ic was gradually hydrolyzed to give IIc, mp 91—96°C (from water). IR: 1730, 1630, 1600 cm^{-1}. (Found: C, 59.3; H, 5.5%. Calcd for $C_{10}H_{10}O_4 \cdot 1/2H_2O$: C, 59.1; H, 5.5%).

4,7-*Dimethylcoumaran*-2,3-*dione (Ie)*. Mp 136—137°C (lit,[2] 136°C).

4,6-*Dimethylcoumaran*-2,3-*dione (If)*. Mp 144—145°C (lit,[2] 144°C).

4,5-*Dimethylcoumaran*-2,3-*dione (Ig)*. From 3,4-dimethylphenol (1 g) a mixture (0.95 g) of Id and Ig was obtained. After standing in an open container the mixture was recrystallized from benzene to give IId (0.64 g) and Ig (0.19 g). Ig; mp 168—169°C (from methanol). IR: 1820, 1730, 1615, 1600, 1480 cm^{-1} (Found: C, 68.0; H, 4.8%).

5,6-*Dimethylcoumaran*-2,3-*dione (Id)*. Sublimation of IId, obtained from 3,4-dimethylphenol, gave Id, mp 176—177°C. IR: 1830, 1740, 1620 cm^{-1}. On standing Id was readily converted into IId, mp 148—150°C (from benzene). IR: 1765, 1640, 1570, 1500 cm^{-1} (Found: C, 62.1; H, 5.4%).

4,6,7-*Trimethylcoumaran*-2,3-*dione (Ih)*. Mp 151—152°C (lit,[6] 149—151°C).

4,5,7-*Trimethylcoumaran*-2,3-*dione (Ii)*. From 2,4,5-trimethylphenol (1 g) Ii (1.36 g) was obtained, mp 192—193°C (from ether-light petroleum). IR: 1815, 1730, 1630, 1595, 1490 cm^{-1} (Found: C, 69.7; H, 5.3%).

UV Spectra of Coumaran-2,3-diones (I). The extents of ring opening of I, summarized in Table 1, were estimated from the UV spectra assuming that the spectra of I measured in 98% aq. ethanol containing triethylamine (0.5 mg/m*l*) and in $CHCl_3$ (Table 2) give the standard absorptions of the open and the closed ring species (II and I), respectively.

The Polymerization of Vinyl Monomers in the Presence of Surface Active Agents. I. The Polymerization of Methyl Methacrylate

Teruzo ASAHARA, Manabu SENŌ, Shinsaku SHIRAISHI and Yoshikazu ARITA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July 2, 1970)

Methyl methacrylate polymerized in the presence of a surface active agent in an aqueous system without any ordinary initiators. Anionic surface active agents, such as sodium tetrapropylenebenzenesulfonate and sodium 2-dodecylbenzenesulfonate, markedly effected the polymerization of methyl methacrylate in the presence of water. The polymerization was inhibited by adding hydroquinone to the reaction system and was also affected adversely by oxygen. Water as a reaction medium was found to be indispensable. The polymerization in organic solvents afforded hardly any polymeric products.

The polymerization of methyl methacrylate (MMA) has been extensively investigated by many workers. Imoto and Takemoto[1] have reported the homo and graft polymerization of MMA onto fibers with hydroxylic pendant groups, especially onto cellulose. They proposed that the initiation step of the polymerization is mainly connected with the formation of a ternary complex of the hydroxyl group, water, and MMA, and also reported that the use of a surface active agent in the polymerization had a slight effect on the reaction. Matsumoto *et al.*[2] reported the polymerization of MMA in an aqueous medium in the presence of poly(methacrylic acid) and proposed that initiation is due to the peroxide of the MMA monomer.

We ourselves have previously reported the polymerization of MMA in the presence of an inorganic substance with a hydroxylic surface, such as clay or silica.[3] During the investigation, we have found that MMA polymerizes readily in the presence of an anionic surface active agent in water, without either hydroxylic surfaces or any ordinary radical initiators, to give poly(methyl methacrylate) with an unusually high molecular weight in a good yield. In this paper, the polymerization of MMA with various surface active substances will be described, and some consideration will be given to the reaction mechanism.

Experimental

Materials. *Monomer.* Methyl methacrylate was purified by the usual method and was stored in a refrigerator until use.

Anionic Surfactants. Sodium tetrapropylenebenzenesulfonate (ABS) was purified by the recrystallization of the methanol-soluble part of a commercial substance (from Lion Fat & Oil Co.) from ether. Sodium 2-dodecylbenzenesulfonate (LAS) was recrystallized from 2-propanol. Sodium lauryl sulfate (SLS) was purified by the procedure used for ABS. Sodium oleate (SO) was recrystallized from ethanol. These purified surfactants were all dried under a vacuum.

Nonionic Surfactants. Octaoxyethylene nonylphenyl ether and polyoxyethylene dodecyl ether were supplied by Kao Soap and Chem. Co. and were used without further purification.

Cationic Surfactant. Cetylpyridinium chloride (CPC) was purified by recrystallization from benzene.

Polymerization. *Method 1.* Into a four-necked, 100-m*l*, round-bottomed flask equipped with a condenser, a dropping funnel, a nitrogen inlet tube, and a thermometer, 0.15 g of a surfactant and 60 m*l* of deionized water were placed; the mixture was then preheated at the desired reaction temperature for 40 min, during which period a slow stream of nitrogen was introduced into the mixture. MMA was then added through the dropping funnel, after which the mixture was heated and stirred continuously under a nitrogen atmosphere for the desired reaction period. At the end of the period, the resultant mixture was poured into 300 m*l* of methanol in order to precipitate the polymer formed, which was filtered, washed with methanol, and dried at 60°C under a vacuum.

Method 2. In a 100-m*l*, round-bottomed flask were placed MMA, a surfactant, and water. The mixture was shaken well and subsequently frozen in an acetone-dry ice bath. It was then subjected to a vacuum below 10^{-3} mmHg in order to degas it, and then allowed to melt. The procedure described above was repeated three times to get a complete degassing. The degassed mixture was then heated at the desired reaction temperature in order to carry out the polymerization reaction. The subsequent procedure to polymerization was the same as that described above.

Determination of Molecular Weight. The molecular weight, $\overline{M}$, of the polymer thus obtained was

determined from the intrinsic viscosity, $[\eta]$, by using this equation:

$$[\eta] = 5.2\times10^{-5}\ \overline{M}^{0.76}$$ [4]

The viscosity of the polymer was measured in benzene at 30°C.

Analysis of Peroxide. The amount of peroxide in the materials used was determined by Wagner's method.[5]

Results and Discussion

The polymerization of MMA in the presence of various types of surfactants in an aqueous system was investigated. Among the surfactants used, all the anionic surfactants except sodium oleate were markedly effective in the polymerization, as is shown in Fig. 1. When either ABS or SLS was used, the polymer yield had a tendency to increase with the reaction time over a period of 6 hours. Sodium oleate, polyoxyethylene nonylphenyl ether, and cetylpyridinium chloride had little effect on the polymerization of MMA compared with the case in which no surfactant was used (Table 1).

None (control)	0.0	0.2

MMA, 5g; surfactant, 0.15 g; water, 60 m*l*; at 80°C; under N_2.

The effects of the polymerization temperature and also of the reaction atmosphere were investigated. In the reaction temperature range from 60 to 100°C, a maximum in the polymer yield was observed at 80°C in every case, as may be seen in Fig. 2. The figure also shows that LAS had a higher efficiency in polymer yield throughout the reaction temperature range investigated than did the other surfactants.

The polymerization was conducted under different reaction atmospheres; the results are summarized in Table 2. The polymerization *in vacuo* gave the highest yield and the highest molecular weight polymer. Under nitrogen or carbon dioxide, a high molecular weight polymer was obtained, but in a smaller yield. When air was passed through into the reaction mixture, however, no polymerization was observed. The addition

of hydroquinone or diphenylpicrylhydrazyl to the reaction mixture also inhibited the polymerization. In each polymerization under a vacuum or a nitrogen or carbon dioxide atmosphere, the polymer formed was recovered as a fine powder by pouring the resultant mixture, which was a rather stable emulsion, into methanol.

The polymerization was also carried out in a non-aqueous medium, such as methanol, ethanol, tetrahydrofuran or benzene, but no polymerization was observed (Table 3). From these results, it is conceivable that water is inevitable for the polymerization under the present conditions, and also that the formation of a micelle may be an essential part of the polymerization reaction. The polymerization undoubtedly proceeds *via* a radical mechanism, in view of the experimental facts presented above.

In order to clarify the initiation step of the polymerization, the peroxide values of the surfactants used and of MMA were determined by Wagner's method. The results are summarized in Table 4. LAS, which afforded the highest efficiency in the polymerization, had the highest peroxide value. The approximate total amount of free radicals appearing in the reaction system is 10^{-6}—10^{-7} mol, as calculated from the molecular weight and the yield of the polymer formed, presuming only a radical coupling for the termination reaction of the polymerization. This value is roughly consistent with the peroxide value of the surfactant. It has not been, however, clear that the peroxides of the surfactants used participate in the initiation step, because no polymerization occurred in organic reaction media. At any rate, the presence of a charged interface in the reaction system may be very important for the propagation and/or initiation step. The most likely effect of anionic surfactants was also observed in the emulsion polymerization of MMA, with di-*t*-butyl peroxide used as a radical initiator, as may be seen in Fig. 3. However, the sulfonate anion itself is not very effective in the polymerization, judging from the results of the polymerization, of MMA with sodium *p*-toluenesulfonate and a nonionic surfactant, shown in Fig. 4.

Table 4. Analysis of peroxide in the surfactants used and in MMA

○ Sodium *p*-toluenesulfonate only.
● With 3 g of polyoxyethylene dodecyl ether.

The effort to detect free radicals in the reaction system by the ESR technique has not been successful. This might be because of the concentration of radicals was too low for them to be detected in such an aqueous emulsion system. The poly(methyl methacrylate) obtained had the same structure as that obtained by a conventional free radical polymerization, judging from the results

of the IR and NMR measurements.

A further mechanistic study of the polymerization and also of the variation of monomers is now in progress and its results will be presented in the near future.

The authors are indebted to Messrs. Tomoyoshi Yokoyama and Shigeki Shiozawa for their helpful technical assistance, and also to Lion Fat & Oil Co. and Kao Soap & Chem. Co. for supplying the surfactants.

Oxidation by Transition Metal Complexes. II. Oxidation of Styrenes Catalyzed by Rhodium Compounds

Kiyotomi TAKAO, Masami WAYAKU, Yuzo FUJIWARA, Toshinobu IMANAKA and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received July 9, 1970)

Catalytic activities of chlorotris(triphenylphosphine)rhodium(I) and rhodium(III) chloride for the oxidation of olefins have been studied. It has been found that the complex and $RhCl_3$ can cause catalytically the oxidation of aliphatic olefins such as styrene, α-methylstyrene or β-methylstyrene to produce carbonyl compounds under oxygen atmosphere. A remarkable solvent effect was observed in the reaction.

We have reported the catalytic oxidation of styrene and triphenylphosphine by means of some organoiridium complexes under oxygen stream.[1] In connection with this work, the catalytic function of oxidation by some rhodium compounds which form O_2-complexes, were investigated.

It was found that the complex ($RhX(PPh_3)_3$), especially chlorotris(triphenylphosphine)rhodium (I) can oxidize styrenes in the presence of oxygen to produce carbonyl compounds.[2] Styrene gave similar products to those reported in the case of organoiridium complex catalysts,[1] α-methylstyrene gave acetophenone, α-phenylpropionaldehyde and formaldehyde, and β-methylstyrene gave benzaldehyde and acetaldehyde in good yields.

In the present paper catalytic oxidation with the rhodium complex, $RhCl(PPh_3)_3$ and $RhCl_3$ will be presented.

Results and Discussion

As the general method of oxidation catalyzed by rhodium compounds, mixtures of the reactant styrene and the rhodium complex in toluene, ethanol or other solvents were heated for 8 hr under a constant bubbling of oxygen.

It was found that styrene can be easily oxidized with the use of $RhCl(PPh_3)_3$ or $RhCl_3$ to give similar oxidation products as those obtained with the use of iridium complexes.[1a] The results are summarized in Table 1. This is the first example of oxidation of aliphatic olefins with the use of rhodium complexes. It is remarkable that the oxidation differing from cases with iridium complexes,[1a] is affected by the solvent polarity. Thus, in dioxane (polar solvent) the oxidation resulted in the cleavage of the C=C double bond of styrene to give benzaldehyde as a main product in 611% yield based on the Rh-complex used.[5]

In contrast to this, in ethanol (protic solvent) acetophenone was obtained in excellent yield with a small amount of the double bond-cleavage product, and in toluene (non-polar solvent) the main products were both acetophenone (348%) and benzaldehyde (148%). This is different from results for dioxane and ethanol. In acetic acid and pyridine only a small amount of oxidation products was detected.

Table 1 shows a similar solvent effect in the

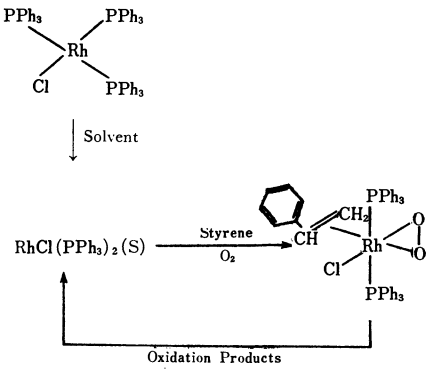
a) Yields are based on the catalyst utilized.

case of the $RhCl_3$ catalyst, but the product distribution differs from that of $RhCl(PPh_3)_3$. The yields of styrene oxide and benzaldehyde increased in toluene, and the total yields decreased in ethanol. A similar result was obtained in the case of $IrCl_3$. The question of catalytic oxidation of styrene with rhodium complexes undergoing a remarkable solvent effect is now being investigated. It seems that the species $RhCl(PPh_3)_2$ (II) which is derived from the dissociation of $RhCl(PPh_3)_3$ has an important role in the reaction.[6]

$$RhCl(PPh_3)_3 \underset{PPh_3}{\overset{Solvent}{\rightleftharpoons}} RhCl(PPh_3)_2 + PPh_3$$

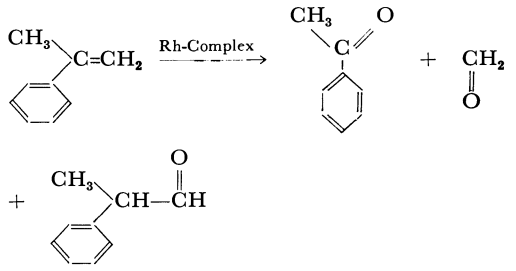
(I) (II)

Species II has a vacant site which may be essential to catalytic activity and will be coordinated easily with oxygen molecule under oxygen atmosphere.[6] We have postulated that oxidation might proceed *via* the coordination of both oxygen and styrene to Rh(I) metal as shown below.



S: Solvent

Oxidation of α-Methylstyrene. The catalytic oxidation of α-methylstyrene with the Rh-complex was also investigated. The results are summarized in Table 2. Oxidation of α-methylstyrene gave acetophenone, formaldehyde, and α-phenylpropionaldehyde in considerable yields. Formations of acetophenone and formaldehyde are derived from the C=C double-bond cleavage of methylstyrene, and the formation of α-phenylpropionaldehyde corresponds to that of acetophenone in styrene. However, no epoxide type product such as styrene oxide could be obtained. The results differ from those of the Wacker process. In the Wacker process, in which $PdCl_2$ is used as an essential catalyst, α-methylstyrene gave only acetophenone and α-phenylpropionaldehyde.[7]



When iridium trichloride was used in the oxidation of α-methylstyrene a similar oxidation mixture (acetophenone and α-phenylpropionaldehyde) was obtained but the yields decreased in comparison with $RhCl_3$.

Oxidation of β-Methylstyrene. β-Methylstyrene was oxidized to benzaldehyde and acetaldehyde. The formation of acetaldehyde was confirmed by converting it to 2,4-dinitrophenylhydrozone. The results are shown in Table 3. We also tried the oxidation of *trans*-stilbene using the Rh-complex in toluene, but no oxidation product was obtained. From the results, it is clear that the reactivities to oxidation of styrenes

decrease as follows: styrene > α-methylstyrene > β-methylstyrene ≫ *trans*-stilbene. This suggests that a more sterically hindered olefin is difficult to coordinate with rhodium(I) and hence is less reactive to oxidation.

In conclusion, it has been found that the rhodium complex and rhodium trichloride have a catalytic function for the oxidation of styrene and methylstyrenes under oxygen atmosphere and that the product distribution undergoes a solvent effect.

Experimental

Materials and Analysis. All temperatures were uncorrected. VPC analysis was made by a Yanagimoto G-8 gas chromatograph usingan Apiezon L column. Rhodium trichloride trihydrate and iridium trichloride were of commercial grade. Toluene and acetic acid were purified as described previously.[1a] Ethanol was refluxed with calcium oxide and distilled. Pyridine was dried over barium oxide and distilled. Tetrahydrofuran was refluxed with sodium metal and distilled. Dioxane was purified by the method of Hess and Frahm.[8] Styrene, α-methylstyrene and β-methylstyrene were dried over anhydrous magnesium sulfate and distilled.

8) K. Hess and H. Frahm, *Ber.*, **71**, 2627 (1938).

Preparation of Chlorotris(triphenylphosphine)-rhodium. $RhCl(PPh_3)_3$ was prepared by the method of Osborn *et al.*[6] Mp 160—161°C (lit,[6] 157—158°C).

Oxidation of Styrene by Rhodium Complex. In a flask similar to that mentioned previously[1a], was placed a mixture containing 2.65 g (2.87 mmol) of $RhCl(PPh_3)_3$, 15 g (0.146 mol) of styrene, and 150 m*l* of toluene. The reaction was carried out at 110°C with continuous bubbling of oxygen for 8 hr. After evaporation of the solvent under reduced pressure, the residual material was chromatographed on alumina (80 g). Elution with 600 m*l* of ether and recrystallization gave 0.82 g of triphenylphosphine oxide. Further elution with methanol gave 0.24 g of an unidentified green complex.

From the solvent evaporated, we obtained styrene, 1.20 g of acetophenone, 0.45 g of benzaldehyde and a trace of styrene oxide.

Oxidation of α-Methylstyrene by Rhodium Complex. The apparatus was similar to that described above, except that the outlet gas from a condenser was bubbled into 2,4-dinitrophenylhydrazine solution. In a flask was placed a mixture containing 2.65 g (2.87 mmol) of $RhCl(PPh_3)_3$, 17 g (0.146 mol) of α-methylstyrene and 150 m*l* of toluene. The solution was refluxed with continuous bubbling of oxygen for 8 hr. Resulting reaction mixture was treated as usual, and the liquid phase was analysed and separated by VPC to give Ia (0.23 g) and Ib (0.09 g). Ia was assigned as acetophenone by comparison of NMR spectrum and retention time with those of an authentic sample. Ib was assigned as α-phenylpropionaldehyde by comparison of NMR spectrum and retention time with those of an authentic sample.

The solid phase was chromatographed on alumina (80 g). Elution with 2 *l* of ether and recrystallization gave 0.90 g of triphenylphosphine oxide. From 2,4-dinitrophenylhydrazine solution, 2,4-dinitrophenylhydrazone of formaldehyde was obtained as yellow crystals.

Oxidation of β-Methylstyrene by Rhodium Complex. The apparatus was similar to that described for α-methylstyrene. In a flask was placed mixture containing 0.55 g (0.60 mmol) of $RhCl(PPh_3)_3$, 2.27 g (19.2 mmol) of β-methylstyrene, and 45 m*l* of toluene. The solution was refluxed with continuous bubbling of oxygen for 8 hr. Resulting reaction mixture was treated as usual, and the liquid phase was separated by VPC to give 0.063 g of benzaldehyde. From 2,4-dinitrophenylhydrazine solution, 2,4-dinitrophenylhydrazone of acetaldehyde was obtained as yellow crystals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3901—3908 (1970)

ν_{O-H} Absorptions and Conformations of Epimeric 1-Tetralols and Chroman-4-ols

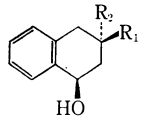
Hiizu IWAMURA and Kaoru HANAYA

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo
and
Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa, Yamagata

(Received August 4, 1970)

The O–H stretching IR absorptions of epimeric 1-tetralols and chroman-4-ols were examined in dilute carbon tetrachloride solutions. The absorption pattern was found to be related to the conformation of the hydroxyl group; the epimers with the quasi-axial OH group showed a singlet ν_{O-H} at 3618 cm^{-1}, while those with the quasi-equatorial hydroxyl had doublet absorption at 3622 and 3600 cm^{-1}. Based on these findings 1-tetralol itself was shown to exist preferentially in the OH axial conformation. The bands at 3618 and 3600 cm^{-1} were assigned severally to the hydroxyl groups bonding to the π-electrons on the benzene ring. When an additional aryl group is present β to the hydroxyl, another O–H$\cdots\pi$ bonding to the aryl group becomes possible in addition to that between the OH group and the benzene ring of the tetralin and the chroman skeletons. The conformation of the aryl substituents was deduced by applying the empirical correlation relating the geometry of the molecule to the bonded ν_{O-H} frequency in a wide variety of aromatic alcohols which incorporate β-arylethanol moiety.

In connection with the stereochemical study of the reduction of α-tetralones, one of the present authors proposed previously a tentative configurational assignment of the resulting 1-tetralol epimers based on their different intramolecular O–H$\cdots\pi$ bonding as revealed by the O–H stretching (ν_{O-H}) absorption spectra.[1,2] A part of the conclusion was, however, found later to be contradictory to that derived from the NMR study and the mechanistic reasoning of their formation by the reductive reactions.[3] Thus the epimers of **1** (mp 96—98°C) and **2** (mp 113—115°C) which were established to be *trans* by the latter studies had been assigned to the contrary because they did not show the apparent O–H$\cdots\pi$ bonding absorption which was expected to be stronger for the *trans* epimer with the axial hydroxyl group.



1a R_1=Ph, R_2=H
1b R_1=H, R_2=Ph
2a R_1=CH_3, R_2=H
2b R_1=H, R_2=CH_3

In view of the recent successful application of the intramolecular O–H$\cdots\pi$ bonding to the structural elucidation,[4,5] the consideration of the above controversy is intriguing. It is the purpose of the present paper to develop a more careful discussion relating the ν_{O-H} data to the conformation of tetralols and chroman-4-ols.

Results

In Table 1 are listed ν_{O-H} maxima of the 1-tetralols and chroman-4-ols, whose configurations have been established on the basis of both the dependence of the vicinal proton coupling constant on the dihedral angle due to the Karplus type equation and the mechanism of their formation.[3] Some of the typical IR absorption traces are reproduced in Figs. 1 and 2. From the data in Table 1 the following conclusions can be derived directly. (1) In a series of the alcohols with the substituent γ to the hydroxyl (**1**, **2**, **5** and **6**), the *cis* epimer has the doublet ν_{O-H} at 3622 and 3600 cm^{-1}, while the *trans* epimer has a skew singlet at 3618 cm^{-1}. (2) In a pair of **4**'s the above correlation between the ν_{O-H} pattern and the configuration is reversed: it is the *cis* isomer which shows a singlet ν_{O-H}. (3) 1-Tetralol itself has a doublet ν_{O-H} more like those with *cis*- γ- or *trans*-β-methyl substituent. The relative intensity of the two bands are, however, reversed. (4) When there is an aryl substituent β to the hydroxyl (**3**, **7**, **8** and **9**), the *trans* epimer gives the doublet absorption at 3614 and 3600 cm^{-1}, while the *cis* at 3616 and 3582 cm^{-1}.

Discussion

There is enough rationalization in regarding the conformation of the cyclohexene moiety of 1-tetralols as a half-chair.[6] As for the chroman skeleton, no direct evidence seems to have been presented for the half-chair conformation of the dihydropyran. Although the sofa conformation in which all the atoms of the ring except $C_{(2)}$ are coplanar has once been proposed,[7] the half-chair model seems to be more consistent with the NMR data.[8] The observed difference in the ν_{O-H} pattern between the epimers means that the benzylic hydroxyl groups should never be equally inclined to the plane of the benzene ring in both cases, and the striking similarity in the IR absorptions with the corresponding 1-tetralol epimers as shown in Table 1 may be considered as another support for the half-chair conformation of

the chroman nucleus.

Due to the conformational preference of the phenyl and the methyl groups over the hydroxyl,[9] the former groups may well be considered to assume preferentially the equatorial disposition on the 1-tetralol and chroman-4-ol skeletons. The conformation of the hydroxyl group should consequently be determined by its configuration with respect to the other substituents. Thus the *cis*- and *trans*-γ-substituted alcohols are expected to have the equatorial and axial hydroxyl groups, respectively. The 1-tetralols and chroman-4-ols with the *cis*- and *trans*-β-substituents are considered to have the axial and equatorial OH groups, respectively. Then the rules (1) and (2) derived in the preceding section can be restated as follows. It is the epimer with the quasi-equatorial benzylic hydroxyl group that shows the doublet absorption at 3622 and 3600 cm^{-1}. The OH quasi-axial epimer, to the contrary, displays only a 3618 cm^{-1} singlet.[11]

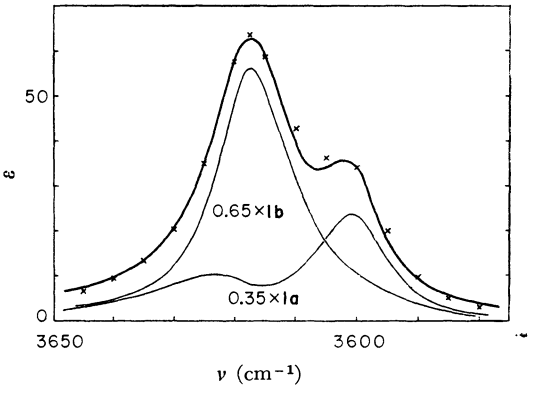

Fig. 3. ν_{O-H} Absorptions of 1-tetralol, **1a** and **1b**.
——— 1-tetralol (observed)
×× 0.35×**1a**+0.65×**1b**

It is instructive to note that graphical superposition of the spectra of **1a** and **1b**, or **2a** and **2b**, reproduces the apparent ν_{O-H} curve of 1-tetralol itself (Fig. 3) when the ratio of mixing is 0.54 to 1.[11a] Thus it is concluded that in 1-tetralol the OH quasi-axial conformation predominates and the apparent conformational energy ($-\Delta G_{25°}$) of the benzylic OH group is calculated to be −0.37 kcal/mol. This is not necessarily due to the O–H⋯π bonding energy because the steric hindrance between the equatorially oriented OH group and the parallelly disposed aromatic hydrogen atom is expected to be more serious than one 1,3-diaxial H–OH interaction in the cyclohexene ring. An analogous situation may be found in the allylic $A^{(1,2)}$ strain proposed by Johnson and Malhotra[12] for the 2,3-disubstituted cyclohexenes in which the substituent at the allylic 3 position often prefers the axial conformation.

Turning now to the interpretation of the ν_{O-H} frequencies, we could assign the bands at 3622 and 3618 cm^{-1} to the free OH group and only the low-frequency band at 3600 cm^{-1} to the one which is O–H⋯π bonded, by applying the naive concept of the effect of the hydrogen bonding on ν_{O-H} frequency. The assignment would be, however, rather confusing because it is at first glance the epimer with quasi-axial hydroxyl group which looks more advantageous for internal O–H⋯π bonding due to the perpendicular approach of the hydroxyl hydrogen to the π-electron cloud on the benzene ring. The interaction of the quasi-equatorial hydroxyl group with the benzene ring might be more horizontal. This is the reason why the opposite configurational assignment was made previously.[1,2] Therefore the truth must be either that the 3622 and/or 3618 cm^{-1} bands are not due to the free ν_{O-H} or that the quasi-axial hydroxyl group is not so favorably disposed for the internal O–H⋯π bonding as the quasi-equatorial epimer.

According to the conformational theory of the multiplicity of the ν_{O-H} absorptions,[13] the free ν_{O-H} frequencies of a pair of the epimeric alcohols under consideration may be expected to be as listed in the first column of Table 2 depending on the conformation of the OH group with respect to the C–O bond. The contribution of the type **a** conformation in which the OH bond is directed towards the center of the cyclohexene and dihydropyran ring may be smaller in the OH quasi-axial epimer because of the 1,3-diaxial interaction.[14] Therefore the singlet absorption at

9) The conformational energies ($-\Delta G_{25°}$) in the cyclohexyl derivatives are 3.1, 1.7 and 0.6 kcal/mol for the phenyl, methyl and hydroxyl groups, respectively.[10]

10) E. L. Eliel, *Angew. Chem.*, **77**, 784 (1965).

11) The same phenomenon has been observed in the epimeric pairs of conformationally fixed cyclohexen-3-ols in which nothing is different from the present system but the benzene ring is replaced by the ethylenic double bond.[5] This apparent reversal in the ν_{O-H} absorption patterns may in general be termed as the anomaly in the benzylic and allylic O–H⋯π bonding.

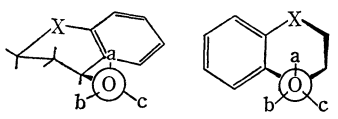
	c	C-C and C-H	3627	3622	5

a) OH Group is not directed towards the π-electrons in these conformations.



X=CH_2 or O

3618 cm^{-1} of the axial epimers is too low in frequency to be assigned to the free ν_{O-H}. Actually it corresponds well to the reported bonding ν_{O-H} of benzyl alcohols[15] in which the C–O bond has been estimated to be "axial" with respect to the plane of the benzene ring.[16] Thus it is more reasonable to regard this singlet absorption as the O–H···π bonded ν_{O-H}. The shift of ν_{O-H} as the result of the interaction ($\Delta\nu_{O-H}$) will be estimated to be 9 cm^{-1} (=3627−3618). In the quasi-equatorial alcohols, it is the type **a** conformation with the O–H bond staggered between the two C–C bonds which is expected to give relatively large ν_{O-H} shift. The OH hydrogen atom in this conformation is shown by molecular models to be favorably situated to overlap with the π-electrons on the benzene ring, while the hydroxyl group stays free in the **b** and lies close to the nodal plane of the π-orbitals on the benzene ring in the **c** conformations, respectively. Therefore the band at 3600 cm^{-1} should be regarded as the bonding ν_{O-H} in the **a** conformation. The second band at 3622 cm^{-1} may be an unresolved overlap of the free and weakly-bonded bands in the conformation **b** and **c**, respectively.[17]

Since the proposal by Badger and Bauer[18] it has been well-documented that $\Delta\nu_{O-H}$ provides a good measure of the strength of the hydrogen bonding especially when the closely related proton donors on the one hand and the acceptors on the other are compared.[19] In the previous papers[5,20] it has been shown that the strength of the O–H···π bonding is governed by the amount of overlap between the orbitals of the π-electrons and the hydroxyl group when a series of compounds with nearly equivalent basicity of the π-electrons and the acidity of the OH groups are compared. As one of the possible measures indicating the overlap between the interacting groups, the overlap integral S between the Slater's hydrogen 1s and the carbon 2p atomic orbitals has been shown to be appropriate.[5,20] In Table 3 are compared these parameters in each interacting conformation based on the geometry which was scaled on a Dreiding model. Although correlation with the observed $\Delta\nu_{OH}$ data is far from quantitative linearity, it is still the type **a** conformation of the quasi-equatorial hydroxyl which has the largest S as expected from the largest $\Delta\nu_{O-H}$. In this conformation, the O–H dipole is disposed anti-parallel to that of the 2$p\pi$ lobe on the adjacent carbon atoms in the benzene ring. The electrostatic force between the dipoles might also be contributing to effecting the largest $\Delta\nu_{O-H}$ shift in addition to the effect of the electron delocalization roughly estimated from S.

In the alcohols with β-aryl substituent (**3, 7, 8**

Table 3. Overlap between the hydroxyl group and the π-electrons on the benzene ring

Conformation of the OH group	Type	$\sum S$[a]	$\Delta\nu_{O-H}$ observed
Quasi-axial	**b**	0.099	9
Quasi-equatorial	**a**	0.110	18
	c	0.050	5

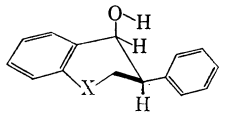
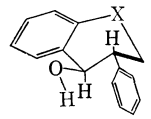
and **9**), the internal bonding of the hydroxyl group with the π-electrons of the aryl group has to be taken into account in addition to the benzylic interaction discussed above. As the result of the preferentially equatorial disposition of the aryl group on the cyclohexene and the dihydropyran nuclei, the hydroxyl group should be quasi-axial in the *cis* epimers. The doublet absorptions at 3616 and 3582 cm^{-1} must have arisen from the O–H$\cdots\pi$ bonding to the benzo-ring and the aryl group (see **11**), respectively. This assignment may be confirmed by the observation that the *p*-methoxyl substitution in the aryl group shifts the latter absorption to the still lower frequency (*ca.* 3582 cm^{-1} in **3a, 7a** and **8a** to 3575 cm^{-1} in **9a**) by enhancing the basicity of the aryl π-electrons.[15,21] In the *trans*-β-aryl substituted series, **3b, 7b, 8b** and **9b,** the quasi-equatorial OH group can interact either with the benzo-benzene ring to exhibit 3600 cm^{-1} band as in the γ-substituted cases or with the β-aryl group to produce the new absorption at 3614 cm^{-1} in the type **b** conformation of the hydroxyl group (see **12**). Alternatively the band at 3600 cm^{-1} might be considered to be an overlap between the two kinds of the bonded bands. The relative intensity of the 3614 cm^{-1} bands is, however, almost unity and too high to be assigned to the hydroxyl group in the **c** type conformation which should be populated one third at best.



11 3582 cm^{-1}



12 3614 cm^{-1}

In an attempt to delineate the spatial configuration of the plane of the aryl group relative to the rest of the molecule in **11** and **12,** it seemed intriguing to examine the ν_{O-H} absorptions in a wide variety of conformationally-fixed β-phenethyl alcohols. As summarized in Table 4, the bonded ν_{O-H} frequencies range from 3616 cm^{-1} down to 3560 cm^{-1}. It is rather apparent from molecular models that the larger ν_{O-H} shift in compounds **17** to **22** may be derived from the geometry which permits closer approach of the hydroxyl group to the π-electrons on the aromatic ring. In compounds **13** and **14,** on the contrary, the hydroxyl hydrogen lies close to the nodal plane of the carbon $2p\pi$ orbitals of the benzene ring with result of the smallest shift in the ν_{O-H} frequency.[22] When alcohols with the same framework are compared, their ν_{O-H}'s fall within the experimetal errors and support the idea that the geometrical factors are playing the major role in determining the absorption frequency.[23] As in the previous treatment,[5,20] one could compute the Slater overlap integral between the hydrogen 1*s* and the carbon 2*p* orbitals to represent the extent of overlap between the two interacting groups in each alcohol, but the dihedral angle θ made by the plane of the aromatic ring and the plane defined by the three carbon atoms, C_α,C_β and C_1 of the benzene ring has now been employed as a convenient measure expressing the geometrical relationship between the OH and the aromatic π-electrons. It is shown in Fig. 4 that it is by definition the quadrant described by θ and not the supplementary angle of θ which should contain the OH group. For each alcohol the angle θ was measured on a Dreiding model and/or estimated on the basis of the geometry of the partial structure when this is known. Thus the exact dimension of cyclopentene[24] was assumed for **15** and **24.** The consistent value of $\theta=144°$ was also obtained for **17** and **22** from the structure of norbornane and norbornadiene determined by the electron diffraction study.[25] The results are included in Table 4. It is not always proper to regard the apparent difference in frequencies of the doublet absorption peaks as the ν_{O-H} shift, because the conformational environment of the hydroxyl group which is well-documented[13] with its influence on the ν_{O-H} frequency does not necessarily coincide in the free and the bonded forms. To avoid ambiguity in

21) M. Ōki and H. Iwamura, This Bulletin, **32**, 1135 (1959).

22) To the authors knowledge, only one attempt has so far been presented which is partly successful in correlating ν_{O-H} data with the distance *r* between the hydroxyl hydrogen and the carbon atom carrying the π-electrons pertaining to the interaction (Y. Matsui, M. Takasuka and T. Kubota, *Shionogi Kenkyusho Nempo* (*Ann. Rept. Shionogi Res. Lab.*), **15** 125 (1965); T. Kubota, M. Takasuka and Y. Matsui, *ibid.*, **16**, 63 (1966)). This approach is, however, too approximate to be applied to conformational analysis.

23) It is noted by comparing pairs of **13a** and **13b**, **13c** and **13d**, and **8a** and **9a** that the methoxyl group produces further low frequency shift by 0, 3 and 7 cm^{-1} at 3616, 3600 and 3582 cm^{-1}, respectively, of the ν_{O-H} frequencies of the unsubstituted alcohols. The lowest frequency of 3560 cm^{-1} observed for epihaemanthamine **21** must be partly due to this electronic effect produced by the methylenedioxy group on the aromatic ring which is known to increase the basicity of the π-electron system just as the methoxyl group does. For the purpose of conformational discussion, it is necessary to eliminate from the observed ν_{O-H} value contribution of the electronic effect. By considering approximately twice as much shift as one methoxyl group, the corrected frequency for the unsubstituted homolog of **21** would be about 3574 $(=3560+2\times7)$ cm^{-1}.

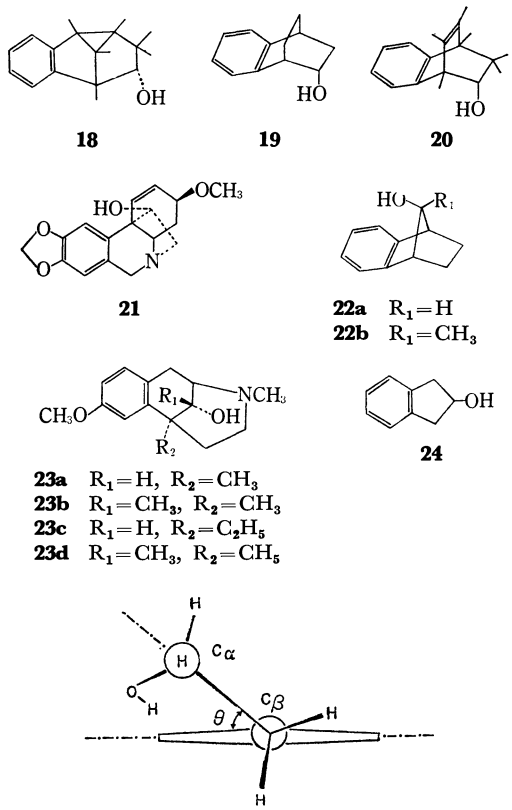

Fig. 4. Definition of the dihedral angle θ in β-phenylethanols.

evaluating the free ν_{O-H} which would be expected for the bonded conformer when it has not O–H···π bonding, the bonded frequency itself is tentatively to be compared without reference to the free ν_{O-H}. It is apparent that the lower the bonded O–H frequency the stronger the O–H···π bonding. Graphic presentation gives reasonably smooth bonded ν_{O-H} *versus* θ curve as shown in Fig. 5. The correlation may well be rationalized by inspection of molecular models (see Fig. 4) in such a way that when $\theta=120°$ the OH hydrogen is situated right above the π-cloud of the C_1 atom on the benzene ring and the overlap between the hydroxyl and the π-electrons is expected to be maximal. At $\theta=30°$ the hydroxyl hydrogen lies on the plane of the benzene ring, pointing the node of the π-electrons with result of no effective bonding at all. Correspondingly ν_{O-H}'s appear at the normal free ν_{O-H} region of 3620—3627 cm^{-1}. The argument is based on the assumption that in most of the bonded conformations of β-phenylethanols the C_α–O bond is staggered with the C_β–C_1 bond; the dihedral angle between the plane of O–C_α–C_β and that of C_α–C_β–C_1 is approximately 60°.

The curve in Fig. 5 could be approximated by Eq. (1) and will be of great use in conformational

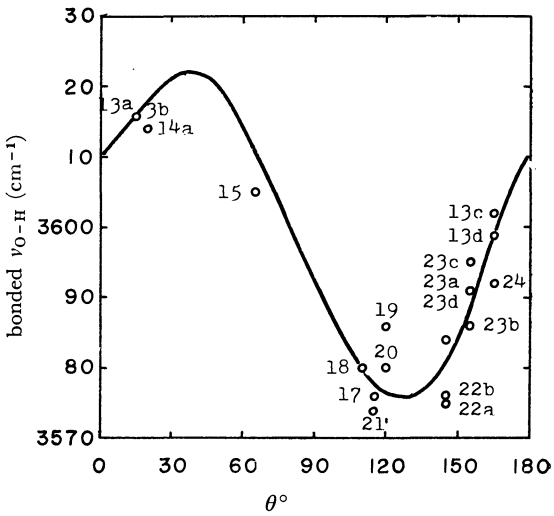

Fig. 5. Angular dependence of the observed ν_{O-H}.

study of β-phenylethanols. Thus it is possible

$$\nu_{O-H}^{bonded}\,(cm^{-1}) = 3625 - 50\cos 2(\theta - 30°) \qquad (1)$$

to estimate that in the bonded conformation of **11** θ must be about 120°. In **12** θ is estimated to be *ca.* 60°. Geometrically these conditions are satisfied in either epimer by fixing the plane of the benzene ring so that the $C_{(2)}$–$C_{(3)}$ bond of the chroman skeleton (bold lined in **11** and **12**) eclipses the plane. Analogously for 2-phenylcyclohexanols (**16a** and **16b**) $\theta=90°$; the $C_{(1)}$–$C_{(2)}$ bond in the cyclohexyl moiety is projected perpendicular to the plane of the benzene ring. This is not consistent with that proposed for phenylcyclohexane itself. The benzene ring has been estimated to be perpendicular to the plane defined by the $C_{(1)}$–$C_{(2)}$–$C_{(3)}$ atoms of the cyclohexane ring.[39] If the latter conformation were kept in **16,** markedly different ν_{O-H} frequencies should at least have been observed for **16a** and **16b,** because the spatial relation between the OH and the aromatic ring is quite different in both epimers. The θ defined as above amounts to 60° and 120° for the *cis* and the *trans* epimers, and the bonded ν_{O-H} of *ca.* 3615 and 3580 cm^{-1} should have been observed, respectively.

As another example on this line, mention should be made of the reported conformation of (+)-catechin teramethyl ether. Birch colaborated with Cole[40] concluded the 2-aryl-3-OH-diaxial

25

conformation on the assumption that the observed ν_{O-H} at 3594 cm^{-1} might be due to the internal hydrogen bonding to the ring oxygen of the chroman skeleton. The conclusion is, however, incompatible with the conformational energy of the axial aryl group.[9,10] Even stabilization of the OH axial conformation by the O-H···O hydrogen bonding does not seem to be enough to allow predominantly axial hydroxyl, because in the case of tetrahydropyran-3-ol the conformer with the equatorial OH group is still present in an appreciable concentration.[41] Therefore the preferred conformation of (+)-catechin tetramethyl ether would better be considered as 2,3-diequatorial with the hydroxyl group bonded to the π-electrons on the aryl group (**25**). The observed frequency of 3594 cm^{-1} is reasonably understood when the electron-donating effect of the two methoxyl substituents on the aryl ring is taken into account[23] in reference to 3599 cm^{-1} observed for the structurally analogous *trans*-2-phenylcyclohexanol (**16b**).[42]

41) S. A. Barker, J. S. Brimacombe, A. B. Foster, D. H. Whiffen and G. Zweifel, *Tetrahedron*, **7**, 10 (1959).

42) The corresponding hydroxyl groups in *cis*- and *trans*-flavan-3,4-diols are reported (E. M. Philbin, T. S. Wheeler, F. V. Brutcher, Jr., and W. Bauer, Jr., *J. Org. Chem.*, **27**, 4114 (1962)) to absorb at 3606 and 3608 cm^{-1}, respectively. Shift to higher frequency by several cm^{-1} when compared with those of **25** and **16b** might somehow be ascribed to the effect of the second 4-OH group which is bonding to the 3-OH consecutively.

Experimental

The infrared absorptions were measured either on a Perkin-Elmer 125 double beam or a 112G single beam grating high resolution IR spectrometer, the spectral slit width being 1.0 cm^{-1} in the region concerned. A quartz cell of 20 mm and a KCl cell of 30 mm in optical length were used. The concentration of the solutions was *ca.* 5 mmol/*l* in carbon tetrachloride distilled over phosphorus pentoxide at which dilution the band due to intermolecular hydrogen bonding was not observed. Sometimes ν_{O-H} absorptions were accompanied by a weak shoulder at 3630 cm^{-1} which was found later to be due to poor cancellation of the absorptions of water vapor in the optical path especially with a double beam spectrometer.

1-Tetralols and chroman-4-ols were prepared by reduction of the corresponding α-tetralones and γ-chromanones according to the literature.[2,43] We are indebted to Prof. N. Inoue who kindly supplied samples of 3-phenylchroman-4-ols.

As to the ν_{O-H} data quoted from the literature, reliable ones were carefully picked up which have been explicitly mentioned to have been measured in dilute carbon tetrachloride solutions on the IR spectrometer equipped with a grating or a fluoride prism.

Study on Oxazolopyrimidines. V. Preparation of 9-Substituted Hypoxanthines *via* 7-Aminooxazolo[5,4-*d*]pyrimidines

Yozo Ohtsuka

Sagami Chemical Research Center, Onuma, Sagamihara, Kanagawa

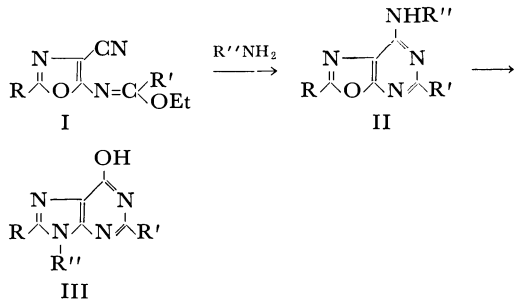
(Received August 8, 1970)

Reaction of 4-cyano-5-ethoxymethylenaminooxazoles with aliphatic amines gave 7-alkylaminooxazolo[5,4-*d*]pyrimidines. The structure of these compounds was discussed on the basis of spectroscopic properties. These oxazolopyrimidines were converted to 9-alkylhypoxanthines by treatment with aqueous alkali (Method A) or by heating in formamide (Method B). Reaction of the ethoxymethylenamino compounds with aromatic amines gave 9-arylhypoxanthines directly (Method C).

Conversion reaction of 7-aminooxazolo[5,4-*d*]pyrimidines into hypoxanthine derivatives has been reported in a previous paper.[1] The present work is concerned with the extension of this reaction to the preparation of 9-substituted hypoxanthines.

The procedure for the synthesis of fused pyrimidines by reaction of amines and heteroaromatic compounds which have a cyano and an ethoxymethylenamino group at adjacent positions has been applied to several systems.[2-5] The application of this method is convenient for preparing variously substituted fused pyrimidines which may be useful to biochemical studies.

Treatment of 4-cyano-5-ethoxymethylenaminooxazoles (I) with ammonia has been shown to afford 7-aminooxazolopyrimidines.[6] Analogous treatment of I with aliphatic amines gave the corresponding products II, most of which were led to 9-alkylhypoxanthines (III) under suitable conditions. The reaction of I with aromatic amines, however, required rather severe conditions, under which the conversion reaction of 7-arylamino intermediates (II) into 9-arylhypoxanthines (III) took place.



I II III

Synthesis and Structure of 7-Aminooxazolo[5,4-*d*]pyrimidines (II). Treatment of Ia (R=R′=H) with a cold aqueous solution of methylamine gave colorless crystals immediately. Its structure was supposed to be an amidine intermediate (IV) on the ground of its spectra (the presence of nitrile band in IR spectrum and the absence of ethoxyl group in NMR spectrum), considering the analogous reaction path with pyrazole derivatives.[2] The compound IV was easily converted into a second product, 7-methylaminooxazolpyrimidine (IIa), on standing in a basic medium. The structure of the latter compound was distinguished from that of 6-methyl-7(6*H*)iminooxazolopyrimidine (V) by the following reasons; *i*) From the study on 7-aminooxazolopyrimidines, a relatively low electron density on the pyrimidine moiety has been suggested,[6,7] and the rate of the Dimroth rearrangement has been known to be greatly enhanced with the pyrimidine derivatives having electron-withdraw-

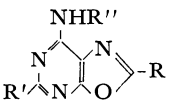
ing substituents.[8] Thus, the compound V was expected to be easily converted into IIa under such conditions as used in this experiment. Moreover, the previously isolated iminopyrimidines have been reported to be somewhat unstable on standing in moist air or on being treated in a polar solvent.[2,9] These properties are completely different from that of the product obtained here. *ii*) The UV spectrum of this compound was investigated at pH 1 and pH 10, and the difference of λ_{max} in acidic and in basic solution were compared with the values of 6-methylaminopurine ($\Delta\lambda=5$ mμ)[10] and of 1-methyl-6-(1*H*)iminopurine ($\Delta\lambda=11$ mμ).[11] While a relatively large value of $\Delta\lambda$ was expected for imino structure (V), the experimental value ($\Delta\lambda=3$ mμ) indicates that the structure of the product is IIa. Little pH-dependence has been observed also with the UV spectrum of 7-aminooxazolopyrimidine.[6] *iii*) Other spectroscopic properties of the compound seem to support the above conclusion. Its IR spectrum shows a band due to a secondary amine. In the mass spectrum, it preferentially expels 28 mass units from the molecular ion. Such a process has been observed previously with 6-methylaminopurine,[12] in which the initial fragmentation was attributed to loss of a methylamino group with concomitant transfer of one or two hydrogen atoms to the purine nucleus.

Table 1. 7-Alkylaminooxazolo[5,4-*d*]pyrimidine derivatives

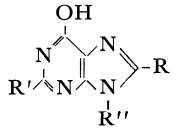


Compd	Substituent			Yield (%)	Mp (°C)
	R	R′	R″		
IIa	H	H	CH_3	80	182—184
IIb	H	CH_3	CH_3	62	170—171
IIc	H	C_2H_5	CH_3	82	140—142
IId	CH_3	H	CH_3	27	194—195
IIe	CH_3	CH_3	CH_3	67	184—185
IIf	H	H	C_2H_5	49	144—145
IIg	H	H	*n*-Pr	31	104—105
IIh	H	H	*i*-Pr	24	121—122
IIi	H	H	*n*-Bu	26	81— 82
IIj	H	H	*t*-Bu	—	—

By the reaction of I with various aliphatic amines, a number of oxazolopyrimidines were obtained. The IR, NMR and mass spectra of these products exhibit the characteristic patterns closely related with those of IIa, indicating that these products have 7-alkylamino structures (II). As shown in Table 1, both the yields and the mp's of these oxazolopyrimidines are dependent mainly upon the substituent R″. The bulkiness of R″ seems to be unfavorable to the reaction. The cyclized product was not obtained from the reaction of Ia with *t*-butylamine. The effect of other substituents, R and R′, seems to be small but the introduction of 2-substituent (R=CH_3) causes the oxazole ring to be somewhat unstable to alkali.

Preparation of 9-Substituted Hypoxanthine (III). 7-Alkylaminooxazolopyrimidines (IIa and IIb) were treated with aqueous alkali under the conditions similar to those with 7-amino compounds,[1] and the corresponding hypoxanthines (IIIa and IIIb) were obtained as shown in Table 2 (Method A). This treatment, however, has a limitation since the isolation of water-soluble products is tedious and hydrolysis with strong alkali is accompanied by the conversion reaction. In these cases, the conversion was carried out by heating II in formamide at around 200°C (Table 2, Method B). As for the reaction of I with aromatic amines, prolonged heating at higher temperatures was needed in contrast to the case of aliphatic amines, and the corresponding hypoxanthines were obtained directly (Table 2, Method C). Method C gave a better result than Method B in reaction of Ia with *n*-butylamine.

Table 2. Total yields of hypoxanthines derivatives



Compd	Substituent			Method[a]	Total yield from I (%)
	R	R′	R″

The decreased yield of hypoxanthines having a bulky substituent at 9-position may be related partly with the formation of isomeric products. Thus, the treatment of IIh by Method B yielded an isomeric product, but the rearrangement accompanying this reaction will be reported in a subsequent paper.

This new route from oxazole derivatives to hypoxanthines may be applied best for the preparation of hypoxanthines having an *n*-alkyl substituent at 9-position.

Experimental

Melting points were measured on a hot-stage apparatus and uncorrected. The IR, NMR and UV spectra were determined with a Perkin-Elmer 337, a Varian HA-100 and a Carry-14 spectrometer, respectively. Mass spectra were recorded at ionization voltage of 70 eV, and samples were introduced directly into the ion source of a Hitachi RMU-6E mass spectrometer. Preparations of starting materials (I) from 5-amino-4-cyanooxazole derivatives and ortho-esters have been described in a previous paper.[6]

7-Methylaminooxazolo[5,4-*d*]pyrimidine (IIa). To an ice-cooled aqueous solution of methylamine (30%, 1 m*l*), 4-cyano-5-ethoxymethylenaminooxazole (Ia, 1.65 g) was added in one portion. A solid started to precipitate immediately from solution,[13] but on continued stirring it rapidly dissolved. After 10 min, a second solid precipitated. Filtration and washing with a small quantity of water gave a crystalline (1.20 g). For analytical purpose, recrystallization from water or ethanol gave colorless needles, mp 182—184°C. λ_{max}^{MeOH} mμ (log ε): 207 (4.20), 258 (4.20), 283 sh (3.71). $\lambda_{max}^{pH\ 1}$: 255 (4.03). $\lambda_{max}^{pH\ 10}$: 258 (3.84). λ_{max}^{KBr} cm^{-1}: 3295 (NH), 3071 (CH), 1630, 1604, 1535, 1492, 1142, 1062, 795. NMR (DMSO-d_6) δ: 3.03 (broad s, 3H, *N*-methyl protons), 8.12 (broad s, 1H, =*N*-proton), 8.33 (s, 1H, C_2-proton), 8.61 (s, 1H, C_5-proton). Mass spectrum (assignment, relative intensity, metastable peak) *m/e*: 150 (M^+, 100), 122 (M^+-28, 42, 99.0), 94 ([121]$^+$—HCN, 23, 73.0), 67 ([94]$^+$—HCN, 31, 48.7).

Found: C, 47.66; H, 4.09; N, 37.45%. Calcd for $C_6H_6N_4O$: C, 48.00; H, 4.03; N, 37.32%.

9-Methylhypoxanthine (IIIa). Method A. A mixture of IIa (1 g) and a 4N aqueous NaOH (5 m*l*) was stirred at room temperature for 30 min and then warmed gradually to dissolve the solid into the solution. After cooling, the solution was neutralized with HCl and resulting precipitate (0.8 g) was collected by filtration.

Method B. The compound IIa (1 g) was heated in formamide (5 m*l*) to a vicinity of 200°C for 40 min and then evaporated to nearly dryness under reduced pressure. Recrystallization from water gave 0.8 g of colorless crystals.

These products were identified as 9-methylhypoxanthine.[14]

13) A crude material was rapidly isolated from the reaction mixture. Its IR spectrum showed a nitrile band and its NMR spectrum showed no ethoxyl group. Furhter purification of the material gave IIa.

5-Methyl-7-methylaminooxazolo[5,4-*d*]pyrimidine (IIb). This compound was prepared from 4-cyano-5-ethoxyethylenaminooxazole (Ib) and methylamine by the procedure described above with 69% yield. Recrystallization from ethanol gave colorless needles, mp 170—171°C. ν_{max}^{KBr} cm^{-1}: 3249 (NH), 3118 (CH), 1677, 1600, 1555, 1519, 1160, 1040, 771. NMR (DMSO-d_6) δ: 3.54 (broad s, 3H, *N*-methyl protons), 7.21 (s, 1H, =N-proton), 8.35 (s, 1H, C_2-proton), 2.50 (s, 3H, C_5-methyl protons). Mass spectrum, *m/e*: 164 (M^+, 100), 149 (M^+-15, 16, 135.4), 136 (M^+-28, 16, 112.8), 96 ([136]$^+-C_2H_2N$, 19, -), 69 ([96]$^+$ -HCN, 47, 49.6).

Found: C, 51.08; H, 4.62; N, 34.61%. Calcd for $C_7H_8N_4O$: C, 51.21; H, 4.91; N, 34.13%.

2,9-Dimethylhypoxanthine (IIIb). This compound was prepared from IIb by Method A with 74% yield. Recrystallization from water gave colorless crystals, mp>320°C. The IR spectrum of the compound exhibited a broad band in the 2800—2600 cm^{-1} region which is characteristic of all the hypoxanthines studied here and a band due to a secondary amine was absent. Mass spectrum, *m/e*: 164 (M^+, 100), 123 (M^+-CH_3CN, 98, 92.3), 95 ([123]$^+$—28, 97, 73.4), 68 ([95]$^+$—HCN, 116, 48.7), 53 ([68]$^+-CH_3$, 50, 41.3), 41 ([68]$^+$—HCN, 84, 25.8).

Found: C, 51.36; H, 4.94; N, 34.29%. Calcd for $C_7H_8N_4O$: C, 51.21; H, 4.91; N, 34.13%.

5-Ethyl-7-methylaminooxazolo[5,4-*d*]pyrimidine (IIc). This compound was prepared from 4-cyano-5-ethoxypropylenaminooxazole (Ic) and methylamine with 82% yield. Recrystallization from ethanol gave colorless needles, mp 140—142°C. ν_{max}^{KBr} cm^{-1}: 3218 (NH), 3085 (CH), 1663, 1600, 1540, 1509, 1147, 1049, 810, 797. NMR (DMSO-d_6) δ: 3.56 (s, 3H, *N*-methyl protons), 8.40 (s, 1H, C_2-proton), 1.22 and 2.84 (5H, ethyl protons). Mass spectrum, *m/e*: 178 (M^+, 100), 177 (M^+–H, 47, 176.0), 163 (M^+-CH_3, 46, 149.3), 150 (M^+-28, 22, 126.4), 149 ([150]$^+$—H, 15, 148.0), 123 ([150]$^+$—HCN, 8, 100.9), 96 ([124]$^+$—28, 11, 74.3), 69 ([96]$^+$—HCN, 33, 49.6), 42 ([69]$^+$—HCN, 53, 25.6).

Found: C, 53.64; H, 5.30; N, 31.75%. Calcd for $C_8H_{10}N_4O$: C, 53.92; H, 5.66; N, 31.45%.

2-Methyl-7-methylaminooxazolo[5,4-*d*]pyrimidine (IId). This compound was prepared from 4-cyano-5-ethoxymethylenamino-2-methyloxazole (Id) and methylamine with 62% yield. Recrystallization from water gave colorless needles, mp 194—195°C. ν_{max}^{KBr} cm^{-1}: 3240 (NH), 3048 (CH), 1665, 1630, 1585, 1502, 1134, 911, 791. NMR (DMSO-d_6) δ: 2.99 (d, 3H, *N*-methyl protons), 7.90 (broad s, 1H, =N-proton), 8.22 (s, 1*H*, C_5-proton), 2.58 (s, 3*H*, C-methyl protons). Mass spectrum, *m/e*: 164 (M^+, 100), 136 (M^+-28, 77, 112.8), 108 ([135]$^+$—HCN, 27, 86.4).

Found: C, 51.18; H, 5.01; N, 33.66%. Calcd for $C_7H_8N_4O$: C, 51.21; H, 4.91; N, 34.12%.

2,5-Dimethyl-7-methylaminooxazolo[5,4-*d*]pyrimidine (IIe). An aqueous solution of methylamine (30%, 3.8 m*l*) was cooled with ice-salt mixture. To this, cooled and powdered 4-cyano-5-ethoxyethylenamino-2-methyloxazole (Ie, 5.4 g) was added in one

14) R. K. Robins and H. H. Lin, *J. Amer. Chem. Soc.*, **79**, 490 (1957).

portion. The mixture was stirred at room temperature for 30 min. The resulting semi-solid was dissolved in chloroform and the aqueous layer was separated. The colorform solution was poured into a large volume of ether. On cooling the mixture, white crystalline material separated gradually and filtration gave an amorphous solid (3.5 g). The solid was dissolved in water (10 ml) and the solution was heated under reflux for 1.5 hr. Filtration after cooling gave light-yellow needles (2.2 g), mp 181—182°C. For analytical purpose, recrystallization from water-ethanol gave colorless needles, mp 184—185°C. ν_{max}^{KBr} cm^{-1}: 3245 (NH), 3045 (CH), 1630, 1580, 1520, 1505, 1141, 1036, 791. NMR (DMSO-d_6) δ: 2.97(d, 3H, *N*-methyl protons), 7.70 (broad s, 1H, =N-proton), 2.53 s, 3H, C_2-methyl protons), 2.42 (s, 3H, C_5-methyl protons). Mass spectrum, *m/e*: 178 (M^+, 100), 150 (M^+-28, 48, 126.4), 137 (M^+-CH_3CN, 21, 105.4), 109 ([137]$^+-28$, 29, 86.7), 108 ([150]$^+-CH_3CNH$, 49, 77.8).

Found: C, 53.85; H, 5.79; N, 31.24%. Calcd for $C_8H_{10}N_4O$: C, 53.92; H, 5.66; N, 31.45%.

2,8,9-Trimethylhypoxanthine (IIIe). This compound was prepared from IIe by Method B with 74% yield. Recrystallization from acetonitrile gave colorless crystals, mp>330°C. The IR spectrum of the compound exhibited a broad band at around 2900 cm^{-1} and a band due to a secondary amine was absent. NMR (D_2O) δ: 2.01 (s, 6H, *C*-methyl protons), 3.88 (s, 3H, *N*-methyl protons). Mass spectrum, *m/e*: 178 (M^+, 100), 164 (M^+-CH_2, 14, —), 137 (M^+-CH_3CN, 28, 105.4), 95 ([137]$^+-CH_3CNH$, 18, 65.9).

Found: C, 53.88; H, 5.76; N, 31.54%. Calcd for $C_8H_{10}N_4O$: C, 53.92; H, 5.66; N, 31.45%.

7-Ethylaminooxazolo[5,4-*d*]pyrimidne (IIf). The compound Ia (1.65 g) was added into an ice-cooled aqueous solution of ethylamine (35%, 2 ml) and stirred for 10 min. Filtration gave a solid (1.24 g), which was quickly dried *in vacuo* for 30 min and then heated under reflux in ethanol (15 ml) for 4 hr. After cooling, the mixture was filtered and the filtrate was concentrated under reduced pressure. Crystals (0.75 g) were obtained from the residue on cooling. Recrystallization from water gave colorless needles, mp 144—145°C. ν_{max}^{KBr} cm^{-1}: 3230 (NH), 3090 (CH), 1630, 1591, 1560, 1516, 1135, 1060, 796. NMR (DMSO-d_6) δ: 8.22 (broad s, 1H, =N-proton), 8.34 (s, 1H, C_2-proton), 8.63 (s, 1H, C_5-proton), 1.22 and 3.62 (5H, *N*-ethyl protons). Mass spectrum, *m/e*: 164 (M^+, 64), 149 (M^+-CH_3, 100, 135.4), 136 (M^+-28. 58, 112.8), 122 ([149]$^+$—HCN, 16, 99.9), 109 ([136]$^+$—HCN, 19, 87.4), 94 ([121]$^+$—HCN, 12, 73.0), 81 ([109]$^+$—CO, 10, 60.2), 67 ([94]$^+$—HCN, 28, 47.7).

Found: 51.37; H, 5.19; N, 33.87%. Calcd for $C_7H_8N_4O$: C, 51.21; H, 4.91; N, 34.13%.

9-Ethylhypoxanthine (IIIf). The above compound (IIf) was treated by Method B and the reaction product (a brown oil) was crystallized from acetone (83%). Recrystallization from water gave colorless crystals, mp 264—266°C. This product was identified as 9-ethylhypoxanthine.[15]

7-*n*-Propylaminooxazolo[5,4-*d*]pyrimidine (IIg). This compound was prepared by the method analogous to that of IIf from Ia and *n*-propylamine in water with 31% yield. Recrystallization from water gave colorless needles, mp 104—105°C. ν_{max}^{KBr} cm^{-1}: 3230 (NH), 3060 (CH), 1629, 1589, 1561, 1518, 1142, 1052, 1044, 794. NMR (DMSO-d_6) δ: 8.23 (broad s, 1H, =N-proton), 8.33 (s, 1H, C_2-proton), 8.63 (s, 1H, C_5-proton), 1.43, 1.65 and 3.53 (7H, *N*-*n*-propyl protons).

Found: C, 53.93; H, 5.85; N, 31.20%. Calcd for $C_8H_{10}N_4O$: C, 53.92; H, 5.66; N, 31.45%.

9-*n*-Propylhypoxanthine (IIIg). Avove compound (IIg) was treated by Method B and the product was recrystallized from *i*-PrOH. Yield 87%. This compound was identified as 9-*n*-propylhypoxanthine.[16]

7-*i*-Propylaminooxazolo[5,4-*d*]pyrimidine (IIh). This compound was prepared in a similar way to the preparation of IIf from Ia and *i*-propylamine with 24% yield. Recrystallization from water gave colorless crystals, mp 121—122°C. ν_{max}^{KBr} cm^{-1}: 3230 (NH). 3075 (CH), 1636, 1590, 1562, 1520, 1113, 1071, 794, NMR (DMSO-d_6) δ: 8.03 (d, 1H, =N-proton), 8.30 (s, 1H, C_2-proton), 8.61 (s, 1H, C_5-proton), 4.5 and 1.26 (7H, *i*-propyl protons).

Found: C, 53.95; H, 5.73; N, 31.42%. Calcd for $C_8H_{10}N_4O$: C, 53.92; H, 5.66; N, 31.45%.

7-*n*-Butylaminooxazolo[5,4-*d*]pyrimidine (IIi). This compound was prepared in a similar way to the preparation of IIf from Ia and *n*-butylamine with 26% yield. Recrystallization from water-ethanol gave colorless crystals, mp 81—82°C. ν_{max}^{KBr} cm^{-1}: 3250 (NH), 3060 (CH), 1660, 1630, 1596, 1521, 1144, 1050, 798. NMR (DMSO-d_6) δ: 7.68 (s, 1H, =N-proton), 8.30 (s, 1H, C_2-proton), 8.59 (s, 1H, C_5-proton), 0.9, 1.5 and 3.5 (9H, *N*-*n*-butyl protons).

Found: C, 56.23; H, 6.50; N, 29.10%. Calcd for $C_9H_{12}N_4O$: C, 56.22; H, 6.29; N, 29.15%.

9-*n*-Butylhypoxanthine (IIIi). By Method B. Above compound IIi was treated by Method B and the product was recrystallized from water. The yield was nearly quantitative.

By Method C. To a solution of *n*-butylamine (1.5 g) in dry pyridine (25 ml), Ia (1.65 g) was added portionwise. The mixture was stirred for 15 min at room temperature and then heated under reflux for 2 hr. After concentration of the solution nearly to dryness under reduced pressure, the residual sirup was kept overnight in a refrigerator. The resulting precipitate was filtered off and washed with benzene. The product (0.8 g) was recrystallized from water and identified as 9-*n*-butylhypoxanthine.[17]

9-Phenylhypoxanthine (IIIk). Aniline (2.0 g) and Ia (3.3 g) were chilled with ice-water separately and mixed in one portion. On stirring at room temperature, the mixture changed into an amorphous solid. This was digested with 50 ml of water and the mixture was heated gradually to 70—80°C in the course of 2 hr. Light brown needles separated from the brown oil. Filtration after cooling and washing of the needles with acetone gave a product (2.0 g), which on recrystallization from 50% ethanol gave colorless needles identified

as 9-phenylhypoxanthine.[18]

9-β-Naphthylhypoxanthine (IIII). Cooled and pulverized Ia (1.65 g) was mixed with β-naphthylamine (1.43 g). On stirring at room temperature, the mixture melted and crystals separated again. After 30 min, this was digested with water (50 ml) and the mixture was heated under reflux for 1 hr. The resulting solid was collected and washed with a small quantity of acetone. Reprecipitation from DMF-ether followed by recrystallization from 50% ethanol gave colorless crystals (0.45 g), mp 320°C. Its IR spectrum showed a broad band at around 2850 cm^{-1} and an intense band at 1700 cm^{-1}. NMR (NaOD-D_2O) δ: 8.58 (s, 1H, C_2-proton), 8.17 (s, 1H, C_8-proton). 8.3 (m, 7H, β-naphthyl protons). Mass spectrum, *m/e*: 262 (M^+, 100), 261 (M^+-H, 21, 260.0), 234 ($[261]^+-HCN$, 6, 209.8), 207 ($[234]^+-HCN$, 5, 183.1), 180 ($[207]^+$-HCN, 4, 156.5).

Found: C, 68.16; H, 3.86; N, 21.09%. Calcd for $C_{15}H_{10}N_4O$: C, 68.69; H, 3.84; N, 21.37%.

This compound was shown to be identical with the product prepared by the method of Robins *et al.*[18] from 5-amino-4,6-dichloropyrimidine and β-naphthylamine.

The author wishes to thank Dr. Shizuo Nakamura for his encouragement throughout this work, and Mr. Kikuo Sugimoto and Mr. Shigeru Kiuchi for their technical assistance.

The Properties of Aqueous Solutions of Sodium 2-Sulfoethyl Alkanoates and Sodium Alkyl β-Sulfopropionates

Takeshi HIKOTA, Kiyoshi MOROHARA and Kenjiro MEGURO

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received May 8, 1970)

A series of sodium 2-sulfoethyl alkanoates $RCOO(CH_2)_2SO_3Na$ was prepared from sodium isethionate and fatty acids containing 9, 11, 13, and 15 carbon atoms. The Krafft point, the critical micelle concentration (CMC), the surface tension, the emulsifying power, the wetting time, the resistance to acid hydrolysis, and the calcium-ion stability of this series of surfactants were examined, and the results were compared with those of the corresponding sodium alkyl β-sulfopropionates $ROCO(CH_2)_2SO_3Na$, which have another structure of ester-linkage. The CMC values of sodium 2-sulfoethyl alkanoates almost coincide with those value of the sodium alkyl β-sulfopropionates with the same number of carbon atoms. However, the Krafft point and surface tension at the CMC of sodium 2-sulfoethyl alkanoates were lower than those of the sodium alkyl β-sulfopropionates with the same number of carbon atoms. Sodium 2-sulfoethyl alkanoates are more stable than sodium alkyl β-sulfopropionates in their resistance to hydrolysis and to the calcium-ion.

In the last few years, several authors have studied the relation between the molecular structure and the properties of surfactants containing an ester group.[1-3] However, ester linkage may be classified into two fundamental types: (a) those in which the hydrophobic group is derived from the higher fatty acid, and (b) those in which the hydrophobic group is derived from the higher alcohol. The object of this report is to clarify how this difference in ester linkage affects the surface and colloidal properties, such as the Krafft point, the CMC value, the surface tension, the emulsifying power, the wetting property, the resistance to acid hydrolysis, and the calcium-ion stability. The surfactants of the first type used for this experiment were sodium 2-sulfoethyl alkanotes, while the surfactants of later type were sodium alkyl β-sulfopropionates.

Experimental

Material. The preparation of sodium 2-sulfoethyl alkanoate and sodium alkyl β-sulfopropionate may be represented by the following equation:

(a) $RCOOH + HO(CH_2)_2SO_3Na \rightarrow RCOO(CH_2)_2SO_3Na + H_2O$

(b) $ROH + Br(CH_2)_2COOH \rightarrow ROCO(CH_2)_2Br + H_2O$

Preparation of Odd-chain Fatty Acid. The odd-chain fatty acid used in the preparation of the (a)-type surfactant was synthesized from the even fatty alcohol with one less carbon atom.[4] The odd-chain fatty acid thus obtained was washed several times with water, dried, and then distilled under reduced pressure. The purity of the odd-chain fatty acids was confirmed by elementary analysis and by a study of the melting points (pelargonic acid, 11.7—12.5°C; undecylic acid, 28.3—29.2°C; tridecylic acid, 39.6—40.8°C; and pentadecylic acid, 50.8—51.9°C). The results of the chemical analyses of the carbon and hydrogen of the compounds gave the calculated values for their composition within ±0.3%. The octyl, decyl, dodecyl, and myristyl alcohols used as starting materials were purified by vaccum distillation from good commercial-grade alcohols, and were confirmed to be more than 98% pure by gas chromatographic analysis.

Preparation of Sodium 2-sulfoethyl Alkanoate. Sodium 2-sulfoethyl alkanoate was prepared by the following reaction. A solution of 0.32 mol of odd-chain fatty acid and 0.3 mol of sodium isethionate in 100 m*l* of toluene was stirred and then heated at the reflux temperature for 10 hr. The water of esterification was removed by azeotropic distillation using a Barrett trap. The reaction mixture was then cooled, and the precipitate, sodium 2-sulfoethyl alkanoate, were separated by filtration. The crude material was recrystallized three times from methanol, and then extracted with petroleum ether for 120 hr. The residue was dried at room temperature under reduced pressure to give the purified sodium 2-sulfoethyl alkanoate as a white flaky powder.

Preparation of Sodium Alkyl β-Sulfopropionate. The sodium alkyl β-sulfopropionates were prepared from β-bromopropionic acid, sodium sulfite, and higher alcohol containing from 8 to 14 even carbon atoms by a previously described method.[2] The crude material was recrystallized three times from ethanol, and then extracted with petroleum ether for 120 hr.

The results of the elementary analysis of these surfactants for carbon and hydrogen are summarized in Table 1.

Measurements. The Krafft point was taken as the temperature at which there was a rapid increase of the solubility of the surfactant in water upon gradual heating. The rapid increase in solubility at the Krafft point accompanied the rapid increase in electrical conductivity.[5] Therefore, the measurement of the rapid increase in the conductivity of the surfactant solution with the temperature in the presence of the solid surfactant made it possible to estimate the Krafft point. The values of conductivity were measured by means of a Towa Denpa Co. electro-conductivity bridge.

The CMC value of the surfactant was estimated by means of the electro-conductivity method[6] at 40°C. These CMC values were determined from the break point in the diagram of equivalent conductivity *vs.* the root of the concentration.

The surface-tension of an aqueous solution of the surfactant was measured by the Wilhelmy plate method at 30°C.

The emulsion was prepared from 5 m*l* of toluene and 10 m*l* of a 20-mmol aqueous solution of the surfactant by hand shaking at 40°C. The duration of the emulsion time was measured by the time elapsed from the moment of the cessation of the shaking to the separation of 9 m*l* of an aqueous volume from the emulsion layer.

The wetting power of the surfactant was measured by the disk-sinking method,[7] in which the wetting time of a felt disk in the surfactant solution become the scale for the wetting. The practical procedure was as follows: 75 m*l* of the 20-mmol surfactant solution to be tested was placed in a 150-m*l* beaker; then the disk (20 mm in diameter and 1 mm thick) was immersed in horizontal position. The time (in seconds) required for the disk to sink was recorded as the wetting time.

The experiment to measure the stability to hydrolysis was carried out by heating a 10-mmol equivalent of the surfactant solution in 20 m*l* of 2N sulfuric acid at 40°C.

The calcium-ion stability of the surfactant solution (10 mmol, 10 m*l*) was measured by a modified Hart method,[8] using 0.1N calcium chloride.

Results and Discussion

Krafft Point. It has been stated that the ionic surfactant can be as soluble as the micelle only above the Krafft point. Therefore, the value of the Krafft point must be determined before the measurement of the CMC by means of electroconductivity and other surface active properties. The Krafft points of the sodium 2-sulfoethyl alkanoates and sodium alkyl β-sulfopropionates series are given in Table 2, and they are plotted against the alkyl chain length in Fig. 1. These plots become two nearly parallel straight lines for each series of surfactants. The Krafft points of the sodium 2-sulfoethyl alkanoates are lower than those of the corresponding sodium alkyl β-sulfopropionates.

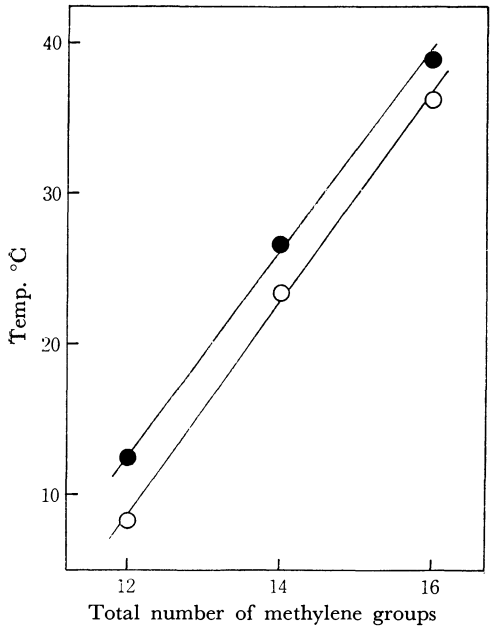

Fig. 1. Relation between Krafft point and total number of methylene groups in the chain. $RCOO(CH_2)_2SO_3Na$ (●), $ROCO(CH_2)_2SO_3Na$ (○).

Critical Micelle Concentration. The CMC values of two series of sodium 2-sulfoethyl alkanoates and sodium alkyl β-sulfopropionates, as estimated by conductivity method, are given in Table 2. The CMC value decreased with the increase in the length of the hydrocarbon chain, and the relation between the logarithm CMC and the alkyl chain length in the each surfactant series can be shown by the following equation:

$$\log \mathrm{CMC} = 1.6 - 0.29N$$

where N is the number of the methylene group in the alkyl chain.

As is shown in Fig. 2, the CMC values of sodium 2-sulfoethyl alkanoates fell on the same line as the CMC values of the sodium alkyl β-sulfopro-

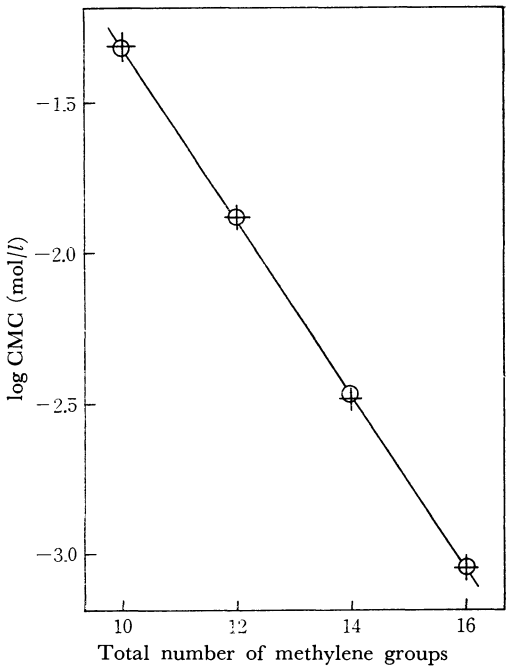

Fig. 2. Relation between log CMC and total number of methylene groups in the chain. $RCOO(CH_2)_2SO_3Na$ (○), $ROCO(CH_2)_2SO_3Na$ (+).

pionates. This indicates that the effect of the ester group on the CMC value is almost independent of the two different types of ester linkage (RCOO– and ROCO–), in sulfonate.[9]

Surface Tension. The values of the surface tension of aqueous solutions of the six surfactants (sodium 2-sulfoethyl pentadecanoate and sodium tetradecyl β-sulfopropionate are not shown) at 30°C are shown in Fig. 3.

The break point in the surface tension diagram coincides with the CMC values obtained by the electroconductivity method. The CMC values thus obtained from Fig. 3 are given in Table 2. As is shown in Fig. 4, the surface tension values at

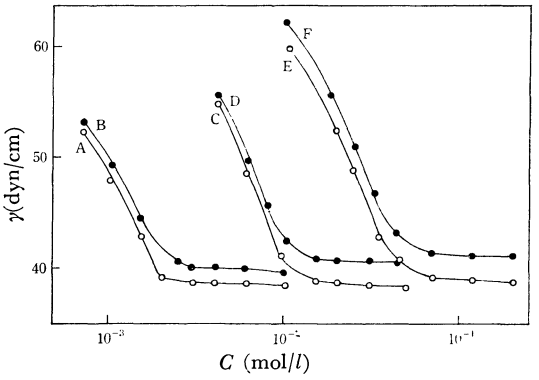

Fig. 3. Surface tension *vs.* concentration curves. SEA-12 (A), SAP-12 (B), SEA-10 (C), SAP-10 (D), SEA-8 (E), and SAP-8 (F).

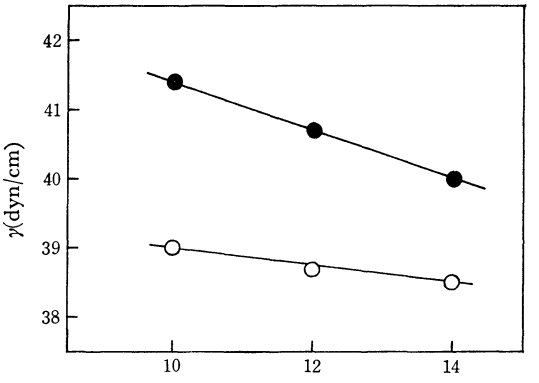

Fig. 4. Surface tension at CMC *vs.* total number of methylene groups. $RCOO(CH_2)SO_3Na$ (○), $ROCO(CH_2)_2SO_3Na$ (●).

9) T. Hikota and K. Meguro, *J. Am. Oil Chemists' Soc.*, **47**, 197 (1970).

CMC lower with an increase in the alkyl chain length. The sodium 2-sulfoethyl alkanoates have a lower surface tension than the sodium alkyl β-sulfopropionates with the same carbon chain.

According to the Gibbs adsorption isotherm equation, the inclination of the curves of the surface tension *vs.* the concentration gives the amount of surfactant adsorbed, Γ:

$$\Gamma = -\frac{1}{2RT} \times \frac{d\gamma}{d \ln C}$$

where γ is the surface tension and where C is the molar concentration. The area, A, occupied per surfactant molecule is calculated by the equation: $A = 1/N\Gamma$ from the amount of surfactant adsorbed; here, N is the Avogadro number. The values of the adsorption, the surface area, and the surface tension at the CMC of sodium 2-sulfoethyl alkanoates are compared with those of sodium alkyl β-sulfopropionates in Table 2.

Emulsion Stability. It is of interest to invesigate the effect of the difference in the ester linkage on the emulsifyng power of the surfactant. The emulsion stabilities of the surfactants are given in Table 2. The emulsions of all these surfactants with the exceptions of sodium 2-sulfoethyl pelargonate and sodium octyl β-sulfopropionate were more stable than that of sodium dodecyl sulfate. A comparison of sodium alkyl β-sulfopropionate and sodium 2-sulfoethyl alkanoate shows the later to be somewhat the better emulsifying agent.

Wetting Power. The wetting properties of the two different types of surfactants of the homologous series are shown in Table 2. It was difficult to find a certain relationship between the wetting properties and the alkyl chain length in the two series, sodium 2-sulfoethyl alkanoates and sodium alkyl β-sulfopropionates.

Stability to Hydrolysis and Calcium-ion Stability. The data obtained for stability to hydrolysis and the calcium-ion stability are shown in Table 2. The stability to hydrolysis of the sodium 2-sulfoethyl alkanoates is more stable than that of the corresponding sodium alkyl β-sulfopropionates, except for sodium 2-sulfoethyl pelargonate and sodium octyl β-sulfopropionate.

The calcium-ion stability of the surfactant decreases with an increase in the number of carbon atoms. This also shows that the calcium-ion stability of the sodium 2-sulfoethyl alkanoates is better than that of the sodium alkyl β-sulfopropionates.

Viccosity of Water Vapor in the Temperature Range from 6°C to 29°C

Isao YASUMOTO

Department of Chemistry, Yonago Technical College, Hikona-cho, Yonago

(Received November 27, 1969)

The viscosities of gases[1,2] have already been measured over a wide range of temperatures and pressures. The viscosity of water vapor[3,4] at room temperature has, however, scarcely been measured because of the technical difficulties involved. This paper will present the results of our viscosity measurement of water vapor in the temperature range from 6 to 29°C by means of a new tandem capillary-flow viscometer.

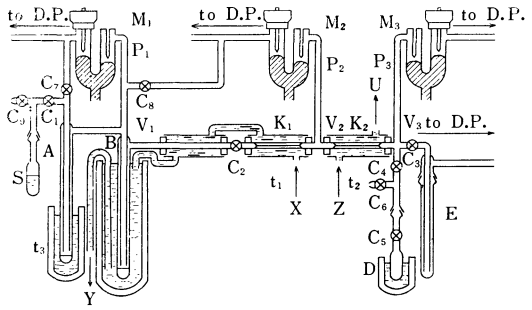

Fig. 1. Schematic diagram of the apparatus used for viscosity measurement of water vapor. The main part of the apparatus is constructed of borosilicate glass.

The apparatus used (Fig. 1) consists of a vapor-supply system, S; two traps, A and B; two capillaries, K_1 and K_2, in tandem; three vacuum gauges, M's; and a water-vapor collector, D. The main capillary, K_1, is 1.207 mm in diameter and 493.5 mm in length, while the auxiliary capillary, K_2, is about 1.2 mm in diameter and about 1.2 meter in length. The vacuum gauges are essentially the same as the mercury U-tube manometer devised by Meyer and Wade.[5] The details of the manometer as modified by the present author have already been published in his other report.[6]

The whole apparatus was evacuated until a pressure below 1×10^{-5} mmHg was attained. In carrying out a run, water was first freed from the dissolved gases by vacuum sublimation from the water reservoir, S, to the trap B, immersed in a dry ice-acetone mixture. The amount of water trapped there was about 10 cc. Then, by circulating water of a constant temperature from X to Y and from Z to U, the temperature of B and K_1 was held constant at t_1, and that of K_2, at t_2. The trap A was immersed in water of a constant temperature, t_3, approximately 0.5°C lower than t_1, in order to prevent the water vapor in the space V_1 from saturating and eventually condensing in the capillary tube K_1.

As the water vapor in the space V_1 flowed through the capillaries, K_1 and K_2, the pressure difference, P_1—P_2, was slowly developed across the capillary K_1 to become stationary after about 20 minutes. As a consequence of attaching K_2 in tandem, a laminar flow was attained throughout the capillary K_1. When the cock C_5 was turned on and C_3 closed, the water vapor in the space V_3 began to be condensed in the collector, D, cooled by liquid nitrogen, the pressures of P_1, P_2, and P_3 remaining practically unaltered. After condensation had proceeded for a certain length of time, C_5 was closed. The weight increase in the collector, D, was then determined.

The weight increase due to mercury and grease vapors condensed in D during a run was ascertained to be negligible. The influence of the total vacuum leak of this apparatus was also negligible, since it was less than 1×10^{-5} mmHg·l/hr. No correction for the thermal expansion of the capillary tube K_1 was made, since the temperature range covered was narrow.

*1 t_1 is an average of temperatures measured at two minute intervals through out a run. The fluctuation of t_1 was ± 0.08°C.

*2 P_1 and P_2 are averages of pressures measured at two minute intervals through out a run.

*3 Calculated by the Hagen-Poiseuille equation from the present author's data given in column 1, 2, 3 and 4.

*4 Corrected for slip.

*5 Calculated by the new viscosity formula proposed by the present author:
$$\eta_3 = KT^{7/6} = 126\times 10^{-9}\times T^{7/6}.$$

*6 Calculated by the Sutherland's formula:
$$\eta_4 = KT^{3/2}/(T+C),$$
where C is 650 as is given by Smith. Using the Smith's data, K was calculated by the present author to be 180.25×10^{-7}.

*7 Calculated by the Sutherland's formula given by Braune and Linke:
$$\eta_5 = 223.6\times 10^{-7}\times T^{3/2}/(T+961).$$

*8 Smith's experimental values.

*9 Braune and Linke's (saturated water vapor).

*10 Braune and Linke's.

*11 Kestin and Leidenfrost's.

are tabulated in Table 1. The viscosity, η_1, of the water vapor, as calculated by the Hagen-Poiseuille equation, is shown in column 5. The viscosity, η_2, corrected for slip is shown in column 6, together with the values obtained by other authors. The correction was made by multiplying η_1 by the factor of $(1+4\zeta/r)$, where r is the radius of the capillary tube K_1 and where ζ is $0.85\,\lambda$. λ is an average of the mean free path inside K_1 expressed by $\lambda = \boldsymbol{k}T/(2^{1/2}\pi\sigma^2 P)$, where σ is the molecular diameter, as will be discussed below, and where P is equal to $(P_1 + P_2)/2$, as was shown by Smith.[7] The precision of the viscosity, η_2, obtained was estimated to be less than 0.5%.

A plot of the author's viscosities, η_2's, against

7) C. J. Smith, *Proc. Roy. Soc.*, **A106**, 83 (1924).

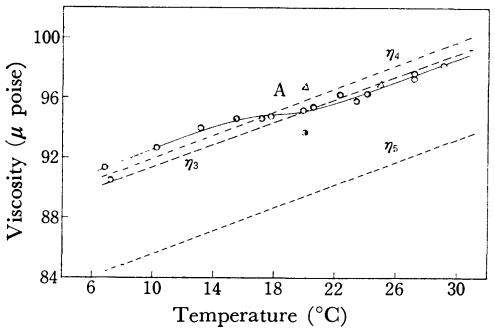

Fig. 2. ○; author's experimental values, ◑; Braune and Linke's (saturated water vapor), △; Kestin and Leidenfeost's. Broken lines represent η_3, η_4 and η_5, respectively.

the temperature shows the inflection shown in Fig. 2. A curve similar in form to the part A of this curve was also observed by Rankine[8] at room temperature in his experiment using bromine vapor. One of the two values obtained by Kestin and Leidenfrost by the oscillating-disk method is in good agreement with the present author's.

In Table 1, η_3 is calculated by the one-constant formula derived by the author, which will be discussed later. Taken in connection with Fig. 2, this formula can represent remarkably well (within 1%) not only one half of the author's experimental results (one half above 17°C because of the inflection), but also Smith's, extending from 100 to 261°C. Sutherland's two-constant formula, with the C value given by Smith and with the K value given by the present author, can also represent excellently (within approximately 1%) the present author's and Smith's results as a whole. The former formula gives a curve slightly concave upward, while the latter gives a curve slightly concave downward, so the latter curve in the highest temperature region gradually deviates from the former to approach the plot of Braune and Linke's experimental values, (Fig. 3). This plot is a nearly straight line extending from 90 to 406°C, and it is nearly perfectly represented by Sutherland's formula, with the C and K values given by Braune and Linke. It is parallel to, and situated lower than, the plot of Smith's data by the amount of *ca.* 50×10^{-7} poise.

The derivation of the author's formula used for the calculation of η_3 is as follows: The potential function, ϕ, for water-molecule interaction is

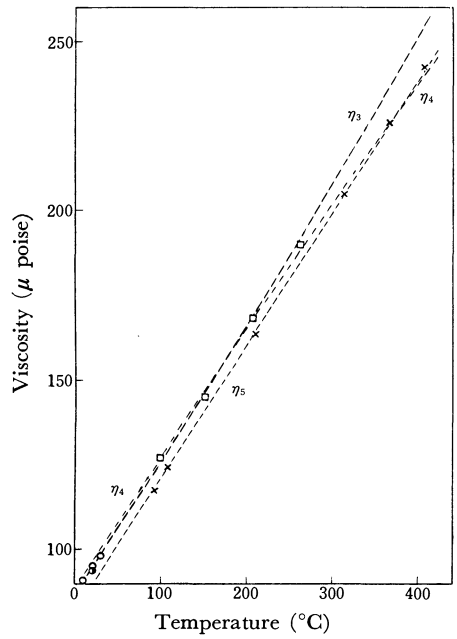

Fig. 3. ○: author's experimental values, ◑: Braune and Linke's (saturated water vapor), ×: Braune and Linke's, □; Smith's. Broken lines represent η_3, η_4 and η_5, respectively.

represented by[9]:

$$\phi = Aa^{-12} - Ba^{-6} - Ca^{-3},$$

where a is the distance between molecules and where A, B, and C are constants. Neglecting the first two terms, the approximate distance, a, in collision is deduced[10] to be:

$$a = (3C/2\boldsymbol{k}T)^{1/3},$$

which we may refer to as the diameter of capture, and which we may identify with σ, the molecular diameter. Denoting the mass of a molecule by m, the expression for the viscosity becomes:

$$\begin{aligned}\eta &= 1/\pi\sigma^2(m\boldsymbol{k}T/\pi)^{1/2} \\ &= 1/\pi(m\boldsymbol{k}/\pi)^{1/2}(2\boldsymbol{k}/3C)^{2/3}T^{1/2+2/3} \\ &= KT^{7/6}.\end{aligned}$$

Plotting η_2 against $T^{7/6}$, K was found to be 126×10^{-9}, from which C was calculated to be 2.55×10^{-36} erg·cm^3.

The author wishes to thank Professor Emeritus N. Sasaki and Professor K. Kodera, Kyoto University, for their interest and encouragement during this work.

The Effect of Solvents on the Optical Rotation of Propylene Oxide

Yoshiyuki KUMATA, Junji FURUKAWA and Takayuki FUENO*1

Department of Synthetic Chemistry, Kyoto University, Kyoto

(Received March 28, 1970)

It is known that the rotation of an optically active substance is varied according to the nature of the solvents. The so-called "rotivity", Ω, which is the rotation corrected for the refractive index of the solvent used, has been defined by the equation:[1]

$$3\Omega = \frac{3}{n^2+2}[\alpha]$$

where n, $[\alpha]$ and $3/(n^2+2)$ are the refractive index, the specific rotation and the Lorentz factor, respectively. This paper deals with the effect of solvents on the rotivity of propylene oxide.

Experimental

The solvents were selected widely from a stand point of chemical structure, dipole moment, dielectric constant and refractive index. Each solvent was purified by a conventional method. The optical rotation was measured by using a JASCO polarimeter Model ORD, UV-5 and a Yanagimoto polarimeter (OR-10) at ambient temperature. The concentration of propylene oxide in various solvents was fixed at 5.00 g/100 m*l*.

Propylene oxide was synthesized according to a fermentation method.[2] The specific rotation of the propylene oxide was +12.53° (neat, at 16°C).

Results and Discussion

The specific rotation, $[\alpha]_D$, and the rotivity multiplied by three, 3Ω, of propylene oxide observed in various solvents are listed in Table 1. Although the rotivity is said to be the specific rotation corrected for the refractive index of the solvents used, it still depends on solvent, as may be seen in Table 1. The tendency of this variation of rotivity with solvent is the same as that of the rotational strength of a steroidal compound.[3]

The rotivity data listed in Table 1 appear to show that the 3Ω value of propylene oxide tends to decrease with the increasing polarity of solvent. In Fig. 1 the 3Ω values are plotted against the solvent Z-values,[4] wherever available. Although the plotted points are somewhat scattered, there does seem to be a correlation between the two quantities.

Figures 2 and 3 are the plots of the 3Ω value of

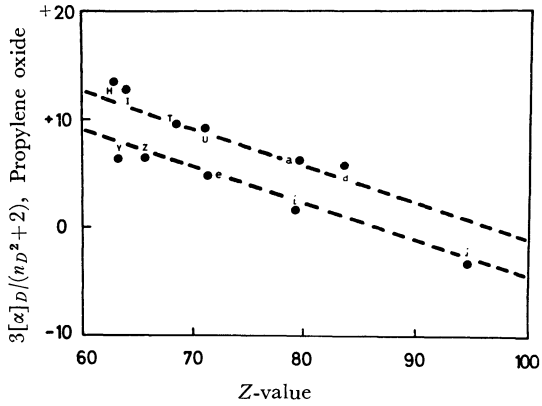

Fig. 1. Z-value *vs.* three times of rotivity.

propylene oxide against other polarity parameters of solvent, $(\varepsilon-1)/(\varepsilon+2)$ and E_T-value,[5] respectively. Addmittedly, these correlations of the rotivity with the various polarity parameters of solvent are poor, they will suffice to indicate a general trend. Thus, with increasing polarity of solvents, the rotivity may be continuously decreased until it may take on a value minus in sign. By this token, therefore, a change in the direction of optical rotation in differing solvents may well be something not abnormal, although it may certainly be an affair encountered only in limited cases.

In any discussion of solvent effects, it seem to be very important to consider the shape of cavity,[6,7] the anisotropy of the polarizability of solute[8,9]

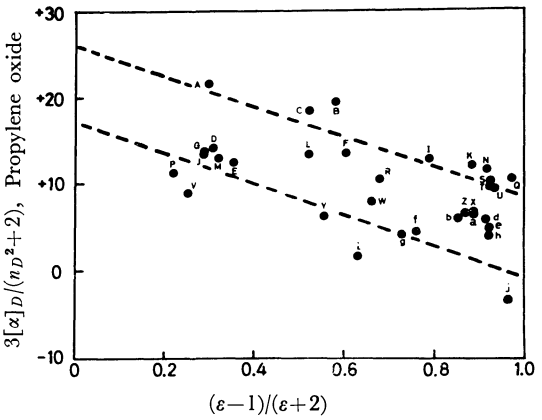

Fig. 2. $(\varepsilon-1)/(\varepsilon+2)$ *vs.* three times of rotivity.

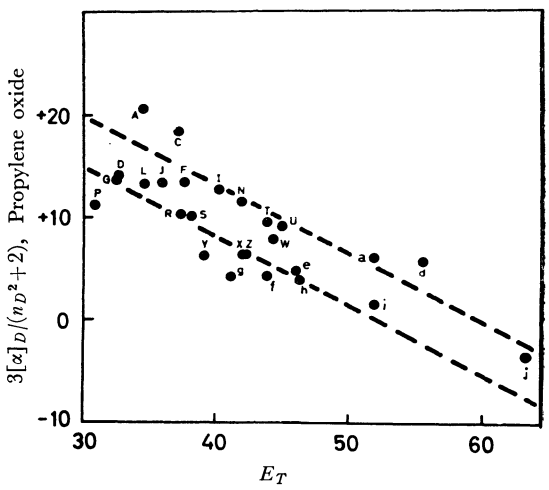

Fig. 3. E_T-values *vs.* three times of rotivity.

and the orientation of solvents to solute.[10,11] However, because the solvent effect on the optical rotation reflects a dynamical electromagnetic interaction between the dielectric groups of solute and solvents which have polarizability tensors, it will in general be extremely difficult to represent the effect with any simple parameter of solvents.

In Fig. 4, the effect of solvents on the optical rotatory dispersion of propylene oxide is shown. It should be noted that even a substance like propylene oxide, which has a rigid three-membered-ring and hence is incapable of changing its conformation in different solvents, shows an anomalous dispersion curve.

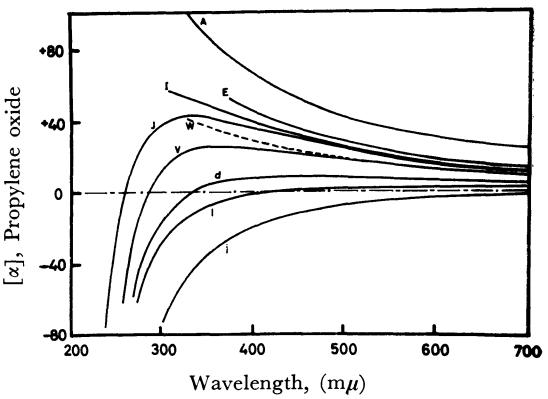

Fig. 4. Optical rotatory dispersion curve of (R)-propylene oxide in several solvents.

All the results described above would combine to give a serious warning against interpreting the optical behaviors of active substances in different solvents directly from their conformational change. Such interpretations might not be valid in general cases and would often be merely illusory.

The Preparation of Halo-nucleosides

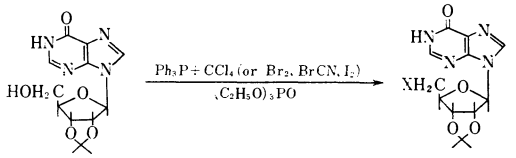
Kazuko HAGA, Masaharu YOSHIKAWA and Tetsuya KATO

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received April 6, 1970)

Attempts at the synthesis of halo-nucleosides have been made by the reaction of *p*-toluenesulfonyl nucleosides with an alkali-metal halide.[1,2] The present authors have also reported that 5′-chloro-5′-deoxy-2′,3′-*O*-isopropylidene nucleosides can be prepared *via* 5′-dichlorophosphoryl derivatives by the direct treatment of 2′,3′-*O*-isopropylidene nucleosides with phosphoryl chloride.[3] Recently, it has been reported that the reaction of suitably-protected nucleosides with methyltriphenoxy-phosphonium iodide affords iodo-nucleosides.[4,5] On the other hand, the conversion of some alcohols into chlorides with triphenylphosphine and carbon tetrachloride has been investigated.[6]

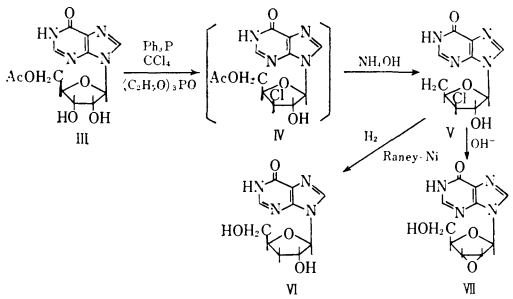
We have studied the preparation of a halo-nucleoside with triphenylphosphine and a suitable halogen source, such as carbon tetrachloride, bromine, cyanogen bromide, or iodine. For example, when 2′,3′-*O*-isopropylideneinosine(I) was treated in triethyl phosphate with three equiv. of triphenylphosphine in an excessive amount of carbon tetrachloride while being heated, 5′-chloro-5′-deoxy-2′,3′-*O*-isopropylideneinosine (IIa) was formed in a quantitative yield. The other halogen derivatives (IIb and IIc) were obtained in good yields by treatment with bromine, cyanogen bromide, or iodine and an equimolar amount of triphenylphosphine. The reactivity was extremely dependent on the kind of halogen source; the reaction with cyanogen bromide proceeded very rapidly at room temperature, while that with iodine required large excess of the reagent and an elevated reaction temperature. When dimethyl-formamide was used as a solvent in place of triethyl phosphate, the reactions did not proceed.



I II

a : X=Cl
b : X=Br
c : X=I

When 5′-*O*-acetylinosine(III) was treated similarly with triphenylphosphine and carbon tetrachloride, only the 3′-chloro derivative(IV) was obtained. The lack of the formation of the 2′-isomer may be due to the steric hindrance of the neighbouring purine base, which does not allow a rear-side attack by bulky phosphonium chloride at the *C*-2′ position. The hydrolysis of the reaction product with methanolic ammonium hydroxide afforded 3′-chloro-3′-deoxy-*β*-D-xylofuranosyl-hypoxanthine (V), together with a small amount of 2′,3′-anhydro-*β*-D-ribofuranosylhypoxanthine (VII).



The NMR spectrum of V indicates that the substitution may have occurred at the *C*-3′ atom. The signals of the 2′-, 3′-, and 4′-protons shifted considerably downfields with respect to those of inosine (Table 1), while the chemical shift of the 1′-proton remained almost constant. Additional proof for the 3′-substitution was obtained from the fact that V afforded the 3′-deoxy compound (VI), the structure of which was characterized by the NMR spectrum (Table 1), on catalytic hydrogenation with Raney-nickel. The substituted chlorine atom was established to have the *β* configuration and so to be easily convertible to the epoxy compound (VII) under the basic conditions.[7] The structure of VII was proved to be that of the 2′,3′-anhydro compound of ribofuranosylhypo-

xanthine (inosine) by the disappearance of $J_{1',2'}$ and $J_{3',4'}$.

Experimental

5′-Chloro-2′,3′-*O*-isopropylideneinosine (IIa). Triphenylphosphine (7.86 g, 0.03 mol) in carbon tetrachloride (80 m*l*) was added to a solution of 2′,3′-*O*-isopropylideneinosine (3.08 g, 0.01 mol) in anhydrous triethyl phosphate (40 m*l*). The mixture was heated at 100°C with stirring for 5 min. After cooling, the reaction mixture was poured into carbon tetrachloride (100 m*l*). A precipitate was collected on a filter, washed with cold water until the filtrate became neutral, and dissolved in chloroform (20—30 m*l*). After the solution had stood for about 30 min, the resulting precipitate was separated and recrystallized from methanol to give 2.8 g (85.8%) of IIa as colorless needles. Their IR spectrum and the melting point of the crystals were identical with those of the authentic sample.

5′-Bromo-5′-deoxy-2′,3′-*O*-isopropylideneinosine (IIb). *Method I.* To a solution of triphenylphosphine (7.8 g, 0.03 mol) in anhydrous triethyl phosphate (40m *l*), 2′,3′-*O*-isopropylideneinosine (3.08g, 0.01 mol) was added. Bromine was then added until the excessive addition of two drops gave the solution with an orange tint. The mixture was then heated at 80°C for 15 min. After cooling, the reaction mixture was poured into carbon tetrachloride (100 m*l*), and the resulting precipitate was collected on a filter. The precipitate was washed with cold water until the washings became neutral, and then with ethanol; then it was recrystallized from methanol to give 1.8 g (48.8%) of IIb, as colorless needles; mp 194°C (dec).

Found: C, 42.36; H, 4.19; N, 14.91; Br, 21.28%. Calcd for $C_{13}H_{15}N_3O_4Br$: C, 42.06; H, 4.07; N, 15.09; Br, 21.53%.

Method II. Cyanogen bromide (3.18 g, 0.03 mol) was used instead of bromine. The reaction proceeded exothermally. After the reaction mixture had been allowed to stand for about 5 min without heating, the solution was worked up in the manner described above (Method I) to give 2.2 g (59.6%) of IIb.

5′-Iodo-5′-deoxy-2′,3′-*O*-isopropylideneinosine (IIc). In a way similar to that used in the case of the 5′-chloro derivative (IIa), 2′,3′-*O*-isopropylideneinosine (3.08 g, 0.01 mol) in anhydrous triethyl phosphate (40 m*l*) was treated with triphenylphosphine (26.23 g) and iodine (25.38 g) for 30 min. After cooling, the solution was poured into ether (200 m*l*). The ether-insoluble materials were dissolved in chloroform (50 m*l*), and the solution was washed repeatedly with cold water until the washings became neutral. The chloroform layer was evaporated to dryness under reduced pressure at 40°C. The dark-reddish residue was redissolved in methanol (10 m*l*) and chromatographed on a column of neutral alumina in benzene. After the column had then been eluted successively with benzene and ether, 10% methanol-ether was passed through the column to elute IIc, the methanolic eluate was evaporated to dryness under reduced pressure, and the residue was crystallized from methanol to give 2.5 g (59.8%) of IIc as colorless plates; mp 195°C. (dec.).

Found: C, 37.38; H, 3.75; N, 13.15%. Calcd for $C_{13}H_{15}N_4O_4I$: C, 37.34; H, 3.62; N, 13.40%.

3′-Chloro-3′-deoxy-β-D-xylofuranosylhypoxanthine (V). To a solution of triphenylphosphine

(23.5 g, 0.09 mol) and carbon tetrachloride (66 m*l*) in triethyl phosphate (160 m*l*) was added 5′-*O*-acetylinosine (9.33 g, 0.03 mol). The mixture was refluxed at 110°C with stirring for 6 hr. After cooling, the solution was poured into ether (1 *l*). The ether-insoluble materials were dissolved in chloroform (300 m*l*), and the solution was extracted five times with an equivolume of cold water. The extractions were collected and evaporated to dryness under reduced pressure at 40°C. The residue was treated with 25 m*l* of concentrated ammonium hydroxide in 100 m*l* of methanol for 4 hr with ice-cooling and stirring. The solution was then evaporated under reduced pressure at 30°C, and the residue was dissolved in water (100 m*l*). A water-insoluble material was filtered off, and the filtrate was evaporated to dryness under reduced pressure. The dark-reddish residue was dissolved again in methanol (30 m*l*) and chromatographed similarly as in the case of the 5′-iodo derivative (IIc); 1.6 g (18.7%) of V was then obtained by recrystallization from aqueous methanol; colorless needles; mp 220°C (dec.).

Found: C, 41.88; H, 4.09; N, 19.77; Cl, 12.24%. Calcd for $C_{10}H_{11}N_4O_4Cl$: C, 41.90; H, 3.87; N, 19.55; Cl, 12.37%.

3′-Deoxyinosine (VI). To a solution of V (1.51 g, 0.006 mol) in a mixture of triethylamine (2.52 m*l*, 0.006 mol) and aqueous 50% methanol (120 m*l*) was added Raney-nickel; hydrogen was then allowed to pass through the suspension with shaking under atmospheric pressure at room temperature for 8 hr. The catalyst was filtered off, and the filtrate was evaporated to dryness under reduced pressure. The residue was washed with ethanol, and subsequently recrystallized from ethanol-water (8 : 1) to give 0.79 g (59.9%) of VI; colorless needles; mp 200°C.

Found: C, 47.38; H, 4.85; N, 22.02%. Calcd for $C_{10}H_{12}O_4N_4$: C, 47.62; H, 4.80; N, 22.22%.

2′,3′-Anhydro-β-D-ribofuranosylhypoxanthine (VII). The compound V (1 g) was dissolved in concentrated ammonium hydroxide and the solution was kept at room temperature for a week. The solvent was then removed under reduced pressure, and the residue was crystallized from water to give 0.6 g (68.9%) of VII; columns; mp 210°C (dec).

Found: C, 47.93; H, 4.31; N, 22.26%. Calcd for $C_{10}H_{10}O_4N_4$: C, 48.00; H, 4.03; N, 22.39%.

The authors wish to thank Mr. Masatsune Kainosho for his measurement of the NMR spectra and for his valuable discussions.

The Preparation of Ethyl 18-Nonadecenoate by a Mixed Coupling Reaction

Yasuo SUHARA and Shoji MIYAZAKI

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received April 13, 1970)

Long-chain terminal olefinic fatty esters are useful intermediates for the syntheses of various long-chain compounds. However, no paper reporting a simple preparation of the esters has been appeared. Concerning the electrolysis of terminal alkenoic acid, the preparation of 1,19-eicosadiene from 10-undecenoic acid by electrolysis with platinum electrodes has been attempted by Weedon *et al.*,[1] but the diene was contaminated by its positional isomers of the double bond. On the other hand, a 1,19-eicosadiene-rich-product was obtained when a platinum anode and a mercury cathode were used.[2]

In the present study, mixtures of 10-undecenoic acid (I) and ethyl hydrogen sebacate (II) were electrolyzed with platinum anode and a mercury cathode (procedures A and B) or with platinum electrodes (procedure C). The molar ratios of I to II employed were from 2 : 1 to 1 : 5. The coupling products were successfully separated by elution chromatography on silica gel.

Typical conditions of electrolysis, together with the products, are shown in Table 1. By procedure A, the desired ester, III, was obtained. The 45% yield of III was given by a 1 : 5 mixture of I and II. On the other hand, the largest weight percentage of III was given by an equimolar mixture of I and II. In procedure B, ester-exchange reaction of III and V proceeded. In procedure C, difficulty in obtaining unsaturated coupling compounds was experienced. The X, XI, and XII fractions comprised some positional isomers of the double bond. The key reaction may be illustrated as follows:

$$\underset{\text{(I)}}{CH_2{=}CH(CH_2)_8COOH} + \underset{\text{(II)}}{HOOC(CH_2)_8COOC_2H_5} \rightarrow$$

$$\underset{\text{(III)}}{CH_2{=}CH(CH_2)_{16}COOC_2H_5} + \underset{\text{(IV)}}{CH_2{=}CH(CH_2)_{16}CH{=}CH_2}$$

$$+ \underset{\text{(V)}}{H_5C_2OOC(CH_2)_{16}COOC_2H_5}$$

Experimental

The GLC was carried out by means of a Hitachi Gas Chromatograph K-23 on a column packed with 20% poly(diethylene glycol succinate) on Chromosorb WAW. The IR spectra were recorded with a Hitachi EPI-S2 Infrared Spectrophotometer in a KBr disk or in a liquid film. The IR spectra of III, IV, and VI showed bands assigned to terminal double bond at 3064—3053, 1825—1820, 1645—1640, 1420—1416, 1302—1298, 990—988, and 908—904 cm^{-1}. The spectra of III, V, VI, VII, and VIII showed a band assigned to the ester carbonyl group at 1740—1738 cm^{-1}. The NMR spectra were recorded with a JEOL JNM C-60HA NMR Spectrometer for a 10% carbon tetrachloride solution. The NMR spectra of III, VI, and VIII showed peaks at τ 5.07 (a, triplet). 4.3 (b, multiplet), 7.94—7.96 (c, doublet), 8.73 (d, singlet), 7.75—7.80 (e, unsymm. triplet), 5.96 (f, quartet), 8.74 (g, unsymm. triplet), 6.39 (h, singlet), and 9.11 (i, unsymm. triplet).

$\underset{\bar{a}}{CH_2}=\underset{\bar{b}}{CH}\underset{\bar{c}}{CH_2}(CH_2)_{14}\underset{\bar{d}}{CH_2}\underset{\bar{e}}{COO}\underset{\bar{f}}{CH_2}\underset{\bar{g}}{CH_3}$ (III),

$\underset{\bar{a}}{CH_2}=\underset{\bar{b}}{CH}\underset{\bar{c}}{CH_2}(CH_2)_{14}\underset{\bar{d}}{CH_2}\underset{\bar{e}}{COO}\underset{\bar{h}}{CH_3}$ (VI),

$\underset{\bar{i}}{CH_3}(CH_2)_{16}\underset{\bar{d}}{CH_2}\underset{\bar{e}}{COO}\underset{\bar{f}}{CH_2}\underset{\bar{g}}{CH_3}$ (VIII)

Oxidative ozonolysis was carried out according to the procedure of Ackman *et al.*[3] The cleavage products were elucidated by GLC.

Materials. Commercially-available Compound I was rectified by vacuum distillation; bp 121°C/1 mmHg. Compound II was prepared according to the procedure used in our previous experiments;[4] bp 150—154°C/1 mmHg; mp 35.5—36.5°C.

Procedures. Cells fitted with a platinum anode and a mercury cathode[5] (procedures A and B) and with platinum electrodes[4] (procedure C) were surrounded with water in order to maintain the electrolyte at the required temperature.

In procedure C, the current direction was changed every 3 sec. The products were treated as in our previous experiments,[4] and the coupling products were separated into three fractions by elution chromatography on silica gel with ligroin (bp 85—115°C) and then with methanol.

Products from Procedure A. The first fraction, mp 20—20.5°C (19.5—20°C[1]), was shown to be IV by elemental analysis and by its iodine value, along with the results obtained from its GLC, ozonolysis, and IR and NMR spectra. The second fraction, white crystals; mp 30—30.5°C (from ethanol), was shown to be III by its iodine and saponification values and also by a study of its GLC and ozonolysis, together with a study of its IR and NMR spectral data.

Found: C, 77.58; H, 12.39%. Calcd for $C_{21}H_{40}O_2$: C, 77.72; H, 12.42%.

The third fraction was shown to be V by comparing it with the specimen obtained by the procedure used in our previous experiments.[4]

Products from Procedure B. The first fraction was composed of IV; this was established by comparing it with the authentic compound obtained in the above paragraph. The second fraction, white crystals; mp 32—32.5°C (from ethanol), was shown to be VI by its iodine and saponification values and by a study of its GLC and ozonolysis, together with a study of its IR and NMR spectral data.

Found: C, 77.51; H, 12.30%. Calcd for $C_{20}H_{38}O_2$: C, 77.36; H, 12.34%.

The third fraction, white crystals; mp 59—59.5°C (57—58°C[6]) (from ethanol), was shown to be VII by elemental analysis and also by a study of its GLC, together with a study of its IR and NMR spectral data.

Products from Procedure C. The first fraction was shown to be a mixture of IX, XI, and XII by means of GLC, together with a study of its IR and NMR spectral data. The ozonolysis of XI gave a mixture of 1-, 2-, and 3-eicosenes, while XII gave a mixture of 1,19-, 1,18-, 1,17-. 2,18-, 2,17-, and 3,17-eicosadienes. The second fraction was shown to be a mixture of VIII and X, by GLC and by a study of its IR and NMR spectral data. The ozonolysis of X gave a mixture of ethyl 18-, 17-, 16-, 15-, and 14-nonadecenoates. The third fraction was successfully identified as V.

We are grateful to Mr. Masanori Yamamoto for his assistance in our experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3926—3927 (1970)

Studies of Diels-Alder-type Additions of Cyclic α-Carbonyl-Azo-Compounds*[1]

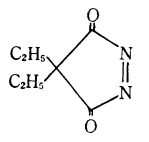
Shin-ichiro TAKASE and Tadayuki MOTOYAMA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

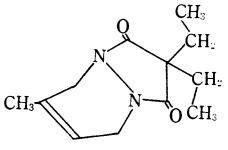
(Received May 25, 1970)

The unstable cyclic diacyl diimides[1-3] and dioxotriazoline,[4] which were generated from the corresponding dihydro-compounds by oxidation with lead tetraacetate or *t*-butyl hypochlorite, gave the Diels-Alder adducts in the presence of the conjugated dienes. In recent papers, it has been shown that 4,4-diethyl-3,5-dioxo-1-pyrazoline[5,6] prepared from diethylmalonic acid hydrazide was reactive as a dienophile.

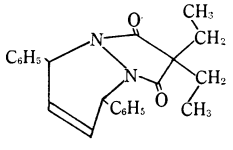
Several cyclic diacyl hydrazides were slowly oxidized with nickel peroxide[7] to prepare dicarbonyl-azo-compounds, they then gave the adducts by means of an *in situ* reaction with dienes. As the process was carried out in heterogeneous system, it was not so troublesome as with the above treatments to isolate the adducts from the degraded oxidants. Thus, the method provided a more convenient one-step synthesis of pyridazine derivatives. The proposed structure of the products is based on the molecular weights, the results of elemental analyses, and the IR and NMR spectra.



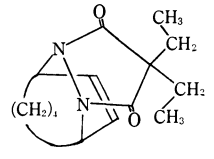
1c



2c



3c



4c

When maleic hydrazide and nickel peroxide were suspended in methylene chloride and stirred at room temperature, 3,6-dioxopyridazine (**1a**) was produced, and a small amount of nitrogen has evolved because of the partial decomposition of hydrazide. A reaction *in situ* with isoprene gave 1,4-dihydro-2-methyl-6,9-dioxopyridazino-[1,2-*a*]pyridazine (**2a**) *via* the process shown by Equations (1) and (2). The IR (KBr) spectrum of **2a** showed a carbonyl absorption at 1638 cm^{-1}, but no imino absorption. The NMR ($CDCl_3$) spectrum exhibited signals at τ 8.10 (s, 3H, 2-CH_3), 5.56 (s, 2H, 1-CH_2), 5.75—5.35 (m, 2H, 4-CH_2), 4.24 (m, 1H, 3-olefinic H), and 3.05 (s, 2H, 7,8-olefinic H). The reactions with *trans,trans*-1,4-diphenyl-1,3-butadiene and 1,3-cyclooctadiene gave 1,4-dihydro-6,9-dioxo-1,4-diphenylpyridazino[1,2-*a*]pyridazine (**3a**) and 1,4-butano-1,4-dihydro-6,9-dioxopyridazino[1,2-*a*]pyridazine (**4a**) respectively.

4c	7.8	137—138[i] (D)	$C_{15}H_{22}N_2O_2$		68.67	8.45	10.68	68.05	8.44	10.53

a) The reagents were refluxed in benzene.
b) The reaction was continued for 88 hr.
c) Lead tetraacetate was used as the oxidant of cyclic hydrazide.
d) Melting points are uncorrected.
e) Recrystallization from the following solvent: A, alcohol; B, benzene - alcohol; C, petroleum ether - *n*-hexane - ethanol; D, water.
f) Lit,[3] mp 208—210°C.
g) Lit,[5] mp 58.5—60°C.
h) Lit,[5] mp 147—148°C.
i) Lit,[5] mp 134—136°C.
j) Molecular weight determinations were made by analysis of the mass spectra.

The same process, when applied to 1,4-dioxophthalazine (**1b**) generated from phthalic acid hydrazide by nickel peroxide oxidation and isoprene, gave 1,4-dihydro-2-methyl-6,11-dioxopyridazino[1,2-*b*]phthalazine (**2b**). In the reaction of *trans*,*trans*-1,4-diphenyl-1,3-butadiene or 1,3-cyclooctadiene with **1b**, 1,4-dihydro-6,11-dioxo - 1,4 - diphenylpyridazino [1,2 - *b*] phthalazine (**3b**) or 1,4-butano-1,4-dihydro-6,11-dioxopyridazino[1,2-*b*]phthalazine (**4b**) respectively was isolated.

The procedure in which nickel peroxide was used as the oxidant of diethylmalonic acid hydrazide gave a small of the reaction product, or no yield at all, with diene. On the other hand, 4,4-diethyl-3,5-dioxo-1-pyrazoline (**1c**) prepared by oxidation with lead tetraacetate gave the 1,4-adducts in a high yield. They were 2,2-diethyl-2,3,5,8-tetrahydro-7-methyl-1,3 - dioxo - 1*H* - pyrazolo[1,2-*a*]pyridazine (**2c**), 2,2-diethyl-2,3,5,8-tetrahydro - 1,3 - dioxo - 5,8-diphenyl - 1*H*-pyrazolo-[1,2-*a*]pyridazine (**3c**), and 5,8-butano-2,2-diethyl-2,3,5,8-tetrahydro - 1,3 - dioxo - 1*H* - pyrazolo [1,2-*a*]-pyridazine (**4c**).

Experimental

General Procedure for the Reaction of Cyclic Diacyl Diimide with Dienes. The reagents, cyclic hydrazide (0.01 mol) and diene (0.01—0.03 mol), were slurried in methylene chloride (50 m*l*) at room temperature. A large excess of diene should be avoided. Fine powder of nickel peroxide (1.2—2.0 times the theoretical amount, as determined on available oxygen[7a]) was added, little by little, with magnetic stirring. Stirring was continued for *ca.* 20—40 hr at room temperature after the addition of the nickel peroxide. The loss of the methylene chloride was compensated for according to circumstances. The reaction mixture was then filtered, and the filtrate was evaporated on a rotary evaporator at <40°C to yield a crude adduct. The residue was purified by crystallization or by distillation under reduced pressure to give an analytical sample.

The Diels-Alder adducts thus prepared, along with their physical properties, yields and analyses, are listed in Table 1. The yields, based on the cyclic hydrazide, were determined from the weight of the raw crystals from the first recrystallization.

IR and NMR Spectra of Adducts. 3a: 1632 cm^{-1} (C=O); τ 3.67 (s, 4H, 2,3,7,8-olefinic H), 3.02 (s, 2H, methyne), 2.82 (s, 10H, phenyl). **4a**: 1637 cm^{-1}; τ 8.90—7.40 (m, 8H, methylene), 4.45 (m, 2H, methyne), 3.85 (m, 2H, 2,3-olefinic H), 3.10 (s, 2H, 7,8-olefinic H). **2b**: 1630 cm^{-1}; τ 8.08 (s, 3H, CH_3), 5.46 (s, 2H, 1-CH_2), 5.60—5.25 (m, 2H, 4-CH_2), 4.24 (m, 1H, 3-CH), 2.21 (m, 2H, 8,9-aromatic H), 1.70 (m, 2H, 7,10-aromatic H). **3b**: 1640 cm^{-1}; τ 3.61 (m, 2H, methyne or olefinic H), 3.50 (m, 2H, methyne or olefinic H), 2.81 (s, 10H, phenyl), 2.17 (m, 2H, 8,9-aromatic H), 1.68 (m, 2H, 7,10-aromatic H). **4b**: 1630 cm^{-1}; τ 8.70—7.30 (m, 8H, methylene), 4.20 (m, 2H, methyne), 3.80 (m, 2H, olefinic H), 2.23 (m, 2H, 8,9-aromatic H), 1.70 (m, 2H, 7,10-aromatic H). **2c**: 1725 and 1685 cm^{-1}; τ 9.16 (t, 6H, $C\underline{H}_3CH_2$), 8.20 (quar, 4H, $CH_3C\underline{H}_2$), 8.12 (s, 3H, 7-CH_3), 5.97 (s, 2H, 8-CH_2), 6.10—5.76 (m, 2H, 5-CH_2), 4.43 (m, 1H, 6-CH). **3c**: 1689 cm^{-1}; τ 9.71 (t, 3H, $C\underline{H}_3CH_2$), 9.15 (t, 3H, $C\underline{H}_3CH_2$), 8.65—8.00 (quin, 4H, $2CH_3C\underline{H}_2$), 4.40 (m, 2H, 2CH), 4.08 (m, 2H, olefinic H), 2.80—2.30 (m, 10H, phenyl). **4c**: 1717 and 1666 cm^{-1}; τ 9.45—8.85 (m, 6H, $2C\underline{H}_3CH_2$), 8.60—7.60 (m, 12H, methylene), 5.15—4.75 (m, 2H, 2CH), 4.00—3.80 (m, 2H, olefinic H).

The Reaction of Aliphatic Amines with *p*-Benzoquinone. The Effect of the Alkyl Group of Amines on the Reaction

Aizo HIKOSAKA

Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 25, 1970)

The most general reaction between quinones and amines has been established for both primary and secondary, aliphatic and aromatic.[1-5] *p*-Benzoquinone undergoes two nuclear substitutions, but single substitutions are frequently observed with secondary amines under selected conditions.

The ease with which an amine enters the quinone nucleus depends to a large extent on the nature of the amine.[6] Under the present conditions (see General Procedure), *p*-benzoquinone gave bis-(alkylamino)-*p*-benzoquinones with primary amines, but with secondary amines it gave monoamino derivatives only.

p-Benzoquinone forms substitution products with 1 or 2 mol of amine, accompanied by the reduction of 1 or 2 mol of the benzoquinone respectively. These substitution products undergo a reversible oxidation or reduction on the dropping-Hg electrode, like the system quinone-hydroquinone itself. To follow the chemical change, polarography has been used.

In the present work, the effects of the alkyl group of the amine on the pattern and the rate of the reaction of *p*-benzoquinone with amines were determined.

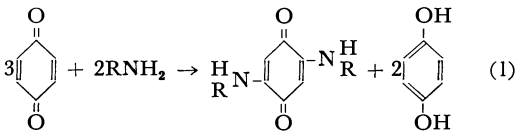
Experimental and Results

General Procedure of the Reaction of *p*-Benzoquinone with Amines. *p*-Benzoquinone (3×10^{-4} mol) was dissolved in 10 m*l* of isopropanol or ethanol, and into the resulting solution we added amine (2×10^{-4} mol) with constant stirring at 25°C. At regular time intervals, 0.1 m*l* aliquots of the reaction mixture were taken out and diluted to 10 m*l* with a polarographic base solution (isopropanol: phosphate buffer = 1 : 1). This dilution practically quenched the reaction. Any oxygen was removed from the solution by bubbling it with nitrogen, and the oxygen-free solution was subsequently polarographed by an ordinary method.

Materials and Apparatus. *p*-Benzoquinone (mp 116°C) was purified by the sublimation of commercially available chemicals. The amines used were commercially available and were identified by means of gas chromatography. The buffers used were prepared by the method of Sörensen in our laboratory.

The gas-chromatographic determinations were made with a Yanagimoto Gas Chromatograph, GCG-5DH, while the polarographic determinations were made with a Yanagimoto Pen Recording Polarograph, PA-102.

The Reaction of Primary Amines with *p*-Benzoquinone. In the reaction of *p*-benzoquinone with alkylamines in alcohols at ordinary temperatures, *p*-benzoquinone undergoes two nuclear substitutions, as is shown in Eq. (1).



(1)

In this study, the effect of branching on the position

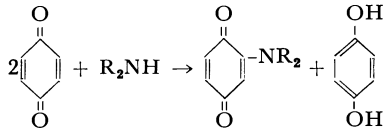
of the carbon atom adjacent to the nitrogen atom of the amine upon the rate of the reaction between alkylamine and *p*-benzoquinone was determined. Furthermore, the effect of the solvents, ethanol and isopropanol, upon the reaction was studied.

According to the procedure described above, methylamine, ethylamine, *n*-propylamine, and *n*-butylamine reacted with *p*-benzoquinone to form 2,5-bis(alkylamino)-*p*-benzoquinone in isopropanol or ethanol at 25°C within 5 min. In the case of isopropylamine and *s*-butylamine, the completion of the reaction in isopropanol required 45 min, the reaction in ethanol required only 15 min, but this was produced an unknown by-product which showed a cathodic wave (see Fig. 1). In the case of the *t*-butylamine-*p*-benzoquinone reaction in isopropanol, the rate of the reaction was still slower; even after 120 min the reaction had not been completed and a part of the quinone remained. In ethanol, *t*-butylamine did not give 2,5-bis(*t*-butylamino)-*p*-benzoquinone under the present conditions, though the quinone used decreased and hydroquinone was produced.

The Reaction of Secondary Amines with *p*-Benzoquinone. With alkylamines, *p*-benzoquinone gives bis(alkylamino)-*p*-benzoquinones; with dialkylamines, *p*-benzoquinone gives monoamino derivatives only.



(2)

In the present work, a study of the condensations of *p*-benzoquinone with dialkylamines was made; the experimental conditions were the same as in the general procedure except for the use of isopropanol only as a solvent.

In these reactions, their rates depended upon the kind of alkyl group in the amine used. In this report, dimethylamine, diethylamine, di-*n*-propylamine, and di-*n*-butylamine were used.

The quinone used disappeared within one minute in the case of dimethylamine, within 90 min in the case of diethylamine, and within 180 min in the cases of di-*n*-propylamine and di-*n*-butylamine. The rate of the reaction of *p*-benzoquinone with dialkylamines depends to a large extent on the size of the alkyl group of the amine in the case of the lower dialkylamine members.

The Electronic Structures and Chemical Properties of O, S Containing Six-membered Heterocycles and Their Benzo-derivatives

Mamoru KAMIYA

Shizuoka College of Pharmacy, Oshika, Shizuoka-shi

(Received May 28, 1970)

It is known that compounds such as 1,4-dithiadiene, -oxathiadiene and -dioxadiene and their benzo-derivatives exhibit several characteristic chemical properties related to the electronic effects of the sulfur and oxygen atoms. That is, 1,4-dithiadiene exhibits a somewhat unusual thermal stability, as was first found by Levi,[1] who reported that the molecule underwent a Friedel-Crafts reaction; later Parham *et al.* reported that the hetero-ring in benzo-1,4-dithiadiene and/or -oxathiadiene exhibited electrophilic substitutions usually associated with an aromatic character. It is also well known that dibenzo-1,4-dithiadiene has a high thermal stability and undergoes a reaction typical of an aromatic system. Such an aromaticity of these molecules, atypical of aliphatic ethers, was correlated, by Parham *et al.*, with the ability of sulfur to expand its valence shell and with the electron-releasing property of oxygen. However, the theoretical support for the observed electronic effects of the sulfur and oxygen atoms seems insufficient, though there have been a few molecular orbital studies of the electronic structure and chemical properties of these molecules, such as simple LCAO calculations neglecting σ-π interaction and the participation of sulfur *d*-orbitals on 1,4-dithiadiene[6] and dibenzo-1,4-dithiadiene,[7] and Pariser-Parr-Pople SCF calculations of 1,4-dithiadiene,[8] benzo-1,4-dioxadiene, and dibenzo-1,4-dioxadiene.[9]

This paper will report semiempirical SCF-MO-CI calculations on all the related molecules and will then consider generally the relative electronic effects of the sulfur and oxygen atoms.

Calculation Method

The P-P-P method,[10] with the CI procedure including all the singly-excited configurations, is used since recent SCF calculations[8,9] on the UV spectra of the related molecules indicate that if the molecule is non-planar, a treatment assuming the separability of σ and π electrons can be allowed for in the proper choice of parameters. The values of the valence-state ionization potentials (I) and the electron affinities (A) of the π-orbitals of several atoms are taken as follows, with reference to the paper of Hinze and Jaffe[11]:

I(=C-) 11.16 eV, I(-O-) 32.90 eV,
I(-S-) 23.59 eV
A(=C-) 0.03 eV, A(-O-) 11.37 eV,
A(-S-) 10.54 eV

The sulfur *d*-orbitals are not explicitly included because it has been pointed out by Johnstone and Ward that the observed π-π^* transitions of sulfur heterocycles are generally reproduced by a small variation in the core integrals.[12] The one-center repulsion integral is obtained by the I-A approximation, while the two-center repulsion integral is evaluated by the Nishimoto-Mataga formula.[13] The core resonance integral is evaluated by adopting the variable β-core approximation,[14] because the effect of the non-planarity of the molecules upon the β_{C-O} and β_{C-S} may be properly included by adjusting the parameters. At present the following equations are tentatively used for all the molecules;

$$\beta_{C-C} = -0.51\ P_{C-C} - 1.84,$$
$$\beta_{C-O} = -0.56\ P_{C-O} - 2.20,$$
$$\beta_{C-S} = -0.33\ P_{C-S} - 1.80$$

Here, P_{rs} corresponds to the usual π-bond order. The bond lengths of all the molecules are taken as 1.395 Å.

Results and Discussion

Electronic Spectra. The theoretical findings on the singlet π-π^* transition energy and oscillator strength are given in table 1, together with the available experimental data. The relative ordering of the intensities of the first allowed transitions of 1,4-dioxadiene and -dithiadiene is predicted correctly, and it is found that the introduction of the oxygen atom causes increase in the first allowed transition energy. As regards benzo-1,4-dithiadiene the assignment of the three observed bands is straight foward because of the agreement between the predicted and observed orderings of the absorption intensity. The effect of the hetero-ring structure upon the oscillator strength of the first allowed transition is quite decreased from the monocyclic molecule to the monobenzo-derivatives. In the case of benzo-1,4-oxathiadiene, the polarization direction of the second allowed transition (5.08 eV) is varied to such an extent that the transition moment makes an angle of 68° to the *x*-axis. This is interesting because it suggests that a shortly polarized structure, such as , contributes to the excited state, just as is to be expected from the relative electron-releasing order of the sulfur and oxygen atoms.

In the case of the dibenzo-derivatives also, the calculated spectra well reflect the effect of hetero-atom replacement. In dibenzo-1,4-oxathiadiene, the first two forbidden bands are little enhanced through the lowering of the molecular symmetry. In dibenzo-1,4-dioxadiene, the observed band at 4.29 eV was assigned by Wratten and Ali[9] to the second forbidden band, which becomes allowed through a slight folding about the line joining the heteroatoms. It is of interest to note that the second and third allowed transitions, with very different intensities, tend to degenerate in all the calculated spectra and to change their mutual order from dibenzo-1,4-dioxadiene to the other two molecules.

Ionization Potentials. The negatives of the ho and lv orbital energies are given in table 2, together with the available experimental data on ionization potentials. It is usually accepted that the ionization potentials calculated by Koopman's Theorem are 1—2 eV too large in comparison with the experimental values; such is also true for the present results. Interestingly, the effect of the hetero-ring structure upon the calculated ionization potentials and electron affinities is almost independent of the introduction of a benzene-ring. The calculated ionization potentials of the dibenzo-derivatives exhibit an ordering identical to that of the experimental values determined by the electron-impact method.

Electron Distributions. The calculated findings on the π-electron densities and π-bond orders are shown in Fig. 1. First, it is established that the sulfur atom in monocyclic molecules more

favours the fixation of the diene-structure. It is of interest to note that such a difference between the sulfur and oxygen atoms is more enlarged in the hetero-ring containing both hetero-atoms. The same thing is true for the benzo-derivatives. In the case of benzo-1,4-dithiadiene, the predicted site for electrophilic attack, C-2(3) in the hetero-ring, is in agreement with that observed by Parham *et al.*[2-5] A further prediction from the electron distributions is that the electrophilic substitutions of benzo-1,4-oxathiadiene and/or -dioxadiene should also occur at the hetero-ring. As regards the dibenzo-derivatives, it is found that a characteristic relation, $P^{\pi}{}_{\beta-\beta} > P^{\pi}{}_{\alpha-\beta}$, previously noted as a result of a simple LCAO calculation of Chandra[7] is also valid for all the molecules, and that this tendency is slightly promoted by the presence of an oxygen atom.

The present calculations were carried out with an HITAC 5020-E computer at the Computation Center of the University of Tokyo. The author wishes to thank Professor Y. Akahori for his interest and valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3933—3935 (1970)

The Far-infrared Torsional Frequencies of Monohalogenoethanes

The (late) Susumu KINUMAKI and Muneteru KOZUKA

Chemical Research Institute of Non-Aqueous Solution, Tohoku University, Sendai

(Received June 12, 1970)

In the case of the "one-top problem", it is known that intramolecular vibrations other than the torsion contribute quite little to the fine structure of the microwave spectrum.[1] Thus, we can obtain some information about the extent of interaction between the torsion and the other intramolecular vibrations by comparing the torsional frequencies observed in the infrared spectra with those obtained from the microwave splitting through the calculation by using the P.A.M.[2] (principal-axes method) or the I.A.M.[2] (internal-axis method).

The far-infrared spectra were recorded on a Hitachi FIS-1 vacuum, grating, double-beam spectrophotometer. All the monohalogenoethanes used were obtained from commercial sources; they were purified by vapor-phase chromatography and then dried with phosphorus pentoxide. Considerable precautions were taken to remove the residual water. The vapor of monohalogenoethane was introduced into a gas-cell which had been especially built for the instrument. Its path length is veriable in increment of 1.2 m up to 6 m. In order to avoid interference, wedged polyethylene sheets were used as the cell windows.

The observed torsional frequencies are given in Table 1, together with those values calculated from the microwave splitting data.[2,3] The torsional frequencies for ethyl fluoride and ethyl chloride have been reported by Sage and Klemperer[4] and Fateley and Miller[5] respectively. We observed not only those frequencies, but also the 3E→4E transition bands for these molecules (see Fig. 1). It is of some interest to note the splitting of the A and E levels for higher vibrational states, as is expected from the theory.[2,3] Such splitting has not previously been observed.[4-6] Although the reason for this is not clear, it may be remembered that the previous data were obtained

with a single-beam spectrometer. The infrared torsional frequencies for gaseous ethyl bromide and ethyl iodide are observed for the first time in the present study (Fig. 2). In the case of ethyl iodide, the agreement between the infrared frequencies and those obtained from the microwave splitting data is not so good. This is probably due to experimental error in the microwave measurements; Kasuya[7] has reported that his microwave datum for ethyl iodide will be refined in the future.

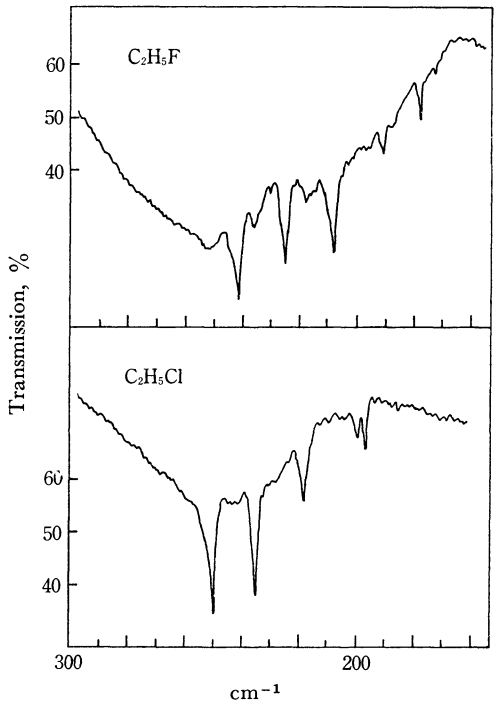

Fig. 1. Far-infrared spectra of ethyl fluoride and ethyl chloride.
(Path length: 4.8 m,
Pressure: Saturated vapor pressure at room temperature)

The 201 cm^{-1} band of the gaseous ethyl iodide in Fig. 2 was identified as the difference band between two fundamentals, 947 cm^{-1} (A') and 741 cm^{-1} (A''), despite the fact that it was stronger than the torsion bands. This assignment is based on the following reasons: (1) In the liquid spectrum, the corresponding band was observed at 204 cm^{-1}, and its envelope was rather sharper than that in the gas (Fig. 3). However, a torsion band is usually weaker and broader in the liquid than in the gas phase. (2) If the torsional frequencies were 201 cm^{-1}, the barrier height, V_3, would be calculated to 2590 cal/mol. This is curiously low, since the value in ethane is 3000

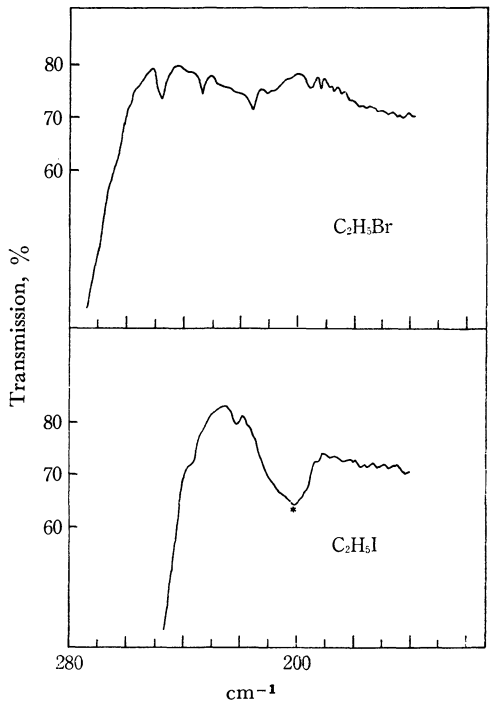

Fig. 2. Far-infrared spectra of ethyl bromide and ethyl iodide.
(Path length: 1.0 m for ethyl bromide, 3.6 m for ethyl iodide.
Pressure: Saturated vapor pressure at room temperature, for the both)
* This band was identified as a difference band.

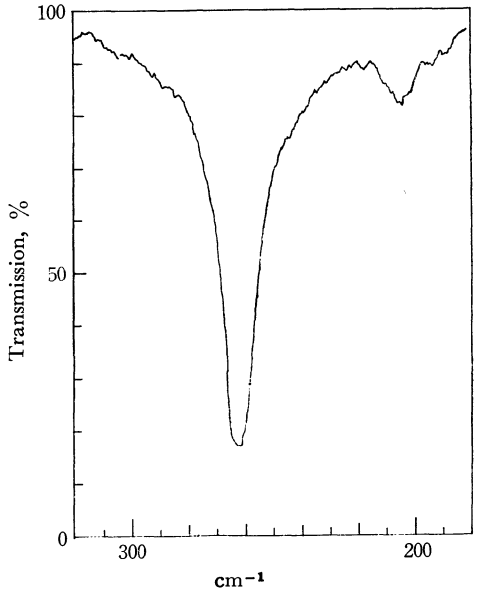

Fig. 3. Far-infrared spectra of liquid ethyl iodide.
Path length: 0.3 mm; The 262 cm^{-1} band is an A' fundamental, associated with CCI bending.

cal/mol.[8] (3) The band remained constant in intensity and frequency in the course of time. No rotation bands of hydrogen iodide were observed, either. Therefore, the band is not due to any decomposition product. (4) The combination band of the fundamentals appeared at 1709 cm^{-1}. The difference between the calculated and observed frequencies, 21 cm^{-1}, seems to be a little large. This is because the 1709 cm^{-1} band is very broad (the half band-width, 120 cm^{-1}) and consists of two combination bands, corresponding to 1712 (1210 A′ + 502 A″) and 1688 cm^{-1} (947 A′ + 741 A″).[9]

Except for the case of ethyl iodide, the agreement between the infrared frequencies and those obtained from the microwave splitting data is excellent. This suggests that the coupling of the CH_3 torsional vibration with the other intramolecular vibrations is quite small. This, in turn, justifies the treatment for obtaining the potential barrier to internal rotation from the infrared torsional frequency.[4-6] This is further supported by the fact that the potential energy distributions for the tosional vibration in the trans configuration of 1,2-dichloro-[10,11] and 1,2-dibromoethane[12] are 90 and 80% respectively.

The Preparation and Properties of Metal Complexes in Non-aqueous Solution. II. Diiodotetrakisdimethylsulfoxidecobalt Iodide*[1]

Masayuki MUTO, Masaaki YAMAGUCHI and Hayami YONEDA

Department of Chemistry, Wakayama University, Masagocho, Wakayama

(Received June 16, 1970)

The object of this investigation was, in its early stage, to obtain diiodotetraamine-type cobalt(III) complexes. With this object in mind, the replacement of Cl^- in $[CoCl_2en_2]^+$, $[CoCl_2pn_2]^+$, *etc.* by I^- in the presence of a small amount of iodine was attempted, using dimethylsulfoxide (DMSO) as the solvent. The product thus obtained was, however, not the expected diiodotetraamine-type complex, but instead, $CoI_3 \cdot 4$(DMSO) in all cases. This means that the substitution of I^- for Cl^- caused a purge of the coordinated amine ligands from the coordination sphere. Here it is surprising that even a tetradentate ligand, triethylenetetramine, is expelled by DMSO molecules. This suggests that DMSO has a strong coordinating ability with cobalt in the presence of I^-. Thus, the direct synthesis of $CoI_3 \cdot 4$(DMSO) was also attempted from CoI_2, I_2, and DMSO in absolute ethanol, the same product was obtained. The present paper will describe the method of preparation and the properties of this complex.

*[1] Presented at the 19th Symposium of Coordination Chemistry held at Tohoku University, Sendai, September 27, 1969.

Experimental

Preparation. *1) From trans-*$[CoCl_2en_2]NO_3$. One half gram of *trans-*$[CoCl_2en_2]NO_3$, 0.2 g of I_2, and 0.8 g of NaI were dissolved in 5 m*l* of warm DMSO. The mixture became a complete solution after one hour's gentle heating under constant stirring. This solution was added to 50 m*l* of ethanol and then placed in a refrigerator overnight. The precipitated sodium chloride was then filtered off, and the filtrate was stirred. A reddish-brown crystalline precipitate came out. The precipitate was filtered, washed with a small amount of ethanol and then with ether, and dried in a vacuum desiccator. Yield, 0.2 g.

Found: C, 12.49; H, 3.34; I. 50.57%. Calcd for $CoI_3 \cdot 4(C_2H_6SO)$: C, 12.77; H, 3.21; I, 50.61%.

From $[CoCl_2pn_2]NO_3$, $[CoCl_2tn_2]NO_3$, and $[CoCl_2$ trien$]NO_3$, the same product was obtained.

2) Direct Synthesis. One half gram of CoI_2 and 0.5 g of DMSO were dessolved in 10 m*l* of warm ethanol. The pink precipitate which appeared at first soon disappeared, and the solution became dark blue. Then, 0.15 g of I_2 in a small amount of ethanol was added slowly. Reddish-brown crystals came out. Crystals were filtered out, washed with ethanol and ether, and dried in a vacuum desicator. Yield, 2 g, In this preparation, the addition of iodine solution should be stopped before the blue color disappeared in

the solution.

Physical Measurements. The IR spectra were recorded with a Hitachi EPI-S2 spectrophotometer equipped with NaCl optics. The KBr disk method was adopted for the complex, but for the ordinary and deuterated DMSO samples sandwiched with NaCl plates were used for the measurements.

The UV absorption spectra of the solutions were obtained with a Hitachi Spectrophotometer 124, using 1-cm quartz cells. The magnetic moment was determined by the Gouy method at 12°C.

Results and Discussion

IR Spectra. Figure 1 shows the IR spectrum of the new complex, $CoI_3 \cdot 4(DMSO)$, together with those of the know complex, $[Co(DMSO)_6]I_2$[1], and the free ligand, DMSO. These spectra consist of a relatively few bands, among which consist of a relatively few bands, among which the two appearing at about 950 cm^{-1} and at 1000–1100 cm^{-1} are significant in discussing the coordinated state of the lignad. There has been confusion concerning the assignment of these two bands.

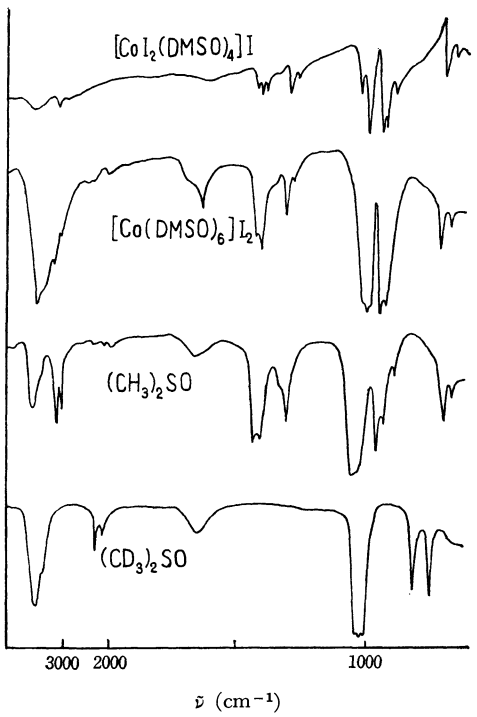

Fig. 1. IR absorption spectra of the free and coordinated states of dimethylsulfoxide.

Cotton and his collaborator[1] studies the IR spectra of sulfoxide complexes and concluded that coordination occurred through oxygen in $[Co(DMSO)_6]I_2$, since the SO stretching frequencies of the complex were lower than those of the free ligand, which absorbed at 1100–1055 cm^{-1}. Their assignment seems unnatural, however, of the two bands, the one at the lower frequencies was taken as the SO stretching band in the case of the complex, while the one at the higher frequencies was taken as the SO stretching band in the case of the free ligand. Thus, Drago and Meek[2] rejected Cotton's assignment and asserted that the band at lower frequencies was due to the methyl rocking mode, and that at higher frequencies, to the SO stretching mode, both in the complex and in the free ligand. If this is valid, the SO stretching frequency is not very sensitive to the nature of the metal.

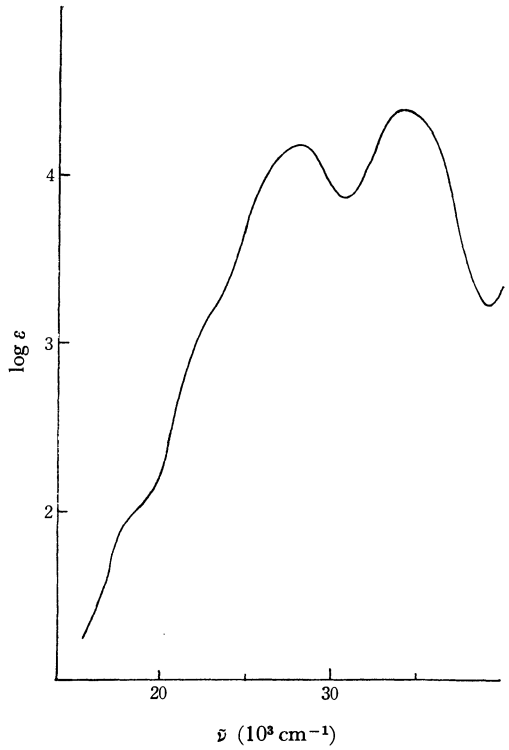

Fig. 2. Visible and UV absorption spectrum of $CoI_3 \cdot 4(DMSO)$ in 0.01 M NaI ethanol solution.

To confirm their assignments, the spectrum of deuterated DMSO was measured and compared with that of the ordinary DMSO. As may be been in Fig. 1, the band at lower frequencies completely disappears, while that at higher frequencies remains almost unchanged. This means that the lower one is due to the methyl rocking mode, which should be shifted further to lower frequencies upon the deuteration of the methyl group. Thus, the validity of Drago's assignment was confirmed. Since the SO stretching band of the free ligand is

1) F. A. Cotton, R. Francis and W. D. Horrocks, *J. Phys. Chem.*, **64**, 1534 (1960).

2) R. S. Drago and D. W. Meek, *ibid.*, **65**, 1446 (1961).

shifted slightly to lower frequencies upon coordination to Co(II) (from 1100–1050 cm^{-1} to 1050–1000 cm^{-1}), coordination through oxygen was also confirmed. In the new complex, $CoI_3 \cdot 4(DMSO)$, the frequency of each band is quite similar to that of $[Co(DMSO)_6]I_2$. Thus, the coordination through oxygen may be presumed. Although the new complex can be formulated as $[CoI_2(DMSO)_4]I$, in which the central cobalt ion is assumed to be tervalent, there is no indication in the IR spectra which positively supports the existence of the tervalent cobalt ion.

Visible and UV Absorption Spectra. Figure 2 show the visible and UV absorption spectra of $CoI_3 \cdot 4(DMSO)$ in an ethanol solution. The large absorption peaks at 28000 and 34200 cm^{-1} are assigned to charge-transfer band due to the coordinated I^-, because the spectrum of $[CoI(NH_3)_5]^{2+}$ has two bands at almost the same frequencies. The spectra have, in addition, two shoulders at about 17000 and 21200 cm^{-1} which are regarded as ligand-field bands.

Magnetic Moment. The magnetic moment of $CoI_3 \cdot 4(DMSO)$ was determined to be 4.45 B.M..

Structure of Complexes. From the above-mentioned data, we can formulate the complex as $[CoI_2(DMSO)_4]I$. The electronic structure of the complex may be represented by a resonance hybrid of the following structures;

$$[Co^{3+}(I^-)_2(DMSO)_4]^+ \leftrightarrow [Co^{2+}(I^-)(I^0)(DMSO)_4]^+$$

The Reactions of Dihydropyridones (II)

Noboru SUGIYAMA, Makoto YAMAMOTO and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received June 17, 1970)

As dihydropyridones are typical β-amino-enones which are sterically fixed to a *cis*-s-*trans* structure,[1] it is interesting to examine the difference in its reactivity from β-amino-enones of other types. Recently, we reported on the protonation, oxidation, reduction,[2] photoisomerization,[3] and the relation between the structure and the spectral properties of dihydropyridone.

The present paper will describe the aldol condensation of dihydropyridone and related reactions.

6-Methyl-1,2-diphenyl-2,3-dihydro-4-pyridone (**1**) was treated with benzaldehyde in an alkaline ethanol solution. The expected condensation product at C-3 methylene was not detected, but an unexpected product, 1,2-diphenyl-6-styryl-2,3-dihydro-4-pyridone (**2**) was obtained in a 33% yield. From the spectral data and elemental analyses, the structure of **2** was determined.

The mechanism of the formation of **2** can be explained as follows: C-6 methyl is more active than C-3 methylene, and benzaldehyde condenses at C-6 methyl to give 6-(β-hydroxyphenethyl)-1,2-diphenyl-2,3-dihydro-4-pyridone (**3**), which then produces **2** by the elimination of water.

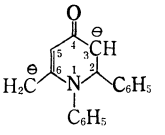
5: R=-$CH_2C_6H_5$
7: R=-CH·C_6H_5 (OH)



6

Fig. 1.

For the purpose of confirming this, the alkylation reaction of **1** with benzyl bromide was carried out in the presence of an equimolar sodium amide in liquid ammonia.[4] If C-6 methyl is more reactive than C-3 methylene, the alkylation product at C-6 methyl, 6-phenethyl-1,2-diphenyl-2,3-dihydro-4-pyridone (**4**), may be expected to be produced. In fact, dihydropyridone **4** was obtained, and a trace of the alkylation product at C-3 methylene,

2) C. Kashima, M. Yamamoto and N. Sugiyama, This Bulletin, **42**, 2690 (1969).

3) C. Kashima, M. Yamamoto, Y. Sato and N. Sugiyama, *ibid.*, **42**, 3596 (1969).

4) N. Sugiyama, M. Yamamoto and C. Kashima, *ibid.*, **42**, 1357 (1969).

3-benzyl-6-methyl-1,2-diphenyl-2,3-dihydro-4-pyridone (**5**), was detected.

The formation of **5** shows that C-3 methylene has a reactivity. In order to confirm this, **1** was treated with benzaldehyde in the presence of two molar equivalents of sodium amide in liquid ammonia. When two molar equivalents of a base are used in liquid ammonia, the dianione (**6**) of **1** will be produced, and it is expected that the C-3 methylene position will be more reactive than that of C-6 methyl, much as is the case with the dipotassium salt of acetylacetone in liquid ammonia.[5]

From the reaction mixture, 3-(α-hydroxybenzyl)-6-methyl-1,2-diphenyl-2,3-dihydro-4-pyridone (**7**) was obtained in a 25.5% yield. No condensation product at C-6 methyl was detected. The structure of **7** was proved by the spectral data and by the results of elemental analyses.

The C-6 methyl of dihydropyridone **1** is the most reactive in the molecule, and aldol condensation occurred at this position. This is a novel type of aldol condensation. C-3 methylene has some reactivity in liquid ammonia, but this position is less reactive than C-6 methyl.

Experimental

6-Methyl-1,2-diphenyl-2,3-dihydro-4-pyridone (1). Compound **1** was prepared from acetylacetone and benzylidenaniline in the presence of three moles of potassium amide in liquid ammonia.[4] NMR (in $CDCl_3$): τ 8.13 (singlet, 3H, C-6 methyl protons), 7.09 (double quartet, 2H, C-3 methylene protons), 5.08 (quartet, 1H, C-2 methine proton), 4.81 (singlet, 1H, C-5 olefin proton), and 2.6—3.2 (multiplet, 10H, aromatic protons).

1,2-Diphenyl-6-styryl-2,3-dihydro-4-pyridone (2). To a solution containing 0.5 g of **1** and 0.3 g of benzaldehyde in 20 m*l* of ethanol, a 5% sodium hydroxide solution (10 m*l*) was added. The reaction vessel was closed with a rubber stopper to prevent oxidation, and, after shaking for 10 min, the mixture was left to stand at room temperature for 12 hr. The mixture was then poured into 50 g of crushed ice and 200 m*l* of water, and acidified with dilute hydrachloric acid. The aqueous solution was extracted with chloroform. The organic layer was washed with water two times, and then dried over calcium chloride. After the removal of the solvent, the residue was chromatographed on a silica-gel (Merck 7729) column with a benzene - ethyl acetate (4 : 1 *v/v*) mixture. A fraction which showed R_f 0.35 upon silica-gel (Wako gel B-5) thin-layer chromatography with a benzene - ethyl acetate (4 : 1 v/v) mixture was collected to give 220 mg (33%) of **2**, as yellow plates; mp 164—165°C.

Found: C, 85.06; H, 6.11; N, 3.97%. Calcd for $C_{25}H_{21}NO$: C, 85.44; H, 6.02; N, 3.99%.
IR (KBr): 1630, 1535, 755 and 690 cm^{-1}.
UV: λ_{max}^{EtOH} 236 (ε 14200), 314 mμ (ε 20600).
$\lambda_{max}^{HCl/EtOH}$ 235 (ε 11900), 353 mμ (ε 28900).
NMR (in $CDCl_3$) (τ): 7.25, 6.69 (double quartet, 2H, C-3 methylene protons), 4.86 (quartet, 1H, C-2 methine proton), 4.80 (singlet, 1H, C-5 olefin proton), 3.58 (doublet, 1H, α-olefin proton of the C-6 styryl group, $J_{\alpha\beta}=16.5$ Hz) and 2.56—2.90 (multiplet, 16H, β-olefin proton of the C-6 styryl group and aromatic protons).

The Condensation of 1 with Benzyl Bromide. In a 200-m*l*, three-necked flask, about 150 m*l* liquid was placed; 0.20 g of metalic sodium was then added to produce sodium amide. To this solution 2.0 g of **1** was added, and it was stirred for an hour; then equimolar benzyl bromide (1.23 g) in 10 m*l* of anhydrous ether was added. After stirring for one hour, the mixture was neutralized with excess solid ammonium chloride. The liquid ammonia was rapidly evaporated on a water bath, and to the residue there was added about 100 m*l* of water. The aqueous layer was extracted with ether, and the ethereal layer was washed with water and dried over anhydrous sodium sulfate. The formation of **4** and **5** was confirmed by thin-layer chromatography by a comparison of their R_f values with those of authentic specimens.[4]

3-(α-hydroxybenzyl)-6-methyl-1,2-diphenyl-2,3-dihydro-4-pyridone (7). In the presence of two molar equivalents of sodium amide, 1.32 g of **1** were allowed to react with equimolar benzaldehyde. The crude reaction product was purified by silciag-el (Merck 7729) column chromatography. The eluting solvent: benzene - ethyl acetate (2 : 1 v/v). Yield, 0.47 g of **7** (25.5%); colorless prisms; mp 122—123°C.

Found: C, 81.12; H, 6.30; N, 3.63%. Calcd for $C_{25}H_{23}NO_2$: C, 81.26; H, 6.28; N, 3.79%.
IR (KBr): 3380, 1625, 1550, 710 and 695 cm^{-1}.
UV: λ_{max}^{EtOH} 338 mμ (ε 16900).
NMR (in $CDCl_3$) (τ): 8.00 (singlet, 3H, methyl protons), 7.20 doublet, 1H, methine proton), 5.63 (singlet, 1H, methine proton), 5.01 (doublet, 1H, methine proton), 4.69 (singlet, olefin proton), 2.72—3.24 (multiplet, 15H, aromatic protons) and 6.25—7.20 (broad, 1H, hydroxy proton, disappeared by D_2O).

The Treatment of 7 with Concentrated Sulfuric Acid. To 200 mg of **7**, 10 m*l* of concentrated sulfuric acid were added; the mixture was then allowed to stand at room temperature for two hours. To the reaction mixture were added about 50 g of crushed ice, and the resulting suspension was extracted with chloroform. The chloroform layer was washed with water and then dried over calcium chloride. However, the expected product, **8** or **9**, was not detected by thin-layer chromatagraphy.[6]

The Conformation of Acid Form γ-Polyglutamic Acid

Takehiko WATANABE, Takafumi INA, Kozo OGAWA,* Takeshi MATSUMOTO, Sumihiko SAWA** and Sôzaburo ONO

*Laboratory of Biophysical Chemistry and** Laboratory of Fermentational Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai*
** Radiation Center of Osaka Prefecture, Shinke-cho, Sakai*

(Received June 22, 1970)

In the previous paper,[1] the dissolved state of γ-polyglutamic acid solution at different pH's was studied by means of rotatory dispersion, flow birefringence and intrinsic viscosity. And it was reported that the polymer molecule in neutral and alkaline media will be in the form of a highly expanded chain while that in acid medium in a contracted form having a some ordered chain conformation. Edelhoch and Lippoldt[2] reported that γ-poly-D-glutamate obtained from the capsule of *Bacillus anthracis* exists in a hydrogen-bonded hyper coiled form in water at low degrees of ionization. Later Rydon[3] suggested that the unionized acid form polymer possesses a helical structure from the optical rotatory dispersion measurement from 250 to 600 mμ.

In the present paper, the conformation of γ-polyglutamic acid in acid form was studied by rotatory dispersion and infrared spectra.

Experimental

Materials. γ-polyglutamic acid, or γ-PGA is a polymer of glutamic acid linked through the γ-carboxyl and α-amino group and is produced by the *Bacillus subtilis* No. 5E[4] from glucose and urea. γ-PGA is isolated by the NaCl-alcohol precipitation method[5] from the culture. The extracted γ-PGA was dissolved in 3% NaCl and 30—35% alcohol aqueous solution and centrifuged for the removal of cells, and then precipitated by pouring the centrifuged solution in alcohol. This procedure was repeated and the centrifuged solution was dialyzed against distilled water until free of chloride and the dialyzed solution was lyophilized. Thus obtained sample is the sodium salt of γ-PGA (Naγ-PGA) and its intrinsic viscosity obtained in 10% NaCl solution at 25°C is 4.71 dl/g and sedimentation constant at infinite dilution (in 10% NaCl solution) is 6.80×10^{-13}. The molecular weight calculated by Mandelkern and Flory equation[6] is 1×10^{6}. To obtain the acid form γ-PGA (Hγ-PGA), the Naγ-PGA was successively treated with ion exchange resin Dowex-50, Amberlite IRA-400 and Dowex-50 as the 0.2% aqueous solution and the treated solution was lyophilized. Both Naγ-PGA and Hγ-PGA were hydrolyzed with 6N HCl at 105—110°C for 15—24 hr. Degree of optical rotation of both hydrolyzed samples was coincided with that of the mixture of 75% D-glutamic acid and 25% L-anomer.

Measurements. Optical rotatory dispersion measurement was carried out with a Yanagimoto ORD-185. Mean residual rotation [R] was calculated as the correction factor $3\overline{M}/100\ (n_\lambda^2+2)\fallingdotseq1$, where $\overline{M}$ is mean residual weight of glutamic acid and n_λ is the refractive index of solvent.

Infrared spectra was measured using a Perkin-Elmer Spectrophotometer Model 221.

Results and Discussion

The optical rotatory dispersion curves of Hγ-PGA at pH=9.0, 4.7 and 2.5 are shown in Fig. 1. The curves show a negative Cotton effect with a trough at 230 mμ*1 and the depth of the trough becomes deeper with decreasing in pH. According to Sarkar and Doty[7] and Iizuka and Yang[8], the appearance of the trough at 230 mμ on optical rotatory dispersion curve suggests that the polymer dissolved in acid medium is in a β-form, not the helical structure which was proposed by Rydon[3] under the deficiency of the data obtained from the optical rotatory measurement at lower wavelength below 250 mμ, where the Cotton effect is

6) L. Mandelkern and P. J. Flory, *J. Chem. Phys.*, **20**, 212 (1952).

*1 In the previous paper (Ref. 1, Fig. 6), a deep trough due to Cotton effect was observed at 225 mμ and a shallow trough was observed on curves at the wavelength of 260—270 mμ. The discrepancies of the results from that of the present one may be brought about by the coexistence of unknown substance (in small amounts) which has a absorption peak at 260—270 mμ. The substance was almost perfectly eliminated from the γ-PGA in the course of the treatment with the ion exchange resins.

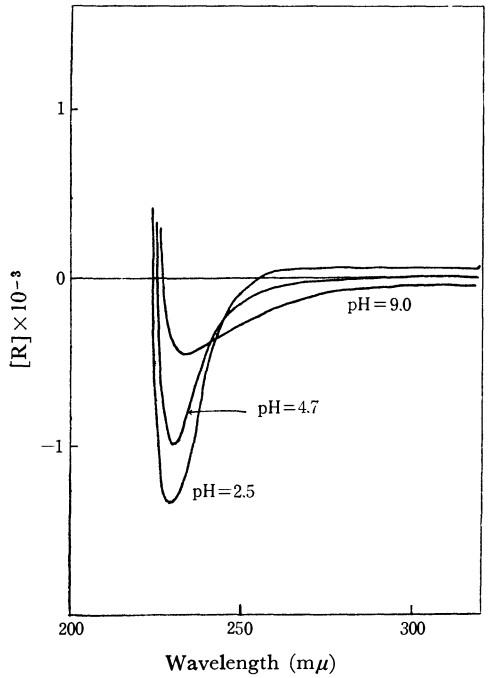

Fig. 1. Optical rotatory dispersion curves of Hγ-PGA at different pH's.

observed. With the value of [R], the negative value is obtained at 230 mμ and this result corresponds to the one reported in literature for α-linked L-polymer,[7,8] in spite of the presence of large excess amounts of D-polymer. The magnitude of the value of [R] expected for pure D-polymer at pH=2.5, is $-1350 \times 2 = -2700$, if we assume a compensative effect on the value of [R] between D- and L-polymer based on the composition ratio of D : L=3 : 1. However, this value of −2700 is far different from the value of $[R] = -6 \times 10^3$ reported for α-linked L-polymer.[7,8]

The infrared spectra of Naγ-PGA and Hγ-PGA obtained with KBr disc method are shown in Fig. 2. With Hγ-PGA, the amide I bands were observed at 1630 cm^{-1} (strong) and 1650 cm^{-1} (weak) and the amide II bands were observed at 1530 cm^{-1}

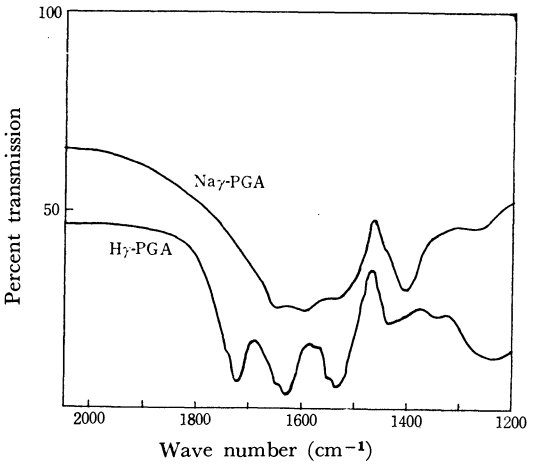

Fig. 2. Infrared spectra of Hγ-PGA and Naγ-PGA.

(strong) and 1550 cm^{-1} (weak), indicating that the Hγ-PGA is in the β-form, according to the results obtained with α-linked polymers by Miyazawa and Blout[9] and Masuda *et al.*[10] With Naγ-PGA, the amide I and II bands in disordered form (random coil)[9,10] were observed at 1655 and 1535 cm^{-1}, respectively, however these bands are quite diffuse due to the overlapping by the band due to the COO^- groups around 1600 cm^{-1}. The above result was obtained with the lyophilized polymer, however, the same conformation may be taken in solution, because the infrared spectrum obtained with acid form α-poly-D-glutamic acid (product of Miles-Yeda Ltd.) by KBr disc method shows the characteristic spectrum of α-helix.

From the above result, γ-PGA molecule will be mostly in a β-form in acid medium and will take a contracted form with folding of the sheet of β-form molecule, as stated in the previous paper.[1]

The Reaction of 3-Methyl-5-methylmercapto-2,4-diphenylthiazolium Iodide with Bases. Preparation of Mesoionic Imidazoles

Toshie SHIBA and Hiroshi KATO*1

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto

(Received June 23, 1970)

In connection with our interest in photolyses and pyrolyses of mesoionic compounds in general,[1] we needed a convenient synthetic approach for various mesoionic ring systems. For this purpose, mesoionic oxazol-5-one derivatives, first prepared by Huisgen and his collaborators[2], are ideal starting materials. The preparation of several mesoionic compounds by the reaction of 3-methyl-2,4-diphenyloxazol-5-one (I) and a few hetero-cumulenes has previously been described.[3] Further, the phenyl isothiocyanate adduct, mesoionic 1-methyl-2,3,5-triphenylimidazole-4-thione (II, R=Ph), has been reported to isomerize to mesoionic *N*-phenyl-3-methyl-2,4-diphenyl-thiazol-5-imine (III, R=Ph) by hydrogen chloride.[3] Since we were unable to reproduce this rearrangement under various conditions, we attempted to prepare this compound *via* methylmercaptothiazolium salt.

The treatment with methyl iodide of mesoionic 3-methyl-2,4-diphenylthiazole-5-thione (IV), prepared by the reaction of I and carbon disulfide,[3] gave the corresponding *S*-methyl salt, 3-methyl-5-methylmercapto-2,4-diphenylthiazolium iodide (V). It was anticipated that the methylmercaptothiazolium salt V would give the corresponding imines, III, by the reaction with amines.[4]

The treatment of V with methylamine gave a product with a composition in agreement with the expected mesoionic imine (III. R=Me), but the NMR methyl signals (τ 6.33 and 6.55) suggested that the two methyl groups are substituted on aromatic-ring nitrogen atoms. Further, its infrared spectrum showed no absorption in the region expected for an imine group, but, instead, absorptions at 1310 and 1071 cm^{-1}, regions earlier assigned to an azole-thione structure.[5] These spectral data strongly suggest that the product is 1,3-dimethyl-2,5-diphenylimidazole-4-thione (II, R=Me). To support further this structural assignment, it was treated with methyl iodide to give methiodide VI (R=Me), the NMR spectrum of which, showing a new methyl signal at τ 7.55 (*S*-Me), is thus wholly consistent with the proposed structure. This is the first example of a mesoionic imidazole-4-thione with an aliphatic substituent on the 3-position; thus, this reaction sequence may be regarded as an attractive synthetic route for this type of compounds.[6]

The reaction of V and aniline took a different course, and gave another quaternary salt, the NMR spectrum of which exhibits the presence of two types of methyl groups by signals at τ 6.33 and 7.85. This suggests that the product is 1-methyl-4-methylmercapto-2,5-diphenylimidazolium iodide (VI, R=Ph); it was identified as such by comparison with a specimen prepared by the methylation of II (R=Ph)[3] by methyl iodide. The two iodides VI (R=Me and Ph) were no longer reactive to aniline or methylamine, even under forcing conditions.

The reaction of imidazolium iodides, VI, with alkali may be expected to give mesoionic imidazol-4-ones, VII, but this reaction only gave resinous products. The expected imidazolone (VII, R=Ph), however, could be prepared by the cycloaddition reaction of I with phenyl isocyanate. In this case, in contrast to the reactions with other hetero-cumulenes, the corresponding cycloadduct, VIIIa or VIIIb, was isolated; this was converted to the imidazolone VII by the elimination of carbon dioxide only after heating in xylene. To date, this compound is the only example of a non-fused

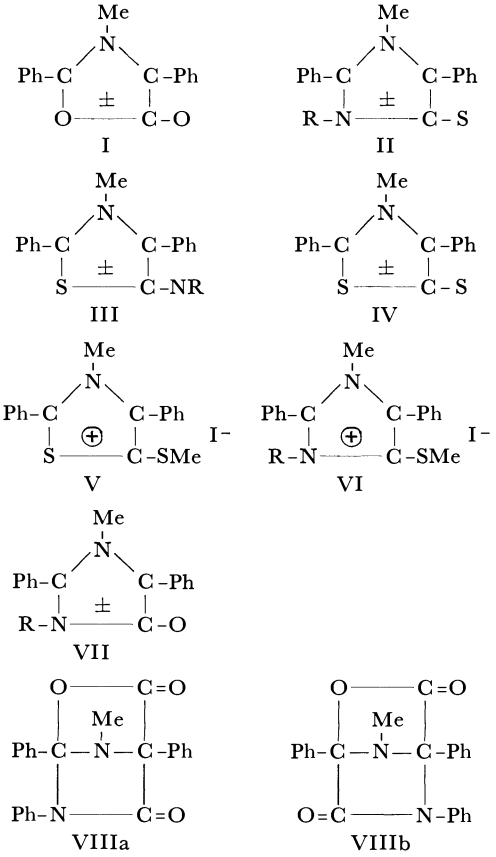
mesoionic imidazol-4-one with no acyl substituents.[7]



Experimental[8]

3-Methyl-5-methylmercapto-2,4-diphenylthiazolium Iodide (V). A mixture of 1 g of IV[3] and 0.6 g of methyl iodide in 10 m*l* of ethanol was stirred at room temperature for two hours. Ether was then added to the mixture, and the precipitate was recrystallized from ethanol to give 1.06 g (70% yield) of pale yellow prisms melting at 133—134°C. NMR: 1.84—2.50 (m, 10H, Ph), 6.12 (s, 3H, *N*-Me), 7.46 τ (s, 3H, *S*-Me).

Found: C, 48.26; H, 3.80; N, 3.19%. Calcd for $C_{17}H_{16}NS_2I$: C, 48.00; H, 3.76; N, 3.29%.

Mesoionic 1,3-Dimethyl-2,5-diphenylimidazole-4-thione (II, R=Me). A mixture of 1 g of V, 3 m*l* of 30% aqueous methylamine, and 10 m*l* of ethanol was stirred at room temperature for ten hours. The mixture was then concentrated, and the crystals which seperated out were recrystallized from ethanol to give 0.6 g (90% yield) of pale yellow needles melting at 191—192°C. IR (cm^{-1}): 1310, 1071. NMR: 2.20—2.72 (m, 10H, Ph), 6.33 τ (s, 3H, Me), 6.55 τ (s, 3H, Me).

Found: C, 72.36; H, 5.70; N, 9.67%. Calcd for $C_{17}H_{15}N_2S$: C, 72.83; H, 5.75; N, 9.99%.

1,3-Dimethyl-4-methylmercapto-2,5-diphenylimidazolium Iodide (VI. R=Me). A mixture of 0.5 g of II (R=Me) and 0.3 g of methyl iodide in 3 m*l* of ethanol was stirred at room temperature for two hours; the crystals which separated out were recrystallized from ethanol to give 0.6 g (80% yield) of colorless prisms melting at 175.8—176.7°C. NMR: 1.90—2.45 (m, 10H, Ph), 6.20 (s, 3H, *N*-Me), 6.50 (s, 3H, *N*-Me), 7.55 τ (s, 3H, *S*-Me).

Found: C, 51.20; H, 4.54; N, 6.60%. Calcd for $C_{18}H_{19}N_2SI$: C, 51.16; H, 4.50; N, 6.63%.

1-Methyl-4-methylmercapto-2,3,5-triphenylimidazolium Iodide (VI, R=Ph). a) A mixture of 0.7 g of V, 0.5 g of aniline, and 10 m*l* of *n*-butanol was refluxed for ten hours. Ether was added to the concentrated mixture, and the precipitate was crystallized from ethanol to give 0.5 g (60% yield) of colorless prisms melting at 236—237°C. NMR: 1.41—2.20 (m, 5H, Ph), 2.40—2.70 (m, 10H, Ph), 6.33 (s, 3H, *N*-Me), 7.85 τ (3H, *S*-Me).

Found: C, 56.66; H, 4.33; N, 5.24%. Calcd for $C_{23}H_{21}N_2SI$: C, 57.03; H, 4.37; N, 5.78%.

b) A solution of 1 g of II (R=Ph)[3] and 0.53 g of methyl iodide in 10 m*l* of acetone was stirred for two hours at room temperature. The solution was then concentrated, and the precipitate was recrystallized from ethanol to give 1.0 g (70% yield) of colorless prisms melting at 236—237°C, identical with the specimen prepared by Procedure **a**.

Phenyl Isocyanate Adduct of I (VIII). A solution of 5 g of I and 4.5 g of phenyl isocyanate in 100 m*l* of xylene was stirred at 70°C for four hours. The mixture was then concentrated, and ether was added; the precipitate was recrystallized from benzene to give 5.5 g (90% yield) of colorless prisms melting at 160—161°C. IR (cm^{-1}): 1735 (lactone C=O), 1640 (lactam C=O). NMR: 2.08—2.29 (m, 5H, Ph), 2.40—2.80 (m, 10H, Ph), 7.28 τ (s, 3H, Me).

Found: C, 74.50; H, 4.70; N, 7.50%. Calcd for $C_{23}H_{18}N_2O_3$: C, 74.59; H, 4.86; N, 7.46%.

Mesoionic 1-Methyl-2,3,5-triphenylimidazol-4-one (VII, R=Ph). A solution of 1 g of the adduct VIII in 30 m*l* of xylene was heated under reflux for thirty minutes. The solution was concentrated and then petroleum ether was added; the precipitate which separated out was recrystallized from acetone to give 0.2 g (23% yield) of pale yellow prisms melting at 190—192°C. IR (cm^{-1}): 1650 (C=O). NMR: 2.50—3.05 (m, 15H, Ph), 6.97 τ (s, 3H, Me).

Found: C, 81.75; H, 5.87; N, 9.14%. Calcd for $C_{22}H_{18}N_2O$: C, 82.21; H, 5.52; N, 8.59%.

We are indebted to Professor Masaki Ohta of Tokyo Institute of Technology and to Professor Kameji Yamane of this Department for discussion and encouragement.

7) The preparation of mesoionic 5-acylimidazol-4-ones by way of a different route has been reported: A. Lawson and D. H. Miles, *J. Chem. Soc.*, **1959**, 2865. After the completion of this work, a report on the preparation of a mesoionic imidazol-4-one which also has an acetyl substituent on the 5-position has appeared: E. B. Roche and D. W. Stansloski, *J. Heterocycl. Chem.*, **7**, 139 (1970).

8) All melting points were determined on a micro hot stage, and are uncorrected. The infrared spectra were recorded as KBr disks on a Hitachi model EPI-SII Spectrophotometer. The NMR spectra were measured using a JEOLCO JNM-4H-100 (100 MHz) Spectrometer in deuteriochloroform solutions containing tetramethylsilane as internal standard, and the chemical shifts are given in τ values.

Triplet-State Zero-Field Splittings. III.[1] Effect of the Two-Center Coulomb Repulsion Integrals

Yasuhiko GONDO and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received June 29, 1970)

We here report that a Pariser-Parr-type approximation[2] for the two-center Coulomb repulsion integrals yields much better triplet-state zero-field splitting (ZFS) parameters for aromatic hydrocarbons and nitrogen heterocycles than the Nishimoto-Mataga-type approximation.[3] Compounds studied are shwon in Fig. 1 with a coordinate system adopted.

In our previous paper,[1] it was shown that the SCF-AO's expanded by Löwdin are useful for the calculation of the electron spin dipolar interactions in the triplet-state ZFS's of aromatic molecules, and particularly for the ZFS calculation the SCF-AO's have formally replaced the Slater AO's used in the wavefunction calculation. In other words, the SCF-AO's have been used for the evaluation of the electron spin dipolar interactions in combination with a set of approximations consisting of (1) the π-electron approximation (Pariser-Parr-Pople method),[2,4] (2) the use of configurations which are only singly excited with respect to the lowest-energy singlet configuration for the triplet-state wavefunctions, and (3) the two-center integral approximation for the electron spin dipolar interactions.

Thus, in Part I[1] we have obtained excellent agreement with experiments for benzene and naphthalene, and also some promising results for aromatic nitrogen heterocycles such as quinoline and isoquinoline, as shown in Table 1 under the heading of Eq. (1), employing the following Nishimoto-Mataga-type formula of the two-center Coublomb repulsion integrals for all interatomic distances R_{pq},

$$(pp|qq) = 6.588/(Z_p^{-1}+Z_q^{-1}+0.457529\,R_{pq})\ \text{eV}, \quad (1)$$

where R_{pq} is given in angstroms, and Z_p stands for the effective nuclear charge of the p-th $2p\pi$AO and was given 3.25 and 3.90 for carbon and nitrogen, respectively. Eq. (1) was obtained by combining the approximations proposed by Paoloni[5]

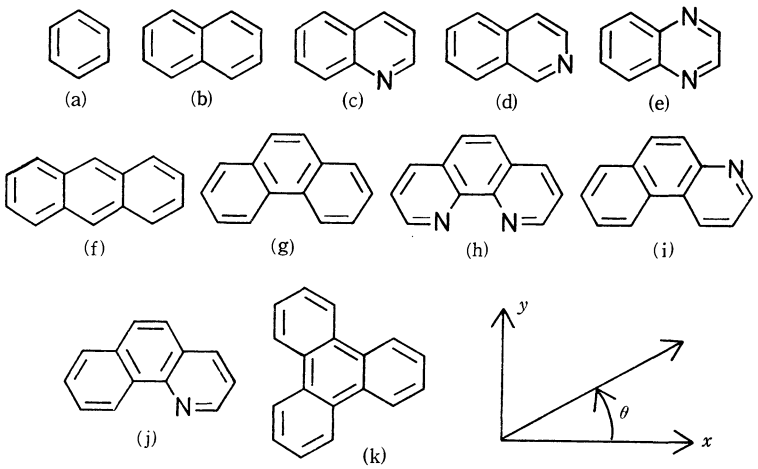

Fig. 1 Compounds studied in this work, with coordinate axes: (a) benzene, (b) naphthalene, (c) quinoline, (d) isoquinoline, (e) quinoxaline, (f) anthracene, (g) phenanthrene, (h) 1,10-phenanthroline, (i) 5,6-benzoquinoline, (j) 7,8-benzoquinoline, (k) triphenylene.

1,10-Phenanthroline	0.1277	−0.0493		0.1158	−0.0564		±0.1038	∓0.0485		12
5,6-Benzoquinoline	0.1219	−0.0461	−5.0°	0.1105	−0.0544	−17.6°	±0.1023	∓0.0477		12
7,8-Benzoquinoline	0.1233	−0.0495	−3.2°	0.1113	−0.0565	−12.0°	±0.1011	∓0.0468		12
Triphenylene	0.1374			0.1316			±0.134			13

a) For the coordinate axes, see Fig. 1.
b) Ref. 1 and this work.
c) For $R_{pq}>2.8$ Å, the multipole expansion formula has been used. See text.
d) Principal axis direction of the ZFS tensor as defined in Fig. 1.

and by Nishimoto and Mataga.[3]

In this note the following quadratic Pariser-Parr-type expression,[6]

$$(pp|qq) = 3.294Z + (3.836-1.993Z)R_{pq} - (0.7661-0.3004Z)R_{pq}^2 \text{ eV}, \quad (2)$$

where $Z=1/2(Z_p+Z_q)$, is employed for $R_{pq}\leq 2.8$ Å, and for $R_{pq}>2.8$ Å a multipole expansion formula.[7] Eq. (2) is derived through the Paoloni approximation[5] and the application of the multipole expansion formula for $R_{pq}=2.8$ and 3.7 Å.[2] The ZFS parameters calculated with this approximation are shown in the columns under the heading Eq. (2), of Table 1. The whole computational scheme is the same as Method 1 of Part I, namely the SCF-AO's are used for all interatomic distances in evaluating the electron spin dipolar interactions.

Comapring the data calculated with the observed ZFS parameters given in Table 1, it can be concluded that the Pariser-Parr-type formula is much better than the Nishimoto-Mataga-type formula at least for the triplet-state ZFS calculation. For quinoxaline, phenanthrene and azaphenanthrenes, agreement with experiments is not so good as that for the other compounds listed in Table 1, although considerably improved. The reason for this is not clear at present.

We are grateful to the Kyushu University Computer Center for the use of its facilities.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3945—3947 (1970)

Drynap Reduction. IV. The Reduction of Cyclic Styrene Derivatives with a Commercial Sodium-Lead Alloy

Katsumi TABEI and Kouichi TAKAZAWA

Tokyo College of Pharmacy, Kitashinjuku, Shinjuku-ku, Tokyo

(Received July 2, 1970)

In a previous paper of this series, one of the present authors reported that a commercial sodium-lead alloy, "Drynap", can be used as a reducing agent in the reduction of α,β-unsaturated carbonyl compounds in place of a sodium amalgam.[1]

In the present experiment, the alloy was used in the reduction of four cyclic styrene derivatives: coumarin, isocoumarin, *N*-methylcarbostyril, and isocarbostyril. A little of the information thus obtained will be reported here.

The reduction of coumarin with Drynap in an aqueous sodium hydroxide solution was attempted using the method of Erlenmeyer[2]; 3,4-dihydrocoumarin was thus obtained in about a 70% yield, as was expected. Isocoumarin, *N*-methylcarbostyril, and isocarbostyril were not reduced with the alloy in an aqueous solvent; isocoumarin was, thereby polymerized in an alkaline solution, even in the cold, and a yellowish brown tar was obtained. *N*-methylcarbostyril and isocarbostyril were recovered almost quantitatively.

In an ethanolic solution, coumarin was reduced with Drynap to 3,4-dihydrocoumarin in a 20% yield, but the main products were two isomers of 3,3′,4,4′-tetrahydro-4,4′-bicoumarin (the total yield of the mixture was about 50%). The mixture was separated by the method of Asahina and Fujita *via* the fractional crystallization of the corresponding carboxylic acid.[3] and two compounds which were difficult to separate were thus obtained: a less soluble isomer, mp 278—280°C (decomp.), and a more soluble one, mp 246—248°C (decomp.). Harle and Lyons have already assigned the above two isomers to the meso and

1) K. Tabei, H. Hiranuma and N. Amemiya, This Bulletin, **39**, 1085 (1966).

2) A. Erlenmeyer, *Ann. Chem.*, **121**, 375 (1862); **137**, 334 (1866).

3) Y. Asahina and Y. Hujita, *Yakugaku Zasshi*, **444**, 97 (1915).

4) A. J. Harle and L. W. Lyons, *J. Chem. Soc.*, **1950** 1575.

racemic forms respectively.[4] The IR and NMR spectra of the compound can not be discussed in detail in the present report.

The NMR spectra of the latter compound, the more soluble isomer, revealed doublet signals of methylene protons attached to the carbonyl group at 6.92 τ (4H), and triplet signals of the methine proton attached to the phenyl group at 7.00 τ (2H), in the deuteriochloroform solution, so it is certain that the dihydrocoumarin rings are united at the 4-position.

N-Methylcarbostyril was reduced with Drynap in the manner which has been described for use with coumarin; a new dimeric reduction product, $C_{20}H_{20}N_2O_2$, (mp 284—286°C) was thus obtained in about a 60% yield. The mass spectra of the dimer gave a characteristic peak of the monomer ion at *m/e* 160 as well as the molecular ion peak at *m/e* 320. The out-of-plane deformation vibration of olefinic hydrogen of *N*-methylcarbostyril disappeared in the IR spectra of the dimer, and the carbonyl stretching mode of the dimer absorbed in a wavelength region shorter by 12 cm^{-1} at 1673 cm^{-1}. The NMR spectra of the dimer exhibit the doublet signals of methylene protons adjacent to carbonyl group at 7.37 τ (4H). and triplet signals of the methine proton adjacent to the phenyl ring at 7.17 τ (2H), in the deuteriochloroform solution. The product can thus be identified as 3,3′,4,4′-tetrahydro-1,1′-dimethyl-4,4′-bicarbostyril.

Isocoumarin and isocarbostyril were also not reduced with Drynap in an ethanolic solution; isocoumarin gave a yellow tar, and isocarbostyril was recovered from the reaction mixture.

The above results were not improved by several alterations of the reduction conditions. We can thus conclude that the α,β-unsaturated carbonyl group is necessary for the Drynap reduction or reductive dimerization of cyclic styrene derivatives, even in a limited experiment.

Experimental

Materials. Commercial coumarin of a GR grade was purified by distillation under reduced pressure before use. The isocoumarin was synthesized from homophthalic acid *via* the decarboxylation of 4-carboxyisocoumarin, following the method of Johnston *et al.*[5] The product was purified by distillation at 155°C/20 mmHg; mp 45°C.

The *N*-methylcarbostyril was derived from quinoline methiodide following the method of Decker.[6] The product was purified by recrystallization from ligroin; mp 72—73°C.

The isocarbostyril was also derived from isoquinoline by the method of Brown and White.[7] The product was purified by recrystallization from methanol; mp 213—214°C.

Measurement of the Spectra. The IR spectra of the compounds were measured by using a JASCO DS-301 infrared spectrophotometer and using tablets of potassium bromide or in a chloroform solution.

The NMR spectra of the compounds were measured by using a JNM 4H-100 NMR spectrometer in a deuteriochloroform solution.

The mass spectra of the reduced dimers were measured by using a Hitachi RMU-7L apparatus.

Drynap Reduction of Coumarin in a Sodium Hydroxide Solution. Three grams of coumarin (0.02 mol) dissolved in 50 m*l* of a 5% NaOH solution were reduced with 30 g of Drynap (0.13 mol of sodium metal): the reaction procedure was the same as has been described in a previous report. The yield of 3,4-dihydrocoumarin was 2.2 g (73%); bp 142—144°C/7 mmHg, mp 24°C. Dihydrocoumarin was identified by a mixed-melting-point determination with an authentic derivative; 3,5-dibromo-2-hydroxyphenylpropionic acid, mp 117—118°C, and by IR and NMR spectral studies of dihydrocoumarin. From the distillation residue, 0.2 g of the starting material, 2-hydroxycinnamic acid, was recovered; mp 207—208°C.

Drynap Reduction of Coumarin in an Ethanolic Solution. To a solution of 3.0 g of coumarin in 50 m*l* of ethanol, 30 g of Drynap and 7.5 g of acetic acid (0.12 mol) were added alternately in small portions at 60—70°C. After 1.5—2.0 hr, the mixture was decanted from the sludge, which was then washed with a new ethanol. The ethanol was evaporated from the combined ethanol solution, and the resultant residue was extracted with ether.

Some of the insoluble material remained after the above extraction. The ether solution was washed with a 5% sodium hydrogencarbonate solution and then with water, and dried over sodium sulfate. After the evaporation of the ether, the residual oil was distilled under reduced pressure; 0.6 g of 3,4-dihydrocoumarin was thus obtained (yield 20%); bp 142—144°C/7 mmHg.

From the distillation residue and the above-cited insoluble material, 1.5 g of a mixture of the two isomeric dimeric reduction products were obtained (total yield, 50%).

Separation of Isomeric Dimers. The isomeric mixture was dissolved in a 10% sodium hydroxide solution and hydrolyzed by boiling. After the acidification of the alkaline solution with concentrated hydrochloric acid, the water-soluble 3,4-bis-(2-hydroxyphenyl)adipic acid thus obtained was extracted with ether and then subjected to fractional crystallization from ether.

A less soluble acid (0.1 g, mp 200—220°C (decomp.)) and a more soluble isomer (0.7 g, mp 153—155°C (decomp.)) were thus obtained.

The acids were re-lactonized, by boiling in a mixture of acetic acid and a few drops of conc. hydrochloric acid, to the corresponding tetrahydro-bicoumarin. After several recrystallizations from glacial acetic acid, 300 mg of the less soluble lactone was obtained from the less soluble acid; mp 278—280°C (decomp.); Found: C, 73.65; H, 4.88%, mol wt (mass) *m/e* 294.

The other acid gave 0.5 g of the more soluble lactone; mp 246—248°C (decomp.); Found: C, 73.46; H,

The Occurrence of (−)-(2R : 5R)-*trans*-2,5-Diethyltetrahydrofuran in "Hōyō" Mint Oil

Yasuaki ITAHARA, Hajime WATANABE and Jun KATSUHARA

Sun Star Dentifrice Company, Research Laboratory, Takatsuki, Osaka

(Received July 2, 1970)

To data, more than fourteen kinds of low-boiling, oxygenated non-terpenoidal compounds have been isolated from the essential oil of *Mentha* genus.

We have recently isolated (−)-*trans*-2,5-diethyltetrahydrofuran (I) as a novel component of the *Mentha* essential oil. To our knowledge, this is the first example of the occurrence of (−)-I in the vegetable kingdom. We wish, at this time, to report on the isolation, structure elucidation, assignment of absolute configuration, and confirmation of this substance by means of the synthesis of enantiomeric (+)-I.

The low-boiling fraction of a "Hōyō" dementholized mint oil was rectified on a helix-packed column to give several fractions, from among which the cut distilling over the range from 131.5 through 152.0°C was further purified by means of preparative vpc to afford a liquid, boiling at 143—144°C, in an over-all yield of 0.009% (based on the crude oil used). The purity of this sample was demonstrated by the sharp single peak in the vapor-phase chromatogram. The molecular ion peak at *m/e* 128 in the mass spectrum, coupled with the results of the elemental analysis, showed the molecular formula of this compound to be $C_8H_{16}O$. The absence of hydroxyl, carbonyl, isopropyl, and geminal dimethyl groups and a double bond were indicated by the IR analysis, the results of which suggested a saturated cyclic ether structure. Similarly, the NMR spectrum showed a methin proton signal centered at τ 6.2 (2H; $\underline{\text{C}}\underline{\text{H}}$–O–$\underline{\text{C}}\underline{\text{H}}$), methylene proton signals at τ 7.9—8.9 (8H), and methyl proton signals at τ 9.1 (6H triplet, J= 6 Hz). The oxiran structure was precluded by the complete inertness of (−)-I toward lithium aluminum hydride. The NMR spectral data, when combined with the intense fragment ion peaks at *m/e* 99 (M-29) and *m/e* 29 (C_2H_5), led us to the convincing deduction of the structure as 2,5-diethyltetrahydrofuran. Moreover, in *a priori* symmetry considerations, the optical activity as manifested in the levorotation found for I, $[\alpha]_D^{24}$ −9.9°, logically necessitates the point group C_2 for this molecule, thus enabling us reasonably to assign the *trans*-geometry.

In order to confirm this deduction, to establish the absolute configuration, and also to ascertain whether or not (+)-(3S)-octanol (II), a constituent of very frequent occurrence in mint oil, is a biogenetic precursor of (−)-I, the oxidative cyclization of (+)-II with silver oxide and bromine was carried out according to the Mihailovic procedure[1] in the following manner (Scheme 1). The structure of the resulting (+)-I was fully substantiated by a comparison of its physical properties, and IR and mass spectra with those of the authentic specimen described in the literature.[2] The IR and mass spectral comparisons gave unambiguous evidence that the naturally-derived (−)-I is the enantiomer of the synthetic (+)-I. The conversion of the (+)-II with the well-defined S-configuration into (+)-I *via* the present process, which does not jeopardize the chiral carbon, permits us to identify the (2S : 5S)-configuration as

(+)−(3S)-II (+)-(2S : 5S)-III (−)-(2R : 5R)-I

Scheme 1

the synthetic (+)-I and, consequently, the (2R : 5R)-configuration as the naturally-derived enantiomer, (−)-I. This implies also that, in contrast to expectation, the naturally-occurring (−)-(2R : 5R)-I can not find its genetic origin in (+)-(3S)-II in the biosynthesis of *Mentha* plants.

Experimental

Isolation of (−)-*trans*-2,5-Diethyltetrahydrofuran (−)-(I). A forerun (5 kg) obtained by the steam-distillation of "Hōyō" dementholized mint oil (300 kg) was redistilled under reduced pressure to yield a low-boiling fraction (420 g). A part of this fraction (300 g) was rectified on a Helipack-type precision still to give a fraction distilling over the range from 131.5 through 150.0°C (23.5 g); this fraction was further purified by means of preparative vpc to yield I; bp 143—144°C; n_D^{24} 1.4201, $[\alpha]_D^{24}$ −9.9° ± 0.1° (c 2.0, ethanol). Fragment ion peaks in the mass spectrum: *m/e* 128 (molecular ion; 3.5%), 99 (24), 81 (100), 59 (21), 57 (45), 55 (100), 43 (63), 42 (53), 41 (45), 39 (27), 31 (11), 29 (68), 28 (15), 27 (39).

Found: C, 74.94; H, 12.65%. Calcd for $C_8H_{16}O$: C, 75.00; H, 12.50%. IR Spectrum: 2980 s, 2950 sh, 2890 sh, 1470 s, 1380 m, 1110 s, 1090 s, 1020 s, 990 sh, 930 m, 875 m cm^{-1}.

Synthesis of (+)-(2S : 5S)-*trans*-2,5-Diethyltetrahydrofuran (+)-(I). Bromine (7.5 g) was stirred, drop by drop, into a mixture of (+)-3-octanol (II) ($[\alpha]_D^{24}$ + 9.0 ± 0.2° (*c* 1.2, ethanol), 96.5% optical purity (3.0 g)) and silver oxide (5.7 g) in 80 m*l* of *n*-pentane in a nitrogen atmosphere over a 3-hr period. The reaction mixture was kept at 18—20°C during the addition, and then the stirring was continued for a further 2 hr. After this period, the reaction mixture was filtered to remove the silver bromide, the filtrate was washed successively with a 10% sodium thiosulfate solution, a 10% sodium hydrogencarbonate solution and water, dried over anhydrous sodium sulfate, and concentrated until a *n*-pentane-free residue was obtained (2.6 g). This residue was further purified by means of vpc to give (+)-I; bp 142—144°C, n_D^{24} 1.4188, $[\alpha]_D^{24}$ + 4.4±0.3° (c 1.2, ethanol). The IR and mass spectra of (+)-I were identical in every respect with those of the authentic specimen described in the literature[2] and also with those of the naturally-derived (−)-I.

The authors wish to thank Professor Yūzō Inouye of Kyoto University for many helpful discussions during the course of this work and Dr. Hideo Urushido of Hokuren for his generous gift of a sample. Thanks are also due to Dr. Shigeru Muraki of the Takasago Perfumery Co., for his measurements of the NMR and mass spectra, and to Dr. Tsutomu Sakai and his staff of the Institute of Food Chemistry for their measurement of the optical rotation.

Relation between the Size of the Electrode and Rotation Velocity at Rotating Ring Disk Electrode

Akira FUJISHIMA, Hideo IKETANI and Kenichi HONDA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July 9, 1970)

In electrolysis it is very difficult to detect and determine quantitatively intermediates produced at the electrode surface, especially in the cases of unstable materials. The rotating-ring-disk electrode method, developed by Frumkin and Nekrasov[1], has been recently regarded as one of the most useful means for the investigation of the intermediates of electrode reactions. Intermediates produced at the disk electrode would be transported by convective-diffusion to the ring electrode, where the electrochemical properties of the intermediates can be identified. When the rotation velocity is changed between 100 and 8000 rpm, a wide range of first-order rate constants of the intermediate reactions can be studied from 4×10^{-2} to 10^{3} sec^{-1}.[2] The higher the rotation velocity becomes, the faster the chemical intermediate reaction that can be measured.

When the species produced electrochemically on the disk electrode are stable, the ratio of the ring-limiting current to the disk-electrode current has been defined as the collection efficiency, N,[3] which is a function of the radii of the disk and ring electrodes. It has been shown that the collection efficiency, N, which is a very important factor in quantitative investigations, is independent of the angular velocity of rotation, the kinematic viscosity of the solution, the diffusion coefficient, and the concentrations of the species involved. The collection efficiency, N, can be calculated from the table which Albery and Bruckenstein[3] reported only when the flow in the vicinity of the electrode surface is laminar. On the contraty, at a high rotation velocity, which is often required in order to investigate fast intermediate chemical reactions, the Reynolds number increases and the flow in the vicinity of the electrode surface may become turbulent. Therefore, it is considered that each ring-disk electrode has a limit of maximum rotation rates, the limit depending on the total radius of the electrode involving the shroud part.

In this paper, as a basic study for the rotating-ring-disk electrode, the collection efficiency, N, was measured with various rotation velocities using an electrode in which the sizes of the disk and ring electrodes were constant, but in which the total radius of the electrode involving the shroud part was changed by setting arbitrary covers. It is shown that there is a maximum value of rotation velocity for each total radius of ring-disk electrodes. Moreover when the rates of the fast intermediate chemical reactions are to be measured, it may be pointed out that both the rotation velocity and the size of the electrode should be taken into consideration.

Experimental

Electrodes. The structure of the rotating-ring-disk electrode is shown in Fig. 1. A platinum disk electrode and a platinum ring electrode with platinum lead wires were fixed into a Teflon rod treated with a lathe. The disk radius was 5.00 mm, while the inner ring radius and outer ring radius were 5.50 and 6.50 mm respectively. The radius of the Teflon rod was

2) W. J. Albery and S. Bruckenstein, *Trans. Faraday Soc.*, **62**, 1946 (1966).

3) W. J. Albery and S. Bruckenstein, *ibid.*, **62**, 1920 (1966).

8.00 mm, and by covering the tubes made with acrylic resin, the total radius of the electrode could be change to 12.5, 15.0, 20.0, or 30.0 mm. The Teflon and the steel shaft were connected by screwing down the shaft into the Teflon; the rotation showed little eccentricity. The shaft was supported by bearings at two points and was rotated by means of the rotation system. The external electrical contact of the shaft was made with silver-carbon brushes. As pretreatment, the electrode was polished to a mirror finish with sandpaper and and alumina powder and then electrolyzed both anodically and cathodically. Such electrode had a satisfactory reproducibility. The immersion depth of the electrode into the electrolyte solution was about 5 mm.

Electrolysis Vessel. The electrolysis vessel, the inner radius of which was 40.0 mm, has an upward capillary in the center and two platinum counter electrodes at the bottom of the vessel. Using a vessel the inner radius of which was 70.0 mm, the effect of the size of the vessel on the relation between the collection efficiency and the rotation velocity was tested.

Reagents, Solutions and Atmosphere. The water was distilled once, after it was treated with an ion-exchange resin. All the chemicals were of reagent-grade quality. The electrolyte solution was a $CuCl_2$ (10^{-3} mol/l) aqueous solution, with KCl (0.2 mol/l) used as a supporting electrolyte. The electrode rotation assembly was set in a large, dry box made of acrylic resin and vekulite sheets. In this box liquid nitrogen was placed in a jar in order to introduce a nitrogen atmosphere; furthermore, by passing purified nitrogen gas through during all the experiments, the electrolyte solution was deoxygenated. The temperature of the electrolyte solution was 17°C.

Measurements. Two potentiostats, Hokuto Denko PS-1000 A, were used to control the potentials of the ring and disk electrodes independently. The reference electrode was a saturated calomel electrode. The ring current was measured with a Toa Recorder, EPR-2T, and the disk current, with a Keithley Electrometer, 610B. The electrode rotation assembly was made so that its rotation velocity could be changed from zero to 7000 rpm, and the rotation velocity was measured by a revolution-indicator.

Results and Discussion

In this investigation, the oxidation-reduction reaction;

$$Cu^{2+} + e^- \rightleftarrows Cu^+ \qquad (1)$$

was taken as a model reaction. The potential of the disk electrode was set to form Cu^+ at -0.15 V, which is the cathodic limiting-current region of Reaction (1), and the ring electrode, at 0.60 V, the anodic limiting-current region. The collection efficiency of the electrode used here was 0.309 (on the base of the table of Albery and Bruckenstein's paper)[3]. The whole outer radii involving the shroud of the ring-disk electrode were changed in the manner described before. The collection efficiencies were measured and plotted against the rotation velocities, as is shown in Fig. 2. The collection efficiencies obtained agreed with the

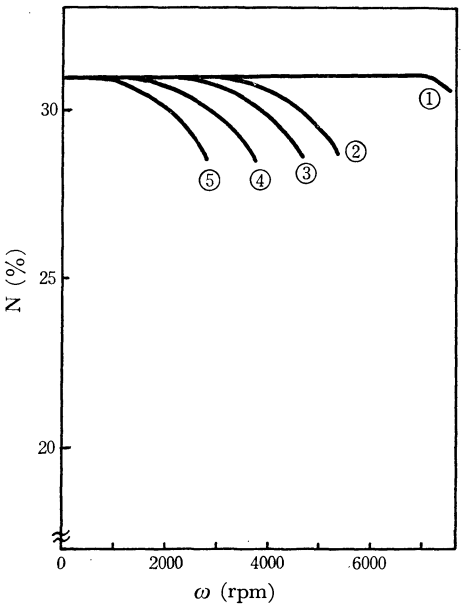

Fig. 2. Relation between rotation velocity and collection efficiency. Total radius of rotating ring disk electrode (cm), ①: 0.80, ②: 1.25, ③: 1.50, ④: 2.00, ⑤: 3.00.

value of 30.9% when the rotation velocity was not so high. As is illustrated in Fig. 2. the value of N began to decrease with the increase in the rotation velocity. Moreover, this decrease appeared at a lower rotation velocity when the electrode radius was larger. When the rotation velocity was higher than a certain critical value, which was related to the radius of the electrode, the collection efficiency, N, came to decrease; at the same time, it was recognized that the electrolyte solution bacame turbulent and that the bubbles were engulfed at the electrode surface. This reason has also been studied at the rotating-disk elecctrode[4,5], as a result of the increase in the Reynolds number N_{Re}, the laminar flow becomes a turbulent flow as the rotation velocity increases. The Reynolds number is related to the kinematic viscosity ν (cm²/sec), the radius of the electrode r (cm), and the rotation angular velocity ω(rad/sec):

$$N_{Re} = \frac{r^2\omega}{\nu} \qquad (2)$$

When the electrode surfaces are smooth enough and there is no eccentricity of rotation, the critical point of the Reynolds number where the flow of the solution changes from laminar to turbulent may be unchanged with the same electrolyte solution even if the radii of the electrodes are different. From Eq. (2) it can be understood that the larger

5) Z. Gaus and R. N. Adams, *J. Phys. Chem.*, **67**, 866 (1963).

the radius of the electrode, the lower is rotation velocity which is the critical point for the change from laminar flow to turbulent.

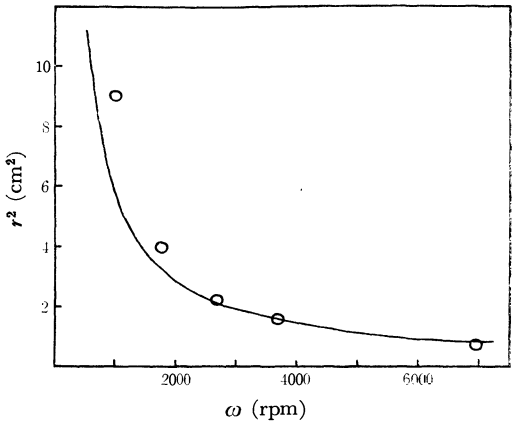

Fig. 3. Relation between r^2 and critical rotation velocity.
Solid line: $N_{Re}=6\times10^4$.

Figure 3 shows the $r^2-\omega$ relation. The solid line indicates the value calculated when $N_{Re}=6\times10^4$. In this case, the kinematic viscosity $\nu=0.01$ (cm^2/sec) is used. The measured points agreed quite well with the solid line. When the radius of the electrode is large, the critical points deviate slightly from the solid line. This may be explained by considering that, though, at the outer side of the shroud, the flow is turbulent, at the inner region, where the ring and disk electrode are locates, the flow may be laminar. In the study of the rotating-disk electrode, it was reported that the critical point is reached when N_{Re} is $10^4\sim10^5$. Therefore, $N_{Re}=6\times10^4$ is a reasonable value. Further, the same results were obtained when the electrolysis vessel with a radius of 70 mm was used instead of one with a 40 mm radius.

It may be concluded that there are limited regions of rotation velocity, depending on the electrode size. In cases where high rates of mass transport are desired, the total radius of the electrodes must be as small as possible for the rotating ring-disk electrode method. For example, when we study the intermediates with a rate constant of 10^3 sec^{-1}, the rotation velocity must be higher than 8000 rpm, but at the same time the total radius of the electrode must be smaller than 0.7 cm because of the laminar flow (probably also dependent on the eccentricity of the rotation). However, in such a high rotation velocity, special regard should be paid to the so-called edge effect, the mixing effect, etc.[6]

On the other hand, a turbulent flow is generally required for effective mixing and shorter reaction times in heterogeneous chemical reactions. Therefore, this method is interesting in connection with a quantitative investigation of the turbulent flow. As the critical point from laminar flow to turbulent can be simply and briefly measured by means of the rotating ring-disk electrode technique, using the relation between the collection efficiency and the rotation velocity, this method is considered to be a good tool for liquid turbulence studies.

The authors wish to thank Dr. M. Sukigara for his useful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3952—3954 (1970)

The Conformation of *trans*-4-Acetoxyisoflavans and Related Compounds*[1]

Shozo YAMAGUCHI, Kuninobu KABUTO, Yoriko NINOMIYA and Naoto INOUE

College of General Education, Tohoku University, Kawauchi, Sendai

(Received July 10, 1970)

As a part of the investigation of the stereochemistry of isoflavan-4-ols,[1] our interest in conformational preference effects in the chroman ring led us to investigate *trans*-4-acetoxyisoflavans and related compounds.

In the NMR spectra (Table 1) of *trans*-4-acetoxy- (I), *trans*-4-acetoxy-7-methoxy- (II), and *trans*-4-acetoxy-4′,7-dimethoxyisoflavan (III), the signals of the C-2 and C-3 protons show a simple pattern; the AB portion (the C-2 proton) appears as a 1 : 1 doublet, the X region (the C-3 proton) shows a 1 : 2 : 1 triplet ($J_{2,3}=J_{3,4}=5.0$ Hz), and none of the diaxial couplings expected for the conformations (Ie), (IIe), and (IIIe) appear in them. Upon irradiation at the C-4 proton of II, the quartet due to the C-3 proton changes to a triplet ($J_{2,3}=5.0$ Hz). These results strongly suggest that I, II, and III exist largely as conformations (Ia), (IIa), and (IIIa), in which the acetoxyl group at C-4 is in a *quasi*-axial environment. The present results can be explained by the pseudo-allylic effect,[2] which has been termed the $A^{(1,3)}$ strain, inherent in the conformations (Ie), (IIe), and (IIIe).

On the other hand, 2-methyl-4,7-diacetoxyisoflavan (2/3 *trans*, 3/4 *trans*) (IV)[3] seems to exist mainly as the conformation (IVe) ($J_{2,3}=J_{3,4}=10.2$ Hz), for there is a severe 1,3-diaxial repulsion in IVa (methyl-acetoxyl, around 1.9—2.4 kcal/mol)[4] which is considerably larger than the $A^{(1,3)}$ strain in IVe.

In the *trans*-4-hydroxyisoflavans, (I′), (II′), and (III′), the preferred conformations seem to be I′e, II′e, and III′e ($J_{3,4}=7.4$—8.5 Hz).*[2] In I′, II′, and III′, the unfavourable $A^{(1,3)}$ strain is considered to be partly overcome by the intramolecular hydrogen bonding[5] between the C-3 phenyl and C-4 hydroxyl groups.

The ABX protons (decoupled at the methyl signal at 100 MHz) of *trans*-3-methyl-4-benzoyloxychroman (V) show no diaxial coupling*[2] ($J_{2,3}=$ 2.4, 4.3: $J_{3,4}=4.1$ Hz); thus, the conformation Va is favoured. This result is substantiated by the existence of the long-range coupling ($J_{2,4}=$

Fig. 1

1.0 Hz) expected from the W letter rule. Unlike as in the spectra of I', II', and III', the $J_{3,4}$ values of *trans*-3-methyl-4-hydroxychroman (V'), in which the stabilization by the intramolecular hydrogen bonding can not be expected, is similar (5.5 Hz) to that of I—III; the preferred conformation is probably V'a, as in the case of V.

For the estimation[6] of the conformational equilibrium of II, standard $J_{3,4}$ valuse are selected as follows; $J_{3a,4a'}$: $J_{3a,4a'}$ (10.2 Hz) in IV[3]; $J_{3e,4e'}$: $J_{3e,4e'}$ (3.2 Hz) in *cis*-4-acetoxy-7-methoxyisoflavan (VI).[1] This assumption seems to be correct on the basis of the following points: (1) as has been described above, the conformation of IV is considered to be almost fixed to IVe; this is also supported by the equal value of $J_{3a,4a'}$ (10.2 Hz) in *cis*-4-benzoyloxyflavan (VII),[7] in which the conformation should be homogeneous. (2) Since the value of $J_{2a,3a}$ (11.9 Hz) in VI[1] is as large as that of *trans*-4-benzoyloxyflavan (VIII),[7] the conformation of VI is almost fixed; the assumption ($J_{3a,4e'}\approx J_{3e,4e'}$) is supported by the experimental data ($J_{3e,4e'}=J_{3e,4e'}=3.0$ Hz in VIII[7] and 3.2 Hz in *trans*-2-alkyl-4-acetoxychromans).*3 The calculation using the above standard $J_{3,4}$ values shows that IIa exists mainly (~75%) in the conformational equilibrium. A consideration of the 1,3-diaxial interaction (acetoxyl-hydrogen, ~0.35 kcal/mol)[4] associated with IIa and the free energy difference of 0.65 kcal/mol between the conformers in favor of IIa implies that the $A^{(1,3)}$ interaction (acetoxyl-hydrogen) in IIe is ~1.0 kcal/mol.*4

In 4-acetoxychroman (IX) and 1-acetoxytetralin (X), the preferred conformations are IXa and Xa, since the signals of the C-4 proton show a pattern [4-H(t), $J_{3,4}=3.8$ and 4.0 Hz respectively] similar to that of VIII [4-H(t), $J_{3,4}=3.0$ Hz][7] and since the conformational equilibrium of IX can be calculated[8] from the distance (4-acetoxychroman; 8.0 Hz) between the two outside peaks of the C-4 proton resonance based on the distances of *cis*- and *trans*-2-methyl-4-acetoxychromans*3 ($J_A=16.5$ Hz and $J_B=6.0$ Hz), selected as model compounds.*5 This calculation affords the results that IXa (~81%) is predominant and that the allylic strain is 1.1—1.2 kcal/mol, as large as that of II.

Experimental

Measurement. The NMR spectra were determined in $CDCl_3$ at 37°C (60 MHz) and 30°C (100 MHz), using a Varian A-60 and H-100 spectrometer with TMS as the internal standard.

Materials. The *trans*-4-acetoxyisoflavan (I),[9] *trans*-4-acetoxy-7-methoxyisoflavan (II)[9], *trans*-4-acetoxy-4',7-dimethoxyisoflavan (III),[9] *trans*-2-methyl-4,7-diacetoxyisoflavan (IV),[3] *trans*-4-hydroxyisoflavan (I'),[9] *trans*-4-hydroxy-7-methoxyisoflavan (II'),[9] and *trans*-4-hydroxy-4',7-dimethoxyisoflavan (III')[9] were prepared by methods previously reported. The 4-acetoxychroman (IX) and 1-acetoxytetralin (X) were obtained by the acetylation of chroman-4-ol and tetralin-1-ol respectively with acetyl chloride in pyridine.

trans-3-*Methyl*-4-*hydroxychroman (V')*. To a solution of 11.0 g of sodium borohydride in 220 m*l* of ethanol, 11.3 g of 3-methylchromone[10] was added. The mixture was refluxed for 4 hrs and then left to stand overnight at room temperature. After the ethanol had been removed under reduced pressure, 200 m*l* of water and 100 m*l* of 50% acetic acid were added to the residue. The solution was then extracted with ether. The extract was washed with 5% sodium hydroxide and with water, and was dried on anhydrous sodium sulfate. The mixture of *cis*- and *trans*-3-methyl-4-hydroxychromans remaining after the removal of the ether was partly crystallized. One of the isomers was obtained by repeated recrystallization from *n*-hexane - benzene; 2.2 g; mp 97.5—98.0°C.

Found: C, 73.31; H. 7.52%. Calcd for $C_{10}H_{12}O_3$: C, 73.14; H, 7.37%.

This isomer was identical with the *trans*-3-methyl-4-hydroxychroman (V') prepared by the hydroboration of the 3-methylchromene obtained by the dehydration

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3954—3956 (1970)

The Solid-phase Synthesis of Ile^5-Angiotensin II to Demonstrate the Use of N^{im}-Tosyl-histidine*[1a,b]

Toshiyuki FUJII*[2] and Shumpei SAKAKIBARA*[3]

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received July 23, 1970)

There are still several problems about the protection of imidazole groups during the incorporation of histidyl residues into peptides by the solid-phase method.[1] Recently, we proposed a new method for protecting the imidazole residue of histidine with a Tos-group, and several N^{α}-protected N^{im}-Tos-histidine derivatives (I) were synthesized.[2] The present study is concerned with the application of I in the solid-phase method.

There are several advantages in the use of the Aoc-, Boc-, Z(OMe)-, or Nps-derivatives of I in the solid-phase method. That is, these derivatives are easily synthesized by conventional methods, and they are soluble in CH_2Cl_2, which is known to be the most suitable solvent for coupling reactions with dicyclohexylcarbodiimide (DCC) in the solid-phase synthesis. Further, as was mentioned in the preceeding paper,[2] the Tos-group can be removed simultaneously with other protective groups in the final stage of the synthesis, when the free peptide is isolated from the peptide-resin with HF.[3] Therefore, many difficulties which are encountered during the incorporation of histidyl residues into peptide chains by the solid-phase procedure can be overcome by the use of I. Among these N^{α}-protected derivatives, Aoc-His(Tos)-OH (II)[2] seemed to be the most suitable for solid-phase synthesis because it is highly soluble in CH_2Cl_2. Some of the Tos-groups are known to be cleaved when the N^{α}-Aoc-groups are removed with anhydrous acids,[2] but partial cleavage is probably not a serious problem in solid-phase synthesis. In this connection, it may be recalled that Gutte and Merrifield tried to synthesize ribonuclease A with unprotected Boc-histidine.[4]

The synthesis of human angiotension II was attempted with Compound II. The standard procedures of Marshall and Merrifield were followed for the synthesis;[5] the Aoc group was used for the N^{α}-protection of the amino acids, and all the coupling procedures were carried out in CH_2Cl_2 with DCC. The tyrosyl and the arginyl residues were incorporated as Aoc-Tyr(Bzl)-OH[6] and Aoc-Arg(Tos)-OH (III) respectively. The final aspartyl residue was coupled with Z-Asp(OBzl)-OH.[7] All the coupling reactions proceeded smoothly in CH_2Cl_2; this was in contrast with reports that Boc-His(Bzl)-OH[5] and Boc-Arg(Tos)-OH[8] had to be coupled in DMF or in a mixture of DMF and CH_2Cl_2 (1 : 9) at the risk of acyl-urea formation.[9] The high solubility and reactivity of Aoc-Arg(Tos)-OH in CH_2Cl_2 should also be counted as favorable properties due to the Aoc-group.

Finally, the free peptide was taken out from the

peptide-resin by the HF-procedure,[3] and the bound HF was removed by passing the crude product through a column of Dowex-1; this procedure was also effective in removing almost all side products. Thus, practically pure angiotensin II was obtained without the use of any other specific procedure.

Experimental

Materials. Chloromethylated polystyrene (divinylbenzene 2%; 100—200 mesh; Cl-content, 1 mmol/g) was obtained from the Protein Research Foundation; it was converted to an Aoc-L-phenylalanyl-resin (0.29 mmol/g) by the procedure of Marshall and Merrifield.[5] The Aoc-amino acids were synthesized as has been reported previously.[6,10]

Aoc-Arg(Tos)-OH (III). Arg(Tos)[11] (9.9 g, 0.03 mol) was allowed to react with Aoc-azide[6] (5 g, 0.032 mol) at 35.0°C for 48 hrs in a mixture of dioxane (30 ml), 1N NaOH (30 ml), and triethylamine (4.2 ml, 0.03 mol). The reaction mixture was treated as described previously,[6] and the crude product was extracted into AcOEt. The AcOEt solution was concentrated under reduced pressure at room temperature. The crystalline residue was recrystallized from AcOEt, and dried over P_2O_5 *in vacuo*; wt, 11.8 g (88.7%); mp 79.5—83°C, $[\alpha]_D^{25}$ −13° (*c* 1.9, pyridine).

Found: C, 50.74; H, 6.85; N, 11.96%. Calcd for $C_{19}H_{30}N_4O_6S \cdot 1/2\,H_2O$: C, 50.54; H, 6.92; N, 12.41%.

Z-Aps(OBzl)-Arg(Tos)-Val-Tyr(Bzl)-Ile-His(Tos)-Pro-Phe-resin (IV). Aoc-L-phenylalanyl-resin (2 g, 0.58 mmol) was placed in a manual solid-phase apparatus, and synthesis was started as has been described in the literature.[1,4] The cleavage of the Aoc-groups was carried out with 50% trifluoroacetic acid in CH_2Cl_2,[4] and the amino groups generated were neutralized with triethylamine in DMF. Each Aoc-amino acid (3 eq) was coupled with DCC (3 eq) in CH_2Cl_2 for 3 hrs at room temperature. The couplings of Aoc-Ile-OH and Compound III were ensured by repeating the coupling procedure twice for each compound.

Finally, the protected peptide-resin (IV) (2.7 g) was obtained and dried over P_2O_5 *in vacuo* at 50°C. The overall yield (about 90%) was estimated at this stage from the weight-increase.

Ile^5-Angiotensin II. The peptide resin (IV) (700 mg) was placed in an HF-reaction vessel and mixed with anisole (0.5 ml). Anhydrous HF (10 ml) was then introduced into the vessel, and the mixture was allowed to react at 0°C for an hour. After the excess HF had then been evaporated off *in vacuo* at 0°C, the generated free peptide was extracted with 1% acetic acid. The extract was washed with ether and lyophilized; wt, 131.4 mg (90%, calcd from the amount of phenylalanyl-resin).

Then, the crude product (100 mg) was applied to a column of Dowex-1 × 2 (AcO^- form, 0.85 × 50 cm). This was eluted with water, and the UV absorption of each fraction was measured at 280 mμ (see Fig. 1).

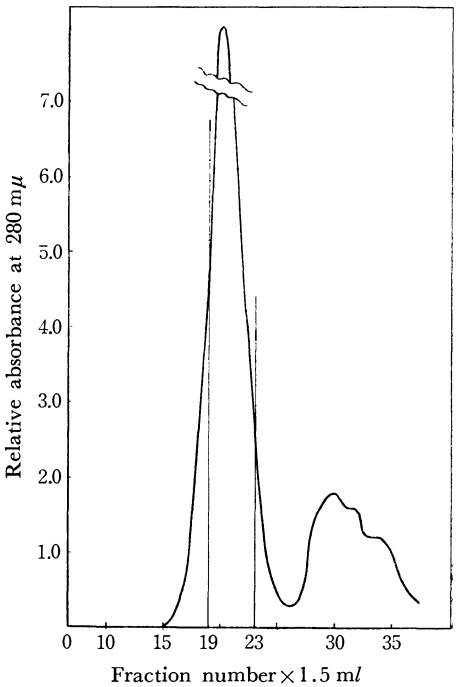

Fig. 1. Purification of synthetic angiotensin II by column chromatography.
Material was eluted from a column (0.85 × 50 cm) of Dowex 1 × 2 (Acetate form, 100—200 mesh) with water. 1.5 ml fractions were collected and their UV-absorption at 280 mμ was measured.

The major fractions (19—23) were combined and lyophilized to obtain the final product; wt, 45 mg (45% calcd from the crude product); $[\alpha]_D^{15}$ −67.8° (c 0.3, N HCl): reported $[\alpha]_D^{20}$ −66.98° (c, 0.4, N HCl),[12] $[\alpha]_D^{23}$ −67.3° (c 1.13, N AcOH),[13] $[\alpha]_D^{25}$ −66° (c 0.8, N HCl).[5]

Found: C, 54.40; H, 6.75; N, 15.35%. Calcd for $C_{50}H_{71}N_{13}O_{12} \cdot C_2H_4O_2 \cdot 3H_2O$: C, 53.83; H, 7.04; N, 15.69%.

This material showed a single spot (R_f 0.26) on paper chromatography with a solvent system *n*-butanol-acetic acid-water (4 : 1 : 1); reported R_f 0.29,[12] R_f 0.28.[5] Ratios of amino acids: Acid hydrolysate; $Asp_{1.02}Arg_{1.02}Val_{0.98}Tyr_{1.00}Ile_{0.93}His_{0.93}Pro_{1.05}Phe_{1.07}$. ESR ^{13}C Hyperfine Structures of the Meta-substituted *t*-Butyl Biphenyl Anion Radical*[1]

Kazuhiko ISHIZU*, Yasuo INUI*, Kazuo MUKAI*, Hideo SHIKATA* and Hideo HASEGAWA**

* *Department of Chemistry, Faculty of Science, Ehime University, Matsuyama*
** *Japan Electron Optics Laboratory, Akishima*

(Received August 13, 1970)

The ESR observation of the ^{13}C hyperfine structure has never been established for biphenyl anion radicals, because the weaker ^{13}C hyperfine structures were incidentally smeared out by superimposed ring proton hyperfine splittings, particularly those due to the meta-protons.

In the present studies, all of the meta positions were substituted by *t*-butyl groups and we attempted to reduce the superposition of the proton hyperfine structures; that is, the 3,3′,5,5′-tetra-*t*-butyl biphenyl was synthesized and the ESR ^{13}C hyperfine splittings were tentatively studies for the anion radical of this alkylated biphenyl.

Experimental

The synthesis of the 3,3′,5,5′-tetra-*t*-butyl biphenyl has not been described in the literature, however, the material was obtained from the Grignard reagent of the 3,5-di-*t*-butyl bromobenzene[1] prepared in an anhydrous tetrahydrofuran (THF) by following the process of Kharasch and Fields.[2] A pure material recrystallized from ethyl alcohol melted at 172.8—173.3°C. Found: C, 88.62; H, 11.17%. Calcd: C, 88.82; H, 11.18%. IR absorption in KBr. γ (=CH); 837 cm^{-1}, δ' (ring); 720 cm^{-1}. UV absorption in *n*-hexane. λ_{max}; 253 mμ ; ε ; 17300 M^{-1} cm^{-1}.

The anion radicals were prepared in a solution of THF by reduction with lithium. The ESR spectra were recorded at room temperature.

Results and Discussion

The proton hyperfine structures shown in Fig. 1, consist of only nine lines, and a_2^H and a_4^H were determined to be $a_2^H=-2.59$ and $a_4^H=-5.14$ gauss respectively, which are closed to those for the biphenyl anion radical. Both $\rho_2^\pi=0.100$ and $\rho_4^\pi=0.218$ were calculated using Colpa-Bolton's equation: for an anion radical, $a_i^H=Q^H_{CH}(0)\rho_i^\pi-K^H_{CH}[\rho_i^\pi]^2$, $Q^H_{CH}(0)=-27$, and $K^H_{CH}=-12$ gauss.[3] As is designated by the figures (1)—(4) in the lower part of Fig. 2, ^{13}C hyperfine splittings are observed as the doublet lines of (1) 0.90, (2) 1.98, (3) 4.34, and (4) 8.20 gauss, and the intensity ratios are (1) : (2) : (3) : (4) = 1 : 2 : 2 : 1. These intensity ratios distinguished either a_1^C or a_4^C from a_2^C and a_3^C. The a_4^C is assumed to be (4) 8.20 gauss, since the contribution of the spin-polarization is negligible as a result of the small value of ρ_3^π, thus, its magnitude depends substantially on the large spin density of ρ_4^π.

Following the method of Karplus-Fraenkel,[4] the a_i^C values have been calculated by the following equation:

$$a_i^C = (S^C + \sum_{i=1}^{3} Q^C_{C_iX_k})\rho_i^\pi + \sum_{i=1}^{3} Q^C_{X_kC_i}\rho_k^\pi$$

where $S^C=-12.7$ is the contribution from the 1s electron of C_i, $Q^C_{C_iX_k}$ ($Q^C_{C_iH}=19.5$, $Q^C_{C_iC_k}=14.4$), the $\sigma-\pi$ interaction parameter produced by ρ_i^π on the C_i atom, and where $Q^C_{C_kC_i}=-13.9$ represents a polarization from the neighboring atom, C_k. By substituting the values of a_4^C and ρ_4^π into the equation, $\rho_3^\pi=-0.016$ was primarily determined. In the same manner, $\rho_1^\pi=0.113$ can be derived from $\rho_2^\pi=0.100$ and $a_1^C=-0.90$. Here, the negative value is assigned for for a_1^C, for the normalization of the spin density,

TABLE 1. EXPERIMENTAL AND THEORETICAL VALUES OF THE ^{13}C COUPLING CONSTANT AND THE SPIN DENSITY

Position		1	2	3	4
a_i^C (gauss)	(Exp)	−0.90	1.98	−4.34	8.20
	(Calcd)[a)]	−0.95	2.53	−4.83	7.02
ρ_i^π	(Exp)	0.113	0.100	−0.016	0.218
	(Calcd)	0.134	0.114	−0.020	0.182

a) Theoretical values of a_i^C were calculated based on the McLachlan's spin density.

$\sum\rho_i^\pi = 1$, cannot be held if the positive value is assumed. Finally, we proved that the observed values of both a_2^C and a_3^C are consistently explainable with the present ρ_i^π value and that a_3^C also has a negative value; that is, a_2^C: Obsd 1.98, Calcd 2.21 gauss, a_3^C: Obs. −4.34, Calcd. *2 −4.98 gauss.

*2 $a_3^C = (S^C + 2Q_{C-C(CH_3)_3}{}^C)\rho_3^\pi + Q_{CiC_3}{}^C(\rho_2^\pi + \rho_3^\pi)$
The spin density on the *t*-butyl group was neglected and $Q_{C-C(CH_3)_3}{}^C \fallingdotseq Q_{C-CH_3}{}^C = 16.3$ gauss[5)] was assumed.

5) R. W. Fessenden, *J. Phys. Chem.*, **71**, 74 (1967).

McLachlan's MO calculation was carried out taking the Coulomb integral of the meta-position to be $\alpha_3=\alpha-0.15\beta$; the results are summarized in Table 1. A good agreement can be obtained between the observed ^{13}C hyperfine coupling constant and their theoretical values. The ^{13}C coupling constants for the biphenyl anion radical would also be similar to those established by the present work, since it has been shown that an alkyl substitution always causes only a minor perturbation in the spin density.[6]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3958—3960 (1970)

ESR Study of Spin-Spin Interactions in Verdazyl Biradicals. II

Kazuo MUKAI, Nagao AZUMA*[1], Hideo SHIKATA and Kazuhiko ISHIZU

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama

(Received August 25, 1970)

The verdazyls, a series of very stable free radicals containing four nitrogen nuclei, were recently studied by Kuhn, Neugebauer and Trischmann[1,2]. Preliminary susceptibility measurements showed the presence of one unpaired electron per molecule. The combination of two 3-verdazylyl residues by a 1,3- or 1,4-phenylene bridge gives fully-conjugated, nearly planar, green biradicals with properties which correspond to those of the simple verdazyls. The results of the paramagnetic susceptibility measurements revealed that the two unpaired electrons in the π-electron system of each biradical are practically free from coupling down to 77°K, in contrast to the case with the other stable biradicals.[3-5]

However, all of the bi- and tri-radicals of this series shows less well resolved ESR spectra than those of the monoradicals. Fischer[6] proposed that, judging from the results of HMO theory, each biradical has a node in the odd electron orbitals at the aryl system connecting the radical parts and should, consequently, exhibit little intramolecular spin exchange, and that, further, through step-by-step polarographic oxidation, the broadening of lines in the ESR spectra can be attributed mainly to dipole-dipole interaction, and not to electron exchange and or slow molecular tumbling motion as a consequence of the large molecular size.

The purpose of this note is to present new ESR spectra which not only yield the quantitative values of dipole-dipole interaction in these verdazyl biradicals, but also show existence of a triplet state in these radicals due to electron-exchange in-

teraction. This has been accomplished through the observation of the dipolar splitting of two verdazyl biradicals in 2-MeTHF at 77°K.

Experimental

1,3,5-triphenyl-verdazyl (I), mp 142.0—142.1°C (lit, 140—141°C), 1,3-bis-(1,5-diphenyl-verdazyl-3-yl) benzene (II), mp 182.2—183.3°C (lit, 184—185°C), and 1,4-bis-(1,5-diphenyl-verdazyl-3-yl) benzene (III), mp 197.5—198.0°C (lit, 195—196°C) were prepared from the corrsponding formazans according to the method of Kuhn, Neugebauer and Trischhmann.[1,2] After the formation of the s-tetrazyl ring with formaldehyde for I and II and with paraformaldehyde for III, the reaction I and II and with paraformaldehyde for III, the reaction mixture was neutralized with sodium hydroxide. A dark green crystalline compound was isolated from the DMF-solution, it was recrystallized three times from acetone-methanol for the I radical and from dioxane-methanol for the II radical, but in the case of the III radical it was washed two times with hot acetone.

All the ESR measurements were carried out using a JES-3BX spectrometer equipped with 100 kc/sec field modulation.

Results and Discussion

We followed the ESR spectrum of a 2-MeTHF solution of the verdazyl biradical (II) in a sealed, degassed system. A nine-line, considerably-overlapped ($a_N=6.0$ gauss) spectrum, as noted by Kuhn *et al.*[2] in a benzene solution, was observed. When this solution was frozen to a rigid glass at 77°K, the broad ESR spectrum clearly showed that it was a triplet species, as is shown in Fig. 1(a).

On the other hand, the spectrum of the verdazyl biradical III in 2-MeTHF at room temperature presents 17 overlapped lines ($a_N=2.8$ gauss), unlike the one observed by Kuhn *et al.* Fig. 2 shows such a spectrum. The existence of the triplet state in the III biradical was also confirmed by ESR measurement in a rigid solution at 77°K, as is shown in Fig. 1(b).

These spectra at 77°K can be interpreted on the basis of a randomly-oriented set of triplets with axial symmetry*[2]; thus the values of the dipolar splitting, D, are 52.7 gauss for the II biradical and 43.1 gauss for the III biradical, as one half of the outer two lines splitting. The observed increase in the splitting constants, $D(\mathrm{II})>D(\mathrm{III})$. is consistent with the structure. Using a model of two-point dipoles, that is the relation $D=(3/2)g\mu_B r^{-3}$, the average interelectronic distances in the II and III biradicals are calculated as 8.1 Å and 8.7 Å respectively. The relative intensity of central singlet varied with the samples, that is, with the radical concentration of the samples. Since the, monoradical I in 2-MeTHF solution at 77°K gives a singlet ESR spectrum of a line width of about 10 gauss, the central singlet spectra of the biradicals of $\Delta H_{msl}=5-10$ gauss in Fig. 1(a) and (b) may be due to unknown species of monoradicals produced as by-products of the synthesis.

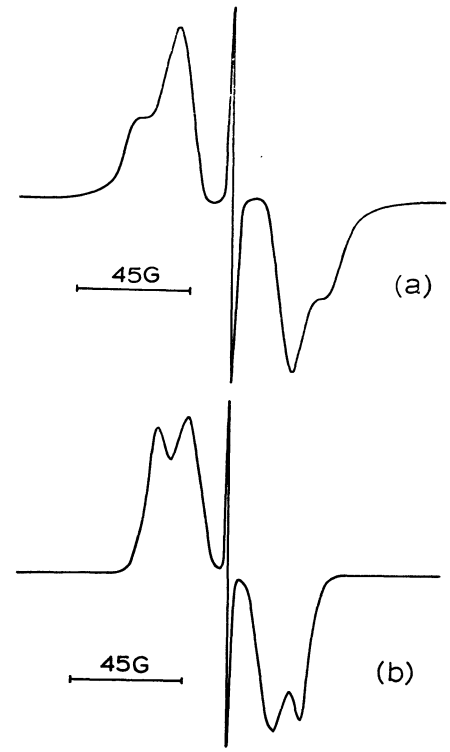

Fig. 1. ESR spectra of the two verdazyl biradicals in 2-MeTHF at 7°K.
(a) Biradical(II) (b) Biradical(III)

The ESR spectrum of a 2-MeTHF solution of the (I) monoradical at room temperature consists of a nine-line, well-resolved ($a_N=5.8$ gauss) spec-

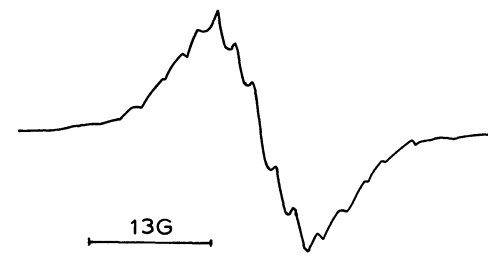

Fig. 2. ESR spectra of the verdazyl biradical (III) in 2-MeTHF at room temperature.

*[2] We have tentatively calculated the zerofield splittings, D and E, for the biradical III, assuming the distribution of the 1/4 unpaired electron on each nitrogen atom, and, further, using a model of a one-point dipole.[7] These values are $D=47.1$ gauss and $E=1.0$ gauss respectively. Therefore, in this note, we shall assume $E=0$ in interpreting the spectra.

7) D. A. Wiersma and J. Kommandeur, *Mol. Phys.*, **13**, 241 (1967).

trum. On the other hand, the ESR measurements of two verdazyl biradicals in a rigid solution at 77°K indicate that a triplet state exists in these radicals. If there is strong scalar exchange interaction, J, between the two electrons such that $J \gg a_N$, the spectrum will consist of 17 lines separated by $a_N/2$, corresponding to an interaction with 8 nearly-equivalent nitrogen nuclei[8]. In fact, the ESR spectrum of the III verdazyl biradical in 2-MeTHF shows 17 lines of $a_N = 2.8$ gauss. However, in the ESR spectrum of the II biradical, a hyperfine interaction with only four nearly equivalent nitrogen nuclei seems indicated, although the distance between the two verdazyl rings is smaller in the II biradical than in the II biradical and thus a larger exchange interaction in the former may be expected. This is probably because of the poorer resolution due to a larger dipolar broadening in the II biradical than in the III biradical.

Spin concentrations for the three species of verdazyl radicals were obtained from the results of the paramagnetic susceptibility measurements[9] at room temperature, after correcting for the diamagnetic contribution calculated by the Pascal method. The values were 97% for the I radical, 110% for II, and 104% for III, assuming the Curie law. The magnetic susceptibilities of usual organic radical solids, including several verdazyl radicals,[10] follow the Curie-Weiss law, and the values of the Curie-Weiss constant, θ, are negative, showing a inter-molecular negative exchange interaction. These facts show the possibility of intra-molecular positive spin coupling for such molecules as the II and III biradicals which have no C_3 or greater symmetry. We are now planning to measure the magnetic susceptibility over the temperature range of 1.8°K—300°K in order to clarify the above experimental results.

The authors wish to express their gratitude to Professors Hideo Takaki and Yasuo Deguchi for making the ESR spectrometer available for this study and for their encouragement throughout the course of this work.

ESR Studies of Radicals Generated by the PbO_2 Oxidation of Some Mono- and Bis-formazans

Nagao AZUMA,*[1] Kazuo MUKAI and Kazuhiko ISHIZU

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama

(Received August 25, 1970)

Several investigators[1-3] have reported that the air oxidation of formazans or the reduction of tetrazolium salts gives rise to a paramagnetic product whose ESR spectrum generally shows 9 lines easily explained by two pairs of equivalent nitrogens, and have proposed two structures for the radical, that is, (a) the openchain formazyl radical and (b) the cyclic tetrazolinyl radical.

Neugebauer and Russel[4] obtained much better resolved spectra due to four nitrogens and further phenyl ring protons in a benzene solution by the

abstraction of a hydrogen atom formazans by di(*p*-tolyl)nitrogen. They attributed these spectra to a cyclic structure, based on McLachlan molecular orbital calculations performed for the above two structures. Moreover, from the fact that the ESR spectrum of the radical derived from *N,N'* diphenyl-C-benzeneazoformazan shows 9 groups easily interpreted by only four nitrogen atoms, Neugebauer[5] concluded that the radical has the cyclic structure.

We with to report here the ESR spectra observed when the mono- or bis-formazans I-III are oxidized with lead dioxide in 2-methyltetrahydrofuran (2-MeTHF) under a vacuum.

Experimental

The formazans I—III (I, mp 177.2—178.0°C, II, mp 204.6—205.0°C, III, mp 222.5—222.8°C), were prepared following the method of Kuhn, Neugebauer and Trischmann[6] and were recrystallized, from alcohol for I, from aceton for II, and from DMF for III, as dark red crystals. All the ESR measurements were carried out using a JES-3BX spectrometer equipped with 100 Kc/sec field modulation.

Results and Discussion

Powder samples of the I-III formazans do not show any ESR spectra in 2-MeTHF at room temperature. An initial slight oxidation of the I-III formazans with PbO_2 gives the ESR spectra shown in Fig. 1(a), indicating an interaction with four equivalent nitrogens. We assign the spectra to the corresponding tetrazolinyl monoradicals (I(M), a_N=6.2 G; II(M), a_N=6.1 G; III(M), a_N=6.2 G), which have tetrazolinyl ring. There is no apparent interaction with the protons in the conjugated phynyl rings. Further oxidation of the monoformazan solution causes a marked decrease in the intensity of the ESR spectrum. However, in the case of the II and III bisformazans, as the oxidation proceeds the nine-line spectra of the monoradicals begin to overlap with each other and, finally, are completely altered to the spectra shown in Fig. 1(b). These spectra, which consist of nine considerably overlapped lines, were unchanged at the lowest concentration at which they could be detected; thus they are thought to be due to tetrazolinyl biradicals (II(B), a_N=6.3 G; III(B), a_N=6.5 G). These facts show that the broadening of lines in the ESR spectra of the tetrazolinyl biradicals can be attributed mainly to electron-electron interaction, and not to slow molecular tumbling motion as a consequence of the large molecular size. These circumstances are very similar to those of verdazyl radicals, which have a π-electron system closely related to that of tetrazolinyl radicals.[6-8]

one can observe dipolar splitting, as is shown in Fig. 2. The spectrum remained unchanged after a period of a few hours at 77°K. Upon annealing at room temperature, however, the reddish-purple color disappeared along with the ESR spectrum. The III (B) biradical gave similar, less resolved spectrum. No triplet signal could be observed from I(M) at 77°K.

The assignment of the observed peaks to the usual triplet-state spin Hamiltonian gave the zero-field splitting parameters, $D=51.2$ G for II(B) and $D=37.9$ G for III(B). These small splittings may be explained by the large separtion between the two tetrazolinyl rings and the small unpaired spin density on the centered phynylene ring and two carbon atoms bonded to the ring.[4,7] The dipolar splittings, $D=51.2$ G and 37.9 G, obtained using a model of two-point dipoles, indicate that the average interelectronic distances in II(B) and III(B) are about 8.2 and 9.0 Å respectively. The observed increase in splitting constants, $D(\text{II}) > D(\text{III})$, is consistent with the structure.

Two Modifications of Bi-Nuclear Copper(II) Chloride Complexes with *N*-Methylsalicylideneimine

Yoneichiro MUTO, Michinobu KATO*, Tadashi TOKII, Kyoko IMAI* and Hans B. JONASSEN**

Department of Chemistry, Saga University, Saga, Aichi Prefectural University, Mizuho-ku, Nagoya*
*** Department of Chemistry, Tulane University, New Orleans, Louisiana, U.S.A.*

(Received February 16, 1970)

We reported previously[1,2] that two modifications of a compound of composition Cu($\overset{2}{O}\cdot C_6H_1\cdot \overset{1}{C}H{=}N{-}CH_3$)Cl (1) were obtained in the reaction of bis-*N*-methylsalicylideneiminatocopper(II) and cupric chloride in ethanol. The brown form (1.5 Bohr magnetons) was prepared by refluxing the alcoholic mixture, whereas the orange one (0.9 B.M.) was obtained at lower temperatures. In order to obtain further information about the polymeric nature of these complexes, we have determined their temperature dependence of magnetic susceptibilities. The observed χ-T data fitted the Bleaney-Bowers equation well,[3] confirming an essentially dimeric structure for both forms (*cf.* Fig. 1) with $J=242$ cm^{-1} and $g=2.10$ for the brown form, and $J=580$ cm^{-1} and $g=2.20$ for the orange form. The d-d bands of these two modifications are markedly different; the brown form showed three bands at 815, 667 and 457 mμ suggesting tetrahedral nature of the stereochemistry around the copper(II) ion,[2] whereas the orange form gave rise to a broad band at 1055 mμ with a shoulder at 855 mμ. In order to investigate some factors which lead to the formation of these two modifications, complexes with a substituent (R) at the 5-position of the benzene ring in (1) have been prepared. The complex

* *cf.* the text

with R=CH_3 was obtained only in a brown form at lower or higher temperatures (J=243 cm^{-1} and g=2.11), whereas the complex with R=Cl was obtained in an orange form (J=553 cm^{-1} and g=2.17). The complex with R=NO_2 was obtained only as an orange form; the shape of its χ-T curve at low temperatures indicated that it contained a small amount of a paramagnetic impurity. The appropriate values of J (574 cm^{-1}) and g (2.17) for this compound were derived from the χ-T data corrected for the impurity contribution. The details of such variations will be reported shortly. This seems to indicate that electron attracting groups (Cl, NO_2) lead preferably to the formation of the orange form, whereas electron donating group (CH_3) forms the brown complex preferably. The medium polarity of H might explain why the unsubstituted (R=H) complex forms both forms depending upon reaction conditions.

The complexes in the present study all exhibit a bridging phenolic C-O band at *ca.* 1550 cm^{-1}.[4] This indicates that the two copper(II) ions in a dimeric molecule are bridged by phenolic oxygen atoms.

SHORT COMMUNICATIONS

A Betaine Intermediate in the Copper Chelate Catalyzed Decomposition of *o*-Methoxycarbonyl-α-diazoacetophenone

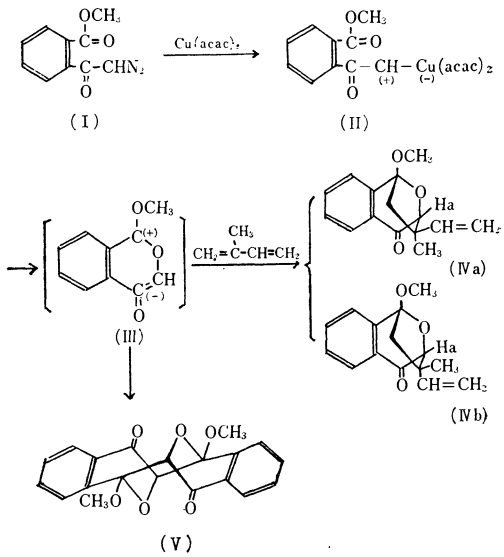
Matsuji TAKEBAYASHI, Toshikazu IBATA, Kozaburo UEDA and Takeshi OHASHI

Department of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received July 27, 1970)

In a previous paper,[1] we showed that the copper chelate catalyzed reaction of α-diazoacetophenone with aromatic compounds such as benzaldehyde and acetophenone gave the corresponding tetrahydrofurans and dioxolanes, and that the mechanism of the reaction could be explained by assuming betaine intermediate, produced by the reaction of a ketocarbene-copper chelate complex with carbonyl compounds. This paper deals with a new type of betaine intermediate.

The copper chelate catalyzed decomposition of *o*-methoxycarbonyl-α-diazoacetophenone[2] (I, 0.0098 mol) was carried out in benzene at 80°C in the presence of conjugated dienes (0.367 mol). In the presence of isoprene, the reaction gave two stereoisomeric products (IVa and IVb) in yields of 43 and 34%, respectively. IR of IVa: 2900, 1700, 1635, 1290, 1050 and 765 cm^{-1}. NMR of IVa (in $CDCl_3$): 1.9—2.8(m, 4H), 4.7—5.8 (m, 3H), 6.55(s, 3H), 6.6—9.2(m, 5H) and 8.13 τ (s, 1H). IR of IVb: The same as above. NMR of IVb (in $CDCl_3$): 1.9—2.8(m, 4H), 4.7—5.8 (m, 3H), 6.55(s, 3H), 6.6—9.2(m, 5H) and 8.27 τ(s, 1H). The Ha of IVa is deshielded by 0.14 ppm in comparison with that of IVb, owing to π-electrons of the ethylenic linkage (Scheme 1). The results indicate that the isoprene employed reacts with a new type of betaine intermediate (III),



Scheme 1

produced from a ketocarbene-copper chelate complex (II), by 1,2-addition to give IVa and IVb. 1,3-Cyclooctadiene also reacted with III to give 1,2-addition products.

When the reaction was carried out without conjugated dienes, a dimer (V), mp 233—235°C, of III was obtained in 30% yield. NMR of V (in $CDCl_3$): 1.8—2.7(m, 8H), 5.08(s, 1H), 5.62 (s, 1H), 6.30(s, 3H) and 6.54 τ(s, 3H).

Solvent Effect on the Reduction of Butenyl Chlorides by Pentacyanocobaltate(II)

Takuzo FUNABIKI and Kimio TARAMA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received August 6, 1970)

We studied the reaction of the two butenyl chlorides with pentacyanocobaltate(II) in several solvents in the absence of hydrogen.

The reaction was carried out in a similar manner to that reported previously,[1] except that chlorides were added by an injection-syringe through a gum-stopper. Composition of the products was generally constant, although the reaction was rapid in water solution and slow in other solutions. Some of these results are shown in Tables 1 (CN/Co=6.0) and 2 (CN/Co=5.0). The data in the tables are those of after 3 hr from the start of the reaction. We obtain the following results; 1) At CN/Co=5.0, *trans*-2-butene is the main product in all solvents. 2) At CN/Co=6.0, mole fraction of 1-butene decreases and that of 2-butene increases in the solvents in which *cis*-2-butene is produced selectively in the butadiene hydrogenation. 3) Two chlorides bring the same results in each solvent. From this result we should consider a common intermediate for the reaction of the two chlorides. 4) Yield of butadiene is generally very low and does not vary in the course of the reaction. This result is differs largely from that by Kwiatek and Seyler. 5) Yield of butenes is larger in H_2O than in other solvents at CN/Co=6.0, and *vice versa* at CN/Co=5.0.

We consider these results are important in the study on pentacyanocobaltate(II). The detailed mechanism of this reaction and the role of the solvent will be discussed later.

Aromatic Substitution of Olefins. XIV. Reaction of σ-Bonded Olefin-Palladium(II) Complexes with Benzene: Evidence for the Mechanism of the Aromatic Substitution of Olefins

Sadao DANNO

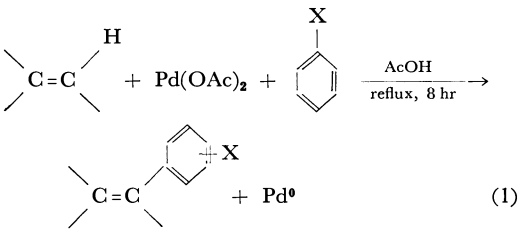
Polymer Research Laboratory, Ube Industries Ltd., Ichihara, Goi, Chiba

and Ichiro MORITANI, Yuzo FUJIWARA and Shiichiro TERANISHI

Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received August 18, 1970)

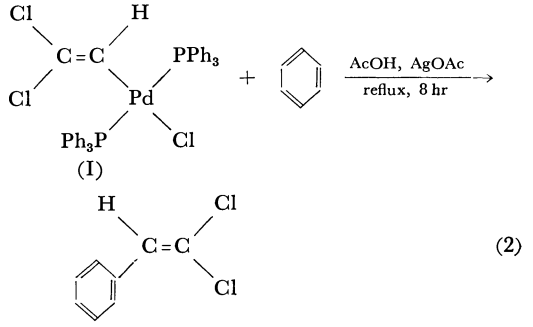
The substitution reaction of olefins is as follows:[1]



(1)

We have demonstrated that this is the general reaction occurring between common olefins and aromatics to produce aromatic-substituted olefins and that the reaction proceeds through a different mechanism from that of the Wacker process.[2]

The mechanism proposed involves σ-bonded olefin-palladium(II) intermediate.[3] In order to prove this mechanism, we have performed the reaction of a σ-bonded 2,2-dichlorovinyl-palladium(II) complex (I) with benzene. If the proposed mechanism is reasonable, the σ-bonded complex bearing a C=C double bond would react with benzene to produce an aryl-substituted olefin. The starting complex (I) was prepared by Fitton,[4] and the reaction was carried out using complex(I), benzene, acetic acid, and silver acetate under reflux for 8 hr. The silver acetate was introduced to abstract a chloride ligand from (I) to enable benzene to coordinate to palladium(II) metal.*1 From the reaction mixture, β,β-dichlorostyrene was obtained in a 7.4% yield based on complex(I) (equation 2).*2*3



(2)

Moreover, σ-bonded *cis*- and *trans*-2-chlorovinyl-palladium(II) complexes reacted with benzene to produce corresponding β-chlorostyrenes.

These results clearly show that the aromatic substitution of olefins proceeds *via* formation of a σ-bond between olefin and palladium(II) metal, and support the proposed mechanism.[3]

4) P. Fitton and J. E. McKeon, *Chem. Commun.*, **1968**, 4.

*1 As silver acetate alone cannot bring about the reaction, it is apparent that the reaction takes place by the action of palladium(II) of complex (I).

*2 That the σ-complex(I) is stable under the reaction condition without benzene was confirmed by a separate experiment.

*3 Note added in Proof. When the reaction time was 1.5 hr to present the polymerization of the styrene formed, the yield increased up to 80%.

Photochemical Interconversion between Norfriedelin and 5α-Vinyl-10β-formylmethyl-des-A-friedelane

Reiko AOYAGI, Takahiko TSUYUKI and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 24, 1970)

The photochemical reaction of aldehyde in the presence of olefin to saturated ketone has already been reported.[1,2] We now wish to describe a photochemical reaction of 5α-vinyl-10β-formylmethyl-des-A-friedelane (I) in *n*-hexane to yield norfriedelin (II)[3] (path A). This would be the first instance of the intramolecular ketone formation reaction of an olefinic aldehyde. As I was formed on irradiation of II in the same solvent (path C), it is noteworthy that the photochemical interconversion between I and II took place.

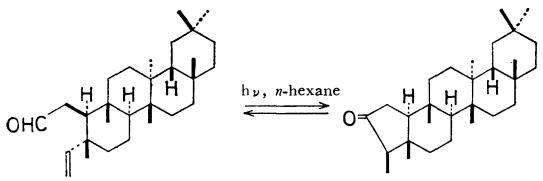

Fig. 1

Norfriedelin (II, 1.00 g) in *n*-hexane (700 m*l*) was irradiated with a high pressure mercury lamp for 50 hr. Dry column chromatography and recrystallization afforded I [223 mg, mp 162.5—163.5°C, IR (Nujol) 3075, 1625, 907 ($CH=CH_2$), 2700, 1715 cm^{-1} (CHO), NMR (in $CDCl_3$, δ; an internal standard: TMS) 9.70 ($-CH_2\underline{C}HO$, t, J=2—3 Hz), MW(mass) M^+ 412].

A solution of I, (35 mg) was heated under reflux with bubbling of argon for 1 hr. The solution was then irradiated with a high pressure mercury lamp at room temperature for 30 hr.

The solvent was distilled off and the reaction products were separated with silica gel dry column chromatography. Elution with petroleum ether–benzene (10 : 1) gave hydrocarbon mixture (~6 mg), and the starting material (13 mg) was then recovered.

Norfriedelin (II) was eluted with benzene and weighed about 2 mg. The IR spectrum ($\nu_{C=O}$ 1750 cm^{-1}), mass spectrum (M^+ 412) and R_f value on TLC were identical with those of the authentic sample. In gas chromatographic examination, however, two peaks appeared at t_R= 31.5 and 28.9 min in the case of Diasolid H-523 at 250°C and t_R=12.0 and 11.0 min in the case of OV-17 at 290°C. The peak with longer t_R was predominant and was shown to be due to norfriedelin (II) and the other due to 4-epinorfriedelin (II′). However, no isolation of II′ has yet been achieved.

Formation of norfriedelin (II) from the olefinic aldehyde (I) could be interpreted by the following mechanism (path A). Intermediate radical (III) may attack either C_4 or C_{23} carbon atom of the double bond, giving rise to IV or V, respectively. Radical (IV) is converted immediately to tertiary radical (VI) by migration of hydrogen atom at C_4 to C_{23}. As hydrogen must attack the resulting radical (VI) from both sides, norfriedelin (II) is accompanied with its 4α-methyl epimer (II′). A part of II′ could be also formed from photochemical isomerization of II. As no cyclohexane derivative was formed, the process leading to radical (V) (path B, or *via* IV) is considered unfavourable under the above conditions. These findings are in accord with the observation that cyclopentane formation is a kinetically favoured process for free radical cyclization.[4]

Photolyses of Aliphatic Ketones Adsorbed on Porous Vycor Glass

Yutaka KUBOKAWA, Masanori KUBO and Gohei NANJO

Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka

(Received August 26, 1970)

In contrast to extensive photochemical studies in gas phase and solution, few studies have been made on the photochemical reactions in the adsorbed layer. In the present work, photolyses of aliphatic ketones (acetone, methyl ethyl ketone and 2-pentanone) adsorbed on porous Vycor glass (Corning, No. 7930) have been investigated. After a certain amount of the vapor of ketone was allowed to be adsorbed, photolysis in the adsorbed layer was carried out at room temperature in the absence of ketone vapor. An ultra high pressure mercury lamp was used. After the photolysis, products which can be desorbed up to 100°C were analysed by gas chromatography. Prior to the experiments, the glass was oxidized in air at 600°C followed by outgassing at 500°C for 7 hr.

Photochemical reactivity of the ketones in the adsorbed layer was as follows: acetone, $R(CH_4) + R(C_2H_6)$, 0.05; methyl ethyl ketone, $R(C_2H_6)$, 1.00; 2-pentanone, $R(C_2H_4) + R(C_3H_8)$, 12.18. R(hydrocarbons)=[(Rate of formation of hydrocarbon, cc. S.T.P./hr)/(Amount of ketone adsorbed, cc. S.T.P.)] × 100. A marked difference can be seen in the reactivity of the three ketones. In contrast to the photolysis in gas phase the appearance of CO in the gas phase was negligible.[1] The results together with those in Table 1 show that in the adsorbed layer 2-pentanone undergoes the Norrish type I process ($CH_3COC_3H_7 \rightarrow CH_3CO + C_3H_7$) as well as the Norrish type II process ($CH_3COC_3H_7 \rightarrow CH_3COCH_3 + C_2H_4$). It is well-known that in gas phase and solution aliphatic ketones with γ hydrogen such as 2-pentanone undergo type II process predominantly at room temperature.[2] The results in Table 1 also show that with increasing outgassing temperature and after removal of acidic sites by nitric acid treatment,[3] $R(C_3H_8)$ decreases, while $R(C_2H_4)$ decreases little or remains unchanged. It can be concluded that the occurrence of type I process (formation of radicals) in the adsorbed layer becomes much easier on the surface with surface hydroxyl groups in a high concentration and also with acidic sites. The effect of the amount of 2-pentanone adsorbed on its photolysis was examined. As seen in Fig. 1, with the decrease of the amount adsorbed, values of $R(C_3H_8)/R(C_2H_4)$ as well as the rate of photolysis increased. Although the nature of such behavior is not clear at present, the results in Fig. 1 might be explained by assuming a heterogeneity of the glass surface.

Table 1. Photolysis of 2-pentanone adsorbed

Temp of outgassing, °C		500	800	800[a]
$R(C_3H_8)$	Type I	5.13	2.66	1.45
$R(C_2H_4)$	Type II	7.05	7.14	7.68

a) The glass was treated by nitric acid before outgassing at 800°C.

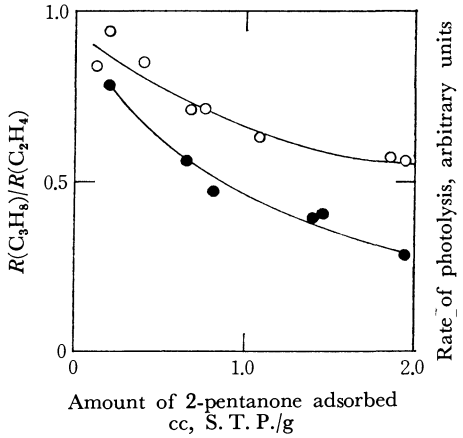

Fig. 1. Photolysis of 2-pentanone adsorbed, -○-, $R(C_3H_8)/R(C_2H_4)$; -●-, rate of photolysis.

1) In the case of 2-pentanone, both R(CO) and $R(CH_4)$ were below 0.2.

2) In the gas phase photolysis of 2-pentanone, no formation of C_3H_8 occurred at 23°C and 7.3 mmHg of 2-pentanone.

Conformational Analysis of Poly-γ-benzyl-glutamates by Monolayer Method

Takuya YAMASHITA and Shinsuke YAMASHITA

Department of Chemistry and Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received September 7, 1970)

It has been found that esters of polyglutamic acid and synthetic polypeptides with long hydrocarbon side-chains yield well defined transition points in force-area curves.[1-3] In the present communication, we wish to report the relation between the temperature coefficient of the monolayer transition pressure and the conformation of synthetic polypeptide in the solid state.

The polymers examined were L, DL-copolymers of γ-benzyl-glutamate (L/(D+L)=0.5—1.0). They consist of regular helix, perturbed helix and random coil, and were analyzed by means of infrared spectroscopy.[4,5] No β-components were detected. The polymers were dissolved in purified chloroform, and spread on the surface of twice-distilled water filled in a Teflon trough. The initial spreading area was 55 Å²/residue, and compressed at the rate of 0.2 Å²/residue/min. The surface pressure was measured by the Wilhelmy method at temperatures 10—20°C, where a linear relationship was obtained between the film transition pressure and temperature.

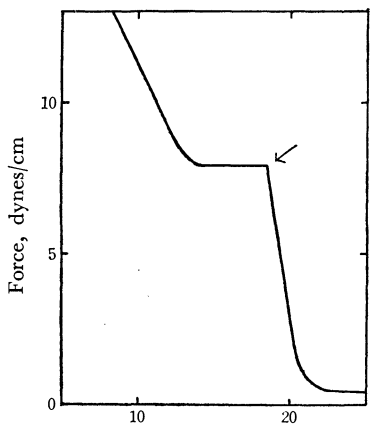

Fig. 1. Force-area curve for poly-γ-benzyl-DL-glutamate.
20°C; $[H_R]=38.5\%$

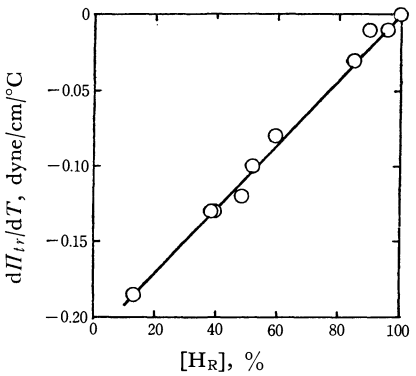

Fig. 2. Plot of $d\Pi_{tr}/dT$ *versus* $[H_R]$.

Figure 1 shows a typical force-area curve for poly-γ-benzyl-DL-glutamate, where a transition point can be seen. In Fig. 2 is shown the plot of temperature coefficient of the transition pressure $d\Pi_{tr}/dT$ *versus* percentage of regular helix $[H_R]$ for poly-γ-benzyl-glutamate monolayers. The value of $d\Pi_{tr}/dT$ is negative, and increases linearly with the increase in $[H_R]$. At 100% regular helix, $d\Pi_{tr}/dT$ is zero. The relation between $d\Pi_{tr}/dT$ and $[H_R]$ can be expressed in the form

$$\frac{d\Pi_{tr}}{dT} = -2.125 \times 10^{-1} + 2.125 \times 10^{-3}[H_R]$$

From this equation, we can estimate the content of regular helix in poly-γ-benzyl-glutamate by means of the monolayer method. Usually, the amount of polymer required to determine a transition pressure is small (less than 50 μg).

As regards the percent total helix (percent regular helix + percent perturbed helix), no simple linear relationship was found between the temperature coefficient and the percent total helix.

The present results appear to indicate that the regular helix is stable even in the monolayer state. Conformation of poly-γ-benzyl-glutamates at the interface will be discussed elsewhere.

Tetracyano-Bis(triphenylphosphine) and -Bis(triphenylarsine)-Cobaltate(III) Complexes

Nobufumi MAKI and Kanji OHSHIMA

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received September 8, 1970)

Previously, we concluded that the disulfito- and diaquo-tetracyanocobaltate(III) complexes take a *trans*-configuration on the evidence of their polarographic behavior and absorption spectra.[1]

The present communication is concerned with the method of preparing and confirming two kinds of tetracyanocobaltate(III) complexes involving triphenylphosphine or triphenylarsine, $Na[Co(CN)_4(P{\equiv}\phi_3)_2]\cdot 3H_2O$ and $Na[Co(CN)_4(As{\equiv}\phi_3)_2]\cdot 3H_2O$ (a new complex),*1 from the *trans*-disulfito complex. The former was ascertained to be quite identical with that prepared by the method of Watanabe *et al.*[2]

The disulfito complex, $Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O$[3] (9.38 g), was suspended in 300 m*l* of glacial acetic acid containing 10.0 g of triphenylphosphine and refluxed at 75—80°C for six hours with stirring. The disulfito complex gradually dissolved into acetic acid.

The slurry residue, which was insoluble in acetic acid, was filtered off if it was yielded in the final stage of the reaction. The yellow filtrate was then diluted to 1200 m*l* by adding water and allowed to stand overnight under ice-cooling. The desired complex crystallized from the solution; it was filtered and washed with water, benzene, and ether to eliminate any excess ligands. Recrystallizations were made from an ethanolic solution by adding water. Found: Co, 7.67; C, 62.94; N, 7.38; H, 4.83%. Calcd for $Na[Co(CN)_4(P{\equiv}\phi_3)_2]\cdot 3H_2O$: Co, 7.71; C, 62.83; N, 7.33; H, 4.75%.

Analogously, the $Na[Co(CN)_4(As{\equiv}\phi_3)_2]\cdot 3HO_2$ complex was prepared as orange-yellow crystals by treating 11.66 g of $Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O$ with 14.52 g of triphenylarsine in 600 m*l* of acetic acid (100%) at 75°C for ten hours. Found: Co, 6.88; C, 56.42; N, 6.61; H, 4.30%. Calcd for $Na[Co(CN)_4(As{\equiv}\phi_3)_2]\cdot 3H_2O$: Co, 6.91; C, 56.36; N, 6.57; H, 4.26%.

Figure 1 shows the absorption spectra of tetracyanocobaltate(III) complexes in the visible and ultraviolet regions.

All the aspects of the polarographic behavior of the tetracyano complexes derived from the disulfito complex are very similar to each other; this suggests that their configurations are all *trans*-form. Table 1 summarizes the electrode processes and their half-wave potentials.

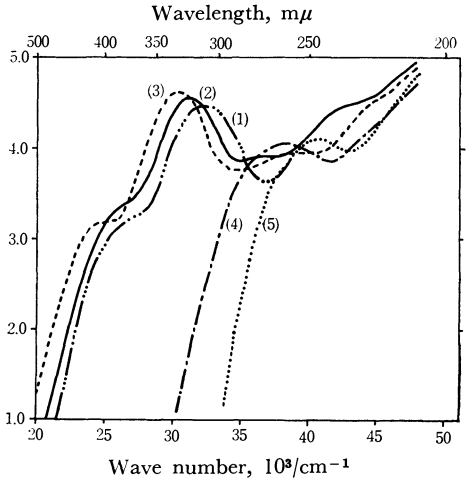

Fig. 1. The absorption spectra of the cobaltate-(III) complexes in methanol solutions (25°C). (1) ----- *trans*-$Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O$; (2) —— $Na[Co(CN)_4(P{\equiv}\phi_3)_2]\cdot 3H_2O$; (3) ---- $Na[Co(CN)_4(As{\equiv}\phi_3)_2]\cdot 3H_2O$; —·—· (4) $P{\equiv}\phi_3$ in ethanol; (5) ····· $As{\equiv}\phi_3$ in ethanol.

The Stereochemistry of Binuclear Complexes of Chromium(III)

Akio URUSHIYAMA, Teruo NOMURA and Masayoshi NAKAHARA

Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-ikebukuro, Toshima-ku, Tokyo

(Received September 19, 1970)

The normal rhodo chromic complex ion, $[(NH_3)_5Cr(OH)Cr(NH_3)_5]^{5+}$, and the basic rhodo complex ion, $[(NH_3)_5Cr(O)Cr(NH_3)_5]^{4+}$, have both been characterized in terms of their magnetic[1] and spectroscopic[2,3] behaviour, which is at least in part, to be ascribed to the Cr–O–Cr angles in the complex ions. In the present work, in order to establish the stereochemistry of binuclear Cr(III) complexes, the crystals of the rhodo compounds have been subjected to three-dimensional X-ray analysis.

Their crystal data are as follows: normal rhodo chromic chloride, $[(NH_3)_5Cr(OH)Cr(NH_3)_5]Cl_5 \cdot H_2O$-tetragonal, space group $P4_12_12$ (or $P4_32_12$), $a=16.26$, $c=14.80$ Å, $Z=8$, $D_m=1.65$, $D_x=1.65$ g·cm^{-3}; basic rhodo chromic chloride, $[(NH_3)_5Cr(O)Cr(NH_3)_5]Cl_4 \cdot H_2O$-orthorhombic, space group *Pbca*, $a=11.94$, $b=11.71$, $c=13.40$ Å, $Z=4$, $D_m=1.58$, $D_x=1.59$ g·cm^{-3}. Their structures have been solved by the heavy-atom method and refined to $R=0.16$ for the acid rhodo salt, and to $R=0.11$ for the basic rhodo salt, by least-squares analysis based on 1169 and 811 three-dimensional data respectively.

The structures of the complexes are shown in

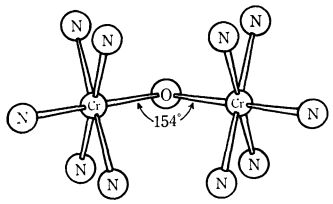

Fig. 1. Perspective drawing of the acid rhodo chromic complex ion, $[(NH_3)_5Cr(OH)Cr(NH_3)_5]^{5+}$.

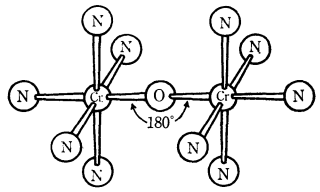

Fig. 2. Perspective drawing of the basic rhodo chromic complex ion, $[(NH_3)_5Cr(O)Cr(NH_3)_5]^{4+}$.

Figs. 1 and 2. In the normal rhodo chromic complex, a bridging oxygen atom is located on the two-fold rotation axis. Approximately, there are two mirror planes, perpendicular to one another, in the complex. Thus, the acid rhodo complex has a quasi-C_{2v} symmetry. The Cr–O–Cr bond angle is 154°. The coordination around the chromium atoms is approximately octahedral, with bond distances of Cr–O 2.00 Å and Cr–N 2.07 Å (average). In the basic rhodo chromic complex, a bridging oxygen atom is situated on the inversion center. Therefore, the complex exactly has a center of symmetry and, accordingly, a linear Cr–O–Cr system. As the complex has approximately a four-fold rotation axis passing through a sequence of the N–Cr–O–Cr–N atoms, it seems reasonable to say that the basic rhodo chromic complex has D_{4h} symmetry. The eight N–Cr–O angles are nearly 90°, and the Cr–N bond distance is 2.11 Å(average). The Cr–O distance is 1.80 Å, which is quite short compared with that in the acid rhodo chromic complex. The linear Cr–O–Cr system and its short bond distance suggest the presence of an extensive π-bonding in this system like that in similar oxo-bridged binuclear complexes, $K_4[Cl_5Ru–O–RuCl_5]$ (Ru–O= 1.86 Å)[4] and $K_4[Cl_5Re–O–ReCl_5]$ (Re–O= 1.80 Å)[5], both of which have been confirmed to be of D_{4h} symmetry by the X-ray method.

Schiff Base Oxovanadium(IV) Complexes with Subnormal Magnetic Moments

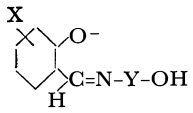
Yoshio KUGE* and Shoichiro YAMADA**

* *Public Health Institute, Morimachi, Higashi-ku, Osaka*

** *Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka*

(Received October 16, 1970)

It was reported previously that *N*-(hydroxyalkyl)-salicylideneimines (Formula I, abbreviated as X-SAL. Y-OH) formed magnetically subnormal copper(II) complexes, which were concluded to have a binuclear structure with exchange coupling between the two copper(II) ions.[1,2] Through the hole-formalism, the oxovanadium(IV) ion with a d^1 configuration is known to be somewhat similar to the copper(II) ion with a d^9 configuration. However, no report is available on the corresponding oxovanadium(IV) complexes. The present communication deals with preparation of new Schiff base complexes with oxovanadium(IV) having subnormal magnetic moments.



I

Oxovanadium(IV) complexes of the type VO (X-SAL. Y-O) were obtained as crystals by the following method. To an ethanolic solution of $VOCl_2$ (0.01 mol) was added the preformed Schiff base, *N*-(hydroxyalkyl)salicylideneimine (0.015 mol), and the resulting solution was stirred at room temperature for a few hours. Microcrystals, which deposited in the solution, were filtered off, and washed with ethanol several times.

Analytical data, which are shown in Table 1, agree with the formula given above. The magnetic moments for these complexes, as shown in Table 1, are much smaller than the spin-only moment for the d^1 system. The subnormal magnetic moments are considered to be due to an exchange interaction between vanadium(IV) ions. It is most likely that these oxovanadium(IV) complexes have a binuclear structure similar to that of the corresponding copper(II) complexes.[1-3] A similar binuclear structure was proposed previously for oxovanadium(IV) complexes with 5-substituted *N*-(2-hydroxyphenol)salicylideneimines, which were also reported to nave subnormal magnetic moments.[4,5] The electronic spectra of these complexes differ significantly from those of the complexes of the type VO(X-SAL. alkyl)$_2$, which involve no interaction between vanadium(IV) ions.

TABLE 1. ANALYTICAL DATA OF COMPLEXES OF THE TYPE VO(X-SAL. Y-O)

Syntheses and Stereochemistry of Optical Isomers of tris(2,4-Pentanediamine)cobalt(III) Complex

Fujio MIZUKAMI, Haruko ITO, Junnosuke FUJITA and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received October 20, 1970)

Tris(trimethylenediamine)-cobalt(III) ion has been found to have chair form chelates in its bromide crystal.[1] The conformation of 2,4-pentanediamine (ptn) metal chelate was studied by PMR spectra.

We have synthesized a diastereomeric pair of $[Co(R,R\text{-ptn})_3]^{3+}$ and an opticaly active $[Co(R,S\text{-ptn})_3]^{3+}$. Racemic and meso-ptn were prepared by the known method.[2,3] The $(-)_D$-ptn was assigned to R,R (D,D)-configuration.[3]

Perchlorate and chloride of *trans*-$[CoCl_2(ptn)_2]^+$ were synthesized with R,R- and R,S-ptn, respectively.[4] The former was warmed with R,R-ptn and activated charcoal to give orange diastereomeric mixture of $[Co(R,R\text{-ptn})_3](ClO_4)_3$. The filtered solution was cooled together with 60% perchloric acid, and the orange prismatic crystals were recrystallized from water. $(-)_{546}$-$[Co(R,R\text{-ptn})_3]\cdot(ClO_4)_3\cdot H_2O$: Found: C, 26.35; H, 6.51; N, 12.07%. Calcd for $CoC_{15}H_{44}N_6Cl_3O_{13}$: C, 26.42; H, 6.50; N, 12.33%.

trans-$[CoCl_2(R,R\text{-ptn})_2]ClO_4$ was converted into chloride, and warmed with R,R-ptn in 50% aqueous ethanol. The orange needles were recrystallized in a similar way. $(+)_{546}$-$[Co(R,R\text{-ptn})_3]Cl_3\cdot 2H_2O$: Found: C, 36.08; H, 9.09; N, 16.12%. Calcd for $CoC_{15}H_{46}N_6Cl_3O_2$: C, 35.47; H, 9.13; N, 16.55%.

trans-$[CoCl_2(R,S\text{-ptn})_2]Cl$ was warmed with R,S-ptn and activated charcoal. The filtered solution was treated with perchloric acid. The reddish orange product was recrystallized from water, resolved with silver *d*-tartrate and converted into needle-like perchlorate. $(-)_{546}$-$[Co(R,S\text{-ptn})_3](ClO_4)_3\cdot 3H_2O$: Found: C, 25.31; H, 6.30; N, 11.72%. Calcd for $CoC_{15}H_{48}N_6Cl_3O_{15}$: C, 25.10; H, 6.74; N, 11.71%. Both isomers of $[Co(R,R\text{-ptn})_3]^{3+}$ give a sharp doublet of methyl signal in its 60 MHz PMR spectrum in D_2O. This suggests that the complex has D_3 symmetry with twist-form six-membered chelate rings and the two methyls have equatorial orientation. On the other hand, the PMR spectrum of $[Co(R,S\text{-ptn})_3]^{3+}$ gives a broader methyl signal, which seems to be due to overlapped two signals. This complex can have two geometrical isomers with respect to the mer and fac coordination of the amino groups near R- and S-α-carbon. Study of molecular models disclosed that the stable chair form has the two methyls equatorial and only the fac isomer is formed without large steric hindrance. The apparent two kinds of methyl signal seem to be due to C_3 symmetry of this fac complex. From the CD sign in the first *d-d* transition region, the prismatic and the needlelike $[Co(R,R\text{-ptn})_3]^{3+}$ are tentatively assigned to absolute configurations *Λ* and *Δ*, respectively. $(-)_{546}$-$[Co(R,S\text{-ptn})_3]^{5+}$ seems to have absolute configuration *Λ*.

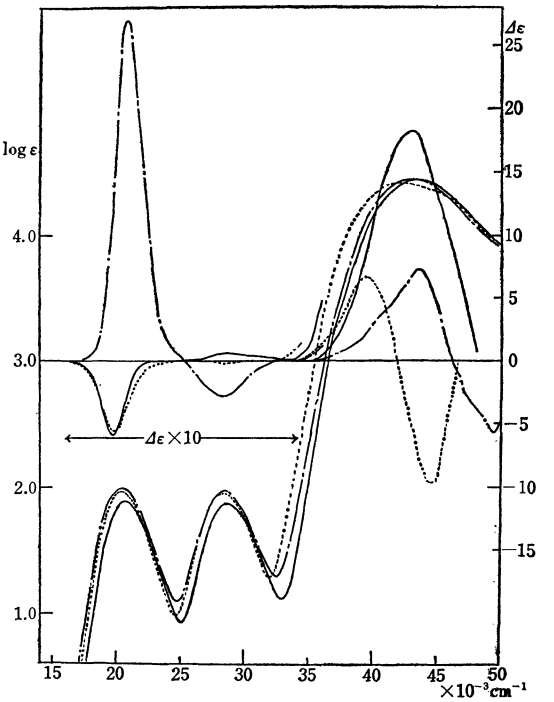

Fig. 1. Absorption and circular dichroism (CD) spectra of
Λ-$[Co(R,R\text{-ptn})_3]Cl_3\cdot 2H_2O$ (——),
Λ-$[Co(R,R\text{-ptn})_3](ClO_4)_3\cdot H_2O$ (——) and
Λ-$[Co(R,S\text{-ptn})_3](ClO_4)_3\cdot 3H_2O$ (- - - - -) in water.
