(Received April 2, 1970)

$[2(C_9NH^8)^+ \cdot (C_{10}N_6)^{2-}]$ crystallizes in the form of the space group of *Pbcn*, with four formula units in the unit cell, and the following unit-cell dimensions: $a=13.18$, $b=15.40$, and $c=11.56$ Å. The structure was determined by obtaining phases directly from the structure-factor magnitudes by means of the symbolic addition procedure. For 1580 non-zero reflections, the final R is 0.147. The crystal structure shows that the packing unit is an "ion-pair" consisting of one di-valent anion and two mono-valent cations. The anion is sandwiched by two cations with weak charge-transfer interaction between them; the closest atomic contact is 2.99 Å. These units stack infinitely, forming a column, along the a axis. Between these stacking columns, there exists a hydrogen bond (N–H···N, 2.84 Å) along the b axis. The $(C_{10}N_6)^{2-}$ anion has a C_2-2 symmetry; cyano-substituents are tilted out of the plane formed by four central carbon atoms, and the anion takes a propeller shape. The one arm is rotated 13° from the completely planar conformation, while the other two are rotated 24°. On the other hand, the $(C_9NH_8)^+$ cation seems not to be planar.

In the electronic spectra of some complexes, charge-transfer bands between organic cation and organic anion have been observed.[3] No studies have yet been reported, however, to explain the charge-transfer bands between organic cations and anions on the basis of the crystal structure.

The electronic spectra and the electrical and other physical properties of the salts of the 2-dicyanomethylene-1,1,3,3-tetracyanopropane anion and *N*-heteroaromatic cations have been studied by Sakanoue *et al.*[4] Among these substances is the quinolinium 2-dicyanomethylene-1,1,3,3-tetracyanopropanediide. The absorption maximum of this salt at 410 nm has been assumed, on the basis of the behavior of this band in solutions, to be due to the charge-transfer interaction between the anion and the cation. This band is also observed in the solid absorption spectrum in 415 nm; the polarized absorption spectrum of single crystals was measured.[4] In order to establish the relationship between the orientation of the ions in the crystal and the polarization behavior of the band, a single-crystal structure analysis of the salts was undertaken by means of X-rays; the preliminary results have already been reported.[5] Interest in the structure of the anion in this crystal also prompted the present study in relation to the structure of the anion in the calcium salt.[6]

Experimental

Yellow crystals were obtained from a saturated aqueous solution by slow evaporation at room temperature. A small, regular-shaped crystal (about $0.20\times0.22\times0.24$ mm) was selected.

Oscillation and Weissenberg X-ray photographs were taken, using nickel-filtered Cu$K\alpha$ radiation ($\lambda=1.5418$ Å), around the a and c axes. The unit-cell dimensions were determined from the Weissenberg photographs, on which powder diffraction patterns of tungsten ($a=3.16535$ Å) were superposed for calibration.

The crystals are orthorhombic, with the unit cell dimensions of $a=13.18$, $b=15.40$, and $c=11.56$ Å. The systematic absence of reflections, $0kl$ with $k\neq2n$, $h0l$ with $l\neq2n$, and $hk0$ with $h+k\neq2n$, uniquely determined the space group to be *Pbcn*. The density, measured at 14°C by flotation in a benzene-carbon tetrachloride mixture, was 1.318 g·cm^{-3}, whereas the calculated value, assuming four formula units, $[2(C_9NH_8)^+ \cdot (C_{10}N_6)^{2-}]$, per unit cell, was 1.314 g·cm^{-3}.

Using nickel-filtered Cu$K\alpha$ radiation, the intensity data were collected, by the multiple-film equi-inclination technique, for the layers from $0kl$ through $8kl$ and from $hk0$ through $hk8$.

The intensities were estimated visually, and were corrected for the Lorentz and polarization effects, but the absorption correction was ignored ($\mu=6.6$ cm^{-1} for Cu$K\alpha$). In all, 2003 independent (1580 non-zero) reflections were obtained.

Structure Determination

There were considerable difficulties in interpreting the sharpened and unsharpened Patterson maps computed from the three-dimensional data. The structure was established by obtaining phases directly from the structure-factor magnitudes by means of the symbolic addition procedure.[7]

The corrected intensity data were placed on an absolute scale, and both the structure-factor magnitude, $|F|$, and the normalized structure-factor magnitude, $|E|$, were computed (Table 1). Five reflections, with large $|E|$ magnitudes and also involving a large number of interactions in the $\sum_2$ relationship, were selected as a starting set. Positive signs were assigned to three linearly-independent reflections in order to specify the

origin of the unit cell, and letter phases, A and B, were assigned to the remaining two reflections in order to facilitate the symbolic addition procedure (Table 2).

As a first step, the signs of 11 reflections out of 98, ($|E| \geqq 2$), were determined by hand calculations. The determination was then carried out on a HITAC 5020E computer. After six cycles, the signs of 161 reflections were determined out of 247 reflections with $|E| \geqq 1.6$ (Table 3). From the interaction list, the signs of the two letter phases were assigned as: $A=-$ and $B=+$. The E-map based on these signs permitted the approximate location of atoms, although a number of ghost peaks were present (Fig. 1). The signs of 21 reflections out of 161 were found to be falsely determined at the end of the structure determination.

Successive Fourier syntheses led to be identification of all the non-hydrogen atoms. At this stage, the calculation of structure factors with a single temperature factor, B, of 3.0 Å^2 for all the non-hydrogen atoms gave a discrepancy factor, R, of 0.34. The positional and thermal parameters of each atom were then refined by the block-diagonal least-squares procedure. In the refinement, the weight was taken as unity for all the reflections, and the hydrogen atoms were not included. Five cycles of refinement improved the R factor to 0.196. Anisotropic thermal parameters were introduced at this stage. After 3 cycles the R value converged to 0.147 for the observed non-zero reflections (the hydrogen atoms were not included in the refinement). The final atomic coordinates, along with their estimated standard deviations, are listed in Table 4. The thermal parameters are shown in Table 5, while the observed and calculated structure factors are given in Table 6. A composite drawing of the final electron density distributions viewed down along the

The expression used is:

$$\exp\{-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+\beta_{12}hk+\beta_{13}hl+\beta_{23}kl)\}$$

a axis is shown in Fig. 2.

Calculations of the symbolic addition procedure were done with the SSGM program revised by one of the present authors (N.Y.). Almost all the calculations in this study were done on a HITAC 5020E computer at the University of Tokyo. The atomic scattering factors used in the calculations were taken from those given by Hanson and his co-workers.[8]

Description and Discussion of the Structure

Structure of the Anion and Cation. The skeleton of the ions, together with interatomic distances and angles, is illustrated in Fig. 3. The estimated standard deviations of the bond lengths and angles are about 0.015 Å and 1°, respectively.

The $(C_{10}N_6)^{2-}$ anion in this crystal has a C_2-2 symmetry instead of the C_3-3 (or approximately D_3-32) in hexahydrated calcium salt.[6] The four central carbon atoms are exactly coplanar (Table 7(a)). The three cyano-substituents, $-C(CN)_2$, are, however, tilted out of this plane; the anion takes a propeller shape. The one arm which lies on the 2-fold axis is rotated 13° from the completely planar conformation, while the

rest are 24° (Table 7(b)). In the calcium salt[6] all the tilt angles are reported to be 24°. Each bond distance and bond angle show an accordance, within the limits of error, with the corresponding distance of the same anion in the calcium salt,[6] except for the C(2)–C(1)–N bond angle, where the difference slightly exceeds three times the estimated standard deviation. The non-bonded N···N distances show a shortening due to the above-mentioned tilt of the cyano-substituents: the N(1)···N(2) distance is 3.32(2), and the N(3)···N(3′) distance, 3.38(2) Å, while 3.48 and 3.48 Å are the corresponding distances in the calcium salt.

C(16)–C(4)^{iv}	3.78(1)
C(16)–C(5)^{iv}	3.59(2)
C(17)–C(6)^{iv}	3.80(2)
C(13)–C(5)^{v}	3.74(1)

Key for superscripts:

i	$-x$,	y,	$1/2-z$
ii	$1/2-x$,	$1/2+y$,	z
iii	x,	$1-y$,	$1/2+z$
iv	$-1/2+x$,	$1/2-y$,	$1-z$
v	$1/2-x$,	$1/2-y$,	$-1/2+z$

From these facts, it may be concluded that the steric repulsions between cyano-groups in adjacent arms are considerably increased by the reduction of the tilt angle of the arm which lies on the 2-fold axis from 24° to 13°, while the π-overlap is increased a little, and that these effects may be due to weak interaction between the anion and the cation.

The quinolinium cation, $(C_9NH_8)^+$, was expected to be planar, but an intersting tendency is observed for the C(11), C(12), and C(13) atoms to deviate slightly toward the anion from the least-squares plane (Table 7(a)). Of these deviated atoms, C(11) makes close contact with N(1) and C(1), which belong to the arm of the anion having the smallest tilt angle. C(13) is also located close to C(6), C(4), and N(3) of a different arm of the anion (Table 8).

Crystal Structure. The crystal structure viewed down the *a* and *b* axes is shown in Fig. 4. The packing unit of the crystal is an ion pair consisting of one di-valent anion and two mono-valent cations, and the anion lies on a crystallographic 2-fold axis between two cations forming a sandwich structure. The tilt angle of the plane of the cation to the *a* axis is about 60°. The N(1)–N(11) distance is 2.99(1) Å (Fig. 5), which is the closest atomic contact between ions in this unit. These sandwiched units stack infinitely, forming a column, along the *a* axis (Fig. 4(b)). The polarized absorption spectra of a single crystal of this

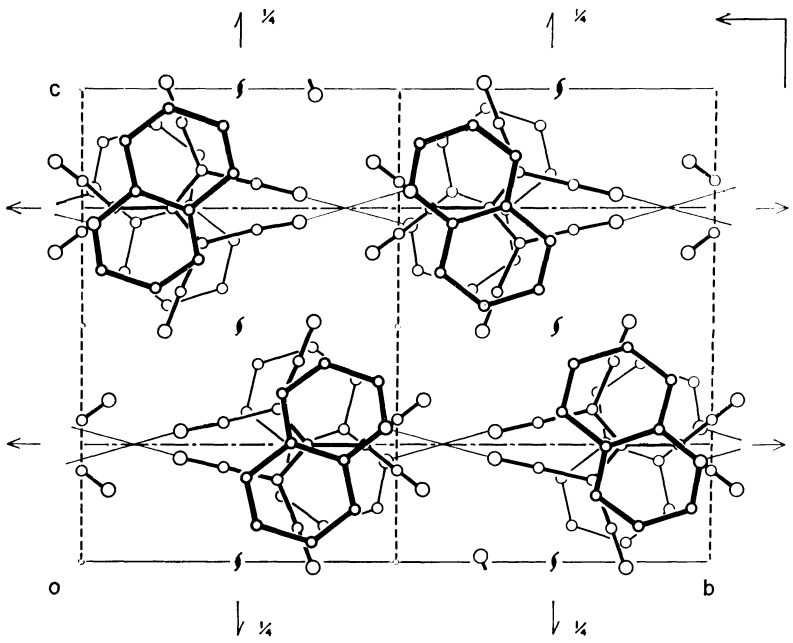

Fig. 4(a). Crystal stustructure viewed down along the *a* axis. Hydrogen bondings are shown by thin solid lines.

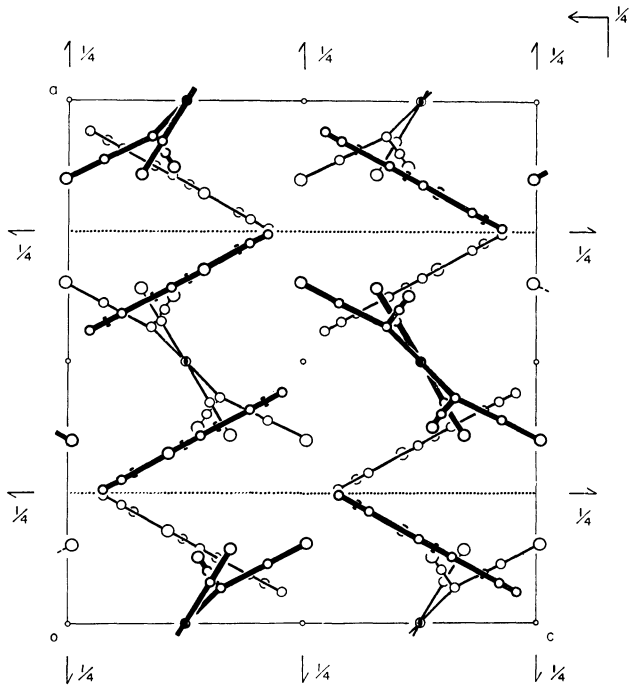

Fig. 4(b). Crystal structure viewed down along the *b* axis.

complex was measured.[4] The optical density of the charge-transfer band at 415 nm is much higher in the *a*-polarization spectrum than in the *c*-polarization spectrum. This result can be explained well in terms of the crystal structure (see Fig. 4(b)) as being due to the charge-transfer phenomenon between ions within the ion pair.

In the contacts between these stacks, the hydrogen bond exists along the *b* axis between the N(3) atom of one unit and the N(11) of the other unit, and the distance is 2.84(1) Å. Some close inter-ionic atomic contacts, including the hydrogen bond, are shown in Table 9.

The authors wish to express their deep thanks to Professor Hiroshi Mikawa for his kindness of supplying crystals and for his helpful discussions.

Polarized Absorption Spectra of Single Crystals of Ion Radical Salts. II. K(TCNQ) and $Cs_2(TCNQ)_3$

Shoji HIROMA, Haruo KURODA, and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 2, 1970)

Polarized absorption spectra in the 10—40 kK region were observed on single crystals of the ion radical salts of tetracyano-*p*-quinodimethane (TCNQ), potassium·(TCNQ) and cesium$_2$·(TCNQ)$_3$. The crystal spectra are shown to be markedly different from the solution spectra of the monomer and dimer of TCNQ ion. It is shown that the 7.8 kK band of K(TCNQ) and the 11.1 kK band of $Cs_2(TCNQ)_3$ are charge-transfer bands associated with the transfer of an electron from a $TCNQ^-$ ion to the neighboring $TCNQ^-$ ion. The first-order and second-order effects were calculated on the local-excitation bands in order to explain the general feature of the observed spectra.

In a previous paper,[1] we reported the polarized absorption spectra of ionic solids composed of the radical anion of 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) and the radical cation of a π-electron donor such as *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD). We showed that the crystal spectra are composed of the local-excitation (LE) bands associated with the transition of each component ion, and the charge-transfer (CT) band associated with the transfer of an electron from an anion to the adjacent cation. In these crystals, the cation and anion are stacked face-to-face on each other to form a molecular column developed along one of the crystal axes, and there is a relatively strong charge-transfer interaction between them. There is another kind of TCNQ salt, composed of the TCNQ radical anion and a closed-shell cation, in which the closely packed molecular column is formed by the stacking of the TCNQ anion, not by the alternate stacking of the anion and cation. In this case, the charge-transfer interaction is expected to occur primarily between the neighboring TCNQ anions, which should have bearing on the electrical and magnetical properties of the TCNQ salts.

Recently, the absorption spectra of the crystalline powder obtained by use of the diffuse reflection method have been reported by Iida[2] on several TCNQ salts of this kind. He described some characteristic features distinguishing the spectra of the TCNQ salts of high electrical conductivity from those of the TCNQ salts of low conductivity, and pointed out that the latter resembles in several respects the absorption spectrum of the TCNQ ion dimer. However, care should be taken in comparing the crystal spectra with the spectrum of the ion dimer, since, in the crystal, the interaction by the TCNQ ions other than the nearest-neighbor ones might influence the absorption spectrum.

In the present study, we have observed the polarized absorption spectra of single crystals of two TCNQ salts, K(TCNQ) and $Cs_2(TCNQ)_3$, and carried out some theoretical considerations on the exciton states in these salts.

Experimental

We measured the polarized absorption spectra of the 9—40 kK region at room temperature by using single crystals of microscopic size with an apparatus modified from a commercial microspectrophotometer, Olympus MSP-A-IV. The details of the appratus have been described elsewhere.[3]

The TCNQ salts were prepared according to the procedures reported by Melby *et al.*[4] We recrystallized the powders of the salts to obtain very small single crystals suitable for the measurement of spectrum. The recrystallized powder occacionally contains a small amount of the crystal of free TCNQ, but is easily distinguishable from salt crystals by the crystal habits and optical properties.

We observed also the absorption spectrum of crystalline powder by means of the liquid-paraffin-mull method. The spectra thus obtained were used only for the purpose of examining the location of an absorption maximum in the low energy part outside the applicable region of our microspectrophotometer.

Experimental Results

(1) Spectrum of K(TCNQ). A preliminary analysis of crystal structure has been done by Anderson

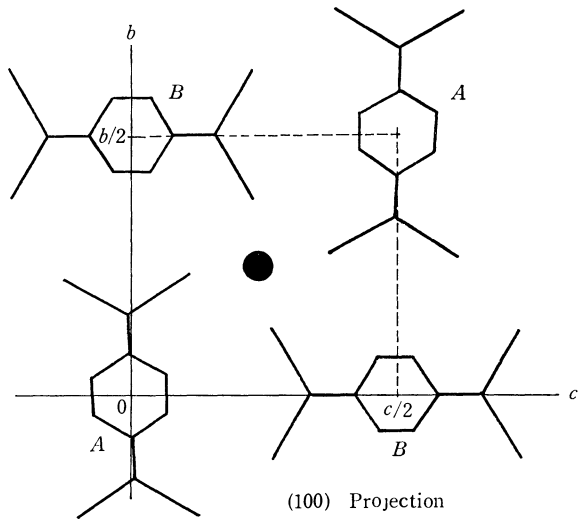

Fig. 1. Model of the crystal structure of K(TCNQ), after Anderson *et al*: ● indicates K^+ ion. $TCNQ^-$ are stacked along the *a*-axis. Two different groups of $TCNQ^-$ sites are indicated as *A* and *B*.

and Fritchie,[5] who reported that the K(TCNQ) crystal is monoclinic of $P2_1/n$ space group, with the lattice constants; $a=7.10$ Å, $b=18.80$ Å, $c=17.88$ Å and $\beta=94°54'$. The unit cell contains eight formula units. Of the eight TCNQ ions, four are mutually transferable by the symmetry operation of $P2_1/n$ space group, and the other four are mutually transferable among themselves. We shall call the former TCNQ sites *A*-site, and the latter *B*-site (see Fig. 1).

We observed the *a*- and *b*-axis polarized spectra from the direction normal to the developed face (001). The spectra are shown in Fig. 2, and the wave number of peak and the polarization ratio are given in Table 1.

30.8	30.8	0.33

For the sake of comparison, the absorption spectrum of the acetonitrile solution of K(TCNQ) and the spectrum of the dimer of TCNQ anion formed in aqueous solution are shown in Fig. 3. It should be noted that the crystal spectra differ markedly from the spectra of both the monomer and the dimer. The former are extended into a lower-energy region well outside the absorption limit of the latter, while the absorption bands of the crystal in the visible and ultraviolet region are located at appreciably higher energy in comparison with the monomer and dimer. A marked difference is also found in the band shape.

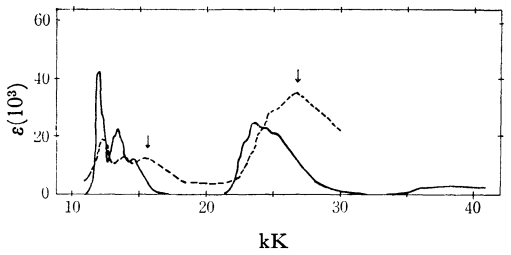

Fig. 3. Solution absorption spectrum of K(TCNQ): ——monomer in acetonitrile, ---- dimer in water (The absorption peaks of the dimer band are indicated by arrows.).

From the spectrum of the powder, we found that the absorption maximum of the low-energy band is located at about 7.8 kK. The polarization ratio, I_a/I_b, is 2.5 at 10 kK, and increases with the decrease of wave number. Thus we can consider that the 7.8 kK band is strongly polarized in the *a*-axis direction, along which $TCNQ^-$ ions are stacked face-to-face on each other. The polarization indicates that the 7.8 kK band is an absorption band associated with the charge-transfer (CT) between $TCNQ^-$ ions. Polarization is quite different in the case of the absorption bands found in the 15—40 kK region. It seems most reasonable to assign them to ones mainly associated with the transition of $TCNQ^-$ ion, which we will call the local-excitation (LE) bands. The bands in the 15—20 kK region appear to be due to the lowest transition of $TCNQ^-$ ion, and those in the 25—35 kK region to the second one.

However, for making a definite interpretation of the observed results, we need to make a theoretical consideration as regards the energy of the CT band, and the crystal shift and factor group splitting of each LE band. This will be discussed in the later part of this paper.

(2) Spectrum of $Cs_2(TCNQ)_3$. In this salt, formally, two electrons are shared among three molecules of TCNQ. The crystal structure has been determined by Fritchie and Arther.[6] According to them, the crystal is monoclinic belonging to $P2_1/c$ space group, with the lattice constants; $a=7.34$ Å, $b=10.40$ Å, $c=21.98$ Å, and $\beta=97.18°$. Two formula units are contained in a unit cell. The projection of the crystal structure from the direction normal to the (001) plane is schematically shown in Fig. 4. It has been concluded from the observed bond lengths that the TCNQ site at the center of symmetry is occupied by a neutral molecule, and is sandwiched by two TCNQ ions

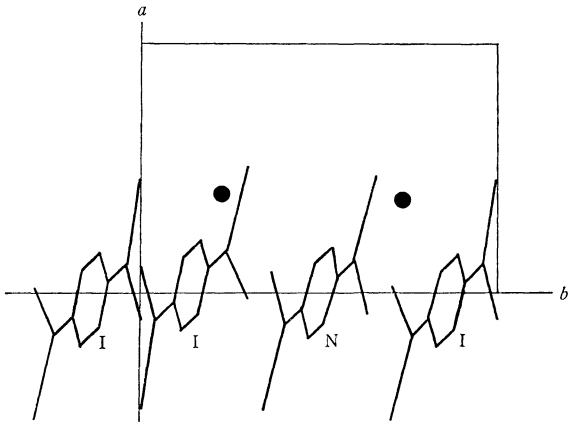

Fig. 4. Stacking of TCNQ ions and molecules in the $Cs_2(TCNQ)_3$ Crystal. (I: ion, N: neutral, ●: Cs)

mutually transferable by the inversion operation.[6]

We observed the *a*-axis and *b*-axis spectra on the (001) plane. The observed spectra are shown in Fig. 5, and the wave numbers and polarization ratios of absorption bands are listed in Table 2.

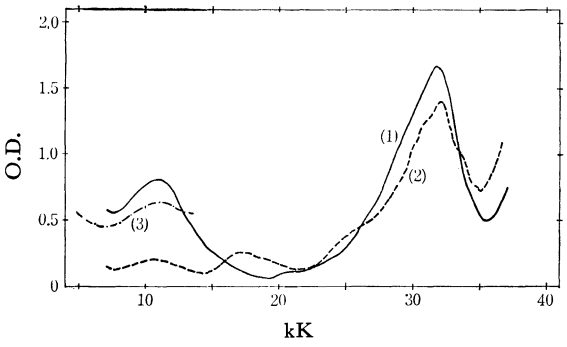

Fig. 5. Crystal absorption spectra of $Cs_2(TCNQ)_3$: (1) *b*-spectrum, (2) *a*-spectrum, (3) spectrum of powder sample.

Table 2. Wave numbers of the absorption peaks and polarization ratios of crystal spectra of $Cs_2(TCNQ)_3$ (wave numbers in kK)

$\tilde{\nu}_a$	$\tilde{\nu}_b$	I_a/I_b
11.1	11.1	0.25
17.3	~21.5	~2.1
25.0	—	*a*-axis polarized
32.3	31.9	0.84

The 11 kK band is strongly polarized in the *a*-axis direction, and other bands exhibit a different polarization. This suggests that the 11 kK band is the CT band whereas others are the LE bands associated either with the transitions of $TCNQ^-$ ion or with those of TCNQ° molecule. However, the relative intensities of the LE bands are markedly different from the ones expected from the oscillator strengths of transitions of the free component according to the oriented-gas model (Table 4). It should be noted also that the crystal spectra exhibit no strong absorption band at the wavelength corresponding to the second absorption band of $TCNQ^-$ ion and the first band of TCNQ° molecule, both of which are at about 25 kK in the solution spectra. Instead, we found one strong absorption band at about 32 kK in the *a*-axis spectrum as well as in the *b*-axis spectrum.

The large difference between the crystal spectra and the spectra of the components makes it hard to give any simple interpretation of the observed spectra. Thus it is particularly interesting in this case to estimate the crystal shift, factor group splitting, and crystal induced mixing.

The absorption spectrum of the crystalline powder shows that there is no absorption maximum from 5 kK to 10 kK, but the absorption increases with the decrease of wave number in the region below 7 kK, suggesting the presence of another low-energy absorption band. This seems to be associated with the charge transfer between an ion and a molecule of TCNQ.

Discussions

(1) Transitions of the Molecule and Anion of TCNQ. Before discussing the exciton states of salt crystals, we will first consider the transitions of TCNQ molecule and its anion. Although their π-electron states have been theoretically studied by Lowitz[7] by means of the semiempirical self-consistent-field molecular orbital (SCF-MO) method, his results are not satisfactory for the analysis of crystal spectra. Recently, the SCF-MO calculation has been carried out in our laboratory on the molecule and anion of TCNQ using the variable-β,γ modification[8] of Pariser-Parr-Pople method carefully choosing semiempirical parameters.[9] Two different procedures were used: [Method I], all β terms are included and are estimated by using Katagiri-Sandorfy's formula[10] for β; [Method II], only the nearest-neighbor β terms are included, which are estimated by using Nishimoto-Forster's formula.[8] In both cases, the configuration interaction (CI) calculation was carried out by taking into account the lower forty singly-excited configurations. The Longuet-Higgins and Pople method[11] was applied in the case of the anion.

The singlet-singlet transitions of TCNQ predicted by this calculation are shown in Fig. 6, together with the observed results. We find that the theoretical predictions are in satisfactory agreement with the observations. Thus the first and second transitions of TCNQ are assigned to $^1B_{1u}\leftarrow{}^1A_{1g}$ (*long-axis* polarized) and $^1B_{2u}\leftarrow{}^1A_{1g}$ (*short-axis* polarized), respectively. In the case of the anion, the agreement with the observation is found to be better in Method I than in Method II, as seen in Fig. 7.

We can safely assign the first absorption band of the anion observed at 12.0 kK to $^2B_{3u}\leftarrow{}^2B_{2g}$ (*long-axis* polarized) predicted at 9.8 kK by Method I and at 11.2 kK by Method II. According to the calculation, the second absorption band should be considered to be the superposition of two transitions, $^2A_u\leftarrow{}^2B_{2g}$ (*short-axis* polarized) and $^2B_{3u}\leftarrow{}^2B_{2g}$ (*long-axis* polarized). The band shape suggests that this absorption band is composed of a weak component (23.5 kK) and a strong component (25.4 kK). We will assign the former to $^2A_u\leftarrow{}^2B_{2g'}$ and the latter to $^2B_{3u}\leftarrow{}^2B_{2g}$. The next absorption band is probably due to $^2A_u\leftarrow{}^2B_{2g}$ although there is a large discrepancy between the predicted and observed energies. In the later part, we will denote the 12.0, 23.5, 25.4, and 35.7 kK transitions respectively as R, S, U, and S'.

(2) Charge Transfer between TCNQ Anions. In the TCNQ salts studied here, the overlap of the π-orbitals between $TCNQ^-$ ions stacked on each other is large enough to give a fairly strong CT band. The energy

for transferring one electron from a $TCNQ^-$ ion to the neighboring $TCNQ^-$ ion to form a pair consisting of TCNQ° and $TCNQ^{2-}$ can be given by

$$\Delta E_{CT} = I - A - C \qquad (1)$$

where I and A are respectively the ionization potential and electron affinity of the $TCNQ^-$ ion, and C the Coulomb energy term. As can be easily seen, the difference, $I-A$, must be equal to the energy of the repulsion between the two electrons in the highest occupied orbital of the $TCNQ^{2-}$, which can be estimated from the molecular orbital by using the semiempirical values of the one-center and two-center repulsion integrals.[12] We obtained 3.9 eV for $I-A$. By considering the energy cycle of the charge-transfer process, we can show that the term C is approximately equal to the repulsion between the two $TCNQ^-$ ions in question. We estimated it by using the charge distribution obtained from the calculated molecular orbitals of $TCNQ^-$, and obtained the value of 3.0 eV for $Cs_2(TCNQ)_3$. It is almost the same also for K(TCNQ). Thus ΔE_{CT} is predicted to be 0.9 eV. We can therefore, expect the CT band to appear at about 7.2 kK. This is in agreement with the observed location of the CT band of K(TCNQ). In the case of $Cs_2(TCNQ)_3$, a CT band is found at 11 kK, which is considerably large as compared with the predicted values. It should be noted, however, that the actual location of the CT band will naturally be affected by the interactions with other CT states as well as by those with LE states.

In the crystal of $Cs_2(TCNQ)_3$, there can be another type of CT band, namely that associated with the transfer of an electron from $TCNQ^-$ to the adjacent TCNQ°. In this case, the value of $(I-A)$ in Eq. (1) becomes zero, and the term C must be very small. Therefore, this CT band should appear at a lower wave number, possibly in the infrared region. We will attribute the absorption below 5 kK to this CT band. A similar low-energy CT band can be expected to appear generally in the case of TCNQ salts which contain a neutral TCNQ molecule.

(3) Local Excitation Bands. Since the LE bands of the crystal spectra are markedly different from the

12) We have taken here the values of one-center repulsion integral, $\gamma_{\mu\mu}$, as 11.13, 10.09 and 11.52 respectively for carbon in the aromatic ring and carbon and nitrogen in C≡N group. The two-center repulsion integral $\gamma_{\mu\nu}$ was estimated by using the Nishimoto-Mataga method, *viz.*,

$$\gamma_{\mu\nu} = \frac{14.3897}{a_{\mu\nu} + R_{\mu\nu}}, \quad a_{\mu\nu} = 2\frac{14.3897}{\gamma_{\mu\mu} + \gamma_{\nu\nu}}$$

spectra of the free components, we will estimate the crystal shift and splitting of the LE bands by the calculation method within the usual approximation of the exciton theory of molecular crystal.[13,14] We will describe the zero-th order wavefunction of an exciton state, associated with the fth excited state of $TCNQ^-$ ion by the following equation neglecting the part associated with other components.

$$\Phi_r^f = \frac{1}{\sqrt{Nh}} \sum_{m=1}^{N} \sum_{\alpha=1}^{h} B_\alpha^r \psi_{m\alpha}^f \tag{2}$$

herewith

$$\psi_{m\alpha}^f = \phi_{m\alpha}^f \prod_{n\beta \neq m\alpha}{}' \phi_{n\beta}^\circ$$

where $\phi_{m\alpha}^f$ and $\phi_{m\alpha}^\circ$ are the wavefunctions of the fth excited state and the ground state of the $TCNQ^-$ ion at the αth site of the mth unit cell, respectively and B_α^r is the numerical factor characteristic of the rth representation of the symmetry group of the crystal.

In the first order approximation, the exciton level relative to the ground state is given as

$$\Delta E_r^f = \varepsilon^f + D^f + \sum_{n\beta \neq m\alpha} B_\alpha^r B_\beta^r I_{m\alpha,n\beta}^f \tag{3}$$

where ε^f is the transition energy of the free ion (or molecule), and D^f, $I_{m\alpha,n\beta}^f$ are defined as follows:

$$D^f = \sum_{n\beta \neq m\alpha} \{\langle \phi_{m\alpha}^f \phi_{n\beta}^\circ | V | \phi_{m\alpha}^f \phi_{n\beta}^\circ \rangle - \langle \phi_{m\alpha}^\circ \phi_{n\beta}^\circ | V | \phi_{m\alpha}^\circ \phi_{n\beta}^\circ \rangle\} \tag{4}$$

$$I_{m\alpha,n\beta}^f = \langle \phi_{m\alpha}^f \phi_{n\beta}^\circ | V | \phi_{m\alpha}^\circ \phi_{n\beta}^f \rangle \tag{5}$$

V being the perturbing potential due to the intermolecular interaction. The off-diagonal matrix element of the second-order calculation is given as

$$H_r^{fg} = \Delta^{fg} + \sum_{n\beta \neq m\alpha} B_\alpha^r B_\beta^r \Gamma_{m\alpha,n\beta}^{fg} \tag{6}$$

where

$$\Delta^{fg} = \sum_{n\beta} \langle \phi_{m\alpha}^f \phi_{n\beta}^\circ | V | \phi_{m\alpha}^g \phi_{n\beta}^\circ \rangle \tag{7}$$

$$\Gamma_{m\alpha,n\beta}^{fg} = \frac{1}{2} \left\{ \langle \phi_{m\alpha}^f \phi_{n\beta}^\circ | V | \phi_{m\alpha}^\circ \phi_{n\beta}^g \rangle + \langle \phi_{m\alpha}^g \phi_{n\beta}^\circ | V | \phi_{m\alpha}^\circ \phi_{n\beta}^f \rangle \right\} \tag{8}$$

Although the equations described above are the same as ones usually given in the exciton theory of molecular crystal, we have to take into account several aspects characteristic of the TCNQ salts in carrying out the numerical calculation. First, we should note that it is the electrostatic interaction between ions that gives the largest contribution to D^f, and, second, we are not allowed to use the dipole-dipole approximation for evaluating $I_{m\alpha,n\beta}^f$ and $\Gamma_{m\alpha,n\beta}^{fg}$ when two TCNQ ions or molecules are in direct contact with each other.

We estimated D^f by the following formula taking the point charge approximation.

$$D^f = \sum_\mu \sum_q \sum_\nu (\rho_{p\mu}^f \rho_{q\nu}^\circ - \rho_{p\mu}^\circ \rho_{q\nu}^\circ)(e^2/R_{p\mu,q\nu}) \tag{9}$$

where $\rho_{p\mu}^f$ and $\rho_{p\mu}^\circ$ are the charge density at the μth atom of the pth ion in the fth excited state and the ground state, respectively, and the summation over q is to include also the cations. We used the charge density of an atom in the $TCNQ^-$ ion estimated from the molecular orbitals. In the evaluation of $I_{m\alpha,n\beta}^f$ we used the following equation when the distance between the $m\alpha$ and $n\beta$ sites was within 10 Å, but used the dipole-dipole approximation when the distance was larger than 10 Å.

$$I_{p,q}^f = a_{i,j}^2 \sum_\mu \sum_\nu c_{i\mu} c_{j\mu} c_{i\nu} c_{j\nu} (e^2/R_{p\mu,q\nu}) \tag{10}$$

we have assumed here that the fth excited state is associated with the excitation of an electron from the ith molecular orbital to the jth molecular orbital; $a_{i,j}$ is the numerial factor equal to 1 or $\sqrt{2}$ depending on the type of orbitals concerned, and $c_{i\mu}$ is the coefficient in the ith molecular orbital. Similarly, when the gth excited state is associated with the excitation from the kth orbital to the lth orbital, $\Gamma_{m\alpha,n\beta}^{fg}$ was evaluated by the following equation for a distance up to 10 Å, and by the dipole-dipole approximation for a larger distance.

$$\Gamma_{p,q}^{fg} = a_{ij} a_{kl} \sum_\mu \sum_\nu c_{i\mu} c_{j\mu} c_{k\nu} c_{l\nu} (e^2/R_{p\mu,q\nu}) \tag{11}$$

The Δ^{fg} term is negligible unless $i=k$ or $j=l$. If $i=k$, it can be estimated by

$$\Delta^{fg} = b_{ij,k} \sum_\mu \sum_q \sum_\nu \rho_{p\mu}^{ij} \rho_{q\nu}^\circ (e^2/R_{p\mu,q\nu}) \tag{12}$$

where $b_{ij,k}$ is a numerical factor characteristic of the types of orbitals with respect to the fth and gth excitation, $\rho_{p\mu}^{ij}$ is a quantity defined as $\rho_{p\mu}^{ij} = c_{i\mu} c_{j\mu}$, and the summation over q is to include the cations.

(a) K(TCNQ): When we label the $TCNQ^-$ ions at A-sites as 1, 1′, 2, and 2′ so that 1 and 1′, or 2 and 2′ are in direct contact with each other, and the $TCNQ^-$ ions at B-sites as 3, 3′, 4, and 4′ in a similar way, the zero-th order wavefunctions are described as follows:

$$\Phi_A^\pm = \frac{1}{\sqrt{4N}} \sum_{m=1}^{N} \{(\psi_{m1} - \psi_{m1'}) \pm (\psi_{m2} - \psi_{m2'})\} \tag{13}$$

$$\Phi_B^\pm = \frac{1}{\sqrt{4N}} \sum_{m=1}^{N} \{(\psi_{m3} - \psi_{m3'}) \pm (\psi_{m4} - \psi_{m4'})\} \tag{14}$$

Φ_A^+ and Φ_B^+ belong to A_u representation, and Φ_A^- and Φ_B^- belong to B_u representation of C_{2h} symmetry group. Since the exact atomic coordinates were not reported by Anderson and Fritchie,[5] we carried out numerical calculation using the approximate coordinates we estimated from the data given in their report.

The exciton levels predicted by the second-order calculations are summarized in Table 3. Each transition of $TCNQ^-$ ion gives four exciton levels, two A_u and two B_u states. Each of them is associated mainly with either one of the wavefunctions given by Eqs. (13) and (14). We will denote the levels associated with

13) A. S. Davydov, "Theory of Molecular Excitons," McGraw-Hill, New York (1962).

14) D. P. Craig and S. H. Walmsley, "Physics and Chemistry of the Organic Solid State," Vol. 1, ed. by M. M. Labes, D. Fox, and A. Weissberger, Wiley, New York (1963), p. 585.

15) The same formula can be used for the exciton state associated with the TCNQ molecule in $Cs_2(TCNQ)_3$, if we replace $\phi_{m\alpha}^f$, $\phi_{m\alpha}^\circ$ with the corresponding wavefunction of the molecule.

Φ_A^+, Φ_A^-, Φ_B^+, and Φ_B^- as $A_u(A)$, $B_u(A)$, $A_u(B)$, and $B_u(B)$, respectively. It should be noted that the energies are almost equal between the $A_u(A)$ and $B_u(B)$ states and between the $B_u(A)$ and $A_u(B)$ states. This means that there will be little difference between the *b*-axis and *a*-axis spectra as regards the locations of LE bands. This is in agreement with the observation except for the difference between the $A_u(A)$ and $B_u(B)$ components of the R-band. The observed shifts of the transitions of $TCNQ^-$ ion are also well predicted by the present calculation.

TABLE 3. EXCITON LEVELS OF K(TCNQ) CRYSTAL PREDICTED BY THE SECOND ORDER CALCULATION[a)]
(in kK)

Band	Solution (obs.)	$A_u(\Psi_A)$	$A_u(\Psi_B)$	$B_u(\Psi_A)$	$B_u(\Psi_B)$
R	12.0	14.98	15.59	15.61	15.00
S	23.5	23.88	24.22	24.23	23.87
U	25.4	28.16	29.70	29.70	28.28
S′	35.7	36.01	35.84	35.84	36.04

a) A_u: *b*-axis polarized component.
B_u: *a*-axis polarized component.

A considerable discrepancy is found between prediction and observation in the case of the R-band. In the *b*-axis spectrum, we find peaks at 15.0 and 17.3 kK, which should correspond to the $A_u(A)$ and $B_u(B)$ components of the R-band predicted respectively at 15.0 and 15.6 kK. The 17.3 kK peak can be found also in the *a*-axis spectrum, but a peak does not appear at 15.0 kK. Instead, it is found at 12.5 kK. The wave number difference between this peak and the 17.3 kK one is very much larger than the predicted splitting between the $B_u(B)$ and $B_u(A)$ components of the R-band, the latter value being only 0.6 kK. However, it is difficult to find the origin of this peak other than the $B_u(B)$ component of the R-band. We can not attribute it to the second CT band, because the energy difference between the half-filled molecular orbital and the next filled orbital exceeds 2 eV, so that the second CT band is expected to appear at about 24 kK. Therefore, we will tentatively assign the 12.5 kK band to the $B_u(B)$ component of R-band. This discrepancy between prediction and observation could be associated with the interaction between the CT and LE exciton states.

(b) $Cs_2(TCNQ)_3$: As already mentioned, the unit cell contains four sites of $TCNQ^-$ ion and two sites of TCNQ° molecule. We will label the former sites 1, 1′, 2, and 2′, and the latter 3 and 4, so that the ions at sites 1 and 1′ are mutually transferable by inversion with respect to site 3. The zero-th order wave functions of the optically allowed states are then described as follows. For the exciton states associated with $TCNQ^-$ ion, we have

$$\Phi_{\mathrm{I}}^{\pm} = \frac{1}{\sqrt{4N}} \sum_{m=1}^{N} \{(\psi_{m1} - \psi_{m1'}) \pm (\psi_{m2} - \psi_{m2'})\} \qquad (15)$$

and, for those associated with TCNQ° molecule,

$$\Phi_{\mathrm{II}}^{\pm} = \frac{1}{\sqrt{2N}} \sum_{m=1}^{N} (\psi_{m3} \pm \psi_{m4}) \qquad (16)$$

We carried out the first-order and second-order calculations taking into account the lower four transitions of $TCNQ^-$ ion, *i. e.* R, S, U, and S′ transitions, and the lowest transition of TCNQ° molecule. We will denote the last one as the *N* transition. The results of the calculations are illustrated in Fig. 8, where the absorption bands predicted for the *a*-axis and *b*-axis spectra are shown as vertical lines with a length proportional to the predicted oscillator strength.

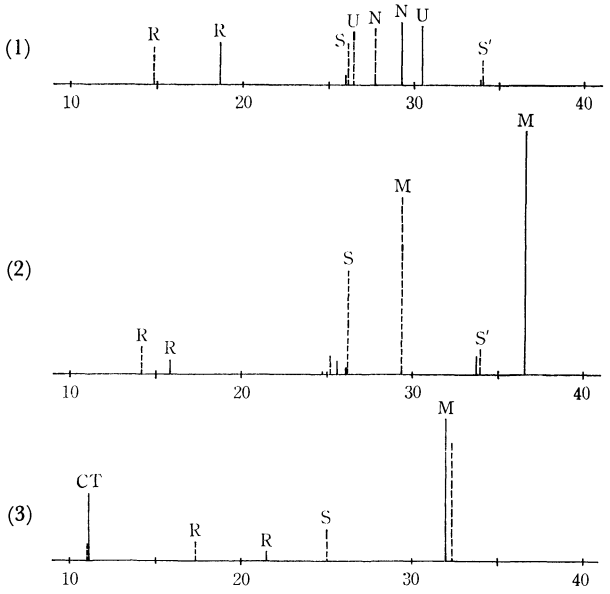

Fig. 8. Results of calculation on the first order and second order effects on the LE bands in $Cs_2(TCNQ)_3$ crystal. (1) Results of the first order calculation, (2) Results of the calculation including the second order effect, (3) Observed spectra. (energy unit in kK)

As shown in Fig. 8, the A_u and B_u components of each intramolecular transition are split appreciably by the first-order effect. The predicted spectra significantly change when the second-order effect is taken into account. Namely, the U- and N-transitions are mixed to give new absorption bands, which are denoted M and M′ in Fig. 8, and the oscillator strength of the R-band is markedly reduced. In Table 4, the oscillator strength of the absorption bands predicted by the second-order calculation are compared with the oriented-gas values. It can be seen that the oscillator strength of the M-band is larger than the sum of the oriented-gas values of the U- and N-bands, the former being about 1.3 times the latter in the *a*-axis spectrum and almost twice in the *b*-axis spectrum. This is mainly caused by the intensity stealing from the R-band.

The observed *a*-axis spectrum seems to be well explained by the present calculation. We will assign the absorption maxima found at 17.3, 25.0, and 32.3 kK to B_u components of R-, S-, and M-bands, respectively. According to the present calculation, the *b*-axis spectrum should exhibit one strong absorption band at 36.5 kK. This is not the case in the observed spectrum. Instead, we find a strong band at 31.9 kK. Within the approximation made in the present study, it seems difficult to find any good explanation for this discrepancy. We observed a very weak shoulder at about 20 kK, which can be assigned to the B_u component of the R-band.

Summary and Conclusion

In the present study, we have observed the polarized absorption spectra of single crystals of K(TCNQ) and $Cs_2(TCNQ)_3$, and have shown that the 7.8 kK band of K(TCNQ) and the 11 kK band of $Cs_2(TCNQ)_3$ are the CT bands associated with the transfer of an electron from a $TCNQ^-$ ion to the neighboring $TCNQ^-$ ion. It is also shown that the LE bands observed in the crystal spectra are appreciably shifted from the locations of the corresponding absorption bands in the solution spectra. We have theoretically estimated the first-order and second-order effects on the LE bands of these crystals. In this calculation, we have adopted the method given for the ordinary molecular crystal, composed of neutral molecules, but have taken into account a few aspects associated with the ionic character of these crystals. Although discrepancies between prediction and observation are found in several respects, the general feature of the observed spectra seems to be explainable by the present calculation. From the various conclusions obtained by this study, we wish to point out, first, that the long-range interactions of Coulombic nature provide a large contribution to the crystal shift, and, second, that there is a marked mixing between the transitions of $TCNQ^-$ ion and those of $TCNQ^\circ$ molecule in the case of $Cs_2(TCNQ)_3$. These aspects should always be taken into account when we consider the interpretation of the crystal spectra of TCNQ salts. We have omitted exchange interaction between molecules, mixing between the CT and LE exciton states. This mixing could have a significant effect on the crystal spectra of TCNQ salts. A more sophisticated calculation might be needed to establish a quantitative interpretation of the crystal spectra of TCNQ salts.

Sound Velocity in Aqueous Solutions of Lead Nitrate and Ammonium Iodide

Otohiko NOMOTO*,** and Harumi ENDO*

* *Department of Applied Physics, Defence Academy, Yokosuka*

** *Kobayashi Institute of Physical Research, Kokubunji, Tokyo*

(Received June 3, 1970)

The sound velocity in aqueous solutions of NH_4I and $Pb(NO_3)_2$ is investigated in relation to the temperature and the concentration. In both solutions the $V(T)$ curves show maxima V_p at the peak temperature T_p, the T_p shifting to a lower temperature with an increase in the concentration. While the shift of T_p is sensibly linear with the concentration for $Pb(NO_3)_2$, the curve for NH_4I is almost constant up to 25 wt%, though it decreases linearly above this concentration. This corresponds to the rather abrupt change in the degree of dissociation obtained from the conductivity data. The constancy of T_p below 25 wt% is tentatively explained on the basis of Danford and Levy's X-ray diffraction study which concluded that NH_3 is included in cavities of the water framework and that the framework molecules are partially replaced by NH_3.

Generally speaking, the sound velocity (V) in a solution is dependent on both the temperature (T) and the concentration (C); *i. e.*, $V=V(T,C)$. No systematic study of the sound velocity in aqueous electrolyte solutions has, however, been made over a wide range of concentration and temperature, except for the studies of Tamm *et al.*[1] and Marks.[2,3] They found that the $V(T)$-curve at a constant concentration in electrolyte solutions exhibits its peak velocity (V_p) at a definite temperature — the peak temperature (T_p) — for each concentration, such as in the $V(T)$ curve of pure water. The $V(T)$ curve shifts upwards with an increase in the concentration, while there is a shift of T_p towards a lower temperature at the same time. This shift of T_p is linearly dependent on the concentration (molarity).

Reviews[4-7] of the water structure have appeared elsewhere. A water model closely related to a slightly-expanded ice-I lattice is proposed by Samoilov[8,9] and supported by Danford and Levy[10] on the basis of their X-ray diffraction studies. In this structure, each network molecule is tetrahedrally surrounded by an average of *ca.* 4.4 first neighbors.[11] The structure of this network is very bulky, with space within the framework of molecules in the tetrahedral coordination sufficiently large to accommodate additional water-molecules, and while these spaces—cavities— are not occupied in solid ice-I, about half the cavities in water are occupied by interstitial molecules which interact with the network by less directional, but by no means negligible, forces (Danford and Levy[10]).

As Debye[12] pointed out, the electrostatic field of the ions exerts an electrostrictive effect on the surrounding water molecules; this electrostatic pressure has the same effect as the application of an external pressure and diminishes the volume as well as the compressibility of water molecules. In general, the addition of an electrolyte to water results in a lowering of the peak temperature because of the destruction of the cluster by the solvation of the ions. In many electrolytes, the sound velocity increases as compared with that of pure water. However, there are electrolytes which exhibit a decrease in the sound velocity with an increase in the concentration, such as LiI, NaI, KI, NH_4I, $AgNO_3$[13]; CsCl, CsBr[14]; $Pb(NO_3)_2$[15]; $ZnBr_2$, ZnI_2[16]; UO_2Cl_2, $UO_2(NO_3)_2$, SnI_2, $(CH_3COO)_2Pb$[17]; $CdBr_2$[18]; CdI_2[19]; $TlNO_3$[20]; and RbBr, RbI.[21]

The purpose of the present study is to clarify the molecular mechanism of sound propagation in aqueous electrolyte solutions in connection with the accepted molecular structure of water and aqueous solutions, and to clarify the dissolved state and the properties of ions in aqueous solutions. We studied ammonium iodide and lead nitrate solutions, both electrolytes showing a decrease in the sound velocity with an increase in the concentration.

Experimental

Apparatus. The sound velocity is measured with a crystal-controlled ultrasonic interferometer equipped with a 5 MHz X-cut quartz transducer. The accuracy of this method depends on the number of standing waves counted. We counted one hundred standing waves. The interferometer cell is immersed in an oil bath controlled within ± 0.1°C at moderate temperatures and within ± 0.4°C at higher tem-

peratures. The dominant cause of error in sound velocity measurement is temperature fluctuations. The temperature coefficient of the sound velocity in usual aqueous solutions being *ca.* −2——3 m/sec/deg at room temperature, the estimated overall error in this study amounts to ±0.2 m/sec at moderate temperatures and ±1.5 m/sec at higher temperatures. Temperature measurement is made with a thermistor. The sound velocity is measured in terms of its dependence on the temperature for various electrolyte concentrations.

Materials. Lead nitrate and ammonium iodide, special reagent grade, are both recrystallized from water. Salts are prepared by maintaining the crystals at 95°C for two weeks under a reduced pressure of *ca.* 1 mmHg. After purification, ammonium iodide completely turned into colorless salt.

Results and Discussions

The $V(T)$-curves at various concentrations for lead nitrate and ammonium iodide aqueous solutions over the temperature range of 20—100°C are shown in Figs. 1 and 2 respectively. Measurements of the concentration dependence of the sound velocity $V(C)$ under a constant temperature in $Pb(NO_3)_2$ and NH_4I aqueous solutions has been reported, but there have, to our knowledge, been no measurements of the temperature dependence of the sound velocity. It is observed that the height of $V(T)$-curves of an aqueous solution of $Pb(NO_3)_2$ or NH_4I is lower than that of water and that the curves are displaced towards a lower temperature with an increase in the concentration in such a way as to maintain the parabolic shape of the $V(T)$-curve of water.

All kinds of somewhat dilute aqueous solutions,

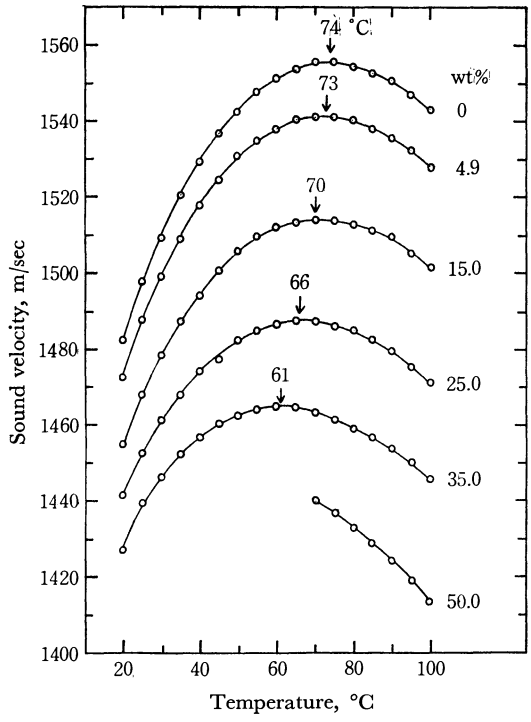

Fig. 1. Sound velocity of lead nitrate aqueous solutions. Arrows show the peak temperature.

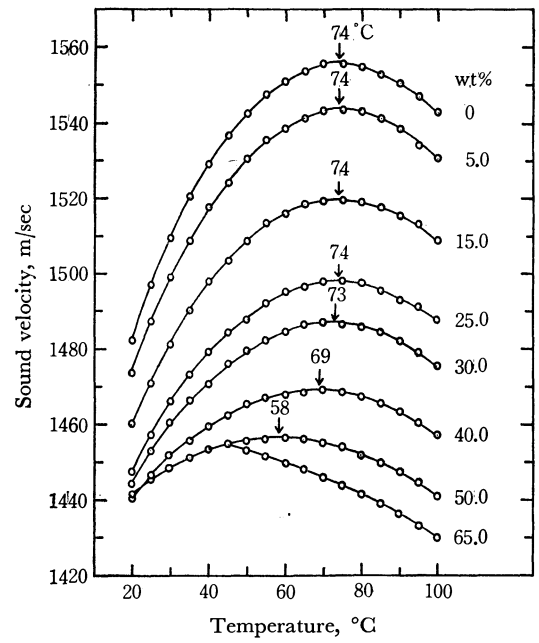

Fig. 2. Sound velocity of ammonium iodide aqueous solutions. Arrows show the peak temperature.

regardless of whether they are ionic[22,23] or non-ionic[24,25] substances, have parabolic curves like that of water. When a solute is added to water, the statistical equilibrium among different species is displaced and there is a partial destruction of the clusters; the decrease in the cluster by the solutes causes the peak temperature to become lower as compared with that of pure water.

The origin of an anomalous temperature dependence of the sound velocity in water and aqueous solutions can be sought in the structure of water. The cluster-part of water decreases with an increase in the temperature, resulting in a decrease in the structural compressibility. The increase in the molecular distance with the temperature-rise is accompanied by an increase in the ordinary compressibility due to the compression of the free space between non-associated water molecules. These opposite effects lead to a minimum of the compressibility at an intermediate temperature, or to the maximum of the sound velocity at a slightly different temperature.

The plot of the peak temperature against the concentration—$T_p(C)$—gives information on the water structure and the dissolved state, and also on the properties of ions in aqueous solutions. The relation between the peak temperature and the concentration has been extensively studied for various sulfates and hydroxides (*cf.* Marks[2,3]). In these solutions, the sound velocity rises with an increase in the concentration. On the other hand, the peak temperature (T_p) decreases with

an increase in molarity (m) along a straight line:

$$T_p = (T_p)_0 - km, \quad \text{where } (T_p)_0 = 74°C$$

with a common negative slope (k) for Li_2SO_4, Na_2SO_4, and K_2SO_4. Here $(T_p)_0$ is the peak temperature for water. Also, the $V(T)$-curves are nearly common for these three salts. The $T_p(m)$-curves for the other salts are straight lines, with a different slope for each salt. Marks concluded that the above-mentioned three salts affect the compressibility and the density of water in such a way that the maximum sound-velocity-changes (ΔV_p) with the concentration become nearly the same. This is evidence that the ionic charge is the determining property rather than the ionic size in electrolyte solutions. We have studied the shift of T_p with the concentration in organic aqueous solutions, and, by ascribing the T_p to the destruction of the water structure, we have found that, regardless of the kind of organic substance, there exists a simple linear relation between T_p and the geometical surface area of the solute.[24]

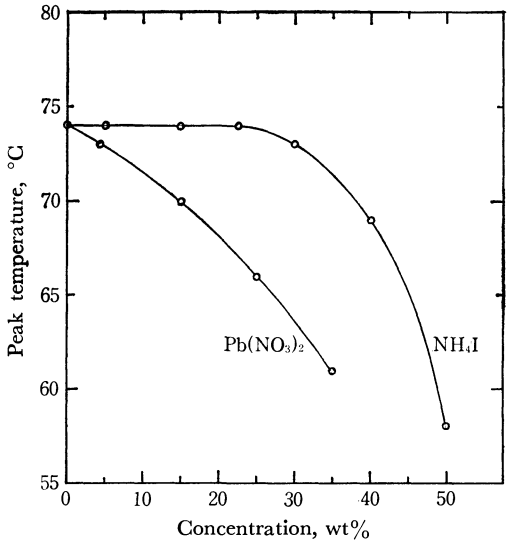

Fig. 3. Peak temperature in dependence of concentrations for lead nitrate and ammonium iodide aqueous solutions.

Figure 3 shows the $T_p(C)$-curves, with the weight-% as the abscissa. As may be seen, the peak temperature of the $Pb(NO_3)_2$ solution decreases linearly with the concentration. On the other hand, the behavior in the NH_4I-solution is very different from that in solutions of the other salts, such as sulfates, hydroxides, and $Pb(NO_3)_2$. The peak temperature in the NH_4I-solution does not change with the concentration up to *ca.* 25 wt%, with the T_p-value of water maintained at 74°C. Above this concentration, the T_p decreases as in other electrolyte-solutions.

The origin of the anomalous concentration dependence of the peak temperature in an NH_4I aqueous solution is to be explained on the basis of a slightly-expanded ice-1-model[8] of the water structure and the peculiarity of the dissolved state of NH_4^+ and I^- ions in an aqueous solution.

There are a number of parameters pertaining to the properties and dissolved state of ions in aqueous solutions, the hydration number being one such parameter. We have many experimental methods[25] for determining the hydration number of ions in aqueous solutions, such as mobility, entropy of mixing, and diffusion. Also, the hydration number has been acoustically determined from the sound velocity by many authors. It must be particularly emphasized, as regards the acoustically-determined hydration number, that the observed quantity is the overall bulk compression of the solution, and that no distinction between the effects to be ascribed to the nearest neighbors of the ions and the far distant molecular species as clusters of water, *etc.*, can be made. The so-called "hydration number," as determined by the acoustical method, is based on a model assuming incompressible hydrated water molecules and non-affected surrounding water. The physical interpretation of the acoustic hydration number is, however, rather the net destruction of the water structure. The hydration numbers for the ions, as obtained by various experimental methods, are remarkably different[26,27] from one another. The values obtained from the sound-velocity data are usually higher than those obtained by the other methods. Nevertheless, the acoustically-determined hydration number is a significant parameter for the study of the properties and the dissolved state of ions in aqueous solutions. Table 1

Tabel 1. The hydration number for various ions

Ion	Author	The other
NH_4^+	NH_4I 3.0	2.0[13]
I^-		0.2,[13] 0.1[27]
Pb^{2+}	$Pb(NO_3)_2$, 10.8	
NO_3^-		2.0,[13] 1.1[27]

shows the hydration numbers for $(NH_4^+ + I^-)$ and $(Pb^{2+} + 2NO_3^-)$ as obtained by acoustical means. Usual ions have acoustical hydration numbers between 5—16.[26] As may be seen in Table 1, NH_4I (NH_4^+ plus I^-) has exceptionally small hydration numbers. Therefore, it may be concluded that NH_4^+ and I^- ions do not destroy the water structure so much. Now we see from Fig. 3 that the peak temperature is not shifted, and that the water structure in the NH_4I-solution is not destroyed, for concentrations up to *ca.* 25 wt%. We reached the conclusion that the NH_4^+ and I^- ions can fill in the cavity positions in an expanded ice-1 structure of water without any serious destruction of the molecular arrangements. The NH_4^+ ion can replace the network-point of water molecules, too. Since the ions packed in the cavities serve only to expand the lattice, without destroying the water structure, the shift of T_p is expected to be small.

We have reported that, in the case of aqueous organic solutions, the shift of T_p is nearly proportional to the total surface area of the solutes. The shift of T_p is discernible for NH_4I solutions in the concentration range higher than *ca.* 30 wt%. This is presumably to be ascribed to the increase in neutral NH_4I molecules in this concentration range, as is also evidenced by

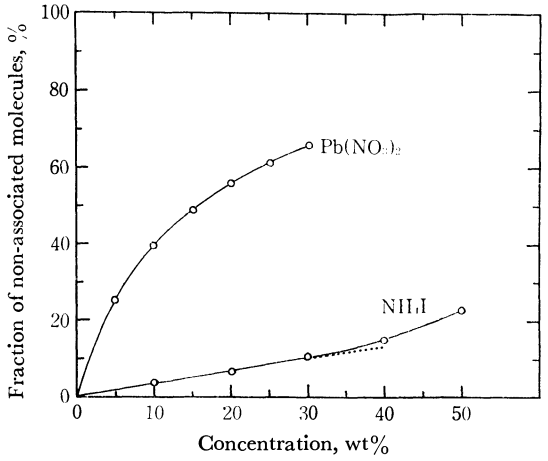

Fig. 4. Fraction of non-associated molecules in dependence of concentrations for lead nitrate and ammonium iodide aqueous solutions.

the change in the conductivity.[28] The fraction of non-dissociated solutes, as obtained from the conductivity data, is also indicated in Fig. 4. The curve shows a rather abrupt turn at 30 wt%. Both the turn of the T_p-curve and that of the degree of dissociation in the NH_4I aqueous solution at nearly the same concentration may correspond to the transformation of the properties and the dissolved state of ions in aqueous solutions.

The model used here is strongly supported by the results of investigations of water,[10,29] an aqueous ammonia[30] solution, and aqueous ammonium halide[31] solutions by the X-ray diffraction method (*cf.* also aqueous tetra-*n*-butylammonium fluoride[32]). That is, it is concluded by the X-ray method that the ammonia and ammonium ions can replace the water molecule in the network of the expanded ice-I structure and also fill up the cavities in this bulky structure. It has been stated that, in pure water,[10] the ratio of the framework to the free water molecules is 4 : 1, and that half the cavities in framework are filled by free water molecules. In the case of the water-ammonia[29] system of 28 mol%, it has been stated that 76% of the available cavities are occupied by ammonia molecules. Although the X-ray analysis may not be able to distinguish between the free single-water molecules and the single-water molecules filling in the cavities of the frameworks of the clusters, the X-ray results[30] do not contradict the present result.

We can see from Fig. 3 that T_p decreases in a $Pb(NO_3)_2$-solution sensibly and linearly with an increase in the concentration. Also, the non-dissociated fraction of $Pb(NO_3)_2$ molecules, as obtained from the conductivity[33] data, increases more rapidly than NH_4I with the concentration (*cf.* Fig. 4). The large hydration number of $Pb(NO_3)_2$ may be the reason why the ions do not fill in the cavities in water frameworks, but destroy the framework from the beginning.

Structure of Polynucleotide Complex with Non-Complementary Nucleosides.[1] II. Poly I, U + Poly C

Hideo AKUTSU and Masamichi TSUBOI

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 18, 1970)

Three copolymers of riboinosinic acid and ribouridylic acid (poly I,U) with uridylic acid contents, 20, 32, and 44% were prepared. The ultraviolet absorption measurements were carried out with aqueous solutions of mixtures of poly I,U and polytribocytidylic acid (poly C) of various mole ratios. It has been shown that a double-helical structure is formed with an I···C type inter-base binding and with the U residue looping out of the helix. The structure was found to break on heating the solution. The process of break down was followed by means of ultraviolet absorption measurements.

Polyriboinosinic acid (poly I) and polyribocytidylic acid (poly C) are known to form a double-helical complex poly I·poly C in aqueous solution.[2,3] The structure involves specific hydrogen bonds (I···C) between inosine and cytidine residues. It can be schematically expressed as in Fig. 1(a). Here, inosine (I) and cytidine (C) are complementary nucleosides. The question now arises: what is the effect of introducting uridine (U) residue (which is complementary to neither I nor C) into this system. In a previous paper[4] we examined the effect of introducing the U residue into the poly C moiety. In this paper we describe the effect of its introduction into the poly I moiety.

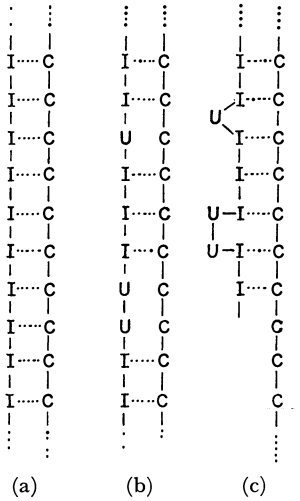

Fig. 1. Schematic drawings of (a) the double-helical structure of poly I·poly C complex, (b) a double-helical structure with the U residues inside, and (c) a double-helical structure with the U residues rotating out.

Preparation of Polynucleotide Samples

The polynucleotide samples were prepared by use of polynucleotide phosphorylase obtained from *Azotobacter vinelandii*. Compositions of the reaction mixtures and incubation times are given in Tables 1 and 2. The incubation temperature was 30°C. After the completion of enzymatic reaction, the product was precipitated with ethanol and then purified by phenol extraction.

Base Composition and Degree of Polymerization of the Products

The base composition of each poly I,U sample was determined by its hydrolysis with 1 N HCl, paper chromatographic separation of the resulting hypoxanthine and uridylic acid and ultraviolet absorption measurements. The composition thus determined is given in Table 2.

The degrees of polymerization of the polymers were not determined, but they are considered to be sufficiently high from the sedimentation constants given in the last column of Table 2. The constants were determined in a solvent with 0.1 M NaCl and 0.01 M Na-cacodylate, pH 7.0.

Experimental

Ultraviolet absorption measurements were carried out with an Ito spectrophotometer Model QU-3. The temperature of the samples was controlled as previously descrived.[5] The polynucleotide concentration (in M) was determined by measuring phosphorus content.[6] The moles of polynucleotide means here moles of phosphorus (or the moles of nucleotide residue).

Mixing Curves

Solutions of poly I,U and poly C of various mole ratios were prepared, and their ultraviolet absorbances at a few points in the 240—250 mμ region were recorded. The results are shown in Fig. 2. From the absorbance *versus* mole-ratio profile, we can judge whether the two polymers in question form a complex or have no interaction. When a complex is formed, its stoichiometric ratio is determined from the observed profile of the mixing curve.

As may be seen in Fig. 2, each poly I,U, shows evidence of interaction with poly C. At room temperature, each of the mixing curves consists of two straight lines which intersect at a proper mole ratio. This should correspond to the stoichiometric mole ratio in which the two polynucleotides form a complex. The stoichiometric mole ratio, poly I,U/poly C, should be 50/50, if the complex has a structure, in which the non-complementary U residues are incorporated in the double-helix as shown schematically in Fig. 1(b). On the other hand, if the U residues rotate out of the helix and thus no C residue fails to form an I···C base-pair (see Fig. 1(c)), then the intersect (or the maximum hypochromicity) should take place at poly I,U/poly C=100/x. Here, x=mol% of I in the copolymer of I and U. The stoichiometric mole ratios expected for structures (b) and (c) in Fig. 1 are indicated by arrows in Fig. 2.

We see that each mixing curve shows its minimum at the mole ratio expected for structure (c) but not for structure (b) in Fig. 1.

I,U-poly C mixtures at the mole ratio with maximum hypochromicity are shown in Fig. 3. In general, such observed profiles do not always represent the melting profiles of the secondary structures of the complex molecules. As Fresco and Alberts[7] indicated, the absorbance of not only the complex but also the non-interacted constituent may depend upon the temperature. In the present case, however, the absorbance of poly I,U and of poly C would not depend too much on the temperature. Therefore, the observed profiles given in Fig. 3 would not greatly differ from the "true melting profile" of the complex molecule.

As may be seen in Fig. 3, the increase in absorbance takes place over a wide range of temperature for every complex even in a solvent with Mg^{2+}. This is in contrast with the case of the complex of poly C,U and poly I,[4] where a sharp rise in absorbance takes place. The midpoint (T_m) of the transition, however, is almost the same for poly C,U·poly I complex and poly I,U·poly C complex when the U contents in these two complexes are almost equal (32—33% in each copolymer). The T_m becomes lower as the U content in the copolymer increases. As in the case of the poly C,U·poly I complex, the cooling curve of each of these complexes was found to be almost equal to the heating curve.

We wish to express our thanks to Professor Sanae Mii for kindness in providing the wet cells of *Azotobacter vinelandii* and to Dr. Kimiko Matsuo for her valuable advice. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 22—27 (1971)

Electronic Structure of Lone Pairs. III.[1] H_2S_2, H_2O_2, N_2H_4, and Diimides

Hiroko YAMABE, Hiroshi KATO,[2] and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 25, 1970)

The electronic structure, the electronic transition, and the interaction of lone pairs of H_2S_2, H_2O_2, and N_2H_4 for several dihedral angles are studied by the semi-empirical ASMO SCF method, and their dependencies on the dihedral angle is discussed. Also, the interaction of the lone pairs of diimides, N_2H_2, N_2F_2, and $(CH_3)_2N_2$, the relative stability of the *cis* forms and of their *trans* form, and the electronic transition energies of these molecules are calculated. The stable forms of N_2H_2 and $(CH_3)_2N_2$ are calculated to be of the *trans* form, but that of N_2H_2 is the *cis* form. An energy component analysis of these compounds has been made. The main factor in the lack of stability of the *cis* form of N_2H_2 is shown to be the core-core repulsion term, V_{nn}. On the other hand, in H_2S_2 and N_2H_4 not only the V_{nn} term but also the electrostatic interaction term, $\sum_{i,j}^{occ}(2J_{ij}-K_{ji})$, contributes to their instability.

In a previous paper,[3] the electronic structure and the interaction of lone pairs of $(CH_3)_2S_2$ and cyclic disulfides were studied theoretically and their dependence on the dihedral angle, ϕ, was discussed.

Hydrogen peroxide, H_2O_2,[4,5] and hydrazine, N_2H_4,[5,6] are known to have dihedral angles of approximately 111° and 90° respectively from the investigation by means of X-ray analysis, by a study of the IR spectra, and so on. Recently, the dihedral angle of H_2S_2 was revealed to be 90°36′ by a microwave study.[7,8] In these molecules, the oxygen and the nitrogen atoms having lone pairs are bonded by a single bond, as in the case of disulfides. The problem of the rotational barriers of these compounds has been studied quantum-mechanically by many authors.[6,8-10] In the present paper, focusing our attention upon the electronic structure of the lone pair, calculations similar to the previous ones for several disulfides[3] are carried out for H_2S_2, H_2O_2, and N_2H_4. The dependence of the total energy and the interaction of the lone pairs on the dihedral angle is discussed, and an energy-component analysis of these molecules is reported.

In this paper we will also discuss the interaction of the lone pair of diimides, RN=NR, in which the nitrogen atoms are bonded by a double bond. The mutual

stability of their *cis* and *trans* forms[11] and the electronic transition energy are calculated. Moreover, the substituent effect of an electronegative atom, such as the F atom, or of a CH_3 group to the lone pairs of the sp^2 type of nitrogen atom is investigated. As Robin *et al.* pointed out in their paper, a few works[12-14] on the electronic states of azoalkanes have been performed. They studied the electronic structure by a non-empirical SCF CI method, using Gaussian-type orbital basis functions. Here, the electronic states of *cis* and *trans* diimides, N_2H_2, $(CH_3)_2N_2$, and N_2F_2 are calculated by the semi-empirical ASMO SCF method.[15]

Calculations

In the calculation by the semi-empirical ASMO SCF method,[15] the approximation and parameters used in the case of the disulfides are adopted. The coordinate axes, bond lengths, and bond angles of H_2S_2, H_2O_2, and N_2H_4 are given in Fig. 1, together with their dihedral angles, ϕ's, while those of the diimides are given in Fig. 2. The conformation of N_2H_4 in the dihedral angle, $\phi=0°$, is assumed to be as follows: The atoms, H_4 and H_6, are placed downward to the x-y plane, as in Fig. 1. The $\angle$NNH angle is put as 112°. In the conformation of the 90° dihedral angle, the group containing the N_2 atom is rotated by 90° around the N–N bond.

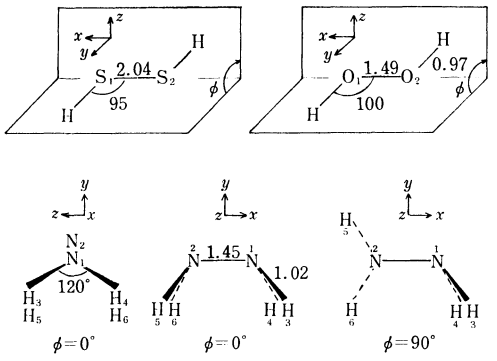

Fig. 1. Bond lengths (in Å) and bond angles (in degree), the dihedral angle ϕ of H_2S_2 and H_2O_2, the employed conformations of N_2H_4 for $\phi=0°$ and $\phi=90°$, and the coordinate axes are shown.

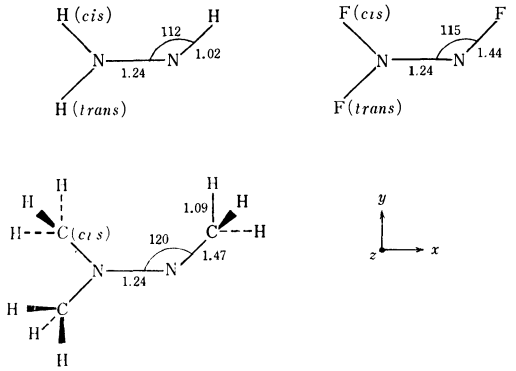

Fig. 2. Bond lengths (in Å), bond angles (in degree), and coordinate axes.

Results and Discussion

The angular dependencies of the atomic density and the atomic orbital (AO) densities of H_2S_2, H_2O_2, and N_2H_4 are given in Tables 1—3. The lone-pair levels and the lowest vacant level (LV) of H_2S_2 and H_2O_2 of various dihedral angles are given in Figs. 3 and 4 respectively.

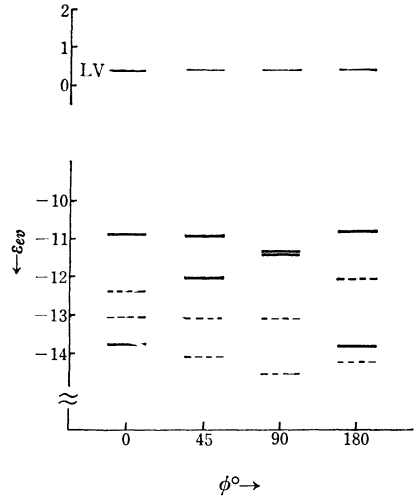

Fig. 3. Lone-pair levels and the lowest vacant level of H_2S_2 *vs.* dihedral angle ϕ. The heavy lines and the dashed lines designate the levels of the p-type lone pair and the sp^2-type lone pair, respectively.

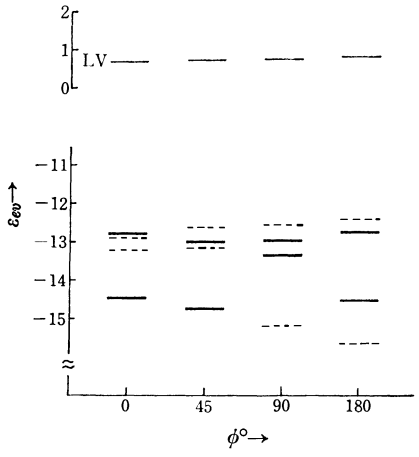

Fig. 4. Lone-pair levels and the lowest vacant level of H_2O_2 *vs.* dihedral angle ϕ. The heavy lines and the dashed lines designate the levels of the p-type lone pair and the sp^2-type lone pair, respectively.

1) H_2S_2: As is shown in Table 1, when the dihedral angle of H_2S_2 is equal to 0°, the p-type lone-pair AO becomes the p_z orbital of the S_1 atom (S_1z). The direction of the lone-pair orbital rotates, keeping its electron density approximately 2.00, following the change in the ϕ angle. When the dihedral angle increases, the atom density of the sulfur atom increases and that of the hydrogen atom decreases. That is, the electron flows from the s orbital of the hydrogen atom to the p_y orbital of the sulfur atom. This tendency has been pointed out for $(CH_3)_2S_2$ by the present authors[3] and for H_2O_2 by Morokuma *et al.* in their ab initio calculation[5] and also by Pitzer *et al.*[10] H_2S_2 also has sp^2-type lone pairs due to the hybridization of $3s$ and $3p$ electrons. These sp^2-type lone pairs rotate according to the change in the dihedral angle, ϕ. That is, the atomic density and the AO density of the sulfur atom of H_2S_2 and their angular dependence resemble those in the case of $(CH_3)_2S_2$. The lowest n–σ^* transition energies are given in Table 4. These

	Transition energy	2.99	4.65	5.73	5.93
N_2H_4	Difference of the total energy	0.16	—	0.00	—
	Transition energy	4.21	—	4.94[c]	—

a) Difference of total energies referred to that in 90°.
b) Lowest $n\rightarrow\sigma^*$ transition.
c) Observed value is about 5.39 eV (S. Imanishi, *Nature*, **127**, 782 (1931)).

transition energies are approximately equal to those of $(CH_3)_2S_2$. Therefore, it is noted that the main factor showing the angular dependency of the atomic density, the AO density, and the transition energy is not a group bonded to a sulfur atom, such as CH_3 and H, but a part of the S–S bond. The total energy decreases monotonically from a maximum at 0° to a minimum at 180°. The experimentally-obtained minimum (about 90.5°) can not be obtained.[16]

2) H_2O_2: The angular dependencies of the atomic density and the AO density of H_2O_2 (Table 2) are analogous to those of H_2S_2 and $(CH_3)_2S_2$.[3] That is the two p-type lone pairs are parallel at 0° and become orthogonal at 90°. The sp^2-type lone pairs are also seen. However, the AO density of the s orbital of the oxygen atom is larger than that of the sulfur atom (Table 2). The order of the lone-pair levels shown in Fig. 4 is different from that in the case of H_2S_2 of Fig. 3. The energy level of the sp^2-type lone pair becomes more unstable than the p type except for $\phi=0°$, which may correspond to the larger s character and the smaller sp^2-type hybridization of the oxygen atom (see Tables 1 and 2). The splitting

16) This may be due to the inappropriate approximation of the calculation for such a small molecule with lone pairs. Recently, by using the basic set of Gaussian orbitals and the ab initio SCF MO method, Schwartz obtained an energy minimum of H_2S_2 for a dihedral angle in the range 90°—100° in fair agreement with the experimental value (about 90.5°) (Ref. 8).

between the p-type lone-pair levels is large when $\phi=0°$ and small when $\phi=90°$. That is, the interaction of the lone pairs aligned parallel is larger than those aligned in a rectangular manner. The total energies referred to that at 90° are shown in Table 4 for the various dihedral angles. The total energy decreases monotonically from a maximum at 0° to a minimum at 180°. The experimentally-obtained minimum (approximately 111°) can not be obtained, such as in the case of H_2S_2.[17] The lowest n–σ^* transition energy in 90° is calculated to be 5.73 eV. Urey *et al.*[18] and Fergusson *et al.*[18] reported that H_2O_2 is decomposed by light in the UV region, thus, the transition energy was not observed experimentally.

3) N_2H_4: The total energy at the dihedral angle of 90° is lower than that at 0°, which is compatible with the observation that the dihedral angle of the stable form is approximately 90°. In Table 3, when $\phi=0°$, the atomic bond order is zero, and it is noted that the lone pair of the nitrogen atom lies on the x–y plane and has a large electron density in the y direction. When $\phi=90°$, the lone pairs of the nitrogen atoms are perpendicular to each other. The splitting between the lone-pair levels at 0° (2.23 eV) is larger than that at 90° (0.22 eV).

Diimides. The electron density, the difference in the relative total energy, and the splitting of the lone-pair levels are listed in Tables 5—7 for the various diimides. Herzberg mentioned[19] that N_2H_2 should take a *trans* form in the ground state, and in our approximate calculation the *trans* form is calculated to be more stable.[20] For N_2F_2 and $(CH_3)_2N_2$, the stable forms are calculated to be the *cis* form and the *trans* form respectively. From the one-center bond orders of s–x, s–y, and s–z, the lone-pair orbital of the nitrogen atom may be approximately identified as a sp^2-type hybrid orbital for all the diimides studied here, and the lone pair of the N_1 atom lies on the molecular plane.

The splitting of the lone-pair levels is larger in the *trans* form than in the *cis* form for the three diimides, as is also pointed out by Robin *et al.*[11] This may be due to the fact that the overlap of the lone pairs is larger in the *trans* form than in the *cis* form. This tendency was also true in H_2S_2 and H_2O_2. (See the dotted line in Figs. 3 and 4. $\phi=0°$ and $\phi=180°$ correspond to the *cis* and *trans* forms respectively.) It is noted that, by the substitution of the fluorine atom, the lone-pair electron density of the nitrogen atom (mainly p_y AO) is greatly diminished and the splitting of the lone pair becomes small compared to N_2H_2. The atom density of the nitrogen atom of the *trans* diimide is larger in each case studied than that of the *cis* diimides, while that of the hydrogen atom of *trans* N_2H_2 is smaller than that of the *cis* form. Similar relations are shown for the atom density of the fluorine atom of N_2F_2 and that of the CH_3 group of $(CH_3)_2N_2$, which is the sum of the atom densities of the carbon atom and three hydrogen atoms.[21]

17) Pedersen and Morokuma have reported, in their ab initio calculation of H_2O_2 using a basic set of 26 Gaussian orbitals, that the energy decreases monotonically from a maximum at 0° to a minimum at 180° (Ref. 5).

18) H. C. Urey, L. H. Dawsey, and F. O. Rice, *J. Amer. Chem. Soc.*, **51**, 1371 (1929); W. C. Fergusson, L. Slotin, and D. W. G. Style, *Trans. Faraday Soc.*, **32**, 956 (1936).

19) G. Herzberg, *Kagaku to Kogyo*, **21**, 474 (1968).

20) Lehn *et al.*, by their ab initio SCF LCAO MO calculations, that *trans* N_2H_2 is more stable than *cis* N_2H_2 by 10.5 kcal/mol (Ref. 12). On the other hand, Gordon *et al.*, in their ab initio calculations, fond that *cis* N_2H_2 and *cis* N_2F_2 are more stable than the corresponding *trans* diimides (Ref. 14).

21) The atom densities of the CH_3 group of $(CH_3)_2N_2$ are 6.759 for the *trans* form and 6.803 for the *cis* form.

Some of the obtained transition energies are listed in Table 8, together with the values calculated and observed by Robin *et al.*[11] Among the calculated values of *trans* N_2F_2 and *trans* $(CH_3)_2N_2$, the lowest singlet-singlet transition is n–σ^* (^1B_g), and the next one is n–σ^* (^1B_u). This sequence is the same as that observed, but the values of these transitions are much smaller than the observed energies. Compared to the values calculated by Robin *et al.*,[11] our transition energies are small. The inclusion of the configuration interaction seems to be necessary. According to Herzberg,[19] the ground state of N_2H_2 is the triplet state. Our obtained transition energy of the $^3B_g(n$–$\sigma^*)$ of the *trans* N_2H_2 is remarkably low.

Energy Component Analysis. The total energies of $(CH_3)_2S_2$, H_2S_2, N_2H_4, and N_2H_2 have been analyzed to their various contributions; the results are given in Table 9, where W, V_{nn}, and E_e denote the total energy, the core-core repulsion energy, and the total electronic energy respectively. The orbital energy and the core integral of the ith MO are designated by ε_i and H_i. The Coulombic and exchange integrals between the ith and the jth MO's are indicated by J_{ij} and K_{ij} respectively. The W and E_e quantities are written as follows:

$$W = E_e + V_{nn} \tag{1}$$

$$E_e = 2\sum_i^{occ} \varepsilon_i - \sum_{ij}^{occ} (2J_{ij} - K_{ij}) \equiv \varepsilon - G \tag{2}$$

or

$$E_e = 2\sum_i^{occ} H_i^{core} + \sum_{ij}^{occ} (2J_{ij} - K_{ij}) \equiv H + G \tag{3}$$

where ε, H, and G imply $2\sum_i^{occ}\varepsilon_i$, $2\sum_i^{occ}H_i^{core}$, and $\sum_{ij}^{occ}(2J_{ij} - K_{ij})$ respectively. $\Delta H(E-H)$ in Table 9 denotes the electronic energy calculated by the extended Hückel method. We will first discuss the case of H_2S_2. As the dihedral angle, ϕ, decreases from 90° to 0°, the molecule becomes less stable. The unstabilization energy of H_2S_2 is given by the difference in the total energy, ΔW between 0° and 90°; it is 0.17 eV. Note that the difference in the core-core repulsion energy, ΔV_{nn}, is 1.26 eV, while that of the total electronic energy, ΔE_e, is −1.09 eV. Hence, the difference in the electronic interaction energy, ΔG, is 0.66 eV, which corresponds the fact that the two lone pairs become parallel at 0°. That is, the ΔW of H_2S_2 being decomposed to ΔV_{nn}, ΔH, and ΔG according to Eqs. (1) and (2), the tendencies of ΔV_{nn} and ΔG are parallel with that of ΔW.

Table 9. Energy component analysis (in eV)

	$(CH_3)_2S_2$			H_2S_2			N_2H_4		N_2H_2

Table 10. Difference of $(2J_{ij}-K_{ij})$ between 0° and 90° of N_2H_4

	1	2	3	4	5	6(n)	7(n)
1	−0.01	+0.02	−0.26	+0.10	−0.15	+0.18	+0.05
2		+0.03	−0.05	+0.04	−0.14	+0.32	+0.04
3			−0.64	−0.02	−1.40	+0.66	−0.06
4				+0.36	+0.15	+0.17	−0.26
5					−0.46	+0.17	+0.43
6(n)						+0.43	+0.20
7(n)							+0.04

(n): (n) denotes a lone-pair MO.

It is also noted that the instability of H_2S_2 towards 0° is contributed to by an increase in ΔV_{nn} and ΔG.[22]

It is noted that the core-core repulsion energy does not cancel the electronic energy. The sum of the orbital energy does not exhibit the same trend as the total energy with regard to the variation in the dihedral angle[24] (see $\Delta\varepsilon$ and ΔW in Table 9). That is, in this case, the stabilization of the molecule at 90° can not be interpreted by the extended Hückel calculation, as is shown in Table 9.

Next, as for N_2H_2, *trans* N_2H_2 is more stable than *cis* N_2H_2. The unstabilization energy, ΔW, is 0.30 eV. In contrast to the other three compounds in Table 9, the difference in the electronic interaction energy, ΔG, is negative. That is, the electronic interaction in the *cis* form is smaller than that in the *trans* form.

In order to known whether the lone-pair levels have a definite relation to the value of $G=\sum_i^{occ}(2J_{ij}-K_{ij})$, each $(2J_{ij}-K_{ij})$ value of N_2H_4 and N_2H_2 is studied. In Table 10, the differences in these values of N_2H_4 between 0° and 90° are listed; they are also compared with the corresponding levels and a standard is made of the value of 90°.[25] That is, $\Delta(2J_{ij}-K_{ij})=(2J_{ij}-K_{ij})$ (at 0°) $-(2J_{ij}-K_{ij})$ (at 90°). The value of the $(2J_{ij}-K_{ij})$ is presented by the element of the ith raw and the jth column, namely, the (ij) element of Table 10. The order of the numbering is that of the level sequences obtained when $\phi=0$. Comparatively large repulsive values are seen in the elements with reference to the lone-pair levels, but they are not definitely large.

As has been noted in the previous section, the interaction of the lone pairs in N_2H_2 is larger at 180° (*trans* form) than at 0° (*cis* form), but the total energy at 180° is slightly lower than that at 0°. This relation between the interaction of the lone pair and the total energy is different from the previously-obtained relation that the stable conformation of such molecules as $(CH_3)_2S_2$, H_2S_2, H_2O_2, and N_2H_4 is the one where the interaction of the lone pairs is smaller. A similar relation appears in Table 9. That is, the electronic interaction, G, of N_2H_2 is large in the unstable conformation, while those of the other three compounds are small in the stable conformation.

Table 11. Difference of $(2J_{ij}-K_{ij})$ between 0° and 90° of N_2H_2

	1	2	3	4	5(n)	6(n)
1	−0.06	+0.11	−0.01	−0.07	−0.10	−0.20
2		+0.17	+0.18	+0.16	+0.70	+0.07
3			+0.23	−0.10	−0.03	−0.83
4				0.00	+0.24	−0.32
5(n)					−0.12	+0.26
6(n)						−0.41

(n): (n) denotes a lone-pair MO.

Comparing Tables 10 and 11, we can also see the following relations with regard to the different contributions of the electronic interaction term $(2J_{ij}-K_{ij})$ to the energies of N_2H_2 and N_2H_4. The 5th and 6th raws and columns of Table 11 are referred to the lone-pair levels of N_2H_2. Among the elements concerned with the lone-pair levels of N_2H_2,[25] negative values are more often seen than in the case of N_2H_4 in Table 10. In fact, the sum of the elements concerning the lone-pair MO's in Tables 10 and 11 is 2.37 eV (repulsive) for N_2H_4 and −0.74 eV for N_2H_2. From these discussions, it may be concluded that one of the main factors in the instability of N_2H_4 at $\phi=0°$ is the lone-pair interaction or the electrostatic interaction in the lone-pair MO's.

One of the authors (H.Y.) wishes especially to thank Mr. H. Nakatsuji for reading the manuscript and for his helpful discussions.

The calculations were carried out on the HITAC 5020 computer at the Computation Center of the University of Tokyo.

22) A parallelism between ΔV_{nn} and ΔW was also seen in the calculation of *cis*- and *trans*- butadienes and glyoxals (Ref. 23).

23) H. Kato, H. Konishi, H. Yamabe and T. Yonezawa, This Bulletin, **40**, 2761 (1967).

24) Fink and Allen also pointed out, in their SCF calculation of H_2O_2, the unparallel behavior of the sum of the orbital energies and the total energy. They said that this may be due to the highly localized ionic character associated with two sets of lone pairs in H_2O_2 (Ref. 9).

25) For N_2H_2, the difference between 0° and 180° is calculated as follows: $\Delta(2J_{ij}-K_{ij})=(2J_{ij}-K_{ij})$(at 0°) $-(2J_{ij}-K_{ij})$(at 180°).

The Crystal and Molecular Structure of *N*-Salicylidene-α-aminoisobutyratoaquocopper(II)

Hiroto FUJIMAKI,[1] Isao OONISHI, Fumio MUTO, Akitsugu NAKAHARA,* and Yoshimichi KOMIYAMA[2]

Department of Applied Chemistry, Faculty of Engineering, Yamanashi University, Kofu

* *Institute of Chemistry, College of General Education, Osaka University, Machikaneyama, Toyonaka*

(Received June 29, 1970)

The crystal structure of *N*-salicylidene-α-aminoisobutyratoaquocopper(II), [Cu{$OOCC(CH_3)_2N{=}CHC_6H_4O$}-($H_2O$)], has been determined from the three-dimensional X-ray diffraction data. The crystals are monoclinic. The cell dimensions are: $a=12.30$, $b=8.45$, $c=23.84$ Å, and $\beta=91.0°$. The space group is $P2_1/c$, with eight formula units in a unit cell. The structure has been refined by the least-squares method, with anisotropic temperature factors, to an *R*-value of 0.10. The molecular structures of the complex are essentially the same as those of *N*-salicylideneglycinatoaquocopper(II) hemihydrate and tetrahydrate. The environments of the copper(II) ions are square pyramidal, with one long and four short coordination bonds. The average distances of the two copper environments are: Cu–O, 1.912 and 1.945; Cu–N, 1.961; Cu–O(H_2O), 1.989, and Cu–O′ (the bond to the carboxyl oxygen of the adjacent molecule), 2.344 Å. The average bond distances of N=C in the salicylaldimine residue and of N–C in the α-aminoisobutyrate group are 1.271 and 1.504 Å respectively. Neighboring molecules related by a center of symmetry are linked together alternately by hydrogen bonds and coordination bonds (Cu–O′), an infinite chain being formed along the *b*-axis. However, there are no interactions other than van der Waals forces along the *a*- and *c*-axes.

An extensive study has recently been made of the copper(II) complexes with tridentate Schiff bases derived from salicylaldehyde and various amino acids by Nakahara and his co-workers.[3]

Kakudo and his co-workers have determined the structure of *N*-salicylideneglycinatoaquocopper(II) hemihydrate[4] (SGCH) and tetrahydrate (SGCT).[5] Concerning the transamination reaction, Kakudo *et al.* concluded, from their consideration of the bond distances around the nitrogen atom, that the N–C single bond of the salicylaldimine moiety and the N=C double bond of the glycine moiety are electron-rich.

It seemed that it would be of interest to investigate whether bulky groups such as the *t*-methyl group affect the bonds around the nitrogen atom of the Schiff-base linkage. Another point of interest is the coordination configuration about the copper atoms. In SGCH and SGCT, the coordination configurations about the copper atoms are both square pyramidal; however, in SGCH the fifth ligand atom is a 'free' carboxyl oxygen of the adjacent complex, while in SGCT it is a water oxygen atom.

In order to obtain more information about these aspects, we attempted to determine the crystal structure for *N*-salicylidene-α-aminoisobutyratoaquocopper(II), [Cu{$OOCC(CH_3)_2N{=}CHC_6H_4O$}($H_2O$)].

Experimental

N-Salicylidene-α-aminoisobutyratoaquocopper(II) was prepared and purified according to the procedure described in a previous paper.[3] The final pure product appears as green plates. The unit-cell dimensions were determined from the higher-order reflections of Weissenberg photographs (Cu$K\alpha$, $\lambda=1.5412$ Å). The systematic absences were: $h0l$ for l odd and $0k0$ for k odd. Hence, the space group was unequivocally determined. The crystal data are listed in Table 1. Sets of

Linear absorption coefficient for Cu$K\alpha$, $\mu=43.9$ cm^{-1}

multiple-film equi-inclination Weissenberg photographs were taken about the *b*-axis (0 to 6th layers), the *a*-axis, and the *c*-axis (0th layer). Cu$K\alpha$ radiation was employed throughout. The crystal used was a rod with dimensions of $0.1\times0.3\times1.0$ mm. The intensities were estimated visually with a standard film strip and were converted to $|F_o(hkl)|$ by applying the usual Lorentz, polarization, and spot-shape corrections. No correction was made for absorption and extinction. The range of relative intensities was from 1 to 7200. 2750 independent reflections fell within this range, whereas 1389 others were too weak to be observed.

Structure Analysis

The presence of eight formula units in a unit cell of the space group $P2_1/c$ requires that the complex molecules occupy two sets of general positions. Three-dimensional Patterson syntheses were performed. From these Patterson maps, the positions of the Cu atoms

were easily deduced, but those of lighter atoms could not be fixed. The structure factors, $h0l$, were calculated with the parameters of the Cu atoms. The discrepancy factor, R, was 0.50. The parameters of the eight lighter atoms coordinated to the Cu atoms were deduced from the two-dimensional electron density diagrams, $\rho(x,z)$ and $\rho(y,z)$, the signs of which were calculated from the parameter values of the copper atoms. After two cycles of calculations of the structure factors and the electron densities, $\rho(x,z)$ and $\rho(y,z)$, the parameters of all the atoms were fixed. At this stage, the discrepancy factors, R_{h0l} and R_{0kl}, dropped 0.20 and 0.25 respectively.

The structure thus obtained was refined by a block-diagonal, least-squares method with a HBLS-4 program written by T. Ashida. After three cycles of the refinements, the R-value was 0.14. Six more cycles of the refinements were carried out on the introduction of anisotropic temperature factors. The following weighting scheme was employed:

$$w = 0.2, \quad \text{if } F_0 \leqq F_{min}\ (=15.0);$$
$$w = 1.0, \quad \text{if } F_{min} < F_0 \leqq F_{max}\ (=200.0);$$

and

$$w = F_{max}/F_0, \text{ if } F_0 > F_{max}$$

The final discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, was 0.10 for all the observed reflections. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[6] The final atomic parameters and their estimated standard deviations are summarized in Table 2. The agreement between the

6) International Tables for X-Ray Crystallography, Vol. III, Kynoch Press, Birmingham (1962), p. 202.

observed and calculated structure amplitudes is reasonable.[7]

Description of the Structure and Discussion

The intramolecular bond distances and angles are listed, with their estimated standard deviations, in Tables 3 and 4, and are shown in Figs. 1 and 2. These distances and angles were calculated by using the DAPH program written by T. Ashida.

The *N*-salicylidene-α-aminoisobutyrate groups is coordinated to the copper atom as a tridentate ligand; it is linked to the metal atom through the two oxygen atoms—carboxylic and phenolic—, and the one nitrogen atom of the Schiff-base linkage.

The coordination configurations about the copper atoms in the molecules I and II are both square pyramidal (Figs. 3 and 4). This type of 5-coordinated configuration has been already found in various copper(II) complexes, for instance, di-μ-hydroxobis[dimethylaminecopper(II)]sulfate monohydrate,[8] sodium glycylglycylglycinocuprate monohydrate,[9] and other copper(II) glycine-peptide complexes, pyruvidene-β-alaninatoaquocopper(II) dihydrate,[10] *N*-salicylidene-

glycinatoaquocopper(II) hemihydrate,[4] and tetrahydrate,[5] and copper(II) yunainate trihydrate.[11]

The fifth coordination bond in one molecule is formed by the 'free' carboxyl oxygen atom of the adjacent, crystallographically-independent molecule, as

11) A. Furusaki and Y. Tomiie, This Bulletin, **43**, 736 (1970).

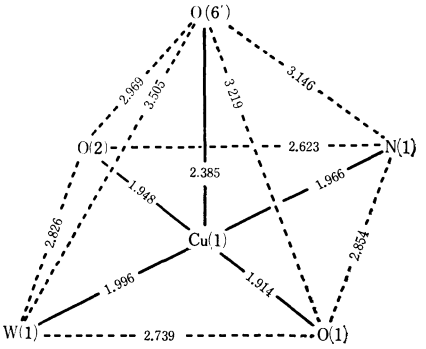

Fig. 3. Five ligand atoms disposed around the copper atom in the molecule I; bond distances are given in Å.

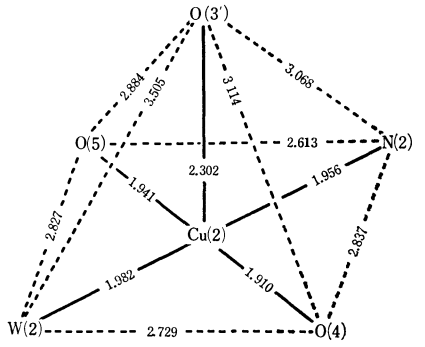

Fig. 4. Five ligand atoms disposed around the copper atom in the molecule II; bond distances are give in Å.

in the case of SGCH, while in SGCT and pyruvidene-β-alaninatoaquocopper(II) dihydrate it is formed by a water oxygen atom.

The Cu–O distances are 1.914 and 1.948 Å in the molecule I, and 1.910 and 1.941 Å in the molecule II, all shorter than those found in SGCH and SGCT. Cu–O distance is 1.966 Å in the molecule I and 1.956 Å in the molecule II, both values being longer than those found in SGCH and SGCT. The Cu–W (W represents the water oxygen atom) distance is 1.966 Å in the molecule I and 1.982 Å in the molecule II. These values are longer than that of 1.965 Å in SGCT, but shorter than that of 2.016 Å in SGCH. The fifth coordinating atoms, O(6'') and O(3'), lie at the apex of the square pyramid at distances of 2.385 and 2.302 Å respectively from the copper atoms in the molecules I and II.

The Cu–O' bond (O' means the apical oxygen atom mentioned above) makes an angle of 80.5° in the molecule I, and one of 79.1° in the molecule II, with the plane of the square base. In the present work, no significant displacement of the Cu atom toward the apical oxygen atom was observed such as is found in the cases of SGCH and SGCT. The angles of N(1)–Cu(1)–O(1) and N(1)–Cu(1)–O(2) in the molecule I are 94.7 and 84.2° respectively. The corresponding angles of N(2)–Cu(2)–O(4) and N(2)–Cu(2)–O(5) in the molecule II are 94.4 and 84.2°. These values are in good agreement with those observed in SGCH and SGCT. The other bond lengths and angles generally agree well with those found in SGCH and SGCT, except for the bond distances around the nitrogen

atoms.

Kakudo and his co-workers[5] concluded, from their consideration of the bond distances, that the N–C single bond and the N=C double bond in SGCT are electron-rich.

In the present work, the N–C single bonds have normal values, and the N=C double bonds are rather shorter than the normal double bond distance (1.29—1.30 Å), while in SGCT and SGCH the N–C bonds are rather shorter than the normal values (1.47—1.49 Å) and the N=C bonds are normal. Thus, such bulky groups as *t*-methyl will certainly affect the bonds around the nitrogen atom of the Schiff-base linkage.

The molecules may be described in terms of a set

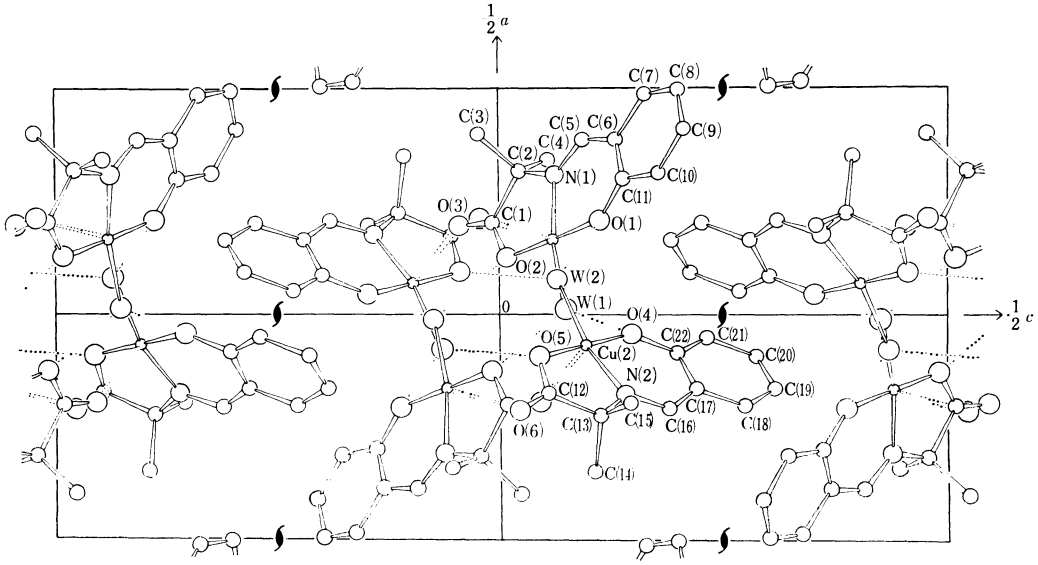

Fig. 5. Projection of the unit cell contents on the (010) plane.

of various plane groups. Tables 5 (molecule I) and 6 (molecule II) list the equations for various least-square planes and the deviations of the atoms therefrom. The largest deviation of any atom from the plane P(1), determined in any of the atoms of the molecule I (except for the two methyl groups) is 0.26 Å for the O(1) atom, whereas it is −0.38 Å for the W(2) atom in the molecule II. Thus, the planarity of the molecule I is slightly better than that of the molecule II, in which several atoms deviate by more than 0.3 Å from the plane. The plane through the α-aminoisobutyrate residue, P(3), and the one containing the salicylaldimine residue, P(5), make dihedral angles of 4.5° in the molecule I and 3.8° in the molecule II; these angles are considerably smaller than the corresponding values of 9.5° in SGCH and 16.5° in SGCT.

The structure projected upon a plane normal to the *b*-axis is shown in Fig. 5. The important intermolecular contacts are listed in Table 7.

The molecules are alternately linked together by the fifth coordination bonds described above to form zigzag chains along the *b*-axis. Two of these zigzag chains are related by the centres of symmetry and are bound laterally by the hydrogen bonds, indicated by dotted lines in Fig. 5. However, there is no interaction other than the van der Waals forces along the *a*- and *c*-axes.

Infrared Absorption Spectra of Silica Gel - $H_2{}^{16}O$, $D_2{}^{16}O$, and $H_2{}^{18}O$ Systems

Masao HINO and Toshio SATO

Government Industrial Development Laboratory, Hokkaido, Higashi-Tsukisamu, Sapporo

(Received July 4, 1970)

Infrared absorption spectra of the systems of silica gel - $H_2{}^{16}O$, $D_2{}^{16}O$, $H_2{}^{18}O$, and some organic vapors were measured in order to assign the bands sensitive to adsorption at 870 and around 950 cm^{-1}. Deuteration of silica gel caused the absorption decrease at 870 cm^{-1} and the appearance of a band at 620 cm^{-1}. The band around 950 cm^{-1} appearing by adsorption not only of water but also of organic vapors showed no shift on deuteration, but shifted toward low frequency side by 25 cm^{-1} on the substitution of ^{16}O of surface silanol groups with ^{18}O. From these facts the bands at 870, 620 and 950 cm^{-1} were assigned to Si–OH bending, Si–OD bending and Si–O stretching vibrations of surface silanol groups, respectively. The oxygen atom of silanol groups of silica gel was found to exchange with that of adsorbed water molecules even at room temperature for a sample treated at temperature below 300°C. On the other hand, higher reaction temperature of *ca.* 200°C was necessary for a sample calcined at 800°C. Mechanism of the oxygen atom exchange reaction was discussed.

A number of investigations have been carried out to elucidate the structure and properties of silica gel surface by use of infrared spectroscopy.[1-3] They were concentrated on measurement of the OH stretching band between 4000 and 2500 cm^{-1}. However, there are very few investigations in other spectrum regions.

Beutelspacher[4] first pointed out that a wet silica gel had a 950 cm^{-1} band, which vanished by heat treatment at 1000°C. Soda[5] also found a 950 cm^{-1} absorption band sensitive to desiccation for a finely ground quartz powder sample. He assumed that it was due to the bending vibration of Si–OH groups on the surface of the particles. On the other hand, Benesi and Jones[6]

assigned this bending vibration to the band at 870 cm^{-1}, from the fact that it disappeared on deuteration.

The purpose of the present work is to establish the assignment of these two bands more directly by measuring the isotopic shift in wider frequency region when H and ^{16}O atoms of silica gel are substituted with D and ^{18}O atoms, respectively, and also by measuring the adsorption effects of various vapors on the surface. The reactivity of the silica gel surface was also studied through the exchange reaction of water with surface silanol groups.

Experimental

Materials. Silica gel for chromatography (Kanto Chemical Co., Inc.) made from sodium silicate and sulfuric acid was ground in an agate mortar and then suspended in deionized water to get a very fine powder sample. The surface area of this material was 450 m^2/g, independent of the heat treatment at temperature lower than 600°C. $D_2{}^{16}O$ (Showa Denko Co., Ltd.) of 99.75 atom % in purity and $H_2{}^{18}O$ (Yeda R. & D., Co. Ltd.) of 97.9 atom % were used. Methanol, diethyl ether, acetone, and carbon disulfide, all of guaranteed reagent grade, were dried, distilled and degassed before the adsorption experiment. Pure hydrogen sulfide (Takachiho Chemical Industrial Co.) was used without further purification

Apparatus and Procedure. A JASCO Model 402-G double beam infrared spectrometer was used for recording the spectra in the wave number region between 4000 and 430 cm^{-1}. An all metal *in situ* cell used for measurement at room temperature is shown in Fig. 1. Another infrared cell with liquid nitrogen cooling system was also constructed by modifying the cell in Fig. 1 for measuring the adsorption of organic vapors and hydrogen sulfide at lower temperature down to −130°C.

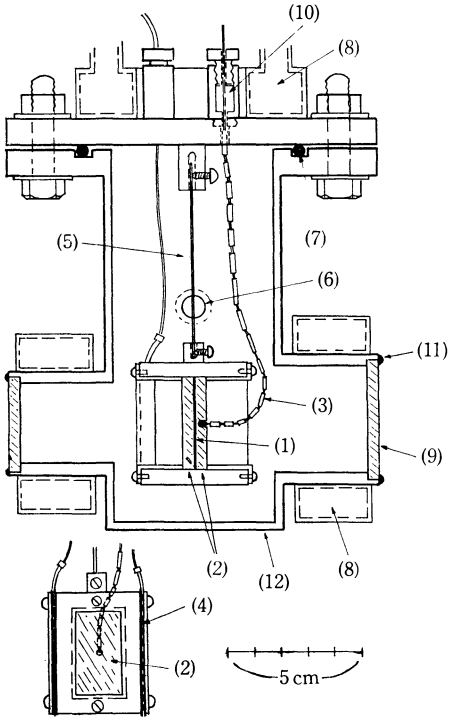

Fig. 1. All metal *in situ* cell.

A sandwich method was used for sample preparation; 6 to 20 mg of silical gel powder dispersed in a few drops of methanol was spread on the transparent KBr plate of 34 mm × 12 mm × 4 mm. After the methanol was evaporated, the silica powder on the plate was made even with a spatula and sandwiched by facing another KBr plate on the sample. As far as infrared spectrometer was used as a monitor, the silica gel was found not to react with methanol during the course of preparation. A vacuum reference cell was set in the light path of the reference side to eliminate the background effect of the spectra. To prepare a sufficiently deuterated silica gel sample, the sample was exposed to $D_2{}^{16}O$ vapor at 10 mmHg for 30 min and then evacuated, both at room temperature. The procedure was repeated six times.[6,7]

Results

1. Silica Gel - $H_2{}^{16}O$ System. Measurement of the spectra was carried out on the silica gel sample after evacuation at various temperatures and also on successive exposure to water vapor at room temperature. As shown in Fig. 2, evacuation at room temperature gave marked decrease of the OH stretching band at 3400 cm^{-1} and the HOH bending band at 1630 cm^{-1}, which were attributed to the hydrogen-bonded hydroxyl groups and physically adsorbed water molecules, respectively. A simultaneous decrease of the absorption at 950 cm^{-1} was observed, while the absorption at 870 cm^{-1} increased in intensity and a sharp OH stretching band at 3748 cm^{-1} due to the "free" silanol groups appeared. Evacuation at elevated temperatures, as represented by Curves 4 and 6 in Fig. 2, produced a similar but stronger effect in the spectral changes, although the band at 870 cm^{-1} exceptionally decreased in intensity. Admission of water vapor on these evacuated surfaces produced the reverse effect on the spectral changes (Curves 3, 5, and 7). However, these five absorptions were completely restored only when the sample was evacuated at room temperature (Curve 3). A small band shift from 950 to 960 cm^{-1} was observed, when the sample was evacuated at 200 and 300°C and then rehydrated at room temperature.

Organic vapors and hydrogen sulfide, which have no absorption around 960 cm^{-1}, were then admitted at low temperatures onto the silica gel samples evacuated at 200°C. In each case, as seen in Table 1, bands were found to come out around 960 cm^{-1} and in the wave number region from 3680 to 3300 cm^{-1}, the peak positions depending on the kind and the amount of adsorbate.

2. Silica Gel - $D_2{}^{16}O$ System. Appearance of a strong ^{16}OD stretching band at 2480 cm^{-1} together with the disappearance of the bands of ^{16}OH at 3400 and 1630 cm^{-1} after deuteration confirmed that the deuteration of the present silica gel sample was completed.[6,7] It should be emphasized that this treatment induced no spectral change at the 950 cm^{-1} band and

a) Not distinguishable from the OH stretching band of CH_3OH.

also much decrease of the absorption at 870 cm^{-1}. On evacuation of the sample at elevated temperatures, the band intensity at 950 cm^{-1} decreased and a new band grew up at 620 cm^{-1} (Curve 3 in Fig. 3). Introduction of $D_2{}^{16}O$ vapor to this evacuated sample gave a reverse spectral change, although the band at 950 cm^{-1} finally settled down to 960 cm^{-1} as in the case of silica gel - $H_2{}^{16}O$ system. The original spectra illustrated in Fig. 2 were restored by treating the deuterated sample with light water vapor.

3. Silica Gel - $H_2{}^{18}O$ System. A preliminary experiment showed that the introduction of $H_2{}^{18}O$ to a silica gel sample evacuated at 300°C for several hours gave small but definite isotopic shifts at the 3750 and 950 cm^{-1} bands, but not at any other bands. Evacuation and introduction of $H_2{}^{18}O$ were then repeated in the order from Curve 1 to Curve 12 in Fig. 4 in order to observe more precise spectral changes with time. As illustrated by Curve 3 of Fig. 4 (b), the band at

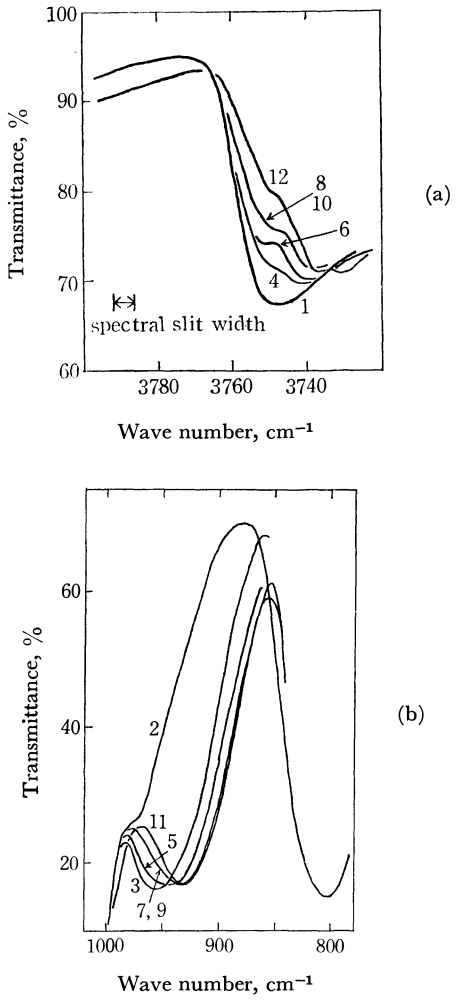

Fig. 4. Spectra of silica gel - $H_2{}^{18}O$ system.
1, evacuated; 2, evacuated at 200°C; 3, exposed to $H_2{}^{18}O$ vapor for 6 min; 4, evacuated; 5, exposed to $H_2{}^{18}O$ vapor for 25 min; 6, evacuated; 7, exposed to $H_2{}^{18}O$ vapor for 40 min; 8, evacuated; 9, exposed to $H_2{}^{18}O$ vapor for 100 min; 10, eavcuated; 11, exposed to $H_2{}^{18}O$ vapor at 100°C for 1 hr and cooled to room temperature in the vapor atmosphere; 12, evacuated.
Evacuation was conducted at room temperature for 5 hr and $H_2{}^{18}O$ vapor of 10 mmHg was introduced also at room temperature unless otherwise described.

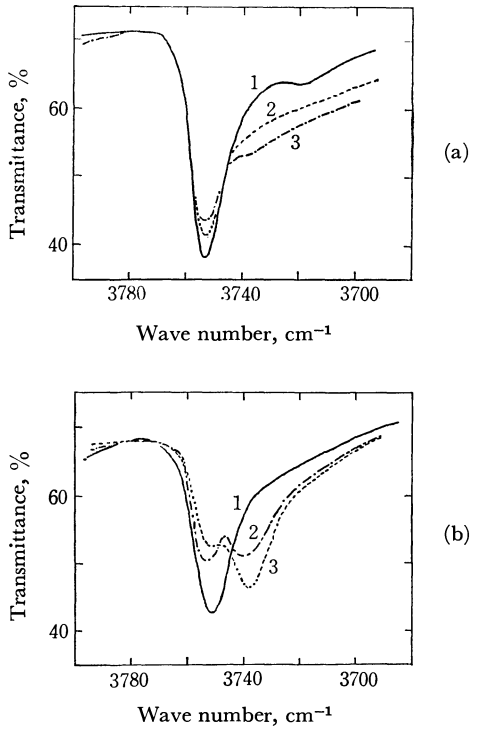

Fig. 5. Spectral changes in free OH stretching band of silica gel calcined at 800°C on exposure to $H_2{}^{18}O$ vapor at room temperature (a) and at higher temperatures (b).
a) before exposure (1), exposed to $H_2{}^{18}O$ vapor for 25 min (1), 2 hr more (2), 15 hr more (3), and 15 hr more (3). Each spectrum was recorded after evacuation at room temperature.
b) before exposure (evacuated at room temperature) (1), exposed to $H_2{}^{18}O$ vapor at 200°C for 20 hr and evacuated at room temperature (2), exposed at 260°C for 8 hr and evacuated at the same temperature (3).

960 cm^{-1} was produced immediately after the introduction of $H_2{}^{18}O$ at room temperature. This band, however, shifted to the lower wave number side with time and reached almost a steady value of 935 cm^{-1} after about 70 min. Successive treatment with $H_2{}^{18}O$ at 100°C gave more shifts, as seen in Curve 11. In a quite similar way, a new band around 3740 cm^{-1} grew up in accordance with the decrease of the OH stretching band at 3748 cm^{-1} with time and reached a steady state after 70 min (Curves 8 and 10, Fig. 4(a)). Treatment with $H_2{}^{18}O$ at 100°C gave a more distinct spectral change, as seen in Curve 12.

The exchange reaction with $H_2{}^{18}O$ was also conducted on a silica gel sample preliminarily calcined at 800°C for 30 hr, which gave very sharp free OH absorption on account of almost complete lack of background due to the broad hydrogen-bonded OH absorption around 3600 cm^{-1}. After the sample was evacuated at room temperature, it was exposed in $H_2{}^{18}O$ vapor at room temperature. As seen in Fig. 5(a), the free ^{16}OH absorption at 3751 cm^{-1} decreased very slowly in intensity and reached a steady state after 17 hr. A very small ^{18}OH absorption at 3737 cm^{-1} was observed. The result confirmed that the oxygen of the surface silanol groups was only partially exchanged by oxygen of $H_2{}^{18}O$ in adsorbed state at room temperature. Figure 5(b) shows the result on the same sample exposed in $H_2{}^{18}O$ vapor at 200 and 260°C and then evacuated. It turned out that the higher the temperature treatment with $H_2{}^{18}O$ the more promoted the oxygen exchange reaction.

Discussion

1. Assignment of the Bands at 960 and 870 cm^{-1}. The band at 870 cm^{-1} can definitely be attributed to the bending vibration of free Si–O–H groups on the surface, because the band increased in intensity on evacuation, at least at room temperature, and shifted to the position of 620 cm^{-1} on deuteration, its frequency being almost consistent with that calculated under the assumption that the band at 870 cm^{-1} was associated with Si–O–H bending vibration and that this can be

* Adsorption sensitive bands. **The band was so broad that an accurate determination of the small isotope shift was impossible.

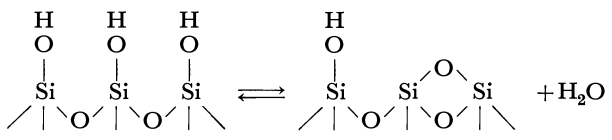
treated by a simple harmonic oscillator model (Table 2).

The band at 960 cm^{-1} is conclusively assigned to the Si–O stretching vibration in surface silanol groups because of the following evidences. 1) No hydrogen isotopic effect was observed for this band. 2) The free OH stretching band and this band shifted quite simultaneously during the course of oxygen exchange reaction. 3) The observed values of the oxygen isotopic shift for these two bands were in harmony with those calculated according to a simple harmonic oscillator model, as illustrated in Table 2.

It should be pointed out, however, that no shift of the band at 960 cm^{-1} was observed immediately after the introduction of $H_2{}^{18}O$ on a silica gel sample. In other words, the band at 960 cm^{-1} was produced by rapid adsorption of $H_2{}^{18}O$ on the surface as in the case of $H_2{}^{16}O$ - silica gel system and then shifted gradually with the progress of the exchange reaction. The band is thus expected to be induced indirectly by the hydrogen bond formation of Si–OH with adsorbed water. This explanation was supported by the fact that the band around 960 cm^{-1} was produced by the introduction of various organic vapors which formed more or less hydrogen bonding with silanol groups. Such a stretching vibration sensitive to hydrogen bonding is not so strange; it is known that Si–O stretching vibration in silanol compounds[8] as well as C–O stretching vibration in alcohols[9] have a big dilution effect in nonpolar solvents.

We can safely rule out the possibility that the two bands at 960 and 870 cm^{-1} are associated with the overtone and combination of Si–O skeletal vibration, judging from their position and sensitivity to adsorption.

2. Reactivity of Silica Gel Surface. Mills and Hindin[10] have concluded indirectly from mass spectrometric analysis that the oxygen exchange reaction between surface silanol groups of silica gel and water takes place at a temperature above 100°C. The present work confirmed directly that the reaction proceeded considerably, but not completely, at room temperature on a silica gel treated at a low temperature below 300°C. Such a silica gel is readily dehydrated and rehydrated. The result can be explained as a consequence of the repetition of these two reactions according to the following scheme hitherto accepted[1]



viz., the production of strained siloxan type species and some free OH groups from the clusters of OH groups adjacent to each other and the reverse reaction. Incomplete exchange of oxygen in the present case would be due to the presence of some genuinely free silanol groups, predominant for the silica gel treated at such a high temperature as 800°C.

Studies on the Electronic Spectra of the Semiquinones of Anthracene and Its Related Heterocycles. II

Hiroshi MASUHARA,[1] Michio OKUDA, and Masao KOIZUMI
Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai
(Received July 9, 1970)

The electronic structures of semiquinones of anthracene and its related heterocycles were calculated, using the open shell SCF procedure combined with configuration interaction calculations. A general classification and some peculiarities of the observed absorption spectra of these semiquinones can be readily explained by the present theoretical results. The effects of resonance integral and configuration interactions were examined in detail. The results obtained by considering the effect of hyperconjugation were added.

Semiquinones have been considered as reaction intermediates in photochemical reactions of aromatic compounds such as acridine dyes, xanthene dyes and triphenylmethane dyes. The photochemical behaviors and absorption spectra of anthracene semiquinone and its heterocycles have previously been reported.[2]

The absorption spectra of these semiquinones are classified into three groups; 1) the first band at 250 nm (4.9 eV in transition energy), 2) the second band at 350 nm (3.5 eV), and 3) the third band in the visible region (2.3—2.8 eV). However, some semiquinones have special features, *i. e.*, 1) anthracene semiquinone has no visible absorption, 2) acridine-*N* semiquinone has no first band, and 3) acridine-*C* semiquinone has a prominent peak at 281 nm.

Theoretical consideration of the electronic structures of their excited states is necessary for the assignment of each band. However, the electronic structures have not been reported because of the complexity of the treatment required for an open shell system.

Pople and Longuet-Higgins have proposed the method of semi-empirical SCF MO calculation with zero differential overlap approximation for open shell system and have calculated the transition energies of the benzyl radical.[3] The calculated energies are higher than the observed ones. Configuration interaction would be more important for the calculation of transition energies of open shell systems than for those of closed shell systems, as shown for the anion radicals of substituted benzenes.[4]

In this paper transition energies and oscillator strengths of the π-π^* transitions of anthracene semiquinone and its heterocycles will be reported and the assignment of absorption bands of the semiquinones will be decided by comparing those values with observed values.[2] The calculations were carried out with appropriate values of reasonance integrals β's. They were chosen by examining the effect of resonance integrals on the transition energies of anthracene anion radical, xanthene semiquinone, anion and cation radicals of six membered *N*-heterocycles. The effect of hyperconjugation of CH_2 group in the aromatic ring will be also examined for anthracene semiquinone and acridine-*N* semiquinone.

Method of Calculation

The method of calculation can be divided into two parts: 1) determination of LCAO-MO's by means of the semi-empirical open shell SCF method proposed by Pople and Longuet-Higgins,[3] and 2) generation of the spectroscopic states by configuration interaction.

The molecular orbitals obtained are the eigenfunctions of the Schrödinger equation

$$F\varphi_i = E_i\varphi_i \tag{1}$$

where F is the SCF Hamiltonian operator, E_i is the energy of ith molecular orbital. This equation can be derived by neglecting electronic repulsion integrals between the half occupied molecular orbital φ_m and other orbitals φ_i: (mi mm). The elements of the energy matrix (F) are given by the formulae

$$F_{pp} = -I_p + 0.5\times P_{pp}\times(pp\ pp) + \sum_{q\neq p}(P_{qq}-Z_q)\times(pp\ qq)$$
$$F_{pq} = \beta_{pq} - 0.5\times P_{pq}\times(pp\ qq) \tag{2}$$

where I_p and Z_p represent the ionization potential and the number of π electrons released from pth atom, respectively. The values of ionization potential and electron affinity of the π electron in the appropriate valence state are taken from the table of Pilcher and Skinner.[5]

Z_p is 1 for –C=, –N= and =O; is also 2 for –O– and –N–. Electronic Coulombic repulsion integrals between two atomic orbitals (pp qq) and resonance integrals β_{CX} were calculated using the Pariser-Parr approximation.[6]

The ground state and four types of excited states of the semiquinones are constructed as follows:

$$^2\Psi_G = |\varphi_1\bar{\varphi}_1\cdots\varphi_{m-1}\bar{\varphi}_{m-1}\varphi_m| \qquad G$$
$$^2\Psi_A = |\varphi_1\bar{\varphi}_1\cdots\varphi_i\bar{\varphi}_m\varphi_{m-1}\bar{\varphi}_{m-1}\varphi_m| \qquad A(i\text{–}m)$$
$$^2\Psi_B = |\varphi_1\bar{\varphi}_1\cdots\varphi_{m-1}\bar{\varphi}_{m-1}\varphi_k| \qquad B(m\text{–}k)$$
$$^2\Psi_{CA} = (|\varphi_1\bar{\varphi}_1\cdots\varphi_i\bar{\varphi}_k\cdots\varphi_{m-1}\bar{\varphi}_{m-1}\varphi_m| + |\varphi_1\bar{\varphi}_1\cdots\varphi_k\bar{\varphi}_i\cdots\varphi_m|)/\sqrt{2} \qquad CA(i\text{–}k)$$
$$^2\Psi_{CB} = (2|\varphi_1\bar{\varphi}_1\cdots\varphi_i\varphi_k\cdots\varphi_m| - |\varphi_1\bar{\varphi}_1\cdots\varphi_i\bar{\varphi}_k\cdots\varphi_m| - |\varphi_1\bar{\varphi}_1\cdots\varphi_k\bar{\varphi}_i\cdots\varphi_m|)/\sqrt{6} \qquad CB(i\text{–}k) \tag{3}$$

where simple notations in the right column represent configurations in the left column, and i and k denote occupied and vacant orbitals, respectively.

Formulas of the transition energies and transition dipole moments are given in Ref. 3.

In the second step, configuration interaction calculations were carried out for 12 or 13 configurations of A and B types of singly excited states, and for 44 or 45 configurations of A, B, CA and CB types of singly excited states. The oscillator strength of each transition was evaluted by the equation

$$f = 1.085 \times 10^{-5} \times E \times M^2 \qquad (4)$$

where E represents the transition energy in cm^{-1} and M a transition dipole in Å.

Most calculations were carried out on the electronic computer HITAC 5020 in the electronic computer center of the University of Tokyo. The solution of CI determinant and other supplemental calculations were performed on the electronic computer NEAC 2230 in Tohoku University.

Parameterization: Effect of Resonance Integral

Calculated values of transition energies do not agree with observed ones in an open shell system as well as in a closed shell system. This discrepancy may be adjusted to some extent by the choice of the best experimental value of resonance integral, and by consideration of many configurations in the configuration interaction. The effects of both resonance integral and configuration interaction were examined carefully for some of the semiquinones and hydrocarbon anion radicals.

The Effect of Resonance Integral β_{CC}. The transition energies of the anthracene anion radical were calculated using the ordinary value of resonance integrals and by consideration of 13 excited configurations. The C–C bond distance and bond angles were taken as 1.39 Å and 120°, respectively. The value of β_{CC} used is −2.39 eV which corresponds to that of the neutral molecule. Using this value we obtained better agreement with the observed values. The results are shown in Table 1. Consequently, the value of β_{CC} for the neutral molecule was used in the following calculations.

The Effect of β_{CX}. The transition energies of xanthene semiquinone were calculated using different β_{CO}'s (Fig. 1). Lower energy levels decrease and higher energy levels increase with the increase in the absolute value of resonance integral β_{CO}. The magnitude of the shift is about 0.2 eV for lower levels, which is within the accuracy of approximation in the calculations.

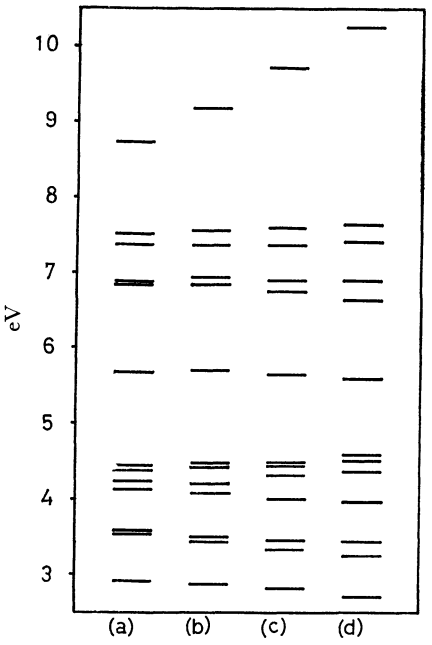

Fig. 1. The transition energies of xanthene semiquinone.
(a) $\beta_{CO} = -1.667$ eV (b) $\beta_{CO} = -1.945$ eV
(c) $\beta_{CO} = -2.223$ eV (d) $\beta_{CO} = -2.501$ eV

Small and more fundamental radicals such as anion and cation radicals of six-memberd *N*-heterocycles, allyl derivatives and pentadienyl derivatives were also used for examination of the effect of β_{CN} (Fig. 2). Although in the case of xanthene semiquinone the larger absolute value of β_{CO} gives the lower transition energies in ultraviolet region, the results for these radicals show the reverse effect. Thus, it is difficult to explain theoretically the shift of transition energy with the change of resonance integral. Consequently, the values of β_{CX} used in the calculations for semiquinones are also those for the neutral molecules.

Effect of Configuration Interaction

The results for the naphthalene anion radical with a different number of excited configurations in CI calculations are given in Table 2. This radical was chosen as a model for the examination of the effect of CI because it is intermediate in complexity between the benzyl radical and anthracene semiquinone. Our calculation of CI included 9 configurations of states A and B, and explained the observed absorption spectra rather well. The calculation including 29 configurations of states A, B, CA, and CB by Ishitani and Nagakura was more successful for explaining the transition energies.[4]

The contribution of states CA and CB becomes more

important for anthracene semiquinone and its heterocycles. Calculation of 12 or 13 configurations of states A and B could not explain the observed results. Generation of the spectroscopic states by including a number of configurations is indispensable for the calculations.

Results and Discussion

Transition energies and oscillator strengths of anthracence semiquinone and its heterocycles have been calculated with the same resonance integral as neutral molecules and also using the 44 or 45 configurations of singly excited states A, B, CA, and CB. The results are given in Table 3. The number of π electron in the semiquinones are 13 for anthracene and acridine-*N* semiquinones, and 15 for acridine-*C*, xanthene, and phenazine semiquinones. Molecular structures of these semiquinones assumed from a consideration of the experimental results are shown in Fig. 3 together with

the values of bond distances and bond angles. All the molecules are assumed to be planar. Calculated π–π^* transitions of these semiquinones can be divided into three groups. The first consists of strong transition (f=1.0) of about 6 eV transition energy, the second of moderate transitions (f=0.5—1.0) of about 4 eV and third of weak transitions of less than 3 eV. The calculated transitions correspond very well to the three groups of observed absorption bands. Discrepancies between theoretical and experimental results become smaller for lower transition energies. The magnitude of difference is about 1 eV for the 250 nm band (transition energy 4.9 eV), about 0.6 eV for the 350 nm band (3.5 eV) and 0.5 eV for the visible band (2.5 eV). The strong absorption band at 250 nm may be assigned to the π–π^* transition to the excited state, to which the CA configuration contributes predominantly. The other two bands may be assigned to the transition to the excited state which is a mixture of configurations A and B. By elimination of configurations which contribute to a small extent, each excited state can be expressed as follows.

$$\Psi(350\text{ nm}) = a\Psi_A - b\Psi_B$$
$$\Psi(\text{visible}) = b\Psi_A - a\Psi_B$$

The energy level of a half-occupied molecular orbital in an alternant hydrocarbon radical is located exactly in the center of the highest fully occupied orbital and the lowest vacant orbital, and then energies of configurations A and B are equal. When a carbon atom in this radical is replaced by a nitrogen atom, the half-occupied orbital is stabilized and its energy falls below its original level. The coefficient a for an alternant hydrocarbon radical is equal to $-b$, as proposed by Pople and Longuet-Higgins,[3] and thus f(visible) should be zero. This consideration explains well the experimental fact that anthracene semiquinone has no visible band. The line of argument is correct in the calculation which considers many configurations in CI calculations. The calculated oscillator strength of the visible band for anthracene semiquinone is 0.0000.

For heterocyclic radical, a is not equal to b, and f(visible) does not disappear. This is the reason why acridine-*N* semiquinone radical has a weak band in the visible region. It is possible to assign this weak band to a lone pair of N atom–π^* transition, but we have no evidence to show this.

The 350 nm and visible bands of acridine-*C*, phenazine and xanthene semiqunones are similarly interpreted, noting the difference of the number of molecular orbitals.

A special band at 281 nm of Acridine-*C* semiquinone can be assigned to the transition, whose excited state consists of CB(7—9) configuration predominantly and both CA(7—9) and A(6—8) configurations in a few percent. Although the transition to CB configurations is forbidden, this 281 nm transition has a moderate oscillator strength due to the contribution of CA(7—9) and A(6—8) configurations which have larger transition moments. A similar phenomenon can be expected in phenazine semiquinone, though this spectrum has not yet been observed.

The oscillator strength of the band at 250 nm for acridine-*N* semiquinone is 0.19 and much smaller than for other semiquinones. Thus, the other type of acridine semiquinone which has no band at 250 nm can be identified as acridine-*N* semiquinone.

The observed spectra of semiquinones are well explained by the present theoretical studies.

The Effect of Hyperconjugation

In the above section 13π type semiquinone structures were assumed for anthracene and acridine-*N* semiquinone, excluding the methylene group from the π-electron conjugated systems. The opposite extreme case is the one where electrons in the methylene group flow out to the π-electron conjugated systems. In this case it is appropriate to take the concept of hyper-

NOTES.

1) The notations I, II, III, and IV in the tables, represent the groups of theoretical transition energies and differ from those appearing in the text.
2) In each group the observed bands are tentatively assigned to the theoretical bands whose f_{cal}'s are large.
3) R. I. denotes the relative intensity of observed band, the highest energy band being taken as a standard. It is easily estimated without precise molecular extinction coefficients.
4) As no data on phenazine semiquinone have been obtained for precise comparison, those on ethylphenazil are compared with theoretical results.
5) The transition with direction x is polarized along the long axis direction.

conjugation of methylene group into consideration. Here the 15π electron model was adopted for these semiquinones and the semi-empirical parameters used are the same as those reported by Morita.[9] This model treats the methylene group as a methylene cation. The real state of semiquinone molecule should be somewhere between these two models, which define the limits of delocalization of methylene electrons.

First the calculated orbital energies are compared with those of 13π electron models. The effect of hyperconjugation on transition energies appears on the orbitals, which have nothing to do with the observed electronic transitions. The difference of the orbital energies of the half-occupied orbitals in the 13π and 15π models is small (about 0.1 eV).

9) T. Morita, This Bulletin, **33**, 1486 (1960).

Calculated transition evergies and oscillator strengths are given in Table 3. The configurations included are 15 (cofigurations A and B) and the assignment of the 250 nm peak is omitted. The calculated intensity of the absorption polarized along the short axis direction is stronger in the 15π model. In the configurations of types A and B, calculated results are in better agreement with experimental ones in the 15π model than in the 13π model for both semiquinones. From the consideration of wave functions, it is concluded that the charge density of unpaired electron is lowered and more delocalized than that predicted by the 13π model. Although the larger conjugated systems, *i. e.* 15π model, have lower absorptions in general, it may be said that the unpaired electron and the electrons of methylene group are delocalized to some degree in anthracene and acridine-*N* semiquinones.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 43—48 (1971)

Modified INDO Calculations of the Electronic Structure of Organic Molecules. I. Electronic Excitation Energies of Some Carbonyl Compounds and Conjugated Dienes

Kizashi YAMAGUCHI and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received July 15, 1970)

The semi-empirical valence-shell SCF MO theory (the INDO method) by Pople *et al.* has been modified for the purpose of calculating the electronic excitation energies of organic compounds. All the necessary one-center parameters have been evaluated from the valence-state ionization data of Hinze and Jaffé, combined with the Slater-Condon atomic parameters. The INDO method thus modified has been applied to carbonyl compounds and conjugated dienes. The calculated excitation energies have been found to be satisfactory in many respects.

The all-valence-electrons SCF MO theory with intermediate neglect of differential overlaps (the INDO method) proposed by Pople *et al.*[1] is currently of gaining recognition as a promising route to theoretical estimation of dipole moments and unpaired spin distributions of various molecular species. Baird and Dewar[2] have modified the INDO method in order to calculate heats of formation and molecular geometry with "chemical" accuracy. This marked success of the theory in predicting the ground-state properties of molecules now urges chemists to explore the applicability of this theory to the calculations of electronic excitation energies of organic compounds.

Along the above line, Giessner-Prettre and Pullmann[3] have already examined the INDO method in its original form and found that the calculated transition energies are generally too great compared with the observed, despite extensive configuration interaction treatments. Thus, in order to be capable of reproducing the energies in fair agreement with observation, one is now required to take due consideration of electronic correlations, which have apparently been left out of account in the original INDO approximation.

One of the best approaches to the above problem will be a procedure involving semi-empirical evaluations of the two-electron repulsion integrals from the atomic spectroscopic data. The strategy is essentially the one that has already received wide acceptance in connection with the π-electron SCF MO theory of the Parier-Parr-Pople type.[4] Recently, Bene and Jaffé[5]

have coupled this empiricism with Pople's simplest version of the all-valence-electrons SCF MO theory (the CNDO method)[6] Kato *et al.*[7] have also availed the empiricism in evaluating various integral parameters to be used in their own valence-shell theory analogous to the INDO method. In both these treatments, the transition energies obtained for various organic compounds are in satisfactory agreement with observation.

In this paper, a modification of the INDO method will be presented in order to calculate the excitation properties of conjugated compounds. All the necessary one-center parameters have been evaluated from the data for the valence-state ionization potentials and electron affinities compiled by Hinze and Jaffé,[8] in combination with the Slater-Condon atomic parameters.[1a] The procedure adopted for this parametrization is much the same as that in the MINDO method presented by Baird and Dewar.[2a] Our specific aim of the present treatment is to assess the applicability of the modified INDO theory to the calculations of electronic excitation energies of conjugated compounds, especially those of geometrical isomers. The results appear to be encouraging in most cases here investigated.

Method of Calculations

Since the INDO formulation has been described in detail by Pople *et al.*,[1a] there is no need to duplicate it here. Suffice it here to note that the Hamiltonian matrix elements for closed shell systems are given as follows:

$$F_{\mu\mu} = U_{\mu\mu} + \sum_{\lambda}^{A} [P_{\lambda\lambda}(\mu\mu|\lambda\lambda) - \frac{1}{2}P_{\lambda\lambda}(\mu\lambda|\mu\lambda)] + \sum_{B\neq A} (P_{BB} - Z_B)\gamma_{AB} \qquad (\mu \text{ on atom A}) \quad (1)$$

$$F_{\mu\nu} = \frac{3}{2}P_{\mu\nu}(\mu\nu|\mu\nu) - \frac{1}{2}P_{\mu\nu}(\mu\mu|\nu\nu) \qquad (\mu\ \nu, \text{ both on atom A}) \quad (2)$$

$$F_{\mu\nu} = \beta_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{AB} \qquad (\mu \text{ on atom A and } \nu \text{ on atom B}) \quad (3)$$

where P_{BB} and $P_{\mu\mu}$ are the atomic and orbital charge densities, respectively; $P_{\mu\nu}$ is the orbital bond order; Z_B is the core charge on atom B; γ_{AB} is the two-center electron repulsion integrals; $(\mu\mu|\lambda\lambda)$ and $(\mu\lambda|\mu\lambda)$ are one-center Coulomb and exchange integrals, respectively; $U_{\mu\mu}$ is the one-center core-electron attraction integral; and $\beta_{\mu\nu}$ is the core resonance integral.

In calculating the transition energies and moments, we have adopted the conventional virtual orbital approximations. The energies required to promote an electron from orbital i to virtual orbital j are given by the following expressions for singlet and triplet states, respectively:[5a]

$$\Delta^1 E = \varepsilon_j - \varepsilon_i - J_{ij} + 2K_{ij} \quad (4)$$

$$\Delta^3 E = \varepsilon_j - \varepsilon_i - J_{ij} \quad (5)$$

where ε_j and ε_i are the energies of the jth and ith molecular orbitals, and where J_{ij} and K_{ij} are the molecular Coulomb and exchange integrals. The dipole moment length for the i–j singlet-singlet transition is given by

$$M_{i-j} = 2\sum_{A}^{N}\sum_{\mu}^{A}\sum_{\nu}^{A} C_{i\mu}C_{j\mu}(\mu|\boldsymbol{r}_A|\nu) \quad (6)$$

where $\boldsymbol{r}_A$ is the coordinate vector operator of atom A.

Refinements of the transition energies by the configuration interaction treatments were not performed in the present calculations. For the geometries of the treated compounds, latest data from Ref. 9 were adopted. The solutions of the Hartree-Fock equations were required to be self-consistent to within 0.001 of all the resulting eigenvalues.

The above procedure was programmed in FORTRAN, and computations were carried out on the FACOM 230-60 Computer at the Kyoto University Computation Center.

Evaluation of Integral Parameters

One-center Parameters. The one-center integrals appropriate to the present calculations are (i) the core-electron attraction integrals, U_{ss} and U_{pp}, (ii) the Coulomb integrals, $(ss|ss)$, $(ss|xx)$, $(xx|xx)$ and $(xx|yy)$, and (iii) the exchange integrals of the types $(sx|sx)$ and $(xy|xy)$. In the framework of INDO approximations, all these energies are related with the Slater-Condon atomic parameters G^1 and F^2.[1a] The principle that we adopt for the evaluation of these one-center integrals is exactly the same as that of Pople *et al.*,[1a] except that we now follow a different semi-empirical procedure in estimating the average one-center electron repulsion integral, F^0.

For a second-row atom X with n valence electrons, the empirical electron repulsion energies may be estimated from[10]

$$g_{ss} = [E(X^-, s^2p^{n-1}) - E(X, sp^{n-1})] - [E(X, sp^{n-1}) - E(X^+, p^{n-1})] \quad (7)$$

$$g_{sp} = [E(X^-, s^m p^{n-m+1}) - E(X, s^{m-1}p^{n-m+1})] - [E(X, s^m p^{n-m}) - E(X^+, s^{m-1}p^{n-m})] \quad (8)$$

$$g_{pp} = [E(X^-, s^m p^{n-m+1}) - E(X, s^m p^{n-m})] - [E(X, s^m p^{n-m}) - E(X^+, s^m p^{n-m-1})] \quad (9)$$

where m may be 0, 1, or 2 wherever appropriate. The various g values can be evaluated from the valence-state ionization data of Hinze and Jaffé.[8] In the case

of a valence-state carbon atom, for example, the g values are 12.10, 11.72, and 11.31 eV.

At the level of the INDO approximation, the empirical repulsion energies may be related with the Slater-Condon parameters by[11]

$$F^0(s,s) = g_{ss} \tag{10}$$

$$F^0(s,p) = g_{sp} + \frac{1}{6}G^1 \tag{11}$$

and

$$F^0(p,p) = g_{pp} + \frac{2}{25}F^2 \tag{12}$$

The parameter, F^0, for each atom with the ground state configuration, s^2p^{n-2}, may then be determined by averaging the values, $F^0(s,s)$, $F^0(s,p)$ and $F^0(p,p)$ over the electron pairs involved. Namely,

$$F^0 = \frac{1}{N}[F^0(s,s) + 2(n-2)F^0(s,p) + \frac{(n-2)(n-3)}{2}F^0(p,p)] \tag{13}$$

with

$$N = 1 + (n+1)(n-2)/2 \tag{14}$$

Using the F^0 values obtained as above and the G^1 and F^2 values given in Pople's INDO paper, the various two-electron parameters can be evaluated.

$$(ss\,|\,ss) = (ss\,|\,xx) = F^0 \tag{15}$$

$$(xx\,|\,xx) = F^0 + \frac{4}{25}F^2 \tag{16}$$

$$(xx\,|\,yy) = F^0 - \frac{2}{25}F^2 \tag{17}$$

$$(sx\,|\,sx) = \frac{1}{3}G^1 \tag{18}$$

$$(xy\,|\,xy) = \frac{3}{25}F^2 \tag{19}$$

The core-electron attraction integrals for atoms from boron to fluorine are[12a]

$$U_{ss} = -\frac{1}{2}(I_s+A_s) - \left(Z_A-\frac{1}{2}\right)F^0 + \frac{1}{6}\left(Z_A-\frac{3}{2}\right)G^1 \tag{20}$$

$$U_{pp} = -\frac{1}{2}(I_p+A_p) - \left(Z_A-\frac{1}{2}\right)F^0 + \frac{1}{3}G^1 + \frac{2}{25}\left(Z_A-\frac{5}{2}\right)F^2 \tag{21}$$

where I and A are the relevant valence-state ionization potential and electron affinity, respectively.

Table 1. Atomic parameters[a]

	H	C	N	O	F
U_{ss}	−13.595	−52.320	−72.078	−104.841	−131.248
U_{pp}		−44.648	−63.946	− 93.819	−116.272
F^0	12.845	11.715	12.860	15.897	17.233
G^1		7.285	9.416	11.817	14.486

I_s	13.595	19.603	23.777	33.234	39.922
I_p		12.309	16.598	20.013	20.452

a) Values given in units of eV.

11) Equations (7)—(9) in the present work, coupled with Eq. (3.16) of Ref. 1a, generate Eqs. (10)—(12). $F^0(p,p')$, where p and p' are different p orbitals centered on the same atom, were assumed to be equal to $F^0(p,p)$.

The one-center parameters evaluated as above for C, N, O, F atoms are listed in Table 1.

For an H atom, the parameters were $U_{ss}=-13.595$ eV and $F^0=12.845$ eV.

Two-center Parameters. The two-center repulsion integrals, γ_{AB}, between atoms A and B, which are R_{AB} apart, were evaluated by the Ohno approximation[12]

$$\gamma_{AB} = 14.397[R_{AB}^2+(\rho_A+\rho_B)^2]^{-1/2} \tag{22}$$

where

$$\rho_A = 7.199/F_A^0; \quad \rho_B = 7.199/F_B^0 \tag{23}$$

The core resonance integrals, $\beta_{\mu\nu}$, between atoms A and B were evaluated by the Wolfsberg-Helmholtz expression[13]

$$\beta_{\mu\nu} = \frac{1}{2}k^\omega S_{\mu\nu}(I_\mu^A+I_\nu^B) \tag{24}$$

where I_μ^A was taken as the valence-state ionization potential of μ AO of atom A. The parameters, k^ω, were so chosen as to reproduce the observed spectroscopic data, namely σ–π^* and π–π^* transition energies. For these purposes, discrimination between k^σ for σ orbitals and k^π for π orbitals was necessary, as was noted by Bene and Jaffé[5a] in their CNDO treatments of electronic spectra. The final values adopted were $k^\sigma=1.1$ and $k^\pi=0.9$.

Results and Discussion

The Values of k^σ *and* k^π. Bene and Jaffé[5] have shown in their CNDO treatments that, in order to obtain consistent spectroscopic data, the core resonance integrals $\beta_{\mu\nu}$ are necessary to be distinguished between σ and π orbitals. In order to examine whether or not

this discrimination will likewise be inevitable in the present INDO treatments, we have calculated Δ^1E of the ethylene molecule for various sets of k^σ and k^π values.

Shown in Fig. 1 are the highest occupied and lowest vacant orbital energies, both σ and π, calculated with different choices of k^σ and k^π.

Figure 1 clearly shows that both the σ–σ^* and π–π^* orbital energy separations tend to increase with the increasing k^σ and k^π values. Further, both the calculated π and π^* orbital heights are almost independent of k^σ. Likewise, the σ and σ^* orbital heights are relatively insensitive to the change in k^π. It is therefore obvious that both the σ–π^* and π–σ^* energy separations are dependent on both k^σ and k^π.

On the other hand, neither molecular Coulomb nor exchange integrals, J and K, shows material change with the variation of the core resonance integral parameters, as may be seen in Fig. 2. This facilitates adequate choice of k^σ and k^π values that may reproduce the observed transition energies.

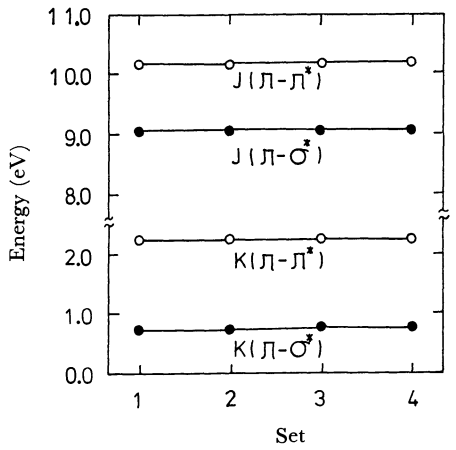

Fig. 2. Variations of the molecular repulsion integrals of ethylene with the change in the resonance integral parameters used.
The parameter sets are the same as those given in Fig. 1.

Similar analyses have been made for a few other compounds. It has been found that the parameter set $k^\sigma=1.1$ and $k^\pi=0.9$ are the most suitable to give consistent spectroscopic data in majority of cases here investigated. In the case of ethylene, the lower transition energies calculated with this parameter set were 8.27, 8.18, and 3.73 eV for the π–π^* ($^1B_{2u}$), σ–π^* ($^1A_{2u}$) and π–π^* ($^3B_{2u}$) transitions, respectively. Although these calculated values are somewhat deviated from the corresponding experimental data, 7.6, 6.4, and 4.8 eV,[3] these deviations are tolerable in view of the neglect of configuration interaction that may be important in such a highly symmetrical molecule.

Carbonyl Compounds. Formaldehyde, formic acid and formamide have been selected for test. The results obtained for lower transitions are summarized in Table 2, together with experimental data.

For each of the three compounds investigated, the calculated values of Δ^1E for both the n–π^* and π–π^* transitions have shown good agreement with the observed. Although the observed data for the triplet

state excitation energies are limited, a good agreement is seen in formaldehyde. Therefore, the present parametrization seems to be satisfactory.

According to the present results, the second singlet-singlet transition band of the carbonyl spectra appearing at 7 to 8 eV is ascribed to a π–σ^* transition. As the assignment of this band is not entirely clear as yet,[3] no decisive assessment of the theory is permissive.

Butadiene and Glyoxal. Calculations have next been extended to butadiene and glyoxal. The electronic excitations of these compounds have already been the subject of the all-valence-electrons treatments by Kato *et al.*[7b] It will be of particular interest to compare the results between their treatments and the present.

The results of calculations for lower energy regions are summarized in Table 3, together with the experimental data. Agreements of the calculated results with the observed data are generally good, except for the energies for the singlet π–π^* transitions of the *s-trans* conformations of both butadiene and glyoxal, in which our calculated values are a little too great. For the n–π^* transitions of glyoxal, our results are more plausible than those of Kato *et al.*[7b]

In both treatments, the energies predicted for the n–π^* and π–π^* transitions of the *s-cis* conformers are lower than those of their *s-trans* counterparts. For the π–π^* transitions, the tendency agrees with observation.[14] Also in the n–π^* transition of glyoxal, there is

an indication of agreement between theory and experiment, if the Δ^1E values (2.66 and 4.43 eV) of a cyclic *cis*-α-diketone[15] may be assumed to closely approximate those of the *s-cis* conformation of glyoxal.

The trend that the π–π^* excitation energies calculated for *s-trans* conformation of a conjugated compound are greater than those for its *s-cis* conformer has long been noticed.[16–18] The trend now appears to be generally true with excitations including those of the n–π^* and σ–π^* types. This generalization seems not to be

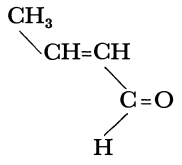
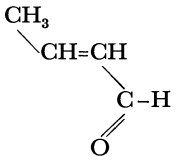
affected by the level of sophistication at which the approximations used have been laid. The π–π^* and n–π^* transition energies calculated for *trans*-crotonaldehyde (I) have been included in Table 3, as an example that may serve to reinforce the above generalization.



I (*s-trans*)

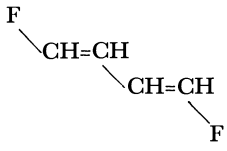


I (*s-cis*)

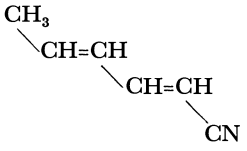
1,4-Disubstituted Butadienes. Butadiene derivatives that are substituted at the terminal carbon(s) have well-defined geometrical isomers, which can be separated from one another.

We here apply the present method of calculations to geometrical isomers of 1,4-difluorobutadiene (II) and sorbonitrile (III), to investigate the effect of geometrical isomerism on electronic spectra.

The reason for the choice of the F, CH_3, and CN groups as substituents is that they introduce no knotty problem of conformational multiformity with respect to the bond through which the substituents are linked with the sp^2 carbon. The butadiene framework will be assumed to be in the *s-trans* form, and various isomers will all be treated as having coplanar structure.



II (*trans,trans*)



III (*trans,trans*)

The results of calculations for low energy transitions are summarized in Table 4, together with experimental data wherever available. The energies and moment lengths for the π–π^* transitions have also been calculated by the Pariser-Parr-Pople π-electron approximation (the PPP method).[4]

The singlet π–π^* transition energies and moment lengths calculated by the Modified INDO and the PPP methods are numerically almost equal. However, these energies are uniformly a little too great as compared with the observed values. Experimentally, the bathochromic (red) shifts are recognizable for the singlet π–π^* transitions on going from the *trans,trans* to *cis,cis* isomers. The theoretical results obtained by the PPP method agree with observation,[19] while those by the Modified INDO method partly fail to reproduce the tendency.

As for the triplet π–π^* transitions, there is no experimental data available. It will only be noted here that the values of Δ^3E calculated by the present method are all greater than those obtained from the PPP calculations.

Finally, according to the results of the present treatments, the singlet π–σ^* excited state of II is lower-lying than the singlet π–π^* excited state. Also, the moment lengths of the transitions leading to the former excited state is sufficiently great to warrant observation in usual cases. Since such transitions were not recorded together with the π–π^* transitions, the calculated values of ΔE are perhaps too small.

Conclusions

The INDO method of Pople *et al.* is useful for the calculations of the quantities concerning the electronic transitions of unsaturated compounds, provided the two-electron repulsion integrals are evaluated from the atomic spectroscopic data. In particular, discrimination between the singlet and triplet states resulting from the n–π^* transition of carbonyl compound comes up with satisfactory accuracy. Success attained in the interpretations of the excited-state properties of molecules allows us to anticipate versatile usefulness of Dewar's MINDO method in various chemical problems.

19) In our separate piece of work, we have measured the lowest singlet π–π^* excitation energies of a great number of 1-substituted and 1,4-disubstituted butadienes and found that the *trans* and *trans,trans* isomers have greater excitation energies and oscillator strengths than do the corresponding *cis* and *cis,cis* isomers, with no exception whatsoever. The PPP calculations have been found to give results that are in accord with all these experimental data. Details will be presented elsewhere.[20]

The Infrared Spectra of Metallooctaethylporphyrins[1]

Hisanobu OGOSHI,* Naruhito MASAI,* Zen-ichi YOSHIDA,*
James TAKEMOTO,** and Kazuo NAKAMOTO**

* *Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto*

** *Todd Wehr Chemistry Building, Marquette University, Milwaukee, Wisconsin* 53233

(Received July 16, 1970)

The infrared spectra of the Mg(II), Co(II), Cu(II), Zn(II), Pd(II), Ni(II), and Ge(IV)Cl_2 complexes of octaethylporphyrins have been studied over the range 4000—100 cm^{-1}. Metal sensitive bands have been observed at about 980, 920, 340, 230, and 130 cm^{-1}.

The metalloporphyrins constitute a large number of biologically important compounds. The wide range of biological activity is due in part to the nature of the interaction of the central metal atom with the porphyrine nucleus. Infrared spectroscopy provides one means by which the nature of metal-ligand interactions can be studied. Previous investigators have reported the infrared spectra of a number of naturally occurring porphyrins and chlorophylls.[2,3] We report here the results of an infrared investigation of the metal complexes of the symmetrical porphyrin, octaethylporphyrin (OEP).

Experimental

The preparation of the OEP complexes of Mg(II), Ni(II), Zn(II), Pd(II), Co(II), and Cu(II) have already been reported in the literature.[4,5] However, no micro analyses have been given for the Ni(II) and Pd(II) complexes.

Ni(II)-OEP. The Ni(II) complex was prepared by the treatment of OEP[6] with nickel acetate in glacial acetic acid.[7] Chromatography on alumina (neutral, activity II—III, Brockman) gave dark red crystals. Found: C, 73.78; H, 7,74; N, 8.91%. Calcd for $C_{36}H_{44}N_4Ni$: C, 73.10; H, 7.50; N, 9.47%.

Pd(II)-OED. The Pd(II) complex was prepared from 101 mg of OEP and 103 mg of $PdCl_2$ using the method of Theorell.[8] The NMR gave $\tau=8.08$ (24H, triplet, $-CH_2\underline{CH_3}$, $J=8.0$), $\tau=5.82$ (16H, quartet, $-\underline{CH_2}CH_3$, $J=7.2$) $\tau=-0.20$ (4H, singlet, $-CH=$).

Found: C, 66.29; H, 6.87; N, 8.32%. Calcd for $C_{36}H_{44}N_4Pd$: C, 67.65; H, 6.94; N, 8.77%.

Ge(IV)-OEP Dichloride. This complex was prepared from OEP and $GeCl_4$ in quinoline.[9] Purification was accomplished by chromatography of alumina using 3 : 1 benzene-chloroform mixture.

Found: C, 63.81; H, 6.56; N, 8.08%. Calcd for $C_{36}H_{44}N_4GeCl_2$: C, 63.94; H, 6.56; N, 8.28%.

Spectral Measurement. The infrared spectra were recorded on a Beckman IR 12 (4000—400 cm^{-1}, KBr pellet) and a Hitachi-Perkin-Elmer FIS-3 (400—100 cm^{-1}, Nujol mull). The UV spectra and NMR spectra were obtained by using a Hitachi EPS-3T spectrophotometer and a Jeolco JNM SH-60 spectrometer, respectively.

Results and Discussion

The observed frequencies of free OEP and its metal complexes are given in Table 1. All the OEP complexes show three weak absorptions above 3000 cm^{-1} which can be assigned to the C–H methine streching vibrations.[10,11] The three strong bands at about 2960, 2940 and 2870 cm^{-1} can be assigned to the C–H stretching vibrations of the ethyl group. Since the strong band at 2960 was very weak in the octamethylporphyrin complexes,[12] it can be attributed to the CH_2 stretching vibration. Free OEP also shows a medium band at 3320 cm^{-1} which is assigned to the N–H strecthing mode. This band disappears in the porphyrin complexes.[2,10]

As has been reported for etioporphyrin II[2,11] three medium to weak bands were observed at about 1670, 1600 and 1560 cm^{-1} and are assigned to the C=C and C=N stretching modes. The four bands at 1470, 1450, 1380, and 1370 cm^{-1} are probably due to the CH_2 asymmetric deformation and the CH_3 asymmetric and symmetric deformation vibrations. In general, the spectra of metal complexes are simpler than those of the free ligand in the region from 1500 to 1000 cm^{-1}. This is probably due to the fact that the symmetry of a metal complex is higher than that of the free ligand. For example, a weak band at 1412 cm^{-1} of OEP disappears on coordination to a metal. The two strong absorptions at 1268 and 1147 cm^{-1} are assigned tentatively to in-plane ring vibrations.[2,13] The latter is much stronger in the metal complex than in the free ligand. The two medium peaks at *ca.* 1150 and 1110 cm^{-1} are probably due to the ring deformation and CH in-plane bending mode of the pyrrole hydrogen, respectively. The bands at 1065 and 1057 cm^{-1} seem to be associated with the in-plane deformation of the porphyrin ring. The strong

a) KBr pellet, b) Nujol mull, c) in $CHCl_3$

band at 1016 cm^{-1} is probably due to the CH_2 twisting vibration of the ethyl group which is slightly sensitive to the metal ion. In fact, it is absent in the spectra of Cu(II)-porphin[10] The increase in absorption intensity of 1016 cm^{-1} may be attributed to the coupling with the in-plane ring deformation vibration at 980 cm^{-1}.

Metal sensitive bands are usually observed near 1000 cm^{-1} in various types of metalloporphyrins.[2,14] OEP complexes show three bands at about 980, 955, and 912 cm^{-1}; the 980 and 912 bands are dependent on the nature of the metal (see Table 2). This metal ion dependence is not as large as that observed for proto- and hematoporphyrin dimethyl esters[2] and is of a comparable magnitude to that observed for tetraphenylporphyrin complexes.[14] The 955 and 912 cm^{-1} bands do not appear in the spectra of Cu(II)-porphyrin.[10] These two bands may therefore be assigned to the rocking vibrations of the ethyl groups. The 980 and 912 cm^{-1} bands shift to higher frequencies in the order Pd≈Ni>Co>Cu>Zn>Mg which is the same order as observed for the hypsochromic shift of the α, β, and soret bands in the electronic spectra (Table 2). Free OEP also shows bands in this region at 975, 950, and 892 cm^{-1}. The 980 cm^{-1} band may be due to a ring deformation vibration involving the motion of a metal atom. The metal dependence of the 912 cm^{-1} band may indicate that this ethyl rocking mode couples strongly with the in-plane deformation vibration of the porphyrin ring.

The strong bands at about 835 cm^{-1} are assigned to the CH out-of-plane deformation vibration of the methine group.[15] The bands at about 848 and 830 cm^{-1} are possibly assigned to the C–C streching of the ethyl group. Several strong bands are observed at about 750, 730, and 700 cm^{-1}. A similar set of bands has been observed for Cu-porphyrin.[10] Consequently, these bands may be assigned to the out-of-plane deformation of the porphyrin ring. The weak bands which occur in the 650—400 cm^{-1} range are difficult to assign empirically.

Far-Infrared Spectra. The metal nitrogen streching vibrations in metalloporphyrins are expected to appear in the far-infrared region. Free OEP shows weak bands at 328 and 320—310 cm^{-1}. The former band shifts to higher frequencies and becomes stronger by complex formation. It may be due to a ligand vibration coupled slightly with a metal-nitrogen stretching mode. The Ni, Co, and Pd complexes exhibit the highest frequencies at 355, 351, and 348 cm^{-1}, respectively, (Table 2), indicating that the metal-nitrogen bond is stronger in the Ni, Co, and Pd than in the Mg and Zn complexes.

In the 300—200 cm^{-1} region, medium to weak bands have been observed for metal complexes but not for free OEP ligand. The frequency of this band is most sensitive to the nature of the metal and increases in the order Zn<Mg<Cu<Co<Pd<Ni. This band may due to a relatively pure metal-nitrogen streching vibraration. However, the exact nature of this vibration cannot be determined without normal coordinate analysis. It is interesting to note that the frequency order of these metal-sensitive bands in a series of metal ions studied is similar to that found for the electronic transitions in the UV region (Table 2). The stronger coordination in metalloporphyrins causes the shift of the α, β, and soret bands to the shorter wave length.[16] This would be attributed to the stabilization in the ground state through π-conjugative interaction between $2p\pi$-orbitals of the ligand and *d*-orbitals of the metal ion.[16,17]

Finally, OEP–$GeCl_2$ exhibits the Ge–Cl stretching mode at 360 cm^{-1}. This frequency is similar to that reported for the $GeCl_6^{2-}$ ion (293 cm^{-1}).[18]

Solvent Effects on the Spin-Lattice Relaxation Times and Chemical Shifts of *N*-Methylacetamide and *N,N*-Dimethylacetamide

Kazuo SATO and Atsuo NISHIOKA

Department of Polymer Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received July 20, 1970)

The spin-lattice relaxation time T_1 and chemical shift of *N*-methylacetamide (NMA) and *N,N*-dimethylacetamide (DMA) were measured in D_2O and CCl_4 solutions. In D_2O solution, it has been found that the weak interamide hydrogen bonding of NMA does not affect the spin-lattice relaxation entirely, and the molecular motion of NMA and DMA is almost identical. However, quite different results were obtained for CCl_4 solution. The molecular association of NMA in CCl_4 solution is strong enough to exhibit appreciable effects on spin-lattice relaxation. The life time of the associated molecules has been estimated to be longer than 10^{-10}—10^{-11} sec. The association of DMA at high concentration region in CCl_4 could be verified from the concentration dependence of the spin-lattice relaxation rate as well as chemical shift.

The contribution of the peptide bond character and the interamide hydrogen bonding to the conformational stability of the synthetic polypeptides and proteins in solutions have long been studied.[1] Quantitative information about model compounds which contain peptide bonds is expected to provide basic insight into the complexity of macromolecules.

So far, the interamide interaction, the double bond character and the hindered internal rotation of various amide compounds in solutions have been studied quantitatively, mainly by using IR, high resolution NMR and thermodynamic technique. IR studies of *N*-methylacetamide in various solvents by Klotz, Fransen, and Fornham[2,3] led us to conclude that in aqueous solution the interamide hydrogen bonding has no intrinsic strength, but is moderately strong in apolar solvent. Recently, Rabinovitz and Pines[4,5] and Neuman *et al.*[6] have studied the proton chemical shift of *N,N*-dimethylformamide, *N,N*-dimethylacetamide in CCl_4 and from the observed concentration dependence of chemical shift they argued the dimerization of amides. Equilibrium properties have been studied extensively, and quantitative features have been obtained and discussed. However, non-equilibrium properties such as microscopic molecular motion or relaxation process have not been studied in detail.

In this study, the proton spin-lattice relaxation time and chemical shift were measured on *N*-methylacetamide (NMA) and *N,N*-dimethylacetamide (DMA) in D_2O (aqueous environment) and CCl_4 (apolar environment). As is well known, the proton spin-lattice relaxation in diamagnetic liquid is mainly due to the dipole-dipole interactions between the nuclear magnetic moments both in the same molecule and in the neighboring molecules.

For most molecular liquids, the observed spin-lattice relaxation time T_1 can be expressed as[7,8]

$$(1/T_1) = (1/T_1)_{\text{rot.}} + (1/T_1)_{\text{transl.}} \quad (1)$$

$$(1/T_1)_{\text{rot.}} = \frac{3}{2}\hbar^2\gamma^4\sum_j \langle r_{ij}^{-6}\rangle \cdot \tau_c \quad (2)$$

$$(1/T_1)_{\text{transl.}} = 3\pi^2\hbar^2\gamma\eta N/kT \quad (3)$$

where $(1/T_1)_{\text{rot.}}$ represents the intramolecular contribution depending on the rotational motion of the molecule, and $(1/T_1)_{\text{transl.}}$ represents the intermolecular contribution which depends on the relative translational motions of the molecules. r_{ij} is the distance between ith and jth nucleus; τ_c is the rotational correlation time for molecule (including the effect of internal rotation in certain circumstances): η and N are solution viscosity and spin density, respectively, and all other notations have their usual meanings.

We measured T_1's and the chemical shifts at various solute concentrations, and obtained the intramolecular spin-lattice relaxation time $(T_1)_{\text{rot.}}$ by the dilution procedure.[9,10] We estimated τ_c values taking molecular geometry into consideration. Based on the results obtained on τ_c values, the concentration dependence of T_1 and the chemical shifts we would like to discuss the molecular motion, intramolecular interaction and the peptide bond character in aqueous and apolar environments.

Information on molecular motion or the relaxation process should help us understand the properties of these molecules in detail in relation to the information from equilibrium measurements.

Experimental

Materials. NMA and DMA were reagent grade samples from Tokyo Kasei Co., Ltd. and used without further purification, because their NMR spectra did not show any observable impurity signals. Heavy water and carbon tetrachloride were provided by E. Merck AG, Darmstadt and

Tokyo Kasei Co., Ltd., respectively. The atmospheric oxygen dissolved in the sample was removed carefully by several freeze-pump-thaw cycles in NMR tube (ϕ=0.5 cm), and the sample tube then was sealed off in a vacuum (10^{-5}—10^{-6} mmHg). After sealing, the sample tube was immediately subjected to experiment.

NMR Measurements. A JNM-C-60H spectrometer of Japan Electron Optics Lab. operated at 60 MHz was used. Measurements of T_1 were carried out at 25±1°C in almost all cases by the adiabatic rapid passage and saturation recovery methods.

Experimental errors were smaller than ±3% for T_1 values longer than about 3 sec. For T_1 smaller than 3 sec, errors were smaller than ±5%. The signal of *N*-methyl protons of NMA splits into doublet due to the indirect spin-spin coupling with N–H proton. However, because of the small coupling constant ($J\simeq$4.8 Hz), only one recovery curve with a broad line width was observed.

trans- and *cis*-*N*-Methyl groups with respect to the carbonyl group of DMA undergo different shielding effects due to the double bond character of the central C–N bond. Thus, *N*-methyl proton resonance reveals a doublet ($\Delta\nu \simeq$ 9—10 Hz).

Two distinct recovery curves were then obtained, but almost all T_1 values calculated from these were equal within experimental errors. Thus we adopted the average value as T_1 for both *N*-methyl protons. The chemical shift was measured at 25±1°C by the usual side-band-technique using Tetramethylsilane (TMS) as an internal reference.

Results and Discussion

The concentration dependence of the relaxation rate $1/T_1$ for methyl protons of NMA and DMA in D_2O and CCl_4 solutions is shown in Figs. 1 and 2, respectively. T_1's of *C*-methyl and *N*-methyl protons in D_2O solutions of NMA or DMA and CCl_4 solution of NMA are equal within experimental errors, but not in CCl_4 solution of DMA. From the observed linear relation between $1/T_1$ and concentration, it is possible to estimate $(1/T_1)_{rot.}$ of the solute molecule for each solution, except for DMA in CCl_4 solution. However, at the concentration range above and below about 3 mol/*l*, linearity, appears again, and an estimation of $(1/T_1)_{rot.}$ or τ_c values is possible by extrapolating to infinite dilution. The results of $(T_1)_{rot.}$ thus obtained and τ_c

	$-\overset{\|}{N}-CH_3$	1.2_5	$14._0$	$-\overset{\|}{N}(CH_3)_2$	12.2 7.8_0	τ_{c1}: 1.4_1 τ_{c2}: 2.2_0

τ_{c1} and τ_{c2} represent the correlation times estimated by extrapolating to infinite dilution from the low and high concentration regions, respectively.

estimated by using Eq. (2) are shown in Table 1. It was found that the relaxation process of NMA molecule in D_2O solution is very similar to that of DMA. Corresponding results and $\tau_c = 1.6 \times 10^{-12}$ sec were also obtained at 45°C. However, in CCl_4 solution a quite different relaxation tendency resulting from aqueous solution was observed for both NMA and DMA molecules.

In order to calculate the interprotonic distance, we adopted the molecular geometry of NMA proposed by Pauling.[11] We have assumed that the geometry of DMA is the same as that of NMA except for the substituted *N*-methyl proton. Moreover, internal rotation of methyl groups is assumed to be almost free. We adopted 1.78 Å for the interprotonic distance in methyl group.

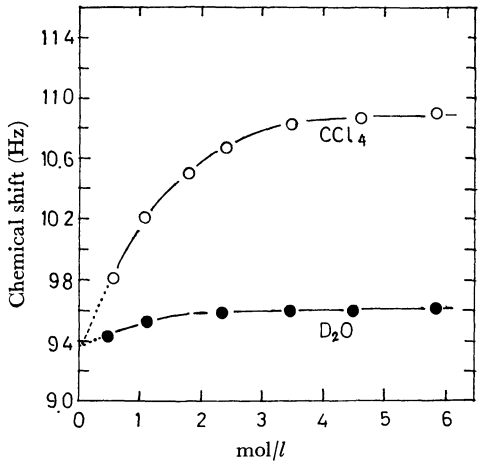

Fig. 3. Concentration dependence of the chemical shift between the two *N*-methyl resonance signals of DMA in CCl_4 (open circles) and D_2O (solid circles) solutions at 25°C.

The concentration dependence of the chemical shift of *N*-methyl protons of DMA both in D_2O and CCl_4 solutions at 25°C is shown in Fig. 3. The behavior in CCl_4 solution agrees qualitatively with the results of Neuman *et al.*[6] The concentration dependence of the chemical shift seems to be similar in its linearity to the concentration dependence of $1/T_1$. The concentration dependence of N–H proton chemical shift of NMA in CCl_4 solution is shown in Fig. 4 with the additional results[12] in $CDCl_3$ solution. It is easily seen that in CCl_4 solution the chemical shift of N–H proton appears at a lower field than that in $CDCl_3$ solution, and depends on the concentration slightly. Considering that the behavior of N–H proton chemical shift of NMA is mainly due to the interamide hydrogen bond and the proton participating in the hydrogen bonding resonates at a lower field, it is suggested that in CCl_4 solution this molecule could form relatively strong intermolecular hydrogen bonding at about 0.5 mol/*l*. This is in accordance with the conclusion of Klotz and Fransen[2] by IR method. They concluded that almost all the molecules (NMA) associate through the hydrogen bonding at 0.5 mol/*l* in CCl_4 solution. Therefore it may be considered that the extrapolated $(T_1)_{rot.}$ of NMA in CCl_4 solution represents the rotational correlation time of the molecule which is restricted in the associated form but not disturbed by the intermolecular dipole-dipole interactions.

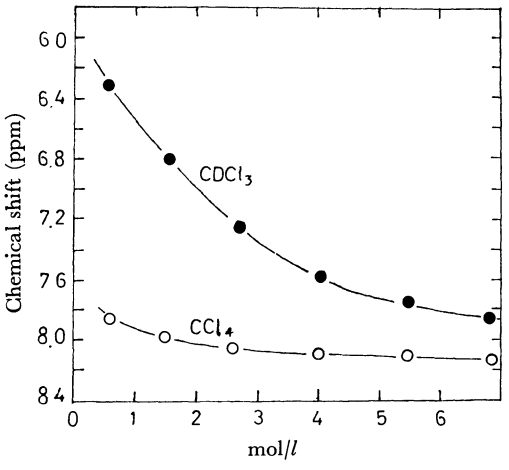

Fig. 4. Concentration dependence of the chemical shift (measured from internal TMS) of N–H protons of NMA in CCl_4 (open circlds) and $CDCl_3$ (solid circles) solutions at 25°C.

Since τ_c values as well as the concentration dependence of T_1 for NMA and DMA in aqueous solution are nearly equal and the chemical shift between the two *N*-methyl groups is almost independent of the solute concentration, the intermolecular interactions between solute molecules do not seem to be appreciable as discussed later. This leads us to the consideration that the estimated τ_c values may be related to the isolated molecule free from solute-solute interactions. Klotz and Fransen[2] also concluded that in aqueous solution the degree of association of NMA molecule is smaller than 10% even at moderately high concentration of about 5 mol/*l*. Their conclusion is in accordance with our present NMR results.

It is clear from Fig. 3 that the chemical shift, $\Delta\nu$, between the *N*-methyl protons of DMA in aqueous solution tends to coincide with that in CCl_4 solution at infinite dilution. This suggests that DMA molecules in dilute CCl_4 solution do not interact with each other as strongly as to affect the spin-lattice relaxation process. Neuman *et al.*,[6] and Rabinovitz and Pines[4,5] concluded from the observed dependence of the chemical shift of *N*-methyl doublet that DMA and *N*,*N*-dimethylformamide molecules dimerize at moderate concentration in CCl_4 solution. We also assume the behavior of $1/T_1$ at the moderate concentration region to be due to the dimerization of solute molecules. Thus it is considered that τ_c extrapolated from high concentration region may be associated with the DMA molecule weakly influenced by the molecular dimerization and not disturbed by the intermolecular dipole-dipole interactions.

Let us discuss the solvent effects in both aqueous and apolar solutions as follows.

Aqueous Solution. For both NMA and DMA molecules τ_c values of *C*-methyl and *N*-methyl groups are nearly equal. The fact that τ_c values of different methyl groups in the same molecule are equal means

11) L. Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca (1960), Chap, 8, p. 281.

12) K. Sato and A. Nishioka, unpublished data.

that the molecular rotational motion may be isotropic with respect to both methyl groups, provided that the internal rotation of methyl groups are almost in the same degree. τ_c values of NMA and DMA are about 2.5×10^{-12} sec, and the concentration dependence of T_1 or the contribution from intermolecular relaxation factors is equal. It can be concluded that the molecular rotational and translational motions are almost the same for NMA and DMA molecule in aqueous solution.

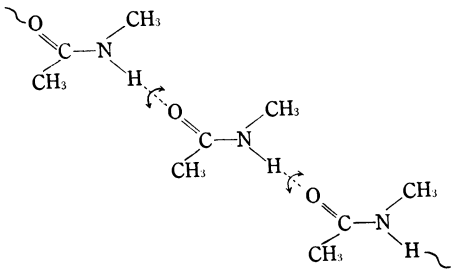
Recently, Anderson and Fryer[13,14] discussed the effect of the molecular association on the molecular rotational motion or the spin-lattice relaxation process, and concluded that if the lifetime of the associated molecules moving as a unit is longer than the rates of chemical exchange between the associated molecules, the effect of association is pronounced, whereas the effect is small if the lifetime of the molecular association is shorter. Thus it may be concluded that in aqueous solution the interamide hydrogen bonding is very weak, and if the molecular association is formed through the hydrogen bonding its lifetime is shorter than 10^{-11}—10^{-12} sec.

Thus the peptide bond character and the interamide interaction are not appreciable in aqueous solution, and do not affect entirely the microscopic molecular motion. From the concentration dependence of the chemical shift of *N*-dimethyl doublet of DMA solution, we conclude that the double bond character of the central C–N bond through the solute-solute interactions is not stabilized by the increase of solute concentration. This means implicitly that in contrast to CCl_4 solution the intermolecular interaction or the molecular association does not exist between DMA molecules in aqueous solution over the range of concentration studied.

Apolar Solution. The rotational correlation times of *C*-methyl and *N*-methyl groups of NMA are equal; $\tau_c=1.4\times10^{-11}$ sec. The concentration dependence of $1/T_1$ is also in the same order of magnitude. It is reasonable to consider that the molecular rotational and translational motions are isotropic as in the case of aqueous solution. τ_c of NMA seems to be about five to ten times longer than the values observed in ordinary low molecular weight compounds.[10] This provides another verification that τ_c estimated in the present study is related to the rotational correlation time of NMA molecule restricted in the associated form of chain. We might conclude that the interamide association through the hydrogen bonding is strong enough to affect the spin-lattice relaxation, and that the life time of the association is longer than 10^{-10}—10^{-11} sec. Considering the fact that the interamide association is strong, and the molecular rotational motion is isotropic with respect to both methyl groups, we conclude that the rotational motion is predominant around the associated chain.

(See below, the *trans* configuration of NMA has been verified and well known.[1])

According to Neuman and Rabinovitz, we may



ascribe the peculiar concentration dependence of the chemical shift and T_1 to molecular dimerization. Another feature in CCl_4 solution differing from that in aqueous solution may be the fact that T_1 values of *C*-methyl and *N*-methyl protons are not equal over the experimental range of concentrations. This probably means that the molecular motion of DMA in CCl_4 is anisotropic with respect to both methyl groups. But the mechanism of this anisotropy is not clear. We might discuss from the effect of dimerization the reason for the concentration depedence of the relaxation rate in the dilute concentration region differing from that in the moderate concentration region. We consider that in dilute solutions the free DMA molecules are dominant and the fraction of the dimerized molecule increases linearly with increasing concentration (above about 3 mol/l). However, almost all DMA molecules dimerize and produce apparently different relaxation contributions from those at dilute solution region. τ_c values (denoted by τ_{c1}) obtained by extrapolating into infinite dilution from lower concentration region is plausible for most low molecular weight compounds. The value may correspond to the rotational correlation time of the isolated DMA molecule. τ_c (denoted by τ_{c2}) estimated from moderately concentration region is smaller than twice τ_{c1} of the isolated DMA.

The BPP theory[7] predicts $\tau_c=4\pi\eta a^3/3kT$ for the rigid molecule, where η and a represent solution viscosity and the radius of spherical molecule, respectively. If the dimerized molecule with a long lifetime is rigid enough to affect the spin-lattice relaxation process considerably, τ_{c2} must be roughly eight times greater than τ_{c1} according to BPP. Therefore we conclude that although the effect of association on spin-lattice relaxation is appreciable, it is not so significant, and that life time of association may be at most 10^{-11}—10^{-12} sec. It seems that both characters of monomer and dimer influence the relaxation process. This is also verified from the fact that T_1 values of *C*-methyl protons differ from those of *N*-methyl protons to the same degree as in dilute concentration region in moderately high concentrations where the fraction of associated molecule is expected to be larger.

τ_c of the isolated DMA is shorter in CCl_4 than in aqueous solution. The reasons might be as follows.

(1) The solution viscosity of aqueous solution at 25°C is larger than that of CCl_4 solution by factor about 1.5.[12] (2) The effect of solvation[10] of water molecules around the DMA molecules is expected to reduce molecular mobilities.

The Crystal and Molecular Structures of a 3 : 2 Adduct of Acetylene and Isonitrile Derivatives

Yoshio SUZUKI and Yōichi IITAKA

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Tokyo

(Received July 24, 1970)

In order to determine the structure of the 3 : 2 adduct (acetylene : isonitrile) obtained by cycloaddition reaction of dimethyl acetylenedicarboxylate with 2,6-dimethylphenylisonitrile and to elucidate the route of the reaction, a heavy atom derivative of this adduct was prepared and subjected to X-ray diffraction analysis. The crystal grown from acetone solution has the composition $C_{36}H_{34}N_2O_{12}Br_2 \cdot CH_3COCH_3$ and belongs to monoclinic system with the lattice constants: $a=34.13\pm0.04$, $b=14.66\pm0.02$, $c=8.10\pm0.01$ Å, $\beta=90.5\pm0.2°$. The space group is $P2_1/n$ containing four formula units in the cell. The structure was solved by the heavy atom method and refined by the block-matrix least-squares method for 1482 observed reflections allowing the anisotropic thermal motions for each atom. It has been shown that the chemical structure of the adduct is 1-(4-bromo-2,6-dimethylphenyl)-2-(4-bromo-2,6-dimethylphenyl)imino-1,2-dihydro-3,4,5,5,6,7-hexacarbomethoxy-5*H*-1-pyrindine.

It has been shown that isonitrile reacts as nucleophile, but substituted acetylene, especially when it has electron withdrawing groups, reacts as electrophile giving rise to cyclic products. Takizawa, Obata, Suzuki, and Yanagida[1] synthesized cyclopententriimine and biskетenimine which correspond respectively to the 1 : 3 and 1 : 2 adducts of acetylene and isonitrile and elucidated the structures of these adducts as well as the reaction mechanism. However, this cycloaddition reaction is very complicated and gives many complex compounds in addition to 1 : 3 and 1 : 2 adducts. We have chosen one of the 3 : 2 adducts obtained in the reaction of dimethyl acetylenedicarboxylate and 2,6-dimethylphenylisonitrile for structure determination. However, the structure is so complicated that it proved to be difficult to solve it merely on the basis of spectral data and chemical reactions.

It was therefore decided to carry out X-ray diffraction analysis by applying the heavy atom method. In order to introduce a heavy atom into the adduct, 4-bromo-2,6-dimethylphenylisonitrile was reacted with dimethyl acethylenedicarboxylate and the 3 : 2 adduct containing heavy atoms was prepared.

Experimental

The crystals of the 3 : 2 adduct, $C_{36}H_{34}N_2O_{12}Br_2 \cdot CH_3COCH_3$, recrystallized from acetone solution are monoclinic deep violet prisms. The amount of the solvent of crystallization was calculated from elemental analysis and NMR spectrum. The lattice constants were determined from the $0kl$ and $h0l$ precession photographs taken with Cu$K\alpha$ radiation. Intensity data were collected from the *c*-axis multiple-film equi-inclination Weissenberg photographs of zero to six layers and the *b*-axis zero layer precession photographs of various exposures. All were taken with Cu$K\alpha$ radiation. The intensities were measured with the aid of a Narumi microdensitometer. From systematic absence, the space group was found to be $P2_1/n$. The unit cell contains four molecules of acetone. After Lorentz and polarization corrections were made, the structure factors of various layers of the *c*-axis were put on the same relative scale by use of $h0l$ structure factors obtained from the precession photographs. Since the cross-section of the crystal used for the *c*-axis Weissenberg photographs was about 0.08×0.10 mm and the μR value was calculated to be less than 0.2 for Cu$K\alpha$ radiation, no absorption correction was applied for the intensity data. All together 1482 independent reflections were observed out of 3085 possible reflections within the sphere of radius corresponding to $2\theta=90°$ in reciprocal space.

Crystal data

$C_{36}H_{34}N_2O_{12}Br_2 \cdot CH_3COCH_3$, MW 904.5, mp 254—255°C
Monoclinic
$a=34.13\pm0.04$, $b=14.66\pm0.02$, $c=8.10\pm0.01$ Å,
$\beta=90.5\pm0.2°$
Volume of the unit cell=4052.8 Å^3

Linear absorption coefficient for Cu$K\alpha$ radiation=33.2 cm^{-1}
Absent reflections: $h0l$ when $h+l$ is odd, $0k0$ when k is odd
Space group: $P2_1/n$
$Z=4$

Structure Determination

The ordinary heavy atom method was applied to phase determination. From the Harker and other vectors in the Patterson map, the positional parameters of the two independent bromine atoms were easily determined. Three-dimensional electron density map was then calculated on the basis of bromine contributions. Several cycles of Fourier and difference Fourier syntheses revealed the fifty-two atoms composing the whole molecule. Three cycles of least-squares refinement were made, in which individual isotropic temperature factors were assigned coding all atoms as carbon except for two bromine atoms. At this stage, twelve oxygen and two nitrogen atoms were distinguished by comparing their temperature factors. Using these positional parameters, difference Fourier synthesis was computed and the atomic parameters of the solvation molecule were determined. The *R* value at this stage was 0.17.

Refinement of the structural parameters for 1482 observed structure factors was carried out by the method of block-matrix least-squares using the program HBLS.[2] Six cycles of calculation with isotropic temperature factors and three cycles with anisotropic temperature factors for all atoms reduced the *R* value to

0.077. In the final calculation, the following weight system was adopted.

$$\sqrt{w} = 76/F_o \quad \text{when } F_o > 76,$$
$$\sqrt{w} = 1.0 \quad \text{when } 76 \geq F_o \geq 7,$$
$$\sqrt{w} = 0 \quad \text{when } 7 \geq F_o.$$

The final atomic parameters and their standard deviations are given in Table 1 and the observed and calculated structure factors in Table 2.

Discussion of the Structure

The present X-ray structure determination has shown the chemical structure of the 3 : 2 adduct to be 1-(4-bromo-2,6-dimethylphenyl)-2-(4-bromo-2,6-dimethylphenyl)imino-1,2-dihydro-3,4,5,5,6,7-hexacarbomethoxy-5*H*-1-pyrindine (I). The chemical structure and conformation of the molecule are shown in Fig. 1. From the result of X-ray analysis, the mechanism of the reaction was clarified which enabled us to suppose the chemical structures of other reaction products. Details of the study have been published in a separate paper.[3]

The bond lengths and angles are shown in Figs. 2 and 3 along with their standard deviations. The average C–C, C–C(methyl) and C–Br bond lengths found in the substituted phenyl groups are 1.41 Å, 1.54 Å and 1.91 Å, respectively, which agree well with the standard values. The average bond lengths found in the ester groups are 1.50 Å for C(ring)–C, 1.20 Å for C=O, 1.31 Å for C–O and 1.49 Å for O–C(methyl) which are also in good agreement with those of normal carbomethoxy groups. The C–C bond lengths found in the pyrindine ring vary from 1.32 Å to 1.46 Å except for C(8)–C(5) and C(6)–C(5) bonds which correspond undoubtedly to single bonds. There are few examples of X-ray analysis of a compound containing the pyrindine ring. The only one we found is 1-methyl-6-[5-(1-methyl-1*H*-1-pyrindinyl)]-1-azoniaindan iodide (II)[4] which was found to consist of 1-methyl-1*H*-1-pyrindine and 1-methyl-1-azoniaindan iodide groups. The bond lengths in the former group

show a characteristic of aromatic systems, and most C–C bond lengths (average value of the seven peripheral bonds is 1.394 Å and the length of the transannular bond is 1.482 Å) are in good overall agreement with those found in azulenes. The bond lengths and angles in the latter group indicate that the five-membered ring can be best described as cyclopentenyl while the six-membered ring can be described as positively charged pyridinum, since the bond lengths involved in the six-membered ring agree with similar parameters in heterocyclic molecules having the character of sp^2 hybridization and electron delocalization. The structure of the pyrindine group in the present compound differs from that of the above two cases in that it has many substituents such as six carbomethoxy, a phenyl and a phenylimino group. Furthermore, the C(2)–N(19) bond length (1.28 Å) is significantly shorter than any other C–N lengths in the present molecule while the bond lengths of C(8)–C(5) and C(6)–C(5) (1.54 Å and 1.48 Å, respectively) are much longer than other C–C lengths involved in the ring. It is therefore reasonable to assume that the six-membered ring has an aromatic nature and the resonance structure is extended to N(19) on one side and to C(6) through C(7) on the other side of the ring. The mean C–C bond length in the six-membered ring (1.39 Å) is almost equal to that in 2-pyridone[5] (1.39 Å) and in pyridine[6] (1.395 Å) while the C–N bond lengths (1.38 Å and 1.44 Å) are longer than those in 2-pyridone (1.34 Å and 1.40 Å) and in pyridine (1.340 Å). The nitrogen atom, N(1), is undoubtedly in a state of sp^2 hybridization as evidenced by the nearly planar configuration of the substituent atoms (C(2), C(9) and C(10), see Table 3).

Least-squares planes through various groups of atoms and the deviations of atoms from each plane are shown in Table 3. Each of the pyrindine ring and the two substituted phenyl groups is almost planar within experimental error. These substituted phenyl groups are twisted with respect to the plane of the pyrindine ring at angles of 77° and 82°, respectively. Each C(ring)–COO– group is planar and the terminal methyl carbon deviates slightly from the plane. The six carbomethoxy groups are also twisted with respect to the plane of the pyrindine ring in various degrees ranging from 28° to 79°.

In the NMR spectrum of the present compound, two signals at 6.7 τ (s. 3H) and 6.9 τ (s. 3H) which are assigned to the methyl protons of C(32) and C(52), appear at a higher field than would be expected for

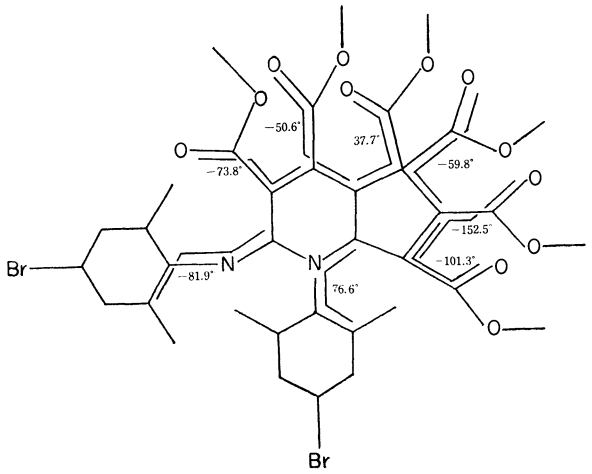

Fig. 4. Internal rotation angles about the bonds joining the pyrindine ring and the substituted groups.
Internal rotation angle A–B–C–D shown in Fig. 4 by bold line, is defined as the angle between the projections of A–B and C–D, when the projection is taken along the B–C bond. The positive angle is taken in the same sense as that of the turning direction of a right handed screw advancing along the B–C bond.

this kind of proton. The reason for this may be the effect of ring current of the proximate phenyl groups which are situated with their planes facing the methyl groups (see Fig. 1).

The crystal structure projected along the *b*-axis is shown in Fig. 5. Intermolecular short distances less than 3.6 Å are indicated in the Figure by dotted lines and are listed in Table 4. The molecules are denoted by Roman numerals and the subscript in parentheses indicates translations along the three edges of the unit cell. It is seen that the molecules lie along ($\bar{4}01$) plane and stack on top of the other mainly by the van der Waals force between the substituents of the phenyl group and carbomethoxy groups. The present molecule has so many bulky substituent groups of the pyrindine ring that there remains a wide space between the stacked molecules. The molecule of acetone is enclosed in the space as a solvent of crystallization and interacts with the surrounding adduct molecules by van der Waals force, the shortest distance being 3.55 Å found between O(56) I(000) and Br(28) III(000). Within ($\bar{4}01$) plane, the molecules are bound together through

Molecule I at (x, y, z)
Molecule II at ($\frac{1}{2}-x$, $-\frac{1}{2}+y$, $\frac{1}{2}-z$)
Molecule III at ($1-x, 1-y$, $1-z$)
x, y and z are the fractional coordinates of atoms given in Table 1.

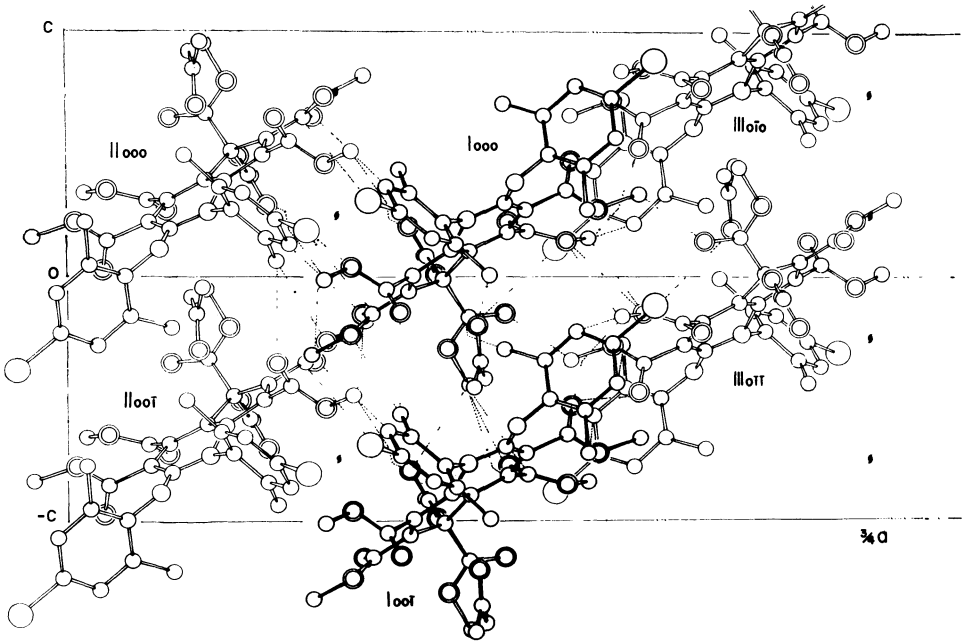

Fig. 5. Projection of the crystal structure along the *b* axis. Intermolecular short distances oi less than 3.6 Å are shown by dotted lines.

van der Waals interactions among the phenylimino groups and methyl groups. Remarkably short intermolecular distances to be noted are 3.01 Å found between C(40) I(000) and O(34) I(00$\bar{1}$) and 3.11 Å between Br(18) I(000) and O(51) II(010). Bolton[7] has already noted that very short distances are often found between a carbonyl oxygen atom and a carbon atom. In the present structure, the four atoms mentioned above belong to the ester carbon, carbonyl oxygen, *p*-substituent bromine of phenyl and ether oxygen atoms, respectively, indicating that they should be highly polarizable.

Studies on Cobaloxime Compounds. I. Synthesis of Various Cobaloximes and Investigation on Their Infrared and Far-Infrared Spectra

Noboru YAMAZAKI and Yorikatsu HOHOKABE

Department of Polymer Science, Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 31, 1970)

Cobaloximes with the general formula: $[CoX(DH)_2B]$ or $[RCo(DH)_2B]$ (X: Cl, CN. R: Alkyl groups such as methyl, ethyl, *n*-propyl, *i*-propyl, *n*-butyl, benzyl, or hydroxypropyl. DH: Dimethylglyoximato monoanion. B: Bases such as water, nicotinamide, *p*-toluidine, pyridine, γ-picoline, imidazole, or 4-vinylpyridine), and polymeric cobaloximes with the general formula: $[Co(OH)(DH)_2(Copoly\text{–}AM\text{-}VPy)]$ (Copoly–AM-VPy: a low molecular weight copolymer of acrylamide and 4-vinylpyridine), were synthesized and their infrared and far-infrared spectra were examined. The frequency shifts by changing the axial ligands were discussed.

The resemblance of cobaloxime compounds, including alkylcobaloximes, to cobalamin compounds in their chemical behavior has been clarified to a great extent by Schrauzer and Kohnle.[1,2] Compounds other than alkylcobaloximes, *e. g.*, the reduced states of cobaloximes, have been reported to serve as catalysts in some reduction reactions.[3,4]

In this paper we wish to report the synthesis of various cobaloximes including polymeric cobaloximes by improved methods and an investigation on their infrared spectra.

Results and Discussion

Synthesis of Cobaloximes. Some chlorocobaloximes were prepared by the general method similar to Tschugaeff's synthesis of $CoX(DH)_2B$:[5]

$$CoCl_2\cdot(6H_2O) + 2DH_2 + 2B + 1/4\,O_2 \rightarrow CoCl(DH)_2B + B\cdot HCl + 1/2\,H_2O\ (+6H_2O).$$

In these reactions, one equivalent amount of base is consumed to neutralize HCl produced in the reactions. Thus, instead of such organic bases, we could employ one equivalent of NaOH as follows:

$$CoCl_2\cdot(6H_2O) + 2DH_2 + B + NaOH + 1/4\,O_2 \rightarrow CoCl(DH)_2B + NaCl + 3/2\,H_2O\ (+6H_2O).$$

The results are summarized in Table 1. The product is essentially the same as those obtained by the former method. The latter method is preferable when the organic base is too invaluable to be used in such a side reaction, or when it is desirable for all basic residues such as polymeric ligands to form cobaloximes:

$$n\,CoCl_2\cdot(6H_2O) + 2n\,DH_2 + \text{(B)}_n + n\,NaOH + n/4\cdot O_2 \longrightarrow CoCl(DH)_2\text{(B)}_n + n\,NaCl + 3n/2\cdot H_2O\ (+6H_2O).$$

When two equivalent NaOH are used in the reaction in the absence of the organic base, hydroxoaquocobaloxime is produced:

$$CoCl_2\cdot(6H_2O) + 2DH_2 + 2NaOH + 1/4\,O_2 \rightarrow Co(OH)(DH)_2(H_2O) + 2NaCl + 1/2\,H_2O\ (+6H_2O).$$

As an extension of this idea, all pyridine residues in a low molecular weight copolymer of acrylamide-(AM) and 4-vinylpyridine(VPy) were completely complexed with cobaloxime, which was confirmed by Co analysis. The molecular weights and AM/VPy molar ratios of polymeric ligands are shown in Table 2.

Cyanocobaloximes were prepared by the general method:

$$Co(CH_3COO)_2\cdot(4H_2O) + 2DH_2 + NaCN + 2B + 1/4O_2 \rightarrow Co(CN)(DH)_2B + B\cdot HOOCCH_3 + CH_3COONa + 1/2H_2O\ (+4H_2O).$$

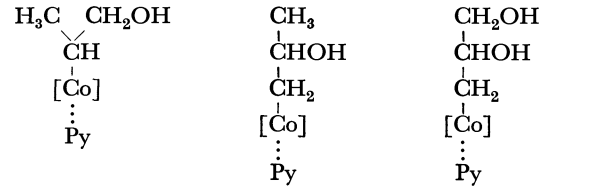
a) Determined by cryoscopic method.
b) Calculated by using the absorbance at 257 mμ due to the pyridine residue.
c), d) Estimated by using $\bar{M}_n$ and AM/VPy ratio of polymeric ligand.

In these reactions, one equivalent base is again consumed to neutralize acetic acid formed in the reaction. We found that without neutralizing acetic acid the cobaloximes are formed with one equivalent base to Co-$(CH_3COO)_2$:

$$Co(CH_3COO)_2\cdot(4H_2O) + 2DH_2 + NaCN + B + 1/4O_2 \rightarrow Co(CN)(DH)_2B + CH_3COOH + CH_3COONa + 1/2H_2O\ (+ 4H_2O).$$

The results of syntheses obtained by one of the two procedures are summarized in Table 3.

Various alkylcobaloximes were synthesized by the general methods according to Schrauzer and Windgassen,[6] from $CoCl_2\cdot 6H_2O$, DH_2, NaOH, and alkyl halide with or without $NaBH_4$ in an anaerobic condition. Some hydroxypropylcobaloximes, *i. e.*, *β*-hydroxy-isopropyl-, *β*-hydroxy-*n*-propyl-, and *β*,*γ*-dihydroxy-*n*-propyl-(pyridine)cobaloximes, were also synthesized with 2-bromo-1-propanol, 1-bromo-2-propanol, or glycerol α-monochlorohydrin, respectively, as the alkylating agents which are schematically described as:



These cobaloximes might be considered as model compounds for possible intermediates in an enzymatic reaction, *i. e.*, in propanediol dehydratase system.

Base Substitution Reaction of Alkylaquocobaloximes. The water molecule coordinating to Co atom in alkylaquocobaloximes is readily displaced by another organic base:

TABLE 3. SYNTHESIS OF CYANOCOBALOXIMES

Composition	Yield (%)	Formula (M. W.)	Found (Calcd) (%) C	H	N	Color
$Co(CN)(DH)_2(H_2O)$	70	$C_9H_{16}N_5O_5Co$ (333.20)	31.39 (32.44)	4.23 (4.84)	20.48 (21.02)	brown
$Co(CN)(DH)_2(py)$[a]	26	$C_{14}H_{19}N_6O_4Co$ (394.28)	42.74 (42.65)	4.77 (4.86)	21.29 (21.32)	ocher

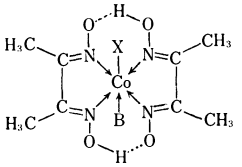
a) nico: nicotinamide, tolu: *p*-toluidine, py: pyridine, pico: *γ*-picoline, imd: imidazole
b) This complex has a water of crystallization: $[CH_3Co(DH)_2(tolu)]\cdot H_2O$.

$$RCo(DH)_2(H_2O) + B \rightarrow RCo(DH)_2B + H_2O.$$

Thus, the addition of equimolar amount of imidazole to methylaquocobaloxime in methanol causes immediate color change in the solution from reddish orange to yellow. This indicates the immediate formation of methyl(imidazole)cobaloxime, which was actually isolated in quantitative yield. The alkylcobaloximes synthesized are summarized in Table 4.

Investigation on the Infrared and Far-Infrared Spectra. All the cobaloximes were identified by elemental analysis and infrared spectra. Characteristic absorption bands of chlorocobaloximes, methylcobaloximes, and (pyridine)cobaloximes are tabulated in Tables 5, 6, and 7, respectively.

The Band between 1700 and 1900 cm^{-1}: All the spectra of the complexes investigated contain a weak broad band between 1700 and 1900 cm^{-1}. It has been proved that this absorption is attributable to intramolecular hydrogen bridges[7] which are schematically shown below.



This conclusion has been supported by NMR spectra.[8] The hydrogen bonded OH frequencies indicated in

Tables 5, 6, and 7 are approximate values, nevertheless they showed the consecutive order of the strength of hydrogen bridges. These frequencies in chloro- or methyl-cobaloximes are shifted to lower wave numbers when the fifth ligand changes in the order H_2O> *p*-toluidine>pyridine>imidazole>*γ*-picoline. This is considered to be in the approximate order of the weakness of the electron donating power, whereas those in (pyridine)cobaloximes are shifted to lower wave numbers when the sixth ligand changes in the order alkyls>Cl>CN which is in the opposite direction from the donating power of the bases, *viz.*, the fifth ligands. This will be discussed later together with the shifts of other frequencies.

The Band at around 1560 cm^{-1}: The band at around 1560 cm^{-1} is attributed to C=N stretching frequency of dimethylglyoximato ligands.[7,9] The band is not affected by the change of the sixth ligand, *e. g.*, CN, Cl, alkyls. It is shifted to lower wave number when the fifth ligand changes in the order H_2O> *p*-toluidine>nicotinamide>pyridine>*γ*-picoline>imidazole>4-vinylpyridine, *i. e.*, with the increase of the interaction of the base with Co atom. Burger *et al.* reported on the basis of the frequency shift of the C=N vibration that the lower the C=N vibration frequency, the stronger the metal→N=C donor *π*-bond.[10] Our results suggest that the increase in electron density on the cobalt causes the increase of back donation from Co to nitrogen atoms of DH ligands, resulting in the increase in conjugation of the five membered chelate rings.

The Bands at around 1240 cm^{-1} and 1090 cm^{-1}: From the experiments by Blinc and Hadži,[9] we could assign the peaks of the spectra at around 1240 cm^{-1} and 1090 cm^{-1} to the N–O stretching vibrations. These two bands are shifted to lower wave numbers when the fifth ligand changes in the order 4-vinylpyridine> pyridine>*γ*-picoline>imidazole>*p*-toluidine>nicotinamide>H_2O, which is in the approximate order of the strength of electron donating power, as well as when the sixth ligand changes in the order CN>Cl> alkyls. Since the increase in the electron density in N–O bond is considered to cause the high frequency shift of the vibration, the high frequency shift caused by the change of the fifth ligand is explained by the electron donating power of the fifth ligands, *viz.*, the axial bases, while that caused by the change of the sixth ligand is unexpectedly in the opposite direction, which appears at first sight to be inconsistent with the effect of the fifth ligand, since cyanide is known as an electron withdrawing group stronger than others and hence it would cause the decrease in the electron density of N–O bond through the interaction with Co atom.

The Band at around 510 cm^{-1}: The band at around 510 cm^{-1} which is attributable to Co–N stretching frequency between Co and nitrogen atoms of dimethylglyoximato ligands is not affected by the change

9) R. Blinc and D. Hadži, *J. Chem. Soc.*, **1958**, 4536.
10) K. Burger, I. Ruff, and F. Ruff, *J. Inorg. Nucl. Chem.*, **27**, 179 (1965).

of the sixth ligand, *i. e.*, CN, Cl, alkyls similarly to the C=N vibration mentioned above, whereas it is shifted to higher wave number when the fifth ligand changes in the order H_2O<nicotinamide<pyridine, imidazole<*p*-toluidine, *γ*-picoline, which is not in an exact but approximate order of the strength of the interaction of the base with Co atom.

Other Bands Occurring in the Infrared Region: All the complexes show the weak broad bands between 2300 and 2400 cm^{-1}, which may be attributed to another hydrogen-bonded O–H frequency of bisdimethylglyoximato moiety according to Hadži.[9,11] The bands at around 1445 cm^{-1} and around 1375 cm^{-1} are due to asymmetric and symmetric deformation vibrations respectively, of methyl groups in dimethylglyoximes. The bands at around 980 cm^{-1} and 880 cm^{-1} may be attributed to deformation vibrations of OH in bisdimethylglyoximato moiety, and the band at around 740 cm^{-1} to C=N–O deformation vibration.

The characteristic absorption bands due to the axial ligands are also observed; pyridine derivatives show the weak bands at 3000—3150 cm^{-1} due to C–H stretching vibrations of pyridine ring, the band at 1600—1610 cm^{-1} to C=C and/or C=N stretching of pyridine ring, and the band at 750—780 cm^{-1} to C–H deformation of pyridine ring. The C–H stretchings of alkyl group linked to Co atom occurring at 2850—2960 cm^{-1} become distinct in intensity in the order CH_3<C_2H_5<C_3H_7<C_4H_9 as expected. In isopropyl(pyridine)cobaloxime, the characteristic absorption bands due to isopropyl group are clearly observed at 1375 and 1366 cm^{-1} which are symmetric deformation bands of CH_3 in isopropyl group, and 1187 and 1161 cm^{-1} which are skeleton vibrations of C–C–C in isopropyl group. In cyanocobaloximes, C≡N stretching vibration occurs at 2130—2200 cm^{-1}. Aquocobaloximes also show the characteristic bands due to H_2O molecule coordinating to Co atom; the ν_{O-H} at 2940—3110 cm^{-1}. δ_{O-H} at 830—838 cm^{-1}, and ν_{Co-O} at 357—378 cm^{-1}.

Other Bands Occurring in the Far-Infrared Region: The band at around 370 cm^{-1} in aquocobaloximes may be attributed to Co–O stretching vibration between Co atom and the coordinating water molecule. A few bands between 420—500 cm^{-1} other than that at around 510 cm^{-1} listed in Tables 5—7 may be attributable to Co–N stretching vibrations. All the alkylcobaloximes show an absorption band at around 325 cm^{-1}, which may be attributed to the Co–C stretching vibration, while methylcobalamin was reported to show the Co–C stretching band at 348 cm^{-1}.[12]

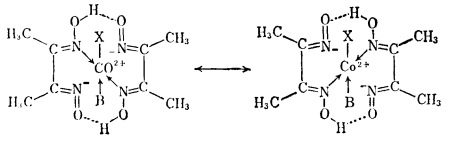
Polymeric Cobaloximes: Polymeric cobaloximes, *i. e.*, Co(OH)$(DH)_2$(Copoly–AM-VPy) showed characteristic absorption bands due to cobaloxime, other than due to the polymeric ligands; *e. g.*, ν_{N-O} at 1230 cm^{-1} and 1090 cm^{-1}, δ_{O-H} at 981 cm^{-1}, and ν_{Co-N} at 510—530 cm^{-1}.

Discussion on the Frequency Shift with Axial Ligands: The characteristic absorption bands mostly due to dimethylglyoximato ligands in these cobaloximes do not shift largely by the change of axial ligands. This suggests that the strength of the Co–N bonds in the equatorial position is not much affected by the change of the axial ligands because the Co–N(equatorial) bonds are very strong due to metal→N=C *π*-bond.

However, the definite relationship between the frequency shifts and the consecutive order of axial ligands was observed as mentioned above. In short, as the donating power of the base increases, $\nu_{O-H\cdots O}$ at around 1750 cm^{-1} and $\nu_{C=N}$ at around 1560 cm^{-1} shift to a lower wave number region, while ν_{N-O} at around 1240 cm^{-1} and 1090 cm^{-1}, and ν_{Co-N} at around 510 cm^{-1} to higher one. These results can be interpreted as follows. The coordination of more electron-donating base to Co atom causes the increase in electron density in Co atom. This facilitates the back donation from Co to the nitrogen atoms of dimethylglyoximato ligands, resulting in the increase in electron densities in C=N, and N–O bonds. The increase in electron density in N–O bonds causes the stronger hydrogen bridges of O–H···O and the higher frequency shifts of N–O stretching vibrations. The facilitated back donation from cobalt to nitrogen atoms of dimethylglyoxime means the increased metal-donor *π*-bond in the equatorial moiety of cobaloximes, which causes the stronger interaction of Co with equatorial N atoms, resulting in higher frequency shift of ν_{Co-N} vibration, and causes more conjugation in five membered chelate rings including Co atom, resulting in lower frequency shift of $\nu_{C=N}$ vibration.

On the contrary, the effects caused by the change of the sixth ligand, *e. g.*, CN, Cl, alkyls, were observed to be inverse. As the donating power of the sixth ligand decreases, $\nu_{O-H\cdots O}$ shifts to lower wave number, while ν_{N-O} to higher. This opposite tendency in the *cis*-effect of two axial ligands might be interpreted as follows: Since the bonding orbitals of both the fifth and sixth ligands are considered to interact most strongly with the d_{z^2} orbital of the central metal than the second probable one, *i. e.*, $d_{x^2-y^2}$ and than other *d* orbitals, the effect of one of the axial ligands is considered to be larger on another axial ligand (*trans*-effect) than on the equatorial ligands (*cis*-effect). More electron-withdrawing ligand in the sixth position causes stronger interaction between the central metal and the fifth ligand in the *trans* position, which could be caused by decrease in the cobalt-base bond length. Donation of electron from the base to Co atom is thus facilitated, which results in stronger back donation from Co to the equatorial nitrogen atoms and hence in increase

11) In principle the appearance of two OH bands could be admitted and explained by the splitting of the vibrational levels due to proton tunnelling. The structure of cobaloxime, $CoX(DH)_2B$, may be schematically described in a resonance as follows:



The hydrogen atoms in the hydrogen bridges may not occupy a central position between the oxygen atoms, which would result in the appearance of two OH bands in 1700—1900 cm^{-1} and in 2300—2400 cm^{-1}.[9]

12) H. P. C. Hogenkamp, J. E. Rush, and C. A. Swenson, *J. Biol. Chem.*, **240**, 3641 (1965).

in electron density in the equatorial bisdimethylglyoximato moiety. More electron-donating ligand in the sixth position causes weaker interaction between Co and the fifth ligand, which results in an increase in the Co-base bond length, and hence in the decrease in electron density in the equatorial moiety.

Similar effects of the axial ligands which were observed in the electronic spectra are considered to be consistent with the results, *viz.*, the stronger the interaction between Co and the axial base, the higher the *d-d* transition energy, whereas the stronger the donating power of another axial ligand, the lower the *d-d* transition energy.

Experimental

Synthesis of Cobaloximes. Chlorocobaloximes: a) Chloro(nicotinamide)cobaloxime: A typical method for the synthesis of chloro(nicotinamide)cobaloxime is as follows. To a hot solution of 2.55 g (0.022 mol) of dimethylglyoxime (abbreviated as DH_2 hereinafter) in 80 m*l* of ethanol, was added 2.38 g (0.010 mol) of $CoCl_2 \cdot 6H_2O$ in 10 m*l* of ethanol with stirring. After a while, 2.68 g (0.022 mol) of nicotinamide in 20 m*l* of ethanol was added to the mixture, followed by stirring with aeration for a few hours at room temperature, resulting in precipitation of the product. The precipitated ocher powders were collected, washed with water, ethanol, and finally with ether, and dried *in vacuo*. The yield was 1.56 g (35%).

Another method in which NaOH is used instead of organic base to neutralize HCl produced is as follows. To a hot solution of 2.55 g (0.022 mol) of DH_2 in 80 m*l* of ethanol, was added 2.38 g (0.010 mol) of $CoCl_2 \cdot 6H_2O$ in 10 m*l* of ethanol with stirring. After a while, 1.34 g (0.011 mol) of nicotinamide in 10 m*l* of ethanol and 0.40 g (0.010 mol) of NaOH in 10 m*l* of H_2O were successively added. The mixture was worked up as above. The yield was 2.60 g (58%).

Other chlorocobaloximes with organic bases were prepared using organic bases instead of nicotinamide.

b) Chloroaquocobaloxime: To a hot solution of 12.8 g (0.11 mol) of DH_2 in 300 m*l* of methanol, 11.9 g (0.050 mol) of $CoCl_2 \cdot 6H_2O$ in 50 m*l* of H_2O was added with stirring at room temperature. Fifty milliliters of a saturated aqueous solution of KCl was added to the mixture which was stood overnight, resulting in crystallization of the product in pale brown fine needles. The yield was 5.8 g (34%).

Cyanocobaloximes: A typical method for the preparation of cyano(pyridine)cobaloxime is as follows. To a hot solution of 6.40 g (0.055 mol) of DH_2 in 200 m*l* of methanol, 6.23 g (0.025 mol) of $Co(CH_3COO)_2 \cdot 4H_2O$ was added with stirring. After a while, 1.23 g (0.025 mol) of NaCN in 20 m*l* of H_2O, and 4.15 g (0.053 mol) of pyridine were added successively at room temperature, followed by stirring with aeration for a few hours, resulting in precipitation of the product. The yellow powders were collected, washed with water, methanol, and finally with ether and dried *in vacuo*. The yield was 1.80 g (18%).

Another method in which one equivalent base is enough to produce this complex instead of two is as follows: To a hot solution of 6.40 g (0.055 mol) of DH_2 in 150 m*l* of methanol, 6.23 g (0.025 mol) of $Co(CH_3COO)_2 \cdot 4H_2O$ was added with stirring. After a while, 2.08 g (0.026 mol) of pyridine and 1.23 g (0.025 mol) of NaCN in 20 m*l* of H_2O were added successively at room temperature, followed by stirring with aeration for a few hours, resulting in precipitation of the product. The product was worked up as above to give 2.55 g (26%) of yellow powders.

Other cyanocobaloximes with organic bases were prepared using organic bases, instead of pyridine.

Cyanoaquocobaloxime was prepared as above without adding any organic base but with additional 50 m*l* of H_2O.

Polymeric Cobaloximes——$Co(OH)(DH)_2$(Copoly-AM-VPy): Preparation of polymeric cobaloximes shown in Table 1 was reported.[13] A typical procedure is as follows: A hot solution of DH_2 in methanol was mixed with an aqueous solution of $CoCl_2 \cdot 6H_2O$ (DH_2: Co molar ratio 2) for an hour. An aqueous solution of the polymeric ligand (Copoly-AM-VPy) was then added to the reaction mixture (Co : VPy-residue ratio *ca.* 4), after the pH of the mixture was adjusted to 8.0—8.3. The reaction was complete within 3—4 hr. After concentration, the reaction mixture was applied to the Sephadex column (Sephadex LH-20 or G-25). From the first fraction, polymeric cobaloxime was recovered, followed by a by-product, *i. e.*, hydroxoaquocobaloxime. Alternatively the product was purified by repeated reprecipitation in water-acetone. The by-product was identified as $Co(OH)(DH)_2(H_2O)$ by elemental analysis and its infrared spectrum:

Found: C, 27.87; H, 5.25; N, 16.53%. Calcd for $C_8H_{17}N_4O_6Co$: C, 29.64; H, 5.29; N, 17.28%.

Hydroxoaquocobaloxime was also prepared as follows: To a hot solution of 12.8 g (0.11 mol) of DH_2 in 200 m*l* of methanol, was added 11.9 g (0.050 mol) of $CoCl_2 \cdot 6H_2O$ with stirring. After a while, 4.4 g (0.11 mol) of NaOH in 70 m*l* of H_2O was added to the mixture, followed by stirring with aeration for a few hours. The solution was evaporated to dryness and the residual product was applied to the Sephadex G-25 column to give dark brown hydroxoaquocobaloxime. The yield was 6.3 g (39%).

Found: C, 29.16; H, 3.95; N, 17.31%. Calcd for $C_8H_{17}N_4O_6Co$: C, 29.64; H, 5.29; N, 17.28%.

Alkylcobaloximes: Alkylcobaloximes were prepared according to two methods by Schrauzer and Windgassen;[6] by the reaction of alkyl halide with Co(I) species reduced by $NaBH_4$, and by that with Co(I) species formed by disproportionation of Co(II) species to Co(I) and Co(III) in alkaline media without any reducing agent. A typical method for the preparation of methylaquocobaloxime is as follows. To a stirred suspension of 29.0 g (0.250 mol) of DH_2 in 300 m*l* of methanol, 29.7 g (0.125 mol) of $CoCl_2 \cdot 6H_2O$ was added under nitrogen atmosphere. Methyl iodide, 25.4 g (0.180 mol), and 15.0 g (0.375 mol) of NaOH in 50 m*l* of H_2O were then successively added at $-20°C$, followed by stirring for an hour in a closed system. After evaporation of methanol under a reduced pressure, the remaining aqueous solution was stood overnight, resulting in the precipitation of dark red crystals. The yield was 15.8 g (80%).

When alkylaquocobaloxime was too soluble to isolate, pyridine or another organic base was added to the reaction mixture and alkyl(pyridine)cobaloxime or alkyl(B)cobaloxime was extracted with ether or methylene chloride. The yields obtained by the method with $NaBH_4$ were generally lower than those by alternative method, whereas alkyl iodides were more effective than bromides or chlorides in the preparation of alkylcobaloximes.

Base Substitution Reaction of Alkylaquocobaloxime. The coordinating water in alkylaquocobaloxime is readily displaced by another organic base only by the addition of an equivalent amount of base to the alkylaquocobaloxime. A typical displacement reaction is as follows. Methylaquocobaloxime, 0.967 g (3.00 mmol), was dissolved in 50 m*l* of methanol followed by addition of 0.204 g (3.00 mmol) of

13) N. Yamazaki and Y. Hohokabe, *Chem. Commun.*, **1968**, 829.

imidazole, resulting in immediate color change in the solution from reddish orange to yellow. By concentrating the solution, 1.05 g (94%) of yellow crystals of methyl(imidazole)-cobaloxime was obtained quantitatively.

Alkylcobaloximes prepared in this work are summarized in Table 4. The yields are not given in order to avoid complexity originating from the various preparatory methods.

Measurements. The infrared spectra were taken in KBr pellets with a JASCO, Model IR-G infrared spectrophotometer, and the far-infrared spectra with a JASCO, Model IR-F, far-infrared spectrophotometer.

Studies of Organic Peroxides. XI. The Reaction of Benzoyl Peroxide with Secondary Amines in Binary Mixed Solvents

Shigeo HASEGAWA, Setsuo KASHINO, and Yoshinobu MUKAHI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received July 31, 1970)

The rate constants of the reaction of benzoyl peroxide with some typical secondary amines, namely, diphenylamine, *N*-methylaniline, and piperidine, were measured in benzene-nitrobenzene binary mixed solvents. The reaction rates of diphenylamine and *N*-methylaniline are little influenced by the compositions of the solvents, while the reaction of piperidine proceeds more rapidly in nitrobenzene than in benzene. The isokinetic relationship holds for the reaction of piperidine in the binary mixed solvents. The isokinetic temperature is calculated to be 265°K. The analysis of the behavior of these reactions in the mixed solvents leads to the conclusion that, in the cases of diphenylamine and *N*-methylaniline, there are no specific interactions between the activated complexes and solvent molecules, whereas in the case of piperidine the activated complex is weakly solvated with the polar nitrobenzene. The reaction of benzoyl peroxide with *N*-methylaniline and *N*-*n*-butylaniline was also studied in benzene. These amines have a higher reactivity than would be expected from their basicity. This higher reactivity is probably due to the resonance stabilization of the activated complex besides the formation of a less-ionic activated complex.

In a previous work,[1] the reaction of benzoyl peroxide with some typical secondary amines was studied in benzene. It was ascertained that the reaction involves a nucleophilic attack by the amines on the peroxide, and it was noted that diphenylamine has rather a higher reactivity in spite of its lower basicity. This higher reactivity of diphenylamine was explained by the formation of a less-ionic activated complex. The explanation, however, was not conclusive.

In the present investigation, in order to obtain more clear-cut information on the activated complex, the reaction of benzoyl peroxide with *N*-methylaniline and *N*-*n*-butylaniline was studied in benzene, further, the rate constants of the reaction of benzoyl peroxide with diphenylamine, *N*-methylaniline, and piperidine were measured in benzene - nitrobenzene binary mixed solvents.

Experimental

The benzoyl peroxide, diphenylamine, piperidine, and benzene were the same as those described in the previous paper.[1] *N*-Methylaniline and *N*-*n*-butylaniline were commercially-available GR-grade reagents. The nitrobenzene was dried with anhydrous sodium sulfate and fractionated at reduced pressure.

The reaction rates were followed by means of the thermal-analysis method at temperatures between 20 and 35°C. The apparatus and procedure were also the same as those described in the previous paper.[1]

Results and Discussion

The reactions of benzoyl peroxide with amines were of the first order with respect to each reactant for all amines examined. It was reported previously[1] that diphenylamine and piperidine reacted with the peroxide in amine-peroxide ratios of 1.3 : 1 and 0.6 : 1 respectively. In the reaction of *N*-methylaniline and *N*-*n*-butylaniline, however, the stoichiometry was found to be 1 : 1.

The values of the second-order rate constants, k, for the reactions of *N*-methylaniline and *N*-*n*-butylaniline in benzene are shown in Table 1, together with those for the other amines studied previously;[1] the values of the enthalpy and entropy of activation are listed in Table 2.

TABLE 1. RATE CONSTANT $k \times 10^3$ (l mol^{-1} sec^{-1}) FOR BENZOYL PEROXIDE-SECONDARY AMINE REACTIONS IN BENZENE

	15°C	20°C	23°C	25°C	30°C	35°C
N-Methylaniline		14.5		20.2	26.9	33.6
N-*n*-Butylaniline		15.0		21.5	27.0	34.8
Diethylamine[a]	1.61	2.43		3.70	5.33	
Piperidine[a]	26.9	35.7		46.1	60.2	
Diphenylamine[a]	7.34		13.8		23.1	

a) Data from Ref. 1.

TABLE 2. ENTHALPY AND ENTROPY OF ACTIVATION FOR THE REACTION OF BENZOYL PEROXIDE WITH SECONDARY AMINES IN BENZENE AT 25°C, kcal mol^{-1} or cal deg^{-1} mol^{-1}

	$\Delta H^{\neq}$	$\Delta S^{\neq}$
N-Methylaniline	7.9	−40.0
N-*n*-butylaniline	7.5	−41.4
Diethylamine[a)]	13.3	−25.1
Piperidine[a)]	8.6	−35.8
Diphenylamine[a)]	12.7	−24.2

a) Data from Ref. 1. $\Delta S^{\neq}$ is calculated from the rate constant at 30°C.

As may be seen in Tables 1 and 2, the alkylanilines have a slightly higher reactivity than diphenylamine. This can be explained by a mechanism which involves a nucleophilic attack by the amines on the peroxide,[1,2] because an inductive effect of the alkyl group would cause the increase in the electron density on the nitrogen atom of the amines, thus reducing the activation enthalpy and increasing the rate of the reaction.

The reactivities of both *N*-methylaniline and *N*-*n*-butylaniline are almost comparable to that of highly-basic piperidine, and are obviously higher than that of diethylamine. It can be said that the alkylanilines as well as diphenylamine have a rather higher reactivity than would be expected from the basicity. This suggests that the aromatic amines, that is, the alkylanilines and diphenylamine, form activated complexes somewhat different from those of the aliphatic amines.

TABLE 3. RATE CONSTANTS FOR BENZOYL PEROXIDE-SECONDARY AMINE REACTIONS IN BENZENE-NITROBENZENE MIXED SOLVENTS

Molar fraction of nitrobenzene x	Rate constant $k \times 10^3$ (l mol^{-1} sec^{-1})					
	Diphenylamine		*N*-Methylaniline	Piperidine		
	25°C	30°C	25°C	20°C	25°C	30°C
0.000	17.6	29.6	20.2	35.7	46.1	60.2
0.224	19.7	28.2	21.8	46.5	65.7	76.1
0.306	20.8	28.5	21.2	48.8	67.9	88.8
0.500	17.3	26.7	23.4	58.2	79.1	104.5
0.635	—	—	22.0	58.6	83.6	111.9
0.673	17.6	28.5	—	—	—	—
0.725	16.7	27.5	22.0	70.5	82.1	116.4
1.000	16.0	27.5	22.4	64.9	97.8	129.9

In order to clarify this difference, the solvent effect was examined. The experimental results are listed in Table 3 and are plotted in Fig. 1. It may be seen that, in the cases of *N*-methylaniline and diphenylamine, the compositions of the solvents have little influence on the rates of reactions, while in piperidine the rates obviously increase with the increase in the molar fraction of nitrobenzene.

These results are in line with the solvent effects

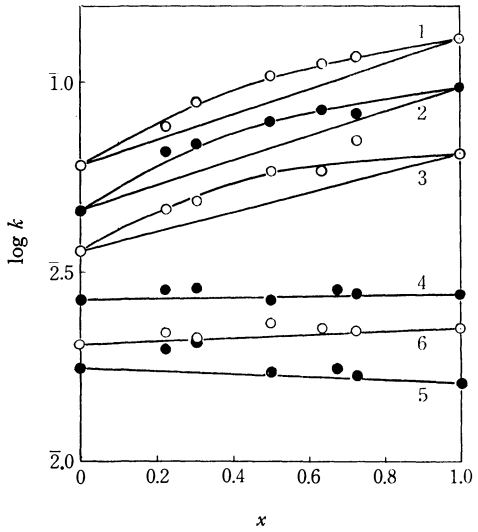

Fig. 1. Plot of log k *vs.* mole fraction of nitrobenzene, x, for the reaction of benzoyl peroxide with secondary amines in benzene-nitrobenzene mixed solvents.
1: piperidine, 30°C, 2: piperidine, 25°C, 3: piperidine, 20°C, 4: diphenylamine, 30°C, 5: diphenylamine, 25°C, 6: *N*-methylaniline, 25°C

observed by Chaltykyan *et al.*[3,4] They have shown that basic aliphatic amines react more rapidly in acetone than in ethyl ether, while diphenylamine has almost the same reactivity in these solvents.

of activation are listed in Table 4. It may be noted that, in this reaction series, a higher enthalpy of activation does mean a higher rate; this is in contrast to the majority of reactions. The enthalpy of activation, $\Delta H^{\ddagger}$, is plotted against the entropy of activation, $\Delta S^{\ddagger}$, in Fig. 2. It may be seen that the isokinetic relationship holds for this reaction. The isokinetic temperature is calculated to be 265°K, below the experimental temperature. Pearson[5] has pointed out that the reactions in which ionic products are formed from neutral molecules frequently have an isokinetic temperature lower than the experimental temperature. Thus, it may be said that the reaction of piperidine with benzoyl peroxide has the same character as many ionic reactions.

Recently, Kondo and Tokura[6] have shown that, in the reactions in which the activated complexes have polar structures and are solvated in such polar solvents as nitrobenzene, the plot of log k *vs.* the composition of the mixed solvent deviates upward. Further, they have derived[7] theoretical expressions for the rate constants in binary mixed solvents on the basis of the theory of the non-electrolyte solution. An application of this theory was made in analyzing the reaction behavior of benzoyl peroxide with secondary amines.

According to Kondo and Tokura,[7] for the system in which all the solutes yield regular solutions the theoretical expression for the rate constant in a binary mixed solvent, k_{mix}, is given by:

$$\ln k_{mix} = x_1 \ln k_1 + x_4 \ln k_4 - \alpha_{14} x_1 x_4 \qquad (1)$$

where k_i and x_i stand for the rate constant in a pure solvent, i, and the mole fraction of the i solvent, respectively, and where α_{14} is a parameter expressing the deviation from the ideal-solution behavior of the solvent system.[8]

For the system in which there are specific interactions between the activated complex and the polar solvent, the expression for the rate constant can be given by:

$$\ln k_{mix} = x_1 \ln k_1 + x_4 \ln k_4 - \{x_1 \ln (K+1) - \ln(x_1 K+1) + x_1 x_4 \alpha_{14}\} \qquad (2)$$

where K is an equilibrium constant, defined in terms of the molar fraction, for the formation of a solvated activated complex from the unsolvated activated complex and the polar solvent.

The values of α_{14} for the benzene - nitrobenzene system have been estimated from the equilibrium vapour pressure data to be 0.10.[7] The values for K is so determined that the value calculated for k from Eq. (2) is equal to the experimental results at $x_1=x_4=0.5$.

The value of K for the reaction of piperidine was calculated to be 2.0. This means that, in pure nitrobenzene, the molar ratio of the solvated activated complex and the unsolvated one is 2 : 1.

The solid lines in Fig. 1 are calculated by means of Eqs. (1) and (2). It may be seen that, in the cases of *N*-methylaniline and diphenylamine, the relations between log k and the molar fraction of nitrobenzene are almost linear and agree with the lines calculated by Eq. (1), and that in piperidine the relation agrees well with the upward curved lines calculated by Eq. (2). Therefore, it can be concluded that, in the cases of diphenylamine and *N*-methylaniline, there are no specific interactions between the activated complex and the solvent molecules, whereas in the case of piperidine the activated complex is solvated with the polar nitrobenzene.

The results presented above show that the aromatic amines form a less-ionic intermediate, whereas aliphatic amines form a more-ionic intermediate, in the course of the reaction with benzoyl peroxide; this is in accordance with the previous proposition.[1]

However, even in the case of piperidine the solvent effect is much smaller than in typical ionic reactions, such as the Menschtkin reaction.[7] Kondo and Tokura[9] have also derived a theoretical expression for the activation energies in binary mixed solvents. In the reaction of piperidine with benzoyl peroxide, the solvent effect is too small to make it possible to discuss the changes in the activation energies in relation to the expression. That is, even in the case of highly basic piperidine the ionic character of the activated complex is rather small. Therefore, it is difficult to ascribe the higher reactivity of the aromatic amines only to the formation of the less-ionic activated complex. It is more reasonable to take other factors into consideration.

With regard to this higher reactivity of aromatic amines, another plausible reason is the resonance stabilization of the activated complex. Horner and Steppan[10] have proved that, by the reaction of *N*-ethylaniline with benzoyl peroxide at 20°C, *O*-benzoyl-*N*-ethyl-*N*-phenylhydroxyamine, *N*-benzoyl-*o*-hydroxy-*N*-ethylaniline, and *p*-benzoyloxy ethylaniline are formed; that the latter two products are not formed by the rearrangement of the former, but are formed directly by the reaction with benzoyl peroxide. Further, Denney and Denney[2] have shown that the reaction of diphenylamine with benzoyl peroxide labeled with oxygen-18 in the carbonyl positions forms, as the main product, *N*-(*o*-hydroxyphenyl)-*N*-phenylbenzamide, which contains 55% of oxygen-18 in the carbonyl oxygen and 45% of oxygen-18 in the phenol oxygen, and that, in the case of dibenzylamine, no such equilibration of oxygen-18 occurs. These facts may be evidence of the resonance of the activated complexes from aromatic amines.

Structure and Intramolecular Motions in Triethylenediamine as Studied by Gas Electron Diffraction

Akimichi YOKOZEKI and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received August 13, 1970)

The structure and intramolecular motions in triethylenediamine have been investigated by gas electron diffraction with a parallel study of bicyclo[2.2.2]octane in our previous paper. The structural parameters determined by a least-squares analysis on molecular intensities, with estimated limits of error, are as follows: r_g(C–N) = 1.472 ± 0.007 Å, r_g(C–C) = 1.562 ± 0.009 Å, ∠C–C–N = 110.2 ± 0.4°, ∠C–N–C = 108.7 ± 0.4°, r_g(C–H) = $1.11_0 \pm 0.01_2$ Å and ∠H–C–H = $111._5 \pm 5._6$°. The gas-phase structure is in good correspondence with that in the crystal phase determined by Weiss *et al.* by X-ray diffraction. The potential function with regard to the twisting motion around the C_3 symmetry axis is shown to have a broad minimum around the D_{3h} conformation, being quite analogous to that for bicyclo[2.2.2]octane; in terms of the torsional angle ϕ about the C–C axis, it probably has a small hump of the order of 100 cal/mol at $\phi = 0°$ and a double minimum around $\phi = 10°$. The above study was made with a new nozzle assembly, by which the sample can be heated to about 200°C. The detail of the design and operation is described.

According to our previous study of gas-phase electron diffraction,[1] bicyclo[2.2.2]octane (hereafter abbreviated as BO) has such a characteristic intramolecular motion with a large amplitude of twisting about the C_3 axis that the molecular symmetry should rightly be called "quasi-D_{3h}". Since triethylenediamine (TEDA), or 1,4-diazabicyclo[2.2.2]octane (Fig. 1), has an analogous

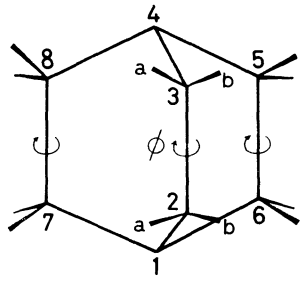

Fig. 1. Triethylenediamine, $(C_2H_4)_3N_2$; ϕ denotes a torsional angle defined by the dihedral angle between the planes N_1–C_2–C_3 and C_2–C_3–N_1.

skeleton, a similar problem of molecular dynamics is expected for TEDA. In fact, the intramolecular and overall motions in the crystal phase have been investigated by various experimental methods;[2-8] a particular attention has been paid to the solid-state properties of TEDA, since it belongs to the so-called "plastic crystals."[9,10]

In spite of such studies, however, the potential function for the twisting motion has not been explored in detail; nor has any conclusion regarding the equilibrium symmetry (D_{3h} or D_3) been reached. Therefore, an electron-diffraction study of gas-phase TEDA was initiated to parallel that of BO. In contrast to the case of BO, where closely-spaced C–C bond distances (C_1–C_2 and C_2–C_3) were hardly separable, the corresponding analysis for TEDA to separate N_1–C_2 and C_2–C_3 distances poses no serious problem.

In order to get a sufficient vapor pressure, a nozzle assembly, which can be heated to about 200°C, has been constructed. A detail of the design and operation is described in the Appendix.

Experimental

Anhydrous TEDA (classified as extra pure) was purchased from the Tokyo Chemical Industry Co. Ltd. The sample was loaded in a sample holder (Fig. 3a) in a dry atmosphere. Diffraction photographs were taken on Fuji Process Hard plates with the camera length of 113 mm at the temperature of 120°C (in the sample holder and on the nozzle tip) for 2 min with an apparatus equipped with an r^3-sector.[11] The accelerating voltage, about 40 kV, was stabilized within 0.1% during the experiment, and the beam current was 0.40 μA. The scale factor of the diffraction pattern was calibrated to

within 0.07% with reference to the r_a(C–O) bond length of carbon dioxide, 1.1646 Å,[11] and to the r_a(N–N) distance of the nitrogen gas, 1.1007 Å.[12] Other experimental and interpretational procedures are similar to those described in Ref. 1. A typical observed molecular intensity[13] and the difference between the observed and theoretical best-fit curves are shown in Fig. 2.

Analysis

The analytical procedures closely followed those empolyed in the study of BO. The mean amplitudes and nonlinear shrinkage corrections[14] on all the internuclear distances were calculated for a D_{3h} structure with sets of the Urey-Bradley force constants transferred from those for cyclohexane[15] and amides.[16] The vibrational frequencies calculated by the use of the force constants given in Table 1 are in fair agreement with the observed values reported in the literature,[2-4] as shown in Table 2. The mean amplitudes and vibrational corrections are insensitive to the moderate changes in the force constants, except for the torsional force constant Y.[1] Systematic variations in Y, 0.11 (estimated upper limit[1]), 0.08, 0.05 and 0.025 md·Å, yielded the lowest vibrational frequencies of 137, 118, 94 and 67 cm^{-1}, respectively. All the other frequencies were independent of Y; this indicates that the normal mode of twisting is separable almost completely from the other modes. The mean amplitudes and vibrational corrections calculated for 120°C are listed in Tables 3 and 4.

Least-Squares Analysis. On the assumption that the H–C–H plane is perpendicular to the N–C–C plane and bisects the N–C–C angle and *vice versa*, the molecular intensity (q=21 to 120) was first analyzed by a standard least-squares method[17] with the sets of constant mean amplitudes and shrinkage corrections, given in Tables 3 and 4, and with the following six variable parameters: the N–C and C–C bond distances, the N–C–C angle, the C–H distance, the H–C–H angle, and the equilib-

b) Sets I through V correspond to those in Table 3.

rium torsional angle ϕ_e defined in Fig. 1. The dependence of the ϕ_e parameters on Y was similar to that observed in the analysis of BO: By the use of Y=0.11, 0.08, and 0.05 md·Å, the cycles converged to nonzero sets (D_3) of ϕ_e, 9.8±1.1°, 8.5±0.9°, and 5.4±3.0° respectively, while ϕ_e tended to 0° (D_{3h}) for Y= 0.025 md·Å.

The situation that the alternative [twisted (D_3) or untwisted (D_{3h})] structures were derived from the analysis is in accordance with that encountered in the crystal-structure study of Weiss *et al.*,[4] where the D_{3h} and D_3 (with a twist angle of about 10° corresponding to $\phi_e\sim16°$) structures, both reasonable answers of their three-dimensional X-ray analysis, made them suggest a double-minimum potential for the twisting motion. A similar trend observed in BO has been explained by a potential with a broad trough and shallow double minima.[1] Therefore, TEDA is also expected to have a large-amplitude motion around the D_{3h} position, as is discussed below.

The rest of the independent parameters were unaffected by the choice of Y. The parameters obtained from the analysis are listed Table 5 with their limits of error (estimated as 2.5 times random errors plus systematic errors).[17-19] The corresponding error matrix is given in Table 6. In contrast to the case of BO,

a) Error matrix for fixed mean amplitudes. Units ($\times10^{-4}$) for the distances are Å those for the angles are rad, and the index of resolution k is dimensionless. Elements of the matrix are given by $\sigma_{ij}=\mathrm{sgn}[(B^{-1})_{ij}]\cdot[|(B^{-1})_{ij}|\cdot V^*PV/(n-m)]^{1/2}$, where the notations follow Ref. 20. The diagonal element σ_{ii} represents the standard error for the parameter i.

the analysis evidenced that none of the distance and angle parameters had strong correlation with the mean amplitudes. Therefore, it was further possible to treat a number of mean amplitudes as variable parameters in the least-squares calculations, from which the amplitudes listed in Table 7 were obtained, with no significant influence on the distance and angle parameters and their uncertainties given in Table 5.

Table 7. Mean amplitudes for triethylenediamine (in Å units)

a) Errors represent random standard deviations obtained by a least-squares analysis (see text).
b) Calculated by Set II of Table 3.

Determination of the Potential Function. The potential function for the twisting motion around the C_3 symmetry axis, as characterized by a single torsional coordinate ϕ illustrated in Fig. 1, was assumed to have a quadratic-quartic type, $V(\phi)=k_2\phi^2+k_4\phi^4$. The molecular intensity function was averaged classically by the Boltzmann weight in regard to ϕ. The coefficients of $V(\phi)$ were determined by a least-squares method, by which the experimental molecular intensity was allowed to fit to the theoretical expression[1] by the use of the mean amplitudes of set I given in Table 3. The most probable set was found to be $k_2=-5.5\pm4.2$ kcal/mol rad^2 and $k_4=86.2\pm50.2$ kcal/mol rad^4. The parameters specifying the potential shape are compared in Table 8 with those for BO.

The radial distribution curve corresponding to the best-fit potential is in good agreement with the experimental curve, as shown in Fig. 3, where a theoretical curve corresponding to a D_{3h} structure with small amplitudes of twisting and frame vibrations is also

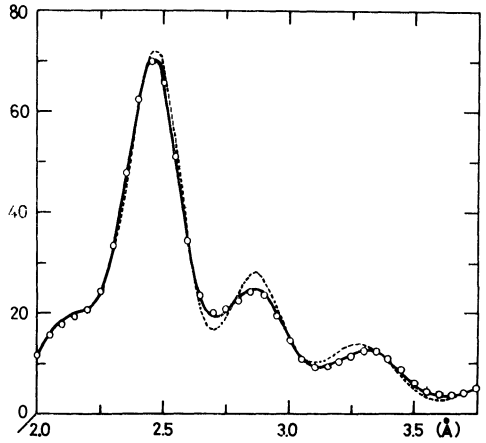

Fig. 3. Radial distribution curves for a region sensitive to the twisting motion.
Solid and broken lines represent synthetic curves calculated for the quadratic-quartic potential function $V(\phi)$ determined in the text and for a quadratic function, $V(\phi)=c\phi^2$ with $c=17$ kcal/mol rad^2, corresponding to the force constant for torsion, $Y=0.08$ md·Å,[1)] respectively; cirlces represent experimental values and their estimated uncertainties.

displayed. The distinct peak at about 2.8 Å is mainly composed of the nonbonded C_2–C_8 and C_3–C_7 pairs; a single sharp peak corresponding to a "rigid" D_{3h} conformation, where those pairs are equidistant, gets flattened as the system exerts a large-amplitude twisting motion. Thus, the contour of this peak offers a sensitive measure for the feature of the twisting potential.

Discussion

Structure. The C–N bond distance, 1.472±0.007 Å, is significantly longer than that of trimethylamine (1.451±0.003 Å)[22)] but is nearly equal to those of dimethylamine (1.466±0.005 Å),[23)] methylamine (1.467±0.002 Å),[24)] and ethylenediamine (1.468±0.005 Å).[25)] The rest of the parameters are almost identical with those for BO, as is contrasted in Table 9. The C_2–C_3 bond length, which has been determined with a much higher accuracy than that of BO, is significantly (about 0.02 Å) longer than that of cyclohexane.[26)] A similar lengthening has recently been observed in the C–C distance of ethylenediamine.[25)] The C–C–N bond angle is found to be equal to that in ethylenediamine, both slightly larger than the tetrahedral angle. The bridgehead angle (∠C–N–C) is about 2° smaller than that in trimethylamine.[22)]

A good correspondence has been observed between the gas-phase and crystal structures of TEDA, as compared in Table 9. A similar correspondence reported in Ref. 1 between the free BO and a crystal-phase BO derivative[27)] suggests that the intramolecular geometrical parameters for such globular molecules are little influenced by intermolecular interactions, which should exist in the solid state.

Potential Function. From the potential function determined in Table 8, one sees that TEDA has a "quasi-D_{3h}" structure analogous to that of BO (Fig. 4). Both molecules have potentials with double minima at $\phi\sim10°$ and small humps at $\phi=0°$. In this connection,

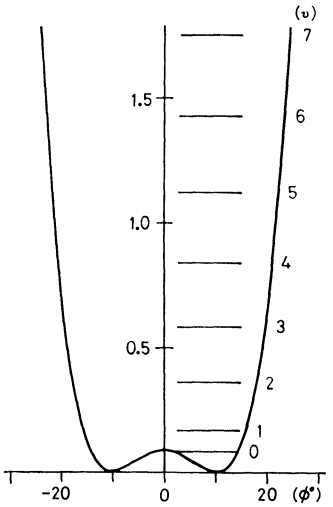

Fig. 4. The twisting potential function determined in terms of a torsional coordinate ϕ, $V(\phi)=-5.5\,\phi^2+86.2\,\phi^4$ (kcal/mol); horizontal lines, calculated energy levels for this potential function (see text).

e) For BO, the letter N should be replaced by C.

a similar potential for the 1-fluoro derivative of BO has recently been observed by Hirota from a microwave study.[28]

The origin of the hump at D_{3h} may be explained by a semi-empirical calculation of strain energy, if plausible models can be estimated for nonbonded N–N and N–H interactions. One of the primitive approaches to this problem is to assume that the N–N and N–H interactions are equal to those for the C–C and C–H pairs, respectively. Such a calculation of the strain energy, analogous to that for BO, yielded a potential hump of about 130 cal/mol with double minima at $\phi \sim 13.5°$, in reasonable agreement with the observed potential.

On the basis of the potential determined above, the energy levels for the twisting mode were estimated by the procedure described in Ref. 1. With an effective reduced mass of 26.8 amu calculated on the assumption of a semi-rigid framework, the levels given in Table 10 were obtained.

Table 10. Estimated energy levels of the twisting motion for triethylenediamine[a] (cm^{-1}).

v	E_v	v	E_v	v	E_v
0	28.8	3	205.6	6	500.2

2	128.0	5	393.7	8	733.3

a) Semiquantitative estimates based on the experimental potential function, $V = -5.5\phi^2 + 86.2\phi^4$ (kcal/mol, ϕ; in rad), determined in the present study.

Appendix

Construction of a High-Temperature Nozzle Assembly. A nozzle assembly which can be heated to about 200°C was constructed for structure studies of compounds with vapor pressures less than several Torr at room temperature. The assembly, illustrated in Fig. 1a, may be classified into three parts: a) the nozzle body equipped with a heating pipe 4 and a cooling pipe 5 with water ducts 12, and a mechanism

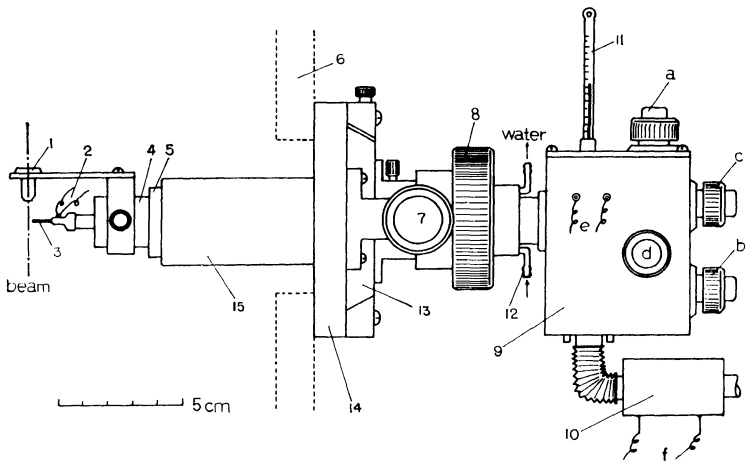

Fig. 1a. Nozzle assembly settled on a side-wall 6 of the diffraction chamber. The system is made vacuum-tight with metal *O*-ring contacts at 5—15, 13—14 (sliding) and 6—14 (fixed).

28) E. Hirota, Private communication (1970).

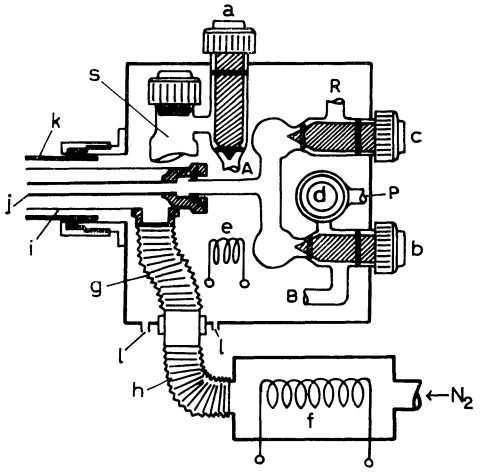

Fig. 2a. Inside section of the box 9 and the heater 10.
The walls are covered with asbestos. *a–d*: valves, *e*, *f*: electric heaters, *g–i*: paths of hot nitrogen gas, *j*: sample inlet, *k*: pipe corresponding to 4 in Fig. 1a, *l*: outlet of the nitrogen gas, *s*: sample holder with a connection *A*, *B* shown in Fig. 3a, *R*: reference gas inlet, *P*: outlet to a vacuum pump.

for adjustment 7, 8; b) an electric heater 10 supplying hot nitrogen gas as a thermal medium; c) values *a*—*d* (Fig. 2a) and a sample holder (Fig. 3a) installed in a box 9.

The sample is heated to a required temperature in the sample holder. Valves *a* and *b* are then opened, and the sample vapor is allowed to flow through a horizontal stainless-steel pipe (3 mm inside diameter) in the heating pipe 4 and emit through a capillary 3 (0.2 mm i. d.) into the diffraction chamber, where it crosses the vertical electron beam at a preset distance (0.4—0.6 mm) from the nozzle tip and condenses on a trap cooled with liquid nitrogen.[11]

Parts *b* and *c* are shown in Fig. 2a. The nitrogen gas heated by *f* (50Ω) flows through bellows *g* and *h* into a pipe *i*, heating the sample path *j*, and returns into the box, where the gas is again heated by *e* (125Ω) and ejected from the box (*l*) after heating the sample holder and the valves. At a normal flow rate of about 500 *l*·atm/min, and with A. C.

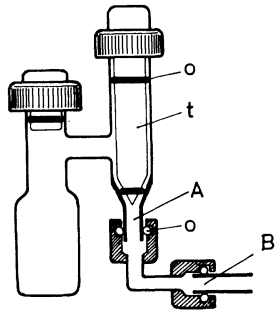

Fig. 3a. Cross section of the sample holder.
A, *B*: see corresponding parts in Fig. 2a, *o*: heat-resistant *O*-rings, *t*: teflon stopper.

voltages of 55 V applied on *f* and 25 V on *e*, the temperatures on the nozzle tip and inside the box reach 100°C. No disturbance on the electron beam caused by the heater currents is observed. The temperatures are measured with a copper-constantan thermocouple and a mercury thermometer, as shown in Fig. 1a. Thermal equilibrium is reached in several minutes, and a constant temperature (within ± 1°C) can be maintained during the experiment (of the order of 10 min). The values (*a*—*d*) made of glass and teflon with heat-resistant O-rings are set up in the box: *a* and *b* for the sample, *c* for a reference gas, and *d* for an exhaust valve. The sample holder with valve *a* can be removed from the other parts in the box (at positions *A* and *B* in Fig. 3a) in order that the sample may be loaded or unloaded outside the box.

The nozzle assembly can be moved in two directions perpendicular to the electron beam so as to make the beam pass through the aperture 1[11] by means of ball-bearing systems 7, 8 and sliding systems 13—15 with O-rings shown in Fig. 1a. The changes in the camera length by this adjustment and by thermal strain are found to be within 0.01 mm. The camera length is first estimated by a cathetometer and is later determined by the analysis of a diffraction pattern for a standard sample (CO_2 or N_2), which can be introduced into the diffraction chamber by the use of valve *c* in place of the sample to be studied at an identical experimental condition. In this way, the scale factor can be calibrated to within 0.07%.

Calorimetric Study of the Glassy State. VI. Phase Changes in Crystalline and Glassy-Crystalline 2,3-Dimethylbutane

Keiichiro ADACHI, Hiroshi SUGA, and Syûzô SEKI
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, Japan
(Received August 14, 1970)

2,3-Dimethylbutane has two crystalline phases, high temperature form (crystal-I) and low temperature form (crystal-II). On account of the supercooling effect of crystal-I, its *glassy crystalline* state (non-equilibrium frozen-in state) is established below T_g (76 K) by rapid cooling. The heat capacities for various phases were determined from 13 to 300 K from principal interest in the thermodynamic properties of the glassy crystal. The transition temperature from crystal-II to crystal-I and melting point were determined to be 136.02 K and 145.05 K, respectively. The heats of transition and of fusion were determined to be 6427 J mol^{-1} and 788 J mol^{-1}, respectively. From these data, the residual entropy and T_2 temperature were determined to be 7.4 JK^{-1} mol^{-1} and 65 K, respectively. We also calculated the ratio of T_g to T_2 for several glassy crystals known hitherto, which amounts to 1.15—1.20. The stabilization effect was studied by the measurement of the change of the configurational enthalpy in the glassy crystalline state. Also, we discovered a new meta-stable intermediate phase (crystal-III) in the course of irreversible transition from the supercooled crystal-I to crystal-II. The thermal properties of this phase were also studied and its residual entropy was determined to be 2.7 JK^{-1} mol^{-1}.

Although the glass transition phenomenon is generally considered to be characteristic of the supercooled liquid state, it is known that the supercooled crystalline state of some materials also shows a similar behavior.[1-3] We studied the heat capacities of cyclohexanol and concluded that the anomalous jump of the heat capacity curve of the supercooled high-temperature form is attributed to the glass transition phenomenon. We have proposed a new term "*Glassy Crystal*" for the frozen-in state of the supercooled crystalline phase which has glass transition point. We would like to present the results of heat capacity measurements on the glassy crystalline state of 2,3-dimethylbutane as well as on various other stable phases and also on a metastable phase of this material. The thermal study of this substance has already been carried out by Douslin and Huffman.[4] They revealed that it has two crystalline phases, a high-temperature form (crystal-I) and a low-temperature form (crystal-II). The easy supercooling effect of the high-temperature form with rapid cooling has been confirmed in the study of nuclear magnetic resonance by Segall and Aston.[5] The thermal data of the supercooled crystal-I, however, were not given by Douslin and Huffman. In this article we report on the residual entropy of the glassy crystal as well as the T_2 temperature which was defined by Gibbs and Adam.[6] The relaxation phenomenon of the enthalpy was observed below glass transition temperature by annealing. An attempt has been also made to clarify the temperature dependence of the relaxation time. Furthermore, in the course of the irreversible transition from the supercooled crystal-I to crystal-II, we have discovered a metastable intermediate phase (crystal-III). Based on the heat capacity data of the crystal-III, the heat of transition from crystal-III to the supercooled crystal-I and the residual entropy of crystal-III have also been estimated.

Experimental

Material. The material was a mixture of two parts which had different purity. About 60 cc of 2,3-dimethylbutane (Tokyo Kagaku Seiki Co., Ltd. standard material 99.0%) was washed with concentrated sulfuric acid (including a small amount of potassium chromate) for ten hours at room temperatures to remove olefins involved. After this treatment the specimen was separated from the sulfuric acid solution by vacuum distillation and finally fractionally distilled. About 30 cc of the middle fraction of the distillate was obtained ——(A). On the other hand, 40 cc of the specimen which was claimed to have near 99.9% purity (Tokyo Kagaku Seiki Co., Ltd.) was purified by vacuum distillation at −70°C and about 20 cc of the middle fraction was obtained ——(B). The fractions (A) and (B) were mixed and the mixture was further distilled in a vacuum at −70°C. The purified specimen was introduced into the sample container for heat capacity measurements by vacuum distillation. The sample which had the same purity as that for heat capacity measurements was used for differential thermal analysis. The purity determined from equilibrium temperatures during fusion process was found to be 99.87% as will be described below.

Apparatus. The heat capacity was measured by a Nernst type adiabatic calorimeter with a platinum resistance thermometer. The details of the apparatus were reported previously.[7,8] The weight of the specimen employed in the measurement was 19.844 g (about 30 cc) after the correction for buoyancy due to air. A small amount of helium gas (0.2—0.5 cc at room temperature and 1 atm) was added as a heat exchange medium. After the sample and helium gas were introduced into the container, the filling tube (copper capillary) was pinched off and shielded with a soft solder. The apparatus for the differential thermal analysis has also been reported.[9]

Experimental Results

Differential Thermal Analysis (DTA). For the preliminary study of thermal behaviors of this material, differential thermal analyses have been carried out. The results are shown in Fig. 1. Run-1 is for a cooling

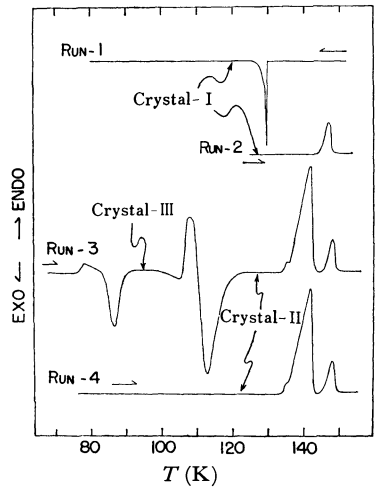

Fig. 1. DTA curves of 2,3-dimethylbutane.

curve with a rate about -1.4 K min^{-1}. The liquid state is supercooled to about 128 K where a sharp exothermic peak due to an abrupt crystallization has been observed. No remarkable thermal anomalies have been observed on further cooling. On account of noise effects and of a slow cooling rate between 80 K and 60 K, a reliable DTA curve has not been obtained. When the temperature was raised rapidly as soon as the sharp exothermic peak was observed at about 128 K in Run-1, only a peak due to the fusion effect was observed at about 145 K. This is shown by the curve for Run-2. From these DTA curves, it was confirmed that the high-temperature form (crystal-I) is easily supercooled. Run-3 is of a heating curve after slow cooling down to 65 K with a similar condition for Run-1. The heating rate of Run-3 is of about 1 K min^{-1}. It is seen that the supercooled crystal-I exhibits an anomaly resembling glass transition at about 78 K. The anomaly has been attributed to the glass transition phenomenon. An exothermic change was successively observed at about 89 K where the supercooled crystal-I was irreversibly transformed into another crystalline phase. We designate this crystalline phase as crystal-III, although we have not confirmed by X-ray analysis whether it is a pure single phase or a mixture of several modifications. After the formation of crystal-III, a gradual heat evolution was observed between 95 K and 105 K. It is considered that a part of crystal-III was transformed into a low temperature form (crystal-II) irreversibly in this temperature region. At about 107 K, the phase transition from crystal-III to an unknown crystalline phase was observed. This unknown phase is, however, unstable and irreversibly transformed to another crystalline phase. The resulting crystalline phase is evidently a stable modification below 136 K as shown by Run-4. Here Run-4 is for the heating curve determined after Run-3 has been stopped at about 125 K and cooled to a lower temperature. We designate this stable phase as crystal-II. Crystal-II was then transformed to crystal-I at 136 K, followed by the fusion of crystal-I at about 145 K. In this case we have always observed a small anomaly at about 135 K just before the II-I transition point in Fig. 1, and the anomaly is rather exaggerated. Occurrence of this anomalous hump[10] was influenced by previous

thermal history and may be attributed to the effect of impurities.

Measurement of Heat Capacity. The results of the heat capacities are listed in Table 1 and heat capacity curves are shown in Fig. 2, where direct results of the measured heat capacities are given by $\Delta H/\Delta T$, that is, an increment of the molar enthalpy divided by the corresponding temperature increment. Series-1 shows the heat capacities of the glassy crystalline state of crystal-I which has been established by supercooling the specimen with an average cooling rate of -2 K min^{-1} from 150 K to 75 K. In series-1 and series-2, the average heating rates were about 10 K/hr and 4 K/hr, respectively, in the glass transition region. The glass transition temperature was determined to be about 75 K from series-1 and 76 K from series-2. As is well known, it is considered that the discrepancy resulted from the difference in heating rates.[11,12] Series-2 also shows the heat capacity of the glassy crystalline state of crystal-I after supercooling with a cooling rate about -2 K min^{-1}. In the glass transition region, the measurements were disturbed by heat evolution due to the relaxation of enthalpy. This phenomenon was observed from 55 K and gradually increased up to 72 K. This heat evolution due to relaxation effect was removed by treating it as if it had arisen from heat inflow due to an incompleteness of adiabatic conditions. In other words, these relaxation effects were subtracted by the correction of a temperature drift in the computation of the heat capacities.[13] If we treat the heat due to the relaxation effect in this way, the calculated values of the heat capacities correspond to those of constant configuration; *i. e.* those measured with an infinitely rapid heating rate. The data of supercooled crystal-I which were obtained successively after the annealing experiments (described later) are shown in series-3. The aim of the measurements of this series was to see whether the irreversible transition from the glassy crystal to another phase had occurred or not during the course of annealing. Series-4 and series-5 give the selected values for crystal-III. The condition for establishing this phase is determined on the basis of the DTA measurements. Series-6 shows the heat capacities for crystal-II. The heat capacities of crystal-I and supercooled crystal-I are given in series-7,8 and 9. The heat capacities of supercooled crystal-I were measured after the specimen was slowly cooled (about -1 K min^{-1}) to about 133 K. However, below 133 K, the irreversible transition from supercooled crystal-I to the low temperature phase occurred gradually before the adiabatic condition for measurement was established. On account of this instability, the heat capacities of supercooled crystal-I between 80 K and 130 K could not be measured. The heat capacities of the liquid state are given in series-10—14. Heat capacities measured in this investigation have been compared with the data of Douslin and Huffman.[4] The deviation is found to be about $\pm 0.5\%$ below 20 K, whereas the data agree quite well within 0.1% between 25 K and 100 K for crystal-II. However, near transition temperature (136 K), our results are larger than those of Douslin and Huffman. The deviation between 110 K and 120 K is from 0.3% to 1% and between 120 K and 130 K about 2%. The deviation near the transition point might be due to impurity. In the region from 136 K to 220 K, the data of Douslin and Huffman is about 0.2% smaller and in the region from 220 K to 300 K, about 0.5% smaller.

Molar Heats of Transition and Fusion. Equilibrium temperatures during fusion process and the molar heats of fusion and transition are given in Tables 2, 3, and 4, respectively. As shown in Table 2, the impurities in the specimen are determined to be 0.13% from the fractional melting data assuming no formation of solid solution. Compared with the data of Douslin and Huffman[4] both the melting point and the transition point of this study are somewhat lower. The values of the heat of fusion and the heat of transition are also smaller than those of Douslin and Huffman. A part of the disagreement may be attributed to the effect of the impurity. Another origin of the discrepancy may be attributed to the ambiguity in the estimation of the normal heat capacity curve. For the determination of the standard entropy, however, an error due to this ambiguity is small enough because the error of the entropy change at the transition point is corrected by heat capacity due to pre-transition. The increment of the molar entropy from 120 K (below transition point) to 150 K (above melting point) is compared with the value calculated from the data of Douslin and Huffman. The difference of these values is only 0.4 J K^{-1} mol^{-1}. Therefore the molar entropy may not be affected severely by the impurity of about 0.1% involved in the present specimen.

Estimation of the Heat Capacity of Supercooled Crystal-I between 80 K and 130 K. The heat capacity of supercooled crystal-I between 80 K and 130 K is estimated to be

$$C_p = 0.18571T + 111.143\,\mathrm{JK^{-1}\,mol^{-1}} \quad (1)$$

which corresponds to the straight line obtained by connecting the values of the heat capacities at 80 and 130 K as shown in Fig. 2 (dotted line). Based on this interpolation equation, the molar enthalpy of supercooled crystal-I was calculated. Here, we have taken the value of the enthalpy of crystal-II at 0 K as 0 for the standard point of the enthalpy of this material. This value is compared with the directly determined value of the molar enthalpy of supercooled crystal-I at 77.72 K. Direct determination of the molar enthalpy of crystal-I was made as follows. If the temperature of glassy-crystal-I be raised up a little above T_g, say 77.7 K, a spontaneous exothermic transition takes place to another metastable phase which is finally transformed into the most stable crystal-II. If an adiabatic condition of the calorimeter cell is maintained during the irreversible changes, the molar enthalpy of supercooled crystal-I at 77.7 K can be determined by measuring the temperature at which the irreversible transitions terminate, since the enthalpy of crystal-II at this temperature is already known. In the actual measurement, an excess electric energy was supplied to terminate the phase change more rapidly. Assuming a complete adiabaticity, the calculation was made as follows.

$$H_{\mathrm{I}}(77.720) = H_{\mathrm{II}}(125.984) + \int_{77.720}^{125.984} C_p(\text{empty cell})\,dT - \sum(\text{supplied electric energy}) \quad (2)$$

Here, $H_{\mathrm{I}}(77.720)$ and $H_{\mathrm{II}}(125.984)$ are the enthalpies of supercooled crystal-I at 77.720 K and of crystal-II at 125.984 K, at which the irreversible transition ends completely under a specified condition for energy supply. Thus the enthalpy of supercooled crystal-I at 77.720 K was determined to be 6084.8 $\mathrm{Jmol^{-1}}$. Calculation from the integration of Eq. (1) gives, on the other hand, 6211.1 $\mathrm{Jmol^{-1}}$. For this discrepancy, the following three possibilities are considered; 1) True heat capacity curve of supercooled crystal-I is located above the estimated one. 2) The actual glassy crystal contains some amounts of the crystal-II phase due to insufficient cooling rate in the preparation of glassy crystal. 3) Experimental error due to the incompleteness of adiabatic conditions. In the calculation of various thermodynamic functions, the mean value 6150 ± 70 $\mathrm{Jmol^{-1}}$ has been employed.

The Residual Entropy of the Glassy Crystalline State. By comparison of the gaseous entropy determined from thermal data with that computed from spectroscopic data, it was concluded by Scott *et al.* that the crystal-II has no residual entropy at 0 K.[14] Based on this result the residual entropy of the glassy-crystalline state at 0 K has been determined by a well defined method. Contributions below 13 K have been determined from extrapolated heat capacities assuming the Debye theory. The Debye temperatures were taken to be 129.44 K and 101.35 K for crystal-II and the glassy crystal-I, respectively, by assuming 6 degrees of freedom. The increment of the entropy of the supercooled crystal-I between 80 and 136 K was calculated by using Eq. (1) with a slight correction (0.6 $\mathrm{JK^{-1}\,mol^{-1}}$) due to the uncertainty of this equation as described above. The calculation is shown in Table 5 and the residual entropy of the glassy crystal is determined to be 7.4 ± 1.3 J $\mathrm{K^{-1}\,mol^{-1}}$.

TABLE 5. THE THIRD LAW ENTROPY OF CRYSTAL-I AT 136.02 K *via* II-I TRANSITION AND *via* GLASSY CRYSTALLINE STATE

Temperature (K)	Contribution	ΔS ($\mathrm{JK^{-1}\,mol^{-1}}$)
via II-I transition		
0— 12.5	Debye extrapolation	1.16
12.5—136.02	$\int C_p(\mathrm{II})\,d\ln T$	98.22
136.02	Transition (6427/136.02)	47.25
		146.63
via glassy crystalline state		
0— 13.5	Debye extrapolation	2.92
13.5— 80.0	$\int C_p$ (Glassy cryst.) $d\ln T$	66.35
80.0—136.02	$\int C_p$ (I) $d\ln T+0.6$[a]	70.0
		139.27

a) Equation(1) is used for C_p(I) and 0.6 $\mathrm{JK^{-1}\,mol^{-1}}$ is added after integration for correction.

Crystal-III. On account of intricate irreversible transitions, the heat capacity of crystal-III between 80 K and 107 K and the heat of transition which occurs at 107 K from crystal-III to other unknown phase could not be measured. The molar enthalpy of the crystal-III at about 80 K has been measured by the same procedure as that employed in the determination of the enthalpy of supercooled crystal-I. The procedure gives 4990 ± 40 J $\mathrm{mol^{-1}}$ at 78.39 K. Using this value, we have attempted to estimate the heat of transition at 107 K. We assumed that the unknown crystalline phase into which crystal-III is transformed at 107 K is supercooled crystal-I. The heat capacity of crystal-III between 80 K and 107 K is estimated by the extrapolation equation which is represented by

$$C_p = 0.782T + 16.3\,\mathrm{JK^{-1}\,mol^{-1}} \quad (3)$$

From these assumptions, the heat of transition from crystal-III to supercooled crystal-I has been calculated to be 2370 J $\mathrm{mol^{-1}}$.

The residual entropy of crystal-III which amounted to 2.7 $\mathrm{JK^{-1}\,mol^{-1}}$ was calculated from the heat of transition determined above and the estimated heat capacity equations 1 and 3. The calculation is given

TABLE 6. THE THIRD LAW ENTROPY OF CRYSTAL-I AT 136.02K *via* III-I TRANSITION

Temperature (K)	Contribution	ΔS ($\mathrm{JK^{-1}\,mol^{-1}}$)
0— 24.5	Debye extrapolation	10.81
24.5— 82.0	$\int C_p$ (III) $d\ln T$	54.72

		143.9

14) D. W. Scott, J. P. McCullough, K. D. Williamson, and G. Waddington, *J. Amer. Chem. Soc.*, **73**, 1707 (1951).

in Table 6 where contributions to the entropy below about 25 K has been estimated by using the Debye function with the value of 107.6 K for θ_D and by assuming 6 degrees of freedom. There appears an anomalous swelling in the heat capacity curve around 70 K. At this temperature range, a fairly long time was required to attain thermal equilibrium (about 25 min). Above 75 K, gradual heat liberation due to the irreversible transition to crystal-II was observed.

Thermodynamic Functions. Thermodynamic functions for the three crystalline phases and for the liquid phase are all listed in Table 7. The molar enthalpies and the molar entropies of respective phases are plotted in Figs. 3 and 4.

Relaxation of Enthalpy below the Glass-Transition Point. It is well known that the configurational degrees of freedom of the glass-forming materials are virtually frozen below T_g on account of the long relaxation time. However, if the temperature is regulated to be constant below glass transition point, the configurational

enthalpy returns gradually to the equilibrium value from that of non-equilibrium frozen state.[15] We have revealed previously[1] that a similar behavior to ordinary glass is observed in the glassy crystalline state of cyclohexanol. The relaxation process for the glassy crystal of 2,3-dimethylbutane was investigated in the same way below T_g by annealing. The experiments were carried out as follows. Crystal-I was supercooled with the cooling rate of about -2 K min^{-1}. Cooling was stopped at a definite temperature below T_g and the temperature was regulated to maintain constant value for at least 20 hr. These studies were carried out at 60.7, 65.1, 69.7 and 72.0 K and the temperatures were regulated in the range of ± 0.3 K. After annealing for 20 hr, the temperature of the specimen was raised by supplying electric energy under adiabatic conditions to a temperature where an internal equilibrium was established, say 76 K. From the supplied energy, the difference in the enthalpies between the annealed glassy crystal at the initial temperature T_i and the supercooled crystal-I at T_f (about 76 K) was determined. Of course a part of the supplied electric energy is used to change the enthalpy of some degrees of freedom which is not frozen at the T_g. Thus, the enthalpy change due to this kind of degree of freedom (increment of the energy of vibrations or so) was subtracted from the total change of enthalpy in order to see directly the change of the configurational enthalpy. The heat capacity due to the vibrations (C_p(vib)) was estimated by the following equation between 60 and 80 K.

$$C_p(\text{vib}) = 0.9200\text{T} + 1.72 \text{ JK}^{-1}\text{ mol}^{-1} \quad (4)$$

The change of the configurational ΔH_c is given by

$$\Delta H_c = \Delta H - \int_{T_i}^{T_f} C_p(\text{vib})\text{d}T \text{ Jmol}^{-1} \quad (5)$$

15) R. O. Davies and G. O. Jones, Advances in Phys., **2**, 370 (1953).

where T_i and T_f were defined above and ΔH is the electric energy supplied per mol. The calculated values of ΔH_c are modified so that the final temperature T_f is 76.40 K by using the measured heat capacities near T_g. We take T_f=76.40 K as the reference point for ΔH_c=0. The results are shown in Fig. 5 and Table 8. During the course of annealing, the rates of the

TABLE 8. RELAXATION OF THE CONFIGURATIONAL ENTHALPY OF THE GLASSY CRYSTAL

	T_i(K)	T_f(K)	ΔH	ΔH(vib)	ΔH_c
1	69.669	76.425	671.7	465.6	206.0
2	65.138	76.346	913.7	748.7	165.0

4	72.028	76.328	493.4	300.9	192.6

The unit of ΔH is Jmol^{-1}. ΔH represents the supplied energy to raise the temperature from T_i where the specimen was annealed to T_f. ΔH(vib) indicates $\int_{T_i}^{T_f} C_p(\text{vib})\text{d}T$. C_p(vib) is given by Eq. (3). ΔH_c represents the difference of the configurational enthalpy, *i.e.* $\Delta H - \Delta H$ (vib).

heat evolution due to the reversion of the enthalpy to the equilibrium state were determined from the rate of spontaneous temperature rise under the temporarily adjusted adiabatic conditions. The rates of the enthalpy change at various temperatures were calculated from these measurements and are shown in Fig. 6. and Table 9.

Discussion

Residual Entropy and Frozen-in State. Crystal-I of this material belongs to the so-called "plastic crystal" named by Timmermans.[16] It is known that in the plastic crystalline phase, the constituent molecules change their orientations rather rapidly at their lattice points. The self-diffusion phenomenon is also observed in many plastic crystals just below their melting points.[17,18] The second moment of NMR absorption line for crystal-I was reported to be 0.7 gauss^2 at about 140 K.[19] This may be explained also as a result of the rapid motion of molecules in the plastic crystal phase. It was also reported that the broadening of the line width of NMR spectrum was observed in the supercooled crystal-I at about 85 K, about 10 K higher than T_g (=76 K).[5] This behavior resembles that of ordinary glasses.[20] On the other hand, we have observed the relaxation effect of the configurational enthalpy below T_g where the relaxation time turns out to be 20 hr or more. These facts indicate that the probability of reorientation of molecules becomes smaller at lower temperatures due to the existence of hindering potential. At a temperature around 10 K higher than T_g, the frequency of the reorientation is estimated to be of the order of 10^3 times per second from the NMR data. Below T_g, on the other hand, the relaxation time becomes longer than the experimental time scale for heat capacity measurement, resulting in an establishment of non-equilibrium state. Therefore, it is expected that the main origin of the residual entropy can be attributed to the randomness of the orientation of molecules. If one calculates from the residual entropy the average number of configurational states permitted for a molecule in the glassy crystalline state by using the relation $S_0=R\ln W$, W amounts to 2.4 ± 0.3. Here, S_0, R and W are the residual entropy, the gas constant and the number of states, respectively. Unfortunately, the crystal structure of crystal–I is unknown and quantitative treatment for the orientational degree of freedom is impossible at the present stage. We should like to discuss, however, its contribution to the residual entropy briefly. If we assume the face-centered or body-centered lattice[21] for crystal-I and the center of gravity of the molecule located at the lattice point, it is plausible that the orientation of the molecular axis is directed to one of the three axis of the cubic cell with respect to their elongated sphere shape of a molecule. Here, the molecular axis is taken as the line parallel to the C–C bond connecting two $(CH_3)_2CH$-groups. There remains further the degree of freedom of the rotation of a whole molecule around this axis. The possible number of orientations permitted for this degree of freedom may be 4, at least even the conformation of the molecule being fixed. Thus, it may be concluded that at the limit of the most random state, the molecule will have about 12 kinds of orientations (3×4). In other word, the configurational entropy due to the orientational degree of freedom may be $R\ln 12$ (21 JK^{-1} mol^{-1}) at high temperature. Comparing this value with the residual entropy ($R\ln 2.4$), it may be said that the ordering of orientation should take place with the decrease of temperature. Furthermore, we may take into consideration the contribution of

the molecular conformations to residual entropy. It is possible for the molecule of 2,3-dimethylbutane to have two different conformations by internal rotation,[22] *i.e.* one *trans*-form and two identical *gauche*-forms. The energy difference between them in the liquid state has been reported from the studies of the infrared and Raman spectra and from the absorption of sound wave. Szasz and Sheppard[23] proposed two possibilities for the energy difference between two conformations in the liquid state, *i.e.* either less than 100 cal/mol or very high value from the temperature dependence of the Raman spectra, based on the fact that no measureable intensity changes were observed in the spectra investigated at various temperatures. Brown and Sheppard studied further the IR and Raman spectra of the crystalline state and concluded the existence of only the *trans*-form.[24] They reported, however, that crystallization took place by raising the temperature of the "*glassy state.*"[25] They also reported that the spectrum in the "*glassy state*" closely resembled that in the liquid state. Accordingly, supercooled crystal-I is considered to be composed of a mixture of the *trans*-form and the *gauche*-form with the ratio of about one to two. On the other hand, Chen and Petrauskas determined the energy difference between two conformations to be 4.0 KJ mol^{-1} from their study of the absorption of the hypersonic sound wave in the liquid state.[26] The energy difference in the gaseous state was estimated to be 6.7 KJ mol^{-1} by Pitzer.[27] Scott *et al.* concluded, however, that it was very small (less than 100 cal mol^{-1}) from studies of the heat capacity and the entropy in the gaseous state.[14] We have reinvestigated the infrared spectrum of the glassy crystal at 40 ± 30 K and found that the spectrum was nearly the same as that of the liquid.[28] The study has been carried out in the region of 1050—800 cm^{-1}. If we assume that the mixing ratio of the isomers is frozen at the glass transition point and that the energy difference is 100 cal mol^{-1}, the contribution of this degree of freedom to the residual entropy amounts to 8.6 JK^{-1} mol^{-1}. Here, the *gauche* form is taken as the higher energy species. This value exceeds the actual value of the residual entropy. Thus, we understand from spectroscopic experiments that most of the residual entropy can be attributed to the randomness in the conformation of molecules. That the residual entropy can be explained only by the freezing of conformational degree of freedom was already observed in the case of the glassy crystalline state of cyclohexanol.[1] This seemingly strange result can be explained if we assume that the conformational degree of freedom is strongly coupled with the orientational degree. It should be noted that if the conformation be independent of the neighboring molecules, its contribution to heat capacity should be Schottky-type and may be much smaller than the actual jump of the heat capacity at T_g which is caused by the release from frozen-in state.

T_2 *Temperature.* In order to explain Kauzmann's paradox,[29] Gibbs and Adam have proposed an equation for the temperature dependence of the relaxation time in terms of the configurational entropy of the supercooled liquid.[6] The theory predicts that the relaxation time of viscoelastic properties becomes infinite at a temperature (T_2) where the configurational entropy disappears. T_2 temperature is determined from the equation described below by assuming that the equilibrium heat capacity is given by the extrapolation of the heat capacity curve above T_g.

$$S_0^\circ = \int_{T_2}^{T_g} [C_p(\mathrm{eq}) - C_p(\mathrm{gl})] \mathrm{d} \ln T, \qquad (6)$$

where S_0°, C_p(eq) and C_p(gl) are the residual entropy, the heat capacity of the supercooled crystal-I and that of the glassy crystal, respectively. Here, Eq. (1) extrapolated to lower temperature is used for C_p(eq). T_2 Temperature determined in this way amounts to 65.0 ± 0.7 K. It is known empirically that for ordinary amorphous glass, the ratio of T_g to T_2 is about 1.3.

24) J. K. Brown and N. Sheppard, *ibid.*, **19**, 976 (1951).
25) They decribed it as a "*glassy state*". It is, however, incorrect, because they did not find any glass transition point. This "*glassy state*" may be the supercooled crystal-I and the crystal (in their notation) is presumably crystal-II.
26) J. H. Chen and A. A. Petrauskas, *ibid.*, **30**, 304 (1959).
27) K. S. Pitzer, *Chem. Rev.*, **27**, 39 (1940).
28) The results are shown in Fig. 7. Almost the same spectra were observed in liquid state. Podlovchenko *et al.* concluded from calculation of the normal modes of vibration that these bands are attributed to those of *trans*-isomer and *gauche*-isomer as shown in Fig. 7. Since the specimen sealed in a polyethylene container was used, transmittance was rather bad. Accordingly, the intensity of each band is not very reliable.

The unit of ΔC_p and S_0; JK^{-1} mol^{-1}
a) From Ref. 1.
b) Calculated from Ref. 2.
c) Calculated from Ref. 3

For the glassy crystals including some other examples known hitherto the ratio T_g/T_2 amounts to about 1.15—1.20 as shown in Table 10. Angell discussed the value of T_g/T_2 for ordinary glass[30)] and considered the glass having the value of $T_g/T_2=1$ to be an ideal glass. The small value of T_g/T_2 for glassy crystal may be explained from the fact that glassy crystal has higher positional order than ordinary glass. It is interesting to compare the glassy crystal of 2,3-dimethylbutane with the glassy state of 2-methylbutane (isopentane), the study of which was reported previously.[31)] The values of T_g/T_2, ΔC_p and $S_0°$ of 2-methylbutane amount to 1.30, 52 JK^{-1} mol^{-1} and 14.1 JK^{-1} mol^{-1}, respectively. Although their structures differ slightly the difference between their residual entropies, 6.7 JK^{-1} mol^{-1}, seems to be attributable to the entropy of positional disorder of the glassy state of isopentane. The glassy crystal is considered to be positionally ideal glass from Angell's viewpoint.

Relaxation of Enthalpy. If one assumes an exponential decay for the change of configurational enthalpy in the period of annealing below T_g, it may be represented by the equation

$$\Delta H_c(t) = \Delta H_c(0) \exp(-t/\tau). \quad (7)$$

Here, ΔH_c is the difference between configurational enthalpy of frozen state and that of equilibrium state and τ the time constant. Differentiation of Eq. (7) with time gives

$$\log(-\dot{H}_c) = -t/\tau + \text{constant}, \quad (8)$$

where $\dot{H}_c$ represents dH_c/dt. The experimental result shown in Fig. 6, however, do not fit such a type of linear equation. From this figure, we recognize immediately that the rate of the enthalpy relaxation is more rapid at the initial stage than the corresponding exponential decay with a nearly equal time constant. This may be explained in two different ways. If one assumes the existence of different relaxation processes with different relaxation times, the results shown in Fig. 6 can be explained. For example, if there exist two relaxation processes, the equation will be given by

$$\Delta H_c(t) = \Delta H_1 \exp(-t/\tau_1) + \Delta H_2 \exp(-t/\tau_2). \quad (9)$$

Co-existence of two relaxation processes has been demonstrated experimentally by Macedo and Napolitano[32),33)] for boro-silicate glass. Another explanation is given by considering that the time constant is not only a function of temperature but also of the thermodynamic variables of the glassy state. Gibbs and Adam considered that the mechanical relaxation time in the supercooled liquid depends on the configurational entropy as well as on the temperature.[6)] We have examined the applicability of their theory to the relaxation of the configurational enthalpy. The $\dot{H}_c(t)$ at time t is given by

$$-\dot{H}_c(t) = \bar{W}(T)H_c(t). \quad (10)$$

Here, $\bar{W}(T)$ is the transition probability of the region in which molecules (or segments) change their configuration co-operatively. $\bar{W}(T)$ is given by

$$\bar{W}(T) = \bar{A} \exp(C/TS_c). \quad (11)$$

Here, $\bar{A}$ and C are constants and S_c the configurational entropy. From Eq. (10) and (11), we obtain

$$\log(-\dot{H}_c/\Delta H_c) = -C/(2.30TS_c) \quad (12)$$

From the data of annealing at 69.7 K and 72.0 K, the values of $\log(-\dot{H}_c/\Delta H_c)$ are plotted against $1/S_c$ in Fig. 8. The values of S_c at various time values are determined by the equation

$$S_c(t) = S_c(0) - \int_0^t (\dot{H}_c/T)dt + \Delta S_{irr}. \quad (13)$$

Here, $S_c(0)$ is equal to the residual entropy and ΔS_{irr} is, the irreversible entropy production.[15)] The latter is however, too small (less than 1% of the integral term) and can be neglected. As is seen in Fig. 8, the

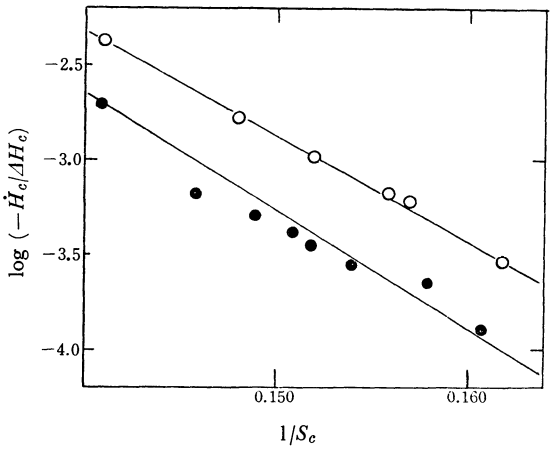

Fig. 8. The plot of ln $(-\dot{H}_c/\Delta H_c)$ *vs.* $1/S_c$.
○ calculated from the data of annealing experiment at 72.0 K
● calculated from the data at 69.7 K

agreement between theory and experiment is roughly established. From the slopes, the value of the constant C in Eq. (12) is determined to be about 9.9 KJ mol^{-1} for 69.7 K and 9.1 KJ mol^{-1} for 72.0 K. In the Gibbs-Adam theory, constant C is related to the number of

molecules or segments Z^* in a minimum cooperative region by the equation

$$C = \Delta\mu S_c Z^*/R, \quad (14)$$

where $\Delta\mu$ is the activation free energy per mole and R the gas constant. We have assumed for a moment that the value of $\Delta\mu$ is equal to the difference between the Gibbs free energies of crystal-I just below melting point and of the glassy crystal at 70 K. It turns out to be 1.5 KJ mol^{-1}. This assessment on $\Delta\mu$ is rather small judging from the fact that the apparent activation energy for the rotational diffusion of molecule in the plastic crystals is known to be about 8 KJ mol^{-1}.[34] Therefore, we take 1.5—8 KJ mol^{-1} for the value of $\Delta\mu$ and determined the value of S_cZ^* to be 10—55 JK^{-1} mol^{-1} by putting 9.9 KJ mol^{-1} for the value of C. Taking the residual entropy (=7.4 JK^{-1} mol^{-1}) for S_c, Z^* is calculated to be 1—7. It may be noted that the relaxation effect was still observed below T_2 temperature as shown in Fig. 5. This fact does not contradict the Gibbs-Adam theory because the glassy crystalline state prepared in this way has a finite value of S_c.

The Heat Capacity Below T_g. As shown in Fig. 2, the heat capacity of the glassy crystal is anomalously large at low temperature compared with that of crystal-II. The frequency spectrum of lattice vibration for the glassy crystalline state seems to be of interest. The data of C_v (the heat capacity at constant volume) is necessary, but as the expansion coefficient and compressibility of this material are unknown at low temperature, it is impossible to know the C_p-C_v. Based upon the theory of Hovi[35] and Pautano, we have tried to find out the difference in the spectra of the glassy crystal and crystal-II from the difference of their heat capacity. Here, it is assumed that the C_p-C_v of each state are equal and all the vibrations are harmonic. According to the notation by Hovi and Pautano, the equations are given by

$$A \cdot X_1 = C_1 \text{ and} \quad (15)$$

$$A \cdot X_2 = C_2, \quad (16)$$

where X_1 and C_1 are the column vectors representing the magnitude of the histogram of the spectrum and that representing the heat capacities for the glassy crystal, respectively, and X_2 and C_2 are those for cystal-II. The difference between Eqs. (15) and (16) is given by

$$A \cdot \Delta X = \Delta C,$$

where ΔX is X_1-X_2 and ΔC is C_1-C_2. In the region from 0 to 30 cm^{-1}, the frequency spectrum is assumed to follow the Debye model. The cut-off frequency is then taken as 130 cm^{-1} judging from the Debye temperature 130 K (=90 cm^{-1}) for crystal-II. The region from 30 to 130 cm^{-1} is devided into five sections with equal width of 20 cm^{-1}. The values of the specific heat

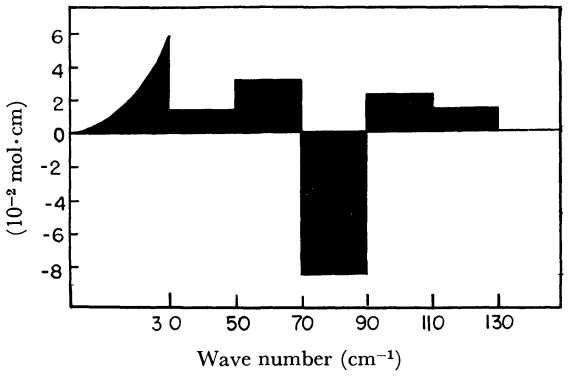

Fig. 9. The difference in the frequency spectrum of the lattice vibration between the glassy crystal and the crystal-II.

at 14, 17, 20, 25, 30 and 40 K are employed for ΔC in Eq. (14). The result is shown in Fig. 9. The positive value of the spectrum below 30 cm^{-1} can be explained by the lower density of the glassy crystal compared with that of crystal-II. Unfortunately, the data of the density of this material at low temperature is not available at present. It is known, however, that the large increase of the molar volume is associated with the transition from the low-temperature phase to the plastic phase, so the lower density of the glassy crystal may be the case. The large negative spectrum at 80 cm^{-1} suggests that a sharp peak (the vibrational mode —) exists in the spectrum of crystal-II whereas the spectrum is smoothed out in the glassy crystalline state. Dean[36] has shown this feature of the smoothing out effect of the spectrum of the perfect crystal by introducing a glass-like disorder.

The Entropy of Transition. Guthrie and McCullough discussed the transition entropy ΔS_t from the low temperature form to the plastic phase for various materials by considering molecular symmetry and symmetry of the crystal lattice of the plastic phases.[37] They interpreted ΔS_t from the viewpoint of the randomness of orientation and of the conformation of molecules. However, we can expect the contribution of entropy of the lattice vibration to be not negligible because the large change of the frequency spectrum is expected on account of softness of the plastic phase. It is considered that ΔS_t is the sum of ΔS_{or}, ΔS_c and ΔS_{vib}, where ΔS_{or} is the difference of entropy due to orientational change, ΔS_c that due to conformational change of the molecule and ΔS_{vib} that due to the change in lattice vibration. We calculated ΔS_{vib} for the 2,3-dimethylbutane from the difference in the spectrum of vibration which is given in Fig. 9. It amounts to 12.8 JK^{-1} mol^{-1} assuming the spectrum of the glassy crystalline state is retained even at transition temperature. ΔS_{or} and ΔS_c have been estimated to be 21 ($\simeq R\ln 12$) and 9 ($\simeq R\ln 3$) J K^{-1} mol^{-1}, respectively at the most random state (see page 85). Their sum becomes 43 JK^{-1} mol^{-1} which is comparable with the experimental value of ΔS_t (=47.25 JK^{-1} mol^{-1}).

The agreement will be improved if we take account of the variation of the frequency spectra (Fig. 9) at a higher temperature. The data[38] of the elastic constant measured with high frequency ultrasonic wave for the plastic phase of the cyclohexanol will be helpful for this consideration. The Debye temperature calculated is 60 K around 265 K whereas the Debye temperature in the glassy crystalline state (at 50 K) has been determined to be about 90 K from thermal data.[1] If the effect is taken into account, the value of ΔS_{vib} becomes larger and a better agreement is obtained between experimental and calculated ΔS_t. We would like to point out that the contribution of ΔS_{vib} is not negligible for the explanation of the content of ΔS_t.

Crystal-III. It has been revealed that the residual entropy of crystal-III is determined to be 2.7 JK^{-1} mol^{-1} and that there exists an anomalous hump in the heat capacity curve around 70 K. From these facts, there is the possibility that the state of crystal-III below 70 K is also glassy crystalline. This can not be confirmed, however, as the relaxation phenomenon has not yet been observed.

Normal Coordinate Treatment and Force Constants of Alkanonitriles

Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 24, 1970)

Force constants of the Urey-Bradley type are calculated for a series of alkanonitriles. The calculation covers the mononitriles: CH_3CN, CH_3CH_2CN, $(CH_3)_2CHCN$, $(CH_3)_3CCN$, and the dinitriles: $NCCH_2CN$, $NCCHDCN$, $NCCD_2CN$, *trans*-$NCCH_2CH_2CN$, *gauche*-$NCCH_2CH_2CN$. The results show that the force constants can be transferred from molecule to molecule as a group. It is also shown that a group of force constants is characteristic of a corresponding chemical structure or a substituent.

One of the most important problems in the field of vibration spectroscopy is to find a reliable set of force constants which may explain the frequencies of many molecules with similar chemical structures. For the purpose of finding transferrable force constants of alkyl cyanides, a series of stadies have been made.

There exist some difficulties in the normal coordinate treatment of rather complicated molecules which are composed of many different atoms or substituents. The most important problem, from the viewpoint of force field, is that the number of force constants which should be considered in calculations often exceeds that of information obtained from vibration spectra. Consequently, the force constants obtained from the calculation are somewhat ambiguous and sometimes cause an erroneous conclusion when they are transferred to other molecules.

In the case of molecules consisting of a few atoms or of many but similar atoms or chemical bonds, the problem is easily settled or does not exist at all, because the number of force constants which should be determined is small, while many pieces of information can be obtained not only from the vibrational frequencies themselves but also from the other experimental results. One solution for this problem may be obtained by carrying out the normal coordinate treatment of many molecules having similar chemical structures. However, there still remain doubts as to whether the method can also be applied to the case in which two or more chemical structures are combined in one molecule.

In the present report the result of the normal coordinate treatment of some basic alkanonitriles will be discussed.

Calculation of Force Constants and Results

The infrared spectra and their frequency assignment necessary for the present work will be found in the references,[1-3] and are not discussed here. The method of calculation exactly follows that of the reference[4]

and is not repeated here.[5]

The process for the determination of the force constants is illustrated in Fig. 1. Prior to the explanation of the process, it is convenient to classify the force constants of alkanonitriles into three groups: a hydrocarbon group, an α-carbon group, and a cyanide group. The significance of these groups is illustrated in Fig. 2.

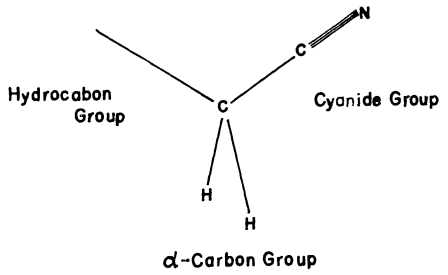

Fig. 2. Classification of Force Constants.

The α-carbon group is composed of the force constants associated with the α-carbon to any extent and the other two groups are composed of those associated with the β-carbon or with the cyanide radical. The force constants of acetonitrile obtained by Nakagawa[9] and those of normal hydrocarbons obtained by Takahashi[10] are a good starting set for the present calculation.

First, malononitrile and its deuterated compounds are treated using the force constants obtained from acetonitrile and propane. In this process, it was found necessary to make essential changes in the values of some force constants. The molecules studied next was ethylcyanide. The force constants determined for malononitrile were directly transferred to those associated with α-carbon and cyanide groups, while those for a methyl part were transferred from ethane. These two processes were designed for finding the force constants of alkanonitriles associated with the cyanide group and the α-carbon group. A little refinement of the force constants was necessary in the process from malononitrile to ethyl cyanide in order to obtain a good agreement between the observed and the calculated frequencies. However, the force constants of the hydrocarbon group and of the cyanide group remain unchanged.

Then the study was extended to larger molecules by two routes. One route was for succinonitrile in order to confirm the reliability of the force constants for the α-carbon and the cyanide groups. The results obtained were satisfactory both for the *trans* and the *gauche* conformations of succinonitrile. The other route was designed for finding the force constants associated with the secondary and the tertiary α-carbons. In this case also, the force constants were transferred from ethylcyanide. It must be emphasized here that in the treatment of the last three molecules, $NCCH_2CH_2CN$, $(CH_3)_2CHCN$, and $(CH_3)_3CCN$, the force constants of the hydrocarbon and the cyanide groups were not changed essentially.

The final set of force constants thus obtained are summarized in Table 1 and in Table 2. The calculated frequencies are compared with the observed frequencies in Figs. 3(a) and 3(b).

Interpretation

In the previous section, the difficulty of the normal coordinate treatment of rather complicated molecules has been emphasized. The alkyl cyanides are just such molecules which are composed of many chemically different atoms, H, C, and N. As easily be understood from many chemical phenomena, the chemical properties of the atoms associated with the α-carbon atoms are much different from those of the β-carbon atom. The effect of the substituent, the –CN radical, extends not only to the α-carbon but also to the atoms attached to the α-carbon atom.

One of the main object of this calculation is to see whether we can obtain a set of force constants which may be transferred as a group from one molecule to another. If the force constants of the hydrocarbon

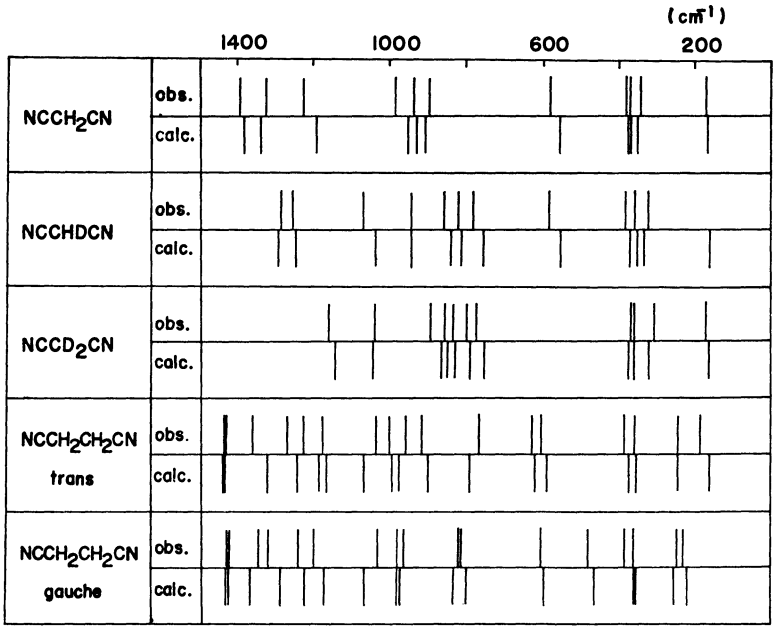

Fig. 3(b). Vibrational Frequencies for Alkanodinitriles.

group and the cyanide group are to be transferred unchanged from one molecule to the other, then the force constants which should be refined through the series of calculations are limited to those of the α-carbon group.

The Cyanide Group (see Table 1). The C≡N stretching vibration has little effect upon the other frequencies because it is an almost completely localized vibration. Consequently, the stretching force constants, K(C≡N), can be determined with good accuracy. The K(C≡N) changes its magnitude from the dinitriles to the mononitriles as is shown in Table 1. The tendency is interesting if the K(C≡N)'s are compared with the values of K(C–CN) of Table 2. The magnitude of K(C–CN) decreases from the dinitriles to the mononitriles, while that of K(C≡N) increases its magnitude. This implies that there exist some interactions between the C–CN and the C≡N bonds. As will be found elsewhere, this is also confirmed by the change of the bond length of the C–CN.

The force constants of the linear part, C–C≡N, are transferred quite successfully from one molecule to another in this series of calculations.

The Hydrocarbon Groups (see Table 1). The force constants belonging to this group have the same values as those of normal hydrocarbons. The K(C–H) of isobutylonitrile is not given in Table 1 because the high frequency separation has been made in the normal coordinate treatment of this molecule.

It may seem rather curious that the K(C–C) of succinonitrile has the value of 2.50 md/A, while the other K(C–C)'s have the values of 2.00 md/A. However the superposed effect from two adjacent α-carbon atoms on the C–C bond of succinonitrile certainly explains the relatively large value of the obtained force constant. The C–C bond of succinonitrile is sandwiched between two α-carbons, so that the effect of the substituents is supposed to be very large. Therefore, it should rather be classified into the cyanide group. Actually, some specific characters of the C–C bond have been reported and a hyperconjugation between the C–C and the C–N bonds has been proposed. Consequently, the anomalous value of this force constant does not spoil the transferability of this group force constants.

The α-Carbon Group (see Table 2). The stretching force constants, K(C–C)'s, are a little smaller than those of hydrocarbon group. This may suggest that the effect of the substituent extends to the nature of the bond between the α-carbon and the hydrogen atoms. A similar conclusion can be obtained from the values of F(H··H) and H(H·C·H). As the correlation between these two force constants is large, we cannot compare the magnitudes of these force constants separately. As a pair, however, an apparent decrease in the magnitude can be recognized for the F(H··H) and the H(H·C·H) values when they are compared with those of normal hydrocarbons.[11] The result is related with the fact that the CH_2 scissoring vibrations occur relatively lower frequencies for the alkanonitriles than for normal hydrocarbons.[12]

The molecular tension around the α-carbon atom does not satisfy the transferability in this group. In the case of a methyl group, the values of 0.01 md·A are commonly used for all the methyl parts of the molecules. According to the discussion of our laboratory, the reliable values are hardly be found as for the molecular tension of the skeletal part. For the purpose of finding reliable and transferable parameters, the result is not desirable (see the last column of Table 2).

In the 7th column of Table 2 the repulsive and the bending force constants, F(C··H) and H(CCH), are given. At first, they were expected to behave just like those for hydrocarbon molecules and were readily transferred from ethane. However, it was found through the calculation of ethylcyanide that their values must be reduced considerably in magnitude so as to obtain the reasonable frequencies for the C–C stretching, the C–CN stretching, and the methyl rocking vibrations. The force constants thus settled must be quite different from those for the simple hydrocarbon group. Nevertheless, they exhibit good transferability as the components of the α-carbon group (see Table 2). This result suggests that the effect of the substituent extends to the α-carbon or to the bond between α- and β-carbon atoms.

Discussion

Reliability of the Force Constants Obtained. The force constants obtained for each group may be quite reliable, because they show good transferability among the eight molecules treated in the present work. Moreover, the force constants of the hydrocarbon group are consistent with those of normal hydrocarbons. The cyanide group force constants are rather consistent with the results for acetonitrile. The agreement of the calculated frequencies with the observed frequencies given in Figs. 3(a) and 3(b) is very satisfactory. This gives ultimate supports for the reliability of the force constants obtained in this calculation.

Determination of the Force Field of a Complicated Molecule. The conclusions we have drawn from the present analysis of the force constants are itemized as follows:

1) Transferability of force constants is satisfied as a group.

2) Let there be two sets of force constants, one for a group A and another for a group B which is chemically different from A. If both sets of force constants are well determined, there is a reasonable hope of calculating the normal vibrations of such a molecule as A-B satisfactorily.

3) Moreover, the force constants of such molecules as A-C-B can be obtained rather definitely. We may well transfer the sets of force constants associated with the groups A and B, while the refinement should be made only for the set which is associated with C.

4) In this process, the number of force constants to be determined is rather small despite the com-

11) After this work was finished, quite different values were reported for the force constants of normal hydrocarbons. However, the magnitude of the F-matrix element does not change at all.

12) It was found later that the CH_2 scissoring vibration decreases its frequency in accordance with the magnitude of the electronegativity of the substituents.

plexities of the molecules.

5) If the force constants obtained from A and B are accurate, then the accuracy of the force constants obtained from the A-C-B will be confirmed. Thus, we can obtain the force constants associated with the C part with little ambiguity and the force constants thus obtained will be able to become good measures for considering the specific character of the C part.

The present work is completed under the guidance of Professor Takehiko Shimanouchi of the University of Tokyo. The author is grateful for his useful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 93—96 (1971)

Dissociation Constants of the Oxalato-Titanium(III) Complex as Determined from Spectrophotometric Measurements

Kuan PAN, Chin Chan LAI, and Teh-Shoon HUANG
Chemistry Research Center, National Taiwan University, Teipei, Taiwan, China

(Received August 25, 1970)

The dissociation constant of $Ti(C_2O_4)_2^-$ ions in hydrochloric acid media was evaluated from the data obtained by spectrophotometric measurements at 25°C. The average value of pK for the reaction, $Ti(C_2O_4)_2^- = Ti(III) + 2C_2O_4^{2-}$, at an infinite dilution was estimated as 9.0, while that for the $Ti(C_2O_4)_2^- = Ti^{3+} + 2C_2O_4^{2-}$ reaction was evaluated as 8.7_4.

The preparation of the oxalato-titanium(III) complex, $MTi(C_2O_4)_2 \cdot 2H_2O$ (M=K, Rb, NH_4), has been reported by Stahler.[1] The composition of the oxalato-titanium(III) ion in an aqueous solution was spectrophotometrically determined as $Ti(C_2O_4)_2^-$ by Pecsok,[2] while Subbanna, Rao, and Bhattacharya[3] asserted the molar ratio to be 1 : 1, corresponding to the formula, $H(TiOC_2O_4)$ from their spectrophotometric and conductometric measurements, however, they did not give an detailed data or the observed pH range. Afterwards, Jørgensen[4] suggested that the complexes $M^{I}Ti(C_2O_4)_2 \cdot 2H_2O$ contain a tetrahedral, $Ti(C_2O_4)_2^-$ anion, while Eve and Fowles[5] proposed the polymetric structure for $M^{I}Ti(C_2O_4)_2 \cdot 10H_2O$ on the basis of the diffuse reflectance spectra.

The present investigation was undertaken in order to redetermine the composition and to evaluate the dissociation constants of the oxalato-titanium(III) complex in a hydrochloric acid solution on the basis of spectrophotometric measurements at 25°C.

Experimental

Titanium(III) chloride was prepared by heating titanium sponge (99.9% purity, Alfa Inorganics, Inc., U. S. A.) with a 3N hydrochloric acid solution. Additional hydrochloric acid was added as the reaction progressed to prevent the hydrochloric acid concentration from falling below the point where hydrolysis could occur. The solution was then cooled and maintained under an atmosphere of nitrogen to prevent the formation of any appreciable quantity of Ti(IV). The Ti(III) content was determined by addition to an excess of ceric sulfate in a sulfuric acid solution, followed by potentiometric back-titration with a standard solution of ferrous sulfate. The chloride ion content was determined by potentiometric titration with silver nitrate. Hydrochloric acid, sodium chloride, and sodium hydroxide were used to adjust the H_3O^+ ion concentration and the ionic strength of the solution.

The oxalato-titanium(III) complex was prepared by the rapid addition of Ti(III) chloride to an aqueous solution of oxalic acid, according to Eve and Fowles,[5] and dried in a vacuum.

A Bausch & Lomb recording spectrophotometer, model 505, equipped with a constant temperature holder controlled to ±0.2°C was used.

For the spectrophotometric determination of the oxalato-titanium(III) complex, calibration curves for a series of solutions in an excess of oxalate at various H_3O^+ ion concentrations and ionic strengths were prepared. All the solutions were prepared from deaerated water and were kept in an atmosphere of nitrogen. All the reactants and their mixtures were kept in a thermostat whose temperature was controlled within ±0.2°C.

Since no time effect on the absorbance of the mixture of Ti(III) and oxalate ions in hydrochloric acid was observed in this pH range, and since the mixture of Ti(III) and oxalate as well as $KTi(C_2O_4)_2 \cdot 2H_2O$ in oxalic acid has the same absorption band at 440 mμ, a mixture containing a known content of Ti(III) in a HCl solution and a desired amount of a slight excess of oxalate was for the spectrophotometric measurements. The absorbance at 440 mμ was taken for the calculation of the dissociation constants.

Results and Discussion

Extinction Coefficients of Ti(III) Ions in Hydrochloric Acid Media. The titanium(III) ion has been known to form chloro-complexes such as $[TiCl(H_2O)_5]^{2+}$ and

1) A. Stahler, *Ber.*, **37**, 4405 (1904).
2) R. L. Pecsok, *J. Amer. Chem. Soc.*, **73**, 1304 (1951).
3) V. V. Subbanna, G. S. Rao, and Bhattacharya, *J. Sci. Ind. Res.*, **18B**, 127 (1959).
4) C. K. Jørgensen, "Inorganic Complexes," Academic Press, New York (1963).
5) D. J. Eve and G. W. A. Fowles, *J. Chem. Soc.*, **1966**, 1183.

$[TiCl_2(H_2O)_4]^+$ [6] even if the formation of the hydrolysis products, *e. g.* $[Ti(OH)(H_2O)_5]^{2+}$ and $[Ti(OH)_2(H_2O)_4]^+$, is neglegible in strong acid media. As a first degree of approximation, however, we may assume only the coexistence of $[Ti(H_2O)_6]^{3+}$ and $[TiCl(H_2O)_5]^{2+}$ (abbreviated as Ti^{3+} and $TiCl^{2+}$) in chloride media at pH 1—2.5 after the independence of the H_3O^+ ion concentration of the absorbance of the Ti(III) ions has been confirmed. Since no detailed data on the extinction coefficients of these ions is available, a series of spectrophotometric measurements were conducted for the determination of the extinction coefficients (ε_1) of Ti(III) ions in a mixture of 0.2—0.6N HCl and KCl solutions at 25°C.

Table 1. The extinction coefficients of Ti (III) in HCl and KCl at 25°C (ε_1 in $l\ mol^{-1}\ cm^{-1}$)

$[Cl^-]/\lambda$ mμ	0.2	0.3	0.4	0.5	0.6	Average
400	1.1	1.3	1.4	1.5	1.5	1.4
420	2.5	2.5	2.4	2.7	2.7	2.6
440	3.7	3.9	4.1	4.3	4.2	4.1
460	5.2	5.4	5.5	5.8	5.7	5.5
500	5.9	6.0	6.1	6.2	6.2	6.1
520	5.5	5.6	6.8	6.7	6.7	6.7
550	4.7	4.8	4.8	4.7	4.8	4.8

Since the extinction coefficient of Ti(III), ε_1, in the presence of a large excess of Cl^- ions was found to be practically independent of the H_3O^+ and Cl^- ion concentrations in the H_3O^+ ion concentration range mentioned above, we took the average value of 4.1 $l\ mol^{-1}\ cm^{-1}$ for ε_1 at 440 mμ.

Extinction Coefficients of Oxalato-Titanium(III) Complexes. Since, even in the acid media of pH 1.5—2.5, the mole ratio of the oxalato-titanium(III) complex was found to be 1 : 2 by the continuous variation plot (Fig. 1), the formation of the $Ti(C_2O_4)_2^-$ ion in the presence of HCl at pH 1.5 to 2.5 was assumed. The extinction coefficient of the complex was determined by plotting the absorbance against the total concentration of Ti(III) in a large excess of oxalate ions over this pH range at a constant ionic strength. The extinction coefficient of the oxalato-titanium(III) complex, ε_2, was found to be practically independent of the H_3O^+ and Cl^- ion concentrations, or of the ionic strength over the pH range of 1.5—2.5. We therefore, also took the average value of 320 $l\ mol^{-1}\ cm^{-1}$ for ε_2 in the calculation of this investigation.

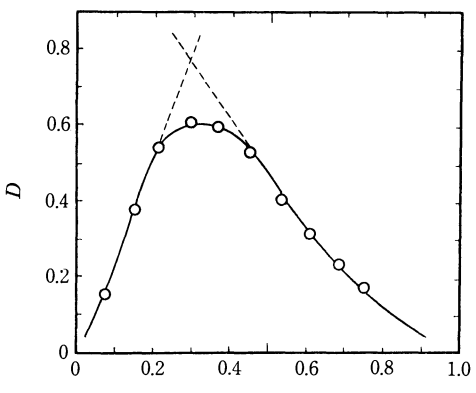

Fig. 1. Continuous variation plot for the Ti(III)-oxalate system. $[Ti(III)]+[H_2C_2O_4]=0.062M$ $[Cl^-]=0.254M$, pH 1.5

Dissociation Constants of the Oxalato-Titanium(III) Complex. When the $Ti(C_2O_4)_2^-$ ion is in equilibrium with Ti(III) and $HC_2O_4^-$ ions in a 10^{-3}—10^{-1}N hydrochloric acid solution, the stoichiometric equilibrium constants for the dissociation of $Ti(C_2O_4)_2^-$ and $HC_2O_4^-$ ions (denoted as TiX_2^- and HX^-),

$$TiX_2^- + 2H_3O^+ = Ti(III) + 2HX^- + 2H_2O \quad (I)$$

and $HX^- + H_2O = H_3O^+ + X^{2-}$

at a constant ionic strength are given by

$$K_1 = \frac{[Ti(III)][HX^-]^2}{[TiX_2^-][H^+]^2} \quad (1)$$

and

$$k_2 = \frac{[H^+][X^{2-}]}{[HX^-]} \quad (2)$$

where k_2 is the secondary ionization constant of the $HC_2O_4^-$ ion.

From Eq. (1) and Eq. (2), the apparent dissociation constant of $Ti(C_2O_4)_2^-$;

$$TiX_2^- = Ti(III) + 2X^{2-} \quad (II)$$

is given by

$$K_2 = K_1k_2^2 = \frac{[Ti(III)][X^{2-}]^2}{[TiX_2^-]} \quad (3)$$

where Ti(III) represents a mixture of Ti(III) ions other than the oxalate complexes.

The molar concentration of the unchelated oxalate ions is represented by

$$[X]_0 - 2[TiX_2^-] = [H_2X] + [HX^-] + [X^{2-}] \quad (4)$$

and that of the free $C_2O_4^{2-}$ ion concentration is given by

$$[X^{2-}] = \frac{[X]_0 - 2[TiX_2^-]}{1 + \frac{[H^+]}{k_2} + \frac{[H^+]^2}{k_1k_2}} \quad (5)$$

where $[X]_0$ is the total concentration of oxalate ions and $[TiX_2^-]$ is the concentration of oxalato-titanium-(III) ion as estimated from the spectrophotometric data.

When the absorption of the solution at 440 mμ is assumed to be associated with the equilibrium between the Ti(III) and TiX_2^- ions, the absorbance of the solution, D, can be expressed by;

$$D = \varepsilon_1(a-x) + \varepsilon_2 x \quad (6)$$

where a is the total molarity of the Ti(III) ions, x is that of the complexes, and ε_1 and ε_2 are the extinction coefficients of the unchelated and chelated ions respectively in a mixture of HCl and NaCl solutions.

From Eq. (6), therefore, the molar concentrations of TiX_2^- and Ti(III) ions can be given by;

$$x = [TiX_2^-] = \frac{D - D_0}{\varepsilon_2 - \varepsilon_1} \quad (7)$$

and;

$$a - x = [Ti(III)] = \frac{D_c - D}{\varepsilon_2 - \varepsilon_1} \quad (8)$$

where $D_0=\varepsilon_1 a$ for $x=0$ in the absence of oxalate ions and $D_c=\varepsilon_2 a$ for $x=a$ in a large excess of oxalate ions.

6) H. Hartmann and H. L. Schläfer, *Z. Phys. Chem.*, **197**, 116 (1951).

Thus, by substituting the ratio of Eq. (8) to Eq. (7) into Eq. (3), the apparent dissociation constant of the complex can be given by;

$$K_2 = \frac{(D_c - D)[X^{2-}]^2}{D - D_0} \tag{9}$$

The substitution of Eq. (5) into Eq. (9) gives;

$$K_2 = \frac{(D_c - D)\{[X]_0 - 2[TiX_2^-]\}^2}{(D - D_0)\left(1 + \frac{[H^+]}{k_2} + \frac{[H^+]^2}{k_1 k_2}\right)^2} \tag{10}$$

where k_1 and k_2 are the step-by-step ionization constants of oxalic acid, given by $k_1 = 5.38 \times 10^{-2}$ [7] and $k_2 = 5.18 \times 10^{-5}$ [8] at 25°C.

Taking the average values of the extinction coefficients, $\varepsilon_1 = 4.1$ and $\varepsilon_2 = 320\ l\ mol^{-1}\ cm^{-1}$ for the unchelated Ti(III) ions and the chelate ion, $Ti(C_2O_4)_2^-$, the values of D_0 and D_c at a specified total titanium(III) ion concentration, a, were evaluated. The substitution of the values of $[TiX_2^-]$ calculated by means of Eq. (7), and that of $[C_2O_4^{2-}]$ calculated by means of Eq. (5), into Eq. (10), the apparent dissociation constant of $Ti(C_2O_4)_2^-$ ion was evaluated. The results are summarized in Table 2.

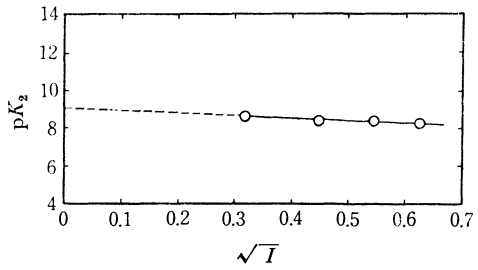

Fig. 2. Plot of pK_2 *vs.* $\sqrt{I}$ at 25°C.

7) W. J. Harned and L. D. Fallon, *J. Amer. Chem. Soc.*, **61**, 3111 (1939).

8) L. S. Darken, *ibid.*, **63**, 1007 (1941).

Table 3. Dependence of average pK_2 values *vs.* ionic strength

I (M)	0.1	0.2	0.3	0.4
$[Cl^-]_0$ (average) (M)	0.0872	0.1876	0.2809	0.3830
pK_2 (average)	8.58	8.47	8.40	8.33

By plotting the average values of pK_2 at each ionic strength against $\sqrt{I}$, as is shown in Fig. 2, and by extrapolating to zero ionic strength, the limiting value of $pK^\circ = 9.0$ at 25°C was obtained. Since the value of K_2 varies slightly with the H_3O^+ and Cl^- ion concentrations, as is shown in Table 2, however, we must also take into consideration the hydrolysis and the formation of chloro-complexes of Ti^{3+} ions;

$$Ti^{3+} + 3H_2O \overset{K_3}{\rightleftarrows} TiO^+ + 2H_3O^+ \tag{III}$$

$$Ti^{3+} + Cl^- \overset{K_4}{\rightleftarrows} TiCl^{2+} \tag{IV}$$

and;

$$TiO^+ + Cl^- \overset{K_5}{\rightleftarrows} TiOCl \tag{V}$$

and represent the stoichiometric equilibrium constants as;

$$K_3 = \frac{[TiO^+][H^+]^2}{[Ti^{3+}]} \tag{11}$$

$$K_4 = \frac{[TiCl^{2+}]}{[Ti^{3+}][Cl^-]} \tag{12}$$

and;

$$K_5 = \frac{[TiOCl]}{[TiO^+][Cl^-]} \tag{13}$$

respectively, at a constant ionic strength. Thus, the total concentration of Ti(III) ions other than the oxalato chelate may be given by;

$$[Ti(III)] = [Ti^{3+}]\left\{(1 + K_4[Cl^-]) + K_3(1 + K_5[Cl^-])\frac{1}{[H^+]^2}\right\} \tag{14}$$

and the apparent dissociation constant for the reaction (II) may be given by;

$$K_2 = \frac{[Ti^{3+}][X^{2-}]^2}{[TiX_2^-]}\left\{(1 + K_4[Cl^-]) + K_3(1 + K_5[Cl^-])\frac{1}{[H^+]^2}\right\} \tag{15}$$

by substituting Eq. (14) into Eq. (3). Therefore, when the true dissociation constant of $Ti(C_2O_4)_2^-$;

$$TiX_2^- = Ti^{3+} + 2X^{2-} \tag{VI}$$

is represented by;

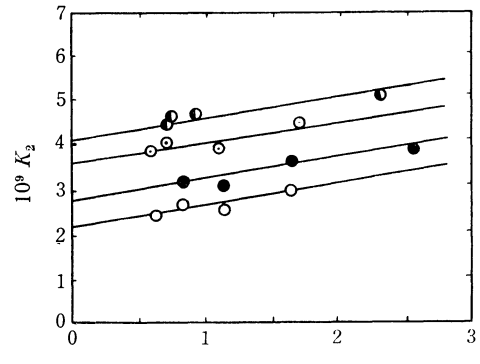

Fig. 3. Plots of K_2 *vs.* $1/[H^+]^2$ at various Cl^- ion concn.
$[Cl^-]_0$(average): ○ 0.085M, ● 0.184M, ⊙ 0.278M, ◑ 0.385M.

$$K_6 = \frac{[Ti^{3+}][X^{2-}]^2}{[TiX_2^-]} \quad (16)$$

the observed value of K_2 is related to that of K_6 by;

$$K_2 = K_6\left\{(1+K_4[Cl^-]) + K_3(1+K_5[Cl^-])\frac{1}{[H^+]^2}\right\} \quad (17)$$

By plotting the K_2 values against $1/[H^+]^2$ at a constant ionic strength and Cl^- ion concentration, as is shown in Fig. 3, a series of straight lines was obtained. The slope (S_1) corresponds to the value of $K_6K_3(1+K_5[Cl^-])$, and the intercept (A), to that of $K_6(1+K_4[Cl^-])$.

Since the slopes of these lines are practically independent of the Cl^- ion concentration, we may estimate that the value of K_4 is smaller than 0.1, and

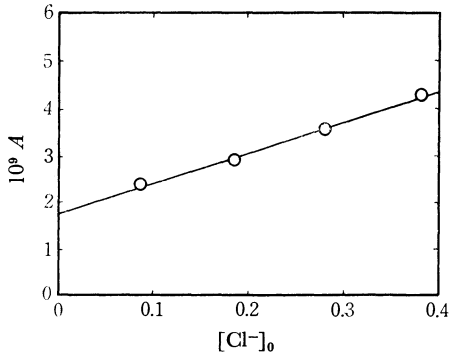

Fig. 4. Dependence of intercept (A) upon total Cl^- ion concn.

that the product, K_6K_3, corresponds to the slope of $S_1=5\times10^{-4}$. On the other hand, by plotting the value of the intercept, (A), obtained from Fig. 3, against the Cl^- ion concentration, a straight line was obtained (Fig. 4). From the intercept, $B=1.8\times10^{-9}$, and the slope, $S_2=6.4\times10^{-9}$, the values of K_6, K_4, and K_3 were evaluated to be 1.8×10^{-9}, 3.6, and 3×10^{-5} respectively. The formation constant of the $TiCl^{2+}$ ion, $K_4=3.6$, obtained in this experiment is in fair agreement with that of 2.18 estimated by Duke and Quinney[9] in their kinetic study of the reduction of the perchlorate ion by Ti(III).

Though there was some inevitable under-estimation of the H_3O^+ ion concentration, which caused some deviation in the evaluation of the K_2 values, the fact that the value of K_2 thus calculated decreases with an increase in the H_3O^+ ion concentration and increases with an increase in the Cl^- ion concentration seems to support the reaction mechanism proposed.

This work was carried out as a part of the research projects of Chemistry Research Center, National Taiwan University, CRC-5802 which was supported by the National Council on Science Development.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 96—99 (1971)

Average Values of Bond Angles

KOZO KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received August 29, 1970)

A number of definitions with clear physical significance regarding the "average bond angles" (nonlinear case) are presented. Simple expressions of the average angles in terms of the linear and quadratic mean values of the displacements in the internuclear distances are given. The differences in the various average angles for H_2O, D_2O, CH_4, CD_4 and SO_2 are estimated by means of a normal-coordinate analysis. The differences are shown to be small fractions of one degree. The root-mean-square angles for linear molecules (HCN, DCN, CO_2 and CS_2) are also calculated.

In a previous paper,[1] the merits and demerits of the two "average structures" (r_g and r_z) have been discussed. The r_g distance, which represents a thermal-average value of an instantaneous internuclear distance, is readily accessible from an experiment of gas electron diffraction.[2] A scheme has been devised relating the r_g distance to the r_e and r_z distances[3] defined as the distances between the "equilibrium" and "zero-point average" positions of the nuclei, respectively, with reference to a molecule-fixed coordinate system.[4] This scheme provides a theoretical basis of a comparative study of the molecular structures determined from electron-diffraction and spectroscopic data.[1,5,6] The purpose of the present paper is to extend the theory to the specification of bond angles: A similar scheme of conversion among the "average bond angles" based on various definitions is presented, and the orders of magnitude of their mutual differences are estimated.

Definitions of Bond Angles

Bond angles can simply be defined in terms of the r_e and r_z representations, since they are based on

2) L. S. Bartell, *ibid.*, **23**, 1219 (1955); K. Kuchitsu, This Bulletin, **40**, 498 (1967).
3) T. Oka, *J. Phys. Soc. Jap.*, **15**, 2274 (1960).
4) Y. Morino, K. Kuchitsu, and T. Oka, *J. Chem. Phys.*, **36**, 1108 (1962).
5) K. Kuchitsu and S. Konaka, *ibid.*, **45**, 4342 (1966).
6) K. Kuchitsu, T. Fukuyama, and Y. Morino, *J. Mol. Structure*, **1**, 463 (1968).

"nuclear positions." For a set of X—Y and Y—Z bonds in a molecule, the cosine rule can be applied to the bonded and nonbonded (r_e and r_z) distances, r_1(X—Y), r_2(Y—Z) and r_3(X—Z), to make equilibrium and zero-point average bond angles, ϕ_e and ϕ_z respectively,

$$\phi = \cos^{-1}[(r_1^2+r_2^2-r_3^2)/2r_1r_2] \quad (1)$$

An effective bond angle, ϕ_s, corresponding to the r_s coordinates[7] is often used in microwave spectroscopy. However, since no definite physical significance can be attached to the r_s coordinates, one needs to be content with a qualitative estimate[8] that ϕ_s should be very close to ϕ_e.

On the other hand, some consideration is needed in gas electron diffraction to define physically significant bond angles,[9] since only thermal-average internuclear distances, instead of angles or nuclear positions, are measured by this technique.[10] The r_g distance for a nonbonded pair does not correspond exactly to any geometrical arrangement consistent with the corresponding r_g distances for bonded pairs. As is known in terms of the linear and nonlinear shrinkage effect,[11,12] an "effective" bond angle (provisionally named ϕ_G) calculated from the bonded and nonbonded r_g distances by Eq. (1) is, in general, different from the ϕ_e or ϕ_z angles.[13,14] It should also be different from the "thermal-average value of an instantaneous bond angle" (here denoted as ϕ_g) defined in parallel with r_g

$$\phi_g = \langle\cos^{-1}[(r_1^2+r_2^2-r_3^2)/2r_1r_2]\rangle_T \quad (2)$$

where T represents the Boltzmann statistical average for temperature T over all the vibrational states of the molecule.[15] The differences between ϕ_g and ϕ_e for simple hydrides (water,[16,17] ammonia[17-20] and methane[21]), often denoted as $\langle\Delta\alpha\rangle$, have been investigated in detail in relation to the anharmonicity in the angle-bending vibrations and to the hydrogen-deuterium isotope effect.[22]

It may also be useful for some purpose to consider ϕ_c defined by

$$\phi_c \equiv \cos^{-1}\langle\cos\phi\rangle = \cos^{-1}\langle(r_1^2+r_2^2-r_3^2)/2r_1r_2\rangle \quad (3)$$

The angles ϕ_α and ϕ_α^0 corresponding to the r_α and r_α^0 structures,[4] which may be derived from electron-diffraction experiments, have been used in some previous studies;[1,6,23] ϕ_α is supposed to be essentially the angle composed of the thermal-average nuclear positions, so that ϕ_α^0, the angle extrapolated to 0°K, should be essentially equivalent to ϕ_z. For PF_3,[24] the ϕ_α^0 angle was estimated to be nearly equal to the ϕ_α within the experimental uncertainty of 0.2°.

Analytical Expressions

Nonlinear Case. For a nonlinear arrangement ($\phi_e<\pi$), Eq. (1) may be expanded in terms of the instantaneous displacements in the internuclear distances around ϕ_e,

$$\Delta r_i \equiv r_i - (r_e)_i \qquad (i=1, 2, 3) \quad (4)$$

$$\phi = \phi_e + \sum_{i=1}^{3} a_i\Delta r_i + \sum_{\substack{i=1\\ i\leq j}}^{3}\sum_{j=1}^{3} b_{ij}\Delta r_i\Delta r_j + \cdots \quad (5)$$

The coefficients a and b are functions of ϕ_e and $\sigma_i \equiv (r_e)_i^{-1}$,

$$\begin{aligned} a_k &= \sigma_k\cot\phi_e - \sigma_l\,\mathrm{cosec}\,\phi_e \\ a_3 &= (\sigma_1\sigma_2/\sigma_3)\,\mathrm{cosec}\,\phi_e \\ b_{kk} &= \frac{1}{2}\sigma_1\sigma_2\,\mathrm{cosec}\,\phi_e - \left(\sigma_k^2+\frac{1}{2}a_k^2\right)\cot\phi_e \\ b_{12} &= (\sigma_1^2+\sigma_2^2)\,\mathrm{cosec}\,\phi_e - (\sigma_1\sigma_2+a_1a_2)\cot\phi_e \\ b_{k3} &= (\sigma_1\sigma_2/\sigma_3)a_l\,\mathrm{cosec}^2\,\phi_e \\ b_{33} &= \frac{1}{2}(\sigma_1\sigma_2\,\mathrm{cosec}\,\phi_e - a_3^2\cot\phi_e) \end{aligned} \quad (6)$$

where $k=1$, 2 and $l=2$, 1 are to be taken in the same order. According to a simple order-estimation, higher-order terms of Eq. (5) do not contribute significantly to the following discussions.

By taking the thermal average of ϕ in Eq. (5), one gets a simple analytical expression of ϕ_g,

$$\phi_g = \phi_e + \sum_i a_i\langle\Delta r_i\rangle + \sum_{i\leq j}\sum b_{ij}\langle\Delta r_i\Delta r_j\rangle + \cdots \quad (7)$$

Since $(r_g)_i$ is defined as $\langle r_i\rangle$, ϕ_G defined above is given by

$$\phi_G = \cos^{-1}[(\langle r_1\rangle^2 + \langle r_2\rangle^2 - \langle r_3\rangle^2)/2\langle r_1\rangle\langle r_2\rangle] \quad (8)$$

so that it may be related to ϕ_g as

$$\phi_G = \phi_g - \sum_{i\leq j}\sum b_{ij}(\langle\Delta r_i\Delta r_j\rangle - \langle\Delta r_i\rangle\langle\Delta r_j\rangle) + \cdots \quad (9)$$

In a similar way, it follows from Eq. (3) that

$$\phi_c = \phi_g + \frac{1}{2}\cot\phi_e\sum_{i=1}^{3}\sum_{j=1}^{3}a_ia_j(\langle\Delta r_i\Delta r_j\rangle - \langle\Delta r_i\rangle\langle\Delta r_j\rangle) + \cdots \quad (10)$$

If ϕ is expanded around the zero-point average nuclear positions, instead of the equilibrium positions as is shown in Eq. (4), ϕ_g can be related to ϕ_z as

a) See text for notations: in 10^{-5} Å for the linear averages and 10^{-5} Å^2 for the quadratic averages.
b) References from which the potential constants were taken. See also Ref. 27.
c) The numbers 1 and 2 represent the C–H and C≡N bonds, respectively. They are equivalent for the other molecules.

$$\phi_g = \phi_z + \sum_i a_i\langle r_i-(r_z)_i\rangle + \sum_{i\le j}\sum b_{ij}\langle[r_i-(r_z)_i][r_j-(r_z)_j]\rangle + \cdots \quad (11)$$

which may be rewritten as

$$\phi_g = \phi_z + \sum_i a_i[(r_g)_i-(r_z)_i] + \sum_{i\le j}\sum b_{ij}(\langle\Delta r_i\Delta r_j\rangle_T + \langle\Delta z_i\rangle_0\langle\Delta z_j\rangle_0 - \langle\Delta r_i\rangle_T\langle\Delta z_j\rangle_0 - \langle\Delta r_j\rangle_T\langle\Delta z_i\rangle_0) + \cdots \quad (12)$$

by noting that $\phi_e\simeq\phi_z$ and that[4] $r_z\simeq r_e+\langle\Delta z\rangle_0$, where Δz is the projection of Δr onto the z axis taken in the direction of the equilibrium nuclear positions of the pair, and the average 0 is taken for the ground vibrational state.

Linear Case. For a linear arrangement, where ϕ_e tends to π, Eq. (5) is no longer valid. Although it is not impossible to define ϕ_g in a similar way to Eq. (2) providing that $\phi\le\pi$, the arccosine function in Eq. (2) can not readily be expanded in terms of the displacements around $\phi=\pi$, so that the problem deviates from that of the ordinary normal-coordinate analysis. It is much simpler, instead, to take the mean-square angle, $\langle(\pi-\phi)^2\rangle$, as a measure of the average bending displacement. It can be shown that

$$\langle(\pi-\phi)^2\rangle = \sum_i c_i\langle\Delta r_i\rangle + \sum_{i\le j}\sum d_{ij}\langle\Delta r_i\Delta r_j\rangle + \cdots \quad (13)$$

where

$$c_k = 2(\sigma_1+\sigma_2) = -c_3,\quad d_{kk} = -\sigma_k(2\sigma_k+\sigma_l),$$
$$d_{12} = -2(\sigma_1^2+\sigma_1\sigma_2+\sigma_2^2),\quad d_{k3} = 2\sigma_k(\sigma_1+\sigma_2),\quad (14)$$
$$d_{33} = -\sigma_1\sigma_2$$

The first sum may be rewritten as

$$\sum_i c_i\langle\Delta r_i\rangle = 2(\sigma_1+\sigma_2)\delta_g \quad (15)$$

where δ_g is the "linear shrinkage" defined by[11]

$$\delta_g = (r_g)_1 + (r_g)_2 - (r_g)_3 \quad (16)$$

One may also define ϕ_c given in Eq. (10) and another effective average angle ϕ_ρ,

$$\phi_\rho = \pi - [\langle\Delta\rho_1^2\rangle^{1/2}/(r_e)_1 + \langle\Delta\rho_2^2\rangle^{1/2}/(r_e)_2] \quad (17)$$

where $\Delta\rho_i$ represents a displacement perpendicular to the equilibrium molecular axis.

Application

The average displacements in the above equations can be calculated by means of a normal-coordinate analysis[16-21,25-27] provided the quadratic and higher-order potential constants for the molecule are known. Thus the present problem is, in principle, straightforward.

Table 1 lists the average displacements for a number of simple hydrides (with their full deuterides) and nonhydrides calculated by the use of the experimental anharmonic potential constants given in the literature.[28-35] It should be noted that the cross mean values of bonded and nonbonded displacements, $\langle\Delta r_1\Delta r_3\rangle$ and $\langle\Delta r_2\Delta r_3\rangle$, are comparable in the order of magnitude with the corresponding mean-square displacements, $\langle\Delta r_1^2\rangle$, $\langle\Delta r_2^2\rangle$ and $\langle\Delta r_3^2\rangle$.

The differences among the various angles calculated for nonlinear molecules are given in Table 2, together with their experimental ϕ_e.[28,36] The differences between the ϕ_g and ϕ_e for H_2O (D_2O) and CH_4 (CD_4) are essentially equal to their equivalents, $\langle\Delta\alpha\rangle$, re-

ported in previous studies.[16,21] In addition, the differences between the $\phi_g-\phi_e$ and $\phi_g-\phi_z$ calculated here are consistent with the corresponding experimental estimates of $\phi_z-\phi_e$ derived from the rotational constants by way of a slightly different procedure.[3,37] As is expected from the previous estimates of nonlinear shrinkages,[12,38] the differences among the various angles are as small as a few tenths of a degree, which are comparable with or smaller than ordinary experimental uncertainties. Nevertheless, it may not always be permissible to simply ignore the differences without discretion. The differences may be significantly larger when the molecule has a low-frequency, large-amplitude bending vibrations. This remark applies particularly to the dihedral angles of torsion[13] and the angles associated with ring-puckering motions, to which the above-mentioned definitions of the average angles can be extended.

Table 3. Average angles (Linear Case) (in degrees)

	$\langle(\pi-\phi)^2\rangle^{1/2}$	$\pi-\phi_c$ [a]	$\pi-\phi_\rho$ [b]
HCN	13.643	13.675	13.894

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 99—103 (1971)

A Remark on the Dipole Moment of Cyclohexane-1,4-dione in Relation to Its Flexible Molecular Conformation

Ariyuki AIHARA and Chikazu KITAZAWA

Department of Materials Science, Denki-Tsushin University, Chofu, Tokyo

(Received September 3, 1970)

A critical remark on the interpretation of the polarity of cyclohexane-1,4-dione molecule has been made taking into consideration a possible contribution of atomic polarization estimated from the electric permittivity of the compound in the solid state. The value 9.6 cc has been assigned as the minimum for atomic polarization which gives dipole moments, 1.16D (28.6°C), 1.20D (42.9°C), and 1.22D (60.8°C) obtained in benzene solutions. A theoretical calculation of the dipole moment has been made also with an assumed potential barrier of the form, $V(\theta)=V_0\cdot[(\pi-\theta)-2\beta]/2\alpha$, in relation to a flexing intramolecular movement of the molecule, where θ is the angle between two carbonyl groups substituted at the opposite sites of the molecule, V_0 is the potential for a boat form A (with two carbonyl groups at the bow and the stern), and α, β are constants to be determined by applying boundary conditions: $V(\theta)=0$ for $\theta=180°-137°$, and $V(91°)=V_0$. By taking 2.46D as the bond moment of carbonyl group, the best fit has been realized between the theoretical and experimental dipole moments when V_0 is assumed to be close to 6000 cal/mol, *i. e.*, twice as large as the hindering potential for the internal rotation of ethane molecule. Mention has also been made of the mechanism of dielectric absorption by this molecule in benzene solution with particular reference to the flexing motion suggested above.

X-ray crystal analyses of cyclohexane-1,4-dione by Mossel and Romers[1] and by Groth and Hassel[2] have revealed very clearly that the molecule exists as a twisted-boat conformation in the crystal. This is of particular interest in view of the peculiar dielectric behavior of the substance which has long been a subject of controversy. Fairly large values of dipole moment, 1.3—1.6 Debye,[3-9] have been obtained by a number

of investigators both in solution and in gaseous state, in spite of the presumed nonpolar conformation of the molecule (chair form), while microwave measurement with benzene solutions[10] suggests a smaller dipole moment of ~0.4 Debye, dielectric loss of the solution being far less than the value which might be expected for a normal polar molecule with dipole moment of 1.3—1.6 Debye. An attempt to solve this problem by measuring the Kerr constant has proved to be unsatisfactory.[11,12]

The flexible conformation of cyclohexane-1,4-dione molecule, as revealed by X-ray analyses,[1,2] might explain the apparent dipole moment of the molecule when it is compared with the calculated values of the moment, assuming that the polarity of the molecule is due to a libration of the two polar moieties of the molecule in some range of angles,[8] or to a fixed polar form in which two carbonyl groups substituted at the opposite sites of the molecule make an angle of 155° between each other.[1]

However, we must not forget that most experimental values in literature have been deduced either neglecting the contribution of atomic polarization or assigning to it a small fraction of electronic polarization (5 to 10 percent); an appreciable contribution from atomic polarization should be considered with a flexible molecule such as cyclohexane-1,4-dione. In this respect, the conclusions of some authors[1,8] seem to be misleading.

Recently Cumper *et al.*[13] reported on the microwave measurement of the dipole moment as well as the relaxation time of cyclohexane-1,4-dione molecule in solutions. They refer to very small values of relaxation time ($\tau=0.57-0.71\times10^{-12}$ sec in benzene solutions) compared with observed dipole moment values, $\mu=1.28-1.32$ D, thereby suggesting some internal flexing motion concerning the dielectric absorption by the molecule. Attention should be paid to the fact that they neglect a possible large contribution of atomic polarization throughout their procedure to calculate μ and τ, and that their quotation of the present author's previous work[10] on the microwave absorption of this compound is somewhat erroneous.

It is appropriate, therefore, to make a critical remark on the interpretation of the polarity of the cyclohexane-1,4-dione molecule with particular reference to our recent work[14] on the estimation of atomic polarization by measuring the electric permittivity of this substance in the solid state.

Experimental

Material. Cyclohexane-1,4-dione was synthesized according to the procedure reported by Vincent *et al.*[15] and recrystallized from ethanol followed by vacuum sublimation, then purified through zone-refining: mp=78.5°C.

Apparatus. Measurement of electric permittivity of the compound in the solid state was performed with the use of a twin-T bridge,[16] (1—150 MHz), the sample being set as a compressed disc of 20 mm diameter and 2.42 mm in thickness. Measurement of the dipole moment in benzene solutions was made using a heterodyne, double-beat electric permittivity measuring equipment constructed in our laboratory (1 MHz), with a sample condenser of Sayce-Briscoe type. Details of these methods were reported before.[14]

Results

Electric Permittivity in the Solid State. Results of the measurement of electric permittivity of cyclohexane-1,4-dione in the solid state are shown in Fig. 1 as a function of temperature. Typical values of ε at 3 MHz are: $\varepsilon=3.10$ (35.0°C), 3.13 (45.0°C), 3.57 (55.0°C), 3.57 (65.0°C), 4.01 (72.0°C).

No appreciable dispersion was observed in the frequency and temperature ranges covered. We see that electric permittivity shows a distinct variation at the transition points 48°C and 69°C,[17] suggesting the onset of some molecular motion above the temperatures so as to give rise to the increase of electric permittivity, despite the increase of molar volume by 2.7% on the

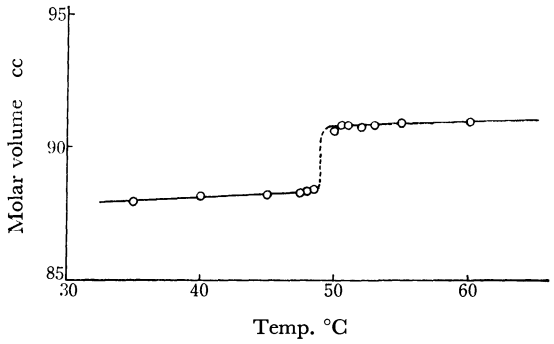

Fig. 2. Variation of the molar volume of cycloane-1,4-dione with temperature.

phase transition at 48°C (Fig. 2).

On the other hand there is a slight decrease in loss tangent (from tan $\delta = 1 \times 10^{-3}$ to ~ 0) at 48°C when the solid undergoes a transition from the low-temperature phase to the high-temperature one. This is in remarkable contrast with the abrupt increase in electric permittivity at this temperature.

The above fact is of importance in considering the mechanism of the phase transition of this compound,[14] although rather large experimental errors ($\pm 0.5 \times 10^{-4}$ in tan δ) prevent us from making any precise argument. It should be added here that Smyth[18] ascribed this transition to "half rotation" of the molecule referring to the experimental results by White and Bishop.[19] The variation of electric permittivity at 69°C is also remarkable, but no detectable changes were observed in tan δ.

Estimation of the Magnitude of Atomic Polarization. By assuming that the molecules of cyclohexane-1,4-dione are almost rigid at the crystalline lattice at temperatures below 48°C,[1,17] the molar distortion polarization may be calculated from the Clausius-Mossotti equation. With electric permittivity $\varepsilon = 3.13$ and molar volume = 88.22 cc (density = 1.271) both at 45°C, distortion polarization P_D has been found to be 36.6 cc. Subtracting electronic polarization $P_E = 27.01$ cc[20] from P_D, 9.6 cc can be assigned as the probable minimum value for the contribution of atomic polarization P_A. This value has been taken into consideration in calculating the dipole moment as measured in benzene solutions.

Dipole Moment in Benzene Solution. Electric permittivity and density as well as refractive index of cyclohexane-1,4-dione in benzene solutions were measured in the concentration range $2.67 \times 10^{-3} - 2.49 \times 10^{-2}$ (weight fraction) and at temperatures 28.6–60.8°C. The values of dipole moment were then calculated from the equations and methods of Halverstadt and Kumler[21] and of Guggenheim and Smith.[22] In Table 1, the values calculated both with and without due consideration of atomic polarization (9.6 cc) are shown. It should be noted that the μ values calculated neglecting P_A (Halverstadt-Kumlers' method) are in good agreement with those calculated by the Guggenheim-Smith equation. These values both correspond to the values in literatures.[3-9]

Table 1. Dipole moment of cyclohexane-1,4-dione in benzene solution (Debye)*

Temp. °C	μ_{H-K} ($P_A = 9.6$ cc)	μ_{H-K} ($P_A = 0$ cc)	μ_{G-S}
28.6	1.16	1.35	1.33
35.6	1.17	1.36	1.35
42.9	1.20	1.39	1.36
51.1	1.21	1.40	1.39
60.8	1.22	1.42	1.40

* Experimental errors in μ's are estimated to be ± 0.20 D. μ_{H-K} and μ_{G-S} refer to the dipole moment according to Halverstadt-Kumlers' and Guggenheim-Smiths' methods, respectively.

Discussion

The values of dipole moment, obtained with due consideration of atomic polarization, $P_A = 9.6$ cc, should be regarded as the maximum value of the experimental dipole moment, since we might expect a still greater contribution of atomic polarization for the molecule, in solution or in vapor phase, because of its large flexibility. For example, 14.9 cc can be obtained as P_A value if we use $\varepsilon = 3.57$ and molar volume = 90.94 cc both at 55°C, for the phase above 48°C, where the freedom of motion of the molecule is thought to be much larger as revealed by IR and NMR measurements.[17]

The flexing motion of the molecule could produce a very large increment of electric polarization making the distinction between atomic and orientation polarization ambiguous. Therefore, let us take the dipole moment values calculated with $P_A = 9.6$ cc as the most probable experimental values at the moment, and compare them with those calculated theoretically.

Calculation of the Theoretical Dipole Moment and the Geometry of the Molecule. The data of molecular dimensions of cyclohexane-1,4-dione, obtained by Mossel and Romers,[1] differ somewhat from the values usually adopted as normal bond lengths and valency angles: C(sp^3)–C(sp^2) 1.515 Å, C(sp^3)–C(sp^3) 1.536 Å, C=O 1.210 Å, $\angle$C(sp^3)C(sp^2)C(sp^3) 116.2°, $\angle$C(sp^2)C(sp^3)-C(sp^3) 112.2°.

Therefore it is necessary to estimate anew, with the above data, the angle between the two carbonyl groups substituted at the opposite sites of the molecule for the two conformations, boats A and B (Fig. 3).

A simple geometrical consideration leads to the following values of the angles between the two carbonyl groups for the two boat conformations: $\theta = 91.2°$ (boat A), $\theta = 136.9°$ (boat B). A comparison is made in Table 2 with the values adopted by Le Fèvre[4] and also by Allinger *et al.*[8c]

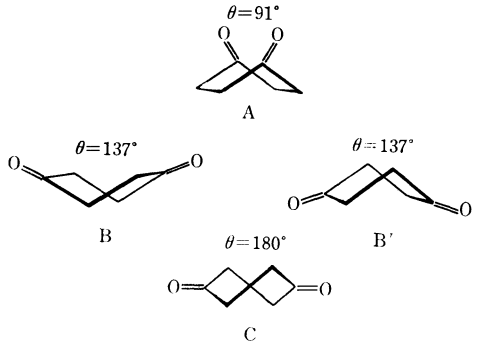

Fig. 3. Boat conformations of cyclohexane-1,4-dione molecule.

TABLE 2. THE ANGLE θ BETWEEN THE TWO CARBONYL GROUPS OF CYCLOHEXANE-1,4-DIONE MOLECULE CALCULATED FOR BOAT FORMS A AND B

	This work	Le Fèvre[4]	Allinger[8c]
Boat A	91.2°	86°	76°
Boat B	136.9°	130°	127°

The angle value observed with the actual molecular conformation in the crystalline state is 154.8°,[1] which means that the molecule is more flattened than boat B. Thus, if this conformation is taken as corresponding to the minimum internal energy even as a free molecule, the dipole moment of the molecule could be calculated with the use of an appropriate value of the C=O bond moment: $\mu=2\,\mu_{C=O}\times\cos(155°/2)$.

It should be noted, however, that the angle of 155° might not necessarily correspond definitely to the minimum of the potential energy of a free molecule, but could vary within an appreciable range of angles under the influence of external forces, as can be seen from the work by Groth and Hassel,[23] who report the value of 175° as the angle between the two carbonyl groups of cyclohexane-1,4-dione forming a molecular complex with $HgCl_2$, and 157° for the complex with C_2I_2.

An inspection of Dreiding model of this molecule reveals that the relative configuration of the two adjacent methylene groups (mutually gauche) does not change under the deformation of the molecule when the deformation is restricted within the two extreme conformations, boats B and B', including an intermediate boat C (nonpolar form). The methylene groups do not make any rotation relative to each other so far as the angle between the two carbonyl groups remains within the range 137°—180°. Furthermore, the relative configuration of a carbonyl group to the two adjacent methylene groups varies in such a way as to compensate each other the increase of the potential energy due to deformation. Allinger *et al.*[8c] also discussed the problem.

Thus, admittedly the Dreiding model should not be taken to represent the real molecular structure, we might safely assume that the polar moiety of the molecule "librates" almost freely in a shallow potential well so far as the angle θ does not decrease beyond 137°. If angle θ decreases further, the potential energy of the molecule will increase due presumably to the interaction between the two adjacent methylene groups known in the cases of ethane and its derivatives.[24]

According to the above reasoning, the dipole moment of the molecule can be expressed as follows:

$$\mu^2=\int_{\theta_1}^{\theta_2}\mu_\theta^2\exp(-V(\theta)/RT)\mathrm{d}\theta\Big/\int_{\theta_1}^{\theta_2}\exp(-V(\theta)/RT)\mathrm{d}\theta, \quad (1)$$

where μ_θ is the resultant moment of the molecule corresponding to the angle θ between the two dipole components $\mu_{C=O}$, the moment of the single carbonyl group, and is given by $\mu^2_\theta=2\,\mu^2_{C=O}\,(1+\cos\theta)$; $V(\theta)$ is the intramolecular potential as a function of θ, R is the gas constant, T is the absolute temperature and θ_1, θ_2 should be taken as the values for boat C (180°) and boat A (91°),[25] respectively.

It is necessary to make a proper choice of the value for the bond moment $\mu_{C=O}$ and also of the potential $V(\theta)$ as a function of θ. Allinger *et al.*[8c] took 3.0 D for $\mu_{C=O}$ and calculated μ values as 1.64 D (291°K) and 1.79 D (490°K), through a graphical integration of Eq. (1) from $\theta_1=76°$ to $\theta_2=180°$, with the assumption that the potential barrier for the boat A conformation is given either by 10.26 kcal/mol (291°K) or 12.00 kcal/mol (490°K). Their μ values are obviously too large compared with the values in literature, and do not give a reasonable explanation of the polarity of this molecule.

The authors have chosen a value 2.46 D for the C=O bond moment. The difference between experimental dipole moment of cyclohexanone, $\mu=2.87$ D, obtained by the measurement of Stark effect on the microwave absorption of the substance,[26] and the moment of methylene group, 0.46 D (the moment of $-CH_3$ is assumed to be 0.40 D), is 2.41 D, while we get $\mu_{C=O}=2.50$ D if we subtract $\mu_{-CH_3}=0.40$ D from the experimental dipole moment of acetone, $\mu=2.90$ D.[27] The average of these two values, 2.46 D, may be regarded as free from any contribution of atomic polarization and, therefore, must be more reasonable as the bond dipole moment of C=O for cyclohexane-1,4-dione molecule.

On the other hand, the following assumption has been made concerning the potential function of this molecule. The potential energy is zero for the range of θ values, 137° to 180°, but varies as $V(\theta)=V_0[(\pi-\theta)-2\beta]/2\alpha$ between 91° and 137°, where V_0 is the potential barrier for the conformation A ($\theta=91°$), α and β are constants. Converting the variable θ to $\varphi=(\pi-\theta)/2$, the potential becomes $V(\varphi)=V_0(\varphi-\beta)/\alpha$, (Fig. 4). α and β can be determined by applying the boundary conditions, $V(\varphi)=0$ for $\varphi=21.5°$ and $V(\varphi)=V_0$ for $\varphi=44.5°$.

Then, rewriting Eq. (1) as

23) P. Groth and O. Hassel, *Tetrahedron Lett.*, **1964**, 65.

24) S. Mizushima, *loc. cit.*, Chapters 1—3.

25) In the case of boat A, the two adjacent methylene groups become mutually "eclipsed," corresponding to the maximum of the intramolecular potential.

26) Y. Ohnishi and K. Kozima, This Bulletin, **41**, 1323 (1968).

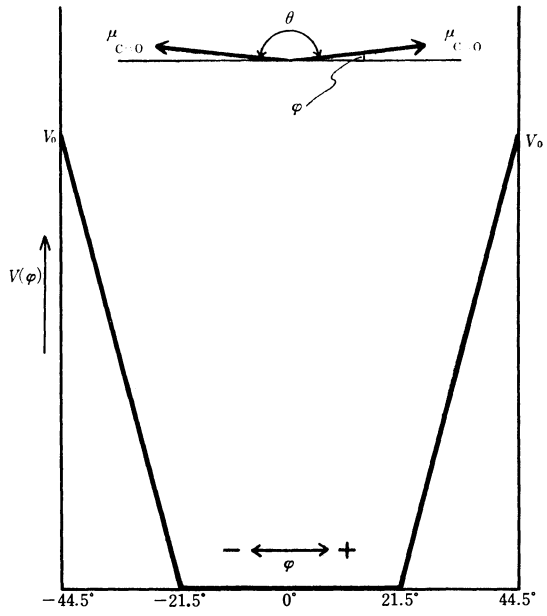

Fig. 4. Assumed potential curve for the flexing motion of cyclohexane-1,4-dione molecule.

$$\mu^2 = 2\mu^2_{C=O}\{1 + \langle\cos\theta\rangle\}, \quad (2)$$

the statistical average of $\cos\theta$, $\langle\cos\theta\rangle$, can be calculated in the following way:

$$\langle\cos\theta\rangle = \int_{0°}^{44.5°} -\cos 2\varphi \exp\{-V(\varphi)/RT\}d\varphi \Big/ \int_{0°}^{44.5°} \exp\{-V(\varphi)/RT\}d\varphi$$
$$= -\left[\int_{0°}^{21.5°} \cos 2\varphi d\varphi + \int_{21.5°}^{44.5°} \cos 2\varphi \exp\{-V_0(\varphi-\beta)/\alpha RT\}d\varphi\right] \Big/ \left[\int_{0°}^{21.5°} d\varphi + \int_{21.5°}^{44.5°} \exp\{-V_0(\varphi-\beta)/\alpha RT\}d\varphi\right] \quad (3)$$

Integration has been performed analytically for three temperatures (28.6°C, 42.9°C, 60.8°C) with the assumption that the potential barrier V_0 can be taken as 6000 cal/mol: the potential for the boat A conformer may approximately be chosen to be twice as large as the hindering potential barrier for the internal rotation of ethane molecule, 3000 cal/mol.[24] The results of calculation are shown in Table 3, together with the results obtained by using the potential barrier of $V_0=$ 5000 cal/mol and $V_0=10000$ cal/mol, the latter being of the same order of magnitude as those adopted by Allinger *et al.*[8c]

Table 3. Theoretical dipole moment of cyclohexane-1,4-dione as compared with experimental values (Debye)

Temp. °C	μ_{calc} $V_0=5000$ cal/mol	$V_0=6000$ cal/mol	$V_0=10000$ cal/mol	μ_{obs}
28.6	1.19	1.17	1.11	1.16±0.02
42.9	1.20	1.18	1.11	1.20±0.02
60.8	1.21	1.19	1.12	1.22±0.02

In spite of a simplified form of the potential function here adopted, the calculated values of dipole moment with $V_0=5000$—6000 cal/mol are in very good agreement with the experimental values with the consideration of atomic polarization. It is, therefore, most probable that the molecule of cyclohexane-1,4-dione behaves, in a solution, as a flexing twisted-boat conformation with the potential for the intramolecular movement of the form as shown in Fig. 4.

With the potential of this form, the molecule will be able to relax quite easily, under the action of high frequency electric field, without being subjected to appreciable hindrance in changing the direction of the molecular dipole. The flexing motion of this molecule could reverse the sense of polarity of the molecule instantaneously without performing rotation of the molecule as a whole, if the angle φ changes from positive to negative values (Figs. 3 and 4). This must be the reason why solutions of cyclohexane-1,4-dione give unexpectedly small dielectric loss[10] as well as small τ values,[13] but rather large increment of electric permittivity.[10]

(Received March 13, 1970)

The radial growth rates of the selenium spherulites were measured by the microscopic method at temperatures ranging from 128.4°C to 192.3°C. The radial growth rate increased with an increase in the crystallization temperature up to about 180°C, reached a maximum value of 87.0 μ/min, and then decreased abruptly, judging from the observation of organic polymers at crystallization temperatures near their melting points. The process of the spherulite growth of selnium near the melting point could not be interpreted by only two elementary processes, that of the segmental jump and that of the formation of a two-dimensional nucleus of a critical size. The variation in the radial growth rates of selenium with the temperature was explained by considering the bond-breaking process as an elementary process. The estimated surface free energy at the liquid-crystal interface was 25.1 erg/cm^2; this value was a reasonable one.

When amorphous selenium is crystallized under atmospheric pressure, it grows in a spherulite form,[1] just like such organic polymers as polyethylene adipate, polyethylene succinate, and nylon 6. In general, the rate-determining step of the spherulite growth well below the melting point is considered to be the process of the segmental jump at the liquid-crystal interface, whereas the process of the spherulite growth near the melting point is governed mainly by the effort needed to overcome the surface free energy of the two-dimensional nucleus formed on the liquid-crystal interface.[2,3]

Because the temperature coefficient of the growth rate of the selenium spherulite is much larger than that expected from the process of the segmental jump well below the melting point, the process of the Se-Se bond breaking was suggested as one of the elementary processes associated with the spherulite growth.[4] In the present work, this concept will be discussed on the basis of the behavior of the selenium spherulite growth near the melting point.

Experimental

Materials. The selenium was obtained from the Yokozawa Chemical Company; its purity was guaranteed to be better than 99.999%. The selenium was melted at 230°C for 1 hr in an electric furnace and was then quenched on a microscopic cover-glass in order to prepare the sample. The samples were stored in a cooled desiccator.

Procedure. An Olympus reflecting microscope, Model STS, was used to measure the radial growth rates of selenium spherulites. The sample was at first melted at 230°C for 1 hr in a heating block mounted on the microscope, was cooled rapidly to 130°C in order to develop the nuclei, and was then heated again quickly to the specified temperatures. The selenium spherulites were grown isothermally at temperatures ranging from 128.4°C to 192.3°C. The radii of the spherulites formed on the surfaces of the selenium samples were estimated by measuring microscopic photographs. The temperatures of the heating block were calibrated by using materials of known melting points.

An X-ray diffractometer, Model JDX-5P, from the Japan Electron Optics Laboratory was used to obtain the X-ray powder diffraction patterns of the selenium crystallized in the temperature range from 99.5°C to 174.4°C.

Results

The radii of the spherulites varied linearly with the heating times, and the slopes of all the radius-time curves were nearly equal at a specified temperature, regardless of the developing periods of the nuclei, as was observed in a previous work.[4] Figure 1 shows the linear variations of the radius-time curve of the selenium spherulites at temperatures ranging from 128.4°C to 192.3°C. The slopes of the linear relationships increased as the crystallization temperatures increased up to about 180°C, whereas they decreased above 180°C. The radial growth rate, G, of the selenium spherulite was estimated from the slope of the radius-time relationship,

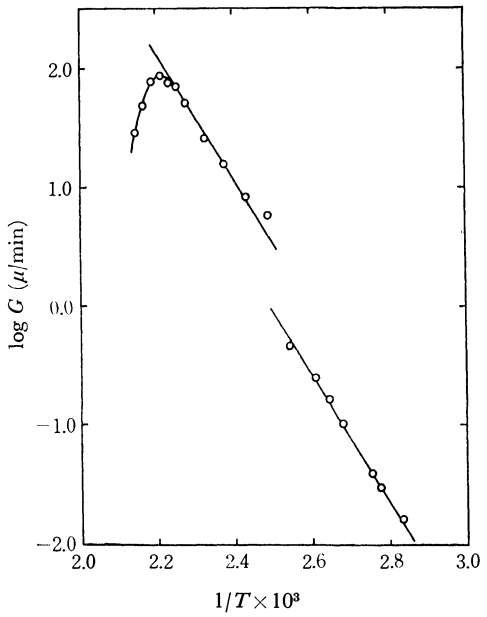

Fig. 3. Arrhenius plot of log G.
(The results below 120°C are reproduced from Ref. 4.)

increased with an increase in the crystallization temperature up to about 180°C, reached a maximum value, and then decreased abruptly. Figure 3 shows the dependence of log G on $1/T$. The relationship of log$G$ to $1/T$ at temperatures ranging from 128.4°C to 165.5°C is regarded as linear, and the slope in the temperature range is nearly equal to that at temperatures ranging from 70°C to 120°C.[4] The linear relationship varied discontinuously at about 125°C, though the slopes in the temperature ranges both above and below 125°C did not change. The results on the spherulite growth rate below 120°C presented in the previous work[4] were obtained from a crystallization without preheating, as has been described in the "Procedure" section of this paper. The discontinuity in the growth rate at approximately 125°C was also observed from the crystallization without preheating in the temperature range above 125°C, but slightly lower values were obtained than those with preheating. Such discontinuous changes in the radial growth rates, G, have often been observed in the growth of organic chain-polymer spherulites.[2]

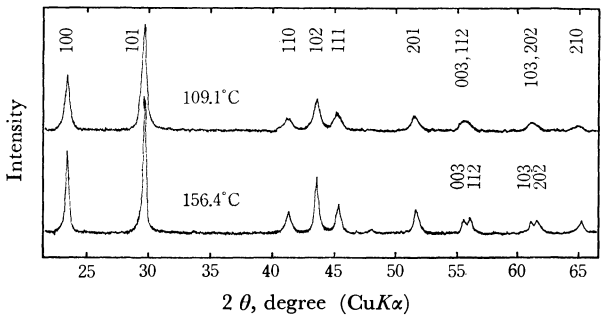

Fig. 4. X-Ray powder diffractograms of selenium crystallized at 109.1°C and 156.4°C.

Figure 4 shows X-ray powder diffraction intensity diagrams of the selenium crystallized at 109.1°C and 156.4°C, as examples for the samples obtained below and above 125°C respectively. A slight shift in the diffraction peaks was observed at crystallization temperatures between 118.9°C and 128.4°C. The values of the unit cell axes, a and c, were estimated by using the diffraction peaks of (003), (112), (103), and (202). The ratios of the axes, c/a, at the specified temperatures are given in Table 2.

The ratios of the axes, c/a, of the crystallized selenium changed discontinuously from 1.118 to 1.131 at temperatures between 118.9°C and 128.4°C, but the details of the change are obscure.

Discussion

Hoffman and Weeks[5] expressed the radial growth rate of spherulite, G, as follows:

$$G = G_0 \exp(-\Delta G^*/kT) \exp(-\Delta G_c/kT) \quad (1)$$

where G_0 is the specific rate; ΔG^*, the free energy of activation for the segmental jump process at the supercooled liquid-crystal interface, and ΔG_c, the free energy

5) J. D. Hoffman and J. J. Weeks, *J. Chem. Phys.*, **37**, 1723 (1962).

TABLE 2. RATIOS OF AXES IN HEXAGONAL SELENIUM

Cryst. temp., °C	99.5	109.1	118.9	128.4	137.9	147.1	156.4	165.5	174.5
c/a	1.118	1.118	1.118	1.131	1.133	1.134	1.134	1.133	1.134

of the formation of a two-dimensional nucleus of a critical size. The ΔG_c is expressed by the following equation:

$$\Delta G_c = 4\sigma_s\sigma_e h T_m/\Delta h_f \Delta T \quad (2)$$

where σ_s and σ_e are the lateral and end surface free energies of the two-dimensional, bundlelike nucleus respectively; h, the thickness of the nucleus; T_m, the melting point of the crystallized polymer; Δh_f, the heat of fusion at T_m, and ΔT, the difference in the melting point and the crystallization temperature, $T_m - T$. Therefore, the radial growth rate of spherulite may be expressed as follows:

$$\ln G = \ln G_0 - \Delta G^*/kT - CT_m/(\Delta T)T \quad (3)$$

where $C = 4\sigma_s\sigma_e h/k\Delta h_f$

Hoffman and Weeks[5] expressed the free energy of activation for the segmental jump process, ΔG^*, as follows, in conjunction with the WLF equation:

$$\Delta G^* = 2.303C_1^g C_2^g RT/(C_2^g + T - T_g) \quad (4)$$

In the crystallization of an organic-chain polymer, the radial growth rate of the spherulite near the melting point was considered to be governed by the third term on the right side of Eq. (3), and the variation in $(\ln G + \Delta G^*/kT)$ with $T_m/(\Delta T)T$ fit well into Eq. (3).

The application of Eq. (3) to selenium spherulite growth was examined. Harrison[6] reported the viscosities of the liquid selenium to be as follows:

TABLE 3. VISCOSITIES[6] AND DENSITIES[7] OF LIQUID SELENIUM

Temp. °K	η, poise	ρ, g/cm³	Temp. °K	η, poise	ρ, g/cm³
533	5.63	3.923	603	1.08	3.810
556	3.03	3.885	615	0.838	3.791
573	2.01	3.858	623	0.723	3.718
591	1.35	3.830			

The values in Table 3 were extremely adaptable to the WLF equation, though the temperatures in Table 3 were much higher than the glass transition temperature of amorphous selenium (305°K). The parameters, C_1^g and C_2^g, in the WLF equation were estimated to be 12.88 and 131.2 respectively from the shift factors calculated by means of the values in Table 3. These values for selenium were different from those for the usual polymers (17.44 and 51.6 respectively); it is probable that this difference arises from the fact that the temperatures used in the experiment were much higher than the T_g of amorphous selenium.

The apparent activation energy for the viscous flow of the liquid selenium was estimated to be 17.8 kcal/mol from the Arrhenius plot of the viscosities of the liquid selenium at temperatures ranging from 220°C to 240°C.[8] On the other hand, the calculated value of the activation energy for the viscous flow of liquid selenium at 230°C was found to be 17.3 kcal/mol by using the estimated parameters, C_1^g and C_2^g, and the following equation derived from the WLF equation:[5]

$$E_a = 2.303C_1^g C_2^g RT^2/(C_2^g + T - T_g)^2 - RT + \alpha RT^2 \quad (5)$$

where α is the expansion coefficient of liquid selenium, 4.8×10^{-4} °C^{-1}. Since the two values of the activation energy for the viscous flow nearly agreed with each other, the estimated values of the parameters, C_1^g and C_2^g, were considered to be reasonable.

The free energies of activation, ΔG^*, for the segmental jump process of amorphous selenium were estimated to be 17.10 and 13.35 kcal/mol at 401.6 and 465.5°K respectively, for example, by using Eq. (4). If the selenium spherulite growth obeys Eq. (3), the plots of $(\ln G + \Delta G^*/kT)$ should be linear with $T_m/(\Delta T)T$. Figure 5 shows the relationship between $(\ln G + \Delta G^*/RT)$ and $T_m/(\Delta T)T$. No linear relationship can be observed, as is shown in Fig. 5. It becomes clear that the process of the selenium spherulite growth can not be interpreted by only two terms, the segmental jump at the liquid-crystal interface and the free energy of the formation of a two-dimensional nucleus of a critical size.

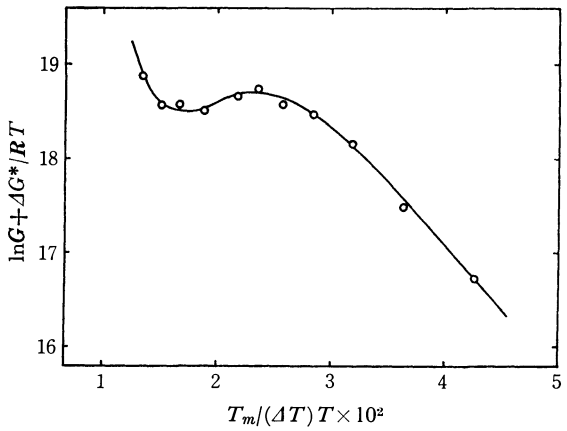

Fig. 5. Plot of $\ln G + \Delta G^*/RT$ against $T_m/(\Delta T)T$.

Turnbull and Cohen[9] pointed out that the crystallization of selenium was performed by the reconstruction of the irregularly-distributed chain molecules created by the breaking of the Se–Se bonds. The concept of the reconstruction in the selenium crystallization is due to a large barrier to internal rotation about Se–Se bonds,[10] which barrier is caused by the repulsion

between lone-pair electrons around selenium chains. Mamedov[11] reached the same conclusion on the basis of X-ray diffraction studies of the bulk crystallization in the selenium. Also, Hillig[12] doubted whether the treatment of Turnbull and Fisher[13] for the homogeneous nucleation on selenium, work based on the molecules across the phase boundary and work which needed to overcome the surface energy of a nucleus of a critical size, was applicable without modification.

Considering the breaking process of Se–Se bonds, that is, $Se_n \rightleftharpoons Se_{n-t} + Se_t$, the elementary processes of selenium crystallization at the liquid-crystal interface may be expressed as follows:

$$\underset{\text{(amorph. Se)}}{\text{State A}} \xrightarrow[k_1]{\text{seg. jump}} \text{State B} \underset{k_3}{\overset{k_2}{\rightleftharpoons}} \text{State C} \rightleftharpoons \underset{\text{(cryst. Se)}}{\text{State D}}$$

(bond breaking; build up)

where k_1, k_2, and k_3 are the rate constants. Since the activity of amorphous selenium, a_0, at the crystal-liquid interface is regarded as constant, the rate from the A state to the C state can be expressed as $k_1Ka_0/(1+K)$, where K is k_2/k_3, from the treatment of the reaction kinetics. If the bond-breaking process of an amorphous selenium chain is nearly equal to the opening process of the ring selenium molecule, the values[14] of K can be calculated to be of orders from 10^{-9} to 10^{-7} at the temperatures ranging from 128.4°C to 192.3°C; therefore, the rate from the state A to the state C can be expressed as k_1Ka_0.

Accordingly, the overall radial growth rate of selenium spherulite can be expressed as follows:

$$\ln G = \ln G_0 - \Delta G^*/kT - \Delta G_s^*/kT - CT_m/(\Delta T)T \quad (6)$$

where ΔG^* and C are the same as in Eq. (3), and ΔG_s^*, the free energy for the bond-breaking process of chain molecules. The ΔG_s^* is considered to be nearly equal to the ΔG for the process of opening ring molecules, Se_8. Eisenberg and Tobolsky[14] estimated the values of ΔH and ΔS for the ring-opening process to be 25 kcal/mol and 23.0 e. u. respectively. Assessing the ΔH_s^* and ΔS_s^* to be 25 kcal/mol and 23.0 e. u. respectively, the plots of the terms of $(\ln G + \Delta G^*/RT + \Delta G_s^*/RT)$ against $T_m/(\Delta T)T$ given in Fig. 6 are obtained. From the linear relationship in Fig. 6, it is clear that the selenium spherulite growth is governed by the breaking process of Se–Se bonds as well as by the processes of the segmental jump and the formation of a two-dimensional nucleus of a critical size.

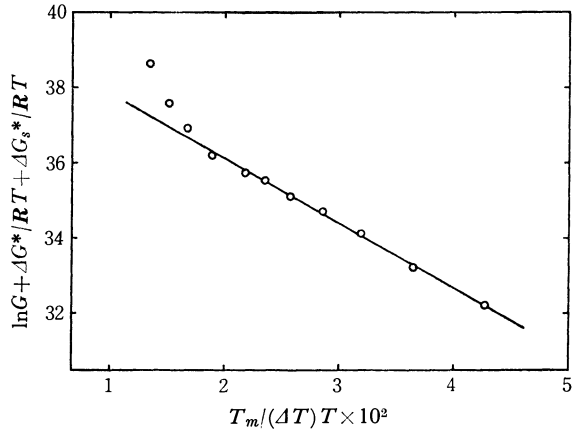

Fig. 6. Plot of $\ln G + \Delta G^*/RT + \Delta G_s^*/RT$ against $T_m/(\Delta T)T$.

The constant, C, was estimated to be 173.3 from the slope in Fig. 6. The radial growth rate of the selenium spherulite at temperatures ranging from 128.4°C to 192.3°C can be expressed by the following empirical formula:

$$\ln G = 39.60 - \Delta G^*/RT - (2500 - 23.0T)/RT - 173.3T_m/(\Delta T)T \quad (7)$$

The calculated values of G are plotted by the solid line in Fig. 2. The thickness of the two-dimensional nucleus at the liquid-crystal interface was calculated to be 3.78 Å on the basis of the crystal dimensions of hexagonal selenium, assuming the two-dimensional nucleus to be a monolayer of the selenium chain. The geometric average of $\sigma_s\sigma_e$, σ^*, was estimated to be 25.1 erg/cm^2 from the estimated value of the term of $4\sigma_s\sigma_e h/k\Delta h_f$ and from the values of h and Δh_f.[15]

Zadumkin[16] calculated the free energies of the melt-crystal interface for selenium and 36 metals to be 8—15% of the surface tension, σ, of their liquids at the melting points, except for Ge, Si, and Sb. The interfacial free energy of selenium at the liquid-crystal interface was calculated to be 15.9 erg/cm^2, assuming its value to be 15% of the surface tension of liquid selenium at the melting point, 217°C, 106 erg/cm^2.[17] Though the empirical value of the geometric average, σ^*, is slightly larger than the calculated value, it is considered to be reasonable.

Purity Determination of Organic Compounds by Time-temperature Freezing or Melting Curves with a Simplified Apparatus[1)]

Hisae ENOKIDO,[2)] Takako SHINODA, and Yo-ichiro MASHIKO
Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo
(Received April 30, 1970)

A simplified apparatus has been constructed for determining the purity of organic compounds by time-temperature freezing or melting curves. The sample cell is small and the amount of the sample needed in only 0.2 m*l* or 2 m*l*. The thermometers used are a Shimadzu platinum resistance thermometer calibrated by the measurement of fixed points and a chromel *p*-constantan thermocouple calibrated against a standard platinum thermometer with a precision better than $\pm 0.03°$. Purities of several hydrocarbons were determined by measuring their freezing and melting curves.

The apparatus and procedure for determining the purity of compounds from time-temperature freezing and melting curves were developed by Taylor and Rossini, and Glasgow *et al.*,[3)] and are widely used. However, the temperature observed by the time-temperature technique is not real equilibrium temperature and differs from that observed with the use of a precision adiabatic calorimeter, especially in a simplified apparatus. Though purity determination by using the adiabatic calorimeter is more accurate, the apparatus and technique are complicated and the time required for measurement usually exceeds several hours.

This paper describes an apparatus and technique to simplify the method and save time in purity determination by means of time-temperature freezing and melting curves. The method was applied to the purity determination of several hydrocarbons. The results show that the well-known method of analyzing data should be improved to give highly accurate results.

Experimental

Apparatus. A small apparatus was constructed to obtain time-temperature freezing and melting curves. The general assembly is illustrated in Fig. 1. The sample cell and container are made of hard and pyrex glass, respectively. The details of the sample cells are shown in Fig. 2. The cells were closed in a vacuum system so that the sample could be analyzed in the absence of air and water vapor. A platinum thermometer or a thermocouple was inserted into the re-entrant well and the cells were then set in a hole of a copper cylindrical block, with wall of 0.2 mm thickness and heater wound around it. The cells were hung inside the container by means of three constantan wires. The container was evacuated, and the cooling and heating rates were controlled by adjusting the amount of helium gas inside the container. The whole assembly was mounted in a constant temperature cooling or heating bath. The temperature at the beginning of measurement was so selected that it differed from the freezing or melting point of a sample by approximately 10—50°C.

The sample temperature was measured with the platinum thermometer or the thermocouple. As the sample cell was small, a standard platinum thermometer could not be fitted. Instead, a small platinum-in-stainless steel resistance thermometer, 3.5 mm in diameter and 3 cm long, (Shimadzu Co.) was employed. It has four platinum leads, and was certified by the measurement of fixed points. The resistance value was about 100 ohms at room temperature. The thermocouple, a chromel *p*-constantan type, was calibrated by comparison with a Leeds & Northrup platinum thermometer certified by the National Bureau of Standards as well as against the melting point of benzoic acid and the freezing point of tin.

Each comparison was made under practically adiabatic conditions: the emf of the thermocouple and the resistance of the standard thermometer were measured at the same time. Some 40 comparisons were made in the temperature range of 15 to 500°K. Two formulas which each fit the data in the temperature regions above and below 0°C, are based on the expansion of emf in terms of absolute temperature T as follows:

$$\text{emf}\,(\mu\text{V}) = \sum_{n=0}^{m} A_n (T)^n \qquad (1)$$

where the upper limit of m is 4 and 9 for above and below 0°C, respectively. Coefficients determined are listed in Table 1. The deviations of the observed values from the calculated

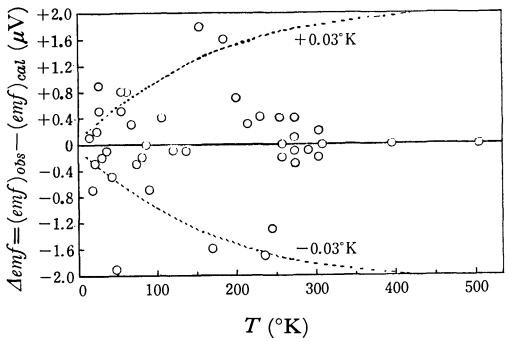

Fig. 3. Deviation of observed emf of a chromel *p*-constantan thermocouple from the calculated one by using Eq. (1).

ones by using Eq. (1) were within ±0.03° as shown in Fig. 3.

The resistance of the thermometer is recorded on a Shimadzu Precision Temperature Recorder CT3. An ice-water bath was used as a reference for the thermocouple, and the difference in emf between the cell thermocouple and a Yokogawa DC Potentiometer P-7B was amplified with an Ohkura DC Microvolt Meter AM-101, and then recorded on a Yamatake-Honneywell Recorder Electronic 19 as a function of time. All measurements were carried out automatically, except for the manual control of freezing or melting rates. The time required for the measurement of a sample was about fifteen minutes.

Material. The thermometer and thermocouple cells were filled at the same time with extra pure grade reagents *n*-octane, *n*-undecane, *n*-tridecane and *n*-docosane obtained from Tokyo Kasei Kogyo Co., Ltd. After removing the trace of air from the sample by pumping out at liquid nitrogen temperature, the cells were sealed in a vacuum system.

The amount of sample used was about 2 m*l* for the thermometer cell and 0.2 m*l* for the thermocouple cell.

Results and Discussion

Principle of Purity Determination from the Freezing or Melting Point. For impurities that are completely soluble in the liquid phase but insoluble in the solid phase, the thermodynamic relation between the amount of impurities and the equilibrium temperature in the case of an ideal or sufficiently dilute solution, is

$$-\ln(1-N)/r = (T^*_{f0}-T)\Delta H_m/R(T^*_{f0})^2 \qquad (2)$$

where N is mole fraction of the impurities, T^*_{f0} the melting point of pure compound, T the given temperature at equilibrium, r the fraction melted or crystallized, ΔH_m the heat of fusion at T^*_{f0} of pure compound and R the gas constant. However, the temperature T given by the time-temperature curve is not always at equilibrium, and the corresponding equation should be derived from irreversible thermodynamics as follows:[4]

$$-\ln(1-N)/r = (\Delta H_m/R)(1/T-1/T^*_{f0}) + (\Delta C_p/R)[\ln(T^*_{f0}/T) + 1 - (T^*_{f0}/T)] + A(T,r)/RT. \qquad (3)$$

Here ΔC_p denotes the difference of heat capacity of pure compound in liquid and solid states, and $A(T,r)$ the affinity. However, A usually has some finite value, and to estimate the value of A as a function of temperature or time is difficult, especially with a simplified apparatus and technique. If $A=0$, the temperature and fraction melted or crystallized are applicable for determining the purity of the sample by means of Eq. (2).

As a matter of principle it may be assumed that in the time-temperature curves of freezing or melting, the temperature of sample when $r=1/2$ is most nearly at equilibrium, and so Eq. (2) is applicable for determining the purity.

Purity Determination of Hydrocarbons. The time-temperature curves of freezing or melting for several hydrocarbons were obtained by using both the platinum thermometer and the thermocouple cells. As was described in the previous section, determination of

4) I. Prigogin and R. Defay, "Chemical Thermodynamics," Longmans Green and Ltd. (1954), p. 373; Y. Mashiko, T. Shinoda, and H. Enokido, to be published.

purity was made by measuring the temperature most nearly at equilibrium. The results were compared with those obtained by using the method of Rossini *et al.*[3]

As an example, time-temperature melting and freezing curves for *n*-undecane and *n*-docosane obtained by using the thermocouple cell are shown in Fig. 4.

i) Purity of n-*Undecane Obtained by the Melting Curve.* Temperature x, shown in Fig. 4(a), which is a point of inflexion of a quasi-equilibrium portion of the melting curve, seems to be the melting point of the sample. Also the temperature when $r=1/2$ seems to be given by the intersection y of the extension of the melting curve, where a major portion of the sample is melted, with the backward extension from the point x of the heating curve of liquid. The amounts of impurities in the sample of *n*-undecane estimated from the temperatures of point x and y corresponding to $r=1$ and 1/2, respectively, and the value of the melting point reported by Finke *et al.*[5] are in good agreement with each other within —0.03 mol%, and give the average value 99.2_3 mol%.

On the other hand, the melting points of the same sample and of zero impurity of *n*-undecane were calculated from the melting curve by Rossini's method. A GHI-line in Fig. 4(a) represents a quasi-equilibrium portion of melting curve which was explained by Rossini *et al.* The obtained values are 247.21_2°K and 248.30_0°K, respectively, and give a purity of 98.3_6 mol%. If the literature value 247.592°K is used as the melting point for zero impurity, the significantly different value of 95.3_7 mol% is obtained. Thus it can be seen that it is not appropriate to analyze the time-temperature melting curve obtained with a simplified apparatus in terms of Rossini's method, since it is difficult to observe the melting curve under equilibrium condition in a simplified apparatus as compared with Rossini's larger apparatus.

ii) Purity of n-*Docosane Obtained by the Freezing Curve.* If supercooling is successfully observed with a small peak, a major portion of the freezing curve may be assumed to be nearly at equilibrium. Therefore, analysis of the freezing curve was made for *n*-docosane by Rossini's method, as shown in Fig. 4(b). The result, 99.1_9 mol%, is in better agreement with ours (99.2_9 and 99.2_2 mol%) obtained by means of the melting curve than that determined by applying Rossini's method.

The results of the purity determination of hydrocarbons are given in Table 2 together with those obtained with a Yanagimoto Gas Chromatograph GCG-5DH.

It can be seen from Table 2 that of the four procedures for determining the purity from freezing and melting curves of the same sample, treatment of the melting curve, where the obtained temperature is not considered to be at equilibrium, gives results which are in good agreement with those obtained from the freezing curve when the sample was successfully supercooled. Application of Rossini's method to the melting curve was unsuccessful. This is probably due to the fact that it is easier to establish an equilibrium in the freezing process than in the melting one. However, if supercooling is carried out to the extent that a quasi-equilibrium portion of the freezing curve is not given, it is difficult to determine the purity with high accuracy. This will be seen in the purity determination of *n*-octane by the freezing curves using a thermocouple cell (97.4_0 mol%) and *n*-undecane using a platinum thermometer cell (97.4_7 mol%) with a high freezing rate. It was observed from many measurements that our treatment of the melting curve also could not give highly accurate results when the heating rate was greater than 0.5°C/min. Point y in Fig. 4(a) did not always give the temperature where $r=1/2$. It can be said that the melting curve may be obtained at an arbitrary heating rate as long as it is smaller than 0.5°C/min. However, results obtained without considering the equilibrium are less accurate than those obtained from a well-performed freezing curve.

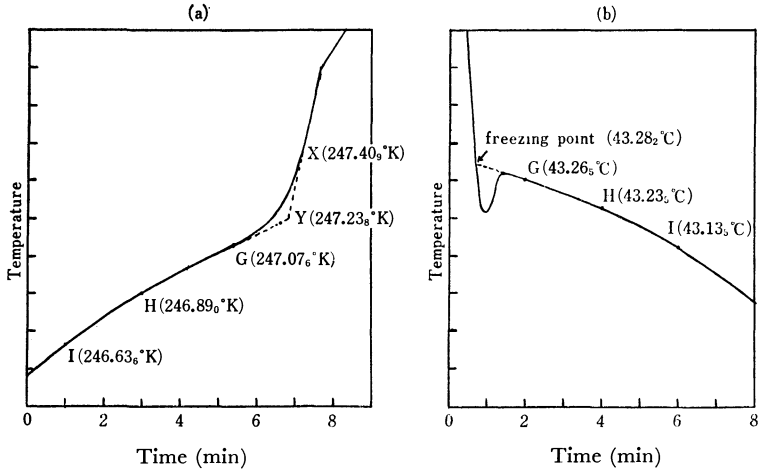

Fig. 4. Time-temperature melting and freezing curves for determining the purity: (a) melting curve of *n*-undecane (b) freezing curve of *n*-docosane.

	T. C. cell	—	—	—	99.1_9	—	0.54
Gas chromatography			99.6			99.5	

The difference in the purity of *n*-tridecane obtained by thermodynamic methods and gas chromatography is probably due to some impurities which could not be observed by gas chromatography (Table 2).

Finally, from the results of the present experiments the following remarks are given for determining the purity of a compound from time-temperature freezing or melting curve with a simplified apparatus.

i) The sample cell should be closed in a vacuum system in order to carry out analysis in the absence of air and water vapor.

ii) The thermometer should be calibrated against a precision temperature scale, since the determination of melting point for zero impurity is less accurate than that obtained with the use of time-temperature curves. Thus, if we can find a value obtained with the use of a precision adiabatic calorimeter, it would be better to use it.

iii) The temperature of the equilibrium portion of the freezing or melting curve is not always at equilibrium. According to the accuracy required for purity determination, the observed curve should be analyzed on the basis of the theory of irreversible thermodynamics instead of by the well known method.

The authors wish to thank Mr. Tatsuhiko Ojima of Tokyo Kasei Kogyo Co., Ltd. for his measurement of gas chromatography.

The Reactions of Dihalogenoalkanes with Dimethyltin Bis-(*N,N*-dimethyldithiocarbamate) and Related Compounds

Toshio TANAKA, Koji TANAKA, and Tokio YOSHIMITSU

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita

(Received May 7, 1970)

Dimethyltin-bis(*N,N*-dimethyldithiocarbamate), $(CH_3)_2Sn[S_2CN(CH_3)_2]_2$, reacts with dihalogenoalkanes to give 1,3-dithiacycloalkyl-2-dimethylimminium dimethyltin halides, $[(CH_3)_2SnX_{n+2}]^{n-}[(CH_2)_m\langle S \rangle C{=}N(CH_3)_2]^+_n$ ($n=1$ or 2; $m=2$, 3, or 4; X=Cl, Br, or I). On the other hand, the reactions between dimethyltin bis(*N*-methyl-*N*-phenyldithiocarbamate), $(CH_3)_2Sn[S_2CN(CH_3)(C_6H_5)]_2$, and dihalogenoalkanes yield preferentially alkylene bis-(*N*-methyl-*N*-phenyldithiocarbamate). The difference in reactivity between the two types of complexes is discussed. The infrared and NMR spectra indicate that the positive charge on the dithiacycloalkylimminium ions is more delocalized in the higher homologues. The configurations of dimethyltin trihalide and tetrahalide anions in the solid state and in solution are also presented on the basis of the infrared spectra; the results suggest that, in solution, dimethyltin trihalide anions are more likely to be formed than are dimethyltin tetrahalides.

We have previously reported that some *N,N*-dimethyldithiocarbamate complexes of tin(IV), $R_2Sn[S_2CN(CH_3)_2]_2$ (R=CH_3 and C_2H_5) and $(CH_3)_2SnCl[S_2CN(CH_3)_2]$, react with 1,2-dihalogenoethanes to give, preferentially, 1,3-dithiacyclopentyl-2-dimethylimminium compounds, (I) or (II):[1]

$$[R_2SnX_4]^{2-}\left[\begin{array}{l}CH_2{-}S\\ |\\ CH_2{-}S\end{array}\rangle C{=}N\langle\begin{array}{l}CH_3\\ CH_3\end{array}\right]^+_2 \quad (I)$$

(a): R=CH_3, X=Cl
(b): R=C_2H_5, X=Cl
(c): R=C_2H_5, X=Br

$$[(CH_3)_2SnBr_3]^-\left[\begin{array}{l}CH_2{-}S\\ |\\ CH_2{-}S\end{array}\rangle C{=}N\langle\begin{array}{l}CH_3\\ CH_3\end{array}\right]^+ \quad (II)$$

This reaction is different in selectivity from the previously-reported one between sodium *N,N*-dimethyldithiocarbamate and 1,2-dihalogenoethanes in some organic solvents, where ethylene bis(*N,N*-dimethyldithiocarbamate) was obtained as well as 1,3-dithiacyclopentyl-2-dimethylimminium salts.[2]

The purpose of the present study is to extend this type of reaction of a variety of dihalogenoalkanes with dimethyltin-bis(*N,N*-dimethyldithiocarbamate), $(CH_3)_2Sn[S_2CN(CH_3)_2]_2$, and -bis(*N*-methyl-*N*-phenyldithiocarbamate), $(CH_3)_2Sn[S_2CN(CH_3)(C_6H_5)]_2$ (abbreviated as $(CH_3)_2Sn(dmdtc)_2$ and $(CH_3)_2Sn(mpdtc)_2$ respectively). The former complex reacts with dihalogenoalkanes to form 1,3-dithiacycloalkyl-2-dimethylimminium dimethyltin halides. On the other hand, the reaction of $(CH_3)_2Sn(mpdtc)_2$ with dihalogenoalkanes gives, preferentially, alkylene bis(*N*-methyl-*N*-phenyldithiocarbamates); in the case of 1,2-dichloroethane, 1,3-dithiacyclopentyl-2-methylphenylimminium salt is also produced.

The infrared and PMR spectra of the compounds obtained are discussed from the viewpoint of the delocalization of the positive charge on the dithiacycloalkylimminium cations and of stereochemistry of the dimethyltin halide anions.

Results and Discussion

The reaction of $Cl(CH_2)_nCl$ ($n=3$, 4) with $(CH_3)_2Sn(dmdtc)_2$ without a solvent at elevated temperatures yielded 1,3-dithiacycloalkyl-2-dimethylimminium dimethyltin trichlorides, (III) and (IV), while $BrCH_2CHBrCH_3$, $Br(CH_2)_3Br$ and $I(CH_2)_3I$ reacted with $(CH_3)_2Sn(dmdtc)_2$ to give the uni-bivalent compounds, (V), (VI), and (VII), respectively.

$$[(CH_3)_2SnCl_3]^-\left[(CH_2)_3\langle S \rangle C{=}N\langle\begin{array}{l}CH_3\\ CH_3\end{array}\right]^+ \quad (III)$$

$$[(CH_3)_2SnCl_3]^-\left[(CH_2)_4\langle S \rangle C{=}N\langle\begin{array}{l}CH_3\\ CH_3\end{array}\right]^+ \quad (IV)$$

$$[(CH_3)_2SnBr_4]^{2-}\left[\begin{array}{l}CH_2{-}S\\ |\\ CH{-}S\\ |\\ CH_3\end{array}\rangle C{=}N\langle\begin{array}{l}CH_3\\ CH_3\end{array}\right]^+_2 \quad (V)$$

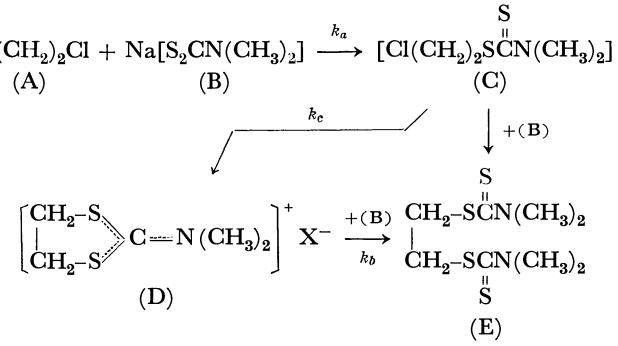
$$[(CH_3)_2SnBr_4]^{2-}\left[(CH_2)_3\langle S \rangle C{=}N\langle\begin{array}{l}CH_3\\ CH_3\end{array}\right]^+_2 \quad (VI)$$

$$[(CH_3)_2SnI_4]^{2-}\left[(CH_2)_3\langle S \rangle C{=}N\langle\begin{array}{l}CH_3\\ CH_3\end{array}\right]^+_2 \quad (VII)$$

The main products in these reactions were 1,3-dithiacycloalkyl-2-dimethylimminium salts, although the yields of III and IV were not very good. Another product expected to be formed, alkylene bis(*N,N*-dimethyldithiocarbamates), was not obtained under the present experimental conditions. Recently, the formation of ethylene bis(*N,N*-dimethyldithiocarbamate) (E) from 1,2-dichloroethane (A) and sodium *N,N*-dimethyldithiocarbamate (B) has been interpreted by the following reaction scheme, involving the intermediate of the isolated anchimetric cation (D), and in which the cyclization of the mono-substituted intermediate (C) occurs very rapidly ($k_c \gg k_a$):[2]

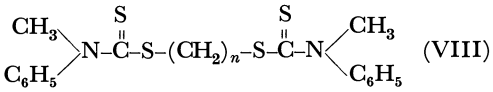
1) T. Tanaka and T. Abe, *Inorg. Nucl. Chem. Lett.*, **4**, 569 (1968).

2) T. Nakai, Y. Ueno, and M. Okawara, *Tetrahedron Lett.*, **1967**, 3831; This Bulletin, **43**, 165 (1970).

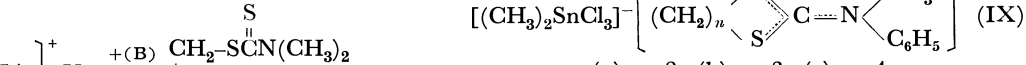


On the basis of this scheme, it may be explained that the reaction of $(CH_3)_2Sn(dmdtc)_2$ with dihalogenoalkanes mainly yielded I—VII, but not the di-substituted products; the I—VII obtained by the cyclization of the mono-substituted products are almost insoluble in dihalogenoalkanes; therefore, it is unlikely that any further reaction of those products with $(CH_3)_2Sn(dmdtc)_2$ will occur. This idea is supported by the results of the reaction of $(CH_3)_2Sn(mpdtc)_2$ with dihalogenoalkanes, as will be described below.

The $(CH_3)_2Sn(mpdtc)_2$ complex reacted with $Cl(CH_2)_2Cl$ to give ethylene bis(*N*-methyl-*N*-phenyldithiocarbamate) (VIIIa) as precipitates. From the filtrate we isolated 1,3-dithiacycloalkyl-2-methylphenylimminium salt (IXa). However, the reactions of $Cl(CH_2)_nCl$ (n=3, 4) with $(CH_3)_2Sn(mpdtc)_2$ yielded only alkylene bis(*N*-methyl-*N*-phenyldithiocarbamates) (VIIIb) and (VIIIc), not the corresponding imminium salts, (IXb) and (IXc).



(a) n=2, (b) n=3, (c) n=4



(a) n=2, (b) n=3, (c) n=4

In contrast to the dimethylimminium salts (I)—(VII), the methylphenylimminium salt (IXa) is appreciably soluble in dihalogenoalkanes, which act as solvents as well as reactants. IXb and IXc will be more soluble in dihalogenoalkanes than IXa, for they have more dithiacycloalkyl rings. In addition, the reaction rate, k_b, in the scheme described above is much faster than k_a in non-polar aprotic solvents.[2] It can reasonably be assumed from these facts that the further reaction of IX with $(CH_3)_2Sn(mpdtc)_2$ will occur to form the di-substituted product (VIII). The infrared spectrum of $(CH_3)_2Sn(mpdtc)_2$ shows the ν(Sn–S) band at 330 cm^{-1}, considerably lower than that of $(CH_3)_2Sn(dmdtc)_2$ (365 cm^{-1}). This lowering in frequency may be related to the bond weakening of the Sn–S bond, which will also enhance the reactivity of the former complex.

The capacity to form both $(CH_3)_2SnX_3^-$ and $(CH_3)_2SnX_4^{2-}$ ions has been known in fluoride,[3] chloride, and bromide,[4] where the counter cations are Cs^+, $N(CH_3)_4^+$, and $N(C_2H_5)_4^+$, but the iodo-complex has never been isolated. The compound VII is the first iodo-complex anion; this is suggests that some bulky

counter cations make it possible to form dimethyltin iodide anions.

Delocalization of the Positive Charge in the 1,3-Dithiacycloalkyl-2-imminium Cations. The relevant infrared frequencies are listed in Table 1. The compounds, Ia, II, and V all exhibit the ν(C=N) band at relatively high frequencies, suggesting an appreciable double-bond character of the C=N bond and, therefore, a high rotational barrier about it. This idea is supported, although qualitatively, by the PMR spectrum of the compound V (Fig. 1), in which the N–CH_3 proton signals are split due to their slightly different magnetic environments. The coalescene temperature is about 125°C in 1,1,2,2-tetrachloroethane, higher than those of most related compounds, such as *S*-methyl-*N*,*N*-dimethyldithiocarbamate, $CH_3SC(S)$-$N(CH_3)_2$ (2.5°C in hexane)[5] and *N*,*N*-dimethylacetamide, $CH_3C(O)$-$N(CH_3)_2$ (87°C as neat liquid),[6] although somewhat lower than that of *N*,*N*-dimethylformamide, HC(O)-$N(CH_3)_2$ (148°C as neat liquid).[6] As is shown in Table 1, the ν(C=N) band shifts to a lower frequency with an increase in the member of the 1,3-dithiacycloalkyl rings. This suggests that the higher homologues receive more contributions from the structure G, resulting in an increase in the electron density on the nitrogen atom. Consistently with this, the N–CH_3 proton signal in chloroalkanes is observed at a higher magnetic field with an increase in the size of the dithiacycloalkyl rings, as is shown in Table 2.[7] The participation of the lone-pair electrons of the sulfur atom in π-bonding is sterically more favorable in the higher homologues, resulting in the delocalization of the positive charge.

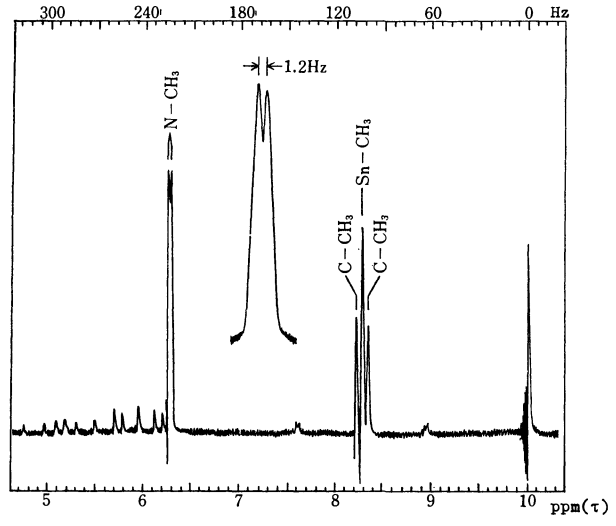

Fig. 1. PMR spectrum of $[(CH_3)_2SnBr_4]^{2-}$.

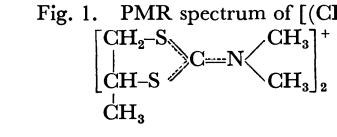
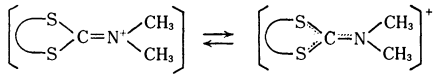


in chloroform, 6 wt %.



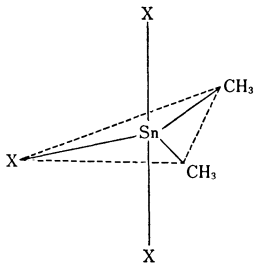
(F) (G)

With the compound IXa, the ν(C=N) band sppears at a somewhat lower frequency than those of the other compounds with five-membered dithiacycloalkyl rings, Ia, II, and V. This may be interpreted by assuming a conjugation between the C=N bond and the phenyl group.

Stereochemistry of the Dimethyltin Halide Anions. As is listed in Table 1, the 1 : 1 electrolytes, II, III, and IV, in the solid state exhibit two infrared bands due to ν(Sn–C), and the symmetric stretching bands are as strong as the asymmetric ones, indicating that the

5) C. E. Holloway and M. H. Gitlitz, *Can. J. Chem.*, **45**, 2659 (1967).
6) M. T. Rogers and J. C. Woodbrey, *J. Phys. Chem.*, **66**, 540 (1962).
7) This is not true fot Ia and II, whose τ(N–CH_3) values are those of a strong donor solvent; DMSO-d_6.

C–Sn–C moiety is not linear. The probable configuration of the $(CH_3)_2SnX_3^-$ anions is a trigonal bipyramid (H), with two methyl groups located in equatorial positions; this is analogous to the structure of the dimethyltin trichloride anion in $[(CH_3)_2SnCl\cdot terpyridyl]^+[(CH_3)_2SnCl_3]^-$, as determined by X-ray analysis.[8]



(H): X=Cl, Br

The spectra of III and IV in dichloromethane closely resemble those of their solid states, except for the region obscured by the solvent. It seems, therefore, that there is essentially no difference between the geometry in the solid state and that in solution for the two compounds. These compounds show a characteristic $J(^{119}Sn–CH_3)$ value of 90 Hz. Extrapolation from the function relating $J(^{119}Sn–CH_3)$ to the apparent *s*-character of the tin atomic orbital in the Sn–C bond[9] indicates a 41% *s*-character, which is much larger than that (33%) expected from the trigonal bipyramid (H). Such a large *s*-character of the tin atomic orbital in the Sn–C bond may possibly be explained by assuming the rehybridization of the tin atomic orbitals due to the electronegativity difference between the methyl group and the chlorine atom.[10] This idea is consistent with the present experimental results that $J(^{119}Sn–CH_3)$ value decreases with a decrease in the electronegativity of the X atom of $(CH_3)_2SnX_3^-$ anions, the bromide and iodide of which result from the dissociation of V, VI or VII in halogenoalkanes, as will be described below.

Of the uni-bivalent electrolytes, Ia, V and VII in the solid state exhibit an intense band due to ν_{as}(Sn–C), while their ν_s(Sn–C) bands are imperceptible. It seems, therefore, that the configuration J with an almost linear C–Sn–C moiety is most plausible for the dimethyltin tetrahalide anions.

The spectrum of V in dichloromethane, however, shows the ν_{as}(Sn–C) band shifting to a lower frequency and the ν_s(Sn–C) band occurring distinctly, whereas there is no appreciable change is the spectrum in the other mid-infrared regions (Fig. 2).

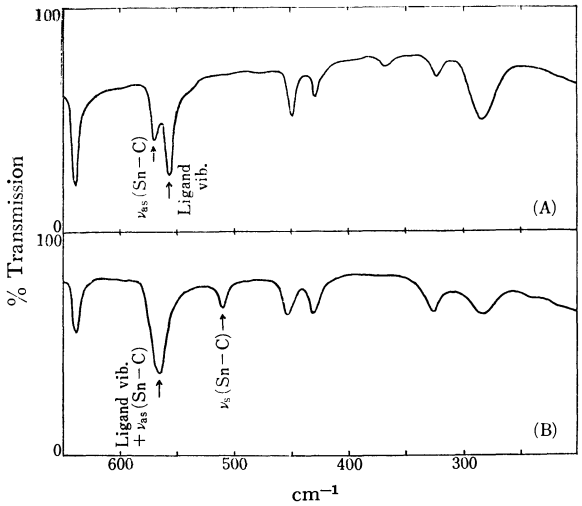

Fig. 2. Infrared spectra of $[(CH_3)_2SnBr_4]^{2-}$·

$$\left[\begin{array}{l} CH_2\text{–}S \\ | \\ CH\text{–}S \\ | \\ CH_3 \end{array}\!\!>\!C\!=\!N\!<\!\begin{array}{l} CH_3 \\ CH_3 \end{array}\right]_2^+$$

in Nujol (A) and in dichloromethane, 3 wt% (B).

These findings confirm that the $(CH_3)_2SnBr_4^{2-}$ dissociates partly into $(CH_3)_2SnBr_3^-$ and Br^-, and/or $(CH_3)_2SnBr_2$ and $2Br^-$. In view of the $J(^{119}Sn–CH_3)$ value of this compound in chloroform (Table 2), the predominant species may be the $(CH_3)_2SnBr_3^-$ rather than $(CH_3)_2SnBr_2$. The $(CH_3)_2SnI_4^{2-}$ anion of VII is assumed to dissociate similarly into $(CH_3)_2SnI_3^-$, $(CH_3)_2SnI_2$, and I^- in tetrachloroethane, judging from the $J(^{119}Sn–CH_3)$ value (Table 2).

Elemental analysis confirms that the reaction product between $(CH_3)_2Sn(dmdtc)_2$ and $Br(CH_2)_3Br$ has the composition VI, but it has no sharp melting point, even when the recrystallization is repeated. The infrared spectrum of this product in the solid state resembles closely that in solution; particularly, the intensity ratio of the two ν(Sn–C) bands dose not change from the solid state to that in solution. These observations and the $J(^{119}Sn–CH_3)$ value in dichloromethane (Table 2) suggest that VI is a 1 : 1 mixture of X and XI.

$$Br^-\left[(CH_2)_3\!<\!\begin{array}{l} S \\ S \end{array}\!>\!C\!=\!N\!<\!\begin{array}{l} CH_3 \\ CH_3 \end{array}\right]^+ \quad (X)$$

$$[(CH_3)_2SnBr_3]^-\left[(CH_2)_3\!<\!\begin{array}{l} S \\ S \end{array}\!>\!C\!=\!N\!<\!\begin{array}{l} CH_3 \\ CH_3 \end{array}\right]^+ \quad (XI)$$

There is a remarkable difference in the infrared spectra of IXa between in the solid state and in solution. The spectrum in dichloromethane shows two each of the ν(Sn–C) and ν(Sn–Cl) bands, which are close in frequency to those of III and IV. In the solid state, however, it gives only one broad band due to ν(Sn–Cl), at a very low frequency, and two ν(Sn–C) bands. as is shown in Fig. 3. This indicates that the

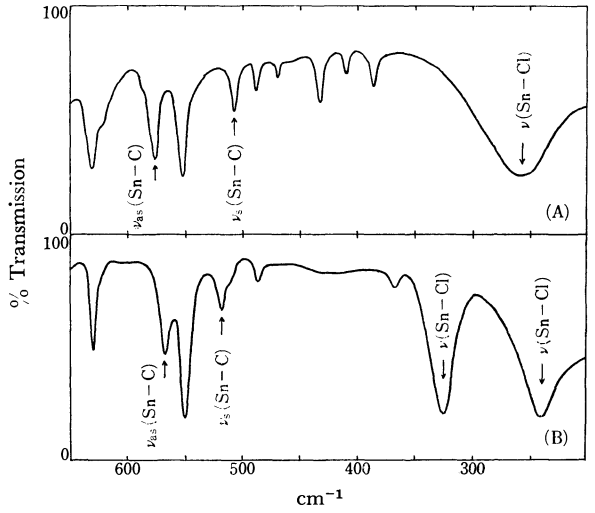

Fig. 3. Infrared spectra of $\left[(CH_3)_2 SnCl_3\right]^-\cdot\left[(CH_2)_2 \begin{matrix} S \\ S \end{matrix} \!\!>\!C\!=\!N\!<\!\begin{matrix} CH_3 \\ C_6H_5 \end{matrix}\right]^+$ in Nujol (A) and in dichloromethane, 3 wt% (B).

structure of the $(CH_3)_2SnCl_3^-$ ion of IXa in the solid state differs from that in solution, and that it is probably a distorted penta-coordinate.

It may be concluded, from above considerations, that the $(CH_3)_2SnX_4^{2-}$ ions are likely to dissociate into $(CH_3)_2SnX_3^-$ and X^-, and/or partly into $(CH_3)_2SnX_2$ and $2X^-$, even in less polar solvents, such as dichloromethane, and that, therefore, in solution the formation of dimethyltin trihalide anions is more likely than that of the tetrahalides. The electronic spectra of the present 1,3-dithiacycloalkyl-2-dimethylimminium compounds are now under investigation by the authors.

Experimental

Materials. The $(CH_3)_2Sn(dmdtc)_2$ was prepared as has previously been described.[11] The $(CH_3)_2Sn(mpdtc)_2$ was similarly synthesized by the reaction of $(CH_3)_2SnCl_2$ with sodium *N*-methyl-*N*-phenyldithiocarbamate in ethanol; mp 200°C (decomp.).

Found: C, 41.71; H, 4.41; N, 5.34%. Calcd for $C_{18}H_{22}N_2S_4Sn$: C, 42.07; H, 4.32; N, 5.46%.

NMR in dichloromethane: τ(Sn-CH_3), 8.55(singlet); τ(N-CH_3), 6.37(singlet); $\tau(C_6H_5)$, 2.72(multiplet) ppm; $J(^{119}Sn-CH_3)$, 84 Hz. The dihalogenoalkanes used in this experiment are commercially available, except for $I(CH_2)_3I$, which was obtained by the reaction of $Br(CH_2)_3Br$ with NaI in acetone.[12]

General Procedure of the Reactions. The dithiocarbamate complexes of tin(IV) were allowed to react with an excess of dihalogenoalkanes at elevated temperature, without any solvent and under dry nitrogen.

1,3-Dithiacyclohexyl-2-dimethylimminium-dimethyltin Trichloride (III). A solution of $(CH_3)_2Sn(dmdtc)_2$ (3.2 g) in 1,3-dichloropropane (20 m*l*) was refluxed for 3 hr. After the evaporation of an excess of 1,3-dichloropropane under reduced pressure, the resulting solid was repeatedly washed with carbon tetrachloride, and then recrystallized from acetonitrile to give colorless needles (1.0 g, 30% yield); mp 169°C.

Found: C, 23.75; H, 4.61; N, 3.58%. Calcd for $C_8H_{18}NS_2Cl_3Sn$: C, 23.03; H, 4.35; N, 3.36%.

1,3-Dithiacycloheptyl-2-dimethylimminium-dimethyltin Trichloride (IV). A solution of $(CH_3)_2Sn(dmdtc)_2$ (5.0 g) in 1,4-dichlorobutane (20 m*l*) was kept at a temperature of about 120°C for 3 hr. A procedure similar to that used in the case of III and recrystallization from a dichloromethane-petroleum ether mixture yielded colorless needles (1.0 g, 10% yield); mp 56—59°C.

Found: C, 24.87; H, 5.07%. Calcd for $C_9H_{20}NS_2Cl_3Sn$: C, 25.06; H, 4.67%.

Bis(1,3-dithia-4-methylcyclopentyl-2-dimethylimminium)-dimethyltin Tetrabromide (V). A solution of $(CH_3)_2Sn(dmdtc)_2$ (5.0 g) in 1,2-dibromopropane (20 m*l*) was heated to 120°C for 20 min to liberate a white precipitate. After the solution had then been cooled to room temperature, the precipitate V was filtered off and recrystallized from acetonitrile (6.8 g, 70% yield); mp 125—128°C.

Found: C, 20.93; H, 3.86; N, 3.48%. Calcd for $C_{14}H_{30}N_2S_4Br_4Sn$: C, 21.21; H, 3.81; N, 3.53%.

1,3-Dithiacyclohexyl-2-dimethylimminium-bromide (X) and -dimethyltin Tribromide (XI). A solution of $(CH_3)_2Sn(dmdtc)_2$ (5.0 g) in 1,3-dibromopropane (20 m*l*) was treated in a manner similar to that used in the case of V to give a white precipitate of a 1 : 1 mixture of X and XI. Recrystallization from acetonitrile yielded the same mixture (8.3 g, 80% yield).

Found: C, 20.62; H, 3.95; N, 3.42%. Calcd for $C_{14}H_{30}N_2S_4Br_4Sn$: C, 21.21; H, 3.81; N, 3.53%.

Bis(1,3-dithiacyclohexyl-2-dimethylimminium)-dimethyltin Tetraiodide (VII). A mixture of $(CH_3)_2Sn(dmdtc)_2$ (2.0 g) and 1,3-diiodopropane (3 m*l*) was heated at 130°C for 2 hr. After subsequent cooling to room temperature, an excess of 1,3-diiodopropane was filtered out; the solid product thus obtained was recrystallized from a dichloromethane-petroleum ether mixture to give colorless needles VII (4.6 g, 90% yield); mp 143—146°C.

Found: C, 16.76; H, 3.20; N, 2.67%. Calcd for $C_{14}H_{30}N_2S_4I_4Sn$: C, 17.14; H, 3.08; N, 2.85%.

Reaction of $(CH_3)_2Sn(dmdtc)_2$ with $Cl(CH_2)_2Cl$. A solution of $(CH_3)_2Sn(dmdtc)_2$ (5.3 g) in 1,2-dichloroethane was refluxed for 1 hr to give a white precipitate. After the mixture had then been cooled to room temperature, the precipitate VIIIa was filtered off, washed with diethyl ether, and dried *in vacuo* (1.2 g, 53% yield); mp 230°C (decomp.).

Found: C, 55.16; H, 5.34; N, 6.99%. Calcd for $C_{18}H_{20}N_2S_4$: C, 55.07; H, 5.13; N, 7.14%. The filtrate was evacuated under reduced pressure, and a light yellow viscous liquid thus obtained was shaken repeatedly with diethyl ether; the resulting insoluble materials in ether were collected by filtration and washed with carbon tetrachloride, giving a white powder IXa (1.9 g, 39% yield); mp 84—87°C.

Found: C, 30.87; H, 3.79; N, 2.89%. Calcd for $C_{12}H_{18}NS_2Cl_3Sn$: C, 30.97; H, 3.90; N, 3.01%.

Propylene Bis(N-methyl-N-phenyldithiocarbamate) (VIIIb). A solution of $(CH_3)_2Sn(mpdtc)_2$ (5.0 g) in 1,3-dichloropropane (20 m*l*) was heated on a bath at 120°C for 2 hr. After it had then been cooled to room temperature, the solution was evaporated to about a half volume under reduced pressure; the white precipitates which appeared were collected by filtration, and subsequent recrystallization from a dichloromethane - diethyl ether mixture gave colorless needles VIIIb (1.2 g, 37% yield); mp 169°C.

Found: C, 55.97; H, 5.33; N, 6.88%. Calcd for $C_{19}H_{22}N_2S_4$: C, 56.12; H, 5.45; N, 6.89%.

Butylene Bis(N-methyl-N-phenyldithiocarbamate) (VIIIc). This compound was obtained from $(CH_3)_2Sn(mpdtc)_2$ (5.1 g) and 1,4-dichlorobutane (20 m*l*) in a manner similar to that

12) H. Finkelstein, *Ber.*, **43**, 1528 (1910).

used in the case of VIIIb, and it was recrystallized from the same solvent (1.3 g, 38% yield); mp 135—137°C.

Found: C, 57.12; H, 5.80; N, 6.80%. Calcd for $C_{20}H_{24}N_2S_4$: C, 57.10; H, 5.75; N, 6.66%.

All the compounds isolated were identified by means of their NMR spectra, as are listed in Table 2.

Infrared and NMR Spectra. The infrared spectra were recorded on Hitachi EPI-2G (5000—400 cm^{-1}) and EPI-L (700—200 cm^{-1}) spectrophotometers. The NMR spectra were measured on a Japan Electron JNM-3H-60 spectrometer, operating at 60 MHz and at room temperature, and using tetramethylsilane as the internal standard.

Extraction and Spectrophotometric Determination of Copper(II) with 2-Thenoyltrifluoroacetone

Hideo AKAIWA, Hiroshi KAWAMOTO, and Masanobu ABE

Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma

(Received July 29, 1970)

A highly sensitive method for the spectrophotometric determination of copper(II) with 2-thenoyltrifluoroacetone (TTA) is described. Copper(II) is extracted with TTA in cyclohexane at pH 5.5 and the residual TTA in the organic phase is removed by washing with sodium hydroxide solution containing pyridine. Pyridine is added to the washing solution so that it forms an adduct and prevents the copper-TTA chelate from decomposing during the alkali treatment process. The absorbance of the organic phase is measured at 340 mμ. Beer's law is followed over the concentration range of 0.1 to 1.0 μg of Cu per m*l*, the sensitivity being 0.0023 μg Cu/cm^2 at 340 mμ. The present method was applied to the analysis of natural water.

So-called synergistic extraction of metal chelate has been utilized for various analytical purposes such as separation of metal ions,[1,2] extractive spectrophotometric[3-7] and fluorometric[8] determination of metals. In most cases, enhancement of the extractability could be explained by the formation of an adduct. In the work described below, the adduct formation in the synergistic extraction is shown to be useful for an improvement in the spectrophotometric sensitivity.

Two methods of the spectrophotometric determination of copper(II) with 2-thenoyltrifluoroacetone (TTA) have already been proposed.[9,10] However, the sensitivities of these methods are low compared with that of the well known dithizone method.[11] Although the dithizone method is very popular mainly due to its high sensitivity, it is not always free from interferences caused by coexisting ions and had a defect that the reproducibility of the method depends largely upon the experimental conditions.

Therefore, by the aid of the formation of pyridine adduct, the previous TTA extraction spectrophotometry for copper[10] has been revised into a method for the highly sensitive determination of the element.

Since the low sensitivity of the above mentioned TTA methods is caused by the presence of the residual TTA in the organic phase which interferes with absorption measurement around 340 mμ (an optimum wavelength for the extracted copper-TTA chelate), the residual reagent should be removed by washing the organic phase with an alkali solution. The above purpose can be attained only when pyridine is present in the washing solution, otherwise not only the residual reagent but the copper-TTA chelate is decomposed.

Experimental

Apparatus and Reagents. Absorption measurements were carried out with a Shimadzu Spectronic 20 type photoelectric photometer and 1.17-cm glass cells. The pH value of the aqueous phase was measured after extraction with a Hitachi-Horiba F-5 type pH-meter and a glass electrode. TTA (Wako Pure Chemical Inc.) and cyclohexane (Nippon Rikagakuyakuhin Co.) were used without further purification. Pyridine and all other materials used in this work were of guaranteed grade.

A 0.001M TTA solution was prepared by dissolving a weighed amount of the reagent in cyclohexane. Standard copper solution (100 mg/*l*) was prepared by dissolving copper sulfate pentahydrate in deionized water.

General Procedure. Transfer 50 m*l* of the sample solution containing 1-10 μg of copper to a separatory funnel and adjust the pH of the solution to about 5.5. Then extract with 10 m*l* of 0.001M TTA-cyclohexane solution by shaking for 3 minutes. Allow the phases to separate and remove the aqueous phase. Add 10 m*l* of aqueous solution of sodium

hydroxide (0.005M) containing 1% (v/v) of pyridine and shake the mixture for 3 minutes. Separate the phases and measure the absorbance of the organic phase at 340 mμ against the reagent blank.

Results and Discussion

Absorption Spectrum. The absorption spectrum of copper-TTA-pyridine complex in cyclohexane obtained by the above procedure is shown in Fig. 1. The spectrum of the extracted complex has a maximum absorbance at around 340 mμ, and the intensity is stable for at least 24 hrs. The absorbance of the reagent blank is considerably lowered by washing the organic phase with alkali solution.

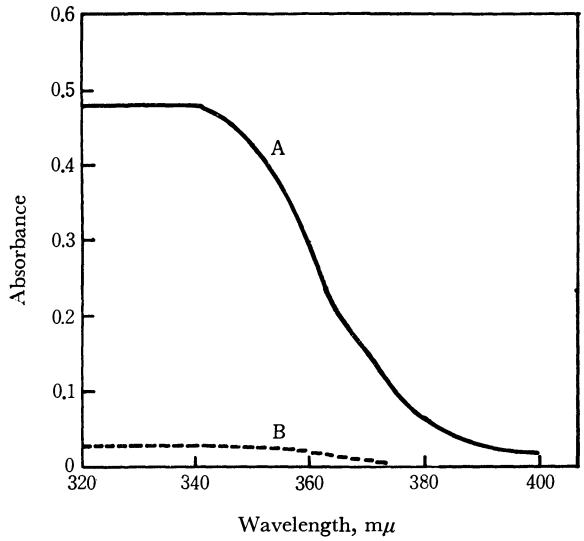

Fig. 1. Absorption spectra of copper-TTA-pyridine chelate (A) and the reagent blank (B).

Effect of pH. The extraction of copper into benzene proceeds according to the reaction: $Cu^{2+} + 2HTTA_{,org.} = Cu(TTA)_{2,org.} + 2H^+$, for which the extraction constant was reported to be 4.8×10^{-2}.[12] The above reaction indicates that the extractability of copper is affected by the TTA concentration and the pH.

Copper can be extracted quantitatively at pH 4.0 by using 0.01 M TTA in benzene.[10] However, since the residual TTA in the organic phase interferes with the absorption measurement, the TTA concentration for the extraction of copper was required to be as low as possible. Considering the above situation, the 0.001M TTA solution was adopted. The extraction curve obtained at the TTA concentration of 0.001M is shown in Fig. 2. As can be seen in the extraction curve, an increase in pH leads to an increase in the extractability of copper, and above 5.2 the absorbance becomes constant. Accordingly, a pH value of 5.5 was adopted.

Removal of Residual TTA. TTA has a strong absorption at around 340 mμ, and interferes with the absorption measurement of the extracted complex in the cyclohexane phase. In order to increase the spectrophotometric sensitivity, the residual TTA which does not combine with copper should be removed from the organic phase.

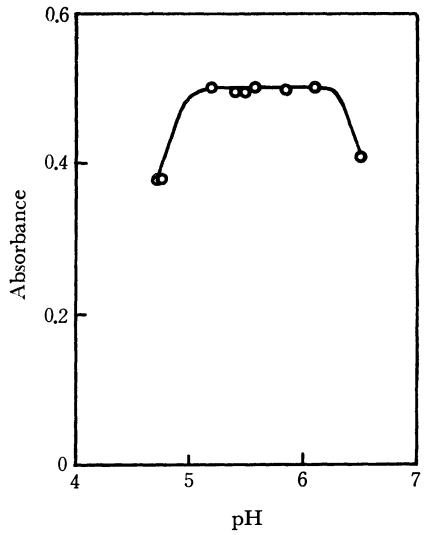

Fig. 2. Effect of pH on the absorbance of the organic phase.

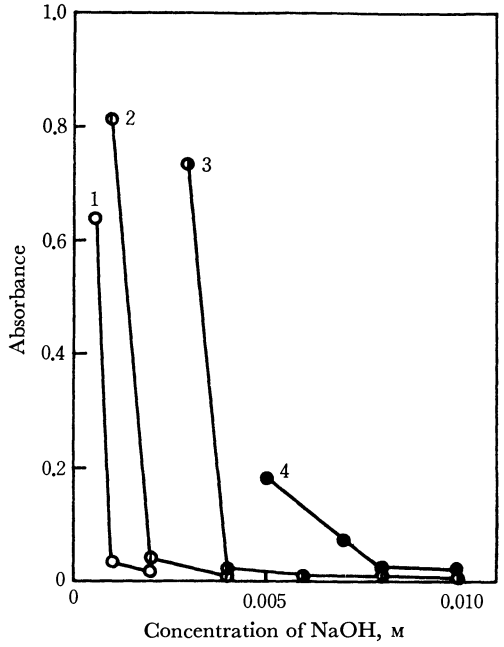

Fig. 3. Removal of the residual TTA.
TTA concentration - 1: 5×10^{-4}M, 2: 1×10^{-3}M, 3: 2×10^{-3}M, 4: 5×10^{-3}M.

By shaking TTA-cyclohexane solution with sodium hydroxide solution, the absorbance of the cyclohexane phase at 340 mμ decreases with increasing alkali concentration (Fig. 3). This decrease in the absorbance indicates the removal of the TTA from the cyclohexane solution, and shaking for 3 min with 0.005M sodium hydroxide solution is sufficient for the present purpose.

Effect of Pyridine. The copper-TTA chelate was decomposed by the alkali treatment of the cyclohexane phase in the absence of pyridine and copper was stripped into the alkali solution. However, the stripping of copper could be avoided by adding pyridine. As is shown in Fig. 4, the absorbance of the cyclohexane

12) R. A. Bolomey and L. Wish, *J. Amer. Chem. Soc.*, **72**, 4483 (1950).

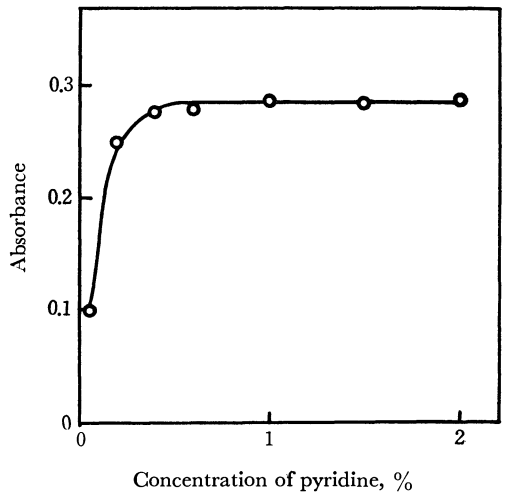

Fig. 4. Effect of pyridine concentration on the absorbance of the organic phase.

phase containing copper-TTA chelate increases along with an increase in the pyridine concentration in the alkali solution, and finally reaches a constant value in the pyridine concentration range above 0.5%. This indicates that the copper-TTA chelate in cyclohexane phase is stabilized by the presence of pyridine and the chelate was prevented from decomposition.

Pyridine Adduct. Visible spectra of benzene solutions of the copper-TTA chelate with various amounts of pyridine were measured and are shown in Fig. 5. The systematic variation in the spectra and

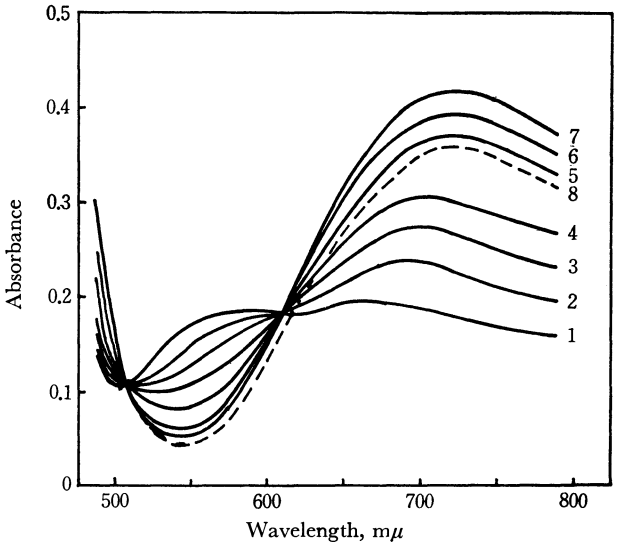

Fig. 5. Effect of pyridine concentration on the spectra of 5×10^{-3}M Cu $(TTA)_2$ in benzene.
Pyridine concentration - 1: 0, 2: 1×10^{-3}M, 3: 2×10^{-3}M, 4: 3×10^{-3}M, 5: 5×10^{-3}M, 6: 1×10^{-2}M, 7: 5×10^{-2}M, 8: 2.5×10^{-1}M.

the presence of two isosbestic points furnish the evidence for the formation of the pyridine adduct (1:1). The formation constant for the adduct was estimated to be $10^{3.45\pm0.25}$ by the method proposed by Ke and Li.[13]

13) C. H. Ke and N. C. Li, *J. Inorg. Nucl. Chem.*, **31**, 1383 (1969).

At high pyridine concentration (0.25M), the isosbestic points disappear probably because of the formation of the adduct (1:2), $Cu(TTA)_2$ $(pyridine)_2$.

In order to obtain further confirmation of the formation of pyridine adduct, the copper-TTA chelate $Cu(TTA)_2$ was prepared by adding the TTA-ethanol solution to the aqueous solution of copper and recrystallizing the resulting chelate from ethanol. The green crystalline solid was obtained by heating the copper-TTA chelate together with pyridine. Elemental analysis of the solid was given in Table 1. As is

Table 1. Elemental analysis of the adduct

	Cu(%)	C(%)	H(%)
Calculated*	9.56	46.7	2.71
Found	9.59	46.8	2.77

* Values for $Cu(TTA)_2(pyridine)_2$

seen in Table 1, the analytical results showed good agreement with the calculated value for $Cu(TTA)_2$-$(pyridine)_2$. These results indicate that the pyridine adduct is formed when the organic phase is treated with alkali solution containing pyridine and the formation of the adduct may prevent the copper-TTA chelate from decomposition.

Synergistic effect in the extraction of copper with TTA has been explained by the formation of an adduct.[14,15] Although the effect enhances the extractability of copper, the synergistic extraction is not suitable for the present case because co-extraction of divalent metal ions occurs. Therefore, the formation of the pyridine adduct should be performed at the stage after the completion of the extraction of the copper-TTA chelate.

Calibration Curve. Calibration curve obtained by the above mentioned procedure is linear for 0—1 ppm of copper in the organic phase and passes through the origin. The reproducibility of absorption mesurements is better than 1%. The sensitivity represented by Sandell's definition is 0.0023 $\mu g/cm^2$ at 340 mμ, which is nearly equal to that of the most sensitive dithizone method.[11] The sensitivity of the previous TTA method (0.7 $\mu g/cm^2$ at 430 mμ)[10] is remarkably improved. The present method is highly sensitive compared with the neocuproine method (0.008 $\mu g/cm^2$ at 457 mμ),[11] the diethyldithiocarbamate method (0.0046 $\mu g/cm^2$ at 436 mμ)[11] and the thiothenoyltrifluoroacetone method (0.01 $\mu g/cm^2$ at 490 mμ).[16]

Diverse Ions. The effect of diverse ions on the determination of copper was investigated by adding the known amount of test ion to a standard copper solution and by comparing the final absorbance with the standard. One milligram each of Ag(I), Ca(II), Cr(III), Mg(II), Mn(II), Pb(II), Sr(II), Tl(I), Zn(II), and 10 μg of Co(II) and Ni(II) gave no interference in the present method. Two hundred micrograms

each of Al(III), Ce(III), Fe(III), Th(IV) interfered with the determination because of the formation of precipitate. However, these elements could be masked and kept in solution by adding 100 mg of fluoride ion.

Among anions, 100 mg each of fluoride and phosphate ions gave no interference, but the same amount of thiosulfate, thiocyanide, cyanide, tartrate and citrate ions interfered with the determination and could not be used for masking purpose.

Determination of Copper in Natural Waters. For determination of copper in natural water samples, 50 m*l* of the sample solution was taken and the general procedure was modified by adding 100 mg of fluoride ion (as NaF) before adjusting the pH. The analytical results are shown in Table 2. Recovery test and reproducibility indicate that the present procedure is applicable to these samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 120—124 (1971)

Kinetics and Mechanism of Aquation and Anation of Some Amino Acid Pentamminecobalt(III) Complexes in Acid Aqueous Solutions

Tasuku MURAKAMI,[1a] Kazuko OGINO, Hiromi KOBAYASHI,[1a]
Hiroshi YAMAZAKI[1b], and Kazuo SAITO
Chemistry Department, Faculty of Science, Tohoku University, Sendai

(Received August 15, 1970)

Kinetics of aquation has been studied with pentamminecobalt(III) complexes containing aliphatic amino acids (γ-aminobutyric acid, ε-aminocaproic acid, α-amino-isobutyric acid, ornithine, and proline), aromatic acids (benzoate, anthranilic, and *p*-aminobenzoic acid), and α-substituted acetates (monochloroacetate and glycolate). Anation rate constants were obtained for glycine, β-alanine, and ε-aminocaproic acid, and equilibrium constants between $[CoH_2O(NH_3)_5]^{3+}$ and $[Co(NH_3)_5amH]^{3+}$ (amH=amino acid), K_{eq} were calculated. The free energy plot log k_{aq} *vs.* log K_{eq} gave a straight line with a gradient 0.6. This value has been discussed in terms of two possible mechanisms. The dependence of acid catalysed aquation rate constant, $k_H{}^+$ on pK_a of carboxylate group of the amino acid is written as log $k_H{}^+$=pK_a+const., while that for α-substituted acetates log $k_H{}^+$=0.5 pK_a+const. Such a difference in the slope is interpreted as due to the electrostatic influence of $-NH_3^+$ group of coordinated amino acid.

In our previous paper we reported on the kinetics of aquation of pentammine-amino acid cobalt(III) complexes, in which glycine, β-alanine, sarcosine, and betaine are combined with the cobalt(III) ion as unidentate through carboxylate oxygen.[2] The aquation had different characteristics from those of other carboxylate complexes.[3] We have now extended the study to some other pentammine cobalt(III) complexes containing various kinds of amino acid and α-substituted acetates, and the effect of positive charge of the ammonium group of coordinated amino acid upon aquation rate as well as the free energy relationship[4] has been discussed.

Aquation of amino acid pentamminecobalt(III) cations in an acid solution proceeds as follows:

$$[Co(NH_3)_5amH]^{3+} + H_2O \xrightarrow{k} [CoH_2O(NH_3)_5]^{3+} + amH \quad (1)$$

where amH denotes the amino acid. The pseudo first order rate constant k was obtained according to the method given in Experimental. When the values k are plotted against the concentration of perchloric acid, straight lines are obtained as exemplified in Fig. 1, the kinetics being expressed by

$$k = k_{H_2O} + k_{H^+}[H^+] \quad (2)$$

The intercept and the gradient correspond to k_{H_2O} and k_{H^+} respectively. The values are listed in Table 1.

Relationship between pK_a and k_{H^+}. The acid catalysed aquation of carboxylato and amino acid complexes is regarded to take place through the following two steps:

—●— [Co $(NH_3)_5$ β-alaH]$^{3+}$ [2] —○— [Co $(NH_3)_5$ γ-ambutH]$^{3+}$ —△— [Co$(NH_3)_5$ ε-amcapH]$^{3+}$

$$[(NH_3)_5Co\text{-}O\text{-}\overset{\overset{O}{\|}}{C}\text{-}R]^{(n+2)+} + H^+ \overset{K}{\rightleftharpoons} [(NH_3)_5Co\text{-}O\text{-}\overset{\overset{OH}{|}}{C}\text{-}R]^{(3+n)+} \quad (3)$$

$$[(NH_3)_5Co\text{-}O\text{-}\overset{\overset{OH}{|}}{C}\text{-}R]^{(n+3)+} + H_2O \xrightarrow{k'} [(NH_3)_5CoH_2O]^{3+} + RCOOH^{n+} \quad (4)$$

and $$k_{H^+} = k'K. \quad (5)$$

In the previous paper we compared the k_{H^+} values of pentamminecobalt(III) complexes of glycine, sarcosine, and betaine and ascribed the small k_{H^+} value to the difficulty with which the protonated species are formed according to Eq. (3). Such a difficulty was considered to come from electrostatic effect due to ammonium group $-NH_xR_{3-x}^+$ rather than the hydrogen bonding between ammonium and carboxylate groups coordinated to cobalt(III).[2]

In Fig. 2, the log k_{H^+} values are plotted against

pK_a values of the acids. The diagram consists of two straight lines at a given ionic strength. Complexes of amino acids give one line with a gradient almost unity, and those of other α-substituted acetate anions, one with a gradient *ca.* 0.5. Aromatic amino acid complexes and benzoato complex fall on neither line. Complexes of glycolate and chloroacetate give plots on the line (broken line) together with acetato- and trifluoroacetato-complexes. The influence of substituting hydroxyl group and halogen atom seems to be appropriately reflected in pK_a values, and the kind of substituting group or atom give no particular influence upon k_{H^+} values.

Whenever the pK_a values are the same, the amino acid complexes give smaller k_{H^+} values than the substituted acetato complexes. The solid line in Fig. 2

indicates that the deviation from the broken line decreases with increase in carbon chain length between the $-NH_3^+$ and $-COO^-$ group of the amino acid, and is very small when the ammonium group is on the ε-carbon atom. It is noticeable that the complex of ornithine, which has two $-NH_3^+$ groups on α- and δ-carbon atom gives the plot on the same line as those of other amino acid complexes. The smaller k_{H^+} values of amino acid complexes must be due to the smaller tendency of forming protonated intermediate given by Eq. (3). Such a trend is brought about by the presence of $-NH_3^+$ group near the coordinated carboxylate. As the carbon chain length between $-NH_3^+$ and $-COO^-$ increases, the probability of such an approach would decrease because the freedom of rotation around the C–C axes increases. Our previous consideration that the electrostatic effect of $-NH_3^+$ group is reflected in the equilibrium constant K of Eq. (5), which is responsible in determining the k_{H^+} values, seems thus adequately reinforced.

There is a significant difference between k_{H^+} values of anthranilic and *p*-aminobenzoic acid complexes. The former gives a plot near the straight line for ω-amino acid complexes. Its $-NH_3^+$ group seems to be capable of giving a similar effect to that in ω-amino acids, because it is situated near the coordinated carboxylate. On the other hand, such an influence seems very unlikely for *p*-aminobenzoic acid complex.

The k_{H_2O} Values. Monacelli, Basolo, and Pearson reported that an antiparallel relationship is seen between the k_{H_2O} of carboxylatopentamminecobalt(III) complexes and the pK_a of the carboxylic acids.[3] Their results are well understood whenever the aquation takes place *via* S_N1(lim) mechanism, *i. e.* the ease with which the carboxylato-cobalt bond breaks depends fully on the bond strength predicted by the pK_a of the given acid. As shown in Fig. 3B, the k_{H_2O} values of ω-amino acid pentamminecobalt(III) ions do not seem to show significant difference from one another at an ionic strength 0.1. Neither do the α-substituted acetato complexes. At an ionic strength 1.0 (Fig. 3A), the k_{H_2O} seems to increase with rise of pK_a. Since the k_{H_2O} values are obtained by extrapolation, they can involve bigger experimental errors and may not be suitable for detailed discussion. However, the anthranilic acid- and the *p*-aminobenzoic acid complex give remarkably different values from each other, and a steric factor could be involved.

Relationship with the Equilibrium Quotient. The anation reaction of aquopentamminecobalt(III) complexes with amino acids (amH) is written as

$$[CoH_2O(NH_3)_5]^{3+} + amH \rightleftharpoons [Co(NH_3)_5amH]^{3+} + H_2O \quad (6)$$

and the rate constant k_{obs} is expressed by the following equation (see Experimental).

$$k_{obs} = k_{aq} + k_{an}[amH] \quad (7)$$

The k_{an} is obtained from the gradient of linear plot of k_{obs} *vs.* [amH], which stands for the concentration of amino acid zwitter ion (see Fig. 4). The equilibrium quotient K_{eq} is expressed by

$$K_{eq} = k_{aq}/k_{an} \quad (8)$$

In Table 2 are given k_{an} and K_{eq} values of some ω-amino acid pentamminecobalt(III) complexes.

Langford[4] and Haim[5] examined the linear free energy relationship[6] between the equilibrium quotient and the rate constant for aquation reactions of various acidopentamminecobalt(III) complexes and obtained a gradient unity on their log-log plot,

$$\Delta \ln k_{aq} = \alpha \Delta \ln K_{eq} \qquad (9)$$

Langford claimed that this value suggests a similarity between the transition state and the product, and that the role of the acido anion ligand in the transition state is very similar to that in the product, *i. e.* the solvated anion.

a) The ΔH^* is 29 kcal/mol. b) from Ref. 2. c) $\Delta H^\circ \fallingdotseq 0$

A similar plot of our results for ω-amino acid pentamminecobalt(III) complexes is shown in Fig. 5. Although the number of plots is only three, an apparent α value 0.6 is obtained. The difference between this value and that for acidopentamminecobalt(III) complexes[4,5] seems significant, although the experimental conditions are not the same (data compiled by Haim[5] are at 25°C, ionic strength variable; ours at 55°C, ionic strength 0.1). It appears as if the transition state in the aquation of $[Co(NH_3)_5amH]^{3+}$ is between the initial and the final state of the reaction. We are thus inclined to consider that some mechanism such as solvent-assisted dissociation mechanism[7] is involved in the k_{H_2O} path. This mechanism was also suggested by Lincoln and Stranks[8] for the aquation of $[Co(NH_3)_5H_3PO_4]^{3+}$ in perchloric acid of medium strength. They found a good correlation between the aquation rate and the activity of water.

Haim[5] discussed the relation between k_{aq} and K_{eq} and gave the equation

$$\log k_{aq} = \log k_x Q_0 - \log K_{eq} \qquad (10)$$

where Q_o is the ion pair or outer sphere complex formation constant between $[CoH_2O(NH_3)_5]^{3+}$ and the incoming ligand, and k_x the inner sphere-outer sphere interchange velocity of the ion pair. He claimed that Q_o is principally dependent on the charge of the complex and the incoming ligand, and applied this correlation

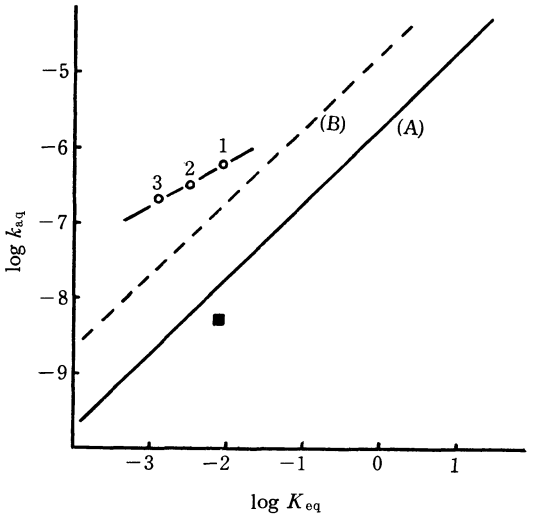

Fig. 5. Linear free energy relationship between the equilibrium quotient K_{eq} and the rate constant for aquation, k_{aq}.
—○— $[Co(NH_3)_5amH]^{3+}$ (55°C, μ=0.1): 1. glycine, 2. β-alanine, 3. ε-aminocaproic acid.
■ for $[Co(NH_3)_5glyH]^{3+}$ extrapolated to 25°C on the basis of ΔH^* and ΔH° value in Table 2.
—— (A) $[Co(NH_3)_5X]^{2+}$ (X, univalent anions, 25°C[5])
------ (B) $[Co(NH_3)_5Y]^{+}$ (Y, bivalent anions, 25°C[5])

to acidopentamminecobalt(III) complexes containing uni- and bivalent anions.

In the case of our amino acid complexes, Q_o is the outer sphere complex formation constant between $[CoH_2O(NH_3)_5]^{3+}$ and the amino acid zwitter ion. Although the net charge of an amino acid is zero, the zwitter ion has a separated minus charge on the carboxylate part, and can undergo ion-pair formation with multivalent complex cation.[9] However, the Q_o values for varying amino acids could be different, because the electrostatic effect of $-NH_3^+$ can differ according to the carbon chain length between $-NH_3^+$ and $-COO^-$ group. If Q_o increased with increase in this carbon chain length, the gradient of our diagram could deviate from unity, even if the inner sphere-outer sphere interchange velocity of the ion pair k_x were the same as those of uni- and bivalent incoming ligand. Hence the smaller α value (0.6) of our diagram does not necessarily indicate the participation of solvent assisted dissociation. These two possible interpretations cannot be distinguished at the present stage.

The ΔH^* value for anation reaction to give $[Co(NH_3)_5glyH]^{3+}$ was obtained to be 29 kcal/mol (Table 2). It is near that for the water exchange of $[CoH_2O(NH_3)_5]^{3+}$ ions,[10] which should involve cobalt-oxygen bond rupture. We can relevantly presume that our reactions also involve cobalt-oxygen bond rupture and formation. The same presumption was made in our previous paper[2] on the basis of comparison among ΔH^* values of $[Co(NH_3)_5glyH]^{3+}$,[2] $[Co(NH_3)_5(CH_3-$

9) When the plot of $[Co(NH_3)_5glyH]^{3+}$ (glyH=glycine zwitter ion) in Fig. 5 is shifted from 55°C to 25°C on the basis of ΔH^*[2] and ΔH° value (Table 2), the plot given by full square is obtained. Since the net charge of glycine zwitter ion is zero, the Q_o value should be smaller than those for univalent anionic ligands.

COO)]$^{2+}$,[11] and $[Co(NH_3)_5(HCO_3)]^{2+}$.[12,13] If a tracer study with ^{18}O were substantiated with our complexes, unambiguous conclusion could be obtained. Unfortunately, the oxygen exchange rate of free amino acid in water and the water exchange rate of $[CoH_2O(NH_3)_5]^{3+}$ are much greater than the aquation rate of $[Co(NH_3)_5amH]^{3+}$ ions in neutral and acid solutions and such a tracer study would not be very useful.

Experimental

Materials. Cobalt(III) pentammine complexes containing aliphatic amino acids were synthesized as perchlorate from $[CoH_2O(NH_3)_5](ClO_4)_3$ and the amino acids by the method of Fujita *et al.*[14] and identified by the analysis of carbon, hydrogen, and nitrogen, and visible and ultraviolet absorption spectra. Complexes containing aminobenzoic acids[15,16] and α-substituted carboxylates[2,17] were prepared by the methods given in literature. All other chemicals were of guaranteed grade and used without further purification.

Kinetic Runs. Aquation rate was measured spectrophotometrically at the given wavelengths (Table 1) as described previously.[2] Aromatic amino acids have marked absorptions in the ultraviolet region in the free state, and the reaction was followed at the *d–d* transition region.

The rate of anation given by Eq. (6) is expressed by the ordinary second order rate formula

$$dx/dt = k_{an}(a-x)(b-x) - k_{aq}x \qquad (11)$$

where x is the concentration of $[Co(NH_3)_5amH]^{3+}$ ion at time t, and a and b are the initial concentrations of $[CoH_2O(NH_3)_5]^{3+}$ and the amino acid in zwitter ion form, respectively. The last is known from the formal concentration and the acid dissociation constant under the given condition. Whenever b overwhelms a, Eq. (11) is integrated to give

$$\ln[(x_\infty - x)/x_\infty] = -(k_{aq}+bk_{an})t \qquad (12)$$

where the suffix ∞ denotes the equilibrated state. When the anation is measured by a spectrophotometric method, Eq. (12) is replaced by

$$\ln[(A_\infty - A_t)/(A_\infty - A_0)] = -(k_{aq}+bk_{an})t \qquad (13)$$

where A_0, A_t, and A_∞ are the extinctions of the reaction mixture at the initial state, time t and the final state, respectively. By plotting $\log(A_\infty - A_t)$ *vs.* t, the apparent rate constant k_{obs} given by Eq. (7) is obtained. The A_∞ value was not experimentally determined because the reaction was very slow. A tentative A_∞ was calculated on the basis of an assumed K_{eq},

$$K_{eq} = k_{aq}/k_{an} = (a-x_\infty)(b-x_\infty)/x_\infty \qquad (14)$$

and k_{obs} and k_{an} were obtained by means of Eqs. (13) and (7). The K_{eq} and A_∞ values were recalculated from this k_{an}. Such a stepwise approximation was repeated until a set of self-consistent k_{an} and K_{eq} was obtained.

Anation reactions were studied in weakly acid solutions (pH∼pK_a), where k_{H^+} path of aquation is negligible compared to k_{H_2O} path and k_{aq} can be approximated to be equal to k_{H_2O}. The rate was followed at the same wavelength at which the aquation was studied.

The Reactions of Aroyl Peroxides with Grignard Reagents. II. Relative Reactivities of Substituted Benzoyl Peroxides.[1]

Masao Ōkubo,* Kazuhiro Maruyama,** and Jirō Ōsugi**

* *Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya*

** *Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto*

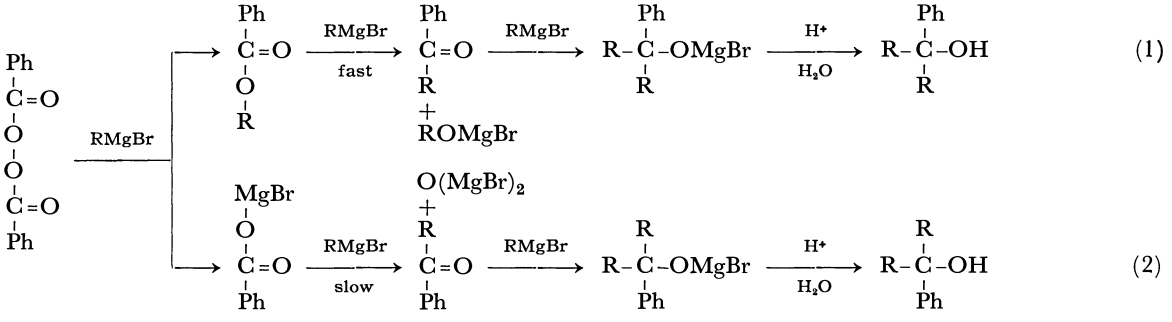
(Received October 20, 1969)

Benzoyl peroxide was found to react with Grignard reagents (RMgBr) in tetrahydrofuran at 0°C to form PhCOOR and PhCOOMgBr. The latter which was isolated as a complex containing two molecules of the solvent, can be coordinated by benzoyl peroxide to form an orange-colored complex. Similar complexes were found to be formed in the cases of some substituted benzoyl peroxides. The initial stage of the reaction was studied with the technique of competitive reaction. The results can be explained by assuming the coordination of the carbonyl oxygen atom of benzoyl peroxide to the Grignard magnesium atom. The effect of the substituent of the peroxide on the reaction was discussed.

The reactions of the carbanionic reagents with the peroxidic linkage are interesting, but scarcely any have been investigated so far.[2] We found that, when benzoyl peroxide was added to the tetrahydrofuran (THF) solution of phenylmagnesium bromide (PhMgBr), a pink color and the ESR signal were observed simultaneously.[3] This aroused our interest, and we investigated the reaction of aroyl peroxides with Grignard reagents. A stable complex containing benzoyl peroxide has been reported.[4] The initial stage of the reaction was investigated using the technique of competitive reaction, and the results are reported in this paper.

Results and Discussions

When benzoyl peroxide (BPO, 0.00184 mol in 50 m*l* THF) was mixed with nearly equimolar PhMgBr (0.612M, 3 m*l*) in THF (20 m*l*) under nitrogen stream at 0°C, about two thirds of BPO decomposed suddenly and the reaction mixture turned orange after being left to stand for about 2 hr. The products were benzoic acid (85—93%), phenyl benzoate(55—60%), small amounts of phenol, benzophenone and triphenylcarbinol. The orange color did not fade by contact with air, and it was confirmed to be not due to molecular bromine. Considering the products obtained in the preliminary experiment, we can construct the following reaction scheme (1) and (2)(R=Ph), though the reaction (2) is not yet confirmed.[5]



These formulas suggest that at least five moles of Grignard reagent is necessary to decompose one mole of benzoyl peroxide completely to form carbinol. When benzoyl peroxide in THF was added to the stirred solution of ten times moles of PhMgBr (solvent THF) under nitrogen stream, a pink color appeared after a few minutes. The color deepened gradually and did not fade after being left to stand overnight. Thus, the pink color and ESR signal can be attributed to the product resulting from interaction of PhMgBr with benzophenone which is produced during the course of the reaction.[6]

On the Complex Containing Peroxide. In the preceding paper,[4] it was reported that two complexes were isolated from the reaction between BPO and PhMgBr, white (Complex I) and orange (Complex II). The formulas previously proposed are written in an over-simplified form.[7] We should examine whether complexes similar to Complex II are formed in the reaction between analogous peroxides and other Grignard reagents.

When methyl- or ethylmagnesium bromide in THF was added to the solution of equimolar BPO, the mixture turned to a similar orange and Complex II was obtained. Substituted benzoyl peroxides such as

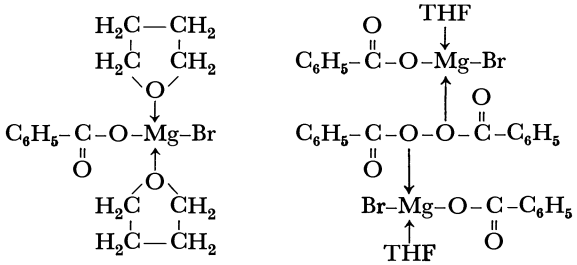
4) M. Ōkubo, K. Maruyama, and J. Ōsugi, This Bulletin, **42**, 1162 (1969).

5) Reaction (2) was confirmed later to proceed but much more slowly than reaction (1). See Experimental.

6) More details on this phenomenon will be published elsewhere. See K. Maruyama, This Bulletin, **37**, 897 (1964).

7) Their more precise structures will be discussed in the following paper.



(Complex I) (Complex II)

p-methyl-, *p,p'*-dimethyl-, *p*-methoxy-, *p,p'*-dimethoxy-, *p*-fluoro-, and *p,p'*-difluorobenzoyl peroxides revealed a similar behavior when they were treated with equimolar PhMgBr. Of these, symmetrically substituted peroxides easily formed orange crystals when the reaction mixtures were left to stand for about 2 hrs at room temperature. However, with the unsymmetrically substituted peroxides, crystallization was difficult even though the solutions colored similarly. Furthermore, when *t*-butyl perbenzoate[2] in THF was added dropwise to the equimolar PhMgBr solution, it turned orange during the course of the reaction and faded by the time the addition was completed. This is also an indication of the transient formation of a similar complex to Complex II.

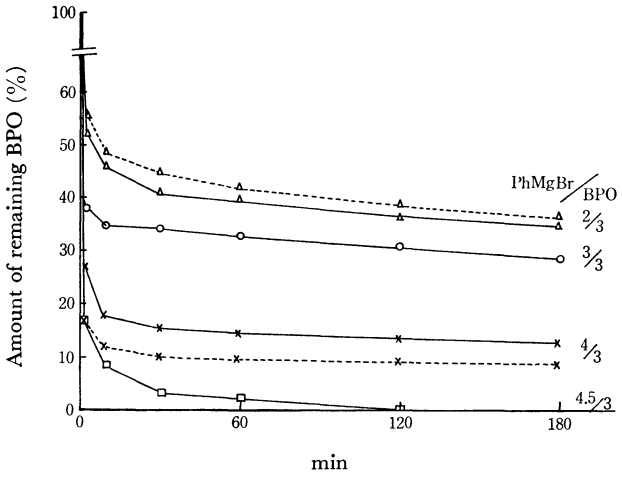


Fig. 1. Effect of molar ratio.
Temperature, 0°C Concentration, 0.007 mol/*l* (PhMgBr/BPO=3/3)

Effect of the Molar Ratio. Complex I was obtained when the molar ratio of PhMgBr : BPO was 1.5 : 1.0, while Complex II was obtained when it was 1 : 1.[4] Thus it is clear that the molar ratio of the two reactants has a remarkable effect on the course of reaction. Effect of the molar ratio on the consumption of BPO in the reaction system is shown in Fig. 1. The solid lines in Fig. 1 show the results obtained from the experiments when the amount of PhMgBr is fixed to 0.007 mol/*l* and that of BPO is varied, while the dotted lines show the results for the fixed amount of BPO and the varied amounts of PhMgBr. The difference between the solid and dotted lines for the same molar ratio shows the effect of concentration of the Grignard reagent. It should be noted that all the curves have creases between the initial and the second stages of the reaction. If the molar ratio is 3 : 3, the crease appears at the point where 35—37% of BPO remained, and hereafter the decomposition of BPO is markedly slowed down. The slow decomposition of BPO in the second stage may be attributed to the fact that benzoyl peroxide is stabilized through its complex formation with the reaction products, namely Complex I. If the molar ratio is 2 : 3, the crease rises up to 52—57% of remaining BPO, and the curve then goes down gradually to 33% of remaining BPO. If the molar ratio is 4 : 3, the crease falls down to 17—25% of remaining BPO. If 1.5 times molar Grignard reagent to the peroxide is used, BPO is completely decomposed after 2 hr. Though it is not shown in Fig. 1, when the two reactants were mixed at −15°C, the crease of the curve for the molar ratio of 2 : 3 rose up to about 66% of remaining BPO, and that for 4 : 3 to about 30%. If the molar ratio is 2 : 3, the reaction mixture turns orange very soon after mixing. Two conclusions can be derived from these facts; (i) Complex II is formed most effectively if the molar ratio is 2 : 3 and this ratio agrees with the composition of Complex II, (ii) twice moles of the Grignard reagent seems to be necessary for the rapid decomposition of one mole of Complex II.

9.		PhMgBr (66%)		18.1 1.00

Effect of the Structure of Peroxide. The technique of competitive reaction was applied to investigate the first stage of the reaction. The experiments were conducted at −15°C. Although just equivalent moles of two reactants were used for the reaction between unsymmetrical acyl peroxide and the Grignard reagent, 66% equivalent moles of the Grignard reagent to the total moles of peroxides were mixed for the comparison of the reactivities of the two symmetrical peroxides.[8] Relative amounts of esters produced were used as a measure of the reactivity. The results are summarized in Tables 1, 2, 3 and 4.

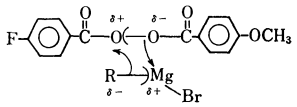
Since RMgBr in THF is coordinated by solvent molecules, the initial stage of the reaction should be the replacement of THF molecules by peroxide molecules. The results of experiments Nos. 2, 4, and 7 may be used as a measure of the relative facility of the coordination of each peroxide. 2 and 7 show that the electron-donating substituent accelerates the reaction. If the results of 4 and 2 are compared, the difference between the yields of two esters is negligibly small in the case of PhMgBr. This seems to be explained on the basis of the following : —first, the phenyl group which is bulkier than the methyl group would make it difficult for PhMgBr-species to be coordinated by peroxide molecules, and would reduce the difference of the yields of phenyl esters. Second, the donation of π-electrons of the phenyl group would also bring about the same effect. Salinger and Mosher[9] found that the infrared absorption band of C_{Ph}-Mg bond appeared at 370—380 cm^{-1} and that of C_{Me}-Mg bond at 500—535 cm^{-1}, respectively. This means that the C_{Ph}-Mg bond is stronger than the C_{Me}-Mg bond. However, it is conceivable that the phenyl group might donate its π-electrons to the vacant *p*- and *d*-orbitals of magnesium atom, and then reduce the positive charge on the magnesium atom. Thus, the facility of the coordination of peroxide molecules to magnesium atom may be more strongly affected in the case of MeMgBr (No. 2) than in the case of PhMgBr (No. 4). The result of No. 8 supports the results.[10] Following the coordination of the peroxide molecule to the Mg-atom, the displacement of carbanionic alkyl or aryl group of Grignard reagent takes place so to form the esters of carboxylic acids. The difference between the values of 0.82(No. 1) and 0.52(No. 3) may also be ascribed to the smaller polarizability of C_{Ph}-Mg bond or to the bulkiness of the phenyl group, both of which may cause a higher selectivity to diaplacement of the carbanionic phenyl group from Mg-atom of Grignard reagent to one of the oxygen atoms in the peroxide molecule. The carbonyl and peroxidic oxygen atoms of peroxide molecules could not be distinguished in the discussions.

8) As the initial stage of reaction is very fast, even the less reactive peroxide was readily decomposed almost completely when the 100% equivalent moles of the Grignard reagent to the total moles of peroxides were used. When 2/3 mol of PhMgBr were used, unreacted BPO (1/3 mol) was converted into Complex II completely by the interaction with PhCOOMgBr (Complex I) produced.

9) R. M. Salinger and H. S. Mosher, *J. Amer. Chem. Soc.*, **86**, 1782 (1964).

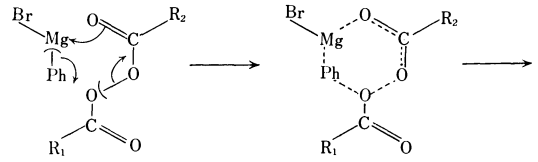
10) The p_π-p_π and p_π-d_π delocalizations which have been proposed to explain the lower reactivities of vinyl-substituted boranes and silanes may be the same as the π-donation discussed here. cf. J. J. Eisch, "The Chemistry of Organometallic Compounds," Macmillan Co., New York (1967), Chap. IV.

The results of the intramolecular competitive reactions, Nos. 1, 3, 5, and 6 are considered to provide information on the facility of displacement of alkyl or aryl groups. At this stage, the possibility of the so-called four-center-type reaction as shown in formula

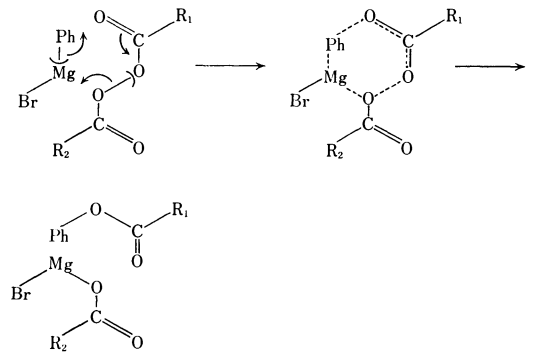


(3)

(3) may be small, since the actual Grignard reagent must have considerable bulkiness due to the coordination of solvent molecules. Thus, the six-membered ring structure for the transition state is more probable. If the carbonyl oxygen coordinates to Mg-atom, the mechanism is expressed as shown in formula (4). Another possible mechanism in which the peroxidic oxygen atom coordinates to Mg-atom is shown in formula (5). Both mechanisms lead to the same products. However, it may be difficult for the latter to occur



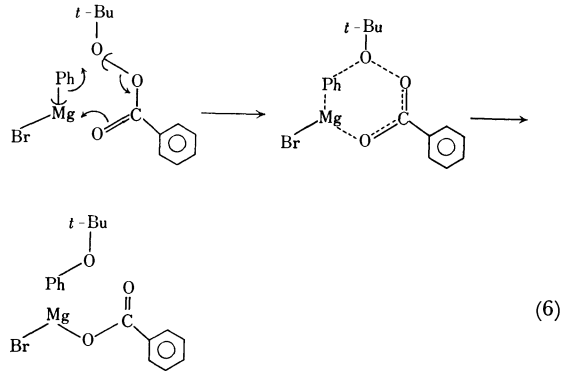
(4)



(5)

when the result of experiment No. 9 is taken into account. The fact that *t*-butyl perbenzoate is known to react with equimolar PhMgBr to produce exclusively *t*-butyl phenyl ether,[2] is explained solely by assuming the transition state in which the magnesium atom of the Grignard reagent is coordinated by the carbonyl oxygen atom as shown in formula (6). The predominant formation of *t*-butyl phenyl ether over phenyl benzoate in No. 9 is thus interpreted on the same assumption. The fact that di-*t*-butyl peroxide cannot react with PhMgBr under the same conditions,[2,11] means that peroxidic oxygen atoms are difficult to coordinate to the magnesium atom. Thus, the transition state can best be expressed by formula (4).

11) See experimental section. Baeyer and Villiger (*Ber.*, **33**, 3387 (1900)) observed that diethyl peroxide could not be decomposed by even sodium metal.



(6)

From this consideration, the more favorable structure for the transition state of No. 5 and No. 6 is expressed by formula (4) in which R_1 is CH_3 or CH_3CH_2 and R_2 is C_6H_5. Similarly, the results of No. 1 and No. 3 are expressed by formula (4) in which R_1 is *p*-FC_6H_4 and R_2 is *p*-$CH_3OC_6H_4$. These results cannot be interpreted if one assumes that the carbonyl group bearing the inductively more electron-donating substituent coordinates predominantly to Mg-atom. On the contrary, as shown in the above discussions, the "electromerically" more electron donating substituent favors the adjacent carbonyl group to coordinate to Mg-atom. Thus, the reaction of aroyl peroxides with the Grignard reagents can be illustrated by considering the electromeric polarizabilities caused by coordination of both the reagents.

Experimental

Grignard Reagents. THF solutions of phenyl-, ethyl- and methylmagnesium bromides were prepared in the usual manner using an excess of magnesium metal. They(about 0.5M, 300 ml) were stored in a tightly stoppered bottle and left standing overnight. A portion of clear solution was pipetted out, and its concentration was determined by alkaline titration.[12] Br^- and Mg^{2+} were also titrated by $AgNO_3$ and oxine-chelate[13] methods, respectively. Three values agreed with each other.

Peroxides. Commercial BPO was examined for its peroxide-content by iodometry, and purified, if necessary, by dissolving in chloroform and reprecipitated by methanol. *p,p'*-Difluoro-, *p,p'*-dimethyl- and *p,p'*-dimethoxy derivatives were prepared by treatment of the corresponding acid chlorides with sodium peroxide.[14] *p*-Fluoro-*p'*-methoxy derivative was prepared from sodium *p*-methoxyperbenzoate and *p*-fluorobenzoyl chloride.[15] *p*-Fluoro-, *p*-methyl- and *p*-methoxybenzoyl peroxides were prepared in the same manner from sodium perbenzoate and the corresponding acid chlorides. However, the differences in yields of the corresponding methyl esters on the reactions with MeMgBr were very small and the peroxide were not used.

Acetyl benzoyl peroxide and propionyl benzoyl peroxide were prepared by aerating the mixtures of acetic and/or

propionic anhydride and benzaldehyde.[16] Dipropionyl peroxide was prepared by treating propionic anhydride with sodium peroxide.[17] *t*-Butyl perbenzoate was obtained by treating *t*-butyl hydroperoxide with benzoyl chloride and sodium hydroxide.[18] Di-*t*-butyl peroxide was prepared by adding *t*-butyl hydroperoxide to a cooled mixture of *t*-butyl alcohol and sulfuric acid.[19]

Reactions of Aroyl Peroxides with Grignard Reagents. From reaction schemes (1) and (2), we see that the primary products of the reaction are PhCOOMgBr and PhCOOPh (from BPO and PhMgBr). Phenyl benzoate reacts easily with the remaining Grignard reagent to produce benzophenone, which again reacts to produce triphenylcarbinol. It is necessary, therefore, to avoid these reactions as far as possible. Thus, the reaction flask as shown in Fig. 2 was used throughout

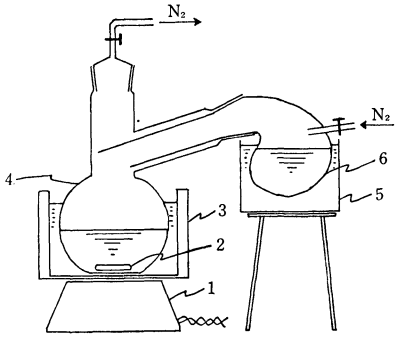

Fig. 2. Reaction flask for rapid mixing.

2. stirring rod
3. ice bath
4. reaction flask (peroxide solution)
5. ice bath
6. reservoir (Grignard solution)

this work. After air in the flask was replaced with nitrogen and the equimolar peroxide and Grignard reagent were cooled to the desired temperature, the resevior was turned upside-down with vigorous stirring of the peroxide solution. After mixing, the one m*l* portions of the mixture were pipetted out at definite time intervals and quickly introduced into a CO_2-purged flask containing acetic acid and potassium iodide. The mixture was titrated with a standard thiosulfate solution according to Wibaut.[20] For comparison, di-*t*-butyl peroxide was added to PhMgBr and the mixture was left standing for 2 hr,* but the peroxide was recovered and no product other than benzene was detected.

The Competitive Reaction. Mixing of perodixe solution with Grignard reagents was conducted by using the devide in Fig. 2. After stirring for 30 min, the reaction mixture was concentrated and decomposed with ammonium chloride. Neutral products were extracted with ether, dried with anhydrous magnesium sulfate, and concentrated to an appropriate volume. For gas-chromatographic analysis, a suitable substance was added as an internal standard. The mixture of known amounts of authentic samples was analyzed under the same gas-chromatographic condition for the calculation of the calibration factor.

In experiments Nos. 2, 4, 7, and 9, in which 66% equivalent amounts of Grignard reagent were used, a considerable amount of peroxides were not decomposed. Since they might interfere with gas-chromatographic analysis, they had to be removed. For this purpose two methods were used. The first was to decompose the peroxide by treating with hydroquinone and palladium-black according to Wieland.[21] Peroxide can easily decomposed to benzoic acid (and its derivatives), and they were removed by alkaline extraction. However, there was some difficulty, since benzoquinone, which is formed from hydroquinone through hydrogen-fransfer, gave a large quantity of precipitates from a concentrated sample solution for gas-chromatographic analysis. The other method was as follows: peroxide which remains as Complex II (or its derivatives) can be almost quantitatively precipitated from the concentrated reaction mixture by addition of a sufficient amount of dry ethyl ether.[4] The precipitate was collected on a glass-filter and washed throughly with dry ether. The filtrate was concentrated for gas-chromatographic analysis.

Reaction of Complex I with PhMgBr. Five milliliters of *ca.* 0.5M PhMgBr was pipetted into a N_2-purged flask and diluted with 20 m*l* of THF. The solution was vigorously stirred and carbon dioxide was introduced. After the absorption of carbon dioxide was completed, 10 m*l* of PhMgBr (0.5M) was added and stirred gently. After a few hours the solution turned wine-red. The color faded after being left standing overnight. The solution was concentrated and decomposed with ammonium chloride. The products were benzoic acid (0.38 g), and the mixture of benzophenone and triphenylcarbinol (1.1 g). The latter was confirmed with TLC.

The Thermal Isomerization of Pinane and Its Products

Juntaro TANAKA, Takao KATAGIRI, and Kiyomi OZAWA[1]

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu-shi

(Received March 6, 1970)

The stereochemistry of the reduced products of the iridenes was studied, and the main product produced by the thermal isomerization from pinane was confirmed to be 1-*trans*-2-dimethyl-*trans*-3-isopropenylcyclopentane, unlike as in the literatures. Moreover, the ozonolyses of the iridenes were reexamined in detail, and the following results were obtained: 1) When the ozonides were decomposed with Na_2CO_3-H_2O_2, the substituent on C-3 was epimerized. 2) On the other hand, when the ozonides were treated with Zn-CH_3COOH, no such epimerization occurred. Consequently, it was found that the former method when used for the confirmation of iridenes, did not give good results for assignments of these compounds.

l-cis-Pinane was isomerized at a high temperature to 3,7-dimethyl-1,6-octadiene (III)(=dihydromyrcene) and 1,2-dimethyl-3-isopropenylcyclopentanes (IVa—d) (=iridenes). The latter were the secondary products isomerized from the former. Those structures had been reported to be IVa and IVd.[2-5] Crowley,[6] however, reported that one of them was not IVa, but IVb, on the basis of his studies of the photochemical reactions of alloocimene. Furthermore, Ohloff[7] got plinols in which methyl on C-2 and isopropenyl on C-3 were *cis* configuration from ring-closure reactions of linalool.

In this paper, it will be reported on how, on the isomerization of pinane, the stereochemistry of iridenes was studied and IVb was obtained as the main product. Moreover, the determination of the structures through ozonolyses was reexamined, and the effect of epimerization on the process was reported.

Experimental

Measurements. The measurements were carried out after glc fractionations. The PMR spectra were recorded on a Hitachi-Perkin Elmer Model R-20, using tetramethylsilane as the internal standard and CCl_4 as the solvent at an ordinary temperature. A Perkin Elmer Model 337 infrared spectrometer was used for the measurements of the infrared absorption spectra in the 4000—400 cm^{-1} region.

Preparation of l-cis-Pinane(II). Into a 300-m*l* autoclave equipped with a magnetic stirrer, 100 m*l* of *l*-α-pinene(I) (bp 52—53°C/20 mmHg, n_D^{20} 1.4675, d^{25} 0.8537, $[\alpha]_D^{20}$ −39.1°), 10 g of Raney nickel W-6 and ethanol (40 m*l*) were added, and then hydrogen was introduced from a pressure bomb (150 kg/cm^2). Reduction was carried out at room temperature.[8] After the reaction, pinane (bp 60.5—62.0°C/20 mmHg, n_D^{20} 1.4630, $d^{12.5}$ 0.8592, $[\alpha]_D^{24.6}$ −14.63. PMR; 8.85(s), 9.00(s), 9.01(d, J=6.5 Hz)) was obtained. These physical data corresponded to those for *l-cis*-pinane.[9]

Thermal Isomerization of II. II was isomerized in a silica tube (20 mm $\phi \times 300$ mm) at a feed rate of 21 m*l*/hr in the range of 400—500°C with preheating (210°C). The isomerization products were carefully distilled, and two fractions, A (bp 160.5—161.0°C, n_D^{20} 1.4480) and B (bp 169.0—170.0°C, n_D^{20} 1.4550), were collected. The fraction A contained 84% of the peak 6, and the fraction B contained 83% of peak 8.

Ozonolyses of the Isomerized Products. A 2.0 g portion of each fraction (A and B) was dissolved in dichloromethane and saturated with ozone at −80°C, and then the solutions were warmed to −20°C. To each solution, the following two methods were applied: *Method 1*: Acetic acid (50 m*l*) and zinc powder (8 g) were then stirred into the solutions. After one hour, carbonyl compounds were obtained (A′ and B′). *Method 2*: Into the solutions, 5 m*l* of 10% aqueous Na_2CO_3 and 5 m*l* of 30% H_2O_2 were stirred. After three hours, these solutions were neutralized with 1N HCl and extracted with ether.

Isomerization of the Carbonyl Compounds with Basic Reagents.

b) PEG 6000/celite, 120°C, H_2: 40 m*l*/min.
c) Peak 6: bp 160.5—161.0°C (lit.[3)] for IVa; 161.1—161.4°C), n_D^{20} 1.4480 (lit.[3)] for IVa; 1.4475), PMR 9.33 (3H, d, J=6.5 Hz), 8.99 (3H, d, J=4.8 Hz), 8.35 (3H, s), 8.70—7.20 (7H, m), 5.42 (1H, m), 5.30 (1H, m), IR 3080, 885 cm^{-1}.
d) Peak 8: bp 169.0—170.0°C (lit.[3)] for IVd; 169—170°C), n_D^{20} 1.4550(lit.[3)] for IVd; 1.4545—1.4560), PMR 9.50(3H, d, J=7.0 Hz), 9.08(3H, d, J=6.0 Hz), 8.31(3H, s), 8.70—7.30(7H, m), 5.42(1H, m), 5.28(1H, m), IR 3080, 885 cm^{-1}.

1) A mixture of A′ and B′ (1.5 g) was added to 30 m*l* of 10% aqueous Na_2CO_3 and refluxed for four hours with vigorous stirring. After the reaction, 1.0 g of an oily product was obtained.

2) A′ and B′ (0.5 g) were each dissolved in 20 m*l* of 1N alcoholic potash, and the mixtures was refluxed for four hours. Then, a 60 m*l* portion of water was added to each solution and they were neutralized with 1N HCl. The isomerized products were obtained by means of the usual treatment.

Results and Discussion

The results of the thermal isomerizations of II are listed in Table 1. The peaks 1,5, and 7 were identified as isoprene, III, and II respectively by reference to authentic samples. According to the literatures,[2,3)] the peaks 6 and 8 seem to be iridenes, IVa and IVd respectively; this assignment is based on the physical constants listed in Table 1. When, however, the fraction A was reduced by the same way as II was, the PMR spectrum of the main product was identical with that of iridane Vb.[10)] Therefore, the peak 6 may be identified as IVb, since, under our experimental conditions, the structure should be retained.

The formation of the iridenes has been considered to proceed through the polycenter-concerted mechanisms, and several 1,6-heptadienes have been cyclized intramolecularly at a high temperature to *cis*-products.[5,11,12)] However, the iridenes obtained from III have been reported to be *trans* IVa mainly.[2-5)] Therefore, Tabushi[12)] considered that the primary product, IVd, was converted thermally to IVa, and Huntsman[5)] presumed that the methyl group at the 3-position of III contributed to form IVa.

On the other hand, Ohloff and his coworkers[7)] obtained *cis*-plinols as the main products on the cyclization of linalool, and they presumed a reaction mechanism.

Since the cyclization of III seems to be the same as in the case of linalool, the following intermediate structures are presumed (Fig. 1). In the [III^c] series, C-7 methyl and terminal methylene are *cis*, while in the [III^t] series they are *trans*. The IV's must be produced from the respective [III's]. Among these, the [III^c_c] and [III^t_d] structures are unstable because of the ecliptic arrangement of methyl on C-3 and terminal vinyl. (With regard to the latter, the interaction of methyls on C-3 and C-7 must also be con-

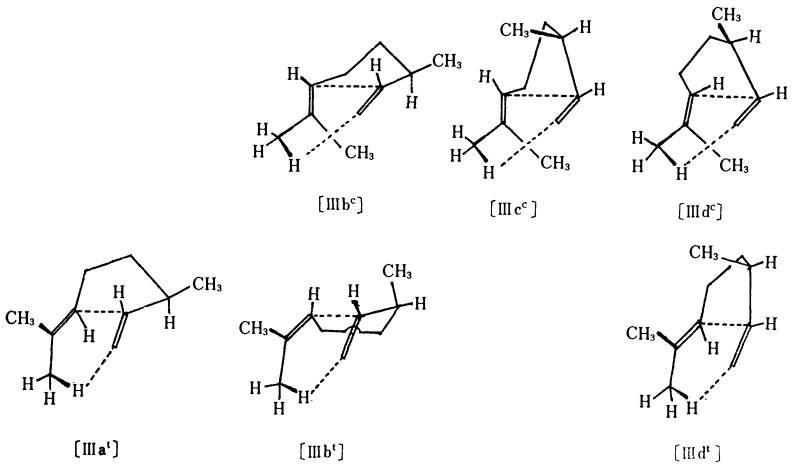

Fig. 1. The Presumptive Intermediates in the Cyclization of III.

10) K. Sisido, S. Kurozumi, K. Utimoto, and T. Isida, *J. Org. Chem.*, **31**, 2795 (1966).
11) H. M. R. Hoffman, *Angew. Chem.*, **81**, 597 (1969).

sidered). Hence, from the standpoint of stability and from that of the number of intermediates, the ease of the formation of iridenes seems to be the following sequence:

$$IVb > IVd > IVa > IVc.$$

TABLE 2. THE RESULTS OF OZONOLYSES OF IRIDENES

Reactant[a]	Method[b]	Product (%)[c]				
		VIa	VIb	VIc	VId	others
A	1	17.3	63.1	7.1	12.5	
B	1	—	4.4	—	95.6	
A+B	2	31.4	30.5	16.3	21.8	
A	2	47.8	45.8	4.8	1.0	
Iridene fraction from thermally isomerized product of II	1	15.1	48.0	6.6	24.7	5.6

a) Fraction A containing 84% of IVb, and B did 83% of IVd.
b) Methods were described in the experimental part.
c) Analyses were carried out by glc (PEG 6000/celite, 126°C, H_2: 41 ml/min).

This agrees with the experimental results.

Moreover, the results of the ozonolyses (Table 2) show that VIb and VId were produced from IVb and IVd respectively; therefore, in the former, the methyl groups on C-1 and C-2 are *trans*, and in the latter, *cis*. On the other hand, VIb and VId were isomerized partly into VIa and VIc respectively by the action of alkalis (Table 3), so it seems that, concerning the methyl on C-2 and the acetyl on C-3, VIa and VIc have more stable configurations than do VIb and VId. Therefore, these two groups may be considered to be *trans* in VIa and VIc, and *cis* in VIb and VId. That is, in the ozonolyses in which the ozonides are decomposed with Zn–CH_3COOH, the configurations do not change, but with alkalis epimerizations occur.

TABLE 3. ISOMERIZATION WITH BASIC REAGENTS[a]

Reactant[b]	Reagent	Product (%)[c]			
		VIa	IVb	VIc	VId
A′	1 N-alc. potash	63.6	2.5	25.2	8.7
B′	1 N-alc. potash	1.0	—	54.4	44.6
A′+B′ (1:1)	10% aq. Na_2CO_3	22.2	38.3	14.9	24.6

a) Reaction conditions; refluxing for four hours.
b) A′ was obtained from fraction A by means of method 1, and B′ was from B.
c) The analyses were same as Table 2.

Furthermore, the Cotton effects of VIa and VId were positive, and those of VIb and VIc were negative. According to Djerassi,[13] the Cotton effects of pregnan-3β-ol-20-one were negative in the case of the α configuration at C-17 acetyl and positive in the case of the β. Since, on the steroid, the steric effects of A, B, and C rings make contributions, the data may be not strictly suitable for our experiments. However, when we use these data in connections with those obtained in our studies, it can be deduced that the configuration of C-3 acetyl is α in VIb and VIc, and β in VIa and VId.

From these results, the decomposition of ozonides with Zn–CH_3COOH may be concluded to give the sterically-corresponding ketones. On the other hand, when the decomposition of ozonides is carried out with Na_2CO_3–H_2O_2, VIa and VIb are obtained from IVb, and VIc and VId from IVd. When the former workers[2,3] studied the structures of iridenes through ozonolyses, they used Na_2CO_3–H_2O_2 as the decomposing reagent of ozonides, they thus deduced that IVa, which is an epimer of IVb, was the main product from the thermal isomerization of II.

Side-chain Nitrooxylation of Polyalkylbenzenes through Ionic Process[1]

Kiyomi NAKAMURA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received March 17, 1970)

The reaction of polyalkylated aromatic compounds with fuming nitric acid has been investigated with respect to the effects of substituents and added electrolytes on the ease and extent of the concurrent side-chain nitrooxylation and nuclear nitration. Relative reactivity of substituted pentamethylbenzenes $C_6(CH_3)_5X$ for side-chain substitution decreases from 1 to 2×10^{-2} to 4×10^{-4} to 3×10^{-6} with the change of substituent groups from methyl to hydrogen to bromine to nitro in accordance with the ionic character of the reaction. Added electrolytes have profound influence on the reaction rates, but the ratio of products from side-chain nitrooxylation and nuclear nitration remains almost unchanged, indicating that both processes share a common intermediate. The relative amount of side-chain substitution depends closely on the positional relationship of alkyl groups in the nucleus, and preferential formation of *p*-alkylbenzyl nitrates is always observed. It is concluded from the results, that the side-chain nitrooxylation products are formed by way of the polar intermediate common with the ring nitration products. Some plausible reaction sequences are briefly discussed.

Electrophilic reaction of highly alkylated aromatic compounds often gives products which are rather unexpected from the reaction of less substituted compounds. The acylation,[2] halogenation,[3] hydroxylation,[4] and nitration[5] of these systems have been studied by several workers to determine the pattern of electrophilic substitution. In a previous paper,[6] we showed that the actions of fuming nitric acid upon pentamethylbenzene and pentaethylbenzene give as the major product 2,3,4,5-tetramethylbenzyl nitrate and α-methyl-2,3,4,5-tetraethylbenzyl nitrate, respectively, and that these unusual nitrations are characterized by their high positional selectivity and peculiar orientation. In the present work, the effects of substituents, added electrolytes and structural features of the substrate upon the rate and extent of the concurrent side-chain nitrooxylation (SNO) and ring nitration (RNA) have been investigated with the aim of providing information on how the displacement of a side-chain proton by ONO_2 group occurs in preference to that of a ring proton by NO_2 group under typical ionic conditions. From the results the possible reaction sequences leading to the formation of side-chain substituted products are briefly discussed.

Experimental

Materials. Hexamethylbenzene,[7] hexaethylbenzene,[8] pentamethylbenzene[7] and its bromo[9] and nitro derivatives,[10] two ethyltetramethylbenzenes,[11] three tetramethylbenzenes[7,12] and thier mononitro derivatives,[13] bromodurene,[14] bromonitrodurene, ethylmesitylene,[15] 5-*t*-butylhemimellitene[16] and its mononitro derivative,[17] mesitylene,[18] pseudocumene,[19] and ethylxylenes[15] were prepared as described in literature. 5-Ethylhemimellitene was obtained by the Clemmensen reduction of 3,4,5-trimethylacetophenone.[20] Nitromethane was distilled after drying over anhydrous sodium sulfate. Nitric acid ($d=1.50$) of guaranteed grade was used without purification.

Kinetic Measurement and Product Analysis. All kinetic measurements were made on a Shimadzu QV-50 spectrophotometer. A volumetric flask containing a nitromethane solution of the reaction mixture was immersed in a constant-temperature bath at 25.0°C. Ten milliliters of aliquots was withdrawn periodically and quenched by pouring into aqueous sodium bicarbonate. The organic part was separated by extraction with ether. The aqueous part was analysed for nitrite ion by Shinn's method[21] and nitrate ion was determined spectrometrically[22] to obtain the amount of nitric acid consumed. The residue from the ether extract was diluted with nitromethane to a suitable concentration and the amount of ring nitration was determined by calculation from the optical densities of nitro compounds at appropriate wavelengths. Adherance to Beer's law was excellent. Since nitromethane used as a solvent had deep absorption below 350 mμ, a comparatively weak band ($\varepsilon=2\times10^2-4\times10^2$) at around 380 mμ was used for the determination of nitro compounds. The wavelengths λ_{max} used were

nitropentamethylbenzene (380), nitrodurene (377), nitroisodurene (379), nitroprehnitene (381), nitromesitylene (379), bromonitrodurene (378), and 4-nitro-5-*t*-butylhemimellitene (378), respectively. Both nitrooxylated products and hydrocarbons exhibited no interference in this region. Nitromethane solutions were concentrated after optical density measurements, and the side-chain nitrooxylated compounds were hydrolyzed by refluxing with a mixture of sodium acetate (2 g), acetic acid (7 m*l*) and water (17 m*l*) for several hours. The organic part was removed by ether extraction and the aqueous part was analyzed for the nitrite ion derived from nitrooxylated products. Results of a typical run are summarized in Table 1. Since the amounts of nitrous acid[23] and benzyl nitrate are comparable at the initial stages of the reaction, the former can be used as a measure of side-chain nitrooxylation. Time t_{10} and t_1, which denote the time required for each of the substrates examined to attain 10% and 1% completion in SNO under identical conditions, were determined graphically. All runs were conducted at least twice and the values obtained were corrected by blank experiments.

Nitrations of polyalkylbenzenes for product analyses were carried out as described previously.[6] The structures of major nitration products were determined.

Mesitylene gave nitromesitylene. Pseudocumene[24] 4-ethyl-*o*-xylene, 4-ethyl-*m*-xylene, and 2-ethyl-*p*-xylene all underwent side-chain substitution at 4-alkyl group. Isodurene and its structure analogs were mainly nitrooxylated at 5-alkyl group: the major nitrooxylation product from 5-ethylhemimellitene was identified as α,3,4,5-tetramethyl-2-nitrobenzyl nitrate. No attempt was made to separate components of the product mixture from isodurene and ethylmesitylene because only small amounts of benzyl nitrates were formed. Prehnitene gave nitro compounds along with a small amount of side-chain substituted product, the structure of which has not yet been established. Durene gave a considerable amount of 2,4,5-trimethylbenzyl nitrate. 5-*t*-Butylhemimellitene yielded mono and dinitro derivatives as sole products.

Results and Discussion

Substituent Effects for Side-chain Nitrooxylation. In previous papers[25] of this series, the mode in which a substituent group determines the orientation of side-chain nitrooxylation (SNO) was briefly described. Strongly electron-withdrawing substituents such as nitro, carboxyl and carbomethoxy groups brought about almost exclusive ortho substitution to give 6-substituted tetramethylbenzyl nitrate, while halogen atoms were found to lead to comparable amounts of 5- and 6-halotetramethylbenzyl nitrates. Pentamethylphenol and its methyl ether gave mainly cyclohexadienones, with a concomitant formation of 3-substituted tetramethylbenzyl nitrate in a small amount.

In order to get further insight into the mechanism of SNO, the substituent effect on the reactivity has been examined for a series of pentamethylbenzene derivatives. The overall process of SNO may be expressed in the stoichiometric equation

$$C_6X_5CH_3 + 2HNO_3 = C_6X_5CH_2ONO_2 + HNO_2 + H_2O \quad (1)$$

Preliminary experiments carried out for dilute nitromethane solutions of hexamethylbenzene and fuming nitric acid at 10°C and 25°C have shown that the rate of SNO can be followed successfully by measuring the increase in the amount of nitrous acid (Table 1).

Table 1. Nitration of hexamethylbenzene in nitromethane at 10°C

$[C_6(CH_3)_6] = 2\times10^{-2}$ mol l^{-1}; $[HNO_3] = 10\times10^{-2}$ mol l^{-1}

Time (sec)	$[HNO_2$[23]$]$ (mol l^{-1})	[benzyl nitrate] (mol l^{-1})	[HNO_3 consumed] (mol l^{-1})
135	0.27×10^{-2}	0.24×10^{-2}	0.60×10^{-2}
210	0.41	0.46	1.06
230	0.47	0.45	1.12
300	0.67	0.63	1.46
324	0.74	0.62	1.66

With the lapse of time, the amount of nitrous acid gradually outweighs that of benzyl nitrate, indicating that nitrous acid can be no longer used as the measure of SNO. This would probably be due to the secondary reactions involving the oxidation or the condensation of the initially formed benzyl nitrate.[26] SNO of polyalkylbenzenes is quite sensitive to the reaction conditions, and the benzyl nitrates produced are usually highly reactive so that they can act as a benzylating agent in the presence of acid catalyst, or undergo further transformation with excess of nitric acid. Thus direct kinetic treatment of the nitration of polyalkylated aromatics for the purpose of determining their relative rates is very difficult. To avoid these complexities, relative rates of hydrocarbons were determined by comparing the time t_{10}, which denotes the time required for each of the substrates examined for 10% completion in SNO under identical conditions. Such a method has been successfully used by several groups of workers in some electrophilic aromatic substitutions.[27] Ob-

Table 2. Substituent effect on the rate of side-chain nitrooxylation of $C_6(CH_3)_5X$ in nitromethane at 25°C

$[C_6(CH_3)_5X] = 2\times10^{-2}$ mol l^{-1}; $[HNO_3] = 10\times10^{-2}$ mol l^{-1}

	X	Relative basicity (*p*-xylene=1)	t_{10}[a] (sec)
Hexamethylbenzene	CH_3	44500	15
Pentamethylbenzene	H	4350	660
Bromopentamethylbenzene	Br		4×10^4
Nitropentamethylbenzene	NO_2		5×10^6
Hexaethylbenzene		13500	800

a) t_{10} denotes the time required for 10% completion in SNO for each of the substrates examined.

23) The term "nitrous acid" used hereafter refers to all the products in the reaction mixture, which after dilution with water could be estimated as nitrous acid by ordinary procedures.

b) Ref. 29—31)
c) Ref. 28)
d) This value is the reactivity of chloro-substituted compound relative to methyl-substituted.

served t_{10} and reactivity relative to hexamethylbenzene are collected in Table 2. Comparisons are made with the substituent effects on the ring nitration of C_6H_5X, and on the oxidation of benzyl alcohols and their methyl ethers by dilute nitric acid (Table 3).

As is apparent from Table 2, the reactivity for SNO follows the order $C_6(CH_3)_6>C_6(CH_3)_5H>C_6(CH_3)_5Br>C_6(CH_3)_5NO_2$ and electron-withdrawing bromo and nitro groups remarkably retard the reaction. Similar orders are followed in ordinary nuclear nitrations, and in the oxidation of benzyl alcohols and their methyl ethers by dilute nitric acid to the corresponding benzaldehydes (Table 3). However, the magnitude of difference in relative rate for SNO differs remarkably from that of the latter process in which the hydrogen abstraction by radical is rate-determining.[28] Relative reactivities for SNO are $II/I=2\times10^{-2}$, $III/I=4\times10^{-4}$ and $IV/I=3\times10^{-6}$, and the overall reactivity range is covered by a factor of as large as 10^5. Marked dependence in the relative rates of SNO on the electronic effect of the substituent groups parallels that found in the nitration of C_6H_5X, $II/I=10^{-1}$—10^{-2},[29] $III/I=10^{-3}$,[30] and $IV/I=10^{-5}$—10^{-8},[31] where the attack of an electrophile to the nucleus to form benzenonium ion is rate-determining. In contrast, the relative rates of the hydrogen atom abstraction from side-chain vary very little with the change of substituents; $II/I=1$—10^{-1}, $III/I=10^{-1}$—10^{-2} and $IV/I=10^{-2}$.[28] A similar response of SNO and RNA to the change of substituents suggests that the processes of SNO and RNA are mechanistically alike and argues against any participation of free-radical pathway in the reaction. SNO proceeds with fuming nitric acid at low temperatures, while the nitric acid oxidation of alkylbenzenes can be effected with dilute aqueous nitric acid only at elevated temperatures. Additional support for the ionic process is put forward by the observation that SNO takes place with primary alkyl groups such as methyl and ethyl, but not with isopropyl or *t*-butyl group.[6] Excellent positional selectivity of SNO leads to the reaction products of simple composition and high purity,[6,25] which are opposed to the free-radical mechanism in which reactive benzyl nitrates would have been oxidized to a complicated mixture of benzaldehydes, benzoic acids and others.

Effects of Added Electrolytes on the Ease and Extent of Side-chain Nitrooxylation. Table 4 shows the effects of added electrolytes on SNO and RNA of pentamethylbenzene, which were carried out with nitric acid ($d=1.50$) in nitromethane at 5°C. The time required for 10% completion in the overall reaction—the sum of SNO and RNA — is indicated by t'_{10}. The relative percentage of the products from SNO and RNA at t'_{10} is also included. As is apparent from the Table, the ratios of both reaction products are almost independent of the concentration of nitric acid or the presence of the added electrolytes such as nitrite, nitrate or hydrogen sulfate. This might indicate that the reaction leading to RNA and SNO shares a common intermediate, presumably benzenonium ion (A) as described in the equation below:

Table 4. Effects of added electrolytes on the ease and extent of side-chain nitrooxylation of pentamethylbenzene with nitric acid in nitromethane at 5°C

$C_6(CH_3)_5H$ (mol l^{-1})	HNO_3 (mol l^{-1})	Added electrolytes (mol l^{-1})	t'_{10}[a] (min)	SNO (%)	RNA (%)	t_{10}[b] (min)

The reaction rates are subject to the influence of the added electrolytes. The reaction is accelerated by the addition of a small amount of sulfuric acid, the role of which is no doubt to form the nitric acidium ion $H_2NO_3^+$, the precursor of the reactive nitronium ion NO_2^+, HSO_4^- acting as a base. A negative effect has been shown by nitrate ion, which retards the reaction by decreasing the concentration of nitric acidium ion according to the equation

$$HNO_3 + HNO_3 \rightleftharpoons H_2NO_3^+ + NO_3^- \qquad (3)$$

Addition of a small amount of nitrite ion into the system brings about a remarkable enhancement of the reaction rate, but the relative ratio of SNO and RNA remains unchanged. Nitrooxylation of hexamethylbenzene and pentamethylbenzene according to Eq. (1) inevitably produces a large amount of nitrous acid with progress of the reaction, and the nitrous acid thus formed restricts the supply of the nitronium ion by lowering the concentration of the nitric acidium ion in the system following the equation[32]

$$H_2NO_3^+ + NO_2^- = N_2O_4 + H_2O \qquad (4)$$

Since the reaction of pentamethylbenzene is apparently autocatalysed, the nitrosonium ion may play some role in the substitution as has been suggested by Shofield and coworkers in the nitration of some activated aromatic systems.[33,34] The reaction rate of SNO is also more enhanced in nitromethane than in acetic acid. This trend has already been well substantiated for ordinary nuclear nitration.[32] Thus it is concluded that the effective species for SNO is the nitronium ion or its precursors ($H_2NO_3^+$ and N_2O_5) depending on the reagent and conditions employed, and the electrophilic attack of these ionic species on the aromatic substrate constitutes the initial stage of the reaction; the proton transfer from the nucleus leads to RNA and the proton removal from the side-chain results in SNO, as in Eq. (2).

Relative Reactivities of Polyalkylbenzenes towards Side-chain Nitrooxylation. Comparison of relative reactivities towards SNO has been made with 18 alkylbenzenes listed in Table 5. With durene and pentaalkylbenzenes, SNO predominates over RNA, but with the decreasing number of alkyl substituents, the situation is gradually reversed so that t_{10} should be replaced by t_1 to provide a sound basis of comparison for the diminished tendency of substrate towards side-chain substitution. In Table 5, a similar comparison of overall reactivities of seven polyalkylated aromatic systems has been made on the basis of t'_{10}, relative basicity and the percentage ratios of SNO and RNA at t'_{10}.

Tetralin and diphenylmethane, which have reactive hydrogen atoms and are readily oxidized by dilute nitric acid, remain mostly unchanged in support of the ionic process for SNO. The basicity of hydrocarbon decreases in the order: isodurene>mesitylene>prehnitene>durene>pseudocumene, whereas a partial reversal of the order was observed in the relative rates of these hydrocarbons for SNO: xylenes<mesitylene<pseudocumene<prehnitene<isodurene<durene. This is rather surprising since it means that mesitylene, which is highly reactive in ordinary electrophilic reactions, reacts more slowly for SNO than durene or pseudocumene, which are much less basic than the former and not so highly reactive in the ordinary sense. The reactivity for SNO is, therefore, closely related to the positional relationship of the substituents in the alkylated aromatic systems. The significance of this aspect of the reaction will be discussed in due course.

The percentage ratio of SNO tends to decrease in the following order: pentamethylbenzene>durene>isodurene>prehnitene>5-*t*-butylhemimellitene>mesitylene. From the results in Table 5 it appears that the more a hydrocarbon possesses a pair of alkyl groups located at ortho and/or para position, the more readily it undergoes SNO. This is clearly understood from the reactions of hexamethylbenzene, pentamethylbenzene, durene, pseudocumene and *p*-xylene. On the other hand, mesitylene and *m*-xylene which have no comparable alkyl group yield only RNA products. It follows, therefore, that a fine balance exists between SNO and RNA, and that the positional features of the substrate are likely to be an important factor for deciding the way the reaction will take place, SNO or RNA.

High positional selectivity for SNO is very likely connected with the slow step of the proton removal from the alkyl side-chain of the benzenonium ion intermediate. Although the nitration of benzene proceeds without any primary isotope effect,[35] sterically hindered compounds usually exhibit some effect since the slow proton transfer now becomes rate-determining.[36] The diminished facility of proton transfer from the nucleus necessarily increases the chance of hyperconjugative release of a proton from the alkyl side-chain. Thus, SNO and RNA are able to compete effectively in a crowded system such as durene, penta-alkylbenzenes and hexamethylbenzene. Taking the nitration of durene as an example, the process can be outlined as follows:

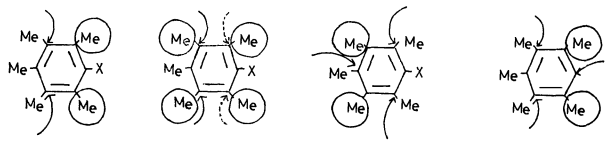
The attack of the nitronium ion upon durene will give two benzenonium intermediates (B) and (C), the latter outweighing the former in amount not only for statistical reasons, but also for more effective stabilization by one methyl group in an ortho position and one in para position than two methyl groups in ortho as (B). Steric factor also favors the formation of (C), in which the position of attack is flanked by one methyl group, over (B) where both sides are flanked. Ordinary proton removal from (B) will lead to RNA, and unusual proton removal from alkyl side-chain will result in the formation of SNO product. The predominance of the latter process in the reaction of durene may be rationalized by the greater contribution of the intermediate (C) over (B), and by the slower removal of the ring proton from (B). Further, the formation of nitrooxylated compound only as a minor product in the nitration of pentamethylphenol may be accounted for by easier proton transfer from the hydroxy group, leading to conversion into cyclohexadienone derivatives.

The methyl groups preferentially nitrooxylated and the most probable positions to be attacked initially by the nitronium ion are illustrated below for some polyalkylated aromatic systems.

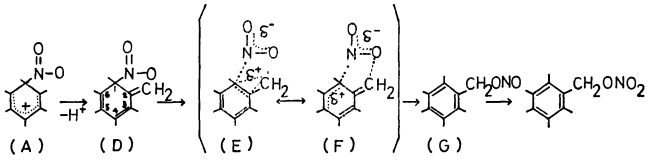


X=NO_2, COOH, $COOCH_3$ X=Cl, Br X=OH, OCH_3, NHAc

A circle indicates the methyl group preferentially nitrooxylated, and an arrow shows the preferred position for electrophilic attack by nitronium ion. Solid line —— the most preferred; dotted line ------ the next preferred.

As can be seen from the figures, the presence of methyl groups in positions ortho and/or para one another seems critical for the facile formation of benzyl nitrates. This might indicate that the hyperconjugative electron release from the methyl group will play some role for side-chain nitrooxylation. In fact, most benzyl nitrates obtained in high yields from the nitration products possess *p*-methyl group, and those having an electron-withdrawing substituent in para position are rarely formed.

On the basis of this study and related previous works,[6,25] we can tentatively construct some plausible sequences for side-chain substitution under heterolytic conditions. The cyclic process involving the migration of nitro group from nucleus to side-chain has been suggested for SNO of pentaalkylbenzenes.[6] This proceeds through a sort of allylic migration of nitro group from the attacking site to α-carbon of the alkyl group, from which the preferential proton removal took place. The benzyl nitrite thus formed will be transformed with nitric acid into the benzyl nitrate and nitrous acid.



(5)

Many findings obtained from SNO are consistent with this mechanism, which has a formal resemblance to those proposed for some Claisen-type rearrangements[37] such as allyl amine oxides, nitramine and alkylpyridine *N*-oxide rearrangement. Transformation from the benzenonium intermediate (A) to the benzyl nitrite (G) can take place in two different ways; a direct conversion, and the intervention of an intermediate methylene cyclohexadiene, (D) and (H). The former process

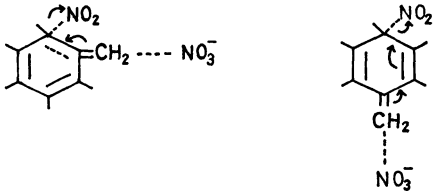
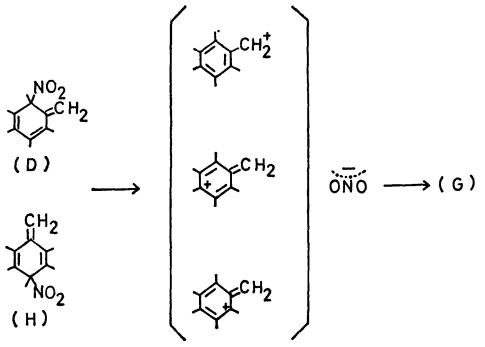
37) B. S. Thyagarajan, "Mechanisms of Molecular Migrations," Vol. II, Interscience Publishers, London, (1969); H. J. Shine, "Aromatic Rearrangements," Elsevier Publishing Company, London, (1967).

involves a simultaneous proton abstraction and nitro group migration in (A). Each pathway requires a transition state in which the scission of the C–N bond occurs in such a way that the departing nitrogen atom is accommodated with the unshared electron pair, leaving C-1 atom to be electron-deficient. This sort of π-σ electron interaction could occur through the overlap between C-1 carbon atom and the α or C-5 carbon atom.[38] The transition state for such a process may be depicted as (E) or (F). The C-5 methyl group at a position meta to C-1 and para to C-2 methylene can partly supplement this deficiency through the hyperconjugative electron release, thus facilitating the nucleophilic migration of the nitro group to the side-chain. Electron-withdrawing group at C-5, on the other hand, increases the electron deficiency at the carbon atom to which the nitro group is attached, making the departure of nitro group as a nucleophile more difficult. This is probably why the benzyl nitrate with the methyl group at para position is preferentially formed over the other isomeric products.

Two other possibilities are also conceivable, although they lack formal analogies in literature as far as the author is aware. One is a process in which a proton is removed hyperconjugatively from the side-chain to form a sort of methylene cyclohexadiene intermediate (D) and (H). Attachment of the nitrate anion to the terminal methylene carbon, departure of the nitro group as an anion, and rearomatization of the system, if occurring continuously, will lead to the formation of the benzyl nitrate.

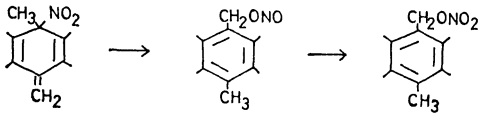


This intermolecular process is apparently difficult for justifying the fact that nitration carried out in dilute acetic acid solution affords a considerable amount of benzyl nitrate along with benzyl acetate at a very early stage of the reaction, and that the ratio of SNO and RNA is nearly independent of the concentration of nitric acid as well as added electrolytes. A speculative alternative may involve the ion-pair intramolecular path proposed for rearrangements of nitramine,[39] and 2- and 4-picoline oxides.[38,40] Formation of ion-pair requires a tight (solvent caged) association of these species, and their combination is required before separation to accommodate this intramolecular process, although the intramolecular nucleophilic cyclization leading to the formation of phthalide, or anthranil analog could not be observed during the nitration of pentamethylbenzoic acid, or pentamethylnitrobenzene.



In view of a preferred attack on the 2-alkyl group in the reaction of 2,4-lutidine *N*-oxide[41] or 2,4-dimethylquinoline *N*-oxide with acetic anhydride, rearrangement to the neighboring ortho position could occur more readily than that to the remote para position. The former would probably proceed intramolecularly, while the latter possibly intermolecularly.[42]

Another possibility is a process similar to the Quinobenzylic rearrangement, where the attacking species migrates intramolecularly to the geminal methyl group to form the benzylic compound.



The principal disadvantage of this mechanism is that the nitropentamethylbenzene and pentamethylbenzoic acid undergo almost exclusive ortho nitrooxylation, because the most favored position for the attack of the nitronium ion in these compounds is not the ortho, but the meta position to the strongly electron-withdrawing nitro or carboxyl groups. Quinobenzylic rearrangement itself has recently been reported to proceed through a radical mechanism.[43]

The author wishes to thank Dr. H. Suzuki, Professor K. Maruyama and Professor J. Osugi for their discussions.

A Modification of Red Blood Cells by Isocyanates[1)]

Masao KITAJIMA, Wataru SEKIGUCHI,[2)] and Asaji KONDO

Research Laboratories, Tokyo, Fuji Photo Film Co., Ltd., Asaka, Saitama

(Received April 23, 1970)

Modified red cells that have a reinforced membrane and hemoglobin which is difficult to denature are prepared by treating red cells with some isocyanates. These modified cells have the same shape as normal red cells, but they are not lysed by osmotic pressure or by the actions of any reagents except for some ionic surface-active agents. No agglutination was observed when they were mixed with the blood of foreign animals or with blood of different blood groups. The hemoglobin within the cell gave a reversible oxygenation curve and had a high oxygen affinity. Toluene-2,4-diisocyanate was found to be the most suitable reagent among the many isocyanates examined. A suspension reaction method which consists of the addition of an isocyanate emulsion to a red-cell suspension at 5°C is developed for the modification process.

The present authors have studied the preparation of artificial red blood cells by using microencapsulation techniques. A hemoglobin solution was microencapsulated with synthetic polymers, such as polystyrene, a silicone derivative, poly-γ-benzyl-L-glutamate, and dextrane stearate, into sphere particles five to ten microns in diameter.[3-5)] The hemoglobin contained in these microcapsules was found to be preserved in a normal state, and it gave an oxygenation curve identical with that of normal hemoglobin. The oxygen permeability of the hemoglobin-containing silicone microcapsules was comparable with that of natural red cells. They are free from problems of agglutination and hemolysis, and can be preserved over a long period. It is expected that the hemoglobins obtained from many mammalias can be used as artificial red cells when subjected to microencapsulation. The present authors are now studying the metabolism of the polymers used as capsulating materials and the rheology of the suspension containing such rigid particles.

This paper will describe a method of preparations and the properties of the modified red cells that have a reinforced membrane and normal hemoglobin. It is known that the shape of red cells can be fixed by treating them with some protein precipitants, such as aldehydes,[6,7)] tannic acid, or hydrogen peroxide.[8)] However, these reagents are soluble in water, so that they can penetrate into the cell to denature hemoglobin. These fixed cells have been used for studies of the morphology or the surface properties of red cells. In this modification reaction, water-immiscible isocyanates are used in the suspension reaction method that consists of the addition of an isocyanate emulsion to a red cell suspension. The modified red cells thus obtained show some specific behavior concerning hemolysis and agglutination. They are considered to be suitable as samples for a biological, physiological, or rheological study of erythrocytes. The present authors are now studying their use in the medical field as a kind of artificial red cell in a way similar to the hemoglobin-containing microcapsules.[9,10)] This modification technique can be employed generally in studying the nature of cell membranes other than that of the erythrocytes.

Experimental

Materials. Toluene-2,4-diisocyanate (TDI), from the Tokyo Kasei Co., was purified by distillation (146°C/38 mmHg). Phenyl and ethyl isocyanate, phenyl and ethyl isothiocyanate, hexamethylene diisocyanate (Tokyo Kasei Co.) and diphenylmethane diisocyanate (Hodogaya Chemicals) were obtained commercially.

Polyoxyethylene hydrogenated caster oil ether (Nikko Chemicals), Tween 20, sodium dodecylbenzenesulfonate (Kao-Atlas Co.), saponin, lecithin from eggs (Merck Co.), and cetyl, dodecyl and ethyl-pyridinium salt (Tokyo Kasei Co.) were obtained commercially. The other surface-active agents were synthesized and purified in our laboratories.

Reagent-grade chemicals were used in all the experiments.

Modification of Red Cells by TDI. The suspension reaction method developed by the authors was used to modify red cells suitably. Mammalian red cells were collected by centrifugation and washed three times with isotonic saline solution. In 200 m*l* of pH 7.2 phosphate-buffered isotonic saline, we suspended 10 g of the washed red-cell slurry at 5°C. The TDI emulsion was prepared by emulsifying 0.15 m*l* of the reagent in 30 m*l* of the saline, by means of an ultrasonic emulsifier, into microdroplets of about one micron in diameter. This TDI emulsion was quickly stirred into the red-cell suspension at 5°C. The modified cells were recovered after 5 min by centrifugal separation at 1500 rpm for 10 min and then washed with the saline twice.

The same method was employed in the cases of the other isocyanates, with varying amounts of the reagents and with varying reaction times.

Measurements of Properties. Hemolysis. Surface-active agents were dissolved in water to make a 1% solution, and the hydrogen-ion concentration was adjusted to neutral by adding dilute hydrochloric acid or a sodium hydroxide solution. In a test tube we placed 5 m*l* of this solution and then added several drops of the modified red cells. The suspension was

stirred for 5 min, and then observed under a microscope in order to see whether the cells were lysed, swelled, or unchanged.

Spectral Measurements. The visible absorption spectra for suspensions of the modified cells were taken with a Hitachi EPS-3T spectrophotometer, according to the opal glass method. A small amount of sodium hydrosulfite was added to deoxygenate hemoglobin. The infrared spectra were taken with a Hitachi Perkin-Elmer 125 spectrophotometer.

Oxygenation Curve. The modified cells were suspended in a solution phosphate-buffered at pH 6.5, and then put in a modified Wyman-type tonometer. The air inside the tonometer was replaced by nitrogen purified with Fieser's solution and saturated potassium chloride solutions. After the hemoglobin had been completely deoxygenated, a measured amount of air was introduced into the tonometer with a syringe. It was shaken for 20 min to equilibrate the hemoglobin with the gas, and then the sample was submitted to absorption spectrum measurements. The percentage of oxygenation, Y, of the hemoglobin was calculated from the spectra according to the following equation:

$$Y=\{[(E_a-E_b)-(D_a-D_b)]/[(O_a-O_b)-(D_a-D_b)]\}\times 100$$

where the terms O, D, and E represent the absorbance at the completely oxygenated state, the completely deoxygenated state, and the state between the two, respectively. The suffixes a and b represent the wavelength at which the absorption was measured: a, 578: b, 562.5 nm.

Results and Discussion

Modification Reaction. Various isocyanates were examined for use in modifying red cells, but most of them were found to be unsuitable. Monoisocyanates such as phenyl and ethyl isocyanate did not reinforce the membrane. The same was true with phenyl and ethyl isothiocyanate. Diisocyanates such as hexamethylene and diphenylmethane diisocyanate reinforced the membrane under some conditions, but they required too long a time to complete the modification, as their reactivity was not high enough,[11] and the hemoglobin within the cell was denatured. It was effective to add some catalysts, such as ferric chloride or sodium phenate, to accelerate the reaction, but they were undesirable because of their deleterious action on hemoglobin.

TDI was found to be the most suitable reagent. It gave modified cells that had a sufficiently reinforced membrane and hemoglobin which was hardly denatured at all. The reactivity of TDI is very high, so that the modification reaction is completed in a few minutes. The excess TDI is exhausted by reactions with water molecules and becomes inert solid particles in this suspension reaction. When the isocyanate is used as an organic solution, the shape of the cells changes into a sphere and a denaturation of the hemoglobin takes place. Actions based on the low surface tension of the solvent or on the extraction of lipids from the membrane must be the reason. Thus, both the high reactivity and the reaction method serve to prevent the reagent from penetrating into the cell to denature hemoglobin.

The amount of TDI to be used was determined by examining the degree of the reinforcement and that of the denaturation of hemoglobin. The optimum amount of TDI to modify 10 g of the red cell slurry properly was found to be 0.15 m*l*. When the amount was insufficient, the cells became more sensitive to hemolytic action than intact cells. A large excess of TDI caused serious denaturation. The use of small amount of surface-active agents served to keep the isocyanate emulsion stable. Polyoxyethylene hydrogenated caster oil ether, which is known to be inert to blood, was added to the suspension in an amount of 0.05%.

Shape. The shape of the modified cells was biconcave discoide, as is shown in Fig. 1. It cannot be distinguished from that of normal cells. These cells were neither ruptured nor deformed when suspended in a hypotonic or hypertonic salt solution.

It was assumed that the cells were fixed hard as rigid particles by the modification. However, viscometric measurements over a shear rate of 2 to 100 sec^{-1} showed that the flow behavior of the modified cell suspension was non-Newtonian, although to a lesser extent than with the intact red-cell suspension.[12] The result for the red cells hardened by formaldehyde was found to be Newtonian. These facts suggest that the membrane of the modified red cells has some flexibility.

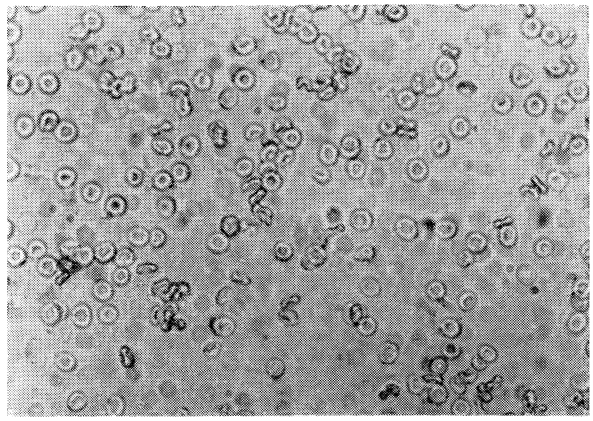

Fig. 1. Micro photograph of the modified human red cells suspended in distilled water.

Hemolysis. The modified cells showed some specific characteristics concerning hemolysis. They were not lysed by the action of osmotic pressure. They were recovered by centrifugation after being suspended in distilled water without releasing free hemoglobin into the medium. Neither lysis nor swelling was observed when they were suspended in a 50% aqueous solution of ethyl alcohol, acetone, or glycerine. No change in shape was observed in 2N sulfuric acid, but they swelled very much in 0.1N sodium hydroxide. Nonionic surface-active agents, such as Tween 20, polyoxyethylene hydrogenated caster oil ether, and saponin, were found not to affect the lysis of the modified cells. The same result was obtained with lecithin from eggs.

On the contrary, some of the ionic surface-active agents caused a lysis or swelling of the cells. The

d) A concentration below 1% was used because of the low solubility.

results are shown in Table 1.

There were clear differences among the hemolysed, the swelled, and the unchanged state. A hemolytically-active agent like dodecylpyridinium chloride caused lysis instantaneously, and a clear hemoglobin solution was obtained. Sodium laurate caused a swelling into a sphere and the hemoglobin within the cell was released into the medium, but a turbidity remained in the solution. No change in shape nor any release of hemoglobin was observed in the case of ethylpyridinium bromide. The hydrogen-ion concentration of the solution affected the hemolytic behavior sensitively. The modified cells were apt to lyse easily in a medium with a high pH value.

Although further investigations are required to establish the mechanism of the hemolysis of the modified cells, some tendencies can be seen in the table. There is some relationship between the structure of the ionic groups and the hemolytic effect. The orders are considered to be as follows: $-SO_4Na$ and $-SO_3Na > -COONa > -PO_4Na_2$ for the anionic series and $-NH_2HCl$ and $-PyCl > -N(CH_3)_3Cl$ for the cationic series. Hydrophobic groups are also considered to greatly affect the hemolytic action. Surface-active agents that have too short or too long alkyl chains cannot cause lysis. An alkyl chain that has ten to fifteen carbons is considered to be most effective.

These facts are in fair agreement with the results obtained for intact red cells. It has been reported that the order of the hemolytic activity of ionic surface-active agents according to the polar groups is as follows:[13]

$$-SO_4Na > -SO_3Na > -NH_2HCl > -COONa > -N(CH_3)_3I$$

Kondo and Tomizawa studied the hemolysis by cationic surface-active agents and proposed a mechanism.[14] They stated that lysis was caused by the adsorption of the detergent molecules onto the cell surface in terms of ionic attraction at first step, followed by the solubilization of lipids in the membrane in terms of hydrophobic interaction. They considered that the bulkiness of the hydrophobic group of reagents was an important factor in effective adsorption.

13) B. A. Pethica and J. H. Schulman, *Biochem. J.*, **53**, 177 (1953).
14) T. Kondo and M. Tomizawa, *J. Pharm. Sci.*, **58**, 255, 1378 (1969).

It is possible to consider that the mechanism of the hemolysis of the modified cells is the same as that for intact cells. This means that the isocyanate molecules do not affect the sites where the ionic surface-active agents attack to lyse. On the other hand, the sites where nonionic agents attack are assumed to be reinforced by the modification reaction.

Agglutination. The modified cells were found to be mixed with the blood of foreign animals or with that of different blood groups. Neither agglutination nor lysis was observed in the mixture. Figure 2 shows microphotographs of the modified human red cells of the A, B, O, and AB blood groups, suspended in plasma of the A blood group. Not much difference can be seen among them. It was also observed that the modified bovine red cells were mixed with the whole blood of a rabbit, homogeneously. No lysis nor agglutination was caused.

These facts suggest that red cells are inhibited or lose the power to agglutinate by the modification reaction. It has been reported that red cells lose their agglutinability towards appropriate antisera when they are treated with a formaldehyde solution.[5] It is expected that some information on the mechanism of the agglutination or other surface activities of red cells can be gotten by studying the properties of the modified cells further.

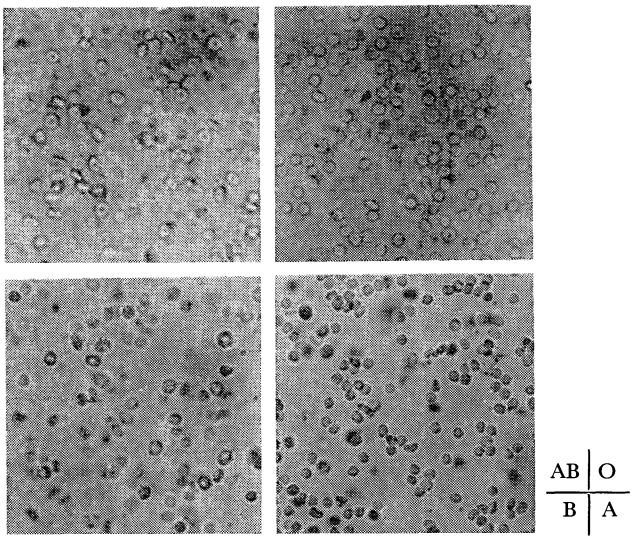

Fig. 2. Micro photographs of the modified red cells of the A, B, O, and AB blood group, suspended in plasma of the A blood group.

Properties of Hemoglobin. Figure 3 shows the visible absorption spectra of the red cells modified by TDI. The spectra for both the oxygenated state and the deoxygenated state are identical with that for normal blood, except that the peak intensity at 430 nm of the deoxygenated is slightly low. Figure 4 shows the oxygenation curves of the modified cells and intact cells. It is known that the hemoglobin within the modified cell retains the property to combine and to release molecular oxygen reversible in relation to the partial pressure of oxygen. It may be seen in the figure that hemoglobin within the modified cell has a higher oxygen affinity than normal hemoglobin, and that the

slope of the curve over the 10 to 90% oxygenated region is less steep. The n value, as calculated by using Hill's equation,[15] is 1.7. This is an intermediate value between 2.8 for normal hemoglobin and 1.0 for myoglobin. These changes in the oxygenation curve are considered to correspond to the decrease in the cooperation of hemoglobins or in the heme-heme interaction.

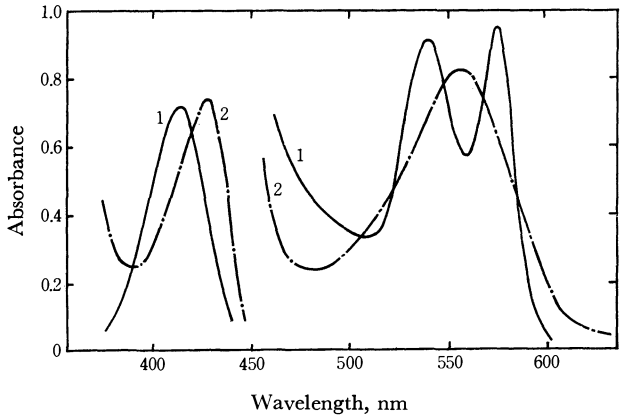

Fig. 3. Absorption spectra of the modified red cells.
(1) oxygenated; (2) deoxygenated with sodium hydrosulfite.
(The normal red cells give almost same absorption spectra as this figure.)

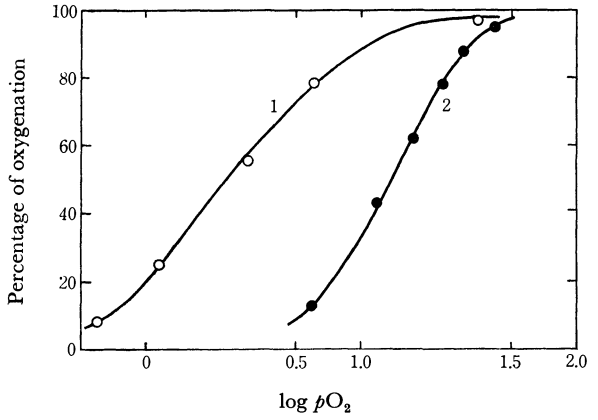

Fig. 4. Oxygenation curves of hemoglobin at pH 6.5. (1) the modified cells; (2) intact cells.

It is known that the absence of organic phosphates, such as D-2,3-diphosphoglycerate, or adenosine triphosphate, makes the oxygen affinity of hemoglobin higher.[16] It is considered that hemoglobins are not affected by the modification reaction, but some steric change or dissociation of the molecules may take place. On the other hand, it is also possible that the permeability of the cell membrane increases and that the organic phosphates within the cell come out, resulting in the high oxygen affinity. Further studies are necessary to ascertain the reasons and to find a way to protect hemoglobin from this change.

Reaction Sites. The facts described hitherto give us an idea of the modification reaction, that TDI reacts rapidly and selectively with specific components of the cell membrane to reinforce it, while the hemoglobin within the cell is kept unreacted. Figures 5 and 6 show the IR spectra of stroma and hemoglobin. The spectral samples of the modified cells were prepared through a process of lysis with sodium dodecylbenzenesulfonate, centrifugal separation of the stroma from the hemoglobin solution, and drying. Some differences can be seen between the spectrum of stroma separated from the modified cells and that for the intact cells. A sharp absorption band at 2250 cm^{-1} due to the stretching vibration of the isocyanate group, and additional bands at 805 and at 865 cm^{-1} corresponding to the out-of-plane deformation vibration of hydrogen on the 1,2,4-tri-substituted aromatic ring, appear in the spectrum for the modified stroma. On the other hand, the spectrum of the hemoglobin recovered from the modified cells is almost identical with that for the intact cells. This indicates that the hemoglobin is kept unreacted.

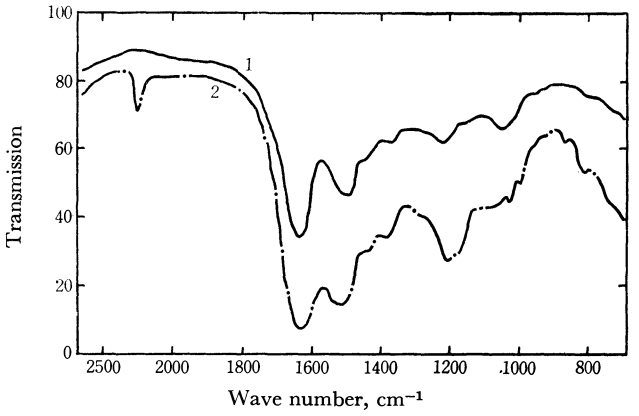

Fig. 5. IR spectra of stroma separated from (1) intact cells and (2) the modified cells.

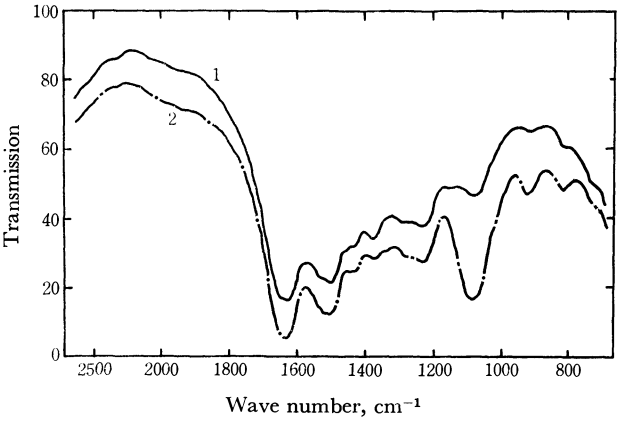

Fig. 6. IR spectra of hemoglobin separated from (1) intact cells and (2) the modified cells.

It is known that isocyanates react with compounds containing active hydrogen to give addition products. The order of reactivity on the bases of functional groups has been reported to be as follows:[17]

15) $Y=Kp^n/(1+Kp^n)$ where Y represents the oxygenated rate at partial pressure of oxygen being p mmHg, and K is the dissociation constant of oxygenated hemoglobin.

17) J. M. Buist and H. Dudgeon Ed., "Advances in Polyurethane Technology," J. Wiley and Sons Inc., New York (1968), p. 8.

Aliphatic NH_2>aromatic NH_2>primary OH>water>secondary OH>tertiary OH>phenolic OH>COOH and RNHCONHR'>RCONHR'>RNHCOOR'

As the modification reaction proceeds in an aqueous suspension, the reaction sites must have more isocyanate-reactive groups than water such as amino and primary hydroxy group. Other functional groups, carboxy, carbamoyl, imino, mercapto, formyl, *etc.*, may be kept unreacted. Diisocyanates are known as a kind of bridging reagents for enzymes and proteins.[18] It has been reported that the lysine residue was attacked exclusively in the treatment of pancreatic ribonuclease with hexamethylene diisocyanates.[19]

It has also been reported that comparatively large amounts of lysine and arginine residues are in the red-cell membrane as components of the protein.[20] Other components which have reactive groups are the cephalin and plasmalogens in the lipid layer and the serine residue in the protein. The isocyanate molecules must react with these components and reinforce the cell membrane through inter- or intra-molecular cross-linkings. It is reasonable to consider that ionic interaction between the polarized isocyanate group and polar group on the cell surface, or hydrophobic interaction between the hydrophobic group of the reagent and lipids in the membrane, gives some additional selectivity to the reaction.

One of the reactants must be the blood-group factor itself or one that is closely related to the agglutination phenomena. The isocyanate molecules may combine directly with it or mask the active site sterically, so that agglutination is inhibited. It is left for further studies now in progress to ascertain the exact mechanism of the modification reaction.

The authors wish to thank Professor S. Kimoto of the University of Tokyo, and Dr. S. Fujisawa and Dr. S. Ooba of Fuji Photo Film Co., Ltd., for their encouragements.

Studies of Peptide Antibiotics. XXIII. Syntheses of Linear Decapeptide Analogs with Gramicidin S Sequence

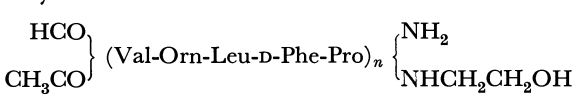
Satoru MAKISUMI, Michinori WAKI, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received June 13, 1970)

Six linear decapeptides having the same sequence of amino acids of gramicidin S, wherein the *N*-terminal amino acid is acylated with formyl or acetyl group, the *C*-terminal amino acid is in a form of its amide or ethanolamide and the *N*,*C*-terminal ones are free, were synthesized to obtain a more reliable picture of the cyclic structure to the antibacterial activity of gramicidin S. All these linear decapeptide analogs were found to be active to some extent against several microorganisms.

As a part of the program to synthesize linear analogs of gramicidin S, the syntheses of decapeptide analogs (II)[1] were undertaken. These compounds differ from gramicidin S in two ways: (a) they are non-cyclic and (b) both their terminal residues are blocked with an acyl and an amide group found in nature. Antibacterial assays of these analogs may clarify the influence of the cyclic structure of gramicidin S to its antibacterial activity.



I (n=1), II (n=2)

H-(Val-Orn-Leu-D-Phe-Pro)$_2$-OH

III

It has been reported[2] that pentapeptide analogs (I) of this type were found to possess no antibacterial activity, although Erlanger and Goode[3] reported that *N*,*C*-terminal free linear decapeptide (III) having the gramicidin S sequence was found to possess weaker activity than gramicidin S itself. In order to obtain a more reliable picture of the cyclic structure to the antibacterial activity of gramicidin S, the activities of various synthetic linear peptides were compared with that of natural peptide. The present paper describes the syntheses and antibacterial properties of several acyl decapeptide amide analogs and the *N*,*C*-terminal free decapeptide which is used as a reference compound.

The steps involved in the syntheses of the acyl decapeptide amide analogs are shown in Fig. 1.[4] The reaction schemes are similar to those of the pentapeptide analogs[2] in general. For removal of the BOC

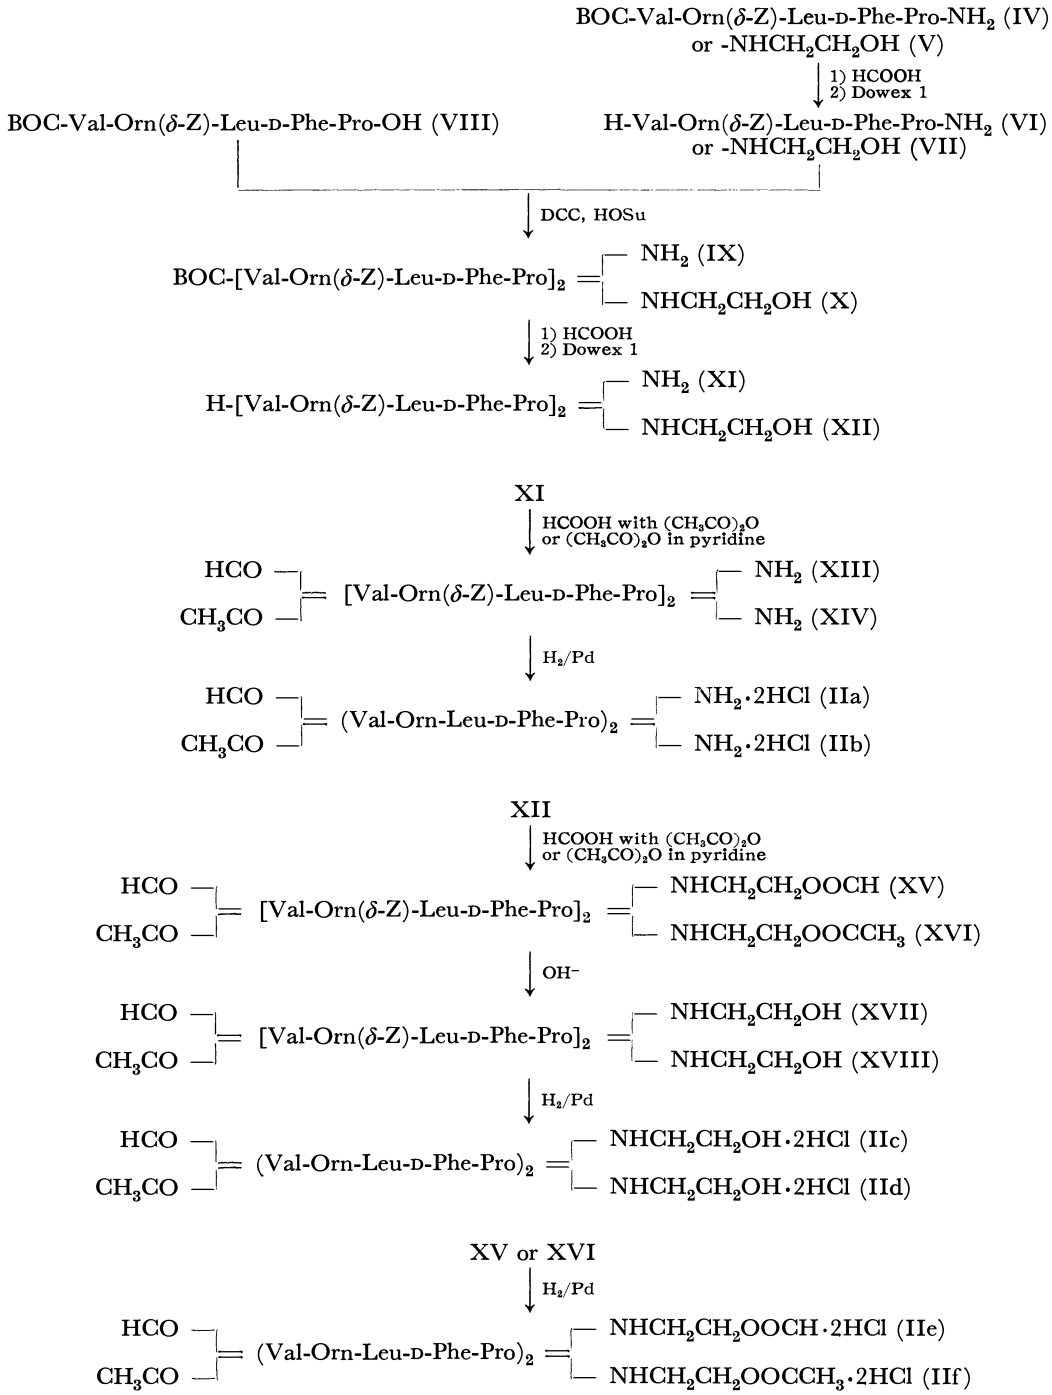

Fig. 1. Synthetic schemes of the acyl decapeptide amides.

group, 98% formic acid was used as reported by Halpern and Nitecki.[5] This method is good enough to prevent the partial deblocking of the Z groups in a peptide. Removal of the BOC group from BOC-pentapeptide amides (IV and V) by treatment with 98% formic acid and subsequent neutralization with Dowex 1 in methanol yielded free base of the pentapeptide amides (VI and VIII), respectively. Further purification of the products with column chromatography on CM-cellulose used in a previous work[2] was not needed in these cases, since the Z group remained intact.

Condensation of BOC-pentapeptide acid (VIII)[6] with VI or VII by the DCC-HOSu procedure[7] gave BOC-decapeptide amide derivative (IX or X) in a good yield. Purification of the crude product was performed by filtration over a column of Dowex 50 (H^+ form) and a Dowex 1 (OH^- form) in methanol. The method, reported by Sarges and Witkop,[8] was

very useful for removing the contaminated amine and acid components in the fully protected peptide product obtained by coupling of the two components. Removal of the BOC group from IX or X by treatment with formic acid yielded a crystalline product of *N*-terminal free decapeptide amide derivative (XI or XII).

Acylation of the decapeptide amide (XI) with formic acid - acetic anhydride[9] or with acetic anhydride in pyridine[10] afforded formyl or acetyl decapeptide amide derivative (XIII or XIV). Removal of the Z groups from XIII or XIV by catalytic hydrogenation in the presence of hydrogen chloride in methanol provided formyl or acetyl decapeptide amide as dihydrochloride (IIa or IIb). On the other hand, acylation of decapeptide ethanolamide (XII) by the methods described above gave *N,O*-diacyl decapeptide derivative (XV or XVI) which was then converted to *N*-monoacyl derivative (XVII or XVIII) by saponification with alkali. Hydrogenolyses of XVII, XVIII, XV, and XVI in the presence of hydrogen chloride afforded *N*-acyl decapeptide ethanolamide analogs (IIc and IId) and *N,O*-diacyl decapeptide ethanolamide analogs (IIe and IIf) as hydrochloride, respectively. The final products IIa, IIb, IIc, IId, IIe, and IIf were shown to be practically homogeneous by thin-layer chromatography and paper electrophoresis. However, the formyl analogs (IIa, IIc, and IIe) were found to be contaminated with a minute amount of the deformylated peptides by paper electrophoresis as shown in Fig. 3. Attempts to remove these impurities have so far not been successful. It seems likely that the formyl group in these peptides is appreciably labile.

Erlanger *et al.* synthesized the *N,C*-terminal free decapeptide (III) by treatment of Z-[Val-Orn(δ-Tos)-Leu-D-Phe-Pro]$_2$-OH with sodium in liquid ammonia.[11] In this study, compound III was prepared *via* a different route shown in Fig. 2. Condensation of VIII with the formate (XIX) of neutral pentapeptide in the presence of two equivalents of triethylamine by the DCC-HOSu procedure gave BOC-decapeptide acid derivative (XX). Removal of BOC group from XX by an exposure to formic acid and subsequent crystallization in the presence of hydrogen chloride yielded *N,C*-terminal free decapeptide derivative as monohydrochloride (XXI). Catalytic hydrogenation of XXI gave III which was crystallized as trihydrochloride.

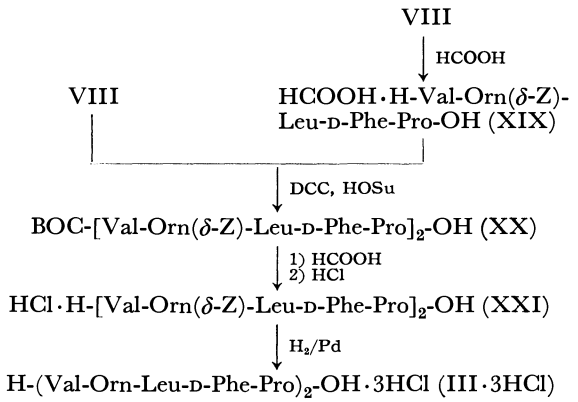

Fig. 2. Synthetic scheme of the *N,C*-terminal free decapeptide analog.

Comparison of the antibacterial activity of gramicidin S with that of the synthetic peptides showed that all of the linear decapeptide analogs have antibacterial activity against several microorganisms, though the activity is not so high compared with natural peptide (Table 1). It is of interest to note that the *N,C*-terminal free decapeptide (III) showed the same high activity as formyl-decapeptide amide (IIa) on Gram positive microorganisms, *S. aureus* and *B. subtilis*. The results we obtained have led us to conclude that even though the cyclic structure of gramicidin S is not essential for antibacterial activity, the specific activity of this compound is related to its unique cyclic structure.

Experimental

Melting points are uncorrected. The purity of the peptide intermediates after each synthetic step was ascertained by thin layer chromatography on silica gel plate. R_f^A refers to the solvent system chloroform-benzene-methanol (6 : 3 : 1, *v/v*) and R_f^B to the system chloroform-methanol (5 : 1, *v/v*). Homogeneity of the final product was confirmed by thin layer chromatography and by electrophoresis on paper. The solvent systems used are abbreviated as follows: C, ethyl acetate-pyridine-acetic acid-water (60 : 20 : 6 : 11, *v/v*); D, *n*-butanol-acetic acid-water (4 : 1 : 4, *v/v*); E, *sec*-buthanol-formic acid-

water (4 : 1 : 1, *v/v*). Gramicidin S was taken as the referene compound for the linear analogs and R_f^{GS} refers to the ratio of the distance which substances traveled to that which gramicidin S traveled from the origin on the same chromatogram. Paper electrophoresis was carried out on Toyo Roshi No. 50 with formic acid-acetic acid-methanol-water (1 : 3 : 6 : 10, *v/v*) buffer of pH 1.8. Electrophoretic mobilities are recorded as R^{His}, the ratio of the distance the compounds moved to that which a standard histidine spot moved on the same electrophoreogram. Compounds possessing free amino group were detected by spraying with ninhydrin and those with blocked amino groups by deblocking with 47% hydrobromic acid followed by staining with ninhydrin. Prior to microanalysis, desiccated samples were opened in air to a constant weight. Air dried samples were also subjected to measurement of specific rotation and $[\alpha]_D$ refers to 1% solution in methanol at 23°C unless otherwise noted.

The following compounds were prepared as described previously.[2] BOC-Val-Orn(δ-Z)-Leu-D-Phe-Pro-NH_2 (IV), BOC-Val-Orn(δ-Z)-Leu-D-Phe-Pro-$NHCH_2CH_2OH$ (V) and BOC-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH (VIII).

H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-NH_2 (VI). BOC-pentapeptide amide (IV, 823 mg, 1 mmol) was dissolved in 25 m*l* of 98% formic acid and the solution kept at room temperature for 3 hr. The reagent was then removed *in vacuo* (bath temperature <30°C)and the residue was triturated with ether. The crude solid (formate) was dissolved in 10 m*l* of methanol and the solution was filtered over a column (1.2×8 cm) of Dowex 1 (OH^- form preserved in methanol). The effluent and washings were combined and the solution was evaporated *in vacuo*. The resulting residue was crystallized by addition of ether. The product was collected by filtration, yield 671 mg (93%), mp 118—122°C, $[\alpha]_D$ −68.1°, R_f^A 0.27, R_f^B 0.62.

Found: C, 62.12; H, 7.84; N, 13.02%. Calcd for $C_{38}H_{55}N_7O_7 \cdot H_2O$: C, 61.69; H, 7.77; N, 13.25%.

H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-$NHCH_2CH_2OH$ (VII). Treatment of 866 mg (1 mmol) of V with 25 m*l* of 98% formic acid followed by crystallization and filtration over a column of Dowex 1 as described above gave 728 mg (95%) of peptide ethanolamide, mp 102—104°C, $[\alpha]_D$ −66.5°, R_f^A 0.29, R_f^B 0.63.

Found: C, 61.61; H, 7.99; N, 12.28%. Calcd for $C_{40}H_{59}N_7O_8 \cdot H_2O$: C, 61.28; H, 7.84; N, 12.51%.

BOC-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-NH_2 (IX). A suspension of 412 mg (0.5 mmol) of BOC-pentapeptide acid (VIII), 361 mg (0.5 mmol) of pentapeptide amide (VI) and 58 mg (0.5 mmol) of HOSu in a mixture of dioxane (5 m*l*) and dimethylformamide (4 m*l*) was cooled in an ice-salt bath. DCC (103 mg, 0.5 mmol) was added to the chilled solution and the mixture was stirred under cooling; meanwhile the suspension dissolved to form a clear solution. After it had been allowed to stand overnight at room temperature, the reaction mixture was stirred again with a few drops of water for 1 hr at 0°C. Crystals of dicyclohexylurea were removed by filtration and washed with cold dioxane. The filtrate and washings were evaporated to a small volume and the residual syrup was solidified by the addition of ice water. The solid obtained was collected by filtration, washed successively with water, 4% sodium bicarbonate, 10% citric acid and water, and dried. The product was dissolved in ethyl acetate and a small amount of insoluble dicyclohexylurea was removed. The filtrate was evaporated and the residue was crystallized by the addition of ether. Further purification was carried out as follow. The crystals were dissolved in 10 m*l* of methanol and the solution was filtered on a series of columns (1.2×8 cm, each) of Dowex 50 (H^+ form) and Dowex 1 (OH^- form) which were equilibrated with methanol. The effluent and the washings were evaporated and the residue was crystallized by the addition of ether and petroleum ether. The product was recrystallized from ethyl acetate-ether, yield 629 mg (82%), mp 203—205°C, $[\alpha]_D$ −123°, R_f^A 0.40.

Found: C, 63.19; H, 7.56; N, 11.64%. Calcd for $C_{81}H_{115}N_{13}O_{16} \cdot H_2O$: C, 62.97; H, 7.63; N, 11.79%.

BOC-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-$NHCH_2CH_2OH$ (X). By the DCC-HOSu method as described above, 823 mg (1 mmol) of VIII was allowed to couple with 766 mg (1 mmol) of pentapeptide ethanolamide (VII) in the presence of equimolar amount of DCC and HOSu. The product was purified as above to give 1399 mg (89%) of BOC-decapeptide ethanolamide, mp 127—130°C, $[\alpha]_D$ −110°, R_f^A 0.45.

Found: C, 62.45; H, 7.69; N, 11.28%. Calcd for $C_{83}H_{119}N_{13}O_{17} \cdot H_2O$: C, 62.74; H, 7.68; N, 11.46%.

H-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-NH_2 (XI). Treatment of 534 mg (0.35 mmol) of BOC-decapeptide amide (IX) with 10 m*l* of 98% formic acid followed by evaporation, crystallization and filtration on a column of Dowex 1 as described for the preparation of pentapeptide amide (VI) gave 481 mg (96%) of XI, mp 199—200°C, $[\alpha]_D$ −136°, R_f^A 0.30, R_f^B 0.66.

Found: C, 62.91; H, 7.56; N, 12.43%. Calcd for $C_{76}H_{107}N_{13}O_{14} \cdot 1.5H_2O$: C, 62.79; H, 7.63; N, 12.53%.

H-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-$NHCH_2CH_2OH$ (XII). Removal of the BOC group from 1304 mg (0.83 mmol) of BOC-decapeptide ethanolamide (X) by treatment with 98% formic acid followed by neutralization with Dowex 1 afforded 1185 mg (97%) of *N*-terminal free decapeptide ethanolamide, mp 114—116°C, $[\alpha]_D$ −123°, R_f^A 0.34, R_f^B 0.68.

Found: C, 62.52; H, 7.80; N, 11.93%. Calcd for $C_{78}H_{111}N_{13}O_{15} \cdot 1.5H_2O$: C, 62.55; H, 7.67; N, 12.16%.

HCO-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-NH_2 (XIII). To a solution of 200 mg (0.14 mmol) of decapeptide amide (XI) dissolved in 5 m*l* of 99.8% formic acid at 0°C was added 1.5 m*l* of acetic anhydride over a period of 15 min under stirring, and the mixture was kept at 0°C for 30 min at room temperature overnight. The solvent was removed *in vacuo* and the residue was triturated with ice water. The solid obtained was collected by filtration and dried. It was recrystallized from ethyl acetate-petroleum ether, yield 193 mg (95%), mp 215—216°C, $[\alpha]_D$ −145°, R_f^A 0.33.

Found: C, 62.03; H, 7.56; N, 12.05%. Calcd for $C_{77}H_{107}N_{13}O_{15} \cdot 2H_2O$: C, 62.04; H, 7.51; N, 12.21%.

CH_3CO-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-NH_2 (XIV). To a solution of 200 mg of XI in 5 m*l* of anhydrous pyridine, cooled in an ice-salt bath, 1.5 m*l* of acetic anhydride was added dropwise during a period of 10 min under stirring, and the mixture was kept in an ice-salt bath for 30 min at room temperature overnight. After the solvent had been evaporated, the oily product was solidified by the addition of ice water. The solid obtained was collected by filtration and dried. It was recrystallized from ethyl acetate-petroleum ether, yield 202 mg (98%), mp 230—232°C, $[\alpha]_D$ −133°, R_f^A 0.37.

Found: C, 62.48; H, 7.57; N, 12.00%. Calcd for $C_{78}H_{109}N_{13}O_{15} \cdot 2H_2O$: C, 62.26; H, 7.57; N, 12.10%.

HCO-(Val-Orn-Leu-D-Phe-Pro)$_2$-$NH_2 \cdot 2HCl$ (IIa). A solution of 102 mg (0.07 mmol) of formyl decapeptide amide (XIII) in 6 m*l* of methanol containing 0.7 m*l* of N/10 hydrochloric acid was hydrogenated in the presence of palladium black. After 3 hr, 0.7 m*l* of the hydrochloric acid was added and hydrogenation was continued. Completion of hydrogenolysis was confirmed by thin-layer chromatography. Palladium black was filtered off and the solution was evaporated *in vacuo*. When the residue was triturated with ether peptide was obtained as a crystalline hydrochloride. Recrystallization from methanol-ether gave 83 mg (94%), mp 247—

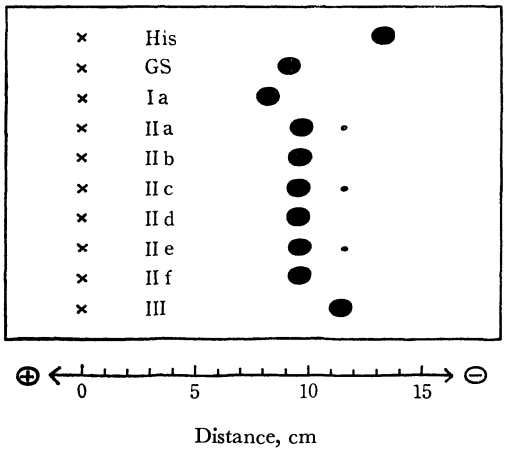

Fig. 3. Paper electrophoretic patterns of gramicidin S and its linear penta- and decapeptide analogs.
Buffer: formic acid-acetic acid-methanol-water (1 : 3 : 6 : 10, *v/v*) of pH 1.8. Duration: 600 V, 2 hr.

248°C, $[\alpha]_D$ −155°; R_f^{GS} 0.88(C), 0.90(D), 0.69(E); R^{His} 0.73.

Found: C, 53.42; H, 8.01; N, 13.32%. Calcd for $C_{61}H_{95}N_{13}O_{11}\cdot 2HCl\cdot 6H_2O$: C, 53.58; H, 8.03; N, 13.32%.

The product was contaminated with a minute amount of the deformylated derivative which was deduced from its higher electrophoretic mobility (R^{His} 0.87) (Fig. 3). Attempts to remove it have so far not been successful.

CH_3CO-(Val-Orn-Leu-D-Phe-Pro)$_2$-$NH_2\cdot 2HCl$ (IIb). When 103 mg (0.07 mmol) of XIV was hydrogenated as described above, after recrystallization from methanol - ether, 86 mg (97%) of the acetyl decapeptide amide dihydrochloride was obtained, mp 245—246°C, $[\alpha]_D$ −134°; R_f^{GS} 0.90(C), 0.80(D), 0.67(E); R^{His} 0.74.

Found: C, 53.59; H, 7.99; N, 13.16%. Calcd for $C_{62}H_{97}N_{13}O_{11}\cdot 2HCl\cdot 6H_2O$: C, 53.90; H, 8.10; N, 13.18%.

HCO-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-$NHCH_2CH_2OOCH$ (XV). Formylation of 441 mg (0.3 mmol) of the decapeptide ethanolamide (XII) was carried out in 10 m*l* of 99.8% formic acid with 3 m*l* of acetic anhydride in a similar manner to that employed for the preparation of XIII. Recrystallization from ethyl acetate-petroleum ether gave 441 mg (96%) of the diformyl decapeptide ethanolamide, mp 153—155°C, $[\alpha]_D$ −136°, R_f^A 0.38, R_f^B 0.60.

Found: C, 62.12; H, 7.44; N, 11.46%. Clacd for $C_{80}H_{111}N_{13}O_{17}\cdot H_2O$: C, 62.20; H, 7.37; N, 11.79%.

CH_3CO-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-$NHCH_2CH_2OOCCH_3$ (XVI). Acetylation of 441 mg of XII was carried out in 10 m*l* of pyridine with 3 m*l* of acetic anhydride in a similar manner to that employed for the preparation of XIV. Recrystallization from ethyl acetate-petroleum ether gave 444 mg (95%) of the diacetyl decapeptide ethanolamide, mp 179—181°C, $[\alpha]_D$ −123°, R_f^A 0.43. R_f^B 0.61.

Found: C, 62.54; H, 7.50; N, 11.45%. Calcd for $C_{82}H_{115}N_{13}O_{17}\cdot H_2O$: C, 62.62; H, 7.50; N, 11.58%.

HCO-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-$NHCH_2CH_2OH$ (XVII). A solution of 242 mg (0.16 mmol) of the diformyl derivative (XV) in 15 m*l* of methanol was saponified with 0.8 m*l* of N sodium hydroxide for 2 hr at room temperature. The reaction mixture was filtered over a column (1.8×8 cm) of Dowex 50 (H^+ form, equilibrated with methanol) and the effluent and washings were evaporated. The residue was dissolved in a mixture of methanol and ethyl acetate, and the solvent was removed. After this treatment had been repeated twice, the residue was crystallized by the addition of ether to yield 213 mg (89%), mp 148—150°C, $[\alpha]_D$ −132°, R_f^A 0.37.

Found: C, 62.47; H, 7.57; N, 11.74%. Calcd for $C_{79}H_{111}N_{13}O_{16}\cdot H_2O$: C, 62.56; H, 7.51; N, 12.00%.

CH_3CO-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-$NHCH_2CH_2OH$ (XVIII). Saponification of 233 mg (0.15 mmol) of XVI in 15 m*l* of methanol with 0.75 m*l* of N alkali as described above gave 219 mg (96%) of the monoacetyl derivative, mp 230—233°C, $[\alpha]_D$ −121°, R_f^A 0.40.

Found: C, 62.73; H, 7.57; N, 11.74%. Calcd for $C_{80}H_{113}N_{13}O_{16}\cdot H_2O$: C, 62.77; H, 7.57; N, 11.89%.

HCO-(Val-Orn-Leu-D-Phe-Pro)$_2$-$NHCH_2CH_2OH\cdot 2HCl$ (IIc). Hydrogenolysis of 105 mg (0.07 mmol) of XVII in 5 m*l* of methanol with 1.4 m*l* of N/10 hydrochloric acid as has been described for the preparation of IIa gave, after recrystallization from methanol - ether, 87 mg (96%) of the dihydrochloride of monoformyl decapeptide ethanolamide, mp 239—241°C, $[\alpha]_D$ −142°; R_f^{GS} 0.83(C), 0.82(D), 0.66(E); R^{His} 0.73.

Found: C, 53.99; H, 7.88; N, 13.02%. Calcd for $C_{63}H_{99}N_{13}O_{12}\cdot 2HCl\cdot 5H_2O$: C, 54.30; H, 8.03; N, 13.07%. This material was contaminated with a minute amount of the deformylated derivative (R^{His} 0.88).

CH_3CO-(Val-Orn-Leu-D-Phe-Pro)$_2$-$NHCH_2CH_2OH\cdot 2HCl$ (IId). By hydrogenolysis of 106 mg (0.07 mmol) of XVIII in methanol in the presence of hydrogen chloride, after recrystallization from methanol - ether, 88 mg (96%) of the dihydrochloride of monoacetyl decapeptide ethanolamide was obtained, mp 226—227°C, $[\alpha]_D$ −124°; R_f^{GS} 0.93(C), 0.76 (D), 0.58(E); R^{His} 0.72.

Found: C, 54.68; H, 8.09; N, 12.99%. Calcd for $C_{64}H_{101}N_{13}O_{12}\cdot 2HCl\cdot 5H_2O$: C, 54.61; H, 8.09; N, 12.94%.

HCO-(Val-Orn-Leu-D-Phe-Pro)$_2$-$NHCH_2CH_2OOCH\cdot 2HCl$ (IIe). Hydrogenolysis of 93 mg (0.06 mmol) of the diformyl derivative (XV) in 7 m*l* of methanol in the presence of hydrogen chloride for 5 hr gave, after recrystallization from methanolether, 76 mg (95%) of the diformyl decapeptide ethanolamide dihydrochloride, mp 234—236°C, $[\alpha]_D$ −138°; R_f^{GS} 0.91(C), 0.76(D), 0.65(E); R^{His} 0.71.

Found: C, 53.62; H, 7.83; N, 12.91%. Calcd for $C_{64}H_{99}N_{13}O_{13}\cdot 2HCl\cdot 6H_2O$: C, 53.39; H, 7.91; N, 12.65%.

The product was contaminated with a minute amount of the deformylated derivative (R^{His} 0.87).

CH_3CO-(Val-Orn-Leu-D-Phe-Pro)$_2$-$NHCH_2CH_2OOCCH_3\cdot 2HCl$ (IIf). By hydrogenolysis of 93 mg (0.06 mmol) of the diacetyl derivative (XVI) in 7 m*l* of methanol in the presence of hydrogen chloride 77 mg (94%) of the dihydrochloride of diacetyl decapeptide ethanolamide was obtained, mp 220—222°C, $[\alpha]_D$−119°; R_f^{GS} 0.84(C), 0.84(D), 0.71(E); R^{His} 0.73.

Found: C, 54.27; H, 7.83; N, 12.53%. Calcd for $C_{66}H_{103}N_{13}O_{13}\cdot 2HCl\cdot 6H_2O$: C, 54.01; H, 8.04; N, 12.41%.

H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH·HCOOH (XIX). BOC-pentapeptide acid (VIII; 101 mg, 0.123 mmol) was dissolved in 2 m*l* of 98% formic acid and the solution was kept at room temperature for 2 hr. The solvent was removed *in vacuo* and the residue was solidified by the addition of ethyl acetate and ether. The product was collected by filtration and washed with ether. The very hygroscopic material was dried in a vacuum; yield 96 mg (99%), R_f^A 0.66, R_f^B 0.34. The formate was used for the next reaction without further purification, since the free pentapeptide had not been crystallized.[6]

BOC-[Val-Orn(δ-Z)-Leu-D-Phe-Pro]$_2$-OH (XX). To a solution of 101 mg of VIII and 14 mg (0.123 mmol) of HOSu in 2 m*l* of dioxane, 25 mg (0.123 mmol) of DCC was added at 5°C and the reaction mixture was stirred for 2 hr. To this solution was added a solution of pentapeptide formate (XIX; 96 mg, 0.122 mmol) in dioxane (3 m*l*) and dimethylformamide (2m*l*) containing 0.034 m*l* (0.244 mmol) of triethylamine, and the mixture was left to stand overnight in

a refrigerator. Crystals of dicyclohexylurea were removed by filtration and washed with dioxane. The filtrate and washings were concentrated to a small volume and the urea deposited further was filtred off. The filtrate was evaporated and the resulting syrup was solidified by the addition of water. The solid was collected by filtration, washed successively with water, 10% citric acid and water, and dried. The dried material was dissolved in 10 m*l* of methanol and filtered over a column (1.2×4 cm) of Dowex 50 (H^+ form) and the filtrate was evaporated. The residue crystallized upon the addition of ether. Recrystallization from methanol-ether gave 160 mg (95%) of the pure peptide, mp 173—175°C, $[\alpha]_D^{25}$ −109°, R_f^A 0.08, R_f^B 0.55.

Found: C, 61.56; H, 7.53; N, 10.86%. Calcd for $C_{81}H_{114}N_{12}O_{17}\cdot 3H_2O$: C, 61.50; H, 7.65; N, 10.63%.

*H-[Val-Orn(δ-Z)-Leu-*D*-Phe-Pro]$_2$-OH·HCl (XXI).* Compound XX (76 mg, 0.05 mmol) was dissolved in 3 m*l* of 98% formic acid and kept at room temperature for 90 min. The solvent was removed and the residue was dissolved in methanol containing 0.55 m*l* of N/10 hydrochloric acid. The solution was evaporated and the residue was dried over sodium hydroxide in a vaccum. The material obtained was then dissolved in a minute volume of methanol and precipitated by the addition of 10 m*l* of petroleum ether. Recrystallization from methanol-petroleum ether gave 69 mg (95%), mp 155—157°C, $[\alpha]_D^{30}$ −132°, R_f^A 0.10, R_f^B 0.57.

Found: C, 59.66; H, 7.30; N, 10.96%. Calcd for $C_{76}H_{106}N_{12}O_{15}\cdot HCl\cdot 4H_2O$: C, 59.42; H, 7.54; N, 10.94%.

*H-(Val-Orn-Leu-*D*-Phe-Pro)$_2$-OH·3HCl (III·3HCl).* By hydrogenolysis of 59 mg (0.04 mmol) of XXI in methanol containing an excess of hydrogen chloride in a similar manner to that employed for the preparation of IIa 49 mg (96%) of the trihydrochloride of the peptide was obtained, mp 233—234°C; $[\alpha]_D$ −135°; R_f^{GS} 0.77(C), 0.72(D), 0.70(E); R^{His} 0.86. Reported values, mp 233°C, $[\alpha]_D^{28}$ −89° (0.5N HCl).[11]

Found: C, 51.83; H, 7.90; N, 12.07%. Calcd for $C_{60}H_{94}N_{12}O_{11}\cdot 3HCl\cdot 6.5H_2O$: C, 52.00; H, 8.00; N, 12.13%.

Microbiological Assay.[12] The minimum amount of compounds needed for the complete inhibition of growth was determined by a dilution method with 10^3—10^4 organisms per milliliter using a Sabouraud bouillon as an incubation medium (Heart Infusion Broth for pre-incubation). The antibacterial activities of the decapeptide analogs are listed in Table 1.

12) We are indebted to Meiji Seika Co., Ltd. for the microbiological assays.

Studies on *s*-Triazines. VII. A New Method of Preparing 2-Methyl-4,6-bis(trichloromethyl)-*s*-triazine[1,2]

Ko WAKABAYASHI, Masaru TSUNODA, and Yasushi SUZUKI

Market Development Research Laboratory, Mitsubishi Chemical Industries Ltd., Kamoshida-cho, Midori-ku, Yokohama-shi, Kanagawa

(Received June 16, 1970)

During the liquid-phase chlorination of CH_3CN, a trimerization reaction occurred to yield four *s*-triazine derivatives, 2-methyl-4,6-bis(trichloromethyl)-*s*-triazine (I), 2-chloromethyl-4,6-bis(trichloromethyl)-*s*-triazine (II), 2-dichloromethyl-4,6-bis(trichloromethyl)-*s*-triazine (III), and 2,4,6-tris(trichloromethyl)-*s*-triazine (IV). The structure of each *s*-triazine derivative has been assigned on the basis of the results of elemental analysis and the spectral (particularly Mass and NMR) data after each derivative had been separated in a pure form using the gas-liquid chromatographic (GLC) method. The product composition was seen to depend upon the rate of the chrorination of CH_3CN and the presence of a catalyst. The *s*-triazine I was shown to be the precursor of the *s*-triazines II and III; the pathways for the formation of the *s*-triazine IV were also investigated. Then, the selective co-trimerization of CH_3CN with its chlorinated compounds was investigated; this yielded the *s*-triazine I, a useful intermediate of pesticides and resines. The reaction was found to provide a new method of preparing *s*-triazine I.

The *s*-triazine I is a valuable intermediate in the preparation of other substituted *s*-triazine derivatives, for example, the monoamino-[2,3] or diamino-*s*-triazines,[4,5] which are both extremely useful pesticides.[6-12] More-

over, the *s*-triazine I itself shows remarkable nitrification inhibitory activity[13] in soil.

It is known that the *s*-triazine I can be prepared by the chlorination[14] of 2,4,6-trimethyl-*s*-triazine (V) or by the co-trimerization[15] of CCl_3CN and CH_3CN.

Schaefer and Ross[14] reported an 89% yield of the *s*-triazine I when chlorine was added to a solution of the *s*-triazine V in acetic acid. The same reaction has been repeated in our laboratory, but their very high yield was not always achieved and a complex mixture of all the possible *s*-triazines (I, II, III, IV, V, and other less chlorinated (Cl_{1-5}) 2,4,6-trimethyl-*s*-triazines) resulted.

In our earlier paper in this series,[15] we have reported that the co-trimerization of CCl_3CN with CH_3CN gave *s*-triazine I selectively in high yields. Therefore, we have investigated the preparation of CCl_3CN, the starting monomer, by the chlorination of CH_3CN, wherein the formation of a large amount of *s*-triazine derivatives as a by-product was observed. Gas-liquid chromatographic (GLC) and mass spectroscopic (Mass) analyses proved that the mixture contained *s*-triazines I, II, III, and IV.

Therefore we have investigated the preparation of the *s*-triazine I in a high yield and with a high selectivity by the co-trimerization of CH_3CN with its chlorinated mixture, without isolating them. It has now been found that the chlorinated mixture of CH_3CN can be co-trimerized with CH_3CN so as to selectively afford the *s*-triazine I. We wish here to report this first technical method for the preparation of the *s*-triazine I.

Results and Discussion

CH_3CN was chlorinated by chlorine in the presence of HCl under UV irradiation in order to prepare CCl_3CN. Table 1 shows some typical results of the chlorination experiments. CCl_3CN was the sole obtainable chlorinated nitrile; CH_2ClCN or $CHCl_2CN$ was detected to only a negligible extent in GLC. In addition, a large amount of a white solid was also obtained as a by-product. The GLC analysis of the solid revealed four peaks (A, B(minor), C(minor) and D); the relative R_t values were A=0.38, B=0.71, C=0.82, D=1.00 (based on D=1.00). The A and D relative R_t values were the same as those of the *s*-triazines I and IV respectively.[15] B, separated by GLC, was found to be the *s*-triazine II by Mass- (*m/e* 361(M^+, molecular peak), 326(M^+-Cl), 325(M^+-HCl) *etc.*); NMR-(τ 5.08 ppm(singlet, CH_2Cl)) and IR-data (1552, 1522, 1346 cm^{-1} (*s*-triazine ring)). C was found

to be the *s*-triazine III by Mass- (*m/e* 395 (M^+, molecular peak), 360(M^+—Cl), 359(M^+—HCl) *etc.*); NMR- (τ 3.12 ppm(singlet, $CHCl_2$)) and IR-data (1550, 1518, 1346 cm^{-1} (*s*-triazine ring)).

The following two pathways are possible for the formation of the *s*-triazine I:

1) by the chlorination of the *s*-triazine V or 2,4-dimethyl-6-trichloromethyl-*s*-triazine (VI), or

2) by the co-trimerization of 2 moles of CCl_3CN with 1 mole of CH_3CN.

The latter is more likely, since the *s*-triazines V[16] and VI were not detected during the chlorination of CH_3CN nor during the co-trimerization of CCl_3CN with CH_3CN,[15] whereas the *s*-triazine I was the sole product when the molar ratio,[17] CCl_3CN/CH_3CN, was less than two in the co-trimerization.[14]

The *s*-triazines II and III may be produced by the chlorination of the *s*-triazine I,[18] because CH_2ClCN and $CHCl_2CN$ were not detected in the chlorination mixture of CH_3CN and because neither CH_2ClCN nor $CHCl_2CN$ could co-trimerize with CCl_3CN.[19]

The trimerization of CCl_3CN does not proceed smoothly in the absence of a Friedel-Crafts catalyst-hydrogen halide complex under ordinary pressure.[15,20] The treatment of the chlorinated mixture of CH_3CN with $AlBr_3$-HCl or with HCl resulted in an increased formation of the *s*-triazine IV (*cf.* Table 2). Apparently a large part of the *s*-triazine IV could be formed by the chlorination of the *s*-triazine I,[18] while a small part of it could arise from the trimerization of CCl_3CN.

On the basis of this experimental result that a large amount of *s*-triazine derivatives was obtained during the chlorination of CH_3CN, we have tested to obtain the *s*-triazine I in a high yield and high selectivity by treating a chlorinated mixture of CH_3CN with a catalyst without isolating CCl_3CN. For this purpose several experiments were carried out under various reaction conditions (see Table 2).

When chlorine was introduced into CH_3CN for less than 15 hr, and when this chlorinated mixture was then treated with a catalyst, the total yield of the *s*-triazine I was lower, as is shown in Table 2, although the selectivity of the *s*-triazine I was higher. On the other hand, when chlorine was introduced into CH_3CN for more than 21 hr and it was then co-trimerized, the total yield was higher, although the selectivity was lower. The total yield of *s*-triazines in Exp. B-1 was higher when the chlorinated mixture was treated with the $AlBr_3$-HCl catalyst after a long chlorination time, since the CCl_3CN produced successively could be converted into the *s*-triazine I and IV smoothly by the aid of this catalyst. The total yield of *s*-triazines in Exp. B-2 was rather lower than that in Exp. B-1. This may have been because CCl_3CN could not be converted into the *s*-triazine I smoothly, because there was little CH_3CN over a long chlorination time, and also because it was hard to convert it into the *s*-triazine IV by means of the HCl catalyst alone.

The best way to obtain the *s*-triazine I is to co-trimerize both nitriles, CCl_3CN and CH_3CN, when the specific gravity of the chlorinated mixture of CH_3CN reaches *ca.* 1.2 — molar ratio, CCl_3CN/CH_3CN, 40/60. The detailed experimental conditions or techniques will be described in the experimental part. The results show that the *s*-triazine I can be prepared in high yields by a less costly and convenient method.

Experimental

All the boiling points and melting points are uncorrected. The gas-liquid chromatography was performed with a Shimadzu GC-2B apparatus fitted with a thermal conductivity detector, with 70 ml/min of helium, and using a ϕ 4 mm×2 m column containing 20% DOP on Shimalite C at 100°C (GLC-1), or with such an apparatus fitted with a flame ionization detector, with 40 ml/min of nitrogen and using a ϕ 4 mm× 2 m column containing 5% SE-30 on Gaschrom P at 170°C (GLC-2). The IR* spectra were obtained with a JASCO model IR-G spectrometer. The NMR spectra were determined

16) *s*-Triazine V are obtainable from CH_3CN under high pressure using alkaline catalyst.[15]

17) *s*-Triazine IV, beside *s*-triazine I, could be also obtained when the molar ratio is more than two and the co-trimerization is carried out in the presence of Friedel-Crafts catalyst.[14]

18) To ascertain this chlorination pathway, *s*-triazine I was chlorinated under UV-irradiation and we obtained *s*-triazines II, III and IV besides the unreacted *s*-triazine I. (See Exp.-E).

at 60 Mc/Mc with a Varian A-60 spectrometer, using TMS the internal standard. The mass spectra were obtained on as a Hitachi RMU-6C spectrometer, using a direct inlet, an ion-accelerating voltage of 1800 V, an electron accelerating voltage of 80 eV, a total emission current of 80 μA, a temperature of the ionization chamber of 200°C, a sample temperature of 100°C, and a vacuum of 1×10^{-6} mmHg.

Materials. The CH_3CN was supplied by Kasei Mizushima, Ltd. The CCl_3CN was prepared by the chlorination of CH_3CN.[21] Authentic 2-methyl-4,6-bis(trichloromethyl)-*s*-triazine (I) and 2,4,6-tris(trichloromethyl)-*s*-triazine (IV) were prepared by the (co-)trimerization of CCl_3CN according to the previously-presented procedures of the present authors.[15] 2-Chloromethyl-4,6-bis(trichloromethyl)-*s*-triazine (II) and 2-dichloromethyl-4,6-bis(trichloromethyl)-*s*-triazine (III) were separated in a pure form with GLC-2 from the trimerized product of the chlorinated mixture of CCl_3CN.

A) Chlorination of CH_3CN. A 10-*l*, five-necked flask was equipped with an efficient mechanical stirrer, a thermometer, a gas-inlet tube reaching nearly to the bottom of the flask, an efficient reflux condenser protected at the top with a calcium chloride tube, and an immersion-type mercury lamp (10—15 W, 2537 Å, Taika Kogyo Co.). The gas-inlet tube was connected to a container of chlorine through a flow meter and a 500 m*l* bottle containing about 200 m*l* of concentrated H_2SO_4. The outlet tube at the back of the calcium chloride tube was connected with a gas-absorption trap in which the evolved HCl was absorbed by running water. It was best to set the apparatus up under a good hood.

In the flask 4.1 kg (100 mol) of CH_3CN were placed and saturated with 1.5 kg of dry HCl at 35—40°C. Then, a current of chlorine (22 kg, 310 mol) was introduced into the reaction mixture under UV irradiation, the temperature of which was maitained at 45—50°C. The rate of the flow of the chlorine (*ca.* 9.9 g per minute) had to be regulated, care being taken that the liquid remain as colorless as possible. This chlorination required about 38 hr; at intervals samples of the chlorinating mixture were taken out. By distillation, the samples were divided into two parts, the distillate (bp 56—88°C) and the residue, each of which was separated by GLC and analysed by spectroscopic methods.

Analysis of the Distillate. Two components were separated in GLC-1; their relative R_t values, 1.00 and 0.70 (based on R_t of CH_3CN, 1.00), were in fair agreement with those of authentic CH_3CN and CCl_3CN.

The component of $R_t=1.00$ (CH_3CN): Bp 81—83°C, n_D^{25} 1.34430, D_4^{15} 0.7875 (lit,[22] bp 81.6°C/760 mmHg, n_D^{30} 1.33934, D_4^{15} 0.78745). NMR ($CDCl_3$): τ 8.04 ppm (singlet, CH_3).

The Component of $R_t=0.70$ (CCl_3CN): Bp 84—86°C, n_D^{25} 1.43851, n_4^{15} 1.4418.

IR (liq. film, 0.05 mm): 2250 cm^{-1} (m, νC≡N), 1580(vw), 1374(vw), 1028(s), 971(m), 919(sh), 868(sh), 790(vs, νC–Cl), 648(w), 490(m).

NMR ($CDCl_3$): no signal.

Analysis of the Residue. Four components (A, B, C, D) were separated in GLC-2; their relative R_t values were A=0.38, B=0.71, C=0.82, D=1.00 (based on R_t of D, 1.00).

The Component A: The relative R_t value was same as authentic *s*-triazine I. Mp 96—97°C (lit,[15] mp 96—97°C).

B) Trimerization of Chlorinated Mixture. Each sample in Experimental-A) was also trimerized in the presence of $AlBr_3$-HCl (Exp. B-1) or HCl only (Exp. B-2). Dry HCl gas (*ca.* 100 g) was introduced into a mixture of the sampling solution (100 m*l*) and $AlBr_3$ (2 g) or the sampling solution (100 m*l*) only at −20—0°C with stirring. The reaction mixture was kept at room temperature for 12 hr to complete trimerization. After HCl gas was removed under reduced pressure by water pump, each residue was analized by GLC-2 (see Table 2).

C) Preparation of the s-Triazine I. In the manner similar to Exp.-A, 4.1 kg of CH_3CN was chlorinated by the use of 10.6 kg of chlorine. Thus, a chlorinated CH_3CN mixture (*ca.* 10 kg; D_4^{45} 1.1945, CCl_3CN/CH_3CN=43.3/56.7 by GLC-1) was obtained. Then 30 g of $AlBr_3$ was added to this mixture with stirring. The resultant mixture was saturated with anhydrous HCl (1 kg) at −20—0°C for 2 hr, and kept at room temperature for 12 hr to complete co-trimerization. The obtained solid was melted by heating at 100—110°C and poured into a large quantity of water to wash out HCl and catalyst. After being cooled to room temperature, the resolidified product was collected, dried in air and then analyzed by GLC-2. Yield 7.0 kg (63.6%). Mp 93—96°C (if a purer product is desired, it may be recrystallized from ethanol. mp 96—97°C).

Analysis of the Crude Product, Mp 93—96°C, by GLC-2. *Ca.* 100% purity of the *s*-triazine I, and trace of *s*-triazines II and III was indicated.

Elemental Analysis of the Recrystallized Product, Mp 96—97°C. Found: C, 21.96; H, 1.04; N, 12.62; Cl, 64.35%. Calcd for $C_6H_3N_3Cl_6$: C, 21.84; H, 0.92; N, 12.74; Cl, 64.49%.

D) Attempted Co-trimerization of CH_2ClCN or $CHCl_2CN$ with CCl_3CN. The mixture of CCl_3CN (2 mol), CH_2ClCN or $CHCl_2CN$ (1 mol), and $AlBr_3$ (5 g) was saturated with anhydrous HCl at −20—−10°C by cooling with a dry ice-methanol bath for 2 hr under stirring. The reaction mixture was then kept for 48 hr at room temperature. After a severe strong heating treatment[15] such as was used in the preparation of 2-alkyl-4,6-bis(trichloromethyl)-*s*-triazines, the *s*-triazine IV became the only trimerized product, while CH_2ClCN or $CHCl_2CN$ was recovered in every case.

E) Chlorination of the s-Triazine I. Chlorine (25 g, 3.5 mol) was passed into a solution of 330 g (1 mol) of the *s*-triazine I in 1000 m*l* of CH_3CN (or CH_3COOH) at 45—50°C under illumination from the same UV lamp as was used in Exp.-A for a 7 hr period. Then the reaction mixture was evaporated at ordinary pressure as completely as possible, leaving a semisolid residue of 354 g (or 375 g in the case of CH_3COOH solution). This residue, containing a small amount of the solvent, was then analyzed by GLC-2, Mass, and NMR.

NMR ($CDCl_3$): three singlets at τ 7.02 (CH_3), 5.08 (CH_2Cl), and 3.12 ppm ($CHCl_3$).

The Composition of the Product Mixture from the Chlorination of the s-Triazine I: GLC and Mass data showed the selectivity of the *s*-triazines to be as follows; I, 56.5; II, 8.7, III, 10.8, and IV, 24.0 mol%. (In the case of the CH_3COOH solution; I, 32.2; II, 14.1; III, 17.2, and IV, 36.5 mol%).

The authors are indebted to the Mitsubishi Chemical Industries Ltd. for their generous support of this publication. They also wish to express their thanks to Mr. Y. Takigawa, Mr. Y. Ihashi and Mr. T. Sato for obtaining and interpreting the spectra which were of great assistance in this work. Valuable technical assistance was also provided by Mr. M. Tsuda and Mr. M. Nakazawa.

Studies of Seven-Membered Heterocyclic Compounds Containing Nitrogen. X. Syntheses of 5,6,8,9-Tetrahydro-7*H*-pyrimido[4,5-*d*]azepines

Hiroshi YAMAMOTO, Masaru NAKATA,[1] Shiro MOROSAWA, and Akira YOKOO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received June 17, 1970)

5,6,8,9-Tetrahydro-7*H*-pyrimido[4,5-*d*]azepine and some of its derivatives were synthesized. 6-Acetyl-3-hydroxy-4,5,7,8-tetrahydro-6*H*-pyrazolo[3,4-*d*]azepine was also synthesized.

The previously-known compounds which have pyrimido-azepine ring systems are 2,3,4,6,7,8,9,10-octahydropyrimido[1,2-*a*]azepine (I)[2] and 5,6,7,8-tetrahydro-9*H*-pyrimido[4,5-*b*]azepines (II).[3] As an extensive investigation of *N*-substituted 5-ethoxycarbonyl-1-azacycloheptan-4-one, which has been prepared from the corresponding *N*-substituted piperid-4-ones by ring expansion with ethyl diazoacetate,[4] and especially in order to obtain azepine compounds by the dehydrogenation of the corresponding hydroazepines, the syntheses of the tetrahydroazepines fused with the pyrimidine ring were undertaken.

Upon the treatment of the *N*-benzyl-5-ethoxycarbonyl-1-azacycloheptan-4-one (IIIa) with thiourea, acetamidine, guanidine, and cyanoguanidine in the usual way, 2-mercapto-, 2-methyl-, 2-amino-, and 2-cyanamino-7-benzyl-4-hydroxy-5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-*d*]azepines (IVa, b, c and d) were obtained. The structures of these compounds were derived by a study of the analytical and the spectral data. They all showed broad bands at 3100—2800 (medium) and 1665—1645 (strong) cm^{-1}, assignable to the amido group, indicating that the pyrimidine ring existed as a 3,4-dihydro-4-oxo form in solid states. The amino-pyrimido-azepine (IVc), when heated with acetic anhydride, readily gave a 2-acetamido derivative (IVe). The reduction of the mercapto compound (IVa) over Raney nickel yielded the hydroxypyrimido-azepine (IVf), and the IR spectrum indicated the presence of the 3,4-dihydro-4-oxo-pyrimidine structure (ν_{max} 2800 and 1660 cm^{-1}). The hydroxyl group of IVf could be replaced by a chlorine atom with phosphoryl chloride in the presence of diethylaniline, giving the chloro-pyrimido-azepine (IVg). The structure of this compound was confirmed by the IR (no absorption due to an amido group) and the NMR spectra. The assignment of the NMR signals is shown in the Table 1. On taking into account the chemical shift (τ 7.35) of the methylene protons at the 2 and 7 positions (*i. e.*, adjacent to the *N*-benzyl group) of 1-benzyl-1,4-diazacycloheptan-5-one,[5] the multiplet at τ 7.25—7.55 was assigned to the four protons at the 6 and 8 positions; thus, the multiplet at τ 6.80—7.10 was considered to be due to the methylene groups at the 5 and 9 positions.

Various nucleophilic substitution reactions took place on the IVg compound under conditions similar to those on 4,5-dialkyl-6-chloropyrimidines. Upon treatment with sodium methoxide in boiling methanol, ethanolic ammonia at 130°C, and hydrazine hydrate in boiling ethanol, 4-methoxy-, 4-amino-, and 4-hydrazino-pyrimido-azepine (IVh, i, and j respectively) were obtained. IVj gave 7-benzyl-5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-*d*]azepine (IVk) on oxidation with silver oxide in methanol. The NMR spectrum of IVk was in conformity with the structure shown in Table 1. The assignment of the singlets at τ 1.20 and 1.74 to the protons at the 2 and 4 positions respectively was made on the grounds of the H(4) signal (τ 1.87) of the 2-methylpyrimido-azepine (IVn). A slight up-field shift of the signal of H(5) compared with that of IVg is

a) Measured by a Hitachi High Resolution NMR Spectrometer, R-20A.
b) In CCl_4 with TMS as an internal standard, except for compound Ve (in D_2O). Suffixes: s, singlet; m, multiplet.
c) Too complicated to determine the accurate chemical shifts.

probably attributable to the removal of the influence of the chlorine atom at the 4 position. The catalytic debenzylation of IVk over 10% palladium on carbon yielded 5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-*d*]azepine (Va) as a colorless oil.

The action of phosphoryl chloride on IVb similarly gave the chloropyrimido-azepine (IVl), but the product appeared to decompose appreciably on distillation. Therefore, the crude product, without purification, was treated with hydrazine hydrate, giving the hydrazinopyrimido-azepine (IVm) in a 67% yield (overall from IVb). IVm was converted into 7-benzyl-2-methyl-5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-*d*]azepine (IVn) by oxidation with silver oxide. The structure was confirmed by the NMR spectrum, the assignment of which is given in Table 1. The catalytic debenzylation of IVn was attempted as in IVk, but the product expected to be similar to Va was not obtained. This is probably due to some decomposition of the starting material during the reaction.

1-Acetyl-1-azacycloheptan-4-one (IIIb) was prepared, by the ring expansion of 1-acetylpiperid-4-one with ethyl diazoacetate, in a relatively good yield (55—65%) compared with that of the same reaction[4)] of 1-benzyl- or 1-ethoxycarbonylpiperid-4-one. The IR spectrum of IIIb showed three strong bands, at 1735, 1715, and 1660 cm^{-1}, assignable to the ethoxycarbonyl, the ring carbonyl, and the acetyl groups respectively. Upon treatment with thiourea and acetamidine, IIIb afforded 2-mercapto- and 2-methyl-7-acetyl-4-hydroxy-5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-*d*]azepine (Vb and c) respectively. The presence of a secondary amido absorption in the IR spectra showed that these compounds exist as the 4-oxo form. Vb was reduced to give the 7-acetyl-4-hydroxypyrimido-azepine (Vd). On refluxing with 6N hydrochloric acid, Vd yielded the hydrochloride of hydroxypyrimido-azepine (Ve) as colorless prisms. The NMR spectrum of the hygroscopic free base in heavy water showed a singlet (1H) at τ 1.98 due to the aromatic ring proton and a complicated multiplet (8H) at 6.55—7.30 due to the tetrahydroazepine ring protons. An attempt to replace the hydroxyl group of Vd with a chlorine atom under conditions similar to those used for the *N*-benzyl compounds (IVb and f) gave only a black, intractable tar. It was found, however, that phosphorus pentasulfide affected both the hydroxyl and acetyl groups of Vd, giving the 4-mercapto-7-thioacetylpyrimido-azepine (Vf). The IR spectrum showed no amido absorption.

6-Acetyl-3-hydroxy-4,5,7,8-tetrahydro-6*H*-pyrazolo-[3,4-*d*]azepine (VIa) was derived from IIIb and hydrazine hydrate as in the case of the benzyl derivative (VIb).[4)]

Experimental

The microanalyses were carried out by Miss H. Ohtani in this department, using a Yanagimoto C.H.N. Corder, MT-1. The solid materials for the analysis were dried over phosphorus pentoxide for 1—2 hr at 80°C/20 mmHg unless otherwise specified. Each of the analytical samples gave a single spot on a paper chromatogram (Toyo Roshi, No. 51) which was developed with 3% aqueous ammonium chloride or 5N acetic acid/1-butanol (29 : 71 v/v) and which was examined under ultraviolet light at 365 and 254 mμ alternately. The IR spectra were taken with a Nihon-Bunko IR-S spectrophotometer; the relatively intense absorption bands of each compound are shown by suffixes (s, strong; br, broad).

*4-Hydroxy-2-mercapto-5, 6, 8, 9-tetrahydro-7*H*-pyrimido[4, 5-d]-azepine (IVa).* Fifteen grams of IIIa hydrochloride[4)] were shaken with 100 m*l* of 10% aqueous potassium carbonate, and the mixture was extracted with ether. After the ether solution had been dried over anhydrous potassium carbonate and the solvent had been completely removed *in vacuo*, the residual oil was dissolved in 50 m*l* of absolute ethanol; a cold solution of 1.75 g (1.5 equiv) of sodium in 150 m*l* of absolute ethanol was then added. Four grams (1.25 equiv) of thiourea were then added, and the whole was refluxed for 7 hr with stirring. The solvent was evaporated *in vacuo*, and the viscous residue was stirred at 0°C with 50 m*l* of water until it became a powder (*ca.* 6 hr). It was collected, dried in a vacuum desiccator with calcium chloride, and boiled with 200 m*l* of methanol. After having been cooled, the precipitate was collected by filtration to give 6.65 g of IVa as an almost colorless powder; mp 232—236°C. On the concentration of the filtrate to *ca.* 30 m*l*, 0.4 g more of the material was obtained (total yield, 51%). Recrystallization from 50% aqueous ethanol gave almost colorless leaflets; mp 236—238°C. The material is moderately soluble in ethanol, and soluble with difficulty in cold water, 10% aqueous sodium carbonate, and N sodium hydroxide, and it gives a hydrochloride as a colorless powder in N hydrochloric acid.

Found: C, 62.83; H, 6.14; N, 14.43%. Calcd for $C_{15}H_{17}N_3OS$: C, 62.69; H, 5.96; N, 14.62%. ν_{max}^{KBr} 3060 br, 2920 br,

1645 sbr, 1590 sbr, 1560 s, 1230 s, 1215, 1118, 950, 910 br, 735 s, and 695 s cm^{-1}.

*7-Benzyl-4-hydroxy-2-methyl-5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-d]azepine (IVb).* To a solution of 1.2 g (5 equiv) of sodium in 50 m*l* of absolute ethanol were added 3.1 g of IIIa hydrochloride and 1.4 g (1.5 equiv) of acetamidine hydrochloride; the mixture was then heated under reflux for 4 hr. The precipitate was removed by filtration, and the filtrate was evaporated to dryness *in vacuo*. Ten milliliters of water were added to the residue, and the resulting solution was washed with ether; then the aqueous layer was brought to pH 5 by the addition of acetic acid. The precipitate which appeared was collected by filtration, washed with a small amount of cold water, and recrystallized from ethanol, thus giving 1.8 g (67%) of IVb as colorless needles; mp 206—208°C. One more recrystallization from ethanol gave an analytical specimen; mp 211—212°C. The material is easily soluble in acetone, and moderately so in chloroform.

Found: C, 71.03; H, 7.08; N, 15.50%. Calcd for $C_{16}H_{19}N_3O$: C, 71.35; H, 7.11; N, 15.60%. ν_{max}^{KBr} 2800 br, 1656 sbr, 1610 s, 1570, 1435, 1352, 1343, 1308, 1222, 1159, 981, 959 s, 809, 751 s, 736, and 700 cm^{-1}.

*2-Amino-7-benzyl-4-hydroxy-5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-d]azepine (IVc).* A mixture of 5.0 g of IIIa hydrochloride, 5.0 g (3.3 equiv) of guanidine hydrochloride, and 1.2 g (3.3 equiv) of sodium in 100 m*l* of absolute methanol was treated such as in the preparation of IVb. After recrystallization from methanol, 2.7 g (63%) of IVc were obtained as a colorless crystalline powder; mp 252—254°C. The material is soluble in water only with difficulty.

Found: C, 62.94; H, 7.34; N, 18.31%. Calcd for $C_{15}H_{18}N_4O\cdot CH_3OH$: C, 63.55; H, 7.33; N, 18.53%. The methanol of crystallization was not removed on drying even at 110°C. ν_{max}^{KBr} 3360 br, 3050 br, 2890 br, 1650 sbr, 1600 sbr, 1497, 1380, 1369, 1309, 1230, 1190, 1029 br, 948, 793, 779, 750 s, and 693 cm^{-1}.

*7-Benzyl-2-cyanamino-4-hydroxy-5,6,8,9-tetrahydro-7*H*-pyrimido-[4,5-d]azepine (IVd).* From 3.1 g of IIIa hydrochloride, 0.84 g (1.0 equiv) of cyanoguanidine, and 2.0 g (3.7 equiv) of sodium methoxide dissolved in 50 m*l* of absolute methanol, IVd was obtained according to the same precedures as those used for IVb. Two recrystallizations from methanol gave 0.7 g (24%) of IVd as a colorless crystalline powder; mp 254—256°C. The analytical specimen was dried at 25°C/20 mmHg.

Found: C, 65.61; H, 6.02; N, 23.78%. Calcd for $C_{16}H_{17}N_5O$: C, 65.07; H, 5.80; N, 23.71%. ν_{max}^{KBr} 2950 sbr, 2800 sbr, 2205 s, 1675 sbr, 1640 sbr, 1545, 1497, 1450, 1440, 1380, 1370, 1308, 1268, 1179, 1117, 948, 782, 770, 748, 733 s and 694 cm^{-1}.

*2-Acetamido-7-benzyl-4-hydroxy-5,6,8,9-tetrahydro-7*H*-pyrimido-[4,5-d]azepine (IVe).* A suspension of 0.5 g of IVc in 2 m*l* of acetic anhydride was heated on a steam bath for 10 min. The precipitate was then collected and recrystallized from methanol, giving 0.4 g (68%) of IVe as colorless prisms; mp 238°C. The analytical sample was dried at 20°C/20 mmHg.

Found: C, 65.37; H, 6.45; N, 17.94%. Calcd for $C_{17}H_{20}N_4O_2$: C, 65.01; H, 6.12; N, 17.77%. ν_{max}^{KBr} 3120 br, 1645 sbr, 1600 s, 1545 sbr, 1391, 1336, 1309, 1240, 1217, 1166 br, 1122, 941, 850, 792, 765, 737, and 692 cm^{-1}.

*7-Benzyl-4-hydroxy-5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-d]azepine (IVf).* To a solution of 6.8 g of IVa in 120 m*l* of 28% aqueous ammonia and 600 m*l* of water were added *ca.* 18 g of freshly-prepared, wet Raney nickel W-2; the mixture was then refluxed for 2 hr. The catalyst was separated while hot and extracted with boiling water. The extract and the filtrate were combined and evaporated *in vacuo*. The recrystallization of the residue from methanol gave 4.8 g of IVf as colorless needles; mp 169—170°C. The concentration of the filtrate afforded a further solid, which was recrystallized from the same solvent to give 0.3 g of the product; mp 167—169°C (total yield, 85%).

Found: C, 70.12; H, 6.38; N, 16.37%. Calcd for $C_{15}H_{17}N_3O$: C, 70.56; H, 6.71; N, 16.46%. ν_{max}^{KBr} 2800 sbr, 1600 sbr, 1605 s, 1432, 1358 s, 1317, 1240, 1205, 1161, 1128, 979, 967 s, 925, 871, 739 s, and 706 cm^{-1}.

*7-Benzyl-4-chloro-5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-d]azepine (IVg).* To a solution of 2.5 g of IVf previously dried for 1 hr at 80°C/20 mmHg in 30 m*l* of boiling phosphoryl chloride was added 1.0 m*l* (0.6 equiv) of diethylaniline during 1—2 min; the mixture was then refluxed for 2 hr. After the solvent had been removed *in vacuo*, 10 m*l* of cold water was added to the residue, and the mixture was stirred at 5°C until it became a solution (30 min). Enough solid sodium carbonate (*ca.* 1.8 g) was slowly stirred into the above ice-cooled solution, and then 30 m*l* of chloroform were added. After having been stirred for 15 min at 5°C, the aqueous layer was separated and extracted with chloroform (3×10 m*l*). The combined organic layer was dried over anhydrous potassium carbonate and evaporated *in vacuo*, and the residue was briefly boiled with 10 m*l* of benzene. After cooling, the precipitate was collected, washed with a small amount of benzene, and recrystallized from 10 parts of methanol, giving 1.7 g of IVg hydrochloride as colorless needles; mp 217—218°C. On concentration, the methanolic filtrate yielded an additional solid, which was recrystallized from the same solvent to give 0.6 g of the product; mp 218—219°C (total yield, 76%). The material is soluble only with difficulty in benzene, and slightly soluble in chloroform, methanol, and ethanol. Two more recrystallizations from methanol and drying at 100°C/20 mmHg gave an analytical specimen; mp 220°C.

Found: C, 58.35; H, 5.64; N, 13.99%. Calcd for $C_{15}H_{16}ClN_2\cdot HCl$: C, 58.07; H, 5.53; N, 13.55%. ν_{max}^{Nujol} 2520 sbr, 1560, 1537 s, 1430 s, 1415, 1383 s, 1320, 1290, 1205, 1080, 953, 917 s, 820 s, 780, 753 s and 705 cm^{-1}.

A mixture of 10 m*l* of 10% aqueous sodium carbonate and 1.75 g of the above crude hydrochloride was stirred for 15 min at 5°C. The mixture was then stirred with 30 m*l* of benzene for 10 min at the same temperature. The aqueous layer was extracted with benzene (3×15 m*l*), and the combined benzene layer, after being clarified by filtration, was evaporated *in vacuo* below 40°C (bath temp.), giving 1.48 g (96%) of the free base (IVg) as an almost colorless crystalline powder; mp 66—67.5°C. The material is easily soluble in ethanol, chloroform, and benzene, and slightly soluble in water. It sublimes at 100°C (bath temp.)/0.2 mmHg with a slight decomposition. The analytical specimen, twice recrystallized from light petroleum (30—70°C) and dried at 25°C/20 mmHg, consisted of colorless prisms; mp 67—68°C.

Found: C, 65.83; H, 5.60; N, 15.41%. Calcd for $C_{15}H_{16}ClN_3$: C, 65.80; H, 5.89; N, 15.35%. ν_{max}^{Nujol} 1555 s, 1540 s, 1498, 1450, 1381 s, 1370 s, 1355 s, 1342, 1335 s, 1310, 1292, 1160, 1121 s, 1000, 970, 950, 830, 819, 799, 741 s, and 705 cm^{-1}.

*7-Benzyl-4-methoxy-5,6,8,9-tetrahydro-7*H*-pyrimido[4,5-d]azepine (IVh).* A solution of 0.15 g of IVg in 5 m*l* of absolute methanol and another solution of 0.02 g (1.3 equiv) of sodium in 5 m*l* of the methanol were mixed and boiled for 1 hr. The solvent was evaporated *in vacuo*, and the residue was extracted with boiling benzene (3×5 m*l*). The evaporation of the solvent below 50°C under reduced pressure left 0.12 g (80%) of the crude product as a colorless liquid which did not solidify at −20°C. ν_{max}^{neat} 2980, 2910, 2860, 2765, 1575 sbr, 1555 s, 1460 sbr, 1380 s, 1350, 1338, 1305, 1190, 1168, 1155, 1138, 1080 s, 1039, 946, 860, 801, 781, 740 s, 700 s, 677, and

660 cm^{-1}.

The *picrate*: yellow leaflets (from methanol), mp 207—208°C (reddened). Drying at 20°C/20 mmHg gave an analytical sample.

Found: C, 46.25; H, 3.38; N, 17.62%. Calcd for $C_{16}H_{19}N_3O \cdot 2C_6H_3N_3O_7$: C, 46.22; H, 3.46; N, 17.33%. ν_{max}^{Nujol} 2550 br, 1625 sbr, 1605 sbr, 1560 sbr, 1540 sbr, 1515, 1480 sbr, 1455 sbr, 1430, 1388 s, 1361 s, 1330 sbr, 1295, 1265 sbr, 1143, 1111, 1080, 1041, 940, 910, 891, 789, 768, 746, and 710 s cm^{-1}.

4-Amino-7-benzyl-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (IVi). A solution of 0.10 g of IVg in 5 m*l* of ethanolic ammonia saturated at 0°C was heated in a sealed tube at 110°C for 2 hr, and then at 130°C for 8 hr. After the evaporation of the solvent *in vacuo*, the residue was stirred with 1 m*l* of 10% aqueous sodium carbonate. The precipitate was collected and recrystallized from benzene, giving 0.07 g (75%) of IVi as colorless fine prisms. One more recrystallization from the same solvent gave the analytical specimen as colorless leaflets; mp 200.5°C. The material is soluble in chloroform and ethanol, but soluble only with difficulty in water.

Found: C, 70.60; H, 6.87; N, 21.85%. Calcd for $C_{15}H_{18}N_4$: C, 70.83; H, 7.13; N, 22.03%. ν_{max}^{Nujol} 3355, 3170, 1663 s, 1583 s, 1550, 1420, 1380, 1343, 1316, 1262, 1168, 1151, 1130, 978, 951, 874, 801, 780, 740 s, and 700 cm^{-1}. No amination took place when IVg was heated under reflux with concentrated aqueous ammonia.

7-Benzyl-4-hydrazino-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (IVj). A mixture of 1.20 g of IVg, 5 m*l* of 80% hydrazine hydrate, and 40 m*l* of ethanol was refluxed for 2 hr. The solvent was then evaporated *in vacuo*, and 5 m*l* of water were added to the residue. After the mixture had been stirred for 5 min at 20°C, the precipitate was collected on a filter and washed with 1 m*l* of cold water, giving 1.12 g (95%) of IVj as a colorless powder; mp 162—165°C. Two recrystallizations from methanol gave an analytically-pure material as colorless plates, mp 165.5—166.5°C; this material is moderately soluble in methanol and ethanol, and slightly soluble in water and benzene.

Found: C, 67.09; H, 7.11; N, 26.11%. Calcd for $C_{15}H_{19}N_5$: C, 66.89; H, 7.11; N, 26.00%. ν_{max}^{Nujol} 3295 s, 3165, 1660, 1595 sbr, 1498 s, 1420 s, 1362, 1350 s, 1340 s, 1323, 1262, 1210, 1168, 990, 985, 961 s, 871, 810, 791, 751, 736 and 706 cm^{-1}. The reaction at 40°C recovered the starting material.

7-Benzyl-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (IVk). A suspension of 0.45 g of IVj and 3.5 g of freshly-prepared silver oxide in 30 m*l* of absolute ethanol was refluxed for 2 hr with stirring. The hot mixture was filtered, and the filtrate was treated with carbon. The solvent was evaporated *in vacuo*, and the residue was sublimed at 130°C (bath temp.)/0.1 mmHg, giving 0.33 (83%) of IVk as colorless prisms. Recrystallization from light petroleum (30—70°C) and drying at 25°C/20 mmHg gave an analytical specimen as colorless plates; mp 66.5—67.5°C. The material is soluble in most organic solvents, but soluble only with difficulty in water.

Found: C, 75.85; H, 7.14; N, 17.96%. Calcd for $C_{15}H_{17}N_3$: C, 75.28; H, 7.16; N, 17.56%. ν_{max}^{Nujol} 1580, 1555, 1410, 1398, 1375, 1359 s, 1312, 1128, 990, 951, 790, 746 s, and 706 cm^{-1}.

The *picrate* was obtained when IVk was added to an ethanolic solution of picric acid (2.1 equiv). It was recrystallized from ethanol and dried at 107°C/20 mmHg to give an analytical sample as yellow prisms; mp 170—171°C.

Found: C, 53.16; H, 4.10; N, 18.25%. Calcd for $C_{15}H_{17}N_3 \cdot C_6H_3N_3O_7$: C, 53.84; H, 4.30; N, 17.94%. ν_{max}^{Nujol} 2700 br, 2570 br, 1620 sbr, 1610 sbr, 1580, 1550 sbr, 1485, 1435, 1403, 1368 s, 1335 sbr, 1310 sbr, 1270 sbr, 1163, 1080, 907 s, 798, 776, 755, and 712 cm^{-1}.

5,6,8,9-Tetrahydro-7H-pyrimido[4,5-d]azepine (Va). A mixture of 0.20 g of IVk, 1 m*l* of acetic acid, and 20 m*l* of ethanol was shaken with hydrogen in the presence of 0.10 g of 10% palladium charcoal until the absorption of hydrogen ceased. The solid was then removed by filtration and washed with hot ethanol. The filtrate and the washings were combined and evaporated *in vacuo*. The residual liquid was suspended in 6 m*l* of 10% aqueous potassium carbonate and extracted with chloroform (3×7 m*l*). The dried extract was freed from the solvent at 60°C (bath temp.)/20 mmHg, giving 0.10 (80%) of Va as a colorless liquid. No crystallization occurred even at −20°C.

The oil was characterized by the *picrate*; yellow needles (from ethanol); mp 224°C (decomp.),.

Found: C, 44.56; H, 3.66; N, 22.00%. Calcd for $C_8H_{11}N_3 \cdot C_6H_3N_3O_7$: C, 44.45; H, 3.73; N, 22.22%. ν_{max}^{Nujol} 2580 br, 2450, 1635 s, 1608 sbr, 1545 sbr, 1480 br, 1450 sbr, 1397 s, 1365 sbr, 1310 sbr, 1270 sbr, 1162 s, 1152, 1079 s, 1026, 928, 912, 839, 780, 743, 721 s, and 710 s cm^{-1}.

7-Benzyl-4-chloro-2-methyl-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (IVl). This was prepared as in the case of IVg; the crude product (77%) was obtained as a pale yellow liquid. When purified by distillation, it gave pure IVl in a 30% yield as a colorless liquid, bp 170°C/0.7 mmHg, which crystallized in part.

Found: C, 67.81; H, 6.48; N, 15.05%. Calcd for $C_{16}H_{18}ClN_3$: C, 66.77; H, 6.30; N, 14.60%. ν_{max}^{neat} 2890 s, 2795, 2522, 2480, 1605, 1560 sbr, 1520 sbr, 1492, 1450 s, 1415 sbr, 1400 s, 1361, 1346, 1312 br, 1277 s, 1162, 1128, 1072, 1026, 942 s, 920, 908, 890, 829, 822, 790, 775, 750, 740, 721, and 698 s cm^{-1}.

7-Benzyl-4-hydrazino-2-methyl-5,6,8,9-tetrahydro-7H-pyrimido-[4,5-d]azepine (IVm). The procedure was similar to that used for IVj, except that benzene was used as the recrystallization solvent. The crude chloropyrimido-azepine (IVl) gave IVm as a colorless crystalline powder, mp 124—125°C, in an 87% yield. The material is easily soluble in methanol, ethanol, ethyl acetate, and chloroform, moderately soluble in benzene, and soluble only with difficulty in water. Drying at 60°C/20 mmHg gave an analytical sample.

Found: C, 68.60; H, 7.89; N, 25.42%. Calcd for $C_{16}H_{21}N_5$: C, 67.81; H, 7.47; N, 24.72%. ν_{max}^{Nujol} 3280 sbr, 3230 sbr, 3190 s, 1668, 1575 sbr, 1490 s, 1440 s, 1409 s, 1380, 1348, 1304, 1212, 1169, 1020, 970, 949 s, 797, 775, 760, 730, 700 s, and 660 cm^{-1}.

7-Benzyl-2-methyl-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (IVn). This was prepared in a 63% yield from IVm by much the same procedure as that used in preparing IVk. It was a colorless, viscous liquid, bp 155—156°C/0.20 mmHg, which did not crystallize on storage at −20°C.

The material gradually become a yellow viscous liquid in the air, while under ultraviolet light at 254 mμ, it was quickly destroyed and gave a substance which exhibited a blue fluorescence.

Found: C, 75.82; H, 7.79; N, 16.21%. Calcd for $C_{16}H_{19}N_3$: C, 75.85; H, 7.56; N, 16.59%. ν_{max}^{neat} 2980, 2880, 2855, 1579 s, 1563 sbr, 1495, 1450 sbr, 1445 sbr, 1402, 1372, 1345, 1272, 1163, 1120 br, 1031, 993, 968, 950 sbr, 782, 750 s, 725 and 701 cm^{-1}.

The *picrate*, yellow leaflets (from ethanol); mp 192.5—194°C (melted with darkening).

Found: C, 47.24; H, 3.87; N, 17.29%. Calcd for $C_{16}H_{19}N_3 \cdot 2C_6H_3N_3O_7$: C, 47.26; H, 3.54; N, 17.72%. ν_{max}^{Nujol} 2580 br, 1620 sbr, 1605 sbr, 1562 s, 1550 sbr, 1520, 1490, 1460 br, 1427, 1362 s, 1315 sbr, 1263 sbr, 1160, 1080, 900, 789, 760, 748, and 711 cm^{-1}.

The *hydrochloride* was obtained as a colorless crystalline

powder, mp 240—242°C (from methanol), when dry hydrogen chloride was passed through a solution of IVn in dry ether.

Found: C, 58.75; H, 6.50; N, 12.78%. Calcd for $C_{16}H_{19}N_3 \cdot 2HCl$: C, 58.90; H, 6.49; N, 12.88%. ν_{max}^{KBr} 2960, 2440 sbr, 2080, 1975 br, 1620, 1609 s, 1465, 1452 s, 1410, 1388, 1374, 1311, 1270, 1212, 1148, 1065 br, 1048, 1022, 971, 960, 932, 898 s, 790, 780, 753 s, 729, 710, and 698 cm^{-1}.

1-Acetylpiperid-4-one. A mixture of 20.0 g of piperid-4-one hydrochloride,[6] 30.0 g (2.0 equiv) of acetic anhydride and 220 m*l* of pyridine was heated under reflux for 2 hr. After cooling, 250 m*l* of water were added and the mixture was heated on a steam bath for 30 min and then concentrated to *ca.* 50 m*l* below 60°C (bath temp.) under reduced pressure. To this were added 20 m*l* of 10% aqueous sodium hydrogen carbonate and enough solid sodium hydrogen carbonate (*ca*, 6 g) to pH 7, after which the contents were thoroughly extracted with chloroform (6×50 m*l*). The combined extract was washed once with saturated aqueous sodium chloride and dried over anhydrous potassium carbonate. After the solvent had been removed, the residue was distilled to give 16.2 g (78%) of the acetylpiperidone as a colorless liquid; bp 122—125°C/0.20 mmHg. ν_{max}^{neat} 3450 br, 2960, 2890, 1735 sbr, 1715 sbr, 1660 s, 1640—1620 sbr, 1450—1420 sbr, 1362, 1349, 1310, 1260, 1230 sbr, 1140, 1032, 978, and 758 cm^{-1}

The liquid was identified by the 2,4-*dinitrophenylhydrazone* (yellow fine needles, 80% yield); mp 209—210°C.

Found: C, 48.72; H, 4.96; N, 21.35%. Calcd for $C_{13}H_{15}N_5O_5$: C, 48.59; H, 4.71; N, 21.80%.

1-Acetyl-5-ethoxycarbonyl-1-azacycloheptan-4-one (IIIb). The procedures of Moriya *et al.*[4] were followed. The treatment of 7.06 g of the above acetylpiperidone with 7.81 g (1.1 equiv) of freshly-distilled boron trifluoride and 17.1 g (3.0 equiv) of ethyl diazoacetate gave 7.35 g (65%) of IIIb as a pale yellow, voscous oil; bp 154°C/0.28 mmHg.

Found: C, 57.84; H, 7.78; N, 5.98%. Calcd for $C_{11}H_{17}NO_4$: C, 58.13; H, 7.54; N, 6.16%. ν_{max}^{neat} 2950 br, 1750 sbr 1710 sbr, 1645 sbr, 1480, 1455 br, 1425 br, 1370, 1315, 1295, 1230 br, 1195 sbr, 1100, 1025, 989 and 896 cm^{-1}.

7-Acetyl-4-hydroxy-2-mercapto-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (Vb). The procedure was essentially the same as that used for the benzyl compound IVa, but a slight modification was employed. To a cold solution of 0.40 g (1.5 equiv) of sodium in 70 m*l* of absolute ethanol was added a solution of 9.08 g of IIIb in 30 m*l* of absolute ethanol, and then 3.80 g (1.25 equiv) of finely-powdered thiourea. The mixture was shaken at room temperature until the thiourea had been almost completely dissolved (5 min), and then it was refluxed for 9 hr with stirring. The solvent was removed *in vacuo*, and the residue was dissolved in 20 m*l* of cold water and filtered. The filtrate was brought to pH 4 with 6N hydrochloric acid under cooling and kept at 5°C for two days to give 6.8 g of a precipitate. The concentration of the filtrate to *ca.* 10 m*l* yielded 1.8 g of the same material. Recrystallization from 50% aqueous ethanol gave 6.6 g (69%) of Vb as an almost colorless crystalline powder; mp 286—287°C. One more recrystallization from the same solvent raised the melting point to 288—289°C, and subsequent drying at 100°C/20 mmHg gave an analytical sample.

Found: C, 49.42; H, 5.41; N, 17.07%. Calcd for $C_{10}H_{13}N_3O_2S$: C, 50.18; H, 5.47; N, 17.54%. ν_{max}^{Nujol} 3120 br, 1660 sbr, 1610 sbr, 1550 sbr, 1425 sbr, 1340, 1276, 1212 s, 1198 s, 1121, 926 br, and 762 cm^{-1}.

7-Acetyl-4-hydroxy-2-methyl-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (Vc). A mixture of 2.27 g of IIIb, 0.70 g (1.2 equiv) of acetamidine hydrochloride, and 0.60 g (2.6 equiv) of sodium was similarly refluxed in 40 m*l* of absolute ethanol. After being changed to pH 4 with hydrochloric acid, the reaction mixture was well extracted with chloroform (5×10 m*l*). The combined and dried (over anhydrous potassium carbonate) extract was evaporated *in vacuo*, and the residue was recrystallized from ethanol to give 0.80 g (36%) of Vc as a colorless crystalline powder; mp 250—252°C. Two more recrystallizations from the same solvent afforded colorless needles, mp 254—255°C, an aliquot of which was then dried at 160°C/15 mmHg to give an analytical sample.

Found: C, 60.31; H, 7.07; N, 19.06%. Calcd for $C_{11}H_{15}N_3O_2$: C, 59.71; H, 6.83; N, 18.99%. The material dried below 120°C/20 mmHg still possessed the ethanol of crystallization. ν_{max}^{Nujol} 3070 br, 2760, 1660 sbr, 1590 sbr, 1455 sbr, 1425 s, 1380, 1337, 1294, 1282, 1251, 1219, 1201, 1144, 1045, 1037, 1030, 990, 943 s, 900, 795, and 734 cm^{-1}.

7-Acetyl-4-hydroxy-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (Vd). This was prepared according to the procedure described for IVf. The treatment of 2.0 g of Vb with 6.0 g of wet Raney nickel W-2, followed by the recrystallization of the crude product from ethanol, gave 1.5 g (87%) of Vd as colorless leaflets; mp 212—213°C. The material is easily soluble in water.

Found: C, 57.94; H, 6.17; N, 20.17%. Calcd for $C_{10}H_{13}N_3O_2$: C, 57.96; H, 6.32; N, 20.28%. ν_{max}^{Nujol} 3050 br, 2700, 1660 sbr, 1630, 1595 sbr, 1551, 1465 sbr, 1380 s, 1275, 1250, 1223, 1192, 1033, 997, 952, 937 s, 919, 864, 812, 785, and 665 br cm^{-1}.

4-Hydroxy-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (Ve). A solution of 0.20 g of Vd in 4 m*l* of 6N hydrochloric acid was refluxed for 4 hr. The solvent was removed under reduced pressure below 60°C (bath temp.), and the residue was boiled with 5 m*l* of ethanol. The precipitate was recrystallized from a mixture of N HCl–EtOH (1:30) to give 0.20 g (97%) of fine, colorless needles; mp 272—275°C (gradual decomp.). Likewise, one more recrystallization gave an analytical specimen; mp 272—274°C (foaming). The hydrochloride contained the water of crystallization, which was lost on drying above 110°C. Drying at 140°C/20 mmHg gave an analytical sample. It is very soluble in water and 10% aqueous sodium hydrogen carbonate.

Found: C, 46.71; H, 5.89; N, 20.52%. Calcd for $C_8H_{11}N_3O \cdot HCl$: C, 47.64; H, 6.00; N, 20.84%. ν_{max}^{Nujol} 3100—2400 br, 1650 sbr, 1630 sbr, 1605 s, 1595 s, 1552, 1450 sbr, 1428, 1403, 1373, 1308, 1250, 1230, 1180, 1129, 1101, 989, 976, 943 s, 890, 861, 831, and 795 cm^{-1}.

The *picrate*; yellow prisms (from 80% aqueous ethanol); mp 117—119°C. The analytical sample was dried at 60°C/20 mmHg.

Found: C, 36.09; H, 3.02; N, 18.98%. Calcd for $C_8H_{11}N_3O \cdot 2C_6H_3N_3O_7 \cdot HCl$: C, 36.40; H, 2.75; N, 19.10%. ν_{max}^{Nujol} 3470, 3230, 3070, 1685 s, 1675, 1630 s, 1615 s, 1565 sbr, 1540, 1465 sbr, 1383, 1373 s, 1355 s, 1335 s, 1303, 1284 s, 1172, 1098, 920, 863, 792, 750, and 720 br cm^{-1}.

A solution of 0.10 g of the hydrochloride in 10 m*l* of water was passed through a column of the Amberlite CC-413 and eluted with water. The eluate (*ca.* 80 m*l*) was evaporated *in vacuo*, giving the free base Ve as an almost colorless powder; this powder gradually melted at about 220°C. The material was very hygroscopic and became a pale yellow viscous tarry oil on being set aside in the air; thus, it was not analyzed. However, the NMR spectrum is shown in Table 1. It is very soluble in water, and slightly so in ethanol, but insoluble in chloroform.

4-Mercapto-7-thioacetyl-5,6,8,9-tetrahydro-7H-pyrimido[4,5-d]azepine (Vf). A mixture of 0.10 g of Vd and 2 m*l* of pyridine was heated at 110°C. After the resultant solution

6) A. Yokoo and S. Morosawa, This Bulletin, **29**, 631 (1956).

had been cooled to 90°C, 0.20 g (2.0 equiv) of powdered phosphoryl pentasulfide was added over a 1-min period and the mixture was heated under reflux for 30 min. The reaction mixture was treated with 2 m*l* of water and evaporated *in vacuo* at 60°C. The residue was stirred with 1 m*l* of water under cooling, and the precipitate was collected and recrystallized twice from ethanol to give 0.075 g (71%) of Vf as a yellow crystalline powder; mp 247—248°C (blackened). The drying of an aliquot of the powder at 140°C/20 mmHg afforded the analytical sample.

Found: C, 49.96; H, 5.32; N, 17.38%. Calcd for $C_{10}H_{13}N_3S_2$: C, 50.18; H, 5.47; N, 17.56%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 158—161 (1971)

Studies of Peptide Antibiotics. XXIV. Synthesis of 4,4'-D-Alanine-gramicidin S

Sannamu LEE, Reiko OHKAWA[1], and Nobuo IZUMIYA[2]

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received June 22, 1970)

In order to investigate the contribution to antibacterial activity of the D-phenylalanine residues at 4- and 4'-position in gramicidin S, 4,4'-D-alanine-gramicidin S (XX) and 4-D-alanine-semigramicidin S (XXI) were prepared and tested for antibacterial properties. XX exhibited recognizable activity though weaker than that of gramicidin S, whereas XXI showed no activity on any of the microorganisms tested.

We reported that 4,4'-glycine-gramicidin S possessed weak antibacterial activity toward several microorganisms.[3] On the other hand, 4,4'-D-valine- and 4,4'-D-leucine-gramicidin S were as active as natural gramicidin S (GS) (Fig. 1);[4] the results indicated that the aromatic side chains of D-phenylalanine residues of 4- and 4'-position can be replaced by the bulky aliphatic side chains without influencing the activity. From these findings, it seemed of interest to investigate the antibacterial properties of an analog of GS with D-amino acid residues at 4- and 4'-position which are larger than glycine and smaller than valine or leucine.

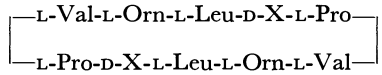

Fig. 1. Structure of GS (X=Phe) and 4,4'-D-Ala-GS (X=Ala).

This paper will describe the synthesis and antibacterial properties of 4,4'-D-alanine-GS besides those of a cyclic pentapeptide, 4-D-alanine-semigramicidin S.

The desired 4,4'-D-Ala-GS (XX) was obtained as a crystalline dihydrochloride by hydrogenolysis of a benzyloxycarbonyl-substituted cyclic decapeptide (XVII) wherein δ-amino functions of ornithine residues were protected with benzyloxycarbonyl groups. The protected cyclic decapeptide (XVII) was prepared from a corresponding decapeptide *p*-nitrophenyl ester trifluoroacetate (XVI) by treatment with pyridine. The trifluoroacetate (XVI) was obtained from *p*-methoxybenzyloxycarbonyl-decapeptide nitrophenyl ester (XV) which was derived from an acyl-decapeptide acid (XIV) and di-*p*-nitrophenyl sulfite.

Synthesis of the protected cyclic decapeptide (XVII) was attempted by possible dimerization reaction of a linear pentapeptide active ester (XVIII). Thus, treatment of the active ester with pyridine afforded a mixture of the protected monomer (XIX) and dimer (XVII) which was prepared as described before; the ratio in weight of XIX and XVII in the mixture was found to be 23 : 77. Separation of the two components was achieved by a Sephadex LH-20 column with methanol, the monomer (XIX) being obtained as a pure material. Hydrogenolysis of XIX in the presence of hydrogen chloride yielded a crystalline monohydrochloride of cyclic pentapeptide (XXI).

The antibacterial activities of the cyclic penta- and decapeptides (XXI and XX) toward several microorganisms were examined. Both compounds exhibited no activity toward Gram negative microorganisms (*e. g.*, *E. coli*). It was also found that 4-D-alanine-semiGS (XXI) possessed no activity toward Gram positive microorganisms (*St. aureus* and *B. subtilis*), whereas 4,4'-D-alanine-GS (XX) possessed recognizable activity though its degree was weaker than that of GS (Table 1). The results indicate that D-alanines can replace D-phenylalanines without drastic drop in activity. The optical rotatory dispersion (ORD) curves of the cyclic decapeptide (XX) and GS were measured with ethanol as a solvent.[5] Both decapeptide afforded a similar shape to a trough at approximately 232 mμ (Fig. 2). Since 4,4'-D-alanine-GS contains no aromatic amino acid residues, the only chromophores in the molecule are amide carbonyls and the shape of the ORD curve will reflect the spatial arrangement of chromophores in the molecule. The results suggest that 4,4'-D-alanine-

Experimental

All melting points are uncorrected. Thin layer chromatography was performed on Merck silica gel G with the following solvent systems: R_f^1, *n*-butanol - acetic acid - pyridine - water 4 : 1 : 1 : 2 v/v; R_f^2, chloroform-methanol 5 : 1 v/v. Paper chromatography was performed with the following solvent system: R_f^3, the same solvent used for R_f^1.

Z-D-Ala-Pro-OEt (I).[6] To a chilled solution of Z-D-Ala-OH (2.32 g, 10 mmol)[7] and TEA (1.4 ml, 10 mmol) in tetrahydrofuran (20 ml), isobutyl chloroformate (1.31 ml, 10 mmol) was added. After 10 min, a mixture of H-Pro-OEt·TsOH[8] (3.15 g, 10 mmol), TEA (1.4 ml, 10 mmol) and chloroform (20 ml) was added to the solution. The reaction mixture was allowed to stand overnight and then evaporated to dryness *in vacuo*. After the residual oil was dissolved in ethyl acetate, the solution was washed successively with water, 2% hydrochloric acid, 4% sodium bicarbonate and water, dried over sodium sulfate, and then evaporated. The product was obtained as oil; yield, 2.51 g (72%); R_f^1 0.98.

H-D-Ala-Pro-OEt·HCl (II). A solution of I (2.51, g 7.2 mmol) dissolved in 0.3N methanolic hydrogen chloride (28 ml) was hydrogenated in the presence of palladium black. The filtrate from the catalyst was evaporated to dryness; yield of oil, 1.80 g (100%); R_f^1 0.80.

Z-Leu-D-Ala-OEt (III). To a solution of Z-Leu-OH·DCHA[9] (6.69 g, 15 mmol) and H-D-Ala-OEt·HCl (1.96 g, 15 mmol)[10] in chloroform (100 ml) was added DCC (3.09 g, 15 mmol) at 0°C. The mixture was stirred for 3 hr at 0°C, and then kept overnight at room temperature. The mixture was evaporated and ethyl acetate was added to the residue. After dicyclohexylurea was filtered off, the filtrate was washed successively with water, 2% hydrochloric acid, 4% sodium bicarbonate, and water, and dried over sodium sulfate. The filtrate was evaporated and the residue was crystallized by addition of ether and petroleum ether. It was recrystallized from ethyl acetate-petroleum ether; yield, 4.45 g (83%); mp 93—94°C; $[\alpha]_D^{20}$ +3.3° (*c* 1, methanol); R_f^1 0.99.

Found: C, 62.49; H, 7.79; N, 7.73%. Calcd for $C_{19}H_{28}O_5N_2$: C, 62.62; H, 7.74; N, 7.73%.

Z-Leu-D-Ala-NHNH$_2$ (IV). A solution of III (4.02 g, 11 mmol) and hydrazine hydrate (5 ml) in DMF (20 ml) was allowed to stand at room temperature for one day. The solution was evaporated, and then water (300 ml) was added to the residue. The resulting crystals were collected by filtration; yield, 3.66 g (95%); mp 171—174°C; $[\alpha]_D^{20}$ −13.8° (*c* 1, DMF); R_f^1 0.87.

Found: C, 58.41; H, 7.58; N, 15.89%. Calcd for $C_{17}H_{26}O_4N_4$: C, 58.27; H, 7.48; N, 15.99%.

Z-Leu-D-Ala-Pro-OEt (V). (*a*) Z-Leu-OH·DCHA (3.2 g, 7.2 mmol) and II (1.8 g, 7.2 mmol) were condensed with DCC (1.48 g, 7.2 mmol) as described for the preparation of III; yield of oil, 2.6 g (77%); R_f^2 0.83.

(*b*) To a solution at −5°C of IV (3.5 g 10 mmol) in DMF (20 ml) containing 2.8N hydrogen chloride in dioxane (7.5 ml), isoamyl nitrite (1.4 ml, 10 mmol) was added.[11] After 10 min, TEA (2.8 ml, 20 mmol) was added. To the solution was added a mixture of H-Pro-OEt·TsOH (3.15g 10 mmol) and TEA (1.4 ml) in DMF (20 ml). The mixture was stirred for 3 days at 0°C and evaporated. The residue was dissolved in ethyl acetate, and the solution was washed successively with 2% hydrochloric acid, 4% sodium bicarbonate and water, dried over sodium sulfate, and then evaporated; yield of oil, 2.6 g (56%); R_f^2 0.83.

Z-Leu-D-Ala-Pro-OH (VI). To a solution of V (2.57 g, 5.6 mmol) in methanol (20 ml), N sodium hydroxide (9 ml) was added. The solution was allowed to stand for 3 hr at room temperature. After the addition of water (20 ml), the solution was evaporated to remove methanol. After the solution was extracted with ethyl acetate, the aqueous layer was acidified with 2N hydrochloric acid. The mixture was extracted with ethyl acetate and the organic layer was dried over sodium sulfate. The filtrate was evaporated to dryness; yield of a semi solid, 2.15 g (89%); R_f^2 0.56.

H-Leu-D-Ala-Pro-OH (VII). A solution of VI (2.15 g, 5 mmol) in a mixture of acetic acid (15 ml), methanol (12 ml) and water (2 ml) was hydrogenated. The filtrate was evaporated to dryness; yield of a semi solid, 1.39 g (93%); R_f^1 0.70.

H-Leu-D-Ala-Pro-OEt·HCl (VIII). This was obtained from V (1.84 g, 4 mmol) as described for the preparation

of II; yield of oil, 1.46 g (100%); R_f^1 0.87.

Z-(OMe)-Val-Orn(δ-Z)-Leu-D-Ala-Pro-OH (IX). The azide[12] derived from Z(OMe)-Val-Orn(δ-Z)-$NHNH_2$ (XXII) (2.49 g, 4.4 mmol) was added to a solution of VII (1.19 g, 4 mmol) and TEA (1.12 ml, 8 mmol) in DMF (50 ml). The mixture was stirred for 2 days at 0°C and evaporated. The residue was triturated with 0.5M citric acid, and the precipitate was collected by filtration. It was recrystallized from methanol - ether; yield, 2.26 g (68%); mp 137—139°C; $[\alpha]_D^{20}$ −35.5° (*c* 1, methanol).

Found: C, 58.13; H, 7.24; N, 9.77%. Calcd for $C_{41}H_{58}O_{11}N_6 \cdot H_2O$: C, 58.14; H, 7.61; N, 9.92%.

Z-(OMe)-Val-Orn(δ-Z)-Leu-D-Ala-Pro-OEt (X). The azide[12] derived from XXII (2.49 g, 4.4 mmol) was condensed with VIII (1.50 g, 4.1 mmol) as described for the preparation of V. The precipitate which formed upon addition of water was collected, washed successively with 4% sodium bicarbonate, 0.5M citric acid and water; yield, 3.96 g (85%); mp 163—165°C; $[\alpha]_D^{20}$ −20.7° (*c* 1, DMF); R_f^1 0.98.

Found: C, 61.18; H, 7.45; N, 10.26%. Calcd for $C_{43}H_{62}O_{11}N_6$: C, 61.55; H, 7.45; N, 10.02%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Ala-Pro-$NHNH_2$ (XI). A solution of X (4.12 g, 5 mmol) and hydrazine hydrate (2 ml) in DMF (20 ml) was allowed to stand for 5 days at 30°C. After evaporation, the hydrazide which precipitated upon addition of water (400 ml) was collected and recrystallized from dioxane - ether; yield, 1.98g (48%); mp 158—160°C; $[\alpha]_D^{20}$ −20.1° (*c* 1, DMF); R_f^1 0.65.

Found: C, 60.01; H, 7.40; N, 13.69%. Calcd for $C_{41}H_{60}O_{10}N_8$: C, 59.69; H, 7.33; N, 13.59%.

H-Val-Orn(δ-Z)-Leu-D-Ala-Pro-OH·HCl (XII). To a mixture of IX (2.05 g, 2.5 mmol) and anisole (0.3 ml), 2.7N hydrogen chloride in dioxane (20 ml) was added at room temperature. After 2 hr, the solution was evaporated, and the residue was triturated with ether; yield, 1.75 g (97%); mp 147—149°C (decomp.); $[\alpha]_D^{20}$ −36.3° (*c* 1, DMF); R_f^1 0.73.

Found: C, 53.39; H, 7.66; N, 11.52%. Calcd for $C_{32}H_{51}O_8N_6Cl \cdot 2H_2O$: C, 53.43; H, 7.56; N, 11.69%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Ala-Pro-Val-Orn(δ-Z)-Leu-D-Ala-Pro-OH (XIV). The azide (XIII) was prepared from XI (2.06 g, 2.5 mmol), N hydrochloric acid (6 ml) and sodium nitrite (0.175 g, 2.5 mmol) in acetic acid (20 ml) as described for the preparation of the azide[12] from XXII. XIII was condensed with XII (1.73 g, 2.4 mmol) as described for the preparation of IX. The product was recrystallized from methanol - ether-petroleum ether; yield, 3.19 g (88%); mp 185—187°C; $[\alpha]_D^{20}$ −59.9° (*c* 1, methanol); R_f^1 0.92, R_f^2 0.66.

Found: C, 59.36; H, 7.26; N, 10.73%. Calcd for $C_{73}H_{106}O_{18}N_{12} \cdot 2H_2O$: C, 59.41; H, 7.51; N, 11.30%.

cyclo-*(Val-Orn(δ-Z)-Leu-D-Ala-Pro-)$_2$ (XVII).* *(a) From XIV.* To a solution of XIV (729 mg, 0.5 mmol) in pyridine (10 ml), di-*p*-nitrophenyl sulfite (1.61 g, 5 mmol) was added. After 8 hr at room temperature, the mixture was evaporated. The residual solid was collected by filtration with the aid of a mixture of ether-petroleum ether (1 : 1, v/v); yield of acyldecapeptide *p*-nitrophenyl ester (XV), 752 mg. To XV (745 mg) thus obtained, anisole (0.5 ml) and trifluoroacetic acid (5 ml) were added at 0°C. After 40 min, the solution was evaporated and the residual powder was collected by filtration with the aid of ether. Decapeptide *p*-nitrophenyl ester trifluoroacetate (XVI) (520 mg) thus obtained was dissolved in DMF (10 ml) and acetic acid (0.1 ml). The solution was added dropwise into pyridine (20 ml) at 50—60°C for 4 hr and stirring was continued for additional 2 hr. After the solvent was removed, the residue was dissolved in a mixture of methanol (40 ml) and water (10 ml). The solution was passed through the columns of Dowex 1 and 50. The effluent was evaporated, and the product was collected by filtration with the aid of water. It was recrystallized from methanol - ether; yield, 151 mg (23% from XIV); mp 234—236°C (decomp.); $[\alpha]_D^{20}$ −199° (*c* 1, methanol); R_f^1 0.95.

Found: C, 56.68; H, 7.61; N, 12.55%; mol wt 1240.[13] Calcd for $C_{64}H_{96}O_{14}N_{12} \cdot 3H_2O$: C, 58.60; H, 7.65; N, 12.81%; wt 1311.

(b) From IX. Acylpentapeptide acid (IX) (405 mg, 0.5 mmol) was converted to pentapeptide *p*-nitrophenyl ester trifluoroacetate (XVIII) (372 mg) as described for the preparation of XV and XVI. XVIII thus obtained was added to pyridine (150 ml) at 60°C as described above. After evaporation, the residue was treated with columns of Dowex 1 and 50, the effluent was evaporated, and the product was collected by filtration with the aid of water; yield of the crude product (XXIII), 110 mg. The solution of XXIII (100 mg) in methanol (5 ml) was applied to a column (2 × 110 cm) with Sephadex LH-20, and the development continued with methanol; a 2 ml fraction was collected in each test tube. The peak of XVII appeared from the test tube number 61 to 70 and the peak of XIX from 80 to 90. The fractions 61—70 were evaporated, and the product was collected by filtration with the aid of water (yield, 64 mg). It was recrystallized from methanol - ether; yield, 52 mg; mp 240—242°C; $[\alpha]_D^{20}$ −192° (*c* 1, methanol); R_f^1 0.95.

cyclo-*(Val-Orn(δ-Z)-Leu-D-Ala-Pro-) (XIX).* The fractions 80—90 were evaporated to afford an oily residue which was crystallized after several days. It was collected by the aid of a mixture of methanol and ether; yield, 19 mg; mp 130—133°C; $[\alpha]_D^{20}$ −64.6° (*c* 0.5, methanol); R_f^1 0.93.

Found: C, 59.49; H, 7.65; N, 13.01%; mol wt 596.[13] Calcd for $C_{32}H_{48}O_7N_6 \cdot H_2O$: C, 59.22; H, 7.74; N, 12.99%; mol wt 647.

cyclo-*(Val-Orn-Leu-D-Ala-Pro-)$_2$·2HCl (4,4′-D-Ala-GS·2HCl) (XX·2HCl).* A solution of XVII (50 mg, 0.038 mmol) in 0.01N methanolic hydrogen chloride (8.4 ml) was hydrogenated and the filtrate was evaporated. The product was recrystallized from methanol - ether - petroleum ether; yield, 31 mg (73%); mp 190—191°C (decomp.); $[\alpha]_D^{20}$ −189° (*c* 1, methanol); R_f^1 0.89.

Found: C, 51.58; H, 7.87; N, 14.05%. Calcd for $C_{48}H_{86}$-

$O_{10}N_{12}Cl_2 \cdot 3H_2O$: C, 51.64; H, 8.31; N, 14.33%.

cyclo-*(Val-Orn-Leu-*D*-Ala-Pro-)·HCl (4-*D*-Ala-semiGS·HCl)* *(XXI·HCl)*. XIX (15 mg, 0.02 mmol) was treated as described above; yield of a semi solid, 9.8 mg (98%); R_f^1 0.86.

Electrophoresis and CMC Chromatography. The experiments were carried out as described before.[4] A part of the crude product (XXIII) obtained after cyclization reaction of the pentapeptide active ester (XVIII), was hydrogenated and the product was designated as XXIV. As shown in Fig. 3, 4,4′-Ala-GS and 4-D-Ala-semiGS were clearly separated in the electrophoresis, whereas two compounds could be only partly separated with a column (0.9×50 cm) of CMC.

Microbiological Assays[14] *and ORD Measurements.*[15] The minimum amount of the compounds necessary for the complete inhibition of growth was determined by a dilution method using a bouillon agar medium and the results are shown in Table 1. ORD measurements were performed with JASCO Spectropolarimeter model ORD-CD/UV-5 over a wavelength range of 220 to 300 mμ in ethanol on the compound, and ORD curves are shown in Fig. 2.

14) We are indebted to Meiji Seika Co., Ltd. for the microbiological assays.

15) We are indebted to Mr. S. Matsuura and Dr. M. Waki in this laboratory for ORD measurements.

The Reactions of α-Substituted Carbonyl-stabilized Sulfonium Ylides with Succinic Anhydride

Teruaki MUKAIYAMA, Katsuaki HAGIO, Hisashi TAKEI, and Kazuhiko SAIGO

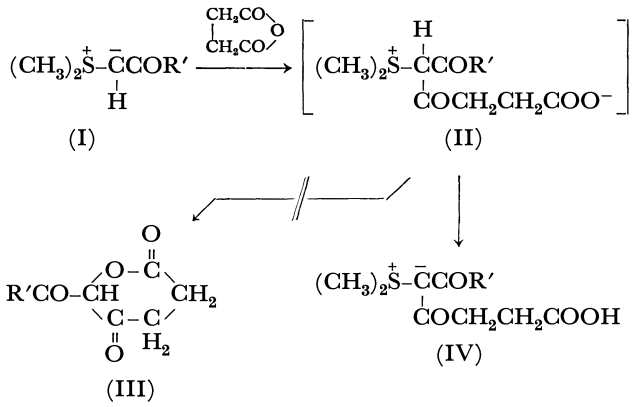
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 25, 1970)

It was found that various kinds of α-substituted carbonyl-stabilized sulfonium ylides were conveniently prepared from the corresponding sulfonium salts by treating with 50% aqueous sodium hydroxide. The reactions of sulfonium ylides with succinic anhydride afforded furofuran derivative by one step procedure in yields ranging these from 5 to 14%. The structures of furofuran derivatives were confirmed by IR spectrum, NMR sepctrum, degradation, and its behavior toward alkali and acid.

It has been recently reported that 3-hydroxyfuran derivatives were obtained in good yields by the reactions of α-unsubstituted carbonyl-stabilized sulfonium ylides with ketene dimer.[1)]

In the present experiment, the reactions of carbonyl-stabilized ylides (I) with succinic anhydride were tried with the expectation that the six-membered lactone derivatives (III) would be formed by way of an intramolecular nucleophilic attack of carboxylate anion to α-carbon of the sulfonium compound (II). In the reactions of α-unsubstituted carbonyl-stabilized sulfonium ylides with succinic anhydride, it was found that the stable adducts (IV) were obtained in good yields instead of the expected six-membered lactone derivatives. These results indicate that the sulfonium ylide (II) is converted to the more stable tautomer (IV) by an intramolecular proton transfer from α-carbon to carboxylate anion.



It was established that, unexpectedly, furofuran derivatives were obtained instead of six-membered lactone derivatives or stable adducts by the reactions of α-substituted carbonyl-stabilized sulfonium ylides with succinic anhydride.

Concerning to the preparation of α-substituted carbonyl-stabilized sulfonium ylides, there are few papers, except the cyclic ylide, dimethylsulfonium 2,6-diacetyl-

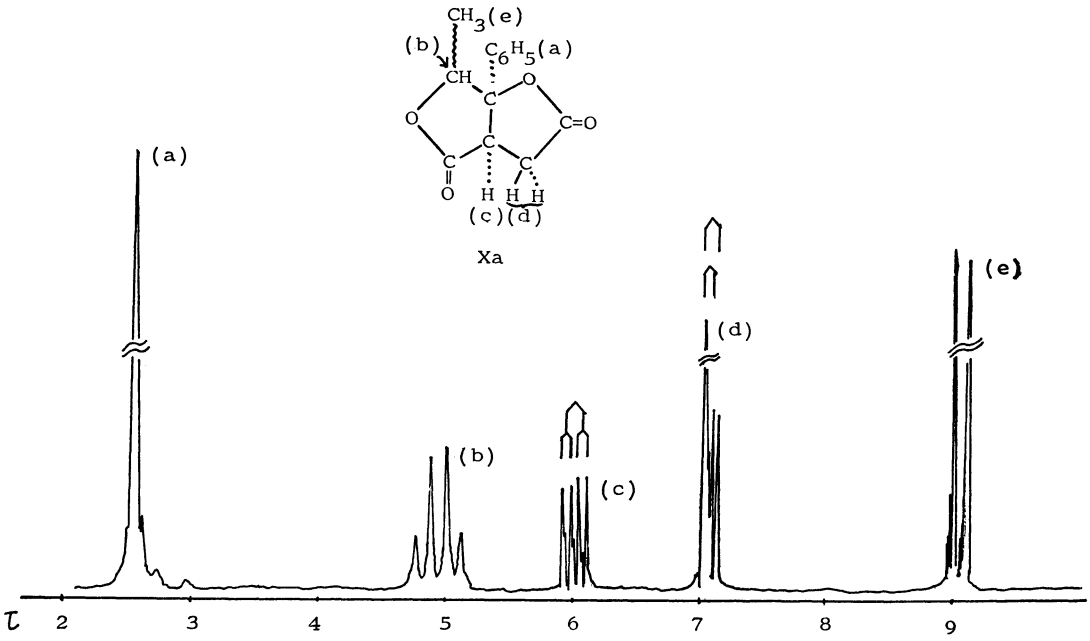

Fig. 1. NMR spectrum of Xa.

2,6-dimethyl-4-oxo-1,3-dioxan-5-ylide.[2] According to this procedure, the preparation of α-substituted sulfonium ylides were tried. When α-bromopropiophenone and dimethyl sulfide were mixed in acetone and allowed to stand for a week at room temperature, the crystalline sulfonium salt (IXa) was obtained in 76% yield. On the other hand, in the case of 3-bromo-2-oxobutane, the reaction took place very slowly and, even after ten days, the sulfonium salt (IXb) was produced only in 40% yield as syrup. When an equimolar amount of silver tetrafluoroborate was added to the resulting reaction mixture of 3-bromo-2-oxobutane and dimethyl sulfide in acetone, the sulfonium salt (IXb′) was obtained in almost quantitative yield within 16 hr. In a similar way, the sulfonium salts, IXc and IXd, were obtained in excellent yields from the corresponding bromides, VIIIc and VIIId. The desired sulfonium ylides (Va—d) were conveniently prepared from the corresponding sulfonium salts in chloroform by the action of 50% aqueous. sodium hydroxide according to the method of Payne.[3] The IR spectra of ylides (Va—d) show bands at 1500, 1505, 1555, and 1560 cm^{-1} attributable to carbonyl groups of sulfonium ylides respectively.

Next, the reaction of the sulfonium ylide with succinic anhydride was tried. When a mixture of the ylide (Va) and succinic anhydride in tetrahydrofuran (THF) was refluxed for 5 hr, evolution of dimethyl sulfide was observed by its characteristic odor and tarry residue remained after the solvent was evaporated. The crystals (Xa), mp 148—149°C, $C_{13}H_{12}O_4$, were isolated from the tarry residue by silica gel column chromatography. The IR spectrum of this compound shows bands at 1795 and 1775 cm^{-1} assigned to a five-membered lactone, and its NMR spectrum shows a singlet at 2.53 τ (5H), a quartet at 4.97 τ (1H), a double doublet at 6.09 τ (1H), a double doublet at 7.05 τ and 7.08 τ (2H) and a doublet at 8.95 τ (3H) (Fig. 1). This compound was stable toward hydrolysis in refluxing concentrated hydrochloric acid-ethanol (1 : 1). On the other hand, this affords acetaldehyde and ketoalcohol (XII) by reducing with lithium aluminum hydride in THF, followed by oxidation with sodium metaperiodate in aqueous ethanol. Acetaldehyde was identified by deriving to its 2,4-dinitrophenylhydrazone. The oily ketoalcohol (XII) reacted with *p*-nitrobenzoyl chloride to give the syrupy ketoester (XIII), which was confirmed by elemental analysis, IR spectrum showing bands at 1730 and 1682 cm^{-1}, and its NMR spectrum having a multiplet at 1.27—2.70 τ (13H), a doublet at 5.28 τ (2H), a triplet at 5.38 τ (2H), a multiplet at 5.72 τ (1H) and a multiplet at about 7.6 τ (2H). From these results, it seems reasonable to conclude that Xa is a furofuran derivative. In this case, Xa is a single product, but the configuration of a methyl group at C_6 in Xa can not be elucidated. Perhaps, a methyl group at C_6 exists in *trans* relation to a phenyl group at C_{6a}

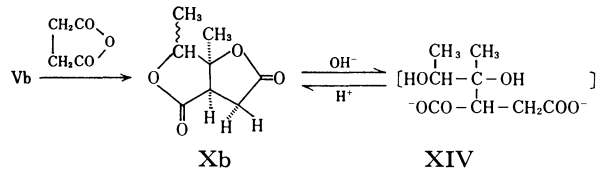
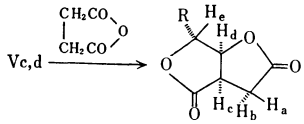
because of the steric hindrance.

Similarly, the ylide (Vb) reacted with succinic anhydride in THF-dimethylformamide (DMF) (1 : 1) to give the crystals (Xb), $C_8H_{10}O_4$, mp 144—146°C. The IR spectrum of Xb shows a band at 1770 cm^{-1} along with shoulder absorption at 1790 cm^{-1} and its NMR spectrum was similar to that of Xa as shown in Fig. 2. The compound (Xb) was stable toward acid hydrolysis, but a viscous oily carboxylic acid was obtained by hydrolysis of Xb with aqueous sodium hydroxide. This carboxylic acid is transformed to the original compound (Xb) by the treatment with acid. Based on these results, the structure of Xb was confirmed to be a furofuran derivative.

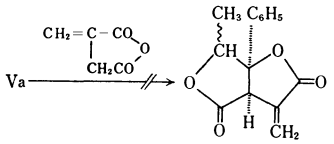


In the cases of the ylides, Vc and Vd, the reactions with succinic anhydride in THF-DMF (1 : 1) gave the furofuran derivatives, Xc, mp 107—108°C, $C_8H_{10}O_4$, and Xd, mp 86—87°C, $C_{10}H_{14}O_4$, in 10% and 5% yields respectively. The IR and NMR spectra of Xc and Xd were similar to those of Xb as shown in Figs. 3 and 4. The coupling constant between H_d and H_e (J_{de}=0 H_z) indicates that these protons have a *trans* relationship.



Xc R=C_2H_5 d R=*n*-C_4H_9

The reaction of Va and itaconic anhydride was tried in order to apply this reaction to the synthesis of the furofuran derivative[4] having an exocyclic double bond. However, the reaction under various conditions, such as with ice cooling or with dry-ice cooling, resulted in resinification of the reaction mixture. Consequently, the furofuran derivative (XVI) could not be isolated.



XVI

On the other hand, 2-methylsuccinic anhydride reacted with the ylide (Va) in THF-DMF (1 : 1) to give the furofuran derivative (XVII), mp 103—104°C, $C_{14}H_{14}O_4$, in only 10% yield. The IR spectrum of

Experimental

All melting points are uncorrected.

Sulfonium Salts. The sulfonium salts were prepared by the following two methods, (A) and (B).

Method (A): A solution of α-bromopropiophenone (21.3 g, 0.1 mol) and dimethyl sulfide (6.8 g, 0.11 mol) in acetone (50 ml) was allowed to stand for a week. Filtration gave the sulfonium salt (IXa), 19.2 g (73%), mp 135—137°C (dec.). Recrystallization from ethanol gave colorless microcrystals, mp 138—139°C (dec.).

Method (B): A mixture of 3-bromo-2-oxobutane (11.7 g, 0.08 mol), dimethyl sulfide (9.3 g, 0.15 mol) and silver tetrafluoroborate (15.5 g, 0.08 mol) in acetone (50 ml) was stirred for 16 hr at room temperature. Silver bromide was filtered off and washed with ethanol. The combined filtrate was

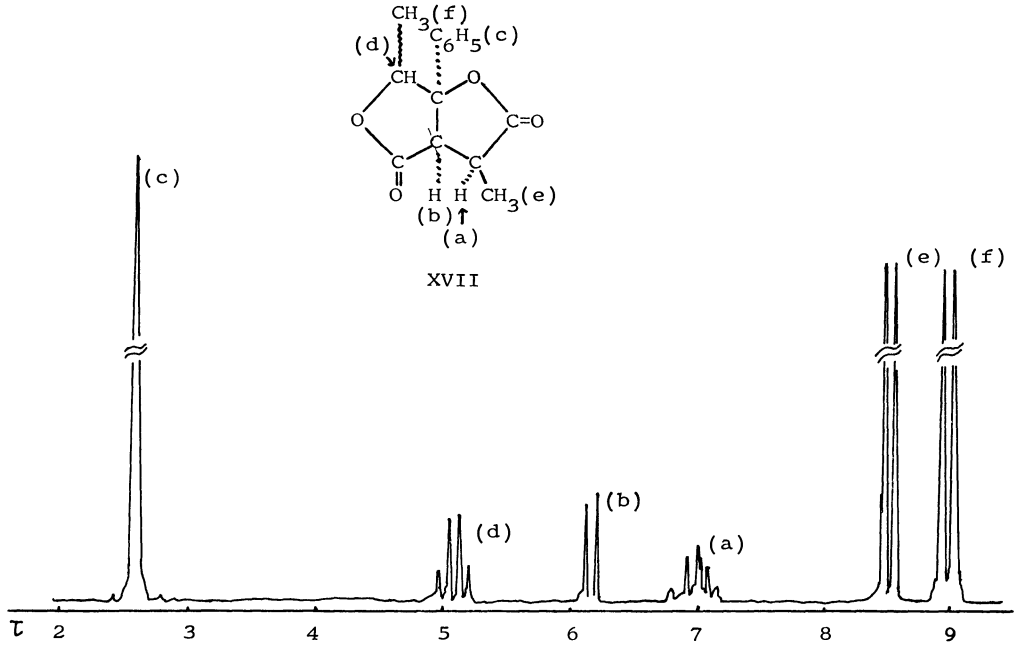

Fig. 5. NMR spectrum of XVII.

evaporated under reduced pressure to give an oily residue. After washing the residue with ether, evaporation of the ether under reduced pressure gave the sulfonium tetrafluoroborate (IXb′) as dark hygroscopic syrup with constant weight of 17.09 g (quantitative yield).

Similarly, various sulfonium salts were obtained by the reactions of α-bromoaldehydes with dimethyl sulfide. The results are listed in Table 1.

ethyl acetate was washed with aqueous sodium hydrogen carbonate followed by water, and dried over sodium sulfate. After removal of the solvent, the residue was chromatographed on silica gel, and elution with methylene chloride gave a yellow oil, which was crystallized from ether, and filtration gave colorless crystals, mp 146—148°C. Recrystallization from ethanol gave Xa, 4.22 g (44%), as colorless needles.

Similarly, various furofurans were obtained by the reaction of ylides with succinic anhydride or 2-methylsuccinic anhydride. The results are listed in Table 3.

Degradation of Xa. To a solution of lithium aluminum hydride (0.74 g) in dry THF (20 m*l*) was added a solution of Xa (1.70 g) in dry THF (10 m*l*). After refluxing for two hours, excess lithium aluminum hydride was decomposed by addition of small amount of water and the mixture was filtered. Evaporation of the solvent gave alcohol (XI), 1.45 g (81%), as syrup. A solution of XI (1.45 g) and sodium metaperiodate (1.33 g) in aqueous ethanol (1 : 1) (30 m*l*) was stirred in bubbling nitrogen atmosphere at room temperature for five hours. Evolved acetaldehyde was led into a solution of 2,4-dinitrophenylhydrazine in ethanol to give 2,4-dinitrophenylhydrazone, 1.04 g (75%), which was recrystallized from ethanol, mp 144—145°C. This hydrazone was identical with an authentic sample by comparing IR spectrum. The reaction mixture was extracted with ether. Evaporation of ether gave ketoalcohol (XII), 1.20 g (quantitative yield), as colorless oil, $\nu_{C=O}$ 1680 cm^{-1}. To a solution of XII (0.75 g) in pyridine (10 m*l*) was added *p*-nitrobenzoyl chloride (1.50 g) with stirring and heated at 70°C for fifteen minutes. After evaporation of pyridine, the reaction mixture was poured into water and extracted with methylene chloride which was washed with dilute hydrochloric acid and water. After evaporation of the solvent, the residue was chromatographed on silica gel, and elution with methylene chloride gave ketoester (XIII), 1.05 g (61%), as viscous syrup: $\nu_{C=O}$ 1730 and 1682 cm^{-1}; NMR (in $CDCl_3$): 1.27—2.70 τ (13H, multiplet), 5.28 τ (2H, doublet), 5.38 τ (2H, triplet), 5.72 τ (1H, multiplet), and 7.60 τ (2H, multiplet).

Found: C, 60.70; H, 3.86; N, 5.50% Calcd for $C_{25}H_{20}O_9N_2$: C, 60.97; H, 4.09; N, 5.69%.

Hydrolysis of Xb and Cyclization of XIV. A suspension of Xb (0.54 g) in 10% sodium hydroxide (40 m*l*) was heated at 70°C for two hours to give a clear solution, which was then cooled, washed with ether, acidified with hydrochloric acid, and immediately extracted with ethyl acetate. Removal of the ethyl acetate gave an oily carboxylic acid (XIV), 0.52 g, ν_{OH} 3430 cm^{-1} (broad) and $\nu_{C=O}$ 1705 cm^{-1}. A solution of 200 mg of the carboxylic acid (XIV) and one drop of conc. hydrochloric acid in ethyl acetate was refluxed for five hours. After removal of the ethyl acetate, the oily residue was crystallized from ether to give Xb; 120 mg, mp 142—144°C, which was identified by IR spectrum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 166—172 (1971)

Hydrogenation and Hydrogenolysis. XIII.[1] The Hydrogenation of Ethyl 4-Methyl-1-cyclohexenyl Ether over Platinum Metal Catalysts

Shigeo NISHIMURA, Mamoru KATAGIRI, Tetsuo WATANABE, and Masayoshi URAMOTO
Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei-shi, Tokyo

(Received June 29, 1970)

The hydrogenation and hydrogenolysis of ethyl 4-methyl-1-cyclohexenyl ether (I) have been investigated with six unsupported platinum metals as catalysts at 25°C under atmospheric pressure of hydrogen. The hydrogenation of I in ethanol was accompanied by the formation of 4-methylcyclohexanone diethyl acetal (II), the extent of which depended on the nature of the catalyst metals. The ratio of the acetal formation to hydrogenation increased with respect to the catalyst metals in the sequence Os$<$Ru$<$Ir$\ll$Rh$<$Pd$<$Pt. The amount of the hydrogenolysis to give methylcyclohexane increased in the order Pd$\cong$Ru$\ll$Os$<$Rh$<$Ir$\ll$Pt at an initial stage of the hydrogenation in ethanol. This order in hydrogenolysis was explained in terms of the action of the ionized hydrogen on the catalyst surface and the olefin isomerization activity of the catalyst metals. The stereochemistry of the hydrogenation of I was also studied and the results were interpreted on the basis of the proposed mechanism. I was also hydrogenated in *t*-butyl alcohol and isopropyl ether as solvents and, except in a few cases, the proportion of hydrogenolysis decreased with solvent in the order ethanol$>$*t*-butyl alcohol$>$isopropyl ether. The stereoselectivity in ether formation did not differ much among the solvents except over palladium.

Detailed studies on the catalytic hydrogenation of an enol ether seem rather few in the literature.[2-4] Howard and Brown, Jr.,[3] hydrogenated various acetals with supported platinum metal catalysts in the presence of hydrochloric acid and interpreted from the results that acetals hydrogenate *via* the corresponding enol ethers under the acidic conditions. Acke and Anteunis[4] hydrogenated some acetals and corresponding enol ethers, in relation to the study of the hydrogenation of cycloalkanones in acidic methanol, with Adams platinum as catalyst. They showed that in the presence of hydrochloric acid the products obtained on hydrogenation of acetals and enol ethers were almost the same and suggested that formation of these compounds would be responsible for the production of ethers and

cycloalkanes on hydrogenation of the ketones in acidic methanol. It is also known from some examples in the literature that formation of alkanes on hydrogenation of enol ethers occurs over platinum, while this does not seem to occur with palladium.[2,4,5] However, no comparative study of the hydrogenation and hydrogenolysis of an enol ether over the six platinum metals seems to have ever been described and, especially, the nature of the rarer platinum metals in this reaction appears little known.

In this study, the catalytic hydrogenation and hydrogenolysis of ethyl 4-methyl-1-cyclohexenyl ether (I) over six unsupported platinum metals have been investigated in ethanol, *t*-butyl alcohol and isopropyl ether as solvents at 25°C and the atmospheric pressure of hydrogen. The properties of the six platinum metals have been compared mainly with respect to their activities for acetal formation in ethanol, their tendencies towards hydrogenolysis as well as their stereoselectivities in the formation of saturated ether. 4-Methylcyclohexanone diethyl acetal (II) has also been subjected to hydrogenation for comparison. We have been interested in the hydrogenation of I, because it is an important intermediate in the catalytic hydrogenation of ethyl *p*-tolyl ether, the results of which will be described in a forthcoming paper.[6]

Experimental

Materials. 4-Methylcyclohexanone Diethyl Acetal (II) was prepared by passing dry hydrogen chloride into a mixture of 4-methylcyclohexanone and ethyl orthoformate in absolute ethanol. Bp 96°C/21 mmHg; n_D^{20} 1.4347 (lit,[7] Bp 76—78°C/15 mmHg; n_D^{20} 1.4350).

Mthyl 4-Methyl-1-cyclohexenyl Ether (I) was prepared by heating II with 0.1% anhydrous *p*-toluenesulfonic acid and distilling off ethanol under the pressure of about 100 mmHg.[7] The residue was then distilled fractionally under reduced pressure. Bp 76—76.8°C/26 mmHg; n_D^{20} 1.4590 (lit,[7] Bp 58—60°C/15 mmHg; n_D^{20} 1.4537). The purity of this preparation was almost 100% as analyzed by gas chromatography. For hydrogenation, the enol ether of 97.3% purity, containing 2.3 mol% of II and 0.4 mol% of 4-methylcyclohexanone, was used throughout the experiments.

Solvents. S.S.G. ethanol of the Wako Pure Chemical Industries was further dehydrated by refluxing with sodium metal and diethyl phthalate.[8] *t*-Butyl alcohol and Isopropyl ether were dehydrated with sodium metal and then carefully distilled.

Catalysts. Unsupported ruthenium, rhodium and palladium catalysts were prepared by reducing the corresponding metal hydroxides in water with hydrogen under atmospheric pressure (at room temperature for rhodium and palladium and at 40—50°C for ruthenium). Unsupported iridium catalyst was prepared by reducing iridium hydroxide in water for 40 min at 90°C under the hydrogen pressure of 80 kg/cm². Unsupported osmium catalyst was obtained by reducing osmium tetroxide in water for 40 min at 90°C under the hydrogen pressure of 60 kg/cm². Unsupported platinum catalyst was prepared by the following procedure: Adams platinum oxide was reduced in water for 10 min at room temperature and atmospheric pressure. The upper layer of water was removed by decantation and a new portion of distilled water was added, and then the reduction was continued further for 5 min. By this procedure satisfactory removal of alkaline substances was effectuated for Adams platinum oxide. The catalyst metals thus prepared were all well washed with distilled water and then dried in vacuum over silica gel.

Hydrogenation. The substrate (0.2 m*l*) was hydrogenated with 10—40 mg of the catalyst metal in 10 m*l* of the solvent at 25°C and the atmospheric pressure of hydrogen in a glass bottle shaken at about 300—350 strokes per minute.

Analysis of Reaction Mixture. The reaction mixture was taken into a microsyringe through a silicone gum stopper during the course of hydrogenation and subjected to gas-chromatographic analysis as soon as possible. A column of 10% PEG 20M on Chromosorb W (column dimensions: 0.3 cm × 3.75 m; column temperature: programmed at 2°C/min for 36—100°C and 4°C/min for 100—160°C) was used except for the product in isopropyl ether, which was analyzed using a column consisting of PEG 6000 (2.25 m) and Apiezon L (1.5 m). The peaks of the *cis* and *trans* isomers of ethyl 4-methylcyclohexyl ether were assigned according to those of corresponding methyl ether, the *cis* isomer of which was reported by Hückel and Kurz to be of smaller retention time.[9] Correctness of this assignment was confirmed by ethylating a *cis*-rich 4-methylcyclohexanol with sodium amide and ethyl iodide in benzene and subjecting the resulting *cis*-rich ether to gas chromatography.

Results

Hydrogenation in Ethanol as the Solvent. Hydrogenation of I in ethanol is accompanied by the formation of the acetal II, the extent of which largely depends on the nature of the catalyst metal used. The rate of hydrogenation of the acetal is in most cases much lower than that of I and the product from the acetal often differs from that obtained from I. Accordingly, the composition of the reaction mixture at initial stages of hydrogenation is not always similar to that of subsequent hydrogenation. Table 1 shows only the composition of the reaction mixture at a final stage of hydrogenation. The varying composition of the reaction mixture during the course of hydrogenation is shown in Figs. 1—6. The results of the hydrogenation of the acetal II is given in Table 2.

1) Hydrogenation over Ruthenium Catalyst (Fig. 1): The acetal formation was slow over this metal, the maximum amount of it being 20.3 mol% at 79.4% hydrogenation. Accordingly, the greater part of I was hydrogenated without the accompanying formation of the acetal. Hydrogenolysis occurred only to the extent of 2.8 mol% and the selectivity for formation of ethyl 4-methylcyclohexyl ether (IV) was very high (95 mol%), until the acetal began to hydrogenate at about 70% hydrogenation. The rate of hydrogenation after this became very small and the main product of hydrogenation was 4-methylcyclohexanol (V), which

b) I: Ethyl 4-methyl-1-cyclohexenyl ether; II: 4-Methylcyclohexanone diethyl acetal; III: 4-Methylcyclohexanone; IV: Ethyl 4-methylcyclohexyl ether; V: 4-Methylcyclohexanol; VI: Methylcyclohexane.

c) Proportion of hydrogenolysis is given by $\frac{100 \times \text{mol (VI)}}{\text{mol (IV+V+VI)}}$.

probably resulted from hydrogenation of 4-methylcyclohexanone (III) formed by the hydrolysis of I or II. This type of hydrolysis was difficult to be avoided although hydrogenation was performed in carefully dehydrated ethanol under dry hydrogen. The alcohol formation was not observed during a much faster hydrogenation of I at earlier stages. The hydrogenation of II under the same conditions was also very slow and the predominant product was the alcohol IV, as expected from the results of the hydrogenation of I.

2) Hydrogenation over Rhodium Catalyst (Fig. 2): The acetal formation occurred to considerable extent during the hydrogenation of I with rhodium. The maximum amount of it formed was 44 mol% at 51% hydrogena-

b) See the footnote (a) in Table 1.

tion. Similarly as with ruthenium catalyst, hydrogenation became slow after about 50% hydrogenation at which the acetal formed began to be hydrogenated and formation of the alcohol increased suddenly. As shown in Table 2, the main product of the hydrogenation of II was also the alcohol IV. Hydrogenolysis occurred to a much greater extent than over ruthenium catalyst and it decreased during the hydrogenation from 10 mol% at the initial stage to 8.5 mol% at a final stage. Hydrogenolysis occurred to a much lesser extent in hydrogenation of II as seen in Table 2. The *cis/trans* ratio of ether IV formed from I was 4.1 which was rather great as compared with those by other platinum metals except palladium.

3) Hydrogenation over Palladium Catalyst (Fig. 3): Hydrogenation of I with palladium catalyst was accompanied by a rapid formation of II which amounted to 53 mol% at 41% hydrogenation. In contrast to the results with ruthenium and rhodium, the product of the hydrogenation of I did not differ much from that formed from the acetal II (see Table 2). Noteworthy features of the palladium-catalyzed hydrogenation are that hydrogenolysis occurred only to a slight extent (0.3 mol%) and the selectivity for the formation

of ether IV was almost quantitative (99.7 mol%). The alcohol was not formed, although the ketone III was found in the reaction mixture in an amount of 2.3 mol% at the maximum in 41% hydrogenation. This is probably due to the fact that with palladium the ketone is hydrogenated to yield the ether IV as the predominant product as reported previously.[10] Another characteristic feature of the hydrogenation with palladium is a high stereospecificity in ether formation. The *cis*/*trans* ratio of the ether IV formed in ethanol was about 10 which was much greater than those obtained by other platinum metals.

4) Hydrogenation over Osmium Catalyst (Fig. 4).: Over this metal the acetal formation occurred to the least extent of the six metals investigated (8.9 mol% at 88.9% hydrogenation). The acetal formed appears not to be hydrogenated to any appreciable extent during hydrogenation as indicated by a linear increase of it with hydrogenation. Formation of the alcohol was also at a low level (0.86 mol%). Since the ketone III is readily hydrogenated to the alcohol V under these conditions, it seems that hydrolysis of I or II to give III did not occur or did only to a slight extent over osmium. Hydrogenolysis, however, occurred to considerable extent and the proportion of it increased from 8.2 mol% at an initial stage to 23 mol% at 88.9% hydrogenation.

5) Hydrogenation over Iridium Catalyst (Fig. 5): The acetal formation was not rapid, but somewhat faster than over osmium and ruthenium (24 mol% at 75.1% hydrogenation). Hydrogenolysis was 14.8% at the initial stage and decreased to about 12% towards the end of hydrogenation. The decrease in the proportion of hydrogenolysis may be due to the participation of the hydrogenation of II formed, since II was hydrogenolyzed to much lesser extent as seen in Table 2. A small amount of the alcohol V was produced after the hydrogenation of II began.

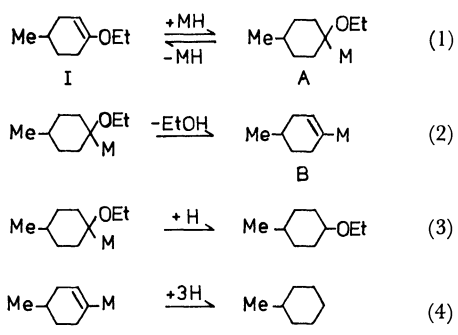
6) Hydrogenation over Platinum Catalyst (Fig. 6): The acetal was formed most rapidly over platinum. It amounted to 73 mol% at 24.8% hydrogenation. It is also noteworthy that hydrogenolysis occurred most extensively of the six platinum metals studied (71.6% at an initial stage and 39.1% at the end of hydrogenation). About 15 mol% of the alcohol V was formed along with 46 mol% of the ether. The ratio of the alcohol to the ether was almost the same with that obtained in hydrogenation of II (see Table 2). Thus the most part of the hydrogenation of I in ethanol is the same with that of II, but at the initial stage of hydrogenation a definitely more extensive hydrogenolysis was observed.

Hydrogenation in t-Butyl Alcohol and Isopropyl Ether as Solvents. The hydrogenation of I was performed in these solvents in order to see the behavior of I under the lack of formation of the acetal and also the effect of the solvent polarity. The results are given in Table 1. The acetal formation was observed only slightly except when hydrogenolysis occurred extensively. Hydrolysis to yield the ketone V occurred over rhodium, palladium and platinum catalysts. Except in a few cases the proportion of hydrogenolysis decreased with the solvents in the order ethanol>*t*-butyl alcohol> isopropyl ether. The *cis*/*trans* ratio of ether IV formed did not differ much among the three solvents except in hydrogenation over palladium where a definite decrease in the ratio was observed from in ethanol to in *t*-butyl alcohol and isopropyl ether.

Discussion

As illustrated in Figs. 1—6, hydrogenation of the enol ether I in ethanol is accompanied by the formation of the acetal II which results from the addition of ethanol to I. The ratio of the acetal formation to hydrogenation is indicated by the initial slope of the curves which show the amounts of the acetal varying with the extent of hydrogenation. The values of this ratio for the six platinum metals are in the following sequence: osmium (0.06)<ruthenium (0.11)<iridium (0.26)≪ rhodium (1.28)<palladium (1.87)<platinum (5.76). Thus, the six metals can be classified into two groups. Osmium, ruthenium and iridium belong to the group which catalyzes the acetal formation only weakly, while rhodium, palladium and platinum to the other group which catalyzes it efficiently. The addition of ethanol to I is an acid-catalyzed reaction. The action of the platinum metals to catalyze this addition is probably due to the presence of the adsorbed hydrogen which is ionized on the catalyst surface. It was previously shown that acetal is formed rapidly in the hydrogenation of cycloalkanones over some platinum metals in methyl or ethyl alcohol and also that the acetal formation is greatly depressed in the absence of hydrogen.[10]

With respect to hydrogenolysis, platinum was definitely more active than any other platinum metals. On the other hand, palladium and ruthenium showed only poor tendency towards hydrogenolysis. At an initial stage of hydrogenation of I in ethanol, the proportion of hydrogenolysis was in the following sequence for the six platinum metals: palladium≅ruthenium≪osmium<rhodium<iridium≪platinum (see Table 3). It is to be noted that palladium showed the lowest activity for hydrogenolysis although the same metal is known to be highly active for the hydrogenolysis of benzyl- and allyl-type ethers.[11]



Scheme 1.

(M indicates catalyst metal)

10) S. Nishimura, T. Itaya, and M. Shiota, *Chem. Commun.*, **1967**, 422.

11) See for instance Ref. 2, p. 433.

The mechanism of the hydrogenation and hydrogenolysis of an enol ether appears not enough known. Probably, the half-hydrogenated state of I is the one which results from the addition of a hydrogen (or proton) to the C-2 carbon of I (A in Scheme 1), as assumed by Acke and Anteunis.[4] If the affinity of the carbon (or carbonium ion) and the catalyst metal is not strong in the resulting half-hydrogenated state, step (1) in Scheme 1 will readily be reversed and in this case the removal of ethanol from the half-hydrogenated state will not occur so easily. On the other hand, such affinity between the intermediate A and the catalyst metal is sufficiently strong, the reversal of step (1) would be inhibited and, rather, elimination of ethanol to give the adsorbed intermediate B would be favored [step (2)]. If we assume that the affinity mentioned above is expressed in terms of the olefin isomerization activity of the metal,[12] it is expected that hydrogenolysis will occur more easily over such metals which are less active in olefin isomerization. Since elimination of ethanol by step (2) would be promoted by acid and, accordingly, by the ionized hydrogen on the catalyst surface, hydrogenolysis will occur more extensively over such metals which can catalyze the acetal formation effectively on hydrogenation of I in ethanol. The activities of the six platinum metals in the acetal formation (r_1) and those in olefin isomerization (r_2) are summarized in

Table 3. Acetal formation and olefin isomerization activities of platinum metal catalysts and their tendency towards hydrogenolysis in hydrogenation of enol ether I

Catalyst	Ratio of acetal formation to hydrogenation[a] (r_1)	Ratio of olefin isomerization to hydrogenation[b] (r_2)	$\frac{r_1}{r_2}$	Proportion of hydrogenolysis in hydrogenation of I (mol%)[a]
Ru	0.11	0.12	0.92	1.9
Rh	1.28	0.125	10.2	10.0
Pd	1.87	2.05	0.91	1.1
Os	0.06	0.0093	6.45	8.2
Ir	0.26	0.025	10.4	14.8
Pt	5.76	0.025	230	71.6

a) These values were obtained at the initial stage of the hydrogenation of I in ethanol.
b) The ratio r_2 was obtained in the hydrogenation of 1-octene in isopropyl alcohol at 25°C under atmospheric presence of hydrogen and is given by the ratio of isomerized 2-octene to octane at about 20% conversion of 1-octene.

Table 3. The value of r_2 was obtained in the hydrogenation of 1-octene in isopropyl alcohol at 25°C under an atmospheric pressure of hydrogen, using the unsupported metals prepared by the same methods as used for the catalysts in this study.[13] Thus we can expect that the extent of hydrogenolysis observed in the hydrogenation of an enol ether would increase with increasing value of r_1/r_2 which is also given in Table 3. For the six platinum metals the value of r_1/r_2 is in the following sequence: Pd≅Ru≪Os<Rh<Ir≪Pt. It is seen that this sequence is in excellent accord with that obtained in the proportion of the hydrogenolysis which occurred at the initial stage of the hydrogenation of I in ethanol (see Table 3). Thus, the very low activity of palladium catalyst towards hydrogenolysis may be due to its weak affinity for the carbon atom as expressed by its unusually high olefin isomerization activity. The low activity of ruthenium in the hydrogenolysis may be explained by the poor action of the ionized hydrogen on that metal. The extremely high activity of platinum towards the hydrogenolysis will result from its properties as expressed by both of the high activity in the acetal formation and the low activity in the olefin isomerization.

The results of the stereochemistry of hydrogenation of I seem consistent with the mechanism described in Scheme 1. The hydrogenation of I over palladium catalyst is noteworthy in that *cis*-ether IV is formed with a high stereospecificity. If the rate-determining step over this metal is assumed to be formation of the saturated ether [step (3)], just as postulated in the hydrogenation of cycloolefins,[14] the preceding steps, including the adsorption of I to the catalyst, would be easily reversed as supposed by its weak affinity toward unsaturation. Under these circumstances, possible half-hydrogenated states A_c, A_t and A_t' (see Fig. 7) will be equilibrated on the catalyst surface. Since

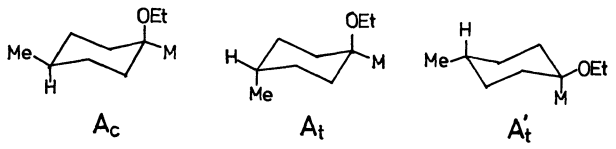


Fig. 7. Conformations of half-hydrogenated state A (M indicates catalyst metal).

the most stable one of them will be A_c, this will predominate at equilibrium and *cis*-ether will be formed in excess *via* A_c, if the rate constants for hydrogenation of them do not differ much among them. In this connection, it is of interest to note that hydrogenation of 1,4-dimethyl-1-cyclohexene, which has a methyl group instead of the ethoxyl group in I, gives the *trans* isomer as major product in the hydrogenation with palladium catalyst.[15] This result may be explained by the assumption made be Siegel and Smith that decreasing stabilities of various possible half-hydrogenated states are in the order primary>secondary>tertiary with respect to the carbon adsorbed on the catalyst surface.[14] On hydrogenation of I, the electromeric effect of the ethoxyl group will direct the first addition of hydrogen (or proton) to the C-2 carbon and this leads to the preferential formation of the half-hydrogenated state A. This assumption is strongly supported by the fact that hydrogenation of 3-

methylcyclohexanone diethyl acetal (VII) in ethanol with palladium catalyst gave rise to *trans*-ether predominantly.[16] The acetal VII is probably hydrogenated *via* the corresponding enol ethers and over palladium the enol ethers are also expected to give the *trans*-ether in excess, as supposed from the comparison of the results obtained with palladium catalyst on their 4-methyl analogues (see Tables 1 and 2).

The stereoselectivity was much lower over the other platinum metals, although always *cis*-ether was formed in greater amount than *trans*-ether. It appears that the nature of the solvents does not have much influence on the stereochemistry of hydrogenation except with palladium. Over the metals other than palladium, the step which determines the stereochemistry of ether formation may be either adsorption of enol ether I or formation of the half-hydrogenated state, as postulated in the platinum-catalyzed hydrogenation of cycloolefins.[17]

16) unpublished results.
17) S. Siegel and G. V. Smith, *J. Amer. Chem. Soc.*, **82**, 6082 (1960).

It has been considered that acetals are hydrogenated *via* the corresponding enol ether in the presence of acid.[3,4] Although this reaction pathway will probably be true also in the absence of acid, hydrogenation of acetal II was in most cases much slower than that of enol ether I. This is also seen by the fact that I is hydrogenated at much greater rates in *t*-butyl alcohol and isopropyl ether than in ethanol (see Table 1). Since at an equilibrium in ethanol II is in a much greater amount than I, slow hydrogenation of II may be due to a slow formation of I by elimination of ethanol from I on the catalyst surface. It is also suggested that II is adsorbed to the catalyst much more weakly than I, since hydrogenation of II appears not to occur until almost all of I has disappeared as seen in Figs. 1—6. Slow hydrogenation of II also leads to the product considerably different from that obtained by hydrogenation of I and yields the saturated ether of a greater *cis*/*trans* ratio than formed from I, with the exception of the hydrogenation over palladium where almost the same product was formed on hydrogenation of I and II.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 172—177 (1971)

Cyclic Acetylenes. XI. The Syntheses of *p,p'*-Bridged Cyclic Tolans by the Fritsch-Buttenberg-Wiechell Rearrangement[1]

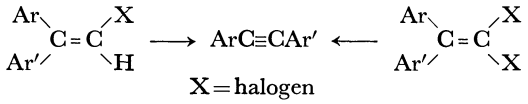
Takashi ANDO and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 13, 1970)

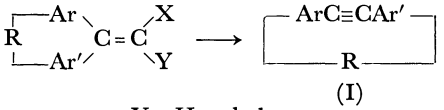
In order to ascertain the effect of ring strain on the electronic spectra of cyclic acetylenes, a series of *p,p'*-bridged cyclic tolans (V_n, $n=11$, 12, 13, 14, and 18) has been synthesized. It was found that the increasing ring strain exerted an appreciable hypochromic effect and also caused a slight bathochromic shift of the absorption band. The bathochromic shift observed in the *p,p'*-bridged cyclic tolans (V_n) forms a contrast with the hypsochromic shift observed in the strained *o,o'*-bridged cyclic diphenyldiacetylene (VI, $n=3$).

The formation of diarylacetylene from 1,1-diaryl-2-haloethylene by dehydrohalogenation, accompanied by rearrangement, has been well-known as the Fritsch-Buttenberg-Wiechell rearrangement.[2] The treatment of 1,1-diaryl-2,2-dihaloethylene with an organometallic compound also results in the formation of diarylacetylene.[3,4]



X=halogen

If a diarylhalo- or a diaryldihaloethylene in which the aryl groups are linked by a bridging chain (R) is subjected to the above-mentioned rearrangement, we can expect the formation of a cyclic diarylacetylene with a bridging chain between the aryl groups (I). As the distance between the *p*- and *p'*-positions of the two aryl groups in the ethylene is shorter than that of in the cyclic acetylene, the rearrangement



(I)

X=H or halogen
Y=halogen

reaction seems to offer a method of synthesizing highly-strained cyclic acetylene. Also, the rearrangement reaction in which the aryl group migrates with a bridging chain seems to be of interest in itself. An analogous

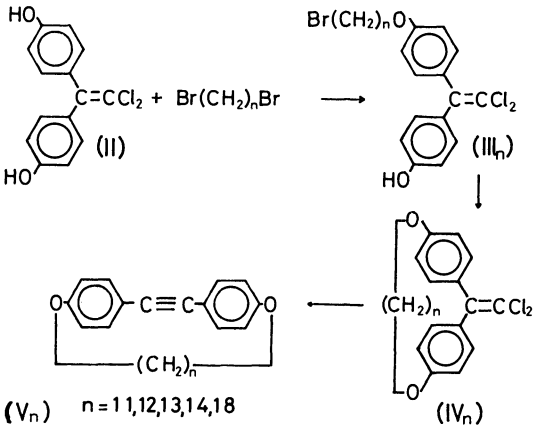
type of rearrangement has been studied by Wittig[5] in the case of the benzidine rearrangement of *N,N'*-polymethylene hydrazobenzenes.

The present paper will deal with the syntheses of polymethylene ether derivatives of *p,p'*-dihydroxytolan according to the Fritsch-Buttenberg-Wiechell rearrangement reaction.

Syntheses. 1,1-Dichloro-2,2-bis(*p*-hydroxyphenyl)-ethylene,[6] which had been derived from 1,1,1-trichloro-



2,2-bis(*p*-hydroxyphenyl)ethane,[7] was treated with a large excess of polymethylene dibromide in the presence of potassium hydroxide to yield the monoether III.[8] The intramolecular alkylation of the monoether III to yield the cyclic ether derivative IV was achieved by the Lüttringhaus method[8] under highly diluted conditions. The monomeric nature of IV was confirmed by a molecular weight determination according to the Rast method. The reaction conditions, the yields, and the melting points of IV are summarized in Table 1. The decreasing yields of the cyclic ethers IV with the diminishing length of the bridging chain clearly indicate the increasing difficulty of the intramolecular alkylation with the shorter chain.

Generally, the rearrangement reaction was carried out in an ether solution by treating IV_n with a 10% excess of *n*-butyllithium at a temperature of −17—−18°C for 1 hr. In the case of IV_{14}, a 100% excess of *n*-butyllithium was employed. Also, in the case of IV_{18}, the dichloroethylene was treated with a 100% excess of *n*-butyllithium at 2°C for 1 hr, and then at 18°C for 1 hr. The yields and the melting points of the cyclic tolans (V_n) are tabulated in Table 2, along with those of the reference substance, 4,4'-di-*n*-butoxytolan.

In the case of IV_{10}, the cyclic tolan (V_{10}) could not be obtained. The amorphous yellow solid which was isolated from the reaction product seemed to be a complex mixture and could not be identified. The colorless crystals of V_{11} and V_{12} were found to be rather unstable. On exposure to a diffused light in the laboratory, the formation of a violet-colored layer on the surface of the crystals of V_{11} and V_{12} was observed. On the other hand, the cyclic tolans of the higher ring member, V_{13-18}, and the open-chain analogue were found to be stable compounds. The tendency toward sublimation observed in V_{12}, V_{13} and V_{14} seems to reflect the rigid structures of these molecules with a tightly-drawn polymethylene bridge.

Table 1. The intramolecular alkylation of III_n

n	III (mmol)	Reaction time (hr)	IV mp (°C)	IV Yield (%)
10	8.0	65	134.2—135.6	39
11	20.6	69	127.5—128.5	46

Table 2. The yields and the melting points of V_n

n	Yield (%)	Mp (°C)	Recovered IV_n(%)
10	0	—	29
11	23	166.0—167.0	46
12	47	151.0—152.0	49
13	75	158.5—159.5[a]	20
		160.0—161.2	
14	90	167.3—168.3	0
18	75	118.4—119.0	0
n-Bu	52	130.5—131.5	43

a) Dimorphism.

It is difficult to reach a definite conclusion from the results of the rearrangement reactions, as the reactions were carried out under different conditions. However, as it has been proved that the presence of a large excess of *n*-butyllithium had no influence on the rearrangement reaction,[3] it seems to be evident that the diminishing length of the bridging chain retards the rearrangement or enhances some side reactions, resulting in a decrease in the yields of the cyclic acetylenes. However, it should be noted that a much higher yield than that of the open-chain analogue was obtained in the case of $n=14$[9] Either the fixation of the phenyl groups in IV_{14} in a favorable position for the rearrangement, resulting from the presence of the bridging chain in an adequate length, or the increased intramolecular nature of the reaction brought about by the linking of the migrating moiety, seemed to be the cause of the high yield of V_{14}.

Electronic Spectra. The electronic spectral data of 1,1-dichloro-2,2-bis(*p*-hydroxyphenyl)ethylene polymethylene ethers (IV_n) are summarized in Table 3, together with those of the open-chain reference. Slight

n-Bu	254 (21,300)	275 (15,900)

The asterisks indicate the inflexions.

bathochromic and hypochromic effects were observed with a decrease in the ring size. A similar, but a more appreciable, spectral trend has been found in the case of [1,*n*]paracyclophanes and has been explained in terms of a transannular electronic coupling of the two phenyl groups and a modification of the benzenoid resonance due to the bending of the two benzene nuclei.[10] However, in the case of IV_n, the cross-conjugation of the phenyl groups with the dichloromethylene group and the interaction of the phenyl groups with the lone-pair electrons in the oxygen atoms in the ether linkages may be altered by the change in the ring size. Because of these situations, it seems to be difficult to deduce a definite correlation between the spectral behavior and the ring size of IV_n.

Figure 1 and Table 4 record the absorption curves and the data of the cyclic tolans (V_n) along with those of *p,p'*-dibutoxy-diphenylacetylene as a reference compound.

It will be seen that the ring formation causes an increase in the absorption intensity. The maximum intensity was observed in V_{13}. However, the absorption intensity decreased with a decrease in the number of *n*, accompanied by a slight bathochromic shift of λ_{max}. The increase in the absorption intensity can be rationalized by the increased coplanarity of the phenyl groups caused by the ring formation. On the other hand, the regular red shift of the λ_{max} with the diminishing ring size and the decrease in the extinction coefficient going from V_{13} to V_{11} seems to be attributable to the effect of strain on the electronic spectra. The bathochromic shift observed in V_n makes a sharp contrast with the hypsochromic shift observed in a strained diphenyldiacetylene derivative (VI, $n=3$).[11]

Infrared Spectra. The 1580-cm^{-1} absorption band due to the skeletal in-plane vibration of an aromatic ring conjugated with the lone-pair electrons in a substituent, which could be observed in the spectrum of V_{18} at 1569 cm^{-1}, was found to be extremely weak in other members of V_n. This fact seems to indicate that the polymethylene bridge ($n=11$—14) would cause a fixation of the conformation of the oxygen atom at a position unfavorable for the conjugation with the aromatic ring. A regular shift of the absorption band due to the skeletal in-plane vibration of a benzene nucleus (*ca.* 1600 cm^{-1}) toward a lower wavenumber with a decrease in the ring size was observed; *i. e.*, the band appearing at 1609 cm^{-1} in the spectrum of V_{18} moved to 1596 cm^{-1} in that of V_{11}. Also, the fact that the spectra of V_{11} and V_{12} exhibit sharper absorption peaks than those of the other higher homologues seems to indicate the limited mode of vibration resulting from the fixed conformation and rigid structure of V_{11} and V_{12}. The characteristic peaks in the IR spectra of V_n are tabulated in Table 5, together

Table 5. The IR spectra of V_n (cm^{-1})

V_n	$\nu_{C=C}$ (arom.)		δ_{C-H} (arom.)

with that of the open-chain analogue, *p,p'*-dibutoxytolan.

Nuclear Magnetic Resonance Spectra. The most characteristic feature of the NMR spectra of V_n is the presence of strong and rather sharp peaks centered around 9 τ, as is illustrated in Fig. 2. The most well-

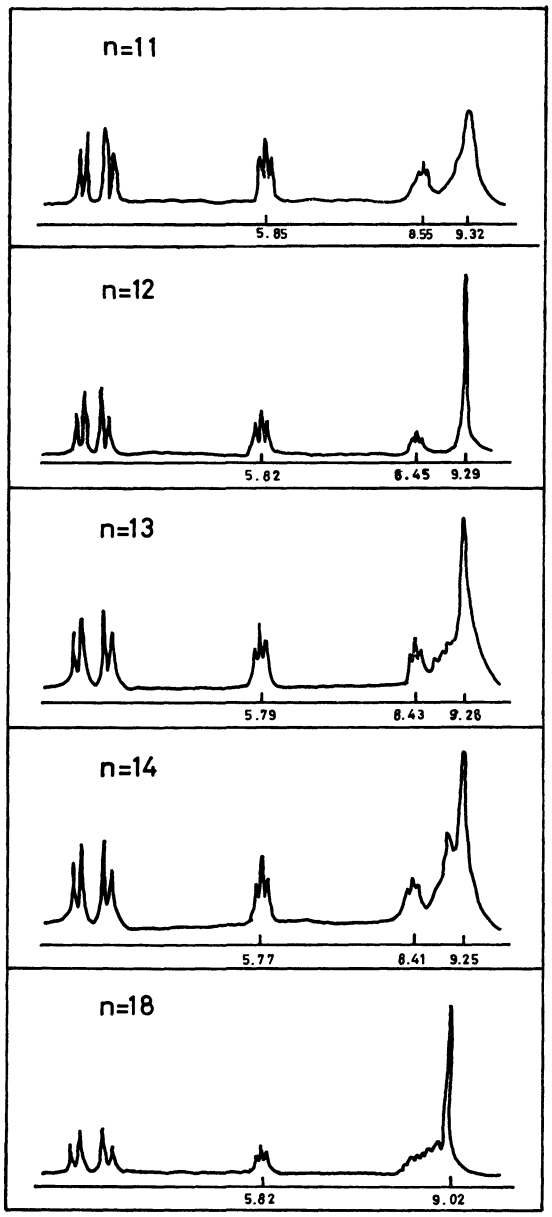

Fig. 2. The NMR spectra of V_n.

defined spectrum was obtained in V_{12}, and the triplet at 5.82 τ changed to a sharp singlet on the irradiation of the peak at 8.45 τ. On the basis of this finding, the triplet centered at 5.82 τ and 8.45 τ can be assigned to the protons of the α- and β-methylene groups of the oxygen atom respectively.[12] Therefore, the peak at 9.29 τ should be attributed to the protons of the other methylene groups. The aromatic nuclei and the triple bond should exert shielding[13] and deshielding effects[14] on the protons situated just on these structural units. However, the observed spectra indicate that an almost uniform magnetic environment is attained in the vicinity of the *p,p'*-disubstituted tolan system. This fact seems to be difficult to understand at first sight; however, the change in the electronic state caused by the conjugation of the phenyl nuclei with the triple bond may be responsible for the formation of the uniform magnetic environment.[15] The low-field shift of the peaks as compared with those of 4,4'-polymethylene biphenyls[16] seems to reflect the effect of acetylenic linkage.

Experimental

All the melting points are uncorrected. The infrared spectra were measured with a Hitachi EPI-2 Spectrophotometer by the KBr-disk method, the electronic spectra, with a Hitachi EPS-2 Spectrophotometer, and the NMR spectra, with a Varian A 60 Spectrometer.

*1,1-Dichloro-2,2-bis(*p*-hydroxyphenyl)ethylene (II).* 1,1,1-Trichloro-2,2-bis(*p*-hydroxyphenyl)ethane[7] was treated potassium hydroxide in methanol according to the reported method,[6] yielding II in a yield of 66.8%.

1,10-Dibromodecane. A commercial product was used.

1,11-Dibromoundecane. 10-Undecenol was prepared by the lithium aluminum hydride reduction of ethyl 10-undecenoate.[17] The acetate of 10-undecenol in benzene was treated with hydrogen bromide in the presence of benzoyl peroxide under the irradiation of UV light, thus affording 11-bromoundecanol acetate in a yield of 85%.[18] The hydrolysis of the bromo-acetate by means of potassium hydroxide in methanol resulted in the formation of a mixture of 11-bromoundecanol and 1,11-undecanediol (*ca.* 1 : 1), accompanied by a small amount of 11-undecenol. After the removal of the olefin under reduced pressure, hydrogen bromide was passed through the molten mixture of the alcohols at 130°C.[19] 1, 11-Dibromoundecane was obtained as a colorless liquid (bp 145—148°C/3 mmHg) in a yield of 81%.

1,12-Dibromododecane. Ethyl undecenoate[17] was converted to ethyl 11-bromoundecanoate according to the known method.[18] A mixture of the bromoester (350 g, 1.19 mol), powdered potassium cyanide (220 g, 3.38 mol), potassium iodide (5 g), cupric sulfate monohydrate (1 g), ethanol (1300 m*l*), and water (400 m*l*) was then refluxed for 8 hr. The crude ethyl 11-cyanoundecanoate obtained by working up the reaction mixture by an ordinary method was refluxed for 2 hr in a mixture of acetic acid (250 m*l*) and concentrated sulfuric acid (250 m*l*). The cooled reaction mixture was poured into ice water (3 *l*), yielding crude 1,12-dodecanedioic acid (251 g). The diethyl ester (241.4 g, 0.84 mol) which had been prepared from the crude dioic acid according to the usual

12) The double-resonance measurement was performed on a nuclear magnetic resonance spectrometer, C-60 of the Japan Electron-Optics Laboratory Co., Ltd. The authors wish to thank Professor Toshio Miwa, Department of Chemistry, Faculty of Science, Osaka City University, for the measurement and for his helpful advice.

method[20] was reduced by means of lithium alminum hydride to yield 1,12-dodecanediol[21] (159.9 g, 93.8%). The method used in the preparation of 1,11-dibromoundecane was used for the conversion of the diol (203.3 g, 1 mol) to 1,12-dibromododecane (248.6 g, 75.8%).

1,13-Dibromotridecane. 1,13-Tridecanedioic acid was prepared by the reaction of ethyl 11-bromoundecanoate (390.3 g, 1.33 mol) and diethyl sodiomalonate according to the reported method.[22] The crude diacid thus obtained was converted to the diethyl ester[20]; bp 159.0—163.0°C/2.7 mmHg, 295.8 g (74% based on the bromoundecanoate). The lithium alminum hydride reduction of the diethyl ester afforded 1,13-tridecanediol.[21] 1,13-Dibromotridecane, bp 162—164°C/3 mmHg, was obtained from the diol according to the above-stated method[19] in a yield of 59.8% (based on diethyl tridecanoate).

1,14-Dibromotetradecane. 1,12-Dibromododecane (164 g, 0.5 mol) was converted to crude 1,14-tetradecanedioic acid (126 g) *via* 1,12-dicyanododecane according to the method in the literature.[23] The diethyl ester derived from the dioic acid[20] was reduced to 1,14-tetradecanediol by means of lithium aluminum hydride.[21] 1,14-Dibromotetradecane was obtained from the diol in a yield of 57% (based on the diethyl ester) by treating it with hydrogen bromide at 130°C.[19]

1,18-Dibromooctadecane. Dimethyl octadecanedioate was prepared by the electrolysis of methyl hydrogen sebacate.[24] The lithium alminum hydride reduction of the dimethyl ester according to the above-described procedure[21] afforded 1,18-octadecanediol in a yield of 89%. The reaction of hydrogen bromide[19] with the diol at 120—135°C yielded 1,18-dibromooctadecane, bp 175—180°C/0.005 mmHg; mp 54—58°C, in a yield of 61%.

Preparation of ω-Bromoalkyl Ether of 1,1-Dichloro-2,2-bis(p-hydroxyphenyl)ethylene (III_{10-13}). The synthesis of ω-bromodecyl ether (III_{10}) will be described as a representative example. To a stirred and refluxing mixture of the bisphenol (II, 12.2 g, 0.0436 mol), anhydrous ethanol (100 m*l*), and 1,10-dibromodecane (91.5 g, 0.279 mol), we added 16.2 m*l* (0.0218 mol) of a 1.34N solution of potassium hydroxide in ethanol over a period of 15 min. The reaction mixture showed pH 5 after having been refluxed for a further 15 min. The cooled reaction mixture was then poured into water (300 m*l*) and extracted with ether. The extract was washed successively with water and a sodium hydrogen carbonate solution, and dried. After the solvent had been removed under reduced pressure, the excess of the dibromodecane was recovered by vaccum distillation under a nitrogen atmosphere (bp 131—137°C/3.7 mmHg, 80.6 g). The residue in benzene was chromatographed on alumina (300 g). The first fraction, on evaporation, gave a small amount of the dibromodecane. A minor amount of the substance obtained from the second fraction seemed to be 1,1-dichloro-2,2-bis(*p*-10-bromodecanoxyphenyl)ethylene; however, further investigation of this substance was not carried out. The crude mono-ether (III_{10}) which was obtained from the third fraction as a yellow waxy solid was rechromatographed on alumina to afford colorless III_{10} in a yield of 41.2% (based on the potassium hydroxide). This was used for the following reaction. The bisphenol (II) was recovered from the final fraction.

The other mono-ethers (III_{11}, III_{12} and III_{13}) were obtained according to the procedure described above. The yields may be summarized as follows: III_{11}: 22%; III_{12}: 33.3%; III_{13}: 34.7%.

Preparation of the Higher ω-Bromoalkyl Ether of the Dichloroethylene (III_{14} and III_{18}). Considering the high boiling and high melting points of 1,14-dibromotetradecane and 1,18-dibromooctadecane, the procedure of the recovery of the dibromoalkanes was slightly modified. After the reaction mixture had been mixed with water, the precipitated solid was repeatedly extracted with petroleum ether. The evaporation of the solvent then gave the crude dibromoalkanes. A material insoluble in petroleum ether was taken up in ether, and the aqueous layer was extracted with ether. The combined ethereal extracts were washed successively with water and a sodium hydrogen carbonate solution, and were then dried and evaporated under reduced pressure. The residue was combined with the distillation residue of the above-mentioned crude dibromoalkane and chromatographed on alumina to afford III_{14} (42%) and III_{18} (52%).

Synthesis of the Cyclic Ethers (IV_n). As all the intramolecular alkylations of III_n were carried out under almost the same conditions, the procedure employed for the preparation of IV_{10} will be described as a typical example. A solution of the mono-ether (III_{10}, 4.00 g, 0.008 mol) in isoamyl alcohol (250 m*l*) was added slowly to a vigorously-stirred and refluxing mixture of anhydrous potassium carbonate (3.3 g, 0.024 mol) and isomyl alcohol (300 m*l*) over a period of 65 hr, employing a high-dilution apparatus. After further refluxing for 2.5 hr, the cooled reaction mixture was filtered to remove any inorganic material. The yellowish-brown residue obtained by evaporating the solvent under reduced pressure was then redissolved in ether and washed thoroughly with a 10% aqueous solution of sodium hydroxide and water successively. The filtered ether solution was dried. The subsequent evaporation of the solvent resulted in a yellowish-brown liquid which crystallized on standing. The crude material was chromatographed on alumina, thus affording IV_{10} as light yellow crystals (1.3 g, 39.1%). The crystals were purified by rechromatography on alumina and by recrystallization from *n*-hexane to yield pure, colorless IV_{10}.

The reaction conditions of the intramolecular alkylation and the melting points and yields of IV_n are summarized in Table 1. Also, the electronic spectral data are recorded in

Table 3. The solvents of recrystallization, the analytical data, and the molecular-weights are recorded in Table 6, together with those of the reference substance.

The Rearrangement Reaction of IV_n. The reactions were carried out under an atmosphere of nitrogen. The procedure used for the synthesis of the cyclic tolan (V_{12}) will be described as a representative instance. A solution of the cyclic ethylene (IV_{12}, 507.9 mg, 1.12 mmol) in anhydrous ether (30 m*l*) was chilled in an ice-salt bath to keep at −17—−18°C. To the stirred solution we then added a solution of *n*-butyllithium (0.0561 mol/*l*, 22 m*l*, 1.23 mmol) over a period of 7 min. After stirring for a further hour at this tempearture, methanol (2 m*l*) and then water were added to the mixture. The organic layer was separated and dried. The colorless crystals (447 mg) obtained by evaporating the solvent were chromatographed on alumina (40 g). The fractions eluted with carbon tetrachloride gave the recovered ethylene (IV_{12}, 200 mg, 48.4%). The cyclic tolan (V_{12}, 200 mg, 46.8%) was obtained as colorless crystals from the fractions eluted with benzene. In the case of the reaction was performed at a temperature of −35°C, the cyclic tolan (V_{12}) was obtained in a yield of 46.4%, together with the recovered ethylene (53.4%)

The reaction conditions used for the preparation of the other cyclic tolans have already been described. The melting points, the yields, and the recovery of the ethylenes are tabulated in Table 7, together with those of the open-chain analogue. The cyclic tolans (V_n) were recrystallized from *n*-hexane.

a) Recrystallized from ethyl acetate.

Attempted Synthesis of the Cyclic Tolan V_{10}. The cyclic ethylene (IV_{10}, 436 mg, 1.04 mmol) was treated with a 10% excess of *n*-butyllithium under the above-described reaction conditions. The reaction mixture turned greenish-yellow and then deep green. The deep green color faded to yellow on the addition of methanol (2 m*l*). The reaction mixture was then worked up, resulting in a greenish-yellow, resinous material. The sole substance which could be identified was the recovered ethylene (IV_{10}, 126 mg, 28.9%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 177—184 (1971)

Cyclic Acetylenes. XII. The Syntheses of *o,p'*-Bridged Cyclic Tolans by the Fritsch-Buttenberg-Wiechell Rearrangement[1]

Mutsuo KATAOKA, Takashi ANDO, and Masazumi NAKAGAWA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 13, 1970)

The polymethylene ether derivatives of *o,p'*-dihydroxydiphenylacetylene (VII_n, $n=7,8,9,10,11$ and 12) have been synthesized by the Fritsch-Buttenberg-Wiechell rearrangement. The electronic, infrared, and NMR spectra of VII_n were examined. It was observed that the increasing ring strain had a hypochromic effect, with a hypsochromic shift of the long-wavelength band in the electronic spectra of VI_n making a contrast with the bathochromic shift in the strained *p,p'*-bridged cyclic tolans.

The successful preparation of *p,p'*-bridged cyclic tolans by the Fritsch-Buttenberg-Wiechell rearrangement[2] prompted the present authors to the syntheses of *o,p'*-bridged cyclic tolans according to the same reaction. Just as in the case of the *p,p'*-series, the distance between the *o*- and the *p'*-positions of the two phenyl groups in the tolans is longer than that of in the 1,1-diarylethylenes; therefore, the rearrangement reaction may provide a route for the synthesis of strained *o,p'*-bridged cyclic tolans. The two benzene nuclei in the *p,p'*-series with a suitably-long bridging chain are forced to take a coplanar conformation. On the other hand, in the case of *o,p'*-bridged tolans, the spanning of the *o*- and *p'*-positions with a short bridging chain should result in a twisting of the two benzene rings. Therefore, the comparison of the electronic and the NMR spectroscopic behavior of the *o,p'*-bridged tolans with those of the *p,p'*-series seemed to be of interest.

Synthesis. As is illustrated in Scheme 1, *o,p'*-dihydroxybenzophenone (I), which had been prepared by the intramolecular rearrangement of phenyl salicylate by stannic chloride,[3] was converted in a high yield to the *p'*-*ω*-bromopolymethylene ether derivative (II) by reaction with a large excess of polymethylene dibromide in the presence of equimolar potassium hydroxide.[4] Small amount of a diether derivative and the unreacted benzophenone (I) were also isolated. However, no *o*-alkylated compound could be obtained. This indicates the low reactivity of the *o*-hydroxyl group

a) III_6 has been prepared according to a modified procedure.

hydrogen-bonded with the carbonyl oxygen. The intramolecular alkylation of II_n to yield the cyclic benzophenone derivative (III_n) was carried out in isoamyl alcohol in the presence of 3 equivalents of potassium carbonate under high-dilution conditions.[4)] The reaction conditions and the yields of the intramolecular cyclization are summarized in Table 1, together with the melting points of the cyclic benzophenones (III_n). The low yields of III_{12} and III_{10} seemed to be due to the insufficient reaction period. On the other hand, the poor yields of III_8 and III_7 clearly indicate that the lengths of the bridging chains are unfavorable for the intramolecular alkylation. This suggests that the preparation of III_6 according to the above-mentioned procedure might not be feasible.

Consequently, the alternative procedure shown in Scheme 2 has been developed. The reaction of chloromethyl methyl ether with the monosodium salt of the dihydroxybenzophenone (I) in toluene afforded *o*-hydroxy-*p'*-methoxymethoxybenzophenone (VIII). The ω-bromohexyl ether (X) which was obtained by the reaction of hexamethylene dibromide with VIII according to the above-stated method, followed by an acid hydrolysis of the protective group, was subjected to intramolecular cyclization under high-dilution conditions to give the cyclic ether (III_6) in a reasonable yield.

The cyclic benzophenones (III_n and III_6) were converted to the corresponding methyl carbinols (IV_n and IV_6) by means of a large excess of methylmagnesium iodide. The 1,1-diarylethylenes (V_n and V_6) which were obtained by the acid dehydration of the carbinols were treated with bromine in carbon tetrachloride.[5)] In the cases of $n=12$ and 11, the dibromides (VI_{12} and VI_{11}) were obtained in good yields. The bromina-

5) P. Pfeiffer and R. Wizinger, *Ann. Chem.*, **461**, 132 (1928).

tion of the decamethylene ether derivative (V_{10}) afforded the dibromide (VI_{10}, X=Br) contaminated with the monobromide (VI_{10}, X=H). The treatment of V_8 with 2 mole of bromine gave no crystalline product, and a prolonged reaction with an excess of bromine resulted in the formation of a product bearing a bromine atom in a phenyl group. Therefore, equimolar bromine was used to give a *cis-trans* mixture of the monobromide (VI_{9-6}) in the case of the lower homologue (V_{9-6}). The rearrangement reaction of VI_{12-6} was performed in ether employing 2 equivalents of *n*-butyllithium and at a temperature of −11——18°C. The yields and the melting points of the cyclic tolans (VII_n) are recorded in Table 2, together with those of an open-chain analogue, *o,p'*-dimethoxytolan.

Table 2. The yields and the melting points of the cyclic tolans (VII_n) and *o,p'*-dimethoxytolan

n	Yield (%)	Mp (°C)
7	22	121.7—122.7

10	73	143.8—144.4
11	75	101.4—102.0
12	63	120.0—120.6
CH_3O	17	68.0— 69.5

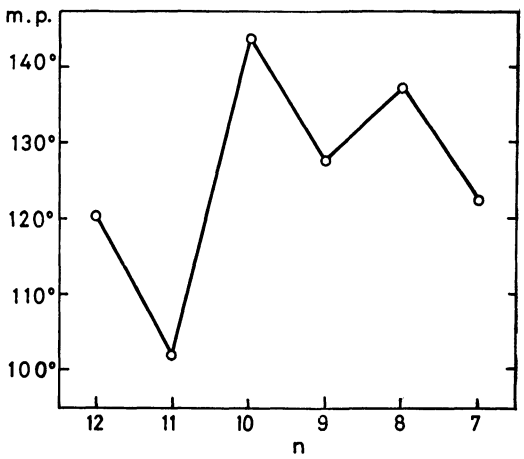

Fig. 1. The oscillation of the melting points of VII_n.

As is shown in Fig. 1, the cyclic tolans (VII_n) bearing an even number of methylene groups in the bridging chain exhibit higher melting points than the next higher or lower homologues having an odd number of methylene groups. This fact seems to indicate that the molecular geometry of VII_n is dependent not only on the length of the bridging chain, but also on whether the number of the methylene groups is odd or even.

In the case of VI_6, no cyclic tolan could be obtained, and the oily reaction product partly crystallized after standing overnight. The crystals were proved to be

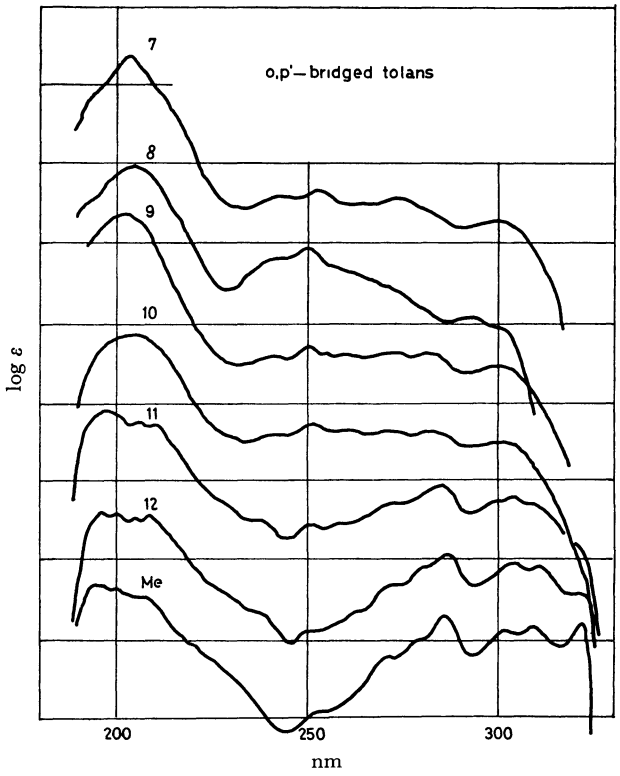

Fig. 2. The absorption curve of VII_n and *o,p'*-dimethoxytolan. The curves, with the exception of the dimethoxytolan at the bottom, have been displaced upward on the ordinate axis by 1/3 log ε unit increments from the curve immediately below, and the each horizontal lines correspond to log ε=4. (in *n*-hexane).

The asterisks indicate the shoulders.

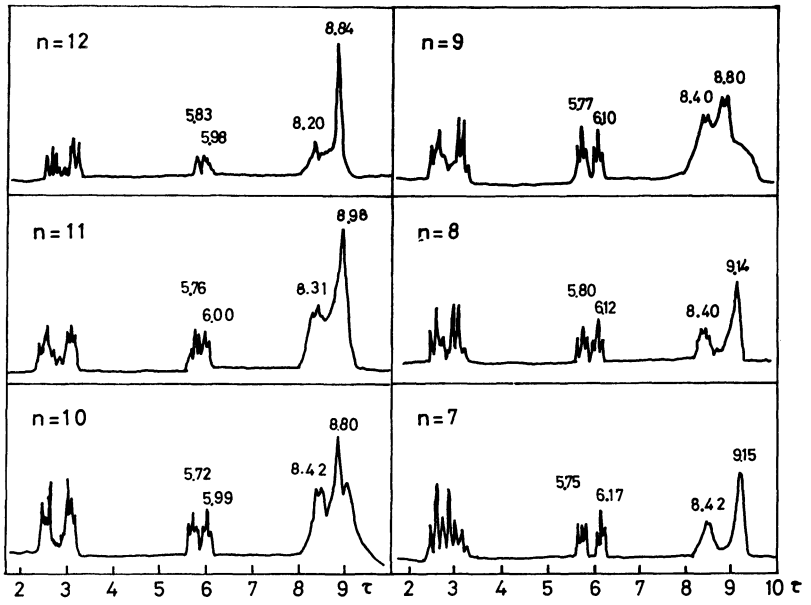

Fig. 3. The NMR spectra of VII_n.

the ethylene (V_6) on the basis of a mixed-melting-point determination and the thin-layer chromatographic, UV, IR, and NMR spectroscopic evidences. The structure of the oily product was not further studied. It is noteworthy that the yields of the cyclic tolans having a bridging chain of sufficient length are much higher than that of the open-chain analogue. As was pointed out previously,[1] the same trend has been observed in the case of the *p,p'*-series.

Electronic Spectra. The electronic spectral data of the cyclic tolans (VII_{12-7}), along with that of *o,p'*-dimethoxytolan as a reference, are recorded in Fig. 2 and Table 3. The reference substance exhibits a distinct, fine vibrational structure in the long-wavelength region. The gradual disappearanace of the fine structure according to the diminishing ring size is characteristic feature of the spectra of the cyclic tolans (VII_{12-7}).

Slight hypsochromic shifts of the absorption maxima at around 286 and 303 nm, accompanied by an appreciable hypochromic effect, were observed as the ring size decreased. On the other hand, the diminishing ring size exerted bathochromic and hyperchromic effects on the absorption peaks *ca.* 240 nm. The maximum ε-value of this peak was attained in the case of VI_{18}. The intensities of the peaks at *ca.* 250 nm gradually increased with the decrease in the number of *n*, and the maximum value was observed also in the case of VII_{18}.

The inspection of a molecular model of VII_7 indicates that the interplanar angle of the two benzene rings is almost rectangular. It is well-known that a twisted biphenyl derivative bearing bulky groups at the ortho positions exhibits an electronic spectrum resembling that of the ortho-substituted benzene moiety. However, no similarity was observed between the spectrum of VII_7 and that of *p*-methoxyphenylacetylene. This seems to indicate the presence of some conjugation of the two phenyl rings across the acetylenic linkage.

As the electronic spectra of the *o,p'*-bridged tolans (VII_n) suffer from the effects of both ring strain and the non-coplanarity of the two benzene nuclei, it is difficult to deduce the effect of strain from the above-mentioned spectral behavior. However, it seems to be pertinent to conclude that the increasing strain has hypsochromic and hypochromic effects on the long-wavelength band in the spectra of VII_n. The same tendency has been observed in the case of *o,o'*-bridged diphenyldiacetylenes.[6]

Nuclear Magnetic Resonance Spectra. The NMR spectra of the cyclic tolans (VII_n) are recorded in Fig. 3. The multiplets at around 2—3 τ can be assigned to the aromatic protons. Intense peaks, consisting of two poorly-resolved portions were observed at 8.0—9.7 τ in the spectra of VII_{12-9}. In the cases of VII_8 and VII_7, the peaks split into two peaks *ca.* 8.4 τ and *ca.* 9.15 τ. The higher-field peak can be assigned to the protons of methylene chain, except the α- and β-methylenes to the oxygen atoms. The peaks at 8.40 τ and 8.42 τ in VII_8 and VII_7 and the lower-field peaks in the poorly-resolved signals in VII_{12-9} were assigned to the protons of β-methylene to the oxygen atoms, considering the results of the assignment in *p,p'*-bridged tolans.[2] The two triplets observed around 6 τ were assigned to the methylene protons adjacent to the ortho- and para-oxygen atoms. The change in the chain length should alter the conformation of the tolan system as well as the relative configuration of $-O-CH_2-$ with respect to the planes of the benzene rings, resulting in a change in the shielding or deshielding effects of the benzene or the acetylene, and also in a change of the electron density on the oxygen atoms. This complicated situation makes it difficult to discriminate between the α-methylene attached to the para-oxygen and that linked with the ortho-oxygen. The above-mentioned assignments are summarized in Table 4, along with that of *o,p'*-dimethoxytolan.

6) F. Toda and M. Nakagawa, This Bulletin, **34**, 862 (1961).

The rather sharp peak at 8.84 τ in the poorly-resolved broad signal of VII_{12} seems to reflect the conformational mobility of the long bridging chain. The broadening of the corresponding signals in VII_{11-9} with the decrease in the number of n is attributable to some restriction of the conformational mobility of the bridging chain of a medium length. Consequently, the splitting of the two portions of the signals which was observed in the spectra of VII_8 and VII_7 seems to indicate a rigid structure in the cyclic tolans bearing short bridging chains.

Table 4. The assignment of the NMR spectra of VII_n (60 MHz in CCl_4, τ-value)

VII_n	Aromatic	α-Methylene		β-Methylene	Other methylene
12	2—3	5.98(2H)	5.83(2H)	8.20	8.84(20H)
11	2—3	6.00(2H)	5.76(2H)	8.31	8.98(18H)
10	2—3	5.99(2H)	5.72(2H)	8.42	8.80(16H)
9	2—3	6.10(2H)	5.77(2H)	8.40	8.80(14H)
8	2—3	6.12(2H)	5.80(2H)	8.40(4H)	9.14(8H)
7	2—3	6.17(2H)	5.75(2H)	8.42(4H)	9.15(6H)
CH_3O	2—3	6.06(3H)	5.77(3H)		

Infrared Spectra. It was observed that the cyclic tolans bearing a bridging chain with an odd number of methylene groups exhibit sharper IR spectra than those of the even-number homologues. This fact seems to have some correlation with the above-mentioned oscillation of the melting points (Fig. 1). The characteristic peaks in the IR spectra of VII_n are summarized in Table 5, along with the spectrum of *o,p'*-dimethoxytolan.

Table 5. The IR spectra of VII_n (KBr-disk)

Experimental

All the melting points are uncorrected. The electronic spectra were measured on a Hitachi EPS-2 Spectrophotometer; the infrared spectra, with a Hitachi EPI-2 Spectrophotometer, and the NMR spectra, with a Varian A 60 Spectrometer. The molecular weights were determined by the Rast method.

1,12-Dibromododecane and 1,11-Dibromoundecane. The polymethylene dibromides were prepared according to the method described in the preceding paper.[2]

1,10-Dibromodecane. A commercial product was used.

1,9-Dibromononane. Dimethyl 1,9-nonanedioate which had been prepared from azelaic acid[7] was reduced by means of lithium aluminum hydride; this yielded 1,9-nonanediol. The treatment of the diol (62.8 g, 0.39 mol) with hydrogen bromide (30% excess) at 130°C[8] afforded 1,9-dibromononane; bp 120—126°C/4 mmHg, 86.1 g (72%).

1,8-Dibromooctane. The Hunsdiecker reaction of silver sebacate[9] gave the dibromide in a yield of 40%.

1,7-Dibromoheptane. Silver 1,9-nonanedioate (200 g, 0.5 mol) in dry carbon tetrachloride was treated with bromine (56 m*l*, 1.1 mol) to yield the dibromide (61 g, 47%).[10]

1,6-Dibromohexane. To a stirred solution of lithium aluminum hydride (45 g, 1.2 mol) in dry ether (1 *l*), there was added a solution of dimethyl adipate (159 g, 0.92 mol) in ether (700 m*l*) at such a rate that the ether refluxed gently (100 min were required). After refluxing for 3 more hr, ethyl acetate (50 m*l*) was added to the cooled reaction mixture, and then 20% sulfuric acid (1.5 *l*) was added under ice-cooling. After the removal of the ether by distillation, the water was evaporated under reduced pressure. The crystalline solid obtained was dried *in vacuo* at 100°C for 8 hr. Ethanol (400 m*l*) was mixed the solid, and the mixture was refluxed for 4 hr. The ethanol was then separated by decantation. This procedure was repeated 6 times. The combined ethanol extracts were evaporated under reduced pressure. The residue was redissolved in anhydrous ethanol, and the insoluble material was removed by filtration. After the removal of the solvent from the filtrate *in vacuo*, the residue was distilled *in vacuo* to afford 1,6-hexanediol (bp 115—124°C/4—7 mmHg, mp 40—42°C, 68 g, 63%). The diol (79 g, 0.67 mol) was converted to 1,6-dibromohexane (bp 128—133°C/23—25 mmHg, 106 g, 65%) according to a previously described method.[8]

Preparation of o-*Hydroxy*-p'-*ω-bromoalkyloxybenzophenones* (II_n). As all the syntheses of *p'*-*ω*-bromopolymethylene ethers (II_n) were carried out under almost the same reaction conditions, the procedure used in the preparation of *p'*-10-bromodecyl ether (II_{10}) will be described as a representative example. To a stirred and refluxing solution of 1,10-dibromodecane (105 g, 0.35 mol) and *o,p'*-dihydroxybenzophenone (10 g, 47 mmol) in anhydrous ethanol (150 m*l*), there was added a solution of potassium hydroxide in ethanol (1.08N, 43.3 m*l*, 47 mmol) over a period of 1 hr. The reaction mixture immediately turned red, and then there was a deposition of fine crystals of potassium bromide. After the addition had been completed, refluxing was continued for a further 40 min. During this period, the reaction mixture turned yellowish brown and the pH-value of the mixture showed 5.5. The residue obtained by evaporating the solvent under reduced pressure was mixed with water (300 m*l*) and extracted with ether. The extract was then worked up according to the usual manner, and the excess of the dibromide was recovered by distillation (bp 138—141°C/5 mmHg). The yellow oily residue (15.2 g) in benzene was chromatographed on alumina (40 g). The fractions eluted with benzene afforded II_{10} (10.2 g, 68%) as a yellow liquid. Small amounts of the diether derivative and unreacted benzophenone (I) were obtained. These compounds could be easily discriminated by the difference in $\nu_{C=O}$ and ν_{O-H} as is shown in Table 6. The monoethers (II_n) were obtained as yellow liquid, except in the case of $n=12$, which gave yellow crystals in a yield of 46%. The yields of the other members were found to be

a) This compound was prepared by a modified method. See below.

as follows: II_{11}: quantitative; II_{10}: 68%; II_9: 74%; II_8: 57% and II_6: 63%. The monoethers (II_n) thus obtained were subjected to the subsequent reaction without further purification.

Syntheses of the Cyclic Ethers (III_n). As the reaction conditions of the intramolecular cyclization of II_n and the yields of III_n have been shown in Table 1, the method of the synthesis of III_8 will be described as an example. The ω-bromoether (II_8, 17.1 g, 42 mmol) in isoamyl alcohol (310 m*l*) was added slowly to a vigorously-stirred and refluxing mixture of potassium carbonate (17.5 g, 0.13 mol) and isoamyl alcohol (960 m*l*) over a period of 74 hr, employing a high-dilution apparatus.[4] After the addition had been completed, the the reaction mixture was refluxed for a further 4 hr under stirring. The inorganic material was then removed by filtration. The resinous material obtained by evaporating the solvent under reduced pressure was dissolved in benzene and chromatographed on alumina (300 g). The fractions eluted with benzene - ether (1 : 1) gave III_8 (4.66 g, 34%) as colorless crystals. This substance was recrystallized twice from *n*-hexane - methanol to yield pure III_8 as colorless plates: mp 125.3—126.3°C. The analytical data, the molecular weights, and the solvents of the recrystallization of III_n are recorded in Table 7. The crude crystals of III_{12} and the liquid III_{10} were used for the following reaction without further purification.

TABLE 7. THE ANALYTICAL DATA, THE MOLECULAR WEIGHT, AND THE SOLVENTS OF RECRYSTALLIZATION OF III_n

a) This was prepared by a modified method. See below.
H=*n*-hexane; B=benzene

o-*Hydroxy*-p'-*methoxymethoxybenzophenone (VIII).* A solution of sodium ethoxide in ethanol, prepared from sodium (1.76 g, 73 mg atom) and ethanol (50 m*l*), was added to a solution of the dihydroxybenzophenone (I, 15.5 g, 73 mmol) in ethanol (150 m*l*). The mixture turned red, and the precipitation of a yellow solid was observed. The solvent was then removed under reduced pressure, and toluene (200 m*l*) was added to the residue. The toluene was subsequently evaporated again under reduced pressure. The procedure was repeated to remove the traces of ethanol and water. The sodium salt obtained as a yellow powder was mixed with toluene (200 m*l*), and then chloromethyl methyl ether (5.85 g, 73 mmol) was added dropwise under stirring. After having been stirred overnight, the reaction mixture was washed successively with a 10% sodium hydrogen carbonate solution, water, and a saturated sodium chloride solution, and then dried. The oily material (17.2 g) obtained by evaporating the solvent was chromatographed on alumina (190 g). The fractions eluted with benzene - ether (1:1), ether, and ether containing 3% of methanol, gave VIII (12.0 g 64%) as a liquid, IR (neat): ν_{O-H} 2900; $\nu_{C=O}$ 1630 cm^{-1}.

o-ω-*Bromo*-n-*hexyloxy*-p'-*methoxymethoxybenzophenone (IX).* Thirty-one m*l* of 1.03N solution of potassium hydroxide in ethanol was added, over a period of 1 hr, to a stirred and refluxing solution of VIII (7.99 g, 31 mmol) and 1,6-dibromohexane (105 g, 0.43 mol) in anhydrous ethanol (150 m*l*). After refluxing for further 1.5 hr, the solvent was removed under reduced pressure. Benzene was added to the residue, and it was washed with a 10% sodium hydroxide solution. The benzene solution was worked up in the usual manner, and the dibromohexane was removed by vaccum distillation; this yielded IX as a yellow liquid (5.63 g, 42%). IR (neat): ν_{O-H} absent; $\nu_{C=O}$ 1660 cm^{-1}. The aqueous layer was neutralized by dilute hydrochloric acid and extracted with benzene. The structure of *o*-ω-bromohexyloxy-*p'*-hydroxybenzophenone (X) was assigned to the oily substance obtained from the benzene layer on the basis of its IR spectrum (ν_{O-H} 3200; $\nu_{C=O}$ 1650 cm^{-1}). The prolonged reaction (7.5 hr) of VIII (11.5 g, 43 mmol) with the dibromohexane (73 g, 0.30 mol) in the presence of 64.5 mmol of potassium hydroxide resulted in the formation of *o,p'*-bis-ω-bromohexyloxybenzophenone (10.2 g, 47%) and *o*-ω-bromohexyloxy-*p'*-hydroxybenzophenone (X, 9.40 g, 58%). The cleavage of the acetal linkage in an alkaline medium seemed to be noteworthy.

o-ω-*Bromo*-n-*hexyloxy*-p'-*hydroxybenzophenone (X).* A mixture of IX (4.51 g, 12 mmol), acetic acid (25 m*l*), water (25 m*l*), and concentrated sulfuric acid (0.2 g) was refluxed for 15 min under stirring. The reaction mixture was then worked up according to the usual manner to afford crude X (4.80 g, 95%, IR (neat): ν_{O-H} 3200; $\nu_{C=O}$ 1650 cm^{-1}). This was subjected to the subsequent reaction without any further purification.

o,p'-*Dihydroxybenzophenone Hexamethylene Ether (III_6).* The intramolecular alkylation under high-dilution conditions described in the preparation of III_n was successfully adapted in this case. The product (4.50 g) obtained from X (4.51 g, 12 mmol) was chromatographed on alumina (135 g). The fractions eluted with benzene - ether (9 : 1～2 : 1) afforded, upon work-up, 1.08 g (31%) of III_6 as colorless crystals. This substance was recrystallized from *n*-hexane - benzene to give pure III_6 (for analytical data, see Table 7).

o,p'-*Dimethoxybenzophenone.* To a stirred and refluxing mixture of the dihydroxybenzophenone (I, 3.0 g, 14 mmol), methyl iodide (5 m*l*, 80 mmol), and anhydrous ethanol (25 m*l*), we added 28 m*l* of a 1N solution of potassium hydroxide in ethanol over a period of 70 min; refluxing was then continued for 1 hr. The presence of the hydroxyl group was revealed by the IR spectrum of the crude product. Therefore, the crude product was treated in the same way, and dimethoxybenzophenone (3.02 g, 89%) was afforded as a liquid.

o,p'-*Di*-n-*butoxybenzophenone.* According to the procedure described above, the reaction of the dihydroxybenzophenone with *n*-butyl bromide gave the dibutoxybenzophenone as a liquid in a yield of 74%.

Syntheses of the Methyl Carbinols (IV_n). The preparation of the methyl carbinol (IV_8) will be described as a re-

presentative example. To a stirred and ice-cooled solution of methylmagnesium iodide, prepared from magnesium (0.5g 0.021 g atom), methyl iodide (21 m*l*, 32 mmol) and ether (20 m*l*), we added, drop by drop a solution of III_8 (1.18 g, 5.6 mmol) in anhydrous benzene (30 m*l*). The mixture was refluxed for 2 hr; then a 10% aqueous solution of ammonium chloride was added to the ice-cooled reaction mixture. The benzene layer was then worked up to yield colorless crystals (1.80 g, 95%). This substance was recrystallized 4 times from *n*-hexane to yield pure IV_8; mp 84.0—86.0°C, colorless needles. The yields of the methyl carbinols were found to be as follows: IV_6: quantitative, IV_7*: 99%, IV_8: 95%, IV_9*: 85%, IV_{10}: quantitative, IV_{11}*: 87%, IV_{12}*: 90%, dimethoxy derivative: 94%, dibutoxy derivative*: 86%. The carbinols denoted by asterisks were obtained as liquids and could not be crystallized. The melting points, the analytical data, and the solvents of recrystallization are summarized in Table 8.

a) Slightly impure material. H=*n*-hexane; B=benzene.

1-(o-Hydroxyphenyl)-1-(p'-hydroxyphenyl)ethylene Polymethylene Ethers (V_n). The Dehydration of the Methyl Carbinols (IV_n). The preparation of V_8 will be described as an example. A mixture of IV_8 (1.82 g, 54 mmol) and 8N sulfuric acid (60 m*l*) was refluxed for 1 hr under stirring, and then it was extracted with benzene. The extract afforded, upon work-up, 1.58 g (91%) of colorless crystals. This substance was recrystallized 3 times from *n*-hexane - methanol to give pure V_8, mp 80.0—81.0°C as colorless plates.

According to the same procedure, all the carbinols (IV_n) gave the ethylenes (V_n) in yields over 90%. The pure ethylenes (V_6, V_8 and V_{11}) were obtained by recrystallizing the crude materials from *n*-hexane - methanol (1 : 1). The melting points, the analytical data of V_n, and the reference substance are given in Table 9.

a) The ethylenes denoted by asterisks were used for the subsequent reaction without further purification.

1-(o-Hydroxyphenyl)-1-(p'-hydroxyphenyl)-2,2-dibromoethylenes (VI_n, n=10, 11, 12, X=Br). The preparation of VI_{12} will be described as a representative instance. To a solution of V_{12} (2.36 g, 6.2 mmol) in carbon tetrachloride (30 m*l*), there was added a solution of bromine in the same solvent (0.63 mol/*l*, 19.8 m*l*, 13 mmol). The mixture was stirred for 1 hr under reflux, resulting in the disappearance of the color of the bromine. The same amount of the bromine solution was added to the reaction mixture, and the new mixture refluxed for 2 more hr. The residue obtained by evaporating the solvent under reduced pressure was mixed with benzene (50 m*l*). The benzene solution was washed successively with a 10% sodium hydroxide solution and water, and then dried. The evaporation of the solvent gave 2.96 g of an oily material. This was chromatographed on alumina (40 g) to afford yellowish crystals; 2.49 g (75%). The crystals were recrystallized 3 times from ethyl acetate - methanol to yield pure VI_{12} as colorless leaflets; mp 99.7—101.5°C.

The melting points, the analytical data, and the molecular weights of V_{10-12} and the reference substances are shown in Table 10, together with the solvents used for the recrystallization.

cis- and trans-1-(o-Hydroxyphenyl)-1-(p'-hydroxyphenyl)-2-bromoethylene Polymethylene Ethers (VI_n, n=9, 8, 7, 6, X=H). The procedure used for the preparation of VI_9 will be described as an example. A solution of V_9 (862 mg, 2.6 mmol) in carbon tetrachloride (40 m*l*) was mixed with a solution of bromine in the same solvent (0.249 mol/*l*, 10.3 m*l*, 26 mmol). After refluxing for 1 hr, the solvent was distilled out under reduced pressure. The residue in *n*-hexane - benzene was passed through a short column of alumina. The oily material obtained by evaporating the solvent *in vacuo* crystallized on standing overnight in a refrigerator. The crude crystals were chromatographed twice on alumina (30 g) to yield 600 mg (56%) of VI_9. An analytical specimen (colorless plates, mp 88—101°C) was obtained by recrystallizing the crystals 4 times from *n*-hexane.

Found: C, 66.99; H, 6.62; Br, 18.94%. Mol wt: 286. Calcd for $C_{23}H_{27}O_2Br$: C, 66.50; H, 6.55; Br, 19.24%. Mol wt: 415.

As the bromoethylenes (VI_8, VI_7, and VI_6) were obtained

as oily materials and could not be crystallized, the bromoethylenes purified by chromatography on alumina were subjected to the following reaction.

Formation of the Cyclic Tolans (VIII$_n$, n=12, 11, 10, 9, 8 and 7). The procedure of the rearrangement to form the cyclic tolan is exemplified by the case of $n=12$. To a solution of VI$_{12}$ (680 mg, 1.3 mmol) in anhydrous ether (30 m*l*) which had been cooled in an ice-salt-bath, there was added, drop by drop a solution of *n*-butyllithium in ether (0.15 mol/*l*, 17 m*l*, 2.6 mmol) under stirring. A rise of temperature from −16°C to −11°C was observed on the addition of the reagent. Stirring was continued for one more hr at a temperature of −16——17°C. The reaction mixture was then washed with water, and the aqueous layer was extracted with benzene. The extract was combined with the organic layer and was worked up in the usual manner to yield colorless crystals (460 mg, 96%). The crude crystals were recrystallized twice from *n*-hexane to afford 300 mg (63%) of pure VII$_{12}$, mp 120.0—120.6°C as colorless cubes.

In the cases of $n=8$ and 7, the crude crystals were subjected to chromatography on alumina 3 times, and the oily by-product could be removed by elution with petroleum benzine - benzene (1 : 1). The pure VII$_8$ and VII$_7$ were obtained from the fractions eluted with ether. Also, the reference substance, *o,p'*-dimethoxytolan, was obtained as liquid; crystallization was achieved after repeating the chromatography on alumina.

The analytical data, the molecular weights, and the solvents of the recrystallization of VII$_n$ are summarized in Table 11 (for the yields and the melting points of VII$_n$, see Table 2).

Attempted Synthesis of VII$_6$. The treatment of VI$_6$ (323 mg, 0.87 mmol) with *n*-butyllithium according to the above-mentioned procedure afforded a yellow, oily product (291 mg) which partly crystallized on standing overnight. The product gave a negative Beilstein test. Thin-layer chromatography of the reaction product 3 gave spots, R_f 6.1 (brown), R_f 5.5 (red), R_f 4.9 (purple), and R_f 1.5 (blue) (adsorbent: alumina; solvent: benzine - benzene (4 : 1); detection reagent: conc. sulfuric acid). It was found that the constituents which gave the spots at R_f 5.5 and 4.9 were the main products. The product which gave the spot at R_f 4.9 could be isolated as crystals by chromatography on alumina. This substance was proved to be identical with the cyclic ethylene (V$_6$) on the basis of the IR and NMR spectroscopic evidence and a mixed-melting-point determinaion. Another product (R_f 5.5), obtained as an oil, has not yet been chracterised.

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received July 13, 1970)

ω-Chloroisonitrosoacetophenone was treated with ethylenic and acetylenic dipolarophiles to afford 3-benzoylisoxazolinines and -isoxazoles, respectively. With *m*-nitrobenzaldoxime or *m*-nitrobenzonitrile, it yielded 3-benzoyl-5-(*m*-nitrophenyl)-1,2,4-oxadiazole. The phenylhydrazones of the 3-benzoylisoxazole and -oxodiazole thus produced were converted to the corresponding 1,2,3-triazoles thermally or by the treatment with a base. The photo-induced rearrangement of 3-benzoyl-5-phenylisoxazole afforded 2-benzoyl-5-phenyloxazole. Treatment of *ω*-chloroisonitrosoacetophenone with aziridine afforded a new type of aziridine oximes, which was converted to 2-benzoyloxazoline.

It is surprising that there have been no reports on the preparation and reactions of benzoyl cyanide *N*-oxide (I) in contrast to abundant reports on benzonitrile oxide, though *ω*-chloroisonitrosoacetophenone (II, phenylglyoxylyl chloride oxime) is a readily available compound[2] and is regarded as its precursor. Holleman[3] postulated the intermediary formation of I in the preparation of 1,5-dibenzoylfuroxan from acetophenone. Because of the presence of a carbonyl conjugated with the nitrile oxide group, I is thought to be stabilized by the resonance, but presumably reactive enough to undergo the 1,3-dipolar cycloaddition reactions. In this paper, the results in the 1,3-dipolar cycloaddition reactions are discussed in comparison with those in similar reactions of benzonitrile oxide. The thermal and basic rearrangement of the phenylhydrazones of 3-benzoylisoxazole and -oxadiazole thus produce and the photo-induced rearrangement of 3-benzoylisoxazole are discussed. The ring-enlargement of the aziridine adduct of I is also described.

Results and Discussion

1,3-Dipolar Cycloadditivity. In order to examine 1,3-dipolar cycloaddition reactivity, II was treated in ether with triethylamine in the presence of a dipolarophile (styrene, for example) according to the general procedure for preparing the nitrile oxides.[4] The oily product was characterized as 3-benzoyl-5-phenylisoxazoline (III) after conversion to its crystalline picrate on the basis of analytical and spectral evidences. A further evidence was provided by its conversion to crystalline 3-benzoylisoxazole (XVIII) with *N*-bromosuccinimide (NBS). A similar treatment of II with acrylonitrile afforded 3-benzoyl-5-cyanoisoxazoline (IV); IV showed no nitril absorption in the IR spectrum, which supports 5-cyano structure.[5] An attempt to convert it to isoxazole with NBS was unsuccessful. Acidic hydrolysis of IV with sulfuric acid gave benzoic acid, while 3-(5-nitro-2-furyl)-5-cyanoisoxazole (V) was convertible to the corresponding amide under similar conditions. Treatment of II with two equivalent amounts of 1-morpholino-2-cyanoethylene in ether at room temperature afforded 3-benzoyl-4-cyanoisoxazole (VI) similar to the 1,3-dipolar cycloaddition of aromatic hydroxamoyl chlorides to the enamine after spontaneous elimination of a morpholine molecule from the initial 1 : 1 adduct.[6] VI was hydrolyzed to amide under acidic conditions. Treatment of II with *o*-aminophenol and methyl anthranilate afforded linear adducts, *N*-phenylglyoxylyl-*o*-aminophenol oxime (VII) and methyl *N*-phenylglyoxylylanthranilate oxime (VIII), respectively, but with *o*-phenylenediamine, a cyclized product, 3-benzoyl-1,4-dihydro-1,2,4-benzotriazine (IX), instead of the expected benzoxazole[7] or quinazoline[8] and benzimidazole[7] in the similar reactions of aromatic hydroxamoyl chlorides. VIII was cyclized, however, to 3-hydroxy-4-oxo-2-benzoyl-3,4-dihydroquinazoline (X) on treatment with hydrochloric acid. With 1-cyano-2-diethylaminoacetylene,[10] II afforded 3-benzoyl-4-cyano-5-diethylaminoisoxazole (XI) as in the case of aromatic hydroxamoyl chlorides,[9] but with ammonium thiocyanate in methanol, II unexpectedly[10] yielded *N*-benzoylthiourethane (XII). Since the products III and IV could be obtained by the thermal 1,3-dipolar cycloaddition reactions of II in almost quantitative yields, the thermal reactions were performed using several dipolarophiles; the results are summarized in Table 1.

As seen from this table, ethylenic and acetylenic dipolarophiles reacted with II to give the corresponding isoxazolidines, III, IV, and XIII—XV, and isoxazoles, XVI—XX, respectively; the yield of the latter was lower because of the thermal instability.[11] It should be mentioned that the yield of the former was almost quantitative.

In order to compare the reactivity of II with that

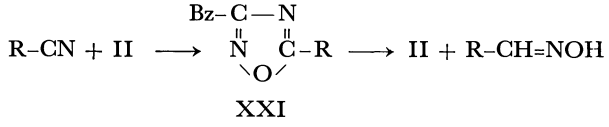
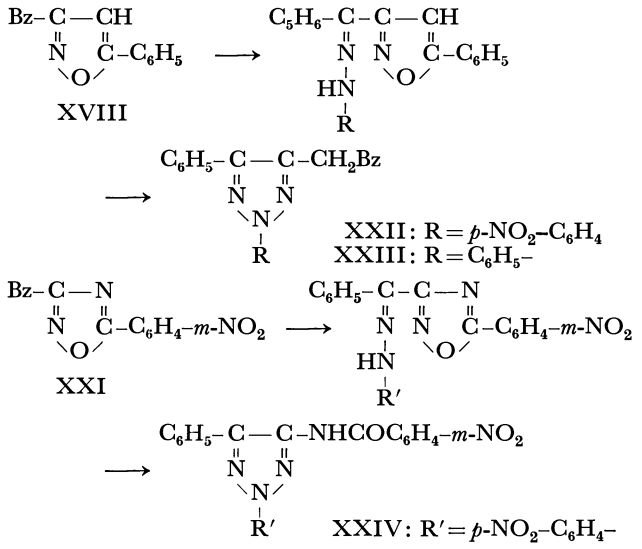
of hydroxamoyl chlorides, II was treated with benzamidine to afford 55% yield of 2,4,6-triphenyl-1,3,5-triazine, a trimer of benzamidine. This indicates no reactivity of II with benzamidine, with which hydroxamoyl chlorides are known to afford oxadiazoles.[7] With *m*-nitrobenzonitrile II afforded 15% yield of 3-benzoyl-5-(*m*-nitrophenyl)-1,2,4-oxadiazole (XXI), while the same compound was prepared from II and *m*-nitrobenzaldoxime in 50% yield. With *m*-nitrobenzaldehyde, II underwent no cycloaddition, while benzonitrile oxide affords the corresponding dioxazole.[4,8] Even taking into consideration these different reactivities from benzhydroxamoyl chloride, II might be concluded to be a good starting material for the preparation of 3-benzoylisoxazolines and -isoxazoles.



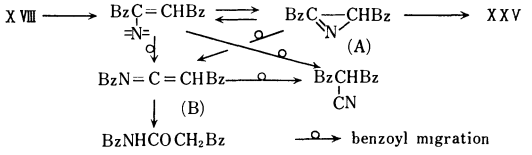
XXI

Rearrangement of 3-Benzoylisoxazole and 3-Benzoyloxadiazole. *a) Thermal and Basic Treatments*: Boulton *et al.*[12] have reported on the interesting thermal rearrangement reactions of one heterocycle to another as exemplified by those of 3-acetylisoxazole to 1,2,3-triazole *via* the phenylhydrazone and to 1,2,3-oxadiazole *via* the oxime. According to the modified procedure by Kano and Yamazaki,[13] *p*-nitrophenylhydrazone of XVIII was melted with copper powder to afford a quantitative yield of 2-(*p*-nitrophenyl)-4-phenyl-5-phenacyl-1,2,3-triazole (XXII), which was also obtained quantitatively by such a basic treatment as ammonia.[13] Similarly, 2,4-diphenyl-5-phenacyl-1,2,3-triazole (XXIII) was obtained from the phenylhydrazone of XVIII in 50% yield by thermal treatment. Thermal and basic treatments of the *p*-nitrophenylhydrazone of 3-benzoyl-1,2,4-oxadiazole (XXI) afforded 1,2,3-triazole (XXIV) in 60 and 90% yields, respectively. A similar rearrangement of *p*-nitrophenylhydrazone of VI failed, presumably because of the presence of a 4-substituent; thermal treatment afforded tarry polymer and the basic treatment resulted in recovery of the starting material. Attempts to obtain the oxime and the semicarbazone of XVIII were unsuccessful in contrast to the results given by Spiro and Ajello.[14]



b) Photochemical Treatment: One feature in the photo-induced rearrangement of five-membered heterocycles is that two vicinal heteroatoms can interchange their positions to 1,3-system when irradiated with ultraviolet light. This example involves the photo-induced rearrangement of 3,5-diphenylisoxazole to 2,5-diphenyloxazole[15] and that of benzisoxazole to benzoxazole,[16] but not that of 3-acylisoxazoles. Thus, XVIII (UV λ_{max}^{EtOH} mμ (ε): 262 (35900) and 233 (21900)) was irradiated at room temperature under nitrogen stream. Chromatography of the reaction mixture afforded 2-benzoyl-5-phenyloxazole (XXV), *N*-benzoylbenzoylacetamide, dibenzoylacetonitrile, benzoic acid and/or benzamide. The product distributions under different conditions are summarized in Table 2.

The thermal and basic rearrangement reactions of XVIII and XXI might be explained by the radical and ionic mechanisms proposed by Kano and Yamazaki,[13] and Ullman and Singh.[15] For photoinduced rearrangement of XVIII, a similar explanation for that from 3,5-diphenylisoxazole to 2,5-diphenyloxazole[15] can be applied by postulating the intermediacy of 2,3-dibenzoylaziridine (A) and/or *N*-benzoylbenzoylketenimine (B) after its benzoyl migration (⌒). The exclusive formation of benzoic acid in the reaction of XVIII in ethanol might be originated from hydrolytic photocleavage by contaminated water in the solvent.



Ring-enlargement. II was treated with two equivalent amounts of aziridine in ether at room temperature to afford oily *N*-phenylglyoxylylaziridine oxime (XXVI), which was converted to crystalline *O*-*p*-nitrobenzoate (XXVII). Since XXVI is regarded as a new type of aziridine oximes,[17] ring-enlargement was carried out. Thus, XXVI was refluxed in acetone with a catalytic amount of sodium iodide to give an oily amine, which was characterized as 2-benzoyloxazoline (XXVIII) after conversion to the crystalline picrate.

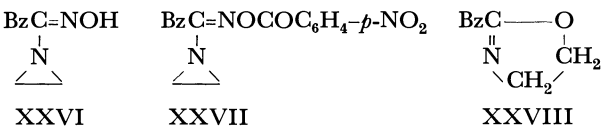
The yield of the conversion to XXVIII was improved up to 60% by treating with concd. hydrochloric acid in acetone at room temperature.[17]



XXVI XXVII XXVIII

Experimental

All melting points were determined on a Yanagimoto electric micromelting point apparatus and are uncorrected. The ultraviolet (UV) and infrared spectra (IR) were recorded on a Jeolco Model ORD/UV-5 and a Jasco Model IR-S spectrometer. The NMR spectra were determined on a Varian A-60 and a Jeolco Minimar, with tetramethylsilane as an internal standard and the peak positions are expressed by τ-values. Column chromatography was carried out on a silica-gel (Mallinckrodt, 100 mesh) using benzene as an eluent.

3-Benzoyl-5-phenylisoxazoline (III). *a) Nitrile Oxide Method*: To a stirred solution of 1.84 g (0.01 mol) of ω-chloroisonitrosoacetophenone (II)[2] and 1.04 g (0.01 mol) of styrene in 50 m*l* of ether was added a solution of 1.2 g (0.012 mol) of triethylamine in 10 m*l* of ether under cooling with ice-water. The reaction mixture was stirred at room temperature overnight. The resulting precipitates (triethylamine hydrochloride) were removed and the filtrate was concentrated. The residual oil was converted to the crystalline picrate, mp 219—220°C, and analyzed (Table I). The yield was 30%.

b) Thermal Treatment: A solution of the same amounts of the two components as above in 50 m*l* of toluene was refluxed for 16 hr. The solvent was removed and the residual oil was purified as above to give a quantitative yield of III (Table 1).

Its Conversion to 3-Benzoyl-5-phenylisoxazole (XVIII). A solution of 1.0 g of III and 0.75 g of *N*-bromosuccinimide (NBS) in 20 m*l* of carbon tetrachloride was refluxed in the presence of a trace of azobisisobutyronitrile (AIBN) for 3 hr. The reaction mixture turned from red to pale yellow. The mixture was filtered and the filtrate was concentrated. The residue was treated with a solution of 0.25 g of potassium hydroxide in 10 m*l* of methanol to afford 0.5 g (50%) of XVIII, mp 91°C, which was identical with a specimen pre pared from II and phenylacetylene (Table 1). Phenylhydrazone, mp 106—107°C.

Found: C, 77.93; H, 5.60; N, 12.54%. Calcd for $C_{22}H_{27}ON_3$: C, 77.85; H, 5.05; N, 12.38%.

p-Nitrophenylhydrazone, mp 191—192°C. UV λ_{max}^{EtOH} mμ (ε): 396 (31700), 278 (16300) and 250 (22100).

Found: C, 68.95; H, 4.35; N, 14.45%. Calcd for $C_{22}H_{16}O_3N_4$: C, 68.74; H, 4.20; N, 14.58%.

3-Benzoyl-5-cyanoisoxazoline (IV). IV was obtained from II and acrylonitrile by the nitrile oxide method in 30% yield, but by the thermal procedure quantitatively. (Table 1).

3-(5-Nitro-2-furyl)-5-cyanoisoxazoline (V) and Its Conversion to Amide. *Thermal treatment*: A solution of 0.95 g (5 mmol) of 5-nitro-2-furylhydroxamoyl chloride[11] and 1.0 g (20 mmol) of acrylonitrile in 40 m*l* of toluene was refluxed for 15 hr. The chromatography afforded 0.74 g (70%) of V, mp 109°C, by recrystallization from ethanol. IR (KBr): no nitrile absorption at around 2200—2400 cm^{-1}.

Found: C, 46.53; H, 2.57; N, 20.41%. Calcd for $C_8H_5O_4N_3$: C, 46.38; H, 2.43; N, 20.29%.

The same compound was obtained in 65% yield by the nitrile oxide method.

Conversion of V to the amide was carried out as follows: a solution of 0.3 g of V in 4 m*l* of concd. sulfuric acid was stirred at room temperature for 2 days. The reaction mixture was poured onto ice-water and the resulting yellow crystals were collected and recrystallized from ethanol - THF to afford the amide in 75% yield, mp 225°C, which was identical with a specimen[11] by IR comparison.

3-Benzoyl-4-cyanoisoxazole (VI). A solution of 1.84 g (0.01 mol) of II and 2.8 g (0.02 mol) of 1-morpholino-2-cyanoethylene[18] in 50 m*l* of ether was stirred at room temperature for one week. The resulting precipitates were filtered and the solvent was removed from the filtrate. The residual solid was recrystallized from *n*-hexane to give 60% yield of VI, mp 73—74°C. IR (KBr) cm^{-1}: 2250 (ν_{CN}), and 1660 (ν_{CO}). NMR ($CDCl_3$) τ: 0.09 (s, 1H, C_5-H).

Found: C, 67.04; H, 3.25; N, 14.07%. Calcd for $C_{11}H_6O_2N_2$: C, 66.66; H, 3.05; N, 14.14%.

Its Conversion to Amide. Similar as in the case of V, VI was treated with concd. sulfuric acid to afford the amide, mp 174—175°C, in 70% yield. IR (KBr) cm^{-1}: 3400, 3350 (ν_{NH}) and 1670 (ν_{CO}).

Found: C, 60.89; H, 3.80; N, 13.05%. Calcd for $C_{11}H_8O_3N_2$: C, 61.11; H, 3.73; N, 12.96%.

N-Phenylglyoxylyl-o-aminophenol Oxime (VII). Treatment of II with two equivalent amounts of *o*-aminophenol in ether at room temperature for 1 day afforded 70% yield of VII, mp 162—163°C, by recrystallization from a 10 : 1 mixture of benzene and ethanol. IR (KBr) cm^{-1}: 1660 (ν_{CO}).

Found: C, 66.17; H, 4.91; N, 10.57%. Calcd for $C_{14}H_{12}O_3N_2$: C, 65.62; H, 4.72; N, 10.93%.

Methyl N-Phenylglyoxylylanthranilate Oxime (VIII). Similarly, a solution of 0.92 g (5 mmol) of II and 1.51 g (10 mmol) of methyl anthranilate in 70 m*l* of ether was left standing at room temperature for two months. Chromatography of the filtrate afforded 0.5 g (30%) of VIII, mp 162—164°C, by recrystallization from ethanol. IR (KBr) cm^{-1}: 3340 (ν_{NH}) and 1675 (ν_{CO}).

Found: C, 64.35; H, 4.75; N, 9.38%. Calcd for $C_{16}H_{14}O_4N_2$: C, 64.42; H, 4.73; N, 9.39%.

3-Benzoyl-1,4-dihydro-1,2,4-benzotriazine (IX). A similar treatment of II with *o*-phenylenediamine for 3 days afforded 75% yield of IX, mp 223—225°C, by recrystallization from a 3 : 1 mixture of benzene and ethanol. IR (KBr) cm^{-1}: 3200 (ν_{NH}) and 1640 (ν_{CO}).

Found: 71.03; H, 4.83; N, 17.57%. Calcd for $C_{14}H_{11}ON_3$: C, 70.87; H, 4.67; N, 17.71%.

Conversion of VIII to 3-Hydroxy-4-oxo-2-benzoyl-3,4-dihydroquinazoline (X). A solution of 0.2 g of VIII in 1 m*l* of concd. hydrochloric acid was warmed at 60—70°C in a sealed tube for 20 min. After cooling, the resulting crystals were collected and recrystallized from benzene - petroleum ether to afford 0.1 g (50%) of X, mp 76—78°C. IR (KBr) cm^{-1}: 3450, 2250 (broad, bound ν_{OH}[19]), 1670 and 1650 (ν_{CO}[8]).

Found: C, 67.75; H, 3.82; N, 10.60%. Calcd for $C_{15}H_{10}O_3N_2$: C, 67.66; H, 3.79; N, 10.52%.

3-Benzoyl-4-cyano-5-diethylaminoisoxazole (XI). Treatment of 1.84 g (0.01 mol) of II and 2.2 g (0.02 mol) of diethylaminocyanoacetylene[9] in 50 m*l* of ether at room temperature for one week afforded 40% yield of XI, mp 133—134°C, on chromatography. IR (KBr) cm^{-1}: 2240 (ν_{CN}) and 1650 (ν_{CO}).

18) T. Sasaki, T. Yoshioka, and K. Shoji, *J. Chem. Soc., C*, **1969**, 1086.

19) A. Dorner and K. Fisher, *Chem. Ber.*, **99**, 72 (1966).

Found: C, 66.90; H, 5.66; N, 15.62%. Calcd for $C_{15}H_{15}O_2N_3$: C, 66.90; H, 5.61; N, 15.61%.

N-Benzoylthiourethane (XII). A solution of 0.45 g (2.5 mmol) of II in 10 m*l* of methanol was added to a stirred solution of 0.35 g (5 mmol) of ammonium thiocyanate in 10 m*l* of methanol at room temperature. Chromatography afforded 0.3 g (70%) of XII, mp 98—99°C from benzene - petroleum ether, which was identical with a specimen prepared from benzoyl isothiocyanate and methanol.[20]

Reaction of II with Benzamidine. To a stirred mixture of a solution of 1.0 g of II in 30 m*l* of ether and a solution of 0.9 g of benzamidine hydrochloride in 20 m*l* of water was added a 5% aqueous potassium carbonate (1.6 g) under ice-cooling. Stirring was continued for 12 hr. Ether layer was separated, from which 0.6 g (55%) of 2,4,6-triphenyl-1,3,5-triazine, mp 240°C (lit,[21] 239°C) was isolated.

Found: C, 81.39; H, 5.03; N, 13.66%. Calcd for $C_{21}H_{15}N_3$: C, 81.53; H, 4.89; N, 13.58%.

3-Benzoyl-5-(m-nitrophenyl)-1,2,4-oxadiazole (XXI). This was prepared by refluxing in toluene for 20 hr of II with *m*-nitrobenzaldoxime and *m*-nitrobenzonitrile in 50 and 15% yields, respectively. Mp 174—175°C. IR (KBr) cm^{-1}: 1675 (ν_{CO}).

Found: C, 61.00; H, 3.21; N, 13.98%. Calcd for $C_{15}H_9O_4N_3$: C, 61.02; H, 3.07; N, 14.23%.

The *p*-nitrophenylhydrazone: mp 294—295°C.

Found: C, 58.65; H, 3.35; N, 19.47%. Calcd for $C_{21}H_{14}O_5N_6$: C, 58.60; H, 3.28; N, 19.53%.

Thermal Rearrangement of The Hydrazones of XVIII. General procedure: the hydrazone was melted with 1/3 of its weight of copper powder in a vacuum at a temperature slightly higher than the melting point for 10 min. The residue was extracted with hot ethanol to give the corresponding triazole.

Thus, 2,4-diphenyl-5-phenacyl-1,2,3-triazole (XXIII) was obtained in 50% yield as an oil from the phenylhydrazone of XVI. IR (KBr) cm^{-1}: 1685 (ν_{CO}). NMR ($CDCl_3$) τ: 5.42 (s, 2H, $-CH_2-$). Its 2,4-dinitrophenylhydrazone, mp 210—211°C.

Found: C, 64.87; H, 4.22; N, 18.52%. Calcd for $C_{28}H_{21}O_4N_7$: C, 64.79; H, 4.08; N, 18.89%.

A similar treatment of the *p*-nitrophenylhydrazone of XVIII afforded a quantitative yield of 2-(*p*-nitrophenyl)-4-phenyl-5-phenacyl-1,2,3-triazole (XXII), mp 137—138°C. UV λ_{max}^{EtOH} mμ (ε): 332 (22300), 242 (14800), and 230 (14200). IR (KBr) cm^{-1}: 1680 (νC_{CO}). NMR ($CDCl_3$) τ: 5.38 (s, 2H, $-CH_2-$).

Found: C, 68.75; H, 4.33; N, 14.44%. Calcd for $C_{22}H_{16}O_3N_4$: C, 68.74; H, 4.20; N, 14.58%.

Basic Rearrangement. The *p*-nitrophenylhydrazone of XVIII was dissolved in a minimum amount of acetone containing one drop of concd. ammonium hydroxide. The solution was refluxed for 5 hr; during that time the solution was kept alkaline by occasional addition of concd. ammonium hydroxide to the solution. By this procedure a quantitative yield of XXII was obtained.

Thermal and Basic Treatment of The p-Nitrophenylhydrazone of XXI. Similar thermal and basic treatments afforded XXIV, mp 280—281°C. IR (KBr) cm^{-1}: 3180 (ν_{NH}) and 1670 (ν_{CO}).

Found: 58.95; H, 3.54; N, 19.25%. Calcd for $C_{21}H_{14}O_5N_6$: C, 58.60; H, 3.28; N, 19.53%.

Photochemistry of XVIII. General procedure: A 0.01 mol/*l* solution of XVIII in a given solvent was irradiated at room temperature under nitrogen stream for a given reaction time. The resulting precipitates were filtered and recrystallized from ethanol - benzene to afford XXV, mp 134—136°C. IR (KBr) cm^{-1}: 1650 (ν_{CO}).

Found: C, 76.77; H, 4.45; N, 5.17%. Calcd for $C_{16}H_{11}O_2N$: C, 77.09; H, 4.45; N, 5.62%.

The solvent was removed from the filtrate and the residue was chromatographed. The first fraction gave unreacted starting material. Then, dibenzoylacetonitrile, mp 160°C,[22] XXV and benzoic acid were successively isolated.

Dibenzoylacetonitrile. IR (KBr) cm^{-1}: 3400 (broad, ν_{OH})[23] and 2220 (ν_{CN}).

Found: C, 77.32; H, 4.47; N, 5.85%. Calcd for $C_{16}H_{11}O_2N$: C, 77.09; H, 4.45; N, 5.62%.

When XVIII was irradiated with a 60-W low pressure mercury lamp in benzene, the main product was *N*-benzoylbenzoylacetamide, mp 170°C.[24] IR (KBr) cm^{-1}: 3250 (ν_{NH}), 1705 and 1680 (ν_{CO}). NMR (DMSO-d_6) τ: −0.82 (NH) and 5.42 ($-CH_2-$).

Found: C, 71.55; H, 4.86; N, 5.53%. Calcd for $C_{16}H_{13}O_3N$: C, 71.90; H, 4.90; N, 5.24%.

The results are summarized in Table 2.

N-Phenylglyoxylylaziridine Oxime (XXVI) and Its O-p-Nitrobenzoate (XXVII). To a stirred solution of 0.92 g (0.005 mol) of II in 50 m*l* of ether was added dropwise a solution of 1 m*l* of aziridine in 50 m*l* of ether under ice-cooling. The mixture was stirred for 30 min at this temperature and then for 24 hr at room temperature. After removal of the precipitates, the filtrate was concentrated to give 80% yield of XXVI as an oil. IR (neat) cm^{-1}: 3325 (ν_{OH}). NMR ($CDCl_3$) τ: 7.64 (s, 1H, OH) and 7.74 (s, 4H, $-CH_2-CH_2-$).[25]

To a stirred solution of 0.5 g (0.0025 mol) of XXVI and 0.5 g (0.05 mol) of triethylamine in 40 m*l* of dry benzene was added a solution of 0.5 g (0.0025 mol) of *p*-nitrobenzoyl chloride in 20 m*l* of dry benzene under ice-cooling. The reaction mixture was left standing overnight. After the solution was saturated with dry hydrogen chloride gas, the precipitates were filtered and the filtrate was concentrated. The residue was chromatographed to afford 0.41 g (50%) of XXVII, mp 147—149°C, by recrystallization from benzene - petroleum ether. IR (KBr) cm^{-1}: 1750 and 1665 (ν_{CO}). NMR ($CDCl_3$) τ: 7.42 (s, 4H, $-CH_2-CH_2-$).[25]

Found: C, 59.93; H, 3.94; N, 12.40%. Calcd for $C_{17}H_{13}O_5N_3$: C, 60.17; H, 3.86; N, 12.39%.

2-Benzoyloxazoline (XXVIII). A solution of 0.7 g of XXVI in 30 m*l* of acetone was refluxed in the presence of 0.2 g of sodium iodide for 30 min. The filtered solution was concentrated and chromatographed to give an oil (XXVIII). IR (neat) cm^{-1}: 1640 (ν_{CO}) and 1610 ($\nu_{C=N}$). Its picrate, mp 179—180°C; the yield was 0.3 g (25%). NMR (DMSO-d_6) τ: 4.8—5.6 (m, 4H, $-CH_2-CH_2-$)[26] and 1.8—2.5 (m, 5H, phenyl protons).

Found: C, 47.10; H, 3.24; N, 14.43%. Calcd for $C_{16}H_{14}O_9N_4$: C, 47.29; H, 3.47; N, 13.79%.

Reactions of Sulfonium and Pyridinium Salts with Alkyl Nitrite

Teruaki MUKAIYAMA, Kazuhiko SAIGO, and Hisashi TAKEI

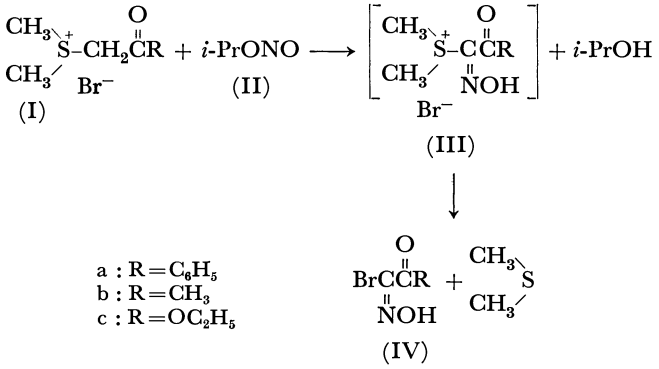
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 18, 1970)

It was found that α-bromo-α-hydroxyimino compounds were obtained in good yields by the reactions of sulfonium bromides, such as dimethylphenacylsulfonium bromide, acetonyldimethylsulfonium bromide and ethoxycarbonylmethyldimethylsulfonium bromide, with isopropyl nitrite. On the other hand, (α-hydroxyiminophenacyl and -acetonyl)pyridinium bromides were obtained in quantitative yields by the reactions of pyridinium bromides, such as phenacylpyridinium bromide and acetonylpyridinium bromide, with isopropyl nitrite. Further, the reactions of α-bromo-α-hydroxyimino compound or (α-hydroxyiminophenacyl)pyridinium bromide, which were obtained by the above mentioned reactions, with several nucleophiles were studied.

It is well known that dimethylphenacylsulfonium salt affords the corresponding stable ylide by treatment with alkali. The result indicates that hydrogen atom attached to α-carbon of the sulfonium salt becomes acidic by the influence of both positively charged sulfur atom and carbonyl group.

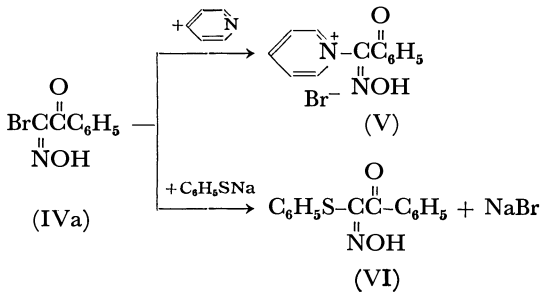
In the present experiment, the reactions of sulfonium salts with alkyl nitrite were tried in order to prepare hydroxyimino derivatives of the sulfonium compounds and to examine their reactions. When a mixture of phenacylsulfonium bromide (Ia) and isopropyl nitrite (II) in dichloromethane was stirred at room temperature, evolution of dimethyl sulfide was observed. After removal of the solvent, α-bromo-α-hydroxyiminoacetophenone (IVa) (93%) was unexpectedly obtained. It was identified by mixed melting point with authentic sample.[1] This result shows that the reaction proceeds by eliminating dimethyl sulfide from the initially formed α-hydroxyiminosulfonium salt by an intramolecular nucleophilic displacement with bromide ion. Similarly, α-bromo-α-hydroxyiminoacetone (IVb) and ethyl α-bromo-α-hydroxyiminoacetate (IVc) were obtained in quantitative yields from the reactions of the corresponding sulfonium salts, acetonyldimethylsulfonium bromide (Ib) and ethoxycarbonylmethyldimethylsulfonium bromide (Ic), with isopropyl nitrite. According to this method, α-bromo-α-hydroxyimino compounds can be prepared in higher yields than the previous methods.[1-3] Whereas, the reaction of benzyldimethylsulfonium bromide with isopropyl nitrite could not be observed and the starting materials were recovered quantitatively.



(I) (II) (III) (IV)

Then, the same reactions by the use of sulfonium tetrafluoroborates were tried with the expectation that the nucleophilic displacement by tetrafluoroborate anion at α-carbon of the sulfonium salts would be obstructed because of its lower nucleophilicity. But, α-hydroxyiminosulfonium tetrafluoroborates could not be obtained by the reactions of the sulfonium tetrafluoroborates, such as dimethylphenacylsulfonium tetrafluoroborate, ethoxycarbonylmethyldimethylsulfonium tetrafluoroborate and benzyldimethylsulfonium tetrafluoroborate, with isopropyl nitrite and the starting materials were recovered quantitatively.

Next, the several reactions[4] of α-bromo-α-hydroxyiminoacetophenone (IVa), produced by the above mentioned reaction, with some nucleophiles were investigated. When pyridine was added to a solution of α-bromo-α-hydroxyiminoacetophenone (IVa) in ether at room temperature, (α-hydroxyiminophenacyl)pyridinium bromide (V) precipitated readily in a quantitative yield. Similarly, when a solution of sodium thiophenolate in ethanol was added to a solution of α-bromo-α-hydroxyiminoacetophenone (IVa) in ethanol at 0°C, the yellow crystals, α-hydroxyimino-α-phenylthioacetophenone (VI), was obtained in an almost quantitative yield after removal of the solvent under reduced pressure.



(IVa) (V) (VI)

On the other hand, it was found that dibenzoylfuroxane (VIII) was obtained in 48% yield by treating α-bromo-α-hydroxyiminoacetophenone (IVa) with an equimolar amount of triethylamine in ether. This result indicates that benzoyl cyanide *N*-oxide (VII) is formed as an intermediate by the elimination of hydrogen bromide from α-bromo-α-hydroxyiminoaceto-

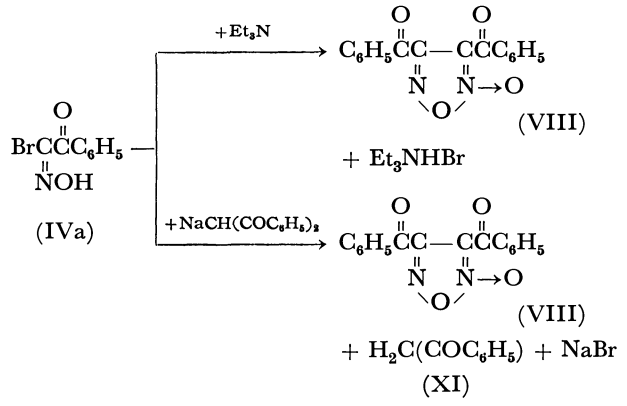
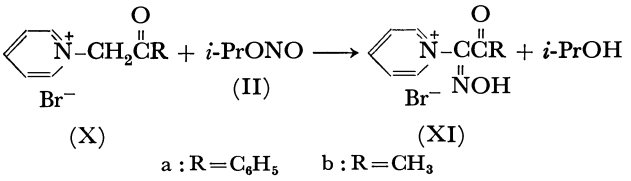
2) G. C. Singhal and M. M. Bokadia, *ibid.*, **35**, 898 (1958).
3) M. Z. Jowitschitsch, *Ber.*, **39**, 785 (1906).
4) There has been recently reported by Dornow that α-anilino-α-hydroxyiminoacetophenone was obtained in good yield by the reaction of α-bromo-α-hydroxyiminoacetophenone with aniline. A. Dornow and W. Sassenberg, *Ann. Chem.*, **594**, 185 (1955).

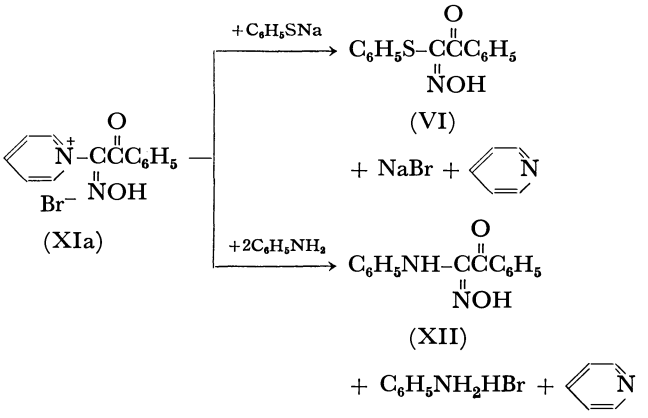
phenone when it is treated with base. Similarly, by the reaction of α-bromo-α-hydroxyiminoacetophenone (IVa) with sodium salt of dibenzoylmethane, dibenzoylfuroxane (VIII) and dibenzoylmethane (IX) were obtained in 62% and 90% yields. In this reaction, sodium salt of dibenzoylmethane behaved as a base to accept hydrogen bromide from α-bromo-α-hydroxyiminoacetophenone instead of a nucleophilic reagent.



Next, the reactions of pyridinium bromides with isopropyl nitrite were tried with the expectation that the nucleophilic displacement by bromide ion at α-carbon of pyridinium salt would not occur because of the lower activity of α-carbon of the pyridinium salts than that of the sulfonium salts described before. When a mixture of phenacylpyridinium bromide (Xa) and isopropyl nitrite (II) in ethanol was allowed to stand at room temperature, the crystalline, (α-hydroxyiminophenacyl)pyridinium bromide (XIa) was obtained in a quantitative yield. Similarly (α-hydroxyiminoacetonyl)pyridinium bromide (XIb) was quantitatively obtained by the reaction of acetonylpyridinium bromide (Xb) with isopropyl nitrite (II). They were identified by the IR spectra and the elemental analyses. Whereas, ethoxycarbonylhydroxyiminomethylpyridinium bromide could not be isolated by the reaction of ethoxycarbonylmethylpyridinium bromide with isopropyl nitrite and the starting materials were recovered quantitatively.



Then, the reactions of (α-hydroxyiminophenacyl)-pyridinium bromide, produced by the above mentioned reaction, with nucleophilic reagents were investigated. When a mixture of (α-hydroxyiminophenacyl)pyridinium bromide (XIa) and sodium thiophenolate in ethanol was allowed to stand at room temperature, α-hydroxyimino-α-phenylthioacetophenone (VI) was obtained in 71% yield. This was identical with that prepared by the reaction of α-bromo-α-hydroxyiminoacetophenone and sodium thiophenolate. Similarly, α-anilino-α-hydroxyiminoacetophenone (XII) was produced in 65% yield by the reaction of (α-hydroxyiminophenacyl)-pyridinium bromide (XIa) with two equimolar amounts of aniline in ethanol at room temperature. These reactions indicate that pyridine can be easily eliminated from the pyridinium salt by the nucleophilic displacement of the nucleophiles, such as aniline and sodium thiophenolate.



Experimental

Reaction of Dimethylphenacylsulfonium Bromide with Isopropyl Nitrite. A mixture of dimethylphenacylsulfonium bromide (1.31 g, 0.005 mol) and excess isopropyl nitrite (0.89 g, 0.01 mol) was stirred in dichloromethane (100 m*l*) for 12 hr at room temperature. The evolution of dimethyl sulfide was observed by its characteristic odor accompanied with disappearance of the crystals of the sulfonium salt. Evaporation of the solvent under reduced pressure gave white crystals, α-bromo-α-hydroxyiminoacetophenone (mp 138—139°C), 1.07 g (93%), recrystallized from cyclohexane. Similarly, various α-bromo-α-hydroxyimino compounds were obtained by the reactions of sulfonium bromides with isopropyl nitrite. The results are listed in Table 1. The α-bromo-α-hydroxyimino compounds were identified by their IR spectra and elemental analyses.

Table 1. The reaction of sulfonium bromides with isopropyl nitrite

Sulfonium bromide	Reaction time	Solvent	Yield	Mp, °C
$CH_3S^+(CH_3)CH_2COC_6H_5\ Br^-$	12 hr	CH_2Cl_2	93%	138—139
$CH_3S^+(CH_3)CH_2COCH_3\ Br^-$	1 day	CH_2Cl_2	quant.	119—120
$CH_3S^+(CH_3)CH_2COC_2H_5\ Br^-$	1 day	CH_2Cl_2	quant.	92—93

Reaction of α-Bromo-α-hydroxyiminoacetophenone with Pyridine. Into a solution of α-bromo-α-hydroxyiminoacetophenone (0.43 g, 0.0019 mol) in ether (50 m*l*), a solution of pyridine (0.15 g, 0.0019 mol) in ether (10 m*l*) was added drop by drop with stirring. After stirring for 30 min at room temperature, white precipitate deposited. The precipitate was collected by filtration and recrystallized from ethanol to give (α-hydroxyiminophenacyl)pyridinium bromide (mp 143.5°C (dec.)) in a quantitative yield.

Found: C, 51.07; H, 3.36; N, 9.31%. Calcd for $C_{13}H_{11}BrN_2O_2$: C, 50.83; H, 3.61; N, 9.12%.

Reaction of α-Bromo-α-hydroxyiminoacetophenone with Sodium Thiophenolate. A solution of sodium thiophenolate (0.66 g, 0.005 mol) in ethanol (50 m*l*) was added dropwise to a solution of α-bromo-α-hydroxyiminoacetophenone (1.14 g, 0.005 mol) in ethanol (50 m*l*) with stirring. After stirring for 12 hr at room temperature, solvent was evaporated. The residue was washed with water (100 m*l*) and extracted with ether (100 m*l*). Then, the solvent was evaporated under reduced pressure to give yellow crystals. Recrystallization from cyclohexane gave α-hydroxyimino-α-phenylthioacetophenone (mp 110—111°C) in an almost quantitative yield.

Found: C, 65.49; H, 4.56; N, 5.35; S, 12.20%. Calcd for $C_{14}H_{11}NO_2S$: C, 65.36; H, 4.31; N, 5.45; S, 12.44%.

Reaction of α-Bromo-α-hydroxyiminoacetophenone with Triethylamine. Into a solution of α-bromo-α-hydroxyiminoacetophenone (1.12 g, 0.005 mol) in ether (50 m*l*), an equimolar amount of triethylamine was added with stirring. The reaction mixture was stirred for 1 day at room temperature. After removal of the solvent, the residue was chromatographed on silica gel and elution with benzene gave dibenzoylfuroxane (mp 86—87°C, 48%).

Found: C, 65.51; H, 3.25; N, 9.27%. Calcd for $C_{16}H_{10}N_2O_4$: C, 65.30; H, 3.43; N, 9.52%.

Reaction of Phenacylpyridinium Bromide with Isopropyl Nitrite. A mixture of phenacylpyridinium bromide (2.78 g, 0.01 mol) and excess amount of isopropyl nitrite (1.78 g, 0.02 mol) in ethanol (50 m*l*) was stirred for 1 day at room temperature. After removal of the solvent, white crystals were obtained. Recrystallization from ethanol gave (α-hydroxyiminophenacyl)pyridinium bromide (mp 143.5°C (dec.)) in a quantitative yield. By a similar procedure, (α-hydroxyiminoacetonyl)-pyridinium bromide (mp 73.5—74.0°C) was obtained quantitatively.

Found: C, 39.48; H, 3.59; N, 11.36%. Calcd for $C_8H_9BrN_2O_2$: C, 39.20; H, 3.70; N, 11.43%.

Reaction of (α-Hydroxyiminophenacyl)pyridinium Bromide with Sodium Thiophenolate. To a suspension of (α-hydroxyiminophenacyl)pyridinium bromide (3.07 g, 0.01 mol) in ethanol (50 m*l*), a solution of sodium thiophenolate (1.32 g, 0.01 mol) in ethanol (20 m*l*) was added with stirring. After stirring for 12 hr, crystals of (α-hydroxyiminophenacyl)pyridinium bromide disappeared. The residue was chromatographed on silica gel after removal of the solvent under reduced pressure, and elution with dichloromethane gave yellow crystals, α-hydroxyimino-α-phenylthioacetophenone (mp 110—111°C), 1.82 g (71%).

Reaction of (α-Hydroxyiminophenacyl)pyridinium Bromide with Aniline. A mixture of (α-hydroxyiminophenacyl)pyridinium bromide (3.07 g, 0.01 mol) and two equimolar amounts of aniline (1.86 g, 0.02 mol) in ethanol (100 m*l*) was stirred for 5 days at room temperature. After removal of the solvent, the residue was washed with water (50 m*l*) and extracted with ether (50 m*l*). Then, the solvent was evaporated and crystalline solid of α-anilino-α-hydroxyiminoacetophenone (mp 145.0—146.5°C) was obtained in 65% yield after removal of the solvent under reduced pressure.

The Preparation of 4′,6′-Di- and 2′,4′,6′-Tri-*O*-acetates of Theophylline Nucleosides of 3′-Deoxy-3′-nitro-β-D-galacto-, gluco- and mannopyranose[1]

Toshio NAKAGAWA and Tetsuyoshi TAKAMOTO

Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo

(Received July 18, 1970)

7-(3′-Deoxy-3′-nitro-β-D-glucopyranosyl)theophylline (**1**) was treated with acetic anhydride in the presence of boron trifluoride, perchloric or phosphoric acid as a catalyst to afford the corresponding 2′,4′,6′-tri-*O*-acetate (**4**) in 87, 60 and 48% yields, respectively. With *galacto*-isomer (**2**), tri-*O*-acetate (**6**) was obtained in a high yield by the use of phosphoric acid or a large excess of perchloric acid as a catalyst, while 4′,6′-di-*O*-acetate (**5**) was selectively prepared in 82% yield when a trace of perchloric acid was used. The similar preparation of 4′,6′-di- and 2′,4′,6′-tri-*O*-acetates (**7** and **8**) of *manno*-isomer (**3**) was also carried out in the presence of boron trifluoride and phosphoric acid, respectively. The positions of the acetyl groups in the diacetates **5** and **7** were unequivocally deduced from NMR data.

On the acetylation of methyl 3-deoxy-3-nitro-hexopyranosides and their 4,6-*O*-benzylidene derivatives with acetic anhydride, Baer *et al*[2] pointed out the favorableness of boron trifluoride as a catalyst and mentioned the inadvisableness of acids such as sulfuric or perchloric acid, because these acids possess an inherent danger of acetolysis in the glycoside and benzylidene acetal structures. For the preparation of model compounds for our studies on aminations of nitro sugars,[3–5] we have examined the acid-catalysed acetylation of theophylline nucleosides of 3′-deoxy-3′-nitro-β-D-hexopyranoses (**1**—**3**) with boron trifluoride, perchloric or phosphoric acid and showed their merits, especially as a catalyst for a selective partial acetylation, and some limitations, as follows.

Results and Discussion

Preparation of Acetates. When 7-(3′-deoxy-3′-nitro-β-D-glucopyranosyl)theophylline (**1**) was treated with acetic anhydride in the presence of boron trifluoride, the corresponding 2′,4′,6′-tri-*O*-acetate (**4**) was easily prepared in 87% yield, a favorable result over those in the case of perchloric or phosphoric acid (yields of **4**: 60 and 48%, respectively) as Baer *et al.* pointed out.[2]

The similar treatment of *galacto*-isomer **2** with boron trifluoride did not afford a single product but a mixture of two or more components including di- and tri-*O*-acetates of **2**. All attempts to isolate these components by a fractional recrystallisation were unsuccessful. When **2** was treated with acetic anhydride in the presence of a trace of perchloric acid, unexpected 4′,6′-di-*O*-acetate **5** was selectively prepared in 82% yield. If a large excess (*ca.* a molar amount) of this catalyst was used, only 2′,4′,6′-tri-*O*-acetate **6** precipitated in 89% yield. The triacetate **6** was also prepared in 60% yield by Fatiadi's method[6] using anhydrous phosphoric acid as a catalyst.

Similarly, the phosphoric acid-catalysed acetylation of *manno*-isomer **3** gave amorphous 2′,4′,6′-tri-*O*-acetate **8** in 45% yield, whereas 4′,6′-di-*O*-acetate **7** was exclusively obtained in 24% yield with boron trifluoride. Repeated trials of the perchloric acid-catalysed acetylation of **3** always produced a mixture of acetates containing both **7** and **8** at least on the basis of NMR spectra.

The 4′,6′-*O*-benzylidene derivatives of **1**—**3** were prepared in the usual manner and then treated with acetic anhydride in the presence of boron trifluoride to yield the corresponding 2′-*O*-acetyl-4′,6′-benzylidene derivatives (**12**—**14**), which were submitted for NMR studies described below.

NMR Studies. Recently, Lichtenthaler *et al.*[7,8] summarized the relationship between chemical shifts of the methyl resonances of *O*- and *N*-acetyl groups and their conformations in a series of pyranose- and cyclitolpolyacetates: In deuteriochloroform ($CDCl_3$), axial *O*-acetyl groups of polyacetates of sugars and aminosugars appear generally in a region of τ 7.80—7.87, equatorial *N*-acetyl groups in a relatively higher field, τ 8.03—8.10 and equatorial *O*-acetyl (including 6-*O*-acetyl group of aldopyranose derivatives) and axial *N*-acetyl groups in a middle region, τ 7.87—8.02.[8] By changing the solvent to dimethylsulfoxide-d_6 (DMSO-d_6) a diamagnetical shift of the signals of *O*-acetyl groups is in general permissible (0.05 ppm), but that of *N*-acetyl groups appreciable (ordinarily 0.15 ppm).[8] In the case of fully acetylated hexopyranosyl nucleosides, the anisotropy of the bases causes a diamagnetical shift of the 2′-acetyl singnals, *i.e.* generally in pyrimidines 0.1 ppm; in purines 0.3 ppm.[8]

The lowest one of the three acetyl signals of *galacto*-isomer **6** (τ 7.82 in $CDCl_3$ and τ 7.86 in DMSO-d_6) is assigned to the axial 4′-*O*-acetyl group, the middle signal (τ 7.95 in $CDCl_3$ and τ 8.02 in DMSO-d_6) to the 6′-*O*-acetyl group, and the highest one (τ 8.11 in $CDCl_3$ and τ 8.18 in DMSO-d_6) to the equatorial 2′-*O*-acetyl group. These assignments are also confirmed by the facts that the 2′-*O*-acetyl signal of **13** appears at τ 8.11 in $CDCl_3$ and τ 8.20 in DMSO-d_6. The *galacto*-diacetate **5** has two acetyl signals at τ 7.82 and 7.94 in $CDCl_3$, and at τ 7.86 and 8.01 in DMSO-d_6, which are easily assigned to the 4′- and 6′-*O*-acetyl

a) Assignments of the spectra are based on a first-oder analysis.
b) See footnote d) in Fig. 1.

groups, respectively, and shows no diamagnetically shifted signal corresponding to the 2'-*O*-acetyl group (*cf.* Fig. 1). Therefore, the structure of **5** is unequivocally deduced to be 4',6'-di-*O*-acetate.

On the other hand, the diamagnetically shifted axial 2'-*O*-acetyl signal of the *manno*-isomers appears at τ *ca.* 8.0 in $CDCl_3$ (*i. e.* compound **14**; τ 8.01: **8**; τ 8.02). From this reason, the two acetyl signals of *manno*-diacetate **7** (τ 7.89 and 7.90 in $CDCl_3$; τ 7.93 and 7.96 in DMSO-d_6) are assigned to the equatorial 4'- and 6'-*O*-acetyl groups and, therefore, the axial hydroxyl group on *C*-2' is free, which indicates the structure of **7** also to be 4',6'-di-*O*-acetate.

These structural elucidations of diacetates **5** and **7** are further confirmed by considerations on the spectra of their ring protons on *C*-2':

a) Their signals, resonated in DMSO-d_6 at τ 4.99 and 5.36 in **5** and **7**, respectively, appear as diffused bands as a result of the coupling with the 2'-hydroxylic proton in the presence of a trace of water in the solvent[10] (*cf.* Figs. 2 and 3);

b) On acetylation (**5**→**6**; **7**→**8**) the chemical shift of the proton on *C*-2' moves paramagnetically in a

considerable extent, 1.1—1.3 ppm,[11] and this effect diminishes remarkably with the degree of the distance from the 2'-carbon atom along the C–C bond, *i. e.* 0.2—0.45 ppm for $H^{1'}$ and $H^{3'}$; 0.0—0.14 ppm for $H^{4'}$ (Table 1), all of which indicate clearly the 2'-hydroxyl group in **5** and **7** to be free.

Experimental

General. All melting points were determined in a capillary and uncorrected. Optical rotations were measured with a CARL ZEISS photoelectric polarimeter. NMR spectra were recorded at 100 MHz with a JEOL spectrometer (Type JNM-4H-100), using tetramethyl silane as an internal standard.

7-(2',4',6'-Tri-O-acetyl-3'-deoxy-3'-nitro-β-D-glucopyranosyl)-theophylline (4). *a) Catalysed by Boron Trifluoride*: To a stirred suspension of **1**[9] (3.0 g, 8.1 mmol) in acetic anhydride (7 ml) was added boron trifluoride etherate (*ca.* 0.3 ml) dropwise. After standing overnight at room temperature the mixture was poured into ice water (200 ml) with sitrring. The acetate separated in gel-like form while the excess anhydride decomposed, was collected by filtration, suspended again in

11) Acylation of secondary alcohols causes the chemical shift of the α-proton to move paramagnetically by 1.0—1.15 τ and this effect is the same for axial and equatorial protons in steroid molecules [Ref. 10, p. 55; J. N. Shoolery and M. T. Rogers, *J. Amer. Chem. Soc.*, **80**, 5121 (1958)].

water (50 m*l*) with vigorous stirring and then filtered. After thorough washing with water and drying *in vacuo* at 40—50°C, the resulting colorless powder (3.5 g, 87%) was analytically pure. All attempts to crystallize were unsuccessful. $[\alpha]_D^{20}$ −7.4° (*c* 1.0, $CHCl_3$). IR (KBr): 1750 cm^{-1} ($\nu_{C=O}$ of Ac). NMR ($CDCl_3$): 3.73 (1H-*d*, $J_{1'2'}=9$ Hz, H$^{1'}$); 4.93 τ (1H-*t*, $J_{2'3'}=J_{3'4'}=10$ Hz, H$^{3'}$).

Found: C, 45.72; H, 4.72; N, 14.26%. Calcd for $C_{19}H_{23}O_{11}N_5$: C, 45.85; H, 4.66; N, 14.08%.

b) Catalysed by Perchloric Acid: To a well stirred suspension of **1**[9] (1.0 g, 2.7 mmol) in acetic anhydride (4 m*l*) were added two drops of 70% perchloric acid. The mixture was stirred for additional 12 hr at room temperature and then worked up as described above to yield 0.80 g (60%) of colorless powder, which was identified with the product obtained above.

c) Catalysed by Phosphoric Acid: To a mixture of Fatiadi's catalyst[6] (1 m*l*) and acetic anhydride (4 m*l*) was added **1**[9] (0.50 g, 1.35 mmol) and warmed with stirring at 50°C for 1 hr. The mixture was then worked up as described under *a*): Yield 0.32 g (48%).

*7-(2′,4′,6′-Tri-O-acetyl-3′-deoxy-3′-nitro-β-D-galactopyranosyl)-theophylline (**6**).* *a) In the Presence of a Large Excess of Perchloric Acid*: To a well stirred suspension of **2**[9] (2.0 g, 5.4 mmol) in acetic anhydride (8 m*l*) was added 70% perchloric acid (4.6 m*l*, 5.4 mmol) dropwise. The mixture became immediately a clear solution and then the acetate precipitated in crystalline form, which was filtered after stirring for 1 hr and washed well with ether. Additional crystals were deposited by further addition of 70% perchloric acid (3.0 m*l*) into the filtrate, filtered and washed with ether. The combined crystals were suspended in cold water (30 m*l*) with vigorous stirring for 1 hr, filtered, washed with water and then dried *in vacuo* at 50°C: 2.4 g (89%) of analytically almost pure, colorless needles, mp 191—193°C (decomp.).

Found: C, 45.95; H, 5.13; N, 14.02%. Calcd for $C_{19}H_{23}O_{11}N_5$: C, 45.85; H, 4.66; N, 14.08%.

Recrystallization from ethanol gave needles with lowered mp: 188—189°C (decomp.); $[\alpha]_D^{20}$ −1.8° (*c* 1.1, $CHCl_3$). (IR) (KBr): 1760 cm^{-1} ($\nu_{C=O}$ of Ac). NMR ($CDCl_3$): 3.71 (1H-*d*, $J_{1'2'}=9$ Hz, H$^{1'}$); 4.84 τ (1H-*q*, $J_{2'3'}=10$, $J_{3'4'}=3$ Hz, H$^{3'}$). Found: C, 45.75; H, 4.50; N, 14.17%.

b) Catalysed by Phosphoric Acid: To a mixture of Fatiadi's catalyst[6] (5 m*l*) and acetic anhydride (20 m*l*) was added **2**[9] (2.5 g, 6.7 mmol) and warmed with stirring at 50°C for 1.5 hr. The reaction mixture was poured into ice water with stirring and the resulting precipitates were filtered. Recrystallisation from ethanol gave 2.0 g (60%) of colorless needles, which were identified with the product obtained above.

*7-(2′,4′,6′-Tri-O-acetyl-3′-deoxy-3′-nitro-β-D-mannopyranosyl)-theophylline (**8**).* To a mixture of Fatiadi's catalyst[6] (2 m*l*) and acetic anhydride (8 m*l*) was added **3**[9] (1.0 g, 2.7 mmol) and stirred at room temperature for 1 hr. The reaction mixture was poured into ice water (100 m*l*) and stirred vigorously for 0.5 hr. The water layer was removed by decantation and the remnant was stirred with new cold water again. This operation was repeated three times more to afford colorless powder, which was collected by filtration and dried *in vacuo* at room temperature over phosphorous pentoxide: Yield 0.60 g (45%). The product obtained was analyticallly pure, but all attempts to crystallize were unsuccessful. $[\alpha]_D^{20}$ +108.6°C (*c* 1.0, $CHCl_3$). IR (KBr): 1750 cm^{-1} ($\nu_{C=O}$ of Ac). NMR ($CDCl_3$): 3.58 (1H-*d*, $J_{1'2'}=1.5$ Hz, H$^{1'}$); 4.84 τ (1H-*q*, $J_{2'3'}=3.5$, $J_{3'4'}=10.5$ Hz, H$^{3'}$).

Found: C, 45.56; H, 4.44; N, 14.38%. Calcd for $C_{19}H_{23}O_{11}N_5$: C, 45.85; H, 4.66; N, 14.08%.

*7-(4′,6′-Di-O-acetyl-3′-deoxy-3′-nitro-β-D-galactopyranosyl)theophylline (**5**).* To a suspension of **2**[9] (1.0 g, 2.7 mmol) in acetic anhydride (7 m*l*) was added a drop of perchloric acid and stirred at room temperature for 10 hr. To the reaction mixture was added 30 m*l* of ice water with vigorous stirring and the resulting precipitates were separated, washed well with water and dried *in vacuo* at 50°C to afford analytically pure, colorless needles (1.01 g, 82%) of mp 170—171°C (decomp.). Even after recrystallisation from ethanol/petroleum ether, the melting point did not change. $[\alpha]_D^{20}$ −19.2° (*c* 0.57, dioxane). IR (KBr): 3400 (ν_{OH}); 1750 and 1730 cm^{-1} ($\nu_{C=O}$ of Ac).

Found: C, 44.84; H, 4.68; N, 15.12%. Calcd for $C_{17}H_{21}O_{10}N_5$: C, 44.84; H, 4.65; N, 15.38%.

*7-(4′,6′-Di-O-acetyl-3′-deoxy-3′-nitro-β-D-mannopyranosyl)theophylline (**7**).* To a well stirred suspension of **3**[9] (0.50 g, 1.35 mmol) in acetic anhydride (10 m*l*) was added a few drops of boron trifluoride etherate and stirred for 3.5 hr at room temperature. To the reaction mixture was added ice water (30 m*l*) and vigorously stirred for 30 min. After extraction with methylene chloride (20 m*l*×4), washing with water and drying over sodium sulfate, the organic solvent was evaporated *in vacuo* at 40°C to dryness. The remained sirup was dissolved in chloroform (2 m*l*) and then allowed to stand overnight. The acetate deposited was collected by filtration and recrystallized from methanol: 0.15 g (24%) of colorless needles; mp 203—204°C (decomp.); $[\alpha]_D^{20}$ +73.4° (*c* 1.0, dioxane). IR (KBr): 3400 (ν_{OH}), 1741 cm^{-1} ($\nu_{C=O}$ of Ac).

Found: C, 44.93; H, 4.29; N, 15.48%. Calcd for $C_{17}H_{21}O_{10}N_5$: C, 44.84; H, 4.65; N, 15.38%.

*7-(4′,6′-O-Benzylidene-3′-deoxy-3′-nitro-β-D-glucopyranosyl)theophylline (**9**).* A mixture of **1**[9] (2.5 g, 6.7 mmol) and zinc chloride (2.5 g) in freshly distilled benzaldehyde (30 m*l*) was stirred for 2 days and then poured into ice water with stirring. The precipitates were collected by filtration washed well with water and petroleum ether, and then recrystallized from ethyl acetate to afford 1.95 g (63%) of colorless crystals; mp 255°C (decomp.); $[\alpha]_D^{20}$ −64.4° (*c* 1.23, dioxane). NMR (DMSO-d_6): 2.61 (5H-nallow *m*, phenyl); 3.52 (1H-*d*, J=6 Hz, OH); 4.07 (1H-*d*, $J_{1'2'}=8$ Hz, H$^{1'}$); 4.24 (1H-*s*, PhCH〈); 4.71 (1H-*t*, $J_{2'3'}=J_{3'4'}=10$ Hz, H$^{3'}$); 4.95 τ (1H-*m*, H$^{2'}$).

Found: C, 52.57; H, 4.53; N, 15.44%. Calcd for $C_{20}H_{21}O_8N_5$: C, 52.28; H, 4.61; N, 15.25%.

*7-(4′,6′-O-Benzylidene-3′-deoxy-3′-nitro-β-D-galactopyranosyl)-theophylline (**10**).* **2**[9] (1.0 g, 2.7 mmol) was treated with freshly distilled benzaldehyde (15 m*l*) in the presence of zinc chloride (1 g) in the same manner described above and then recrystallized from ethanol/petroleum ether to yield 0.78 g (63%) of **10**; mp 224—226°C (decomp.); $[\alpha]_D^{20}$ −86.0° (*c* 1.04, dioxane). BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 196—199 (1971)

Phosphorylation of Alcohols and Phosphates by Oxidation-Reduction Condensation

Teruaki MUKAIYAMA and Mitsunori HASHIMOTO

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

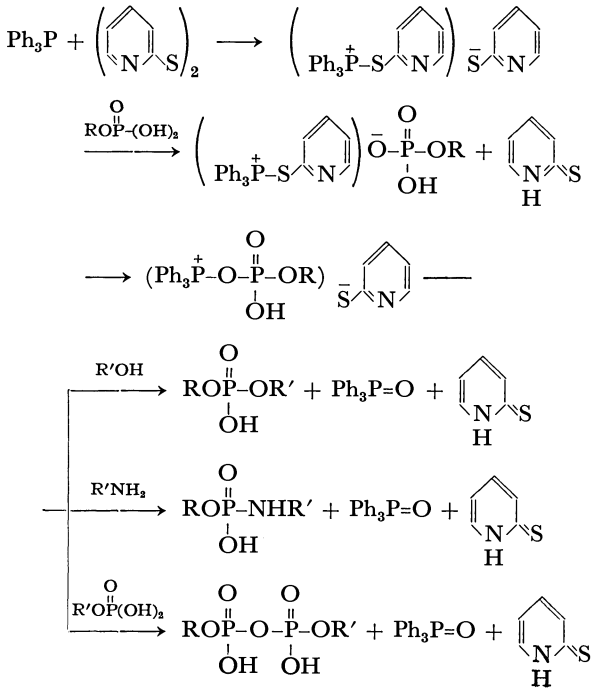
(Received July 20, 1970)

Phosphorylation of alcohols and phosphates forming mixed esters of phosphoric acid and pyrophosphate by the oxidation-reduction condensation with triphenylphosphine and 2,2′-dipyridyl disulfide has been investigated. *n*-Butyl *p*-nitrophenyl phosphate was obtained in 80% yield when *p*-nitrophenyl dihydrogen phosphate was treated with one equiv. each of triphenylphosphine and 2,2′-dipyridyl disulfide in the presence of three equiv. of anhydrous *n*-butyl alcohol at room temperature. It was found that P^1,P^2-bis(*p*-nitrophenyl)pyrophosphate was obtained in 91% yield when *p*-nitrophenyl dihydrogen phosphate was treated with 1.5 equiv. each of triphenylphosphine and 2,2′-dipyridyl disulfide.

Recently, it was reported that peptides are synthesized in high yields with optical purity by use of triphenylphosphine and 2,2′-dipyridyl disulfied as the coupling reagents.[1] Dehydration from free carboxylic components and free amino components proceeds by eliminating one oxygen atom (reduction) and two hydrogen atoms (oxidation) with triphenylphosphine and 2,2′-dipyridyl disulfide, respectively, to afford peptides, triphenylphosphine oxide and 2 mol of 2-mercaptopyridine.

In the present study the phosphorylation of alcohols and phosphate was investigated. It was considered that the reaction of triphenylphosphine, 2,2′-dipyridyl disulfied and phosphates would yield a reactive intermediate, phosphoryloxyphosphonium salt, which in turn would further react with alcohols of phosphate to give mixed esters of phosphates and pyrophosphate, respectively, according to the following equation.

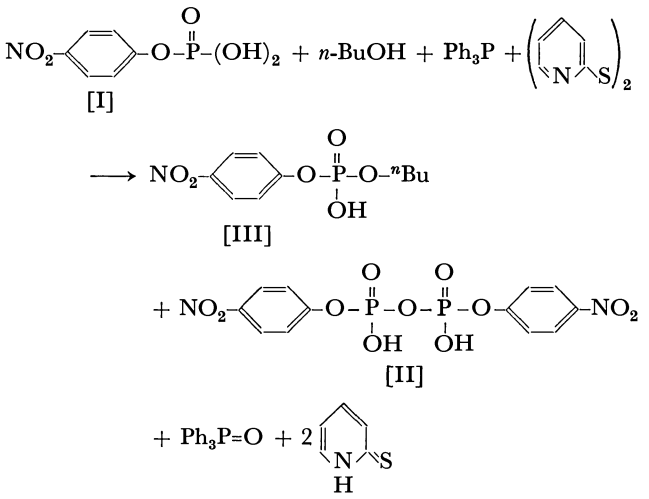
Selective phosphrylation can be effected successfully by this method without isolating the intermediate, since it reacts exclusively with nucleophilic reagents



1) T. Mukaiyama, R. Matsueda, and M. Suzuki, *Tetrahedron Lett.*, **1970**, 1901.

such as alcohols, amines and phosphates under mild conditions.

When *p*-nitrophenyl dihydrogen phosphate was treated with triphenylphosphine and 2,2′-dipyridyl disulfide in excess anhydrous *n*-butyl alcohol at room temperature, an instantaneous reaction took place and *n*-butyl *p*-nitrophenyl phosphate was obtained in high yield along with a small amount of symmetrical P^1,P^2-bis(*p*-nitrophenyl) pyrophosphate.



When I was treated with one equiv. each of triphenylphosphine and 2,2′-dipyridyl disulfide in the presence of ten equiv. of *n*-butyl alcohol, III was obtained in 80% yield. The results are nearly the same as those obtained when dicyclohexylcarbodiimide is used as a coupling reagent (see Table 1).

The effects of the solvent and base were examined in order to find a suitable condition for the preparation of III without accompanying the undesirable formation of II.

It was found that III was obtained in 50—70% yield together with 10—40% yield of II when phosphorylation was carried out in the presence of three equiv. of *n*-butyl alcohol (see Table 2). Of various solvents examined, it was found that the yield of II increased when pyridine is used as the solvent. However, when a catalytic amount of acetic anhydride was added to the pyridine solution, the formation of II decreased and III was obtained in fairly good yield.[2,3]

the same as those obtained when 3 equiv. of *n*-butyl alcohol were used as shown in the above experiments. Thus, it can be said that the use of a small excess of the coupling reagents, triphenylphosphine and 2,2′-dipyridyl disulfied, is effective for this type of phosphorylation (see Table 4).

Phosphorylation of *n*-butyl alcohol was attempted with the use of 5,5′-dinitro-2,2′-dipyridyl disulfide in place of 2,2′-dipyridyl disulfide in oder to know the effect of the substituents of the disulfide component. It is worth mentioning that the undesirable by-pro-

a) mercaptan scavenger

duct, pyrophosphate II, was scarcely formed when 5,5′-dinitro-2,2′-dipyridyl disulfide was used as the disulfide component as shown in Table 5.

In a similar way, various disubstituted phosphates and phosphoramidates were prepared from I and benzyl alcohol or amines by using triphenylphosphine and 2,2′-dipyridyl disulfide as the coupling reagents. The results are summarized in Table 6.

Finally, the preparation of symmetrical pyrophosphate II was attempted. When a solution of one eqiuv. of I was treated with 1.5 equiv. each of triphenylphosphine and 2,2′-dipyridyl disulfide at room temperature, the reaction started instantly and symmetrical P^1,P^2-bis(*p*-nitrophenyl) pyrophosphate II was obtained in 91% yield. (see Table 7).

In conclusion, phosphorylation of alcohols and phosphates by oxidation-reduction condensation with triphenylphosphine and 2.2′-dipyridyl disulfide affords the corresponding mixed esters of phosphoric acid and pyrophosphate, respectively, in good yields under mild condition.

Differing from the case of the phosphorylation with the use of dicyclohexylcarbodiimide, the oxidation-reduction condensation proceeds rapidly even in the presence of strong bases such as triethylamine and tributylamine[4] to afford the phosphorylated products in good yields.

Experimental

Reagents. *p*-Nitrophenyl dihydrogen phosphate was prepared by hydrolysis of *p*-nitrophenyl phosphorodichloridate. *p*-Nitrophenyl phosphorodichloridate was prepared by an improved procedure, of which an example is given below. A mixture of 1 mol of *p*-nitrophenol, 3 mol of phosphorus oxychloride and 0.2 mol of potassium chloride was heated at 110°C for 28 hr. After removal of hydrogen chloride and excess phosphorus oxychloride, 179 g (70%) of *p*-nitrophenyl phosphorodichloridate bp 135°C/0.6 mmHg, was obtained. 2,2′-Dipyridyl disulfide[5,6] and 5,5′-dinitro-2,2′-dipyridyl disulfide[7,8] were prepared by procedures given in literature. Triphenylphosphine was obtained from a commercial source and purified by recrystallization.

General Methods. *Reaction of* n-*Butyl Alcohol and* p-*Nitrophenyl Dihydrogen Phosphate with Triphenylphosphine and 2,2′-Dipyridyl Diculfide*: To a solution of anhydrous *n*-butyl alcohol (111 mg, 1.5 mmol), *p*-nitrophenyl dihydrogen phosphate (110 mg, 0.5 mmol) and *2,2′*-dipyridyl disulfide (110 mg, 0.5 mmol) in anhydrous tetrahydrofuran 5 m*l*, triphenylphosphine (131 mg, 0.5 mmol) was added at room temperature with vigorous stirring. After stirring for 2 hr, the amount of III formed was determined by UV absorption after separation with paper chromatography. Yield 70%.

P^1,P^2-*Bis(*p-*nitrophenyl) Pyrophosphate*: To a solution of *p*-nitrophenyl dihydrogen phosphate (220 mg, 1 mmol) and 2, 2′-dipyridyl disulfide (165 mg, 0.75 mmol) in anhydrous pyridine 5 m*l*, triphenylphosphine (197 mg, 0.75 mmol) was added with vigorous stirring at room temperature. After 2 hr, the amount of II formed was determined by the method mentioned above. Yield 91%.

Paper chromatography was carried out by the desending technique on Toyo Roshi No. 50 paper using isopropyl alcohol-concentrated ammonium hydroxyde-water (7 : 1 : 2 (v/v)). In this solvent, *p*-nitrophenyl dihydrogen phosphate has R_F 0.3, ($\lambda_{max}^{H_2O}$ 310 mμ, $\varepsilon=0.96\times10^4$), P^1,P^2-bis(*p*-nitrophenyl) pyrophosphate R_F 0.65, ($\lambda_{max}^{H_2O}$ 288 mμ, $\varepsilon=1.95\times10^4$), *n*-butyl *p*-nitrphenyl phosphate R_F 0.80, ($\lambda_{max}^{H_2O}$ 290 mμ, $\varepsilon=10^4$), benzyl *p*-nitrphenyl phosphate R_F 0.80, ($\lambda_{max}^{H_2O}$ 290 mμ, $\varepsilon=1.05\times10^4$), *p*-nitrophenyl phosphoroanilidate R_F 0.82, ($\lambda_{max}^{H_2O}$ 291 mμ, $\varepsilon=10^4$), *p*-nitrophenyl phosphorobenzylamidate R_F 0.79, ($\lambda_{max}^{H_2O}$ 289 mμ, $\varepsilon=1.05\times10^4$) and *p*-nitrophenyl phosphoromorpholidate R_F 0.83, ($\lambda_{max}^{H_2O}$ 289 mμ, $\varepsilon=10^4$).

The authors wish to express their hearty thanks to Dr. Tsujiaki Hata, Dr. Rei Matsueda and Dr. Masaaki Ueki for their kind advice given during the course of this experiment.

Macro Rings. III[1,2]. The Synthesis of [2.1.1.1]Paracyclophane

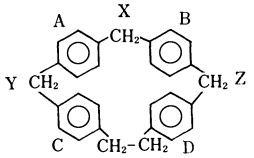
Toshio KAWATO,[3] Takahiko INAZU, and Tamotsu YOSHINO

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received July 20, 1970)

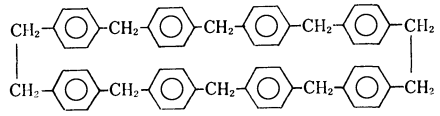
Two new macrocyclic compounds, I and II, which incorporate, respectively, four or eight benzene rings and intervening methylene bridges attached to their *para* positions, were synthesized. The UV, IR, and NMR spectra of these paracyclophanes were compared with a corresponding open-chain compound, III.

Some paracyclophanes have been shown to have interesting characteristics compared with an open-chain analog because of the interaction of the π-electrons of adjacent benzene rings. An interesting characteristic of forming charge-transfer complexes and clathrate compounds may be expected, especially in a cyclophane in which the planes of benzene rings assume such a perpendicular configuration with each other as to form a square prism. The synthesis of [2.1.1.1]paracyclophane I was thus undertaken.



[2.1.1.1]Paracyclophane I

Formula 1



[2.1.1.1.2.1.1.1]Paracyclophane II

Formula 2

As is shown by a Dreiding molecular model of the paracyclophane I, four benzene rings are situated in planes so as to form a slightly deformed square prism whose respective parallel planes are slightly inclined to each other, and four pairs of adjacent benzene rings are connected by an ethylene and three separate methylene bridges, involving a slight strain in the valence angle of each methylene carbon and a slight warp in the planes of the benzene rings. The molecular model also shows that the [2.1.1.1]paracyclophane molecule should exist in the form of two nonsuperposable mirror-image conformers due to the pair of skew conformations of the 1,2-diphenylethane moiety in the macro ring.

A pair of such enantiomeric conformers appear to be interconverted so rapidly at an ordinary temperature by a flip that, because of the equalization of the shielding effects, the signals of the ethylene protons merge into one sharp peak, as will described later, in the NMR spectra. Judging from an inspection of the model of the cyclophane, I, the rocking motion of the benzene ring may be possible, but complete rotation about the para axis is considered to be extremely difficult. In the paracyclophane, II, the situation is quite different. The molecule may be free from strain and the macro ring may be so sufficiently flexible that the benzene rings in it may rotate about the para axis. This difference seems to be associated with the difference between the NMR spectra.

The synthetic routes are shown in Schemes 1 and 2. Diphenylmethane and ethyl *p*-chloroformylbenzoate IV were treated with anhydrous aluminum chloride to give a diketo diester, V. The carbonyl groups of V were then reduced by the Huang-Minlon modification of the Wolff-Kishner reduction to give a dicarboxylic acid, VIII, which was then esterified to give a diester, IX. The diester, IX, was also obtained by the Friedel-Crafts acylation of ethyl *p*-benzylbenzoate and phosgene and by subsequent Wolff-Kishner reduction and esterification. The diester, IX, was reduced with lithium aluminum hydride to a diol, X, which was then treated with phosphorus pentachloride or thionyl chloride to obtain a dichloro compound, XI. The *para*-substituted structures of Compounds V, VIII, IX, X and XI were

Paracyclophane I and II Open chain analog III

Scheme 2

shown by their characteristic infrared spectra over the 1650—2000 cm^{-1} range.

The [2.1.1.1]paracyclophane I and the dimeric [2.1.1.1.2.1.1.1]paracyclophane II were prepared by the cyclization of the dichloro compound, XIV, with a sodium adduct of tetraphenylethylene[4] in anhydrous tetrahydrofuran under nitrogen, using the high-dilution technique. The separation of the cyclophanes, I and II, was carried out by fractional crystallization.

An open-chain analog, III, was prepared by the reduction of the dichloro compound, XI, with lithium aluminum hydride or by the Wolff-Kishner reduction of a diketone, which had been produced by the Friedel-Crafts reaction of diphenylmethane-4,4′-dicarbonyl dichloride with toluene.

Between the IR spectra of the cyclophane, I or II, and that of the open-chain analog, III, small and yet characteristic differences were observed. Whereas weak absorption bands were observed in the spectra of the I and II cyclophanes at 1610 and 1575 cm^{-1} (double-bond region), they were not observed for the open-chain analog, III. From this fact, it was assumed that these bands are due to the vibrational transition which is

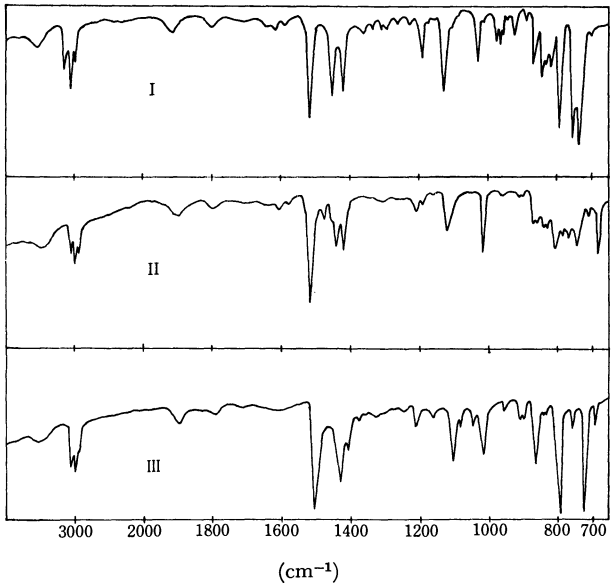

Fig. 1. The IR spectra of compound I, II, and III in KBr disk.

4) E. Müller and G. Röscheisen, *Chem. Ber.*, **90**, 543 (1957).

allowed for benzene rings in the macro ring compounds and forbidden for benzene rings in the open-chain analog. A weak absorption band assigned to the symmetric bending of the methyl group was observed at 1380 cm^{-1} for the open-chain analog, III; this band was necessarily absent in the IR spectra of the cyclic compounds. The intensity of the band at 1415 cm^{-1} due to the bending of the methylene groups increased upon ring closure. A similar tendency was observed in the region of the C–H in-plane bending of the benzene rings. In the 800—900 cm^{-1} region of the ring C–H out-of-plane bending vibration, more complicated spectra were observed for the I and II cyclophanes than for the open-chain compound, III. This complication in the spectra by ring closure may be attributable to the appearance of deformation vibrations not allowed for the open-chain compound.

The NMR spectra of the paracyclophanes, I and II, were different from that of the open-chain analog, III, in several respects. In the region of the alkyl protons, the open-chain compound, III, showed a peak due to methyl protons at τ 7.74 and one due to methylene protons at τ 6.16, in an equal area ratio.

On the other hand, the cyclophanes I and II showed no peak due to methyl protons, but, instead, showed a peak indicating the existence of an ethylene bridge resulting from cyclization. The peak of the ethylene protons was at τ 7.21 for the compound I and at τ 7.22 for the compound II. The fact that the peak due to ethylene protons is a singlet means that all the ethylene protons are equivalent. This fact may be readily understandable provided that the pair of conformers due to the two skew conformations of the 1,2-diphenylethane moiety of the macro ring is rapidly interconverted by flip rotation about the C–C axis of the ethylene group, as has been described before.

The singlets at τ 6.25 and 6.33 for the compound I and the singlet at τ 6.13 for Compound II are assigned to methylene protons. In Compound I, on the basis of the area ratio of 1 : 2, the peak at τ 6.25 is assigned to the protons of methylene remote from the ethylene bridge (indicated by X in formula 1), and the peak at τ 6.33, to those of methylenes near the ethylene bridge (indicated by Y and Z). Such a difference in the chemical shift between the methylene protons may be explained by their being shielded unequally by the ring current of the neighboring benzene rings.

The open-chain compound, III, showed a sharp singlet peak of benzene protons at τ 2.97, whereas the cyclophane I and II showed two different peaks. In the cyclophane I, the ring protons exhibit two well-separated peaks, at τ 3.45 and τ 3.10, equal in area. Such a difference in the chemical shift between aryl protons seems to be caused by the same reason as that in the case of methylene protons. From a molecular-model consideration of the cyclophane I, the lower-field peak was assigned to the protons of benzene rings remote from the ethylene bridge (indicated by A and B), and the higher-field peak, to those of benzene rings near the ethylene bridge (indicated by C and D).

In case of the cyclophane II, no such upfield shift of the aryl protons was observed. This fact may be

explained from an inspection of the molecular model, which shows that the molecule of the cyclophane II may be free from strain and that the macro ring may be so flexible that the benzene rings in it may rotate around the para axis.

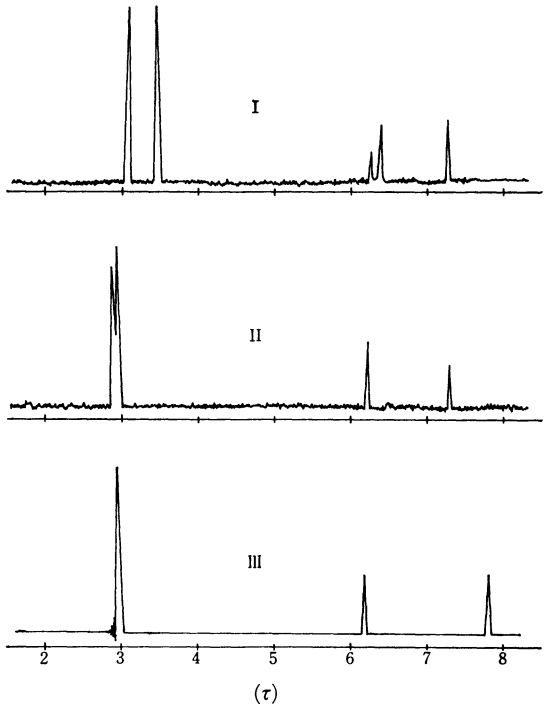

Fig. 2. The NMR spectra of compound I, II, and III in $CDCl_3$.

The UV spectra of the cyclophanes I and II were compared with that of the open-chain compound, III. A loss of the fine structure around 270 mμ in the cyclophane I is noticeable when its spectrum is compared with the spectrum of the open-chain compound, III. This fact is attributable to transannular electronic interactions of the benzene rings. In case of the compound I, compared with the compound III, the major peaks are observed to shift to longer wavelengths and to be weakened in intensity. Furthermore, the fine structure of the peaks becomes less apparent. The new absorption at 242 mμ for I indicates strong transannular electronic interactions of the benzene ring.

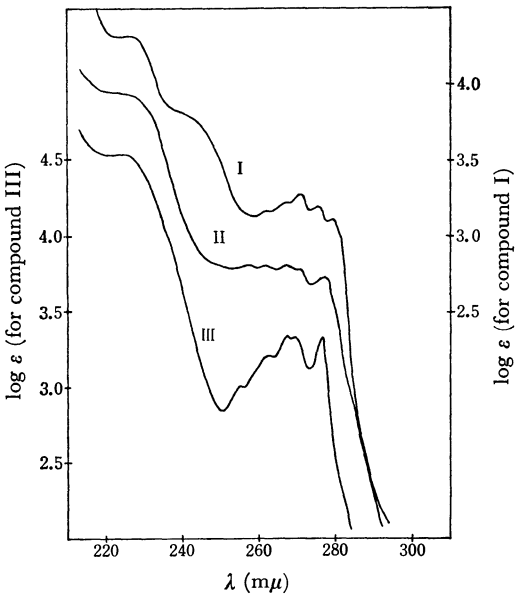

Fig. 3. The UV spectra of compound I, II, and III in ethanol.
I: λ_{max} 269.5 mμ, log ε=3.25
II: λ_{max} 266.5 mμ, log ε=3.30
III: λ_{max} 267.0 mμ, log ε=3.32
The graduation in the ordinate axis for compound II is displaced upward by 0.5 log ε unit increments from that for compound III.

The cyclic structures of the cyclophanes I and II were confirmed by the results of the elementary analysis and by molecular-weight determination, and by the absence of an end methyl group indicated by the IR and NMR spectra, as well as by a comparison of their IR, NMR and UV spectra with that of the open-chain analog, III.

The possibility of the formation of inclusion compounds is now under investigation.

Experimental

All the melting points are uncorrected. The IR spectra were determined in potassium bromide disks or films by means of a Hitachi EPI-S2 spectrophotometer, while the UV spectra were measured in ethanol by means of a Hitachi EPI-3T spectrophotometer. The NMR spectra were recorded at 60 MHz in $CDCl_3$ solution by means of a Varian Associates A-60 photometer. The chemical shifts are quoted as τ values relative to tetramethylsilane. The molecular weights were determined by means of a Hitachi Perkin-Elmer 115 molecular-weight-determination apparatus, using benzene as the solvent.

*4,4'-Bis(*p*-ethoxycarbonylbenzoyl)diphenylmethane, V.* Into an ice-cooled mixture of 70 g of ethyl *p*-chloroformylbenzoate, IV,[5] and 200 g of powdered anhydrous aluminum chloride in 600 m*l* of carbon disulfide, we stirred, drop by drop, a solution of 27 g of diphenylmethane in 200 m*l* of carbon disulfide at 0°C. The reaction mixture was then refluxed for 5 hr. The removal of carbon disulfide by distillation and the addition of crushed ice and hydrochloric acid yielded a pale yellow powder, which was then crystallized from ethanol to give 60 g (72% yield) of colorless needles; mp 130—130.5°C.

Found: C, 76.20; H, 5.47%. Calcd for $C_{33}H_{28}O_6$: C, 76.14; H, 5.42%.

*4,4'-Bis(*p*-ethoxycarbonylbenzyl)benzophenone, VII.* A mixture of 50 g of ethyl *p*-benzylbenzoate, VI, and 80 g of powdered anhydrous aluminum chloride in 500 m*l* of cabon disulfide was cooled to −15°C, and then 10 g of phosgene were slowly stirred into the mixture at a temperature below −10°C. The temperature was then allowed to rise slowly to room temperature. After a similar treatment of the reaction mixture, 44 g of the keto diester, VII, were obtained as a pale yellow powder, this powder was used without further purification for the preparation of the dicarboxylic acid, VIII.

*4,4'-Bis(*p*-carboxybenzyl)diphenylmethane, VIII.* A mixture of 50 g of the diketo diester, V, 200 g of potassium hydroxide, and 200 m*l* of 85% hydrazine hydrate in 500m*l* of ethylene glycol was refluxed for 1 hr. The water and excess hydrazine were removed by a take-off condenser until the temperature rose to 195—200°C, after which reflux was continued for 6 hr. The cooled solution was diluted with

5) J. B. Cohen and H. S. de Pennington, *J. Chem. Soc.*, **113**, 63 (1918).

water and acidified with concentrated hydrochloric acid. Almost a theoretical amount (42 g) of a white crystalline powder was thus obtained.

The same acid was also obtained by a similar reduction of Compound VII with potassium hydroxide and hydrazine hydrate in ethylene glycol.

*4,4'-Bis(*p*-ethoxycarbonylbenzyl)diphenylmethane, IX.* A mixture of 42 g of the dicarboxylic acid, VIII, 100 g of benzene, and 50 m*l* of concentrated sulfuric acid in 500 m*l* of ethanol was refluxed for 20 hr, the resultant water was removed as a volatile azeotrope composed of benzene, ethanol, and water. After working-up in the usual way, an almost theoretical amount (47 g) of the product was obtained; it was then purified by recrystallization from ethanol to colorless needles with a mp of 120—121.5°C.

Found: C, 80.51; H, 6.61%. Calcd for $C_{33}H_{32}O_4$: C, 80.46; H, 6.55%.

*4,4'-Bis(*p*-hydroxymethylbenzyl)diphenylmethane, X.* A solution of 40 g of the diester, IX, in 400 m*l* of anhydrous tetrahydrofuran was stirred, drop by drop, into a suspension of 5 g of lithium aluminum hydride in 400 m*l* of tetrahydrofuran at room temperature. After being refluxed for 1 hr, the mixture was cooled and treated with water and then with hydrochloric acid. The tetrahydrofuran was removed by distillation, and the resultant precipitate was collected and recrystallized from tetrahydrofuran to give an almost theoretical amount (33 g) of colorless needles; mp 180.5—181°C.

Found: C, 85.25; H, 7.08%. Calcd for $C_{29}H_{28}O_2$: C, 85.26; H, 6.91%.

*4,4'-Bis(*p*-chloromethylbenzyl)diphenylmethane, XI.* A mixture of 30 g of the diol, X, and 35 g of phosphorus pentachloride in 500 m*l* of chloroform was refluxed for 3 hr. After the removal of the solvent and phosphoryl chloride by distillation under reduced pressure, the residue was recrystallized from tetrahydrofuran to give 27 g (83% yield) of colorless needles; mp 164—164.5°C.

Found: C, 78.44; H, 5.98. Calcd for $C_{29}H_{26}Cl_2$: C, 78.20; H, 5.88%.

A mixture of 5 g of the diol, X, and 50 m*l* of thionyl chloride also gave the dichloro compound, XI, in an almost theoretical yield.

*4,4'-Bis(*p*-methylbenzyl)diphenylmethane, III.* To a stirred suspension of 0.03 g of lithium alminum hydride in 30 m*l* of anhydrous tetrahydrofuran, we slowly added a solution of 0.2 g of the dichloro compound, XI, in 20 m*l* of tetrahydrofuran at room temperature. After the usual treatment, 0.17 g (the theoretical amount) of the product was recrystallized from ethanol to give colorless crystals; mp 118—119°C.

Found: C, 92.36; H, 7.65%. Calcd for $C_{29}H_{28}$: C, 92.50; H, 7.50%.

This open-chain model compound was also prepared as follows. By the Friedel-Crafts reaction of 3 g of diphenylmethane-4,4'-dicarbonyl chloride, XII, 2 g of toluene, and 3.5 g of powdered anhydrous aluminum chloride in 70 m*l* of carbon disulfide, 3.1 g (73% yield) of the diketone, XIII, was obtained as pale yellow crystals with a mp of 140°C.

Found: C, 85.95; H, 6.14%. Calcd for $C_{29}H_{24}O_2$: C, 86.11; H, 5.98%.

A mixture of 0.75 g of the above-mentioned diketone, XIII, 3 m*l* of 85% hydrazine hydrate, and 5 g of potassium hydroxide in 50 m*l* of ethylene glycol was refluxed to give 0.7 g (the theoretical amount) of a colorless crystalline product, whose identity was confirmed by a mixed-melting-point determination (118°C) with the sample described above and by a comparison of their IR spectra.

[2.1.1.1]Paracyclophane I and [2.1.1.1.2.1.1.1]Paracyclophane, II. Into a dark-violet solution of 4 g of sodium and 1.5 g of tetraphenylethylene in 400 m*l* of anhydrous tetrahydrofuran, a solution of 5 g of the dichloro compound, XI, in 800 m*l* of anhydrous tetrahydrofuran was stirred, drop by drop, through a modified Hershberg dropping funnel[6] at room temperature under nitrogen over a period of 50 hr. After the careful addition of ethanol, and then water, the removal of the solvent from the mixture gave a white powder; when this powder was washed with water and fractionally crystallized from benzene-ethanol mixture, Compounds I and II were obtained in yields 200 mg and 120 mg respectively.

Compound I was crystallized from ethanol to give colorless crystals; mp 219—220°C.

Found: C, 92.95; H, 7.11%; mol wt, 390. Calcd for $C_{29}H_{26}$: C, 93.00; H, 7.00%; mol wt, 374.5. Compound II was recrystallized from benzene to give colorless needles.

Found: C, 92.87; H, 7.26%; mol wt, 742. Calcd for $C_{58}H_{52}$: C, 93.00; H, 7.00%; mol wt, 749.0.

Stereochemical Studies of Monoterpene Compounds. X.[1] Intramolecular Interaction of Oxirane and Cyclopropane Rings with a Hydroxyl Group[2]

Satoru WATANABE, Takayuki SUGA,[3] Tsuyoshi SHISHIBORI, and Tamon MATSUURA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima
(Received July 20, 1970)

The intramolecular interaction of oxirane and cyclopropane rings with a hydroxyl group in the alicyclic α,β-epoxy-, β,γ-epoxy-, and cyclopropyl alcohols was investigated by means of the infrared spectroscopy. *cis*-α,β-Epoxyalcohols (II, IV and V) showed a free hydroxyl band, an interacted hydroxyl band with a C–O bond of the oxirane ring, and/or a band due to a O–H···O hydrogen bond, whereas *trans*-epoxyalcohols (I and III) showed only a free hydroxyl band. The interaction between the hydroxyl group and a C–C bond of the oxirane ring was likely to be absent. β,γ-Epoxyalcohols revealed a hydroxyl band interacting with lone-pair electrons of the oxirane oxygen, in addition to a free hydroxyl band. The O–H··· cyclopropane interaction was found with 2-(1-methylcyclopropyl)-5-methylcyclohexanols (VII and VIII). The correlation of the infrared spectra with the conformation of the interacting groups is also discussed.

A hydroxyl group interacts with the π-electrons of a double bond and a carbonyl group.[4-6] Cyclopropane and oxirane rings are known to show properties like those of the π-electron system. It seemed, therefore, that it would be interesting to investigate the intramolecular interaction between the hydroxyl group and the oxirane and cyclopropane rings. For acyclic epoxyalcohols, the interaction between the hydroxyl group and the oxirane ring can be created by using electrons of the C–O bond, and it is favored when the hydroxyl group approaches not from the top, but from the plane of the ring.[7] However, the correlation of the infrared spectrum with the geometry of the interacting groups has not yet been clarified for cyclic compounds, in which the approach of the hydroxyl group can be regulated both in site and in direction. This paper will report on the intramolecular interaction of the hydroxyl group with the oxirane and cyclopropane rings in cyclic monoterpene alcohols, such as *trans*- and *cis*-1,2-epoxy-*p*-menth-8-en-6-ols (I and II), *trans*- and *cis*-4,8-epoxy-*p*-menthan-3-ols (III, IV, and V), 8,9-epoxy-*p*-menthan-3-ol (VI), and 2-(1-methylcyclopropyl)-5-methylcyclohexanols (VII and VIII).

Results and Discussion

The structure and the infrared (IR) spectral data of α,β- and β,γ-epoxyalcohols are collected in Chart I.

We will first deal with the interaction between the hydroxyl group and the oxirane ring of the α,β-epoxyalcohols. The hydroxyl stretching absorption of *trans*-1,2-epoxy-*p*-menth-8-en-6-ol (I) showed only one peak, at 3635 cm^{-1}, which corresponds to the free, secondary hydroxyl group. The *trans*-epoxyalcohol I, therefore, takes a conformation in which the hydroxyl group is unable to interact with the oxirane ring, as is shown in Chart I. Now, the IR spectrum of *cis*-epoxy-*p*-menth-8-en-6-ol (II), an isomer of I in respect of the hydroxyl group, showed three bands, at 3629, 3594, and 3572 cm^{-1} (Fig. 1). The highest-frequency band is similar in position to the free hydroxyl absorption band of the isomer I. The remaining peaks are, thus, due to the intramolecularly-interacting hydroxyl group. The nuclear magnetic resonance (NMR) spectrum of the C-6 proton revealed the hydroxyl group to take an axial orientation, as is shown in Chart I. The molecular models suggest, then, that the interaction between an axial hydroxyl group and an oxirane ring would be possible in three cases, shown as A, B, and D in Chart

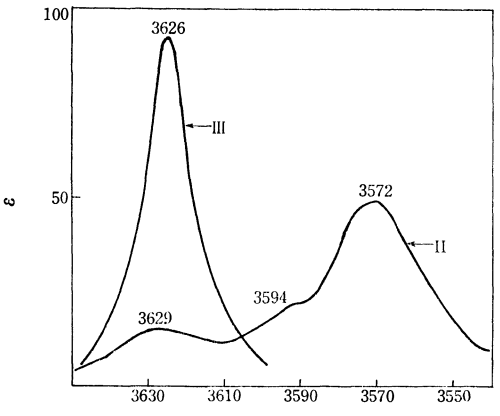

Fig. 1. IR spectra of epoxyalcohols (II and III) in a carbon tetrachloride solution.

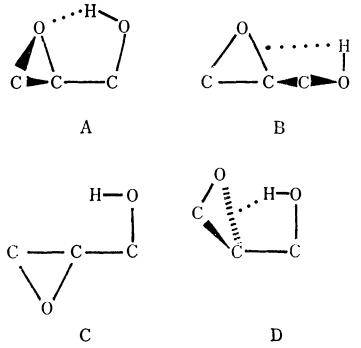

Chart II. Possible interactions between a hydroxyl group and an oxiran ring.

II. By comparison with the spectra of 2,3-epoxypropanols,[7] the peak at 3572 cm^{-1} ($\Delta\nu$=57 cm^{-1}) can be assigned to the interaction between the lone-pair electrons of an oxygen atom and the hydroxyl group which can approach the top of the oxirane ring surface; *cf.* A in Chart II. The other peak, at 3594 cm^{-1}, seems to be due to the hydroxyl group which interacts with electrons of the C–O bond in a plane of the oxirane ring; *cf.* B in Chart II.

The hydroxyl stretching absorption of *trans*-4,8-epoxy-*p*-menthan-3-ol (III), an exocyclic epoxide, showed only one peak, at 3626 cm^{-1} (Fig. 1); this peak is assignable to an absorption due to only the free secondary hydroxyl group. However, the hydroxyl group of III may interact with the C_4–C_8 bond in a plane of the oxirane ring, as in the case of C in Chart II; if any such interaction is present, however, it seems to be too little to detect by usual infrared measurements. *cis*-4,8-Epoxy-*p*-menthan-3-ol (IV), an isomer of III concerning the hydroxyl group, exhibited hereon three bands, at 3629, 3600, and 3566 cm^{-1}, which are similar in position to those of II. Thus, these were assigned to an absorption resulting from a free hydroxyl group and an interacted one, such as B and A (Chart II), respectively. On the other hand, epoxyalcohol V, an isomer of IV with respect to a methyl group, showed two bands, at 3626 and 3582 cm^{-1}, due to the free hydroxyl group and the intramolecular OH···O hydrogen-bonded hydroxyl group, shown in A, respectively. Although the hydroxyl group of V may approach the C–O bond from the top of the three-membered rings, as is shown in D, no such interaction was observed. This result indicates the impossibility of the interaction D for the epoxyalcohol V; this is in agreement with the literature.[7] The NMR spectrum of the C-3 proton of V showed double doublets (J_{vic}=10 and 6.5 Hz) at 3.88 ppm, which indicates the proton to be in a perfectly axial orientation. On the other hand, IV revealed the scarecely separated peak, suggesting some twisted conformations favorable for an approach of the hydroxyl group in a plane of the oxirane ring.

The IR spectrum of 8,9-epoxy-*p*-menthan-3-ol (VI) had two hydroxyl-stretching absorptions, at 3620 and 3524 cm^{-1}. The former was assigned to a free hydroxyl group, though the frequency of the band seems to be slightly low in comparison with a normal free secondary hydroxyl band; also, the hydroxyl proton may approach geometrically the C–O bond in a plane of the oxirane ring. On the other hand, the latter is shifted greatly from the free hydroxyl band. The extent of the shift is similar to that of *trans*- and *cis*-*p*-menthane-3,8-diols,[6] in which the hydroxyl group bonds intramolecularly with lone-pair electrons of the other hydroxyl oxygen atom. Thus, the band may be attributed to an intramolecular hydrogen bond between the hydroxyl group and the lone-pair electrons of an oxygen atom of the oxirane ring.

We now wish to deal with the interaction between the hydroxyl group and the cyclopropane ring of β,γ-cyclopropyl alcohols. The infrared spectral data are shown in Chart III. The spectrum of (−)-2-(1-methyl-

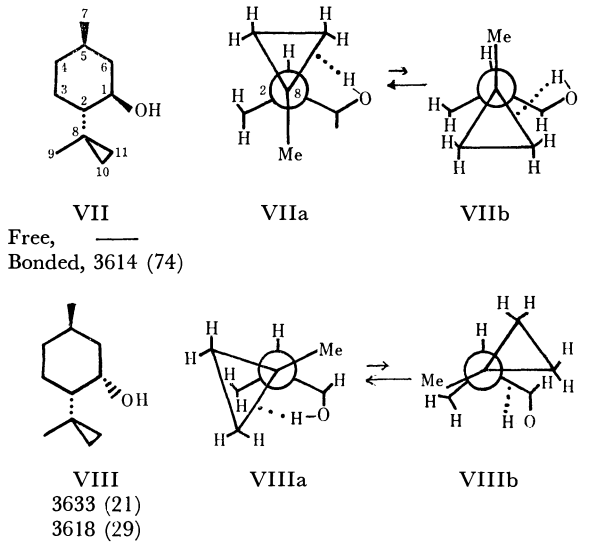

Chart III. Free and bonded peak possitiosn of cyclopropylalconhols (VII and VIII), cm^{-1} (ε).

cyclopropyl)-5-methylcyclohexanol (VII) has only one peak, at 3614 cm^{-1} (also Fig. 2). This shifted band was assigned on the basis of an internal O–H···cyclopropane interaction, since the free hydroxyl band of *l*-menthol[8] appears at 3628 cm^{-1}. Two conformers, VIIa and VIIb, can be considered for the preferred conformation of VII, because the preferred site for

8) Y. R. Naves and J. Lecomte, *Bull. Soc. Chim. Fr.*, **1955**, 792.

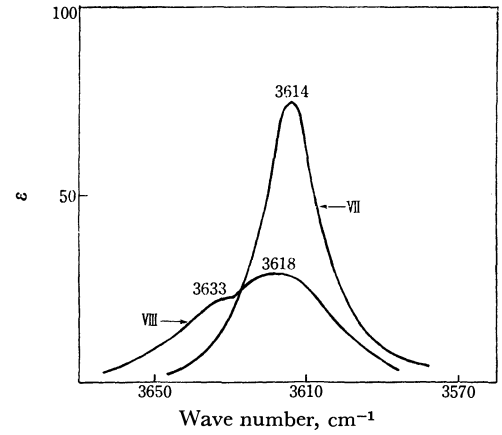

Fig. 2. IR spectra of cyclopropyl alcohols (VII and VIII) in a carbon tetrachloride solution.

the O–H···cyclopropane interaction is the "edge" of a plane of the ring.[9,10] Of those two, the *gauche* conformer VIIa is energetically more favorable than the *eclipsed* one, VIIb. On the other hand, (+)-2-(1-methylcyclopropyl)-5-methylcyclohexanol (VIII), an isomer of VII in respect of the hydroxyl group, had two peaks, at 3633 (weak) and 3618 cm^{-1} (*cf.* Fig. 2), attributable to the free hydroxyl group and the O–H··· cyclopropane interaction respectively. An interaction would be possible in both VIIIa and VIIIb. The interacted species may, then, be thought more populous in VII than in VIII, judging from the infrared spectra shown in Fig. 2. This may be interpreted as follows: a steric repulsion would be at a minimum in the *gauche* conformer VIIa, which is further stabilized by an internal O–H···cyclopropane interaction. On the other hand, the conformers, VIIIa and VIIIb, are favorable for the intraction, but are destabilized by the repulsion of the *eclipsed* groups. Therefore, both free and bonded hydroxyl absorptions appear in VIII.

Experimental

The IR spectra in the hydroxyl-stretching region were measured with a Perkin-Elmer Model 621 Infrared Spectrometer. A salt absorption cell (20 mm long) was used; the concentration of the carbon tetrachloride solution was 0.005 mol/*l*, at which concentration the association of the solute is negligible. The measurements were made at 25°C. The NMR spectra were recorded with a Hitachi Perkin-Elmer R-20 high-resolution spectrometer at 60 MHz, using tetramethylsilane as the internal standard. Gas-chromatographic analyses were made at 95—150°C, using a Hitachi Perkin-Elmer F6-D gas chromatograph with a flame ionization-type detector and a 3 mm × 1 m column packed with 3%-polyethylene glycol on Celite. Compounds I and II were separated preparatively using a Shimadzu (Kyoto) GC-2B gas chromatograph with a thermal conductor-type detector and a 4 mm × 3 m column packed with 10%-diethylene glycol succinate on Diasolid L (80—100 mesh). Helium was used as the carrier gas.

trans- *and* cis-*1,2-Epoxy*-p-*menth-8-en-6-ols (I and II).* (−)-Carvone (78.0°C/4 mmHg; n_D^{25} 1.4944; d_4^{25} 0.9539; $[\alpha]_D^{25}$ −61.14° (neat)) was epoxydized with 6 N sodium hydroxide and 30% hydrogen peroxide in methanol to (+)-α,β-epoxycarvone (107—109°C/8 mmHg; n_D^{25} 1.4788; d_4^{25} 1.0282; $[\alpha]_D^{25}$ +79.44° (neat), lit:[9] $[\alpha]_D^{25}$ +87.60° (neat)), according to the published procedure.[11] A mixture of $NaBH_4$ (2.0 g) and 700 m*l* of 80% dioxane in water was added to a solution of (+)-α,β-epoxycarvone (10 g) in 200 m*l* of 80% dioxane in water. After the entire reaction mixture has been left to stand at room temperature for three days, it was worked up in the usual manner to give 8.0 g of a mixture of I and II. The fractionation of the mixture was carried out by gas chromatography, as has been described above (peak area, I: 65%, II: 35%). The first peak was II: n_D^{25} 1.4831; NMR (CCl_4), $-\underset{|}{C}-CH_3$, 1.38 ppm (singlet, 3H), $>C\underline{H}-OH$ 3.70 (triplet, J=1.5 Hz, 1H), −OH 3.80 (broad singlet, 1H), $CH_2=\underset{|}{C}-C\underline{H}_3$ 1.72 (triplet, J=1.1 Hz, 3H), $=C\underline{H}_2$ 4.69 (multiplet, 2H); ν_{max}^{liq} 889 cm^{-1} (=CH_2), 3413 (OH). The second peak was I: n_D^{25} 1.4878; mp 31.0—31.5°C; NMR (CCl_4), −OH 3.14 ppm (broad singlet, 1H), $>C\underline{H}-OH$ 3.75 (double doublets, J_{vic}=11.0 and 6.0 Hz, 1H), $-\underset{|}{C}-CH_3$ 1.32 (singlet, 3H), $CH_2=\underset{|}{C}-C\underline{H}_3$ 1.69 (triplet, J=1.1 Hz, 3H), $=C\underline{H}_2$ 4.68 (multiplet, 2H); ν_{max}^{liq} 888 cm^{-1} (=CH_2), 3448 (OH).

4,8-Epoxy-p-*menthan-3-ol (III, IV, and V).* Two isomers, A (mp 55°C) and B (mp 59°C), of pulegone oxide were prepared[12] by the epoxidation of pulegone in the same manner as used for carvone. The reduction of the isomer A by the procedure described above afforded a mixture (2.0 g) of III and IV, which was then fractionated into two eluates by column chromatography on silica gel with a mixture of petroleum ether and ethyl ether (1 : 1). The initial eluate (1.0 g) was IV: mp 24.5—25.0°C; bp 80.0—81.0°C/2 mmHg; n_D^{25} 1.4770; d_4^{25} 1.115; $[\alpha]_D^{25}$ −3.97° (neat); NMR ($CDCl_3$), $>CH-C\underline{H}_3$ 1.05 ppm (doublet, J=6.0 Hz, 3H), −OH 1.61 (singlet, 1H), $>C\underline{H}-OH$ 3.64 (broad singlet, 1H), $>C(CH_3)_2$ 1.31 and 1.38 (each singlet, 6H); ν_{max}^{liq} 3441 cm^{-1} (OH). The second eluate was III: mp 54.0—55.0°C; $[\alpha]_D^{25}$ +52.8° (*c* 6.66, $CHCl_3$); NMR ($CDCl_3$), $>CH-C\underline{H}_3$ 0.91 ppm (doublet, J=6.0 Hz, 3H), −OH 1.61 (singlet, 1H), $>C\underline{H}-OH$ 3.64 (broad singlet, 1H), $>C(CH_3)_2$ 1.31 and 1.38 (each singlet, 6H); ν_{max}^{liq} 3394 cm^{-1} (OH). The isomer B (3.0 g) was reduced as above to afford V (2.0 g): bp 83.5—84.0°C/0.5 mmHg; n_D^{25} 1.4672; d_4^{25} 1.0007; $[\alpha]_D^{25}$ +3.30° (neat); NMR ($CDCl_3$), $>CH-C\underline{H}_3$ 1.04 ppm (doublet, J=6.0 Hz, 3H), $>C(CH_3)_2$ 1.33 and 1.56 (each singlet, 6H), $>C\underline{H}-OH$ 3.88 (double doublets, J_{vic}=10.0 and 6.0 Hz, 1H), −OH 2.38 (singlet, 1H); ν_{max}^{liq} 3438 cm^{-1} (OH).

(−)-8,9-Epoxy-p-*menthan-3-ol (VI).* (−)-Isopulegol (15.4 g, 93.0°C/10 mmHg, n_D^{25} 1.4676, d_4^{25} 0.9052, $[\alpha]_D^{25}$ −22.27° (neat)) was added to a solution of monoperphthalic acid (22.0 g) in ether (127 m*l*) below 0°C. The mixture was allowed to stand overnight at room temperature; subsequently, an usual working-up of the mixture afforded a crude product (15.3 g). The purification of the product by column chromatography and subsequent recrystallization afforded VI: mp 53.5—54.0°C; $[\alpha]_D^{25}$ −15.6° (*c* 3.33, $CHCl_3$), lit:[13] α_D = −14.5°; NMR ($CDCl_3$), $>CH-C\underline{H}_3$ 0.91 ppm (doublet, J=6.0 Hz, 3H), $>C\underline{H}-OH$ 3.25 (broad singlet, 1H), $-O-CH_2-$ 2.59 and 2.85 (each doublet, J=4.0 Hz, 2H), $-O-\underset{|}{C}-CH_3$

1.35 (singlet, 3H); ν_{max}^{KBr} 3523 cm^{-1} (OH).

(−)-2-(1-Methylcyclopropyl)-5-methylcyclohexanol (VII).[14] Methylene iodide (57.5 g) was added to a well-stirred suspension of anhydrous ether (125 m*l*), zinc-copper couple[15] (18.0 g), and iodine (0.1 g). To this gently-refluxing mixture, we then added a solution of (−)-isopulegol (15.4 g) in anhydrous ether (20 m*l*) over a period of 20 minutes. The mixture was stirred under reflux for an additional hour, and then it was worked up in the usual manner to yield VII (10.2 g): bp 105.0°C/15 mmHg; n_D^{25} 1.4696; d_4^{25} 0.9236; $[\alpha]_D^{25}$ −33.07° (neat); the 3,5-dinitrobenzoate derivative, mp 130.0—130.5°C; NMR ($CDCl_3$) >CH–C$\underline{H}_3$ 0.95 ppm (doublet, J=6.0 Hz, 3H), –C(–)–CH_3 0.99 (singlet, 3H), –OH 2.25 (singlet, 1H), >C$\underline{H}$–OH 3.55 (triple doublets, J_{vic}=11 and 4 Hz, 1H), $-CH_2-CH_2-$ (cyclopropane ring) 0.08—0.81 (4H); ν_{max}^{liq} 3589 cm^{-1} (OH);

(+)-2-(1-methylcyclopropyl)-5-methylcyclohexanol (VIII). The oxidation of VII with a chromium trioxide-pyridine complex afforded a ketone, which was then reduced by the Meerwein-Ponndorf-Verley method. The purification of the reaction mixture by column chromatography on silica gel with a mixture of 30% *n*-hexane in ethyl acetate gave VIII: bp 80.0—85.0°C/7 mmHg; n_D^{25} 1.4720; d_4^{25} 0.9294; $[\alpha]_D^{25}$ +28.72° (neat); mp 7.5—8.5°C; the 3,5-dinitrobenzoate derivative, mp 150.0—150.5°C; NMR ($CDCl_3$), >CH–C$\underline{H}_3$ 0.88 ppm (doublet, J=6.0 Hz, 3H), >C$\underline{H}$–OH 4.12 (multiplet, 1H), $-CH_2CH_2-$ (cyclopropane ring) 0.08—0.50 (4H), –OH 1.68 (singlet, 1H), –C(–)–CH_3 1.11 (singlet, 3H); ν_{max}^{liq} 3449 cm^{-1} (OH).

The authors wish to thank Dr. Motoichi Indō of the Takasago Perfumery Co. for his gifts of carvone, pulegone, and isopulegol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 207—210 (1971)

Ferrocene Polymers Obtained by the Polycondensation of Ferrocene with Dicarboxylic Acid Chlorides

Teruzo ASAHARA, Manabu SENŌ, Keiryo MITSUHASHI[1], and Yohsuke ICHIKAWA
The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July 24, 1970)

The polycondensation reactions of ferrocene with terephthaloyl and adipoyl chloride were investigated in the presence of $AlCl_3$, $ZnCl_2$, or $FeCl_3$ as the catalyst and in dichloromethane, *n*-hexane, carbon tetrachloride, or dioxane as the solvent. With terephthaloyl chloride, the highest polymer yield was obtained when $AlCl_3$ in *n*-hexane was used, and the product was mainly of a polyketone structure. The polycondensation with adipoyl chloride afforded the most satisfactory result when ferrocene was treated in liquid adipoyl chloride with neither catalyst nor solvent, and a product with the expected structure was obtained. The average molecular weights of the products are in the range of 3000—7000. Polymers obtained by polycondensation with terephthaloyl and succinyl chloride are paramagnetic and show the temperature dependence characteristic of semi-conductivity.

Ferrocene possesses a high reactivity toward electrophilic substitution, especially toward the Friedel-Crafts acylation, and the acylation of monoacylated ferrocene affords 1,1′-disubstituted ferrocene as the main product. Therefore, it may be expected that a polyketone containing ferrocene nucleus will be produced through the polycondensation of ferrocene with a dicarboxylic acid chloride.

Recently, Neuse and Koda reported their findings on the polycondensation of ferrocene with terephthaloyl chloride.[2] They obtained the expected product, together with various by-products formed through the cleavage of the ferrocene nucleus and oxidation-reduction processes.

In the present investigation, the formation of polyketone was examined, under several sets of reaction conditions with various catalysts and solvents, by using adipoyl chloride or terephthaloyl chloride as the bifunctional acylating agent. The electric and magnetic properties of the products obtained were also measured. The results will be presented in this paper.

Experimental

Materials. Ferrocene was prepared according to the method reported by Hata *et al.*[3] and was purified by sublimation *in vacuo*; mp 172—173°C.

Terephthaloyl chloride and adipoyl chloride were prepared by the reaction of the corresponding acids with thionyl chloride in the presence of a small amount of pyridine; the former was purified by recrystallization from dry *n*-hexane, mp 81—82°C, and the latter by distillation at a reduced pressure, bp 120—123°C/12 mmHg.

Aluminum chloride, zinc chloride, and ferric chloride were dried and stored in a desiccator.

The solvents were purified by the usual methods.

Polycondensation Reactions. Ferrocene, dicarboxylic acid chloride, and a Lewis acid catalyst were mixed in a molar ratio of 1 : 1 : 2 (or >2) in a solvent and were heated at the prescribed temperature with stirring under a stream of

a) The yield of product was calculated according to Eq. (1).

nitrogen gas. After a definite period, the reaction mixture was poured onto ice-water; the solid product was then collected by filtration and washed successively with water, dilute hydrochloric acid, a dilute sodium hydroxide solution, water, and hot methanol. After being dried, this product was fractionated into a soluble part and an insoluble part in chloroform. The soluble part was subsequently represipitated from methanol or *n*-hexane.

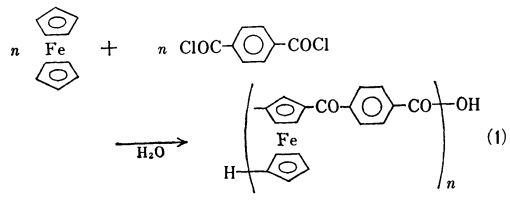
Analytical Procedures. The structure was analysed by means of a study of its IR spectrum (KBr disc). The molecular weight was measured with a vapor-pressure osmometer.

The electric conductivity and the magnetic susceptibility were measured using powdered samples packed under 1.5 kg/cm^{-1}.

Results and Discussion

Solution Polycondensation with Terephthaloyl Chloride. The results of polycondensation using various solvents and catalysts are summarized in Table 1. Each product is a reddish or dark brown powder. The products soluble in chloroform, obtained from polycondensation using $AlCl_3$ and *n*-hexane, were analysed to be as is shown in Table 2. The IR spectra of the soluble and insoluble products are shown in Fig. 1.

From these results, the main reaction to afford a soluble product may be assumed to be as follows:



I

However, the results of the elemental analysis show a higher H content than the value calculated for I, and the IR spectrum shows a strong absorption at 2900 cm^{-1} which is assignable to a methylene group. These results suggest the occurrence of side reactions involving the cleavage of ferrocene nucleus and the reduction of carbonyl group to afford the compounds with structures II and III. This is in accord with the results obtained by Neuse and Koda.[1] They used sulfolane as the solvent.

Such a dipolar aprotic solvent was considered to be favorable for this reaction, but no noticeable difference was observed in the present results, which were obtained using *n*-hexane, a nonpolar solvent.

When dichloromethane was used as a solvent, the product was mostly insoluble in chloroform. This solvent acts as a Friedel-Crafts alkylating agent to lead to cross-linking products. A similar reaction has been reported on ferrocene and dichloroethane.[4] Therefore,

an attempt to obtain a soluble methylene-bridged ferrocene polymer was made; such a polymer was indeed obtained, in 35% yield, from the reaction of ferrocene with dichloromethane catalysed by $AlCl_3$; mp 210—220°C; average molecular weight, 1600.

(Methylene group links at 1,1'-, 1,2-, or 1,3-position.)

Melt Polycondensation with Terephthaloyl Chloride. The polycondensation of ferrocene in liquid terephthaloyl chloride was carried out at 85°C without any solvent; the results are shown in Table 3. When $AlCl_3$ was used as a catalyst, a violent reaction occurred to give a decomposition product with a large carbon content. In the case of $ZnCl_2$ catalyst, a rather moderate reaction proceeded, with a low yield of polymers.

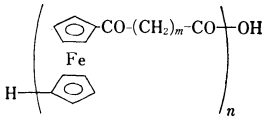
21	$AlCl_3$	0.01	—	—
22	$ZnCl_2$	0.015	3	4

Polycondensation with Adipoyl Chloride. Ferrocene reacted with adipoyl chloride in a certain solvent or without any solvent in the manner shown in Eq. (1). The rseults are shown in Table 4.



IVa: $m=4$ IVb: $m=2$

The products, the structures of which were assumed to be IVa, are pale or dark brown solids. The highest yield was obtained in the reaction at 80—100°C without any catalyst or solvent, whereas no polymeric product was obtained from the reaction with terephthaloyl chloride under similar conditions. This is likely to be the result of the difference in the solubility of ferrocene in liquid dicarboxylic acid chloride and the homogeneity of the reaction mixture.

The product (Exp. No. 43), purified by recrystallization from chloroform - *n*-hexane, was analysed as follows:

Average molecular weight, 7000 (Degree of polymerization assuming structure IVa, 24).

Found: C, 62.56; H, 5.48%. Calcd for IVa: C, 64.72; H, 5.46%.

The IR spectrum of this product shows absorptions at 2900 (CH_2), 1660 (C=O), 3050, 1440, 810 (ferrocene nucleus), 1100, and 1000 cm^{-1} (the unsubstituted cyclopentadienyl ring of terminal ferrocene) (Fig. 2). These results are in good accord with structure IVa.

Electric and Magnetic Properties of Ferrocene Polymers. The electric conductivity and magnetic susceptibility of the products from the polycondensation reactions of ferrocene with terephthaloyl and succinyl chloride in dichloromethane are shown in Table 5. The temperature dependences of specific resistance, ρ, are shown in Fig. 3. This is characteristic of semi-conductive substances, and the order of specific conductivity agrees with the expected one. The magnetic susceptibility of ferrocene has been reported to be $\chi_a = -99.0 \times 10^{-6}$ cgs units,[5] while Karimov and Shchegolev stated that the magnetic properties of ferrocene polymers varied from paramagnetic to diamagnetic according to the method of preparation and purification.[6] Since the present specimens could not be completely purified because of insolubility, it was not possible to examine the relation of the magnetic properties to the chemical structures. In this respect, more detailed examinations are now in progress.

The authors wish to express their thanks to Professor Hiroo Inokuchi of The Institute for Solid State Physics for his kind suggestions regarding the measurement of the electric and magnetic properties.

Studies of Peptide Antibiotics. XXV. Synthesis of an Immediate Precursor of Gramicidin S[1]

Satoru MAKISUMI, Shuji MATSUURA, Michinori WAKI, and Nobuo IZUMIYA
Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received July 29, 1970)

A linear decapeptide, HCO-D-Phe-Pro-Val-Orn-Leu-D-Phe-Pro-Val-Orn-Leu-$NHCH_2CH_2OH$, which has been identified as an immediate precursor of gramicidin S was synthesized in order to define the physical and biological properties of this peptide. The synthetic product possessed practically no antibacterial activity against any of the microorganisms tested, though the optical rotatory dispersion feature of this peptide was quite similar to that of gramicidin S. Stability of the terminal blocking groups of this peptide to the action of hydrogen chloride in methanol was also discussed.

For clarifying the influence of the cyclic structure of gramicidin S (GS) (I) on its antibacterial activity, several linear decapeptide analogs (II) having an amino acid sequence of the gramicidin S in which the α-amino group is acylated with formyl or acetyl and *C*-terminal amino acid in the form of its amide or ethanolamide have been synthesized in this laboratory.[2] Recently, Pollard *et al.*[3] observed the formation of another linear decapeptide (III), with formate linked to the *N*-terminal amino acid and ethanolamine to the *C*-terminus of the chain, in the cell-free biosynthesis systems as a possible intermediate of GS. However, they did not describe any of the physical and biological properties of this immediate precursor of GS. It can easily be seen that the natural analog (III) and the synthetic analogs (II) are very similar structurally, differing only in the sequence of amino acids. In connection with our original program it appeared of interest to synthesize the naturally occuring linear decapeptide and test its biological activity. This paper describes the details of the synthesis and properties of the product.

GS (I)

Val-Orn-Leu-$NHCH_2CH_2OH$

Immediate precursor of GS (III)

The steps involved in the synthesis of the formyl decapeptide ethanolamide are shown in Fig. 1.[4] Z-leucine ethanolamide (IV) was prepared by the reaction of Z-leucine with ethanolamine by means of the mixed anhydride method.[5] Compound (IV) was hydrogenolyzed to remove the Z-group and the product was isolated as the crystalline hydrochloride (V·HCl). BOC-tripeptide ethanolamide (VI) was synthesized from BOC-dipeptide hydrazide and V with the use of isoamylnitrite. Syntheses of BOC-dipeptide hydrazide (XIII) and BOC-pentapeptide acid (XIV) have already been described.[6]

Removal of the BOC-group from VI by treatment with 98% formic acid[7] and subsequent neutralization with Dowex 1 in methanol afforded free base of the tripeptide ethanolamide (VII). Condensation of BOC-pentapeptide acid with VII by the DCC–HOSu procedure[8] gave BOC-octapeptide ethanolamide (VIII) in a good yield. The BOC-group was removed from VIII by the method described above giving the free base of

Octapeptide ethanolamide (IX).

Formyl dipeptide benzyl ester (X) was synthesized from formyl-D-phenylalanine and proline benzyl ester with the use of DCC.[9] Dipeptide (X) was obtained as an oil and could not be crystallized. X was hydrogenolyzed to remove the benzyl ester group and the product was isolated as crystalline dicyclohexylammonium salt. Pure formyl dipeptide (XI) obtained from the salt by treatment with Dowex 50 in methanol was coupled with IX by the DCC-HOSu procedure. This gave the protected decapeptide ethanoalmide (XII) in a good yield. Hydrogenolysis of XII in the presence of two equivalent amounts of hydrogen chloride in methanol provided the desired formyl decapeptide ethanolamide (III) as dihydrochloride.

The final product (III·2HCl) was found to be practically pure by means of elemental analysis and amino acid analysis. However, it was found to be contaminated with a minute amount of deformylated peptide by paper electrophoresis as shown in Fig. 2. It seems probable that the *N*-terminal formyl group of the peptide (III) is easily decomposed. This is comparable to the finding obtained for the formyl analogs of compound II.[2] On the contrary, Pollard *et al.*[3] reported that the formyl group in the natural peptide could not be removed from the peptide by treatment with 1.5N hydrogen chloride in methanol for 1 hr at room temperature. However, it was found that the formyl group in the synthetic peptide was relatively labile and removed easily under acidic conditions. It can be seen from Fig. 2 that the *C*-terminal ethanolamide group is apt to be rearranged by N→O acyl migration[10] with hydrogen chloride in methanol affording a deformylated decapeptide 2-aminoethyl ester (XV) to some extent. Peptide XV was easily converted to the parent peptide (W or Y) by treatment with ammonia. A supposed reaction sequence is summarized in Fig. 3.

Optical rotatory dispersion measurement at the region of 220—300 mμ revealed that the linear decapeptide exhibited apparent negative Cotton effect (see Fig. 4). This suggests that the conformational feature of the linear peptide is similar to that of GS, though the solution-state conformation of the latter compound has so far not been characterized completely.[11] In view of this experimental fact, it was expected that the linear peptide would have antibacterial activity. However, it was found that peptide (III) possessed practically no activity for any of microorganisms tested, whereas another formyl decapeptide ethanolamide (IIc) showed appreciable activity toward several strains of the Gram-positive microorganisms (Table 1). The result indicates that some linear decapeptide derivatives such as IIc possess substantial antibacterial activity though weaker than GS. Therefore, an amino acid sequence of a linear derivative affords important influence on the activity.

Experimental

Melting points are uncorrected. In thin-layer chromatography on a silica gel plate, the solvent systems used are abbreviated as follows: A, chloroform - benzene - methanol (6 : 3 : 1, *v/v*); B, chloroform - methanol (5 : 1, *v/v*); C, *s*-butanol - formic acid - water (4 : 1 : 1, *v/v*); D, ethyl acetate - pyridine - acetic acid - water (60 : 20 : 6 : 11, *v/v*); E, *n*-butanol - acetic acid - water (4 : 1 : 4, *v/v*) and F, *n*-butanol - acetic acid -

pyridine - water (4 : 1 : 1 : 2, *v/v*). Paper electrophoresis was carried out on Toyo Roshi No. 50 with formic acid - acetic acid - methanol - water (1 : 3 : 6 : 10, *v/v*) buffer of pH 1.8 at 600 V/30 cm for 2 hr. Prior to analysis, desiccated samples were left in air to a constant weight. $[\alpha]_D$ of air dried samples refers to 1% solution in methanol at 23°C.

Z-Leu-NHCH$_2$CH$_2$OH (IV). To a mixed anhydride prepared at −20°C from 2.65 g (10 mmol) of Z-Leu-OH, 1.32 m*l* (10 mmol) of isobutyl chloroformate and 1.4 m*l* (10 mmol) of triethyamine in 40 m*l* of tetrahydrofuran, a chilled solution of 0.61 g (10 mmol) of ethanolamine dissolved in 5 m*l* of tetrahydrofuran was added. The mixture was then allowed to stand in a refrigerator overnight. The solvent was removed *in vacuo* and the residue was dissolved in 50 m*l* of ethyl acetate. The solution was washed successively with 3% sodium bicarbonate, 10% citric acid and water, dried over sodium sulfate, and then evaporated. The residual syrup was solidified by the addition of petroleum ether. The product was recrystallized from ethyl acetate - ether; yield 2.20 g (71%); mp 125—126°C; $(\alpha)_D$ −17.9°; R_f 0.32 (A).

Found: C, 62.23; H, 7.86; N, 8.99%. Calcd for $C_{16}H_{24}N_2O_4$: C, 62.32; H, 7.84; N, 9.08%.

H-Leu-NHCH$_2$CH$_2$OH·HCl (V·HCl). A solution of 1.23 g (4 mmol) of IV dissolved in 45 m*l* of methanol containing 4.2 m*l* of N hydrochloric acid was subjected to hydrogenolysis in the presence of palladium black. After 3 hr, the filtrate from the catalyst was evaporated to dryness and left in a desiccator over sodium hydroxide. The residue was crystallized from methanol-ethyl acetate-ether; yield 0.78 g (93%); mp 153—154°C; $[\alpha]_D$ +22.7°; R_f 0.09 (A), 0.43 (C).

Found: C, 45.42; H, 9.04; N, 13.11%. Calcd for $C_8H_{18}N_2O_2$·HCl: C,45.60; H, 9.09; N, 13.30%.

BOC-Val-Orn (δ-Z)-Leu-NHCH$_2$CH$_2$OH (VI). To a chilled solution of 959 mg (2 mmol) of BOC-Val-Orn(δ-Z)-N_2H_3 (XIII)[6] in 10 m*l* of dimethylformamide were added successively with stirring 1.45 m*l* (4 mmol) of 2.76N hydrogen chloride in dioxane and 0.272 m*l* (2 mmol) of isoamylnitrite at −5°C. After 10 min, 0.56 m*l* (4 mmol) of triethylamine and a solution of 421 mg (2 mmol) of V·HCl in 6 m*l* of dimethylformamide containing 0.28 m*l* (2 mmol) of triethylamine were added successively to the solution, and the mixture was stirred for 3 days at 0°C. After removal of the solvent, the residue was triturated with a mixture of ethyl acetate (5 m*l*) and water (50 m*l*). The product solidified was collected by filtation, washed successively with 4% sodium bicarbonate, 10% citric acid and water, and dried. It was recrystallized from methanol - ethyl acetate - ether; yield 949 mg (76%); mp 197—198°C; $[\alpha]_D$ −35.2°, R_f 0.41 (A), 0.95 (C).

Found: C, 60.09; H, 8.27; N, 11.12%. Calcd for $C_{31}H_{51}N_5O_8$: C, 59.88; H, 8.27; N, 11.26%.

H-Val-Orn(δ-Z)-Leu-NHCH$_2$CH$_2$OH (VII). BOC-tripeptide ethanolamide (VI, 622 mg, 1 mmol) was dissolved in 20 m*l* of 98% formic acid and the solution was kept at room temperature for 3 hr. The reagent was removed and the residue was triturated with ether. The crude solid (formate) was dissolved in 10 m*l* of methanol and the solution was filtered over a column (1.2×8 cm) of Dowex 1 (OH^- form, equilibrated with methanol). The effluents and the washings were evaporated. The resulting residue was crystallized by the addition of ether. The product was collected by filtration; yield 491 mg (94%); mp 180—182°C; $[\alpha]_D$ −19.8°; R_f 0.20 (A), 0.51 (B).

Found: C, 59.39; H, 8.24; N, 13.21%. Calcd for $C_{26}H_{43}N_5O_6$: C, 59.86; H, 8,31. N, 13.43%.

BOC-Val-Orn(δ-Z)-Leu-D-Phe-Pro-Val-Orn(δ-Z)-Leu-NHCH$_2$CH$_2$OH (VIII). A suspension of 412 mg (0.5 mmol) of BOC-pentapeptide acid (XIV),[6] 261 mg (0.5 mmol) of VII and 58 mg (0.5 mmol) of HOSu in a mixture of dioxane (5 m*l*) and dimethylformamide (5 m*l*) was cooled in an ice-salt bath. DCC (103 mg, 0.5 mmol) was added to the solution and the mixture was stirred under cooling; meanwhile the suspension dissolved to form a clear solution. After it had been allowed to stand overnight at room temperature, the reaction mixture was stirred again with one drop of acetic acid for 3 hr at 0°C. Crystals of dicyclohexylurea were removed by filtration and washed with cold dioxane. The filtrate and the washings were evaporated to a minute volume and the residual syrup was solidified by the addition of ice water. The solid obtained was collected by filtration, washed successively with water, 4% sodium bicarbonate, 10% citric acid and water, and dried. The product was dissolved in ethyl acetate and an isoluble material was removed. The filtrate was evaporated and the residue was crystallized by the addition of ether. The crystals obtained were dissolved in 10 m*l* of methanol and the solution was filtered over a series of columns (1.2×8 cm, each) of Dowex 50 (H^+ form) and Dowex 1 (OH^- form) which were equilibrated with methanol. The effluent and the washings were evaporated and the residue was crystallized by the addition of petroleum ether; yield 622 mg (94%); mp 156—158°C; $[\alpha]_D$ −91.0°; R_f 0.42 (A), 0.82 (B).

Found: C, 61.18; H, 7.79; N, 11.36%. Calcd for $C_{69}H_{103}N_{11}O_{15}\cdot 2H_2O$: C, 60.82; H, 7.91; N, 11.31%.

H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-Val-Orn(δ-Z)-Leu-NHCH$_2$CH$_2$OH (IX). Treatment of 398 mg (0.3 mmol) of VIII with 6 m*l* of 98% formic acid followed by crystallization and filtration over a column of Dowex 1 as described above gave 335 mg (91%) of the octapeptide ethanolamide, mp 113—117°C; $[\alpha]_D$ −107°; R_f 0.22 (A), 0.56 (B).

Found: C, 60.99; H, 7.90; N, 11.84%. Calcd for $C_{64}H_{95}N_{11}O_{13}\cdot 2H_2O$: C, 60.88; H, 7.90; N, 12.20%.

HCO-D-Phe-Pro-OBzl (X). A solution of 0.97 g (5 mmol) of HCO-D-Phe-OH and 1.2 g (5 mmol) of H-Pro-OBzl·HCl in a mixture of 15 m*l* of chloroform and 15 m*l* of tetrahydrofuran containing 0.70 m*l* (5 mmol) of triethylamine was cooled in an ice-bath. With vigorous stirring 1.03 g (5 mmol) of DCC was introduced. After it had been allowed to stand overnight at 0°C, the mixture was evaporated, and ethyl acetate was added to the residue. After the insoluble dicyclohexylurea was filtered off, the filtrate was washed with 4% sodium bicarbonate, 10% citric acid and water, and dried over sodium sulfate. The filtrate was evaporated; yield of oil, 1.66 g (87%); R_f 0.44 (A).

HCO-D-Phe-Pro-OH·DCHA (XI·DCHA). A solution of 1.14 g (3 mmol) of X in 15 m*l* of methanol containing 3 drops of acetic acid was subjected to hydrogenolysis in the presence of palladium black. The filtrate was evaporated to dryness and the residue was dissolved in 10 m*l* of ethyl acetate. To the solution 0.6 m*l* (3 mmol) of dicyclohexylamine was added, and the mixture was allowed to stand in a refrigerator for 3 hr. The DCHA salt precipitated was collected, washed with ethyl acetate and ether, and dried; yield 1.02 g (72%); mp 177—178°C; $[\alpha]_D$ −51.1°.

Found: C, 66.19; H, 8.80; N, 8.58%. Calcd for $C_{27}H_{41}N_3O_4\cdot H_2O$: C, 66.23; H, 8.85; N, 8.58%.

HCO-D-Phe-Pro-Val-Orn(δ-Z)-Leu-D-Phe-Pro-Val-Orn(δ-Z)-Leu-NHCH$_2$CH$_2$OH (XII). The DCHA salt (94 mg, 0.2 mmol) of XI was dissolved in 5 m*l* of methanol and the solution was filtered through a column (1.2×4 cm) of Dowex 50 (H^+ form) in methanol. The effluent and the washings were evaporated. The formyl dipeptide acid (XI) thus obtained was reacted with 245 mg (0.2 mmol) of IX by the procedure using equimolar amount of DCC and HOSu as

has been described for the preparation of VIII. The product was purified by filtration over a series of columns of Dowex 50 and Dowex 1; yield 257 mg (86%); mp 132—135°C; $[\alpha]_D$ −81.0°; R_f 0.39 (A).

Found: C, 62.00; H, 7.50; N, 11.97%. Calcd for $C_{79}H_{111}N_{13}O_{16}\cdot 2H_2O$: C, 61.82; H, 7.55; N, 11.86%.

The molecular weight of a dried sample of XII was determined with a Hitachi Type 115 apparatus using methanol as a solvent. Found: 1477. Calcd: 1499.

HCO-D-Phe-Pro-Val-Orn-Leu-D-Phe-Pro-Val-Orn-Leu-NHCH$_2$-CH$_2$OH·2HCl (III·2HCl). A solution of 150 mg (0.1 mmol) of XII in 8 m*l* of methanol containing 0.4 m*l* of 0.25N methanolic hydrogen chloride was hydrogenolyzed over palladium black catalyst. After 3 hr, another portion of 0.4 m*l* of the hydrogen chloride was added and hydrogenolysis was continued. The progress of the reaction was checked by thin-layer chromatography. After additional 3 hr the filtrate was evaporated. When the residue was triturated with ether the peptide was obtained as a crystalline hydrochloride. Recrystallization from methanol - ether gave 107 mg (82%); mp 204—205°C; $[\alpha]_D$ −113°.

Found: C, 55.11; H, 8.06; N, 13.23; H_2O, 5.1%. Calcd for $C_{63}H_{99}N_{13}O_{12}\cdot 2HCl\cdot 4H_2O$: C, 55.01; H, 7.99; N, 13.24; H_2O, 5.2%.

The product was practically pure. However it was found to be contaminated with a minute amount of a ninhydrin positive compound which was deduced as a deformylated derivative (W) of III on the basis of electrophoretic mobility as shown in Fig. 2. The R_f values of III·2HCl and GS in several solvent systems are summarized in Table 2. Amino acid analysis of the hydrolysate of this peptide gave the molar ratios of the components as follows: Phe 2.2, Pro 1.9, Val 2.2, Orn 1.8, Leu 2.3 and ethanolamine 1.0.

TABLE 2. R_f VALUES OF SYNTHETIC LINEAR DECAPEPTIDE AND GS IN THIN LAYER CHROMATOGRAPHY

Solvent	III·2HCl	GS·2HCl
C	0.48	0.56
D[a)]	0.47	0.60
E	0.33	0.56
F	0.66	0.66

a) Pollard *et al.*[3] reported that the naturally occurring linear decapeptide (III) migrated in this solvent system with an R_f value of 0.82, whereas GS had an R_f of 0.45.

Methanolysis of III. A few mg of III·2HCl was dissolved in about 10 m*l* of 0.8N hydrogen chloride in methanol and the solution was allowed to stand at room temperature. After various periods of time two aliquots of the reaction mixture were withdrown and evaporated to dryness *in vacuo*. One of them was dissolved in methanol and the solution was subjected to paper electrophoresis. The other was dissolved in ammonia in methanol and evaporated immediately after mixing prior to electrophoretic analysis. Another few mg of III·HCl was dissolved in about 10 m*l* of 0.9N hydrochloric acid and the mixture allowed to reflux for 3 hr. The reaction products obtained before and after treatment with ammonia were subjected to electrophoresis on paper. A typical electrophoreogram is shown in Fig. 2 (B). Two unidentified peptides spots were detected. Peptide spot migrated a little more rapidly than peptide III was not characterized completely but deduced to be a mixture of a deformylated decapeptide (Y) and its ethanolamide (W) (Fig. 3). The second peptide (XV) in small amounts was not also characterized but was deduced as a 2-aminoethyl ester (Fig. 3) of Y. Occurrence of the spot corresponding to ethanolamine suggests the formation of deformylated decapeptide (Y) after the hydrolysis of 2-aminoethyl ester bond of XV. However, Y could not be distinguishable from W on this electrophoreogram because of their similar electric character under the conditions applied as for *N*, *C*-terminal free decapeptide and deformylated decapeptide ethanolamide.[2] XV peptide was not found in the reaction mixture after ammonia treatment, suggesting the loss of one basic group resulting from the reverse rearrangement of XV to W or the hydrolysis of XV to Y under alkaline condition. From the results it seems likely that the *N*-terminal formyl group is labile to be cleaved and that the *C*-terminal ethanolamide is apt to be rearranged by $N\rightarrow O$ acyl migration by mild methanolysis in presence of hydrogen chloride.

Optical Rotatory Dispersion. ORD measurements were performed with a JASCO Model ORD/UV-5 spectropolarimeter. Cell of path length 1.0 cm was used and the runs were made at ambient temperature. In Fig. 4 are reported the ORD curves (range 220—300 mμ) of the synthetic peptide and GS in ethanol solution (7.8 mg/50 m*l*).

Microbiological Assays.[12] Minimum amounts of the compounds for the complete inhibition of growth were determined by a dilution method with 10^3—10^4 organisms per milliliter using a Sabouraud bouillon as an incubation medium.

12) We are indebted to Meiji Seika Co., Ltd. for the microbiological assays.

Organic Photochemical Reactions. XIV. The Photocycloaddition of Acetone to Cyclooctene and 1,3-Cyclooctadiene[1]

Kensuke SHIMA, Yoshiki SAKAI, and Hiroshi SAKURAI
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

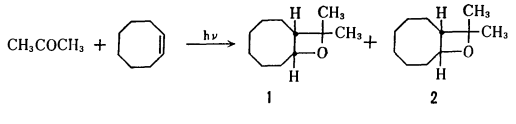
(Received August 1, 1970)

The photocycloaddition of acetone to cyclooctene (COE) or 1,3-cyclooctadiene (COD) yields isomeric *cis*- and *trans*-oxetanes in good yields. Kinetic studies of these reactions reveal that the photoaddition of acetone to COE proceeds *via* the attack of the triplet acetone on the ground state COE, while the addition to COD probably occurs by the attack of the excited singlet acetone on the ground state COD.

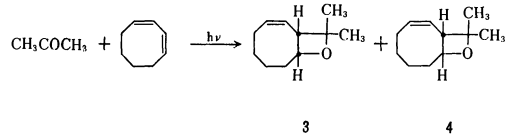
The photoaddition of carbonyl compounds to olefins to yield oxetanes (the Paterno-Büchi Reaction) has been the subject of much recent study. However, only a few papers on the photoreactions of ketones with eight-membered cyclic olefins or dienes have been published. The photocycloadditions of benzophenone, several *p*-quinones, and thiobenzophenone to cyclooctene and/or cyclooctadienes to yield oxetanes or thietanes have been reported.[2-4] We found that the photoaddition of acetone to cyclooctene (COE) or 1,3-cyclooctadiene (COD) afforded oxetanes in fairly good yields, while it is well-known that the photoreactions of acetone with cyclopentene or cyclohexene give mainly the products derived from hydrogen abstraction from these olefins by the acetone triplet, while oxetanes are minor products.[5] We also wish to report on the stereochemistry of oxetanes and on the kinetics of oxetane formation.

Results and Discussion

Photoaddition (Syntheses of Oxetanes). Acetone, when irradiated in the n–π^* region of the carbonyl group, readily adds to COE to give roughly equimolar mixtures of *cis*- and *trans*-oxetanes (**1** and **2**) in fairly good yields. Similarly, the irradiation of acetone and COD gives mainly *cis*- and *trans*-oxetanes (**3** and **4**, *ca.* 4 : 1).



1 **2**



3 **4**

The products, **1**—**3**, were isolated by preparative VPC on a 3-m PEG-6000 column at 160°C. The structural identification of **1**—**4** is based on spectral analysis. The NMR spectra of **1**—**3** exhibit a low-field double triplet or septet at 5.45—5.65 τ. These absorptions are assigned to the ring hydrogen α to oxygen.[6] It is also well known that the coupling constant between H_a and H_b in *cis*-oxetanes are larger than that in *trans*-oxetanes.[7] The NMR data are shown in Table 1. These results support the stereochemical assignments for **1**, **2**, and **3**. **4** could not be separated by preparative VPC. Since the catalytic hydrogenation of **3** using an Adams catalyst gives **1**, and mixtures of **3** and **4** give those of **1** and **2**, **4** surely has a *trans*-configuration. The NMR data for **3** are similar to that of the thietane, **5**.[4,8] **1** and **2** give the same cracking patterns in the mass spectra.

TABLE 1. SUMMARY OF NMR DATA FOR OXETANES

	Chemical shift (τ)	Multiplicity	Proton assignment	Coupling constant (Hz)
	5.65	dt	H_a	$J_{ab}=J_{ac}=10$

 **5** $J_{ab}=10$ Hz

cyclopentene or cyclohexene are mainly unsaturated alcohols and dimers of olefins.[5] The photoreaction of acetone and COE, on the other hand, yields mainly oxetanes (**1** and **2**). These differences may be partly explained by the fact that the cycloocten-2-yl radical is less resonance-stabilized than the cyclohexen-2-yl or cyclopenten-2-yl radical, since it is well known that the two double bonds in COD are not coplanar.[4a] Consequently, in COE the addition of the acetone triplet to the double bond is more likely than the hydrogen abstraction.

Kinetic Studies. Degassed benzene solutions containing acetone (0.1—0.2 M) and varying amounts of COE or COD were irradiated using a 350-W high-pressure mercury lamp through quartz glass and a 10-mm filter solution of chromium potassium sulfate, which served to eliminate the absorption of the benzene used as a solvent. The quantum yields were determined by the simultaneous irradiation of actinometer solutions.[9] The quantum yield for oxetane formation in benzene was independent of the percentage of reaction up to 10%.

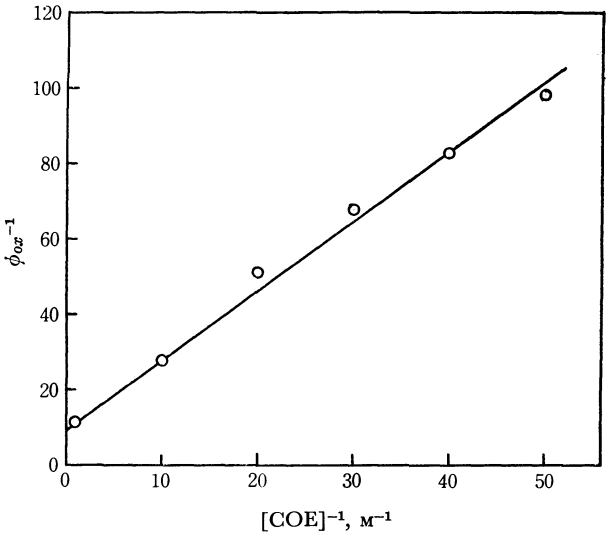

Fig. 1. Dependence of the reciprocal of the quantum yield for oxetane formation on the reciprocal of COE concentration.
Acetone (0.2 M) in benzene, Slope=1.83 M, Intercept=9.5.

Kinetics for the Acetone-COE System. Figure 1 shows the effect of the COE concentration on the quantum yields for oxetane formation.[11] Recently, Turro and Wriede have shown from kinetic analysis and quantum yield studies,[12] that the photocycloaddition of acetone to *trans*- or *cis*-1-methoxy-1-butene involves both the acetone singlet and the acetone triplet. In our experiment, however, the Stern-Volmer plot is linear, indicating that there are no significant contributions from either state of acetone under these reaction conditions. Since it is known that the acetone singlet is not measurably affected by low concentrations of piperylene, while the acetone triplet is quenched by piperylene at a rate close to that for diffusion-controlled quenching,[12] we examined the effect of piperylene on oxetane formation. The results are shown in Fig. 2. It is apparent that oxetane formation proceeds *via* the acetone triplet on the basis of the Stern-Volmer plots.

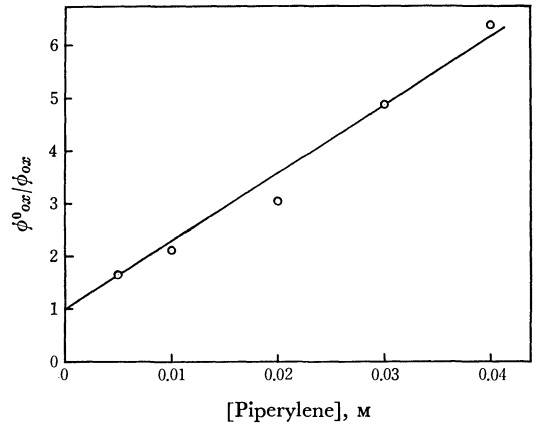

Fig. 2. Stern-Volmer plot of the quenching of oxetane formation by piperylene.
Acetone (0.2 M), COE (0.1 M) in benzene, Slope=132 M.

These observations are consistent with the following mechanism (Scheme 1):

$$A_0 \xrightarrow{h\nu} A_1 \quad (1)$$

$$A_1 \xrightarrow{k_f} A_0 + h\nu_f \quad (2)^{13}$$

$$A_1 \xrightarrow{k_{isc}} A_3 \quad (3)$$

$$A_3 \xrightarrow{k_t} A_0 \quad (4)$$

$$A_3 + O1 \xrightarrow{k^3_c} [A_3\text{-}O1] \quad (5)^{15}$$

$$[A_3\text{-}O1] \xrightarrow{k^3_{ox}} \text{Oxetane} \quad (6)$$

$$[A_3\text{-}O1] \xrightarrow{k^3_d} A_0 + O1 \quad (7)$$

$$A_3 + Q \xrightarrow{k_q} A_0 + Q_3 \quad (8)$$

Scheme 1

In this scheme, O1 represents COE, $[A_3\text{-}O1]$, a triplet 1,4-biradical intermediate, and Q, a triplet quen-

9) Acetone–2-methyl-2-butene system was employed as an actinometer. The limiting quantum yield for this system (0.50) was determined using ferrioxalate actinometry.[10]

10) H. Sakurai, K. Shima, and S. Toki, *Nippon Kagaku Zasshi*, **89**, 537 (1968).

11) In this paper, the quantum yields for oxetane formation are the sum of the quantum yields for oxetane **1** and **2** or oxetane **3** and **4**. We also have found that the ratio of **1** to **2** varies with the irradiation time, the concentration of cyclooctene, the amount of piperylene added, and the solvent used. These interesting problems are now under investigation and will be presented in near future.

12) N. J. Turro and P. W. Wriede, *J. Amer. Chem. Soc.*, **92**, 20 (1970).

13) Borkman and Kearns have shown that in the absence of singlet quenchers, all acetone singlets either intersystem cross or fluoresce and $k_{isc} \gg k_f$.[14] Therefore, unimolecular nonradiative decay process of the acetone singlet is negligible.

14) R. F. Borkman and D. R. Kearns, *J. Chem. Phys.*, **44**, 945 (1966); *J. Amer. Chem. Soc.*, **88**, 3467 (1966).

15) In other words, this is the quenching process of the acetone triplet by cyclooctene. We previously proposed the intermediacy of such 1,4-biradical intermediate in the photoaddition of benzophenone to furan.[16]

16) S. Toki and H. Sakurai, This Bulletin, **40**, 2885 (1967).

cher (piperylene). Since it has been established that the quenching of the acetone singlet by COE can very probably be excluded, kinetic analysis of Scheme 1 using the steady state approximation leads to the following expression:

$$\frac{1}{\phi_{ox}} = \left(1+\frac{k_f}{k_{isc}}\right)\left(1+\frac{k^3_d}{k^3_{ox}}\right)\left(1+\frac{k_t}{k^3_c[\mathrm{Ol}]}\right) \quad (9)$$

In the presence of a triplet quencher,

$$\frac{\phi^0_{ox}}{\phi_{ox}} = 1 + \frac{k_q[\mathrm{Q}]}{k_t + k^3_c[\mathrm{Ol}]} = 1 + k_q[\mathrm{Q}]\tau_t \quad (10)$$

where ϕ_{ox} is the quantum yield for oxetane formation and where ϕ^0_{ox} is the quantum yield for oxetane formation in the absence of an added quencher.

From the slope and intercept in Fig. 1 and $k_{isc} \gg k_f$,[14] we obtain the limiting quantum yield, $\phi_{ox}=0.11$, $k^3_d/k^3_{ox}=8.5$, $k^3_c/k_t=5.19$ M^{-1}. We can now calculate the value of the rate constants, k_t and k^3_c, from Fig. 2, since k_q, the rate constant for the quenching of A_3 by piperylene in benzene, is known to be equal to the diffusion-control quenching constant, which we shall estimate to be 5×10^9 M^{-1} sec^{-1}.[17] Thus, $k_t=2.5\times10^7$ sec^{-1} and $k^3_c=1.3\times10^8$ M^{-1} sec^{-1}. These values are in reasonable agreement with the values obtained from the photoaddition of the acetone triplet to 1-methoxy-1-butene by Turro *et al.*[12,18]

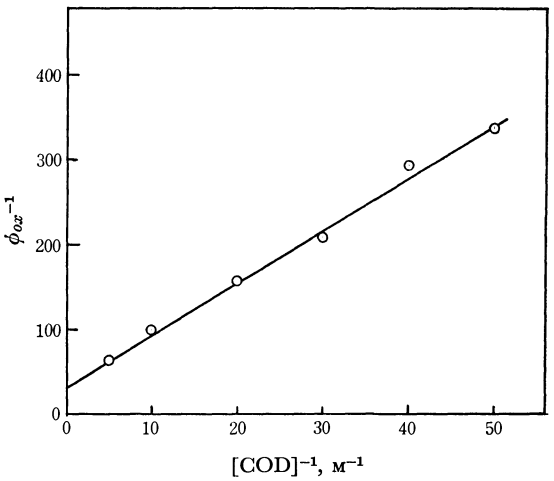

Fig. 3. Dependence of the reciprocal of the quantum yield for oxetane formation on the reciprocal of COD concentration. Acetone (0.2 M) in benzene, Slope=6.0 M, Intercept=32.

Kinetics for the Acetone-COD System. The quantum yields for oxetane formation at various COD concentrations are plotted as reciprocals in Fig. 3. In this acetone-COD system, the Stern-Volmer plot is also linear. Recently, we proposed that the photoaddition of propionaldehyde to conjugated dienes, such as 1,3-cyclohexadiene, 2,3-dimethyl-1,3-butadiene, isoprene, and piperylene, occurs from an excited singlet state of propionaldehyde.[19] The photoreaction of acetophenone with COD did not afford oxetanes at all, but gave the dimers of COD as the main products. These dimers are obtained from the attack of the triplet COD produced by acetophenone sensitization on the ground-state COD. These aromatic ketones have singlet state lifetimes of the order of 10^{-10} sec, too short for efficient bimolecular reactions to occur.[20] The oxetane formation from acetone and COD was little affected by the addition of 1,3-cyclohexadiene, which is very efficient triplet quencher.[21] These observations support the concept that oxetanes are produced from the interactions between an excited singlet state of acetone and ground state COD.

Scheme 2 accomodates our observations of the acetone-COD reaction:

$$A_0 \xrightarrow{h\nu} A_1 \quad (1)$$

$$A_1 \xrightarrow{k_f} A_0 + h\nu_f \quad (2)$$

$$A_1 \xrightarrow{k_{isc}} A_3 \quad (3)$$

$$A_1 + D \xrightarrow{k^1_c} [A_1\text{-}D] \quad (11)^{22}$$

$$[A_1\text{-}D] \xrightarrow{k^1_{ox}} \text{Oxetane} \quad (12)$$

$$[A_1\text{-}D] \xrightarrow{k^1_d} A_0 + D \quad (13)$$

Scheme 2

D is COD, and $[A_1\text{-}D]$, a singlet complex. A Stern-Volmer analysis of the oxetane formation from acetone and COD as a function of the COD concentration, assuming Scheme 2, results in Eq. (14).

$$\frac{1}{\phi_{ox}} = \left(1+\frac{k^1_d}{k^1_{ox}}\right)\left(1+\frac{k_f+k_{isc}}{k^1_c[\mathrm{D}]}\right) \quad (14)$$

From the slope and intercept in Fig. 3, we obtain the limiting quantum yield, $\phi_{ox}=0.031$, $k^1_d/k^1_{ox}=31$, and $k^1_c/(k_f+k_{isc})=5.3$ M^{-1}. $(k_f+k_{isc})^{-1}$ is equal to τ_s, the measured acetone singlet lifetime in the absence of the singlet quencher,[14] while τ_s has been reported to be *ca.* 2 nsec.[23,25] Using this value of τ_s, the calculated

Table 2. Limiting quantum yields and rate constants for oxetane formation

Carbonyl compounds	Diene	ϕ_{ox}	k^1_d/k^1_{ox}	$k^1_c/(k_f+k_{isc})$ M^{-1}

21) L. M. Stephenson and G. S. Hammond, *Pure Appl. Chem.*, **16**, 125 (1968).

22) This is the quenching process of the acetone singlet by COD. The nature of the singlet complex is uncertain yet. We have considered that the inefficiency in this photocycloaddition is attributed to the formation of the intermediate complex, which combines to give oxetanes or dissociates to ground-state acetone and COD. This concept has been suggested by Turro *et al.*[23] and Singer *et al.*[24]

23) J. C. Dalton, P. A. Wriede, and N. J. Turro, *J. Amer. Chem. Soc.*, **92**, 1318 (1970).

rate constant for the formation of the singlet complex (k^1_c) is 2.7×10^9 M^{-1} sec^{-1}. This rate constant is within an order of magnitude of the diffusion-controlled rate constant in benzene, and it is in good agreement with that of the quenching of the singlet acetone by 1,2-dicyanoethylene.[23,26]

Table 2 summarizes the results of oxetane formation from the acetone singlet, as well as the preliminary results obtained from the singlet addition of propionaldehyde to 1,3-cyclohexadiene (CHD) and COD.

Since the rate constants for intersystem crossing or fluorescence in propionaldehyde are still unknown, a detailed comparison of the results is impossible, but the large limiting quantum yield in the case of propionaldehyde is probably due to the more efficient oxetane formation from a singlet complex.[27]

Experimental

General. The nuclear magnetic resonance spectra were taken on a Hitachi Perkin-Elmer R-20 High Resolution NMR Spectrometer, using tetramethylsilane as the internal standard. The gas-chromatographic analyses were run on a Shimadzu Gas Chromatograph, GC-3AF. The acetone (Wako Pure Chem. Co.) was purified by the ordinary method.[28] The COE and COD were purified by fractional distillation using a spinning-band column, and were redistilled prior to use. The benzene was purified by three successive crystallizations, with a rejection of about one-fourth of the benzene at each freezing, and by distillation with a spinning-band column.

Photoaddition of Acetone to Cyclooctene. Pyrex, doughnut-type vessels containing acetone (29 g) and COE (55 g) were placed outside a quartz immersion well and irradiated for 50 hr with a 350-W high-pressure mercury lamp at room temperature. The unreacted materials were then distilled off, and the portion boiling at 70—85°C/4 mmHg (10.8 g) was collected. Residues, 16.6 g. The adducts were isolated by preparative VPC on a 3-m PEG-6000 column (10 mm i. d.) at 160°C. Bp 73—74°C/4 mmHg; n_D^{27} 1.4644.

Found: C, 78.55; H, 11.91%; mol wt, 171. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%; mol wt, 168.

Adduct **1** had a retention time of 11.2 min at 160° and was collected as a colorless oil by preparative VPC: IR spectra 970 and 945 cm^{-1}: NMR ($CDCl_3$) τ 5.65 (H_a, dt, $J_{ab}=J_{ac}=10$ Hz; $J_{ad}=3.4$ Hz), 8.72 ($2CH_3$, 6H, s), 7.4—9.5 (13H, m); $m/e=168$ (parent), 110 ($M-CH_3COCH_3$).

Adduct **2**: retention time, 12.5 min. (160°C); IR spectra 960 cm^{-1}; m/e, 168 (parent), 110 ($M-CH_3COCH_3$); NMR ($CDCl_3$), τ 5.45 (H_a, sept, $J_{ab}=6$ Hz; $J_{ac}=10$ Hz); $J_{ad}=3.5$ Hz), 8.63 and 8.81 (CH_3, s), 7.4—9.4 (13H, m).

Photoaddition of Acetone to 1,3-Cyclooctadiene. A mixture of acetone (34 g) and COD (53 g) was irradiated through Pyrex for 50 hr. After the removal of the unreacted materials, the fraction boiling at 100—110°C/18 mmHg was collected; yield, 19.0 g. Residue, 9.5 g. The 1 : 1 adducts were isolated by preparative VPC; bp 102—103°C/17 mmHg, n_D^{25} 1.4769.

Found: C, 79.63; H, 10.96%; mol wt, 169. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92%; mol wt, 166.

Quantum Yields. Benzene solutions (4 m*l*) containing 0.1—0.2 M acetone and 0.02—1.0 M COE or COD were degassed and sealed in 10-mm o. d. quartz tubes which had been attached to Pyrex tubes *via* graded seals. The sample tubes were then irradiated on a merry-go-round apparatus at room temperature, using a 350-W high-pressure mercury lamp and a filter solution with a path length of about 1 cm containing 150 g chromium potassium sulfate made up to 1 *l* with distilled water. This filter system completely eliminated the absorption of the benzene used as the solvent. Photolyses were carried out to 10% or less conversion (irradiation time, less than 6 hr); the conversion was linear to the irradiation time in these regions. Actinometers (acetone-2-methyl-2-butene system) were photolyzed simultaneously, and the quantum yields were computed relative to the actinometers. The solutions were analyzed on a Shimadzu Gas Chromatograph, GC-3AF, with a 3-m column packed with PEG-6000 (25%) on Shimalite at 160°C, using acetophenone (in the case of COE) or propiophenone(COD) as the internal standard.

Quenching Studies. The samples were prepared, degassed, and analyzed in the same way as in the quantum-yield determination, except that varying amounts of quenchers were added to the solution.

26) Turro *et al.* report the following values. $k^1_c/(k_f+k_{isc})=5.1$ M^{-1}, $k^1_c=2.5-5.0\times10^9$ M^{-1} sec^{-1}.

27) Quantum yields for oxetane formation from the propionaldehyde triplet and olefins are also as about 10 times as larger than those from the acetone triplet and olefins.[10] We have proposed that these differences are due to the more efficient oxetane formation from a triplet 1,4-biradical intermediate in the case of propionaldehyde.[10]

The Nitrosation of β-Keto Sulfoxides[1]

Yoshio Otsuji, Yasuhiro Tsujii, Akihiko Yoshida, and Eiji Imoto

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received August 3, 1970)

β-Keto sulfoxides were prepared by the reaction of the esters with the methylsulfinyl carbanion. The nitrosation of the β-keto sulfoxides, $RCOCH_2SOCH_3$ ($R=C_6H_5$, $C_6H_5CH_2CH_2$, n-C_3H_7), with sodium nitrite and hydrochloric acid gave the corresponding α-chloro-α-isonitroso ketones, RCOC(=NOH)Cl, in high yields. However, the nitrosation of α-substituted β-keto sulfoxide, $RCOCH(R')SOCH_3$, in a similar manner afforded the α-isonitroso ketones, RCOC(=NOH)R′. The mechanisms of these reactions were studied.

Aliphatic and aromatic carboxylic esters have been converted to β-keto sulfoxides by the reaction of the esters with the methylsulfinyl carbanion.[2,3] The active methylene group lying between the keto and sulfoxide groups is very reactive toward electrophilic reagents and is readily brominated or alkylated to give the corresponding substituted β-keto sulfoxides.[4,5] In a previous communication[6] we reported that ω-(methylsulfinyl)-acetophenone (IIa), which can be prepared from ethyl benzoate (Ia), afforded ω-chloro-ω-isonitrosoacetophenone (IIIa) in a high yield upon treatment with sodium nitrite and hydrochloric acid.

In this paper we will describe the results of a detailed study of this reaction and of an extension of it to other compounds; it provides a useful general method for the preparation of α-keto-α-chloro-isonitroso compounds.

Results and Discussion

Preparation of β-Keto Sulfoxides. Four carboxylic esters (Ia—Id) were treated in dimethyl sulfoxide (DMSO) with 2 equiv. of the methylsulfinyl carbanion, prepared by the reaction of DMSO with sodium hydride.[2] This treatment afforded the corresponding β-keto sulfoxides (IIa—IId) in high yields.

$$\underset{\text{I}}{RCO_2C_2H_5} + {}^{-}CH_2SOCH_3 \longrightarrow \underset{\text{II}}{RCOCH_2SOCH_3}$$

a, $R=C_6H_5$; b, $R=C_6H_5CH_2CH_2$;
c, $R=n$-C_3H_7; d, $R=n$-C_6H_{13}

Ethyl phenylacetate could not be converted to the β-keto sulfoxide by this method, but it produced phenylacetic acid in an almost quantitative yield after the treatment of the reaction mixture with dilute hydrochloric acid. These results indicate that, in the case of ethyl phenylacetate, the proton transfer from the α-carbon of the ester to the methylsulfinyl carbanion predominates over the carbonyl addition of the anion because of the high acidity of the ester relative to the carbanion.

The treatment of the sulfoxide IIa with sodium hydride in tetrahydrofuran, followed by the addition of methyl iodide to the solution, gave a mixture of diastereoisomers of ω-methyl-ω-(methylsulfinyl)-acetophenone (IIe).[5] Upon the cooling of this mixture, one of the diastereoisomers crystallized; it was used for the successive reaction.

$$\underset{\text{IIa}}{C_6H_5COCH_2SOCH_3} + CH_3I \xrightarrow{NaH} \underset{\text{IIe}}{C_6H_5COCH(CH_3)SOCH_3}$$

Nitrosation of β-Keto Sulfoxides. When an aqueous solution of the sulfoxides (IIa, IIb, and IIc) containing an equiv. of sodium nitrite was acidified with hydrochloric acid and the mixture was then stirred for 1—3 hr at room temperature, α-chloro-α-isonitroso ketones (III) were obtained in the yields indicated in Table 1. No appreciable change in the yield of III was observed by the use of 2 equiv. of sodium nitrite. The application of this reaction to the sulfoxide IId produced a brown oil which could not be purified. It was also shown that the isonitroso compounds, III, can be obtained without the isolation of the sulfoxides, II, by starting with the carboxylic esters. For example, Ia afforded IIIa in an overall yield of 80%.

$$\underset{\text{II}}{RCOCH_2SOCH_3} + NaNO_2 \xrightarrow{HCl} \underset{\text{III}}{RCOC(Cl)=NOH}$$

Table 1. Formation of α-chloro-α-isonitroso ketones (III)

Compound	R	Yield, %
IIIa	C_6H_5	80
IIIb	$C_6H_5CH_2CH_2$	84
IIIc	n-C_3H_7	82

The IR and NMR spectra of III were in accordance with the assigned structures. For example, IIIa showed an absorption due to the carbonyl group at 1660 cm^{-1} in the IR spectrum and an absorption due to an extremely acidic proton of the hydroxyl group at τ −3.68 in the NMR spectrum.

However, when the α-substituted β-keto sulfoxide IIe was nitrosated in a similar manner, a mixture of isonitrosopropiophenone (IV) and 1-phenylpropane-1,2-dione (V) was obtained. The relative yields of IV and V depended upon the reaction conditions employed.

$$\text{IIe} + NaNO_2 \xrightarrow{HCl} C_6H_5COC(CH_3)(NOH) + C_6H_5COCOCH_3$$
IV V

Under conditions where the reaction was conducted at 0—5°C using an excess of sodium nitrite, IV was isolated only when the reaction time was 15 min; an extension of the reaction time to 2 hr gave only V as an isolable product.

In order to explain these observations, the hydrolysis of IV to V was studied in some detail. When IV was subjected to hydrolysis in dilute hydrochloric acid and in the presence of sodium nitrite at 0—5°C, V was obtained in a high yield. However, the treatment of IV with hydrochloric acid in the absence of sodium nitrite under identical conditions resulted in the recovery of the starting material. These results clearly indicate that the hydrolysis of IV is assisted by nitrous acid. Brooks and his co-workers[7] have previously found that steroidal ketoximes can readily be hydrolyzed to the corresponding ketones in the presence of nitrous acid, and they have proposed the following mechanism for the action of nitrous acid:

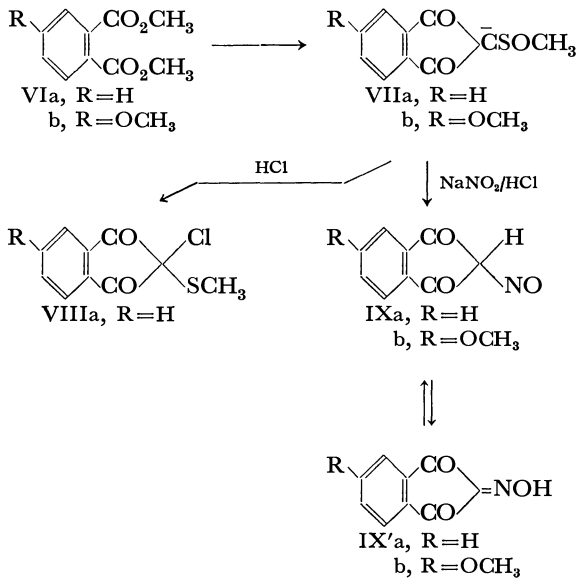
$$RR'C{=}\overset{\curvearrowright}{N}{-}O{-}H \longrightarrow RR'C{=}\overset{+}{N}{-}O^- \longrightarrow RR'CO + N_2O$$
$$\searrow NO^+ \qquad\qquad | NO$$

The hydrolysis of IV in hydrochloric acid in the presence of nitrous acid must proceed by a mechanism similar to that shown above.

The structure of IV was confirmed by comparing it with an authentic sample prepared by the nitrosation of propiophenone.[8] The structure of V was established by converting it to its disemicarbazone.

Becker and Russell[9,10] have recently found that the treatment of dimethyl phthalate (VIa) with 2 equiv. of the methylsulfinyl carbanian, followed by the acidification of the reaction mixture with hydrochloric acid, yields 2-chloro-2-methylthio-1,3-indanedione (VIIIa) through the intermediate (VIIa), which is analogous in structural type to IIe, *i.e.*, α-substituted β-keto sulfoxide. In the light of their investigations, VIa was treated with 2 equiv. of the methylsulfinyl carbanion, and the resulting mixture was nitrosated with sodium nitrite and hydrochloric acid. As expected, the reaction took place in a manner similar to that for IIe to give 2-nitroso-1,3-indanedion (IXa) in a 37% yield.[6] In a similar manner, dimethyl 4-methoxyphthalate (VIb) was converted to 5-methoxy-2-nitroso-1,3-indanedione (IXb) in a 66% yield.[6]

The structure of IXa was confirmed by comparing it with an authentic sample prepared by the nitrosation of 1,3-indanedione,[11] its IR and NMR spectra (see Experimental section) showed that IXa exists predominantly in the form of IX'a. The structure of IXb was established by comparing it with an authentic sample obtained by a method previously reported.[12] However, the predominant form among the possible isomeric structures for IXb remains unestablished.



Mechanistic Studies. Inspection of the structures of the products obtained above suggests that two reactions, the Pummerer rearrangement of the sulfoxide group and the nitrosation of the active methylene group, may somehow be involved in the nitrosation of the β-keto sulfoxide. Which reaction takes place first? In order to solve this question, the following experiments were undertaken.

Compound VIIIa, prepared by the method of Becker and Russell,[9] was subjected to nitrosation under conditions similar to those employed for the nitrosation of β-keto sulfoxides. This experiment resulted in the recovery of the starting material, implying that the nitrosation takes place in advance of the Pummerer rearrangement. Futher evidence was obtained by the isolation of a plausible intermediate of the reaction.

The treatment of IIa with isoamyl nitrite in ethanol, using sodium ethoxide, gave ω-nitroso-ω-(methylsulfinyl) acetophenone (X). The IR and NMR spectra (see Experimental section) showed again that X exists predominantly in the form of X'. Upon refluxing X' in hydrochloric acid for 5 hr, IIIa was isolated from the reaction mixture.

$$\text{IIa} + i\text{-AmONO} \xrightarrow{C_2H_5ONa} C_6H_5COCH(NO)SOCH_3$$
X

$$\rightleftharpoons C_6H_5COC(=NOH)SOCH_3 \xrightarrow{HCl} \text{IIIa}$$
X'

These results suggest that the reaction proceeds through the pathways represented in Scheme 1:

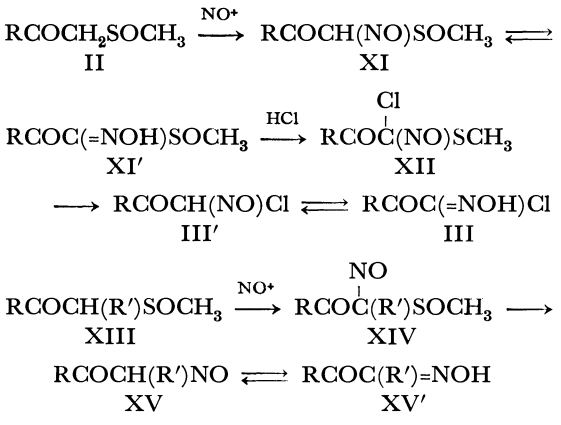
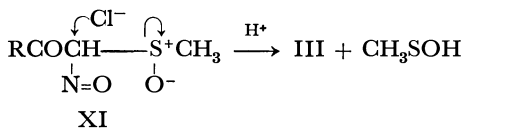


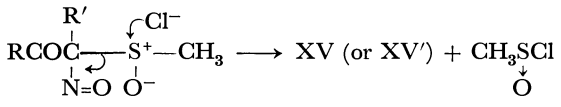
Scheme 1

For the β-keto sulfoxides (II), the nitrosation takes place first to produce XI, which would be in equilibrium with XI'. The Pummerer rearrangement of XI[13] gives XII, which then affords the final product, III, by an unusual cleavage of the C–S bond. The driving force of this cleavage might be an accumulation of the electronegative groups on the α-carbon which stabilizes the carbanion. Thus, upon the hydrolysis of XII, the sulfur bore a positive charge and was removed as methylsulfenic acid. The other plausible mechanism of the cleavage of XI would be a direct nucleophilic attack of the chloride ion on the α-carbon of XI to form III:



However, the above both mechanisms remained undiscriminated in this investigation.

For the α-substituted β-keto sulfoxides, XIII, the nitrosation gives XIV, which then produces the final product, XV or XV'. A possible mechanism of this final conversion would be:



Although this kind of nucleophilic substitution on the sulfoxide sulfur is very rare, the electronegative groups at the α-position may force it to take place.

Experimental

The melting points are uncorrected. The IR spectra were recorded on a Hitachi EPI-S2 infrared spectrophotometer. The NMR spectra were obtained on a Hitachi H-60 high-resolution NMR spectrometer, with TMS as the internal standard. The elemental analyses were performed with a Yanagimoto MT-1 CHN Corder.

13) It is necessary, if the Pummerer rearrangement is to take place, that β-keto sulfoxides have an acidic hydrogen at the α-position. Thus, the rearrangement of the β-keto sulfoxides must occur from the form of XI (not from the form of XI'). In the rearrangement of the isolated X, relatively vigorous conditions were required for the reaction; this supports the idea that the favorable form of the compound is X (not X').

Reagents. DMSO was purified by two distillations over calcium hydride under reduced pressure. A commercial sodium nitrite (97% purity) was used without further purification. Unless otherwise noted, the methylsulfinyl carbanion in DMSO was prepared by the method of Corey and Chaykovsky[2] from sodium hydride and DMSO.

Preparation of β-Keto Sulfoxides. General Procedure: A 1.5 to 2 M solution of the methylsulfinyl carbanion in DMSO was prepared and diluted with an equal volume of dry tetrahydrofuran (THF). A solution of the carboxylic ester (0.5 equiv. based on 1 equiv. of the carbanion) in THF was stirred, over a period of 30 min, into the solution of the carbanion under cooling in an ice bath. The ice bath was then removed, and stirring was continued for 1 hr; the reaction mixture was then poured into three times its volume of water, acidified with hydrochloric acid to a pH of 3—4, and thoroughly extracted with chloroform. The combined chloroform extracts were washed four times with water, dried over anhydrous sodium sulfate, and evaporated to dryness to yield the crude β-keto sulfoxide. The crude product, if solid, was triturated with cold ether or isopropyl ether and collected by filtration to give the product, which was generally in a good state of purity and which could be used for the successive reactions without further purification. The crude product, if liquid, was distilled under reduced pressure to give the pure product.

The reaction of the methylsulfinyl carbanion with ethyl phenylacetate under similar conditions did not afford the corresponding β-keto sulfoxide, but it did give the hydrolysis product, phenylacetic acid, in an almost quantitative yield.

ω-(Methysulfinyl)acetophenone (IIa).[2] The treatment of 15 g (0.1 mol) of ethyl benzoate (Ia) with 0.2 mol of the methylsulfinyl carbanion yielded 14.4 g (79%) of IIa as a white crystalline solid after the trituration of the crude product with ether; mp 86—87°C (lit,[2] mp 86—86.5°C).

Methylsulfinylmethyl β-Phenethyl Ketone (IIb). The treatment of 8.9 g (0.05 mol) of ethyl dihydrocinnamate with 0.1 mol of the methylsulfinyl carbanion yielded 8.7 g (88%) of IIb as a white crystalline solid after recrystallization from isopropyl ether; mp 64—65°C.

Found: C, 62.74; H, 6.81%. Calcd for $C_{11}H_{11}O_2S$: C, 62.86; H, 6.67%.

IR (KBr): 1700 (C=O), 1360, 1020 cm^{-1} (SO). NMR ($CDCl_3$): τ 6.30 (2H, *s*, $COCH_2SO$), 7.10(4H, *s*, CH_2CH_3), 7.44 (3H, *s*, $SOCH_3$).

Methylsulfinylmethyl n-*Propyl Ketone (IIc).* The treatment of 5.8 g (0.05 mol) of ethyl butyrate (Ic) with the methylsulfinyl carbanion yielded a brown liquid. The distillation of the liquid gave 4.0 g (54%) of IIc as a yellow liquid; bp 114—115°C/2 mmHg.

Found: C, 48.38; H, 8.24%. Calcd for $C_6H_{12}O_2S$: C, 48.64; H, 8.16%.

IR ($CHCl_3$): 1720 (C=O), 1310, 1030 cm^{-1} (SO). NMR (CCl_4): τ 6.22 (2H, *s*, $COCH_2SO$), 7.4 (3H, *s*, $SOCH_3$), 8.22—9.20 (7H, *m*, $CH_3CH_2CH_2$).

Methylsulfinylmethyl n-*Pentyl Ketone (IId).*[2] The treatment of 7.2 g (0.05 mol) of ethyl caproate (Id) with 0.1 mol of the methylsulfinyl carbanion yielded 6.8 g (72%) of IId after the recrystallization of the crude product from 1 : 1 isopropyl ether-petroleum ether; mp 44—45°C (lit,[2] mp 45—46.5°C).

ω-Methyl-ω-(methylsulfinyl)acetophenone (IIe).[5] This compound was prepared by the method of Russell, Sabourin, and Mikol[5] from IIa and methyl iodide. The crude product, obtained as a yellow oil, was cooled in an ice bath to give a solid which was a diasteroisomer. The crude solid was then washed with ether to afford a white solid which melted

at 74—75°C and which was used for the successive reactions without further purification.

Nitrosation of β-Keto Sulfoxides with Sodium Nitrite in Hydrochloric Acid. General Procedure. Into a mixture of the β-keto sulfoxide (0.01 mol) and sodium nitrite (0.02 mol) in water (25 m*l*), we stirred, drop by drop, an equal volume of a concentrated hydrochloric acid with cooling in an ice bath. After the ice bath had then been removed, stirring was continued for 2 hr at room temperature. The solid thus obtained was separated by filtration and recrystallized to yield the nitroso compound.

The nitrosation of methylsulfinylmethyl *n*-pentyl ketone (IId) by this procedure gave a brown oil which could not be solidified and which was decomposed upon distillation under reduced pressure.

ω-Chloro-ω-isonitrosoacetophenone (IIIa). **A.** The treatment of 1.5 g (0.008 mol) of IIa with 1.2 g (0.016 mol) of sodium nitrite and hydrochloric acid immediately gave the crude product as a white precipitate. Recrystallization from chloroform afforded 1.23 g (84%) of IIIa as white needles; mp 132—133°C (lit,[14] 131—132°C).

Found: C, 52.40; H, 3.29; N, 7.76%. Calcd for $C_8H_6O_2NCl$: C, 52.33; H, 3.29; N, 7.63%.

IR (KBr): 3350 (OH), 1660 cm^{-1} (C=O). NMR (DMSO-d_6): τ −3.68 (1H, *s*, OH), 1.95—2.46 (5H, *m*, aromatic).

This compound was identical in every respect with the authentic sample prepared by the method of Rheinbodt and Dumont.[14]

B. A similar treatment of 3.8 g (0.025 mol) of IIa and 1.8 g (0.025 mol) of sodium nitrite and hydrochloric acid gave 3.4 g (80%) of IIIa. Thus, no appreciable change in the yield of IIIa was observed upon using equal molar quantities of IIa and sodium nitrite.

1-Chloro-1-isonitroso-4-phenylbutanone-2 (IIIb). The treatment of a mixture of 3 g (0.014 mol) of IIb and 2 g of sodium nitrite in 50 m*l* of water with 50 m*l* of hydrochloric acid for 2.5 hr yielded a yellow solid which was collected by filtration and washed with water. The recrystallization of the solid from carbon tetrachloride gave 2.5 g (84%) of IIIb as white needles; mp 98°C.

Found: C, 56.74; H, 4.67; N, 6.69%. Calcd for $C_{10}H_{10}O_2NCl$: C, 56.73; H, 4.73; N, 6.62%.

IR (KBr): 3230 (OH), 1695 cm^{-1} (C=O). NMR ($CDCl_3$): τ 0.73 (1H, *s*, OH), 2.30—3.25 (5H, *m*, aromatic), 6.64—7.16 (4H, *m*, CH_2CH_2).

1-Chloro-1-isonitrosopentanone-2 (IIIc). The treatment of a mixture of 3 g (0.02 mol) of IIc and 3 g of sodium nitirte in 50 m*l* of water with 50 m*l* of hydrochloric acid for 2 hr, after which the mixture was allowed to stand overnight, yeilded a brown solid. The recrystallization of the solid from carbon tetrachloride gave 2.5 g (82%) of IIIc as white crystals; mp 65—67°C.

Found: C, 39.98; H, 5.42; N, 9.31%. Calcd for $C_5H_8O_2NCl$: C, 40.14; H, 5.39; N, 9.37%.

IR (KBr): 3250 (OH), 1680 cm^{-1} (C=O). NMR ($CDCl_3$): τ 2.65 (1H, *s*, OH), 7.1 (2H, *t*, J=7.0 Hz, $CH_3CH_2\mathbf{CH_2}CO$), 7.98—8.73 (2H, *m*, $CH_3\mathbf{CH_2}CH_2CO$), 9.05 (3H, *t*, J=7.0 Hz, $CH_3\mathbf{CH_2}CH_2CO$).

Formation of Isonitroso Compounds from Esters. ω-Chloro-ω-isonitrosoacetophenone (IIIa). A solution of the methylsulfinyl carbanion in DMSO was prepared by the method of Becker and Russell[3] from 2 g (0.05 g-atom) of potassium, 50 m*l* of *t*-butyl alcohol, and 40 m*l* of DMSO. To this mixture 3.8 g (0.025 mol) of ethyl benzoate were added in a stream of nitrogen at room temperature. We continued to agitate the reaction mixture by a stream of nitrogen for 2 hr, then most of the solvent was evaporated under reduced pressure on a water bath, with the temperature kept bellow 60°C. A solution of 5.2 g (0.075 mol) of sodium nitrite in 30 m*l* of water was then added to the residue, and the mixture was extracted with 30 m*l* of ether. The aqueous layer was acidified with 40 m*l* of 6N hydrochloric acid to give yellow oil, which solidified on standing overnight. The recrystallization of the solid from chloroform gave 3.6 g (80%) of IIIa.

Nitrosation of ω-Methyl-ω-(methylsulfinyl)acetophenone (IIe). **A.** Into a solution of 1.0 g (0.005 mol) of IIe and 0.6 g (0.0065 mol) of sodium nitrite in 30 m*l* of 50% aqueous dioxane, 20 m*l* of concentrated hydrochloric acid were stirred at 0—5°C. Stirring was continued for 15 min, and then the reaction mixture was extracted with ether. The ether layer was washed with 10% sodium carbonate and then with water. The ether was dried over sodium sulfate and then evaporated. The brown residue was chromatographed on a column packed with silica gel. The development was carried out by using two different solvents. Methylene chloride was used first, and then 95% ethanol. The evaporation of the first solvent, methylene chloride, and the subsequent distillation of the residue afforded 1-phenylpropane-1,2-dione (V); bp 101—102°C/7 mmHg (lit,[15] 123°C/22 mmHg). IR ($CHCl_3$): 1700, 1660 cm^{-1} (C=O).

The disemicarbazone formed from the above residue by the usual manner melted at 230°C (lit,[15] mp 229—230°C) and was identical in every respect with the disemicarbazone prepared from the authentic sample of V.

The evaporation of ethanol and the recrystallization of the residue from toluene gave 400 mg (48%) of isonitrosopropiophenone (IV); mp 111—113°C (lit,[8] 112—113°C).

B. The same reaction was carried out under similar conditions, but stirring was continued for 2 hr instead of for 15 min. A similar work-up of the reaction mixture gave 0.53 g (70%) of V. In this case, IV was not obtained.

Hydrolysis of Isonitrosopropiophenone (IV) in the Presence of Sodium Nitrite in Hydrochloric Acid. Into a stirred mixture of 1 g (0.006 mol) of IV and 0.42 g (0.006 mol) of sodium nitrite in 30 m*l* of 50% aqueous dioxane, we added 20 m*l* of concentrated hydrochloric acid over a period of 30 min at 0—5°C. The reaction mixture was then extracted with ether. The ether layer was washed with water, dried over sodium sulfate, and then evaporated. The IR spectrum of the residue was identical with that of V. Furthermore, the treatment of the residue with an excess of semicarbazide gave the disemicarbazone of V; mp 231—232°C.

The treatment of IV with hydrochloric acid under the same conditions in the absence of sodium nitrite resulted in the recovery of the starting material in a 90% yield.

2-Nitroso-1,3-indanedione (IXa). A suspension of 2.7 g (0.05 mol) of sodium methoxide in 30 m*l* of DMSO was stirred for 15 min at room temperature in a stream of nitrogen. To this suspension we then added, drop by drop, a solution of 2.5 g (0.0125 mol) of dimethyl phthalate (VIa) in 10 m*l* of DMSO. We continued to stir the reaction mixture, which soon turned yellow, for 3 hr in a stream of nitrogen, and then most of the solvent was evaporated at 1 mmHg on a water bath at 60°C. The residue was mixed with a solution of 1.8 g (0.025 mol) of sodium nitrite in 25 m*l* of ice water, and the mixture was extracted with ether. The aqueous layer was acidified by striring in 50 m*l* of 6N hydrochloric acid with cooling in an ice bath. The precipitated solid was collected by filtration and recrystallized from acetic acid to

give 800 mg (37%) of IXa; mp 196—198°C (decomp) (lit,[11] 197—198°C).

Found: C, 61.56; H, 2.73; N, 7.98%. Calcd for $C_9H_5O_3N$: C, 61.72; H, 2.88; N, 8.00%.

IR (KBr): 3500 (OH), 1738, 1705 cm^{-1} (C=O).

This compound was identical in every respect with the authentic sample prepared by the nitrosation of 1,3-indanedione by the method of Wislicenus.[11]

5-Methoxy-2-nitroso-1,3-indanedione (IXb). A solution of the methylsulfinyl carbanion in DMSO was prepared from 0.8 g (0.02 g-atom) of potassium, 20 m*l* of *t*-butyl alcohol, and 15 m*l* of DMSO. Into this solution we then stirred a solution of 1.0 g (0.0045 mol) of dimethyl 4-methoxyphthalate (VIb) in 5 m*l* of DMSO in a stream of nitrogen at room temperature. Stirring was continued for 2.5 hr, and then most of the solvent was evaporated under reduced pressure. To the residue 10 m*l* of ice water were added, and the mixture was extracted with 10 m*l* of ether. The aqueous layer was separated, poured into an aqueous saturated solution containing 0.8 g of sodium nitrite, and then acidified with 40 m*l* of 6N hydrochloric acid. The solid thus precipitated was recrystallized from ispropyl alcohol to yield 0.65 g (70%) of IXb; mp 204—206°C (decomp).

This compound was identical in every respect with the sample prepared by the method previously reported.[12]

Nitrosation of ω-(Methylsulfinyl)acetophenone (IIa) with Isoamyl Nitrite. To a solution of 0.25 g (0.011 mol) of sodium in 50 m*l* of absolute ethanol, we added 2 g (0.011 mol) of IIa. Isoamyl nitrite (2 g, 0.017 mol) was then stirred in at room temperature. Stirring was continued for 2 hr, and the solvent was evaporated. The residue was poured into 50 m*l* of ice water, and subsequently extracted with 50 m*l* of ether. The aqueous layer was acidified with hydrochloric acid to pH 4—5 to yield a yellow solid. Recrystallization from ethanol gave 1.2 g (40%) of ω-nitroso-ω-(methylsulfinyl)acetophenone (X) as a white solid; mp 124°C.

Found: C, 51.85; H, 4.49; N, 6.66%. Calcd for $C_9H_9O_3NS$: C, 51.28; H, 4.30; N, 6.63%.

IR (KBr): 1640 (C=O), 1040 cm^{-1} (SO). NMR (DMSO-d_6): τ −3.96 (1H, *s*, OH), 1.87—2.41 (5H, *m*, aromatic), 6.92 (3H, *s*, $SOCH_3$).

Pummerer Rearrangement of ω-Nitroso-ω-(methylsulfinyl)acetophenone (X). A suspension of 1 g of X in 30 m*l* of concentrated hydrochloric acid was refluxed for 5 hr and then cooled to room temperature. The solid separated was collected by filtration and recrystallized from chloroform to yield 0.3 g of IIIa; mp 131—133°C.

The Preparation and Reactions of Benzoylnitrile Oxide from Dimethylphenacylsulfonium Bromide[1]

Yoshio Otsuji, Yasuhiro Tsujii, Akihiko Yoshida, and Eiji Imoto

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received August 3, 1970)

The nitrosation of dimethylphenacylsulfonium bromide (I) with sodium nitrite and hydrochloric acid in water gave 3,4-dibenzoyl-1,2,5-oxadiazole 2-oxide (II) in a 76% yield. The nitrosation of I in a similar manner in 1 : 1 dioxane-water afforded ω-chloro-ω-isonitrosoacetophenone (III) in an 80% yield. The treatment of III with triethylamine produced II through benzoylnitrile oxide (IX). 1,3-Dipolar cycloadditions of IX generated from III were conducted, using methyl methacrylate, styrene, acrylonitrile, and ethyl chloroformate as dipolarophiles, to yield the expected cycloadducts. The mechanisms of these reactions are discussed.

The α-hydrogen in β-keto sulfonium compounds is extremely acidic and is readily removed by bases such as triethylamine or sodium hydroxide to yield the corresponding sulfonium ylides. The ylides thus formed can be subjected to such electrophilic substitutions as acylation and sulfonation at the α-carbon.[2] The α-hydrogen in β-keto sulfoxides is of a similar character, and such electrophilic substitutions as alkylation and bromination take place at the α-carbon of the sulfoxides.[3,4]

In a previous paper,[5] we have reported that β-keto sulfoxides are nitrosated at the α-position with nitrous acid in hydrochloric acid, and that, at the same time, the sulfoxide group is eliminated; thus, β-keto sulfoxides with no substituent at the α-position are converted to the α-chloro-α-nitroso (or isonitroso) ketones, and α-substituted β-keto sulfoxides, to the α-nitroso ketones.

Recently we found that the nitrosation of dimethylphenacylsulfonium bromide (I) with nitrous acid in hydrochloric acid affords 3,4-dibenzoyl-1,2,5-oxadiazole 2-oxide (II) or ω-chloro-ω-isonitrosoacetophenone (III) in high yields, the yields depending on the reaction conditions employed. In the present paper we will describe the results of a detailed study of this reaction. We will also report on some 1,3-dipolar

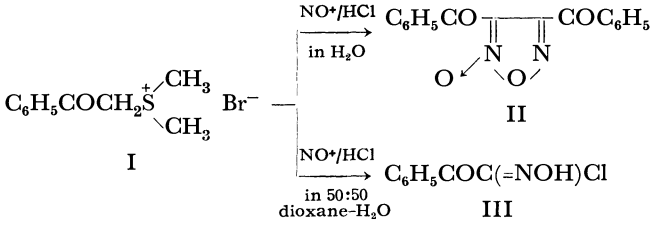
cycloaddition reactions of benzoylnitrile oxide (IX), which is readily derived from III and which would constitute a new type of reactive 1,3-dipole.

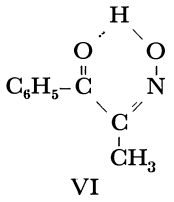
Results and Discussion

Nitrosation of Dimethylphenacylsulfonium Bromide (I). The treatment of a mixture of I and sodium nitrite in water with hydrochloric acid gave 3,4-dibenzoyl-1,2,5-oxadiazole 2-oxide (II) in a 76% yield, plus a small amount of ω-chloro-ω-isonitrosoacetophenone (III). However, the similar treatment of the same mixture in a 1:1 dioxane-water mixture afforded III in an 80% yield, along with a small amount of II.

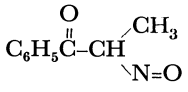


The structure of II was established by the elemental analysis, by a molecular-weight determination (302, calcd 294), and by a study of its spectra data. The IR spectrum (KBr) showed two carbonyl absorptions around 1660 cm^{-1} as a doublet. The NMR spectrum ($CDCl_3$) showed only multiplet absorptions due to aromatic protons at τ 1.75—2.35. The assigned structure for II was also supported by the fact that II could be obtained by the treatment of III with bases, as will be discussed later. The structure of III was confirmed by comparing it with the sample prepared in the previous paper,[4] they were identical in every respect.

One of the most significant features of the nitrosation of the sulfonium salt is its remarkable solvent effect on the proportions of the products formed. How can this solvent effect be explained?. The first step of the reaction, both in water and an aqueous dioxane, is no doubt an attack of the nitrosonium ion at the α-carbon of the sulfonium salt to produce the nitroso sulfonium bromide (IV), which might be unstable under the reaction conditions.[6] We assumed that the configurations of IV in the solvents determined the proportions of the products, and we chose α-nitroso-propiophenone (V) as a model compound of IV. Its configurations were then studied in the mixed solvents of dioxane and water. The UV spectrum of V in dioxane and in dioxane-water (1:1) showed, respectively, absorption maxima at 250 mμ ($\varepsilon=1.1\times10^4$) and 255 mμ ($\varepsilon=1.2\times10^4$); these values are very close to that of benzene in the same solvent (255 mμ). On the other hand, the spectrum of V in water showed a maximum at 280 mμ ($\varepsilon=9\times10^3$), a value which is very close to that of benzaldehyde in the same solvent. These results suggest that V exists predominantly in the form of VI in dioxane-water and in the form of VII in water. In VI the keto and hydroxyimino groups form a stabilized, six-membered ring system by means of intramolecular hydrogen bonding; hence, the conjugation between the benzene ring and carbonyl group would be considerably reduced by the loss of the coplanarity between them. Thus, the UV spectrum of VI resembles that of benzene. On the other hand, an intermolecular hydrogen bonding between water and the keto and/or nitroso groups would dominate the intramolecular hydrogen bonding which is realized in VI. Therefore, the keto group conjugates with the benzene ring and the UV spectrum of VII resembles that of benzaldehyde.



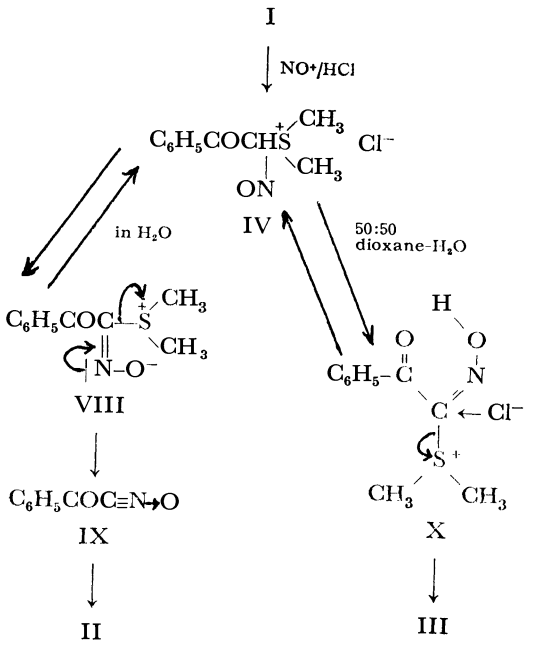
VI



VII

On the basis of the above considerations, we propose the tentative mechanisms represented in Scheme 1 for the nitrosation of the sulfonium salt I.

The intermediate IV is stabilized in water by the elimination of a proton to form VIII, which in turn produces benzoylnitrile oxide (IX). The nitrile oxide, IX, then dimerizes to afford II. However, IV is stabilized in an aqueous dioxane by forming an intramolecularly-hydrogen-bonded X, which then produces III.



Scheme 1

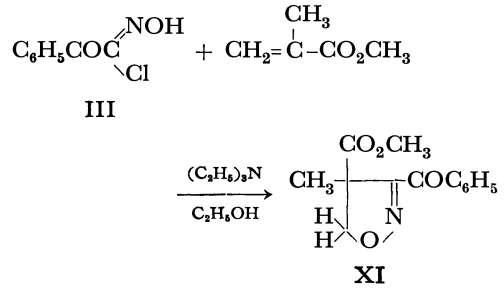
Reaction of ω-Chloro-ω-isonitrosoacetophenone (III) with Bases. The treatment of III with one equiv. of triethylamine in ethanol afforded II in a quantitative yield. The compound, II, thus produced was identical

6) M. Mukaiyama, N. Takei, and K. Saigo (Abstract of the papers presented at the 23rd Meeting of the Chemical Society of Japan, III, Tokyo (1970) p. 1516) have found that the nitrosation of I with isopropyl nitrite in methylene dichloride gives ω-bromo-ω-isonitrosoacetophenone in a 77% yield. They could not isolate a plausible intermediate, IV, because of its unstability, even in an organic medium.

with the sample obtained in the previous paragraph. The similar treatment of III with a sodium hydroxide solution also yielded II, but in a low yield. Considering that the formation of a 1,2,5-oxadiazole 2-oxide ring system (furoxan) is characteristic of the nitrile oxides,[7] it is apparent that the nitrile oxide, IX, is an intermediate of the above reactions; the reaction can feasibly be regarded as a 1,3-dipolar cycloaddition of one molecule of the nitrile oxide onto the CN bond of the other.

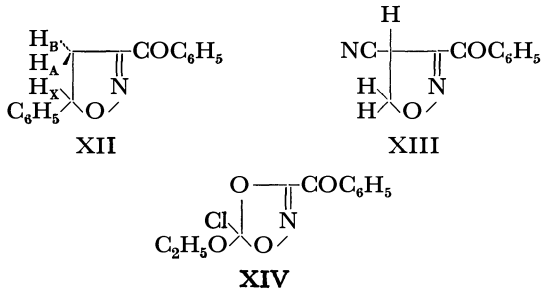
1,3-Dipolar Cycloadditions of Benzoylnitrile Oxide (IX). Since the above results indicated that IX can be liberated from III, the 1,3-dipolar cycloadditions of IX were studied using four unsaturated compounds as dipolarophiles. During the studies it was found that, in order to avoid the interfering dimerization of the reactive nitrile oxide, IX, to the furoxan II, the reaction must be carried out with low stationary concentrations of IX. The slow addition of a dilute solution of triethylamine to an alcoholic solution of III and a dipolarophile at a low temperature (−5—0°C) favored the cycloaddition.

The treatment of III with an equiv. of methyl methacrylate in this manner afforded 3-benzoyl-4-methyl-4-methoxycarbonyl-Δ^2-isoxazoline (XI) in a 91% yield.



III XI

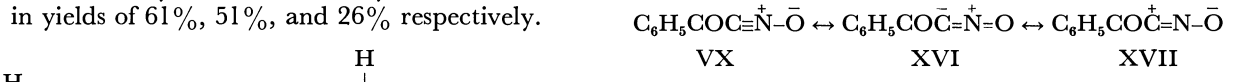
Similar treatments of III with styrene, acrylonitrile, and ethyl chloroformate produced 3-benzoyl-5-phenyl-Δ^2-isoxazoline (XII), 3-benzoyl-4-cyano-Δ^2-isoxazoline (XIII), and 3-benzoyl-5-chloro-5-ethoxy-1,4,2-dioxazole (XIV) in yields of 61%, 51%, and 26% respectively.



XII XIII XIV

The structures of XI, XII, XIII, and XIV were derived from their analytical and spectral data. The results of the elemental analyses, the molecular-weight determinations, and the IR spectra for these compounds were consistent with the assigned structures, as will be described in the "Experimental" section. However, the structures of these compounds were finally established by their NMR spectra. The NMR spectrum of XI in carbon tetrachloride exhibited a multiplet at τ 1.75—2.25 (5H, C_6H_5CO), two singlets at τ 6.22 (3H, $COOCH_3$) and 8.36 (3H, CH_3 at 4-C), and an AB quartet at τ 6.85 (2H, J=17 Hz, 5-CH_2). These signals, especially the chemical shift and the spectral pattern of the AB quartet, support the assigned structure for XI. The NMR spectrum of XII in carbon tetrachloride showed a multiplet at τ 1.70—2.72 (10H, C_6H_5CO at 3-C and C_6H_5 at 5-C) and an ABX pattern due to H_A, H_B, and H_X protons. The signals of this ABX system appeared at τ 6.27 and 6.76 (2H, H_A and H_B of 4-C) and at τ 4.35 (1H, H_X of 5-C). The coupling constants were as follows: J_{AB}=17.8 Hz, J_{AX}=11.2 Hz and J_{BX}=9.7 Hz. These data strongly support the assigned structure for XII. The NMR spectrum of XIII in carbon tetrachloride was relatively simple in its pattern as compared with that of XII. The spectrum showed a multiplet at τ 1.69—2.72 (5H, C_6H_5-CO), a triplet at τ 4.60 (1H, J=9.0 Hz, 4-CH), and a doublet at τ 6.25 (2H, J=9.0 Hz, 5-CH_2). The chemical shifts of the triplet and doublet signals indicate that the assigned structure for XIII is correct and that no other structures can be derived from these spectral data. Finally, the NMR spectrum of XIV in carbon tetrachloride showed a multiplet at τ 1.78—2.55 (5H, C_6H_5CO), a quartet at τ 5.36 (2H, J=7.5 Hz, OCH_2CH_3), and a triplet at τ 8.59 (3H, J=7.5 Hz, OCH_2CH_3). These data are again in agreement with the assigned structure for XIV.

As can be seen from these examples, the nitrile oxide, IX, undergoes 1,3-dipolar cycloadditions onto the C=C and C=O double bonds. It also adds preferentially to the C=C rather than to the C≡N bond in acrylonitrile, as is commonly observed with such aromatic nitrile oxides as benzonitrile oxide.[7] The orientation of the cycloaddition can be interpreted in a manner similar to that proposed for benzonitrile oxide;[7] *i. e.*, the resonance structures of IX would be XV, XVI, and XVII, and its principal polarized formula would be XVII:



VX XVI XVII

Experimental

The melting points are uncorrected. The IR spectra were recorded on a Hitachi EPI-S2 infrared spectrometer. The NMR spectra were obtained on a Hitachi H-60 high-resolution NMR spectrometer, with TMS as the internal standard. The UV spectra were recorded on a Hitachi EPU-2V recording spectrophotometer. The elemental analyses were performed with a Yanagimoto MT-1 CHN Corder. The molecularweight determinations were carried out with a Hitachi-Perkin Elmer 115 molecular-weight apparatus, using benzene as the solvent.

Reagents. A commercial sodium nitrite (97% purity) was used without further purification. The α-isonitropropiophenone was prepared by the method of Hartung and Crossley.[8] The other chemicals were of commercial origin and

7) R. Huisgen, *Angew. Chem., Int. Ed. Engl.*, **2**, 565 (1963).

were used after purification by distillation or recrystallization.

Dimethylphenacylsulfonium Bromide (I)[9]. A solution of 80 g (0.4 mol) of phenacyl bromide and 25 g (0.4 mol) of dimethyl sulfide in 250 m*l* of methanol was refluxed for 10 hr, and then the solvent was evaporated to dryness to give a white solid. Recrystallization from ethanol afforded 73 g (70%) of the pure sulfonium bromide (I); mp 142—143°C.

Nitrosation of I in Water. Into a solution of 10 g (0.04 mol) of I and 3.5 g (0.05 mol) of sodium nitrite in 100 m*l* of water, 100 m*l* of concentrated hydrochloric acid were stirred over a period of 1 hr at room temperature. Stirring was continued for 2 hr to yield a yellow solid, along with a small amount of an orange solid. Both solids were precipitated on the bottom of the flask. The orange solid was picked out from a mixture of the solids by a spatula. The recrystallization of the yellow solid from isopropyl alcohol gave 4.3 g (76%) of 3,4-dibenzoyl-1,2,5-oxadiazole (II) as white crystals; mp 78—80°C.

Found: C, 65.55; H, 3.45; N, 9.81%. Calcd for $C_{16}H_{10}O_4N_2$: C, 65.30; H, 3.43; N, 9.52%.

The orange solid was recrystallized from benzene to yield 120 mg of ω-chloro-ω-isonitrosoacetophenone (III) as white crystals; mp 130—132°C.

Nitrosation of I in an Aqueous Dioxane. Into a solution of 10 g (0.04 mol) of I and 3.5 g (0.05 mol) of sodium nitrite in 50 m*l* of water and 50 m*l* of dioxane, 100 m*l* of concentrated hydrochloric acid were stirred over a period of 1 hr at room temperature. Stirring was continued for 2 hr to produce a white solid, along with a small amount of a yellow solid; these solids were then separated by filtration. The yellow solid was picked out from a mixture of the solids by a spatula. The recrystallization of the white solid from chloroform afforded 6 g (80%) of III as white crystals; mp 130—132°C.

The yellow solid was recrystallized from isopropyl alcohol to yield 60 mg of II as white crystals, the IR spectrum of which was completely identical with that of the authentic sample of II obtained above.

Reaction of ω-Chloro-ω-isonitrosoacetophenone (III) with Bases. A. With Triethylamine. A solution of 2 g (0.02 mol) of triethylamine in 50 m*l* of ethanol was stirred into a solution of 3 g (0.016 mol) of III in 50 m*l* of ethanol under cooling in an ice bath over a period of 30 min. Stirring was continued for 2 hr, and then the solvent was evaporated to dryness. The residue was recrystallized from isopropyl alcohol to yield II as white crystals in an almost quantitative yield; mp 78—80°C. The material thus obtained was identical with the sample prepared above in every respect.

B. With Sodium Hydroxide. Into a suspension of 2 g of III in 40 m*l* of benzene, we stirred, drop by drop, 12 m*l* of a 14% aqueous sodium hydroxide solution at 0°C. After stirring for 1 hr, the benzene layer was separated, dried over calcium chloride, and then evaporated to yield a white solid. The recrystallization of the solid from isopropyl alcohol gave about 200 mg of II; mp 78—80°C.

Formation of 3-Benzoyl-4-methyl-4-methoxycarbonyl-Δ^2-isoxazoline (XI). Into a solution of 3 g (0.016 mol) of III and 1.6 g (0.016 mol) of methyl methacrylate in 50 m*l* of absolute ethanol, we stirred, at −5—0°C, a solution of 2 g (0.02 mol) of triethylamine in 50 m*l* of absolute ethanol over a period of 2 hr. The mixture, which soon turned yellow, was stirred for 3 more hr at the same temperature, concentrated to half its volume under reduced pressure, and then poured onto 100 m*l* of water. The aqueous mixture was extracted several times with methylene dichloride. The organic layer was washed with water and dried over sodium sulfate, and the solvent was evaporated. The distillation of the residue afforded 3.6 g (91%) of XI as a pale yellow oil; bp 190—191°C/7 mmHg.

Found: C, 62.84; H, 5.05; N, 5.87%. Calcd for $C_{13}H_{13}O_4N$: C, 63.15; H, 5.30; N, 5.67%.

Molecular weight: 252 (calcd 247). IR (KBr): 1740, 1655 cm^{-1} (C=O).

Formation of 3-Benzoyl-5-phenyl-Δ^2-isoxazoline (XII). A solution of 3 g (0.016 mol) of III and 1.7 g (0.016 mol) of styrene in 50 m*l* of absolute ethanol was treated with a solution of 2.02 g (0.02 mol) of triethylamine in 50 m*l* of absolute ethanol as has been described above. After stirring for 3 hr under cooling in an ice bath, the reaction mixture was concentrated to half its volume under reduced pressure and then poured onto 100 m*l* of water. The aqueous mixture was extracted several times with methylene dichloride. The organic layer was washed with water and dried over sodium sulfate, and then the solvent was evaporated. The distillation of the residue gave 2.5 g (61%) of XII as a yellow oil; bp 185°C/3.5 mmHg.

Found: C, 75.87; H, 5.33; N, 5.93%. Calcd for $C_{16}H_{13}O_2N$, C, 76.47; H, 5.22; N, 5.57%.

Molecular weight: 250 (calcd 246). IR ($CHCl_3$): 1700, 1660 cm^{-1} (C=O).

Formation of 3-Benzoyl-4-cyano-Δ^2-isoxazoline (XIII). A solution of 3 g (0.016 mol) of III and 0.85 g (0.016 mol) of acrylonitrile in 50 m*l* of absolute ethanol was treated with 2.02 g (0.02 mol) of triethylamine in 50 m*l* of absolute ethanol as has been described above. A similar work-up of the reaction mixture produced a brown oil after the evaporation of the methylene dichloride. The oil solidified upon cooling in a dry ice-acetone mixture. The solid was separated by filtration and recrystallized from water-ethanol to afford 1.7 g (52%) of XIII as pale yellow crystals; mp 70—71°C.

Found: C, 66.40; H, 4.13; N, 14.09%. Calcd for $C_{11}H_8O_2N_2$: C, 66.02; H, 4.03; N, 13.99%.

Molecular weight: 203 (calcd 200). IR (KBr): 1770 cm^{-1} (C=O).

Formation of 3-benzoyl-5-chloro-5-ethoxy-1,4,2-dioxazole (XIV). A solution of 3 g (0.016 mol) of III and 1.7 g (0.016 mol) of ethyl chloroformate in 50 m*l* of absolute ethanol was treated with 2.02 g (0.02 mol) of triethylamine in 50 m*l* of absolute ethanol as has been described above. A similar work-up of the reaction mixture and evaporation of the solvent (methylene dichloride) produced a brown oil which solidified upon cooling in a dry ice-acetone mixture. The solid was separated by filtration and recrystallized from ethanol to yield 1 g (26%) of a white solid; mp 56—59°C.

Found: C, 51.96; H, 4.08; N, 5.61%. Calcd for $C_{11}H_{10}O_4NCl$: C, 51.66; H, 3.91; N, 5.48%.

Molecular weight: 256 (calcd 256). IR (KBr): 1800, 1680 cm^{-1}.

Nitration of Pentamethylnitrobenzene, Pentamethylbenzoic Acid and Its Methyl Ester, Pentamethylacetanilide, and Pentamethylphenol and Its Methyl Ether. Orienting Effect of the Substituents for the Side-chain Nitrooxylation[1]

Hitomi SUZUKI and Kiyomi NAKAMURA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received August 3, 1970)

The nitration of a series of the titled pentamethylbenzene derivatives has been investigated in order to know the orienting effect of substituent groups for the side-chain nitrooxylation. The nitrooxylation was found to occur almost exclusively at the methyl groups adjacent to the electron-withdrawing substituents (NO_2, COOH, and $COOCH_3$), while with the compounds containing electron-donating groups (OH and OCH_3) the main reaction led to the conversion into cyclohexadienone, with the concomitant formation of small amounts of meta-nitrooxylated product. Pentamethylacetanilide underwent side-chain nitrooxylation along with some deacetylation. The location of the nitrooxymethyl group seems to be most likely ortho and meta, the latter being predominant.

Polyalkylated aromatic compounds often suffer side-chain substitution to give benzyl nitrates when they are treated with fuming nitric acid at low temperature. A particularly important feature of this unusual reaction is the peculier orientation and high positional selectivity. Nitration of pentamethylbenzene, for example, gives 2,3,4,5-tetramethylbenzyl nitrate as the major product,[2] while halopentamethylbenzenes yield comparable amounts of 5-halo-2,3,4,6-tetramethylbenzyl nitrate and 6-halo-2,3,4,5-tetramethylbenzyl nitrate.[3] Other isomeric products were never formed in any significant amounts. Such high positional selectivity seems to make this reaction an attractive pathway for the synthesis of the otherwise with difficulty accessible polysubstituted aromatic compounds, because the nitrooxymethyl group is known to be quite versatile for various transformations. To obtain a further information about the character of this reaction, especially the orienting effect of substituent groups, the action of fuming nitric acid upon pentamethylnitrobenzene (I), pentamethylbenzoic acid (II) and its methyl ester (III), pentamethylphenol (IV) and its methyl ether (V), and pentamethylacetanilide (VI) has been studied.

Pentamethylnitrobenzene (I) was comparatively stable towards nitric acid, and remained essentially unchanged under the conditions successfully employed for halopentamethylbenzenes. However, by treating with a large excess of fuming nitric acid at somewhat elevated temperature, it gave a light yellow half-crystalline solid with infrared bands characteristic of nitrobenzyl nitrates, at 876, 1277, 1535, and 1636 cm^{-1}. This was shown by TLC and PMR spectroscopy to contain five components, the principal of which was readily identified as 6-nitro-2,3,4,5-tetramethylbenzyl nitrate (VII) by the comparison of its infrared spectrum with that of an authentic specimen, prepared by the chloromethylation of 5-nitro-1,2,3,4-tetramethylbenzene and the subsequent treatment of the benzyl chloride with silver nitrate in acetonitrile. A close spectroscopic inspection confirmed the formation of some 5-nitro-2,3,4,6-tetramethylbenzyl nitrate (VIII, less than 5% of the total nitrate), but 4-nitro-2,3,5,6-tetramethylbenzyl nitrate (IX) could not be detected. The products were usually accompanied by some dinitroprehnitene. The anisotropic effect of the adjacent nitro group makes the methylene protons of VII to absorb considerably at high-field (4.68 τ) as compared to VIII (4.32 τ) and IX (4.30 τ). A minor peak at 4.70 τ which might arise from 6-nitro-2,3,4,5-tetramethylphenylnitromethane was also observed. VII could be isolated from the reaction mixture by chromatography on a short alumina column, followed by fractional crystallization from light petroleum. When refluxed with excess of dilute hydrochloric acid, the reaction product was converted into a light brown solid, from which 6-nitro-2,3,4,5-tetramethylbenzyl alcohol was obtained as a light yellow prisms.

An ortho-directing effect of electron-attracting groups for side-chain nitrooxylation was further evidenced by the nitration of pentamethylbenzoic acid (II) and its methyl ester (III). II was nitrated with fuming nitric acid in dichloromethane at 0—5°C to yield a white crystalline solid, TLC and PMR spectroscopy of which indicated that it was almost a single compound. Crystallization of the product from dichloromethane - light petroleum mixture gave white fine needles, mp 150—152°C, which had a molecular formula $C_{12}H_{15}NO_5$; PMR peaks at 7.66 (2 Me), 7.72 (2 Me), 4.38 (CH_2), and 2.28 τ (OH, broad); infrared bands at 863, 1272, 1617 (ONO_2), and 1685 cm^{-1} (COOH), consistent with it being a nitrooxymethyltetramethylbenzoic acid. A quite similar result was obtained by the nitration of III. The product was white needles, mp 104—105°C, with a composition $C_{13}H_{17}NO_5$; PMR peaks at 7.84 (Me), 7.77 (2 Me), 7.72 (Me), 6.16 (COOMe), and 4.60 τ (CH_2); infrared bands at 877, 1279, 1613 (ONO_2), 1193, and 1718 cm^{-1} (COOMe), and was readily formulated as methyl nitrooxymethyltetramethylbenzoate. When both products from II and III were heated with concentrated hydrochloric acid, it gave a light brown solid, from which the identical product was obtained as white needles in high yield. This compound, of formula $C_{12}H_{14}O_2$, exhibited PMR peaks at 7.78

(Me), 7.70 (2 Me), 7.37 (Me), and 4.92 τ (CH_2); infrared bands at 1123, 1262, and 1735 cm^{-1} ($CO\cdot OCH_2$). No absorption due to hydroxyl group was observed. It did not dissolve into aqueous sodium hydrogen carbonate, but on prolonged heating with dilute sodium hydroxide it slowly went into solution and was again precipitated on acidification. From its mode of reaction and spectral data, therefore, the product was formulated as 3,4,5,6-tetramethylphthalide, the identity of which was further confirmed by preparing the authentic specimen in low yield from the condensation of chloromethyl methyl ether with 2,3,4,5-tetramethylbenzoic acid in the presence of anhydrous zinc chloride. When a methylol or chloromethyl group is located ortho to a carboxyl group, a loss of water or hydrogen chloride usually occurs to produce a phthalide.[4] Since the ortho relationship of carboxyl and methylol groups was established, the original nitrooxylated products were identified as 6-nitrooxymethyl-2,3,4,5-tetramethylbenzoic acid (X) and methyl 6-nitrooxymethyl-2,3,4,5-tetramethylbenzoate (XI), respectively. Further supporting evidence for the predominant ortho substitution was obtained by reducing the product mixtures with lithium aluminum hydride to bis-hydroxymethyl-tetramethylbenzenes, which, after conversion into bis-acetoxymethyl compound, was gas-chromatographed to prove 1,2-bis(acetoxymethyl)-3,4,5,6-tetramethylbenzene as the sole main product.

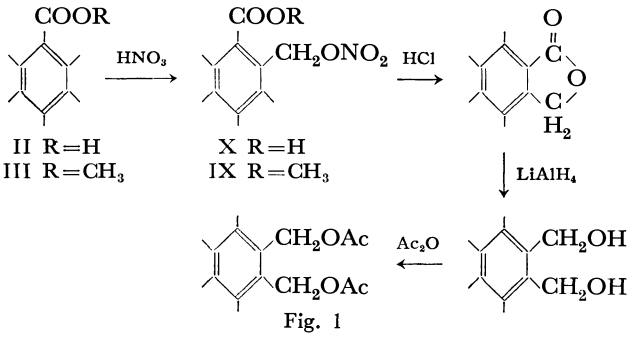

Fig. 1

In a previous paper of this series, directing effect of halogen atoms for the side-chain nitrooxylation of halopentamethylbenzenes has been shown to be a comparable extent of ortho and meta.[3] With highly electron-withdrawing nitro and carboxyl groups, the nitrooxylation was found to occur almost exclusively at ortho methyl groups. From the electronic points of view, therefore, the orientation exhibited by the electron-releasing groups is of special interest. Thus, pentamethylphenol (IV) and its methyl ether (V), and pentamethylacetanilide (VI) were treated with nitric acid. Since fuming nitric acid was found to react with these highly activated aromatic systems destructively under ordinary conditions,[5] the nitration was carried out cautiously in a very dilute methylene chloride solution at −10——5°C with a limited reaction time. Both IV and V reacted actively with nitric acid to give light brown oil of almost identical composition. The methyl group bonded to the oxygen atom of V was completely cleaved during nitration. These products showed a very weak PMR peak at 4.79 τ (CH_2ONO_2) and infrared bands at 845, 1270, and 1630 cm^{-1} (ONO_2), indicating the formation of a benzyl nitrate only as a minor product. When stored at cool place, the syrupy product partly solidified to a sticky, half-crystalline mass, which could be separated into white prisms (mp 138—140°C) by fractional crystallization from light petroleum and diethyl ether. However, a considerable part of it was lost as a non-crystallizable syrup during recrystallization. The PMR spectrum of the carbon tetrachloride solution showed three methyl signals at 8.63, 8.16, and 7.96 τ of relative intensities 1 : 2 : 2. Its infrared spectrum contained strong bands for unsaturated ketones and hydroxyl group, at 1084, 1613, 1662, and 3390 cm^{-1}, and its ultraviolet spectrum produced a single intense band at 242 mμ ($\log \varepsilon = 4.20$) which is characteristic of cross-conjugated cyclohexadienones.[6] The analysis and spectral data are in agreement with the structure of 4-hydroxy-2,3,4,5,6-pentamethylcyclohexa-2,5-dienone, $C_{11}H_{16}O_2$. The isolation of hydroxycyclohexadienone and the numerous examples of parallel reactions of polysubstituted phenolic systems[7] are, therefore, consistent with the formulation of the major component of the original mixture as 4-nitro-2,3,4,5,6-pentamethylcyclohexa-2,5-dienone (XII). Trituration of the pasty mixture in cold ethanol gave small amounts of white powder, melting with decomposition up to *ca.* 260°C, which had an elemental analysis (C, 64.6; H, 7.4; N, 4.5%) and showed a complicated PMR spectral pattern. It was probably a secondary product from the cyclohexadienone and no further attempt was made to elucidate the structure.

In view of the supposed instability of 2- and 4-hydroxytetramethylbenzyl nitrates and their possible degradation product, quinomethide, the accumulation of these nitrates to any significant amount in the reaction mixture seems very unlikely.[8] Therefore, a small amount of benzyl nitrate found in the nitration product is probably 3-hydroxy isomer. With the aim to confirm this, attempts were made to prepare the authentic 3-hydroxy-2,4,5,6-tetramethylbenzyl nitrate (XIII) from the reaction of the corresponding benzyl chloride with silver nitrate in acetonitrile. The product was unfortunately a yellow to light brown syrupy mixture of several substances, although the nitrate appeared still to be the main component. Since the

amount was very small, the identity of this nitrooxy compound was inferred by indirect means of spectral comparison of the product mixture with the above impure reference compound. It revealed, in fact, that all the major peaks belonging to the impure XIII were contained in the spectra of the nitration products from IV and V. When the syrupy product from IV was treated with cold concentrated hydrochloric acid for some days, a pale yellow pasty solid was obtained, PMR spectrum of which showed several new prominent peaks in the methylene protons region (4.32, 4.72, and 5.25 τ).

Pentamethylacetanilide (VI) underwent the nitration under similar condition much more smoothly than did IV and V. A light brown gummy product with ordor of acetic acid showed prominent PMR peaks due to $-CH_2ONO_2$ at 4.48 and 4.43 τ; infrared bands at 876, 1280, 1613 (ONO_2), 1645 (CONH), and 3220 cm^{-1} (NH), indicating the formation of benzyl nitrate and the partial deacetylation. Several crystallization of the product from dichloromethane - light petroleum mixture gave the major component as white needles, which was identified by analysis, infrared and PMR spectroscopy as a nitrooxymethyltetramethylacetanilide. The minor nitrate with the benzylic protons signal at lower field of 4.43 τ could not be isolated. Because of the difficulty involved in the preparation of the authentic samples, a firm structural assignment for these nitrooxy compounds has not been made yet. However, it is expected that the acetamido group will exhibit anisotropic deshielding effect on the benzylic protons at the ortho positions, but will exert a net shielding effect on these at meta and para positions. Considering the appearance of the methylene protons signal of the minor nitrate at lower field, the orientation of these nitrate seems most likely to be ortho and meta substituted, the latter outweighing the former in its amount.

The nitration of acetanilides has been known to involve the interaction of p- or π-electron on nitrogen or carbonyl oxygen with the nitrating species, leading to the formation of XIV as the most readily accessible σ-complex (Fig. 2). The observed partial deacetylation would probably arise from such interaction. When this special effect was superimposed with ordinary ortho and para activating and somewhat meta deactivating effect of acetamido group, the most favored intermediates will be ions XIV and XV, which, according to the previously suggested cyclic process for side-chain nitrooxylation,[2] will form the meta substituted nitrate as the most preferred isomeride. The minor nitrate is probably ortho-substituted and would be derived from the less important contributor XVI (Fig. 2), in which the preferred proton release will occur from the methyl groups adjacent to the acetamido group ($X=NHCOCH_3$), because the protons of these groups are more positively polarized and the transition state for the migration of the nitro group to the neighboring side-chain will be stabilized more effectively, as in XVII (Fig. 3), through the electron supply from the methyl group meta to the attacking site as well as through the polar interaction between the p-electrons on carbonyl oxygen and the leaving hydrogen atom.

In the case of para substitution, the conjugative electron release from the acetamido group is greatly disturbed by the methyl groups on both sides, and so the former group will act in an opposite way during the electron-redistribution, by increasing the electron deficit at the attacking site and thus rendering the departure of the nitro group with its unshared electron pair more difficult, as depicted in XVIII (Fig. 3). In view of the almost exclusive ortho substitution for I, II and III, and a comparable extent of ortho and meta substitution for halopentamethylbenzenes, this interpretation seems quite reasonable.

Predominant ortho directing effect of nitro, carboxyl and methoxyl groups probably involves a similar mechanism. Strongly electron-attracting nitro group or carboxyl group will direct the entering nitronium ion at the meta position to yield the benzenonium ion XVI ($X=NO_2$ or COOH) as the most stable intermediate species, which has three methyl groups at the most favorable position to delocalize the positive charge. Methyl protons next to the nitro or carboxyl group are subject to the further activation due to the nitronium ion introduced at the another neighboring position. Hyperconjugative proton release from this highly activated methyl group, followed by the migration of the nitro group to this side-chain according to the outlined sequence will result in the expected ortho-substitution (Figs. 2 and 3).

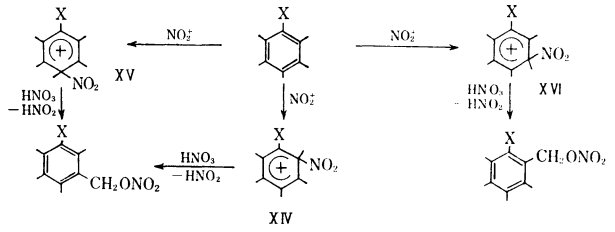

Fig. 2

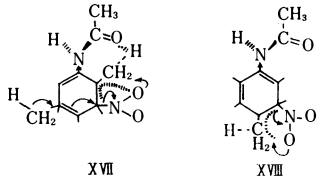

Fig. 3

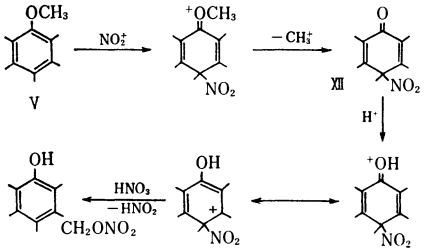
A small amount of meta-substituted product would arise from the less stabilized ion XIV, in which only two methyl groups can contribute to the stabilization.

The methoxyl cleavage and subsequent meta-nitrooxylation observed in the nitration of pentamethylanisole (V) may be rationalized on a similar basis:



XIII Fig. 4

Initial step of the reaction would be the attachment of nitro group at 4-position, and the methyl group is rapidly cleaved from the oxygen atom to form a dienone XII, which will be partly protonated on the oxygen atom to give the hydroxybenzenonium ion and then transformed into meta-substituted benzyl nitrate XIII (Fig. 4).

Experimental

Melting points were determined on a hot stage apparatus and were uncorrected. Infrared spectra were measured with a KBr disc on a Jasco DS-402 G spectrophotometer, and ultraviolet spectra were recorded in methanol solution with a Shimadzu QV-50 spectrophotometer. PMR spectra were obtained in carbon tetrachloride and deuteriochloroform with a Varian A-60A spectrometer and with a Jeolco 3H-60 spectrometer against internal TMS.

Materials. Pentamethylnitrobenzene (I, mp 158—159°C),[2] pentamethylbenzoic acid (II, mp 210—211°C) and its methyl ester (III, mp 68—69°C),[9,10] and pentamethylacetanilide (VI, mp 212—214°C)[11] were prepared as described in the literatures.

Most of the previously reported synthetic methods for pentamethylphenol (IV) were found to be not entirely satisfactory as a simple laboratory procedure, owing to a difficult access for the material, low yield, or the laborious procedure involved in the synthesis and purification processes.[11,12] A simple and rapid synthesis of pure IV (mp 126—128°C) was accomplished by reducing 3,5-bis(chloromethyl)-2,4,6-trimethylphenol,[13] readily prepared from mesitol by chloromethylation in acetic acid, with lithium aluminum hydride in anhydrous tetrahydrofuran, followed by the purification through steam-distillation. *O*-Methylation of IV required quite long time and was still incomplete.

Pentamethylanisole (V, mp 62—63°C)[14] was similarly prepared by the reduction of the bischloromethylation product from 2,4,5-trimethylanisole. Direct methylation of anisole with boron trifluoride - methanol complex according to the Kolka and Vogt's procedure[15] was found unsatisfactory since the major product of the reaction was not the expected V, but the 2,3,4,4,5,6-hexamethylcyclohexa-2,5-dienone,[16] although some V could be isolated from the reaction mixture. The reaction could hardly be controlled to stop at the stage of pentamethylation, and it always went too far to yield the dienone as the final stable product.

Tetramethylbenzyl nitrates used as a reference compound were prepared in 70—85% yield by treating the corresponding benzyl chlorides[17] with silver nitrate in acetonitrile, and recrystallized from *n*-hexane.

6-Nitro-2,3,4,5-tetramethylbenzyl Nitrate (VII): mp 102—103°C. IR, 707, 758, 842, 876, 974, 1277 (ONO_2), 1535 (NO_2), and 1637 cm^{-1} (ONO_2); PMR, 7.84 (Me), 7.72 (2 Me), 7.67 (Me), and 4.68 τ (CH_2).

Found: C, 52.0; H, 5.8%. Calcd for $C_{11}H_{14}N_2O_5$: C, 52.0; H, 5.6%.

5-Nitro-2,3,4,6-tetramethylbenzyl Nitrate (VIII): mp, 132—134°C. IR, 705, 756, 838, 871, 967, 1281 (ONO_2), 1528 (NO_2), and 1638 cm^{-1} (ONO_2); PMR, 7.67 (Me), 7.58 (2 Me), 7.50 (Me), and 4.32 τ (CH_2).

Found: C, 52.0; H, 5.6%. Calcd for $C_{11}H_{14}N_2O_5$: C, 52.0; H, 5.6%.

4-Nitro-2,3,5,6-tetramethylbenzyl Nitrate (IX): mp, 157—158°. IR, 713, 757, 848, 867, 966, 1274 (ONO_2), 1531 (NO_2), and 1633 cm^{-1} (ONO_2); PMR, 7.76 (2 Me), 7.55 (2 Me), and 4.30 τ (CH_2).

Found: C, 52.2; H, 5.6%. Calcd for $C_{11}H_{14}N_2O_5$: C, 52.0; H, 5.6%.

Bis(acetoxymethyl)tetramethylbenzenes were obtaind in 80—90% yield from the bis(chloromethyl)tetramethylbenzenes[18] by treatment with silver acetate in gently refluxing glacial acetic acid, and crystallized from ethanol.

1,2-Bis(acetoxymethyl)-3,4,5,6-tetramethylbenzene: mp, 117—118°C. IR, 906, 954, 1025, 1235 (CO·O, broad), and 1731 cm^{-1} (CO·O); PMR, 7.94 (O·$COCH_3$), 7.68 (Me), 7.65 (Me), and 4.67 τ (CH_2).

Found: C, 69.2; H, 8.2%. Calcd for $C_{16}H_{22}O_4$: C, 69.1; H, 8.0%.

1,3-Bis(acetoxymethyl)-2,4,5,6-tetramethylbenzene: mp, 114—115°C. IR, 912, 958, 979, 1031, 1243 (CO·O, broad), and 1731 cm^{-1} (CO·O); PMR, 7.93 (O·$COCH_3$), 7.68 (Me), 7.62 (2 Me), 7.55 (Me), and 4.82 τ (CH_2).

Found: C, 69.0; H, 8.1%. Calcd for $C_{16}H_{22}O_4$: C, 69.1; H, 8.0%.

1,4-Bis(acetoxymethyl)-2,3,5,6-tetramethylbenzene: mp, 191—192°C. IR, 917, 962, 1027, 1239 (CO·O, broad), and 1732 cm^{-1} (CO·O); PMR, 7.81 (O·$COCH_3$), 7.52 (Me), and 4.68 τ (CH_2).

Procedure for Nitration of Pentamethylnitrobenzene (I), Pentamethylbenzoic Acid (II) and Methyl Pentamethylbenzoate (III). Fuming nitric acid (d=1.50, 6.3 g) was added over a period of 30 min to a vigorously stirred solution of II (3.8 g) or III (4.1 g) in dichloromethane (30 m*l*). During the addition, the temperature of the system was kept at −5—0°C. Since I (3.9 g) was recovered mostly unchanged under the same condition, it was treated with a large excess of fuming nitric acid (12.6 g) in dichloromethane (20 m*l*) at somewhat elevated temperature (30—32°C). The mixture was poured into water and the organic layer was washed thoroughly with water. Removal of the solvent left a solid, which was directly subjected to the infrared and PMR spectral determinations.

The nitration product from I showed PMR peaks at 7.76, 7.73, 7.68, and 4.68 τ along with a minor peak at 4.70 τ; infrared bands at 708, 760, 878, 976, 1277, 1535, and 1636 cm^{-1}. On hydrolysis with hydrochloric acid and subsequent recrystallization from ligroin, it gave 6-nitro-2,3,4,5-tetramethylbenzyl alcohol as light yellow prisms, mp 175—176°C. The same compound was obtained from the unsuccessful

3,4,5,6-Tetramethylphthalide: mp, 233—235°C.

Found: C, 75.5; H, 7.1%. Calcd for $C_{12}H_{14}O_2$: C, 75.8; H, 7.4%.

Procedure for Nitration of Pentamethylphenol (IV), Pentamethylanisole (V) and Pentamethylacetanilide (VI). A solution of fuming nitric acid (d=1.50, 2.0 g) in dichloromethane (10 m*l*) was added dropwise to a magnetically stirred solution of IV (3.3 g) or V (3.6 g) in the same solvent (25 m*l*) over a period of 20 min. The temperature was cautiously kept at −10—−5°C during the addition. The solution rapidly yellowed, and the color intensified to orange to light brown. VI (4.1 g) reacted less vigorously under the same condition. After the end of the addition, the mixture was diluted with water and the organic part was thoroughly washed with water. After drying over anhydrous sodium sulfate, the solvent was evaporated to give a yellow syrup or a light brown pasty cake, on which infrared, ultraviolet and PMR spectroscopic inspections were performed.

The nitration products (*ca.* 3.5—3.8 g) from IV and V both showed almost identical infrared and PMR spectral pattern. IR: 852, 1002, 1024, 1083, 1272, 1340, 1374, 1445, 1540—1550, 1617—1635, and 1735 cm^{-1}; PMR, 8.79, 8.69, 8.66, 8.88—8.30, 6.58, 5.40, and 4.79 τ. When the syrupy product was dissolved in a minimum amount of light petroleum - ether mixture and set aside in a refrigerator for weeks, it slowly separated crystalline solid of wide melting range (70—90°C), which was purified through fractional crystallization from a mixture of light petroleum and ether to give white prisms (mp 138—140°C) and was formulated as 4-hydroxy-2,3,4,5,6-pentamethylcyclohexa-2,5-dienone on the basis of analysis, infrared, ultraviolet and PMR spectral data.

Found: C, 72.4; H, 8.9%. Calcd for $C_{11}H_{16}O_2$: C, 73.3; H, 8.9%.

A white powder obtained from the above syrup by trituration in cold ethanol melted at up to 260°C with decomposition. It showed infrared bands at 1020, 1074, 1345, 1372, 1540—1545, 1630, and 3420 cm^{-1}, and PMR peaks at 8.79, 8.61, 7.90—8.20 (complicated multiplet), and 6.52 τ.

Found: C, 64.6; H, 7.4, N, 4.5%.

The nitration product (*ca.* 4.2 g) from VI exhibited PMR peaks at 8.73, 8.31, 7.97, 7.86—7.67, 4.48, and 4.43 τ; IR bands at 876, 1280, 1365—1380, 1510, 1613, 1645, 1725, 2900, and 3218 cm^{-1}. Upon crystallization from a mixture of light petroleum and methylene chloride, it gave a nitrooxymethyltetramethylacetanilide, mp 126—127°C, which had PMR peaks at 7.83 (Me), 7.75 (3 Me), 7.66 (COMe), and 4.45 τ (CH_2); IR bands at 877 (ONO_2), 1282 (ONO_2), 1368, 1382, 1613 (ONO_2), 1685 (COMe), and 3220 cm^{-1} (NH).

Found: C, 58.4; H, 7.0; N, 10.3%. Calcd for $C_{12}H_{17}NO_4$: C, 58.6; H, 6.8; N, 10.5%.

A New Phosphorylating Reagent. III.[1] Preparation of Mixed Diesters of Phosphoric Acid by the Use of an Activatable Protecting Group

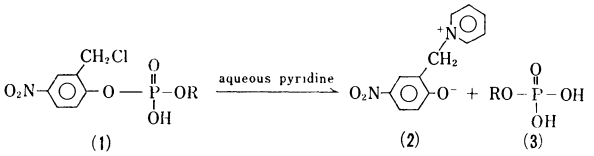
Yoshitaka MUSHIKA, Tsujiaki HATA, and Teruaki MUKAIYAMA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 4, 1970)

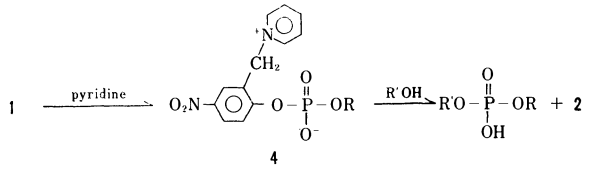
A novel method for the preparation of mixed diesters of phosphoric acid has been investigated. It was found that mixed diesters of phosphoric acid were prepared by the reaction of alkyl 2-chloromethyl-4-nitrophenyl hydrogen phosphates with alcohols in dry pyridine. On the other hand, these diesters were also obtained from dialkyl 2-chloromethyl-4-nitrophenyl phosphates on hydrolysis under mild conditions. By using both of these methods, analytically pure samples of mixed diesters of phosphoric acid could be obtained in high yields.

In a previous paper,[2] it has been reported that highly pure samples of alkyl dihydrogen phosphates (**3**) were prepared in high yields under mild conditions by treating alkyl 2-chloromethyl-4-nitrophenyl hydrogen phosphates (**1**) with aqueous pyridine.



(1) (2) (3)

This result shows that 2-chloromethyl-4-nitrophenyl group functions to facilitate the elimination of this group through an intermediate, inner salt of 1-(2-alkyl hydrogen phosphoroxy 5-nitrobenzyl)pyridinium hydroxide (**4**), formed by an attack of pyridine on the chloromethyl group of **1** as sketched below. Therefore, it can be expected that mixed diesters of phosphoric acid would be successfully synthesized when **1** is treated with alcohols in dry pyridine.



4

When a mixture of one equiv. of **1** and two equiv. of *n*-pentyl alcohol in five equiv. of pyridine was allowed to stand at room temperature for two days and then was heated at 90°C for 6 hr, ethyl *n*-pentyl hydrogen phosphate (**5a**) was obtained in 81% yield along with inner salt of 1-(2-hydroxy-5-nitrobenzyl)pyridinium hydroxide (**2**).

In a similar manner, various mixed diesters of phosphoric acid were obtained in high yields as shown in Table 1.

In the cases of *n*-hexadecyl derivatives (**5b**, **5i**, **5j**, **5k**, and **5l**), it is necessary to carry out the reaction by using ten equiv. of pyridine because *n*-hexadecyl derivatives are less soluble in pyridine than the other

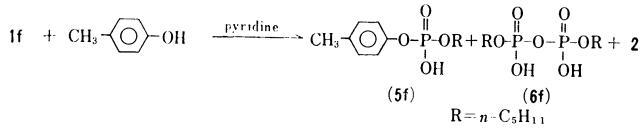
a) Yields are based on the phosphate **1**.
b) Paper chromatography was carried out by ascending technique using Toyo Roshi No. 50 paper. Solvent system used was: isopropyl alcohol, conc. ammonium hydroxide, water (7 : 1 : 2 v/v).
c) The compound **5e** is pale yellowish oil.

1) Paper II: T. Hata, Y. Mushika, and T. Mukaiyama, *Tetrahedron Lett.*, **1970**, 3505.

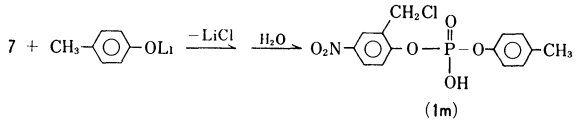
2) T. Hata, Y. Mushika, and T. Mukaiyama, *J. Amer. Chem. Soc.*, **91**, 4532 (1969).

derivatives.

It was also found that phenols are successfully phosphorylated to give the corresponding alkyl aryl hydrogen phosphates. When *n*-pentyl 2-chloromethyl-4-nitrophenyl hydrogen phosphate (**1f**) was treated with *p*-cresol, *n*-pentyl *p*-tolyl hydrogen phosphate (**5f**) was obtained in 57% yield as a major product and a small amount of P^1,P^2-di-*n*-pentyl pyrophosphate (**6f**) was detected as a by-product.



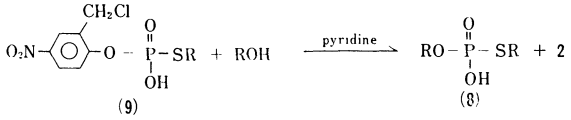
The formation of **6f** would be explained by considering the competitive reaction of **1f** with **4f** (R=*n*-C_5H_{11}). In order to avoid the undesirable formation of **6f**, *p*-tolyl 2-chloromethyl-4-nitrophenyl hydrogen phosphate (**1m**), prepared from lithium phenoxide and 2-chloromethyl-4-nitrophenyl phosphorodichloridate (**7**), was chosen with the consideration that **5f** would be exclusively produced because alcohols can react with **1m** much faster than phenols.



When the phosphate **1m** was treated with *n*-pentyl alcohol in dry pyridine, *n*-pentyl *p*-tolyl hydrogen phosphate (**5f**) was isolated in 72% yield without accompanying the formation of the pyrophosphate.

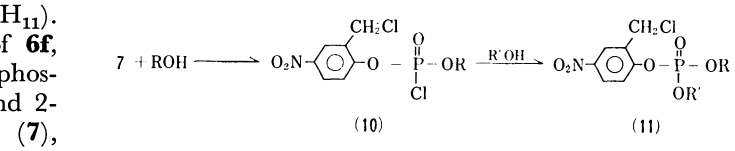
$$\mathbf{1m} + n\text{-}C_5H_{11}OH \xrightarrow{\text{pyridine}} \mathbf{5f} + \mathbf{2}$$

The reaction of thiols with **1** proceeded very sluggishly even when they were refluxed in dry pyridine. Similar to the cases of phenols mentioned above, *O*,*S*-di-*n*-pentyl hydrogen phosphorothioate (**8**) could be prepared in 42% yield starting from *S*-*n*-pentyl *O*-2-chloromethyl-4-nitrophenyl hydrogen phosphorothioate (**9**) by the treatment with *n*-pentyl alcohol in dry pyridine as shown in the following equation.



In the next place, the preparation of mixed diesters of phosphoric acid from 2-chloromethyl-4-nitrophenyl phosphorodichloridate (**7**) and two different kinds of alcohols was investigated.

It was established that one of the two chlorine atoms of **7** reacts selectively with one equiv. of an alcohol in the presence of exactly one equiv. of pyridine to afford the corresponding alkyl 2-chloromethyl-4-nitrophenyl phosphorochloridate (**10**). The phosphorochloridate **10** was further, without isolating, treated with one equiv. of another alcohol in the presence of one equiv. of pyridine. The triester, dialkyl 2-chloromethyl-4-nitrophenyl phosphate (**11**) was obtained in high yield and it was purified by silica-gel column chromatography in order to remove **1**, formed by hydrolysis of **10**.



The structure of **11** was confirmed by elemental analysis as well as infrared and ultraviolet spectra. Several triesters **11** were obtained by this method as shown in Table 2.

Table 3. Preparation of dialkyl hydrogen phosphates (**5**) from dialkyl 2-chloromethyl-4-nitrophenyl phosphates (**11**)

Compd.[a]	R	R′	Yield[b] (%)	Appearance

Experimental

Reagents. Alcohols, mercaptans, phenols and pyridine were purified and dried by ordinary procedures. 2-Chloromethyl-4-nitrophenyl phosphorodichloridate (**7**) and alkyl 2-chloromethyl-4-nitrophenyl hydrogen phosphates (**1**) were prepared as described in a previous publication.[2]

Paper Chromatography. Paper chromatography was carried out by ascending technique using Toyo Roshi No. 50 paper. Solvent system used was: isopropyl alcohol, concentrated ammonium hydroxide, water (7 :1 : 2 v/v).

*Preparation of Dialkyl Hydrogen Phosphates (**5**) from Alkyl 2-Chloromethyl-4-nitrophenyl Hydrogen Phosphates (**1**).* *General Procedure*: Alkyl 2-chloromethyl-4-nitrophenyl hydrogen phosphate (**1**) (0.01 mol) and an alcohol (0.02 mol) were dissolved in 4-8 m*l* of dry pyridine. The mixture was allowed to stand at room temperature for 2 days and then heated at 90°C for 6 hr. After addition of 30 m*l* of ethanol, a pale yellowish precipitate, inner salt of 1-(2-hydroxy-5-nitrobenzyl)pyridinium hydroxide separated. It was removed by filtration and washed with 30 m*l* of ethanol. The combined filtrate and washings were concentrated to dryness. Dialkyl hydrogen phosphate was isolated from the oily residue by means of either *Method A* or *Method B*. The compounds (see Table 1), **5d**, **5f**, and **5g** were prepared by *Method A-1*. The compounds, **5a**, **5b**, **5c**, **5e**, and **5h** were obtained by *Method A-2*. The other compounds, **5i**, **5j**, **5k**, and **5l** were isolated by *Method B*.

The results are summarized in Table 1.

Method A: The oily residue was dissolved in 50 m*l* of water containing 1.7 g (0.02 mol) of sodium hydrogencarbonate and the solution was washed with ether. The aqueous layer was acidified with hydrochloric acid and extracted with three 30 m*l* portions of petroleum ether (*Method A-1*) or ether (*Mothod A-2*). The combined extracts were washed with three 10 m*l* portions of water and dried over anhydrous sodium sulfate. After removal of the solvent, pure sample of dialkyl hydrogen phosphate (**5**) was obtained without further purification.

Method B: After complete removal of the solvent under high vacuum, the residue was dissolved in 100 m*l* of petroleum ether (bp 45—60°C). The solution was washed with dilute hydrochloric acid and then three 10 m*l* portions of water. After drying the solution over anhydrous sodium sulfate, petroleum ether was removed by evaporation. Highly pure sample of dialkyl hydrogen phosphate (**5**) was obtained as white powder (**5i** and **5l**) or colorless oil (**5j** and **5k**).

S-n-*Pentyl* O-*2-Chloromethyl-4-nitrophenyl Hydrogen Phosphorothioate (**9**).* A suspension of lithium *n*-pentyl mercaptide, which was prepared from 2.42 m*l* (0.02 mol) of *n*-pentyl mercaptan in 20 m*l* of tetrahydrofuran (THF) and 12 m*l* (0.02 mol) of 10% solution of *n*-butyllithium in *n*-hexane, was slowly added at −20°C to a solution of 6.08 g (0.02 mol) of 2-chloromethyl-4-nitrophenyl phosphorodichloridate (**7**) in 30 m*l* of tetrahydroquran. The stirring was continued at −20——10°C for 3 hr and further at room temperature for 2 hr. The mixture was poured into 50 m*l* of water containing 1.6 m*l* (0.02 mol) of pyridine at a temperature below 20°C and then stirred for 30 min. THF was removed and the solution was extracted with three 50 m*l* portions of benzene. The extract was washed with three 10 m*l* portions of water and dried over anhydrous sodium sulfate. After removal of benzene, *S-n*-pentyl *O*-2-chloromethyl-4-nitrophenyl hydrogen phosphorothioate (**9**) (3.30 g, 49%) was obtained as reddish oil; R_f: 0.92; $\lambda_{max}^{H_2O}$ 290 mμ (ε: 8400).

Found: C, 39.89; H, 4.77; N, 4.22%. Calcd for $C_{12}H_{17}ClNO_5PS$: C, 40.74; H, 4.84; N, 3.96%.

O,S-*di*-n-*Pentyl Hydrogen Phosphorothioate (**8**).* A solution of 3.40 g (0.01 mol) of *S-n*-pentyl *O*-2-chloromethyl-4-nitrophenyl hydrogen phosphorothioate (**9**) and 2.16 m*l* (0.02 mol) of *n*-pentyl alcohol in 4 m*l* (0.05 mol) of dry pyridine was allowed to stand at room temperature for 2 days and further heated at 90°C for 6 hr. Thirty m*l* of ethanol was added and pale yellowish precipitate, inner salt of 1-(2-hydroxy-5-nitrobenzyl)pyridinium hydroxide (1.76 g, 66%) separated and was filtered off. The filtrate was concentrated and the residue was dissolved in 30 m*l* of water containing 1.7 g of sodium hydrogencarbonate. The aqueous solution was washed with ether and acidified with hydrochloric acid and then extracted with three 30 m*l* portions of petroleum ether. The combined extracts were washed with three 10 m*l* portions of water and dried over anhydrous sodium sulfate. After decolorizing with charcoal, the solvent was removed by evaporation. *O,S*-di-*n*-pentyl hydrogen phosphorothioate (**8**) (1.19 g, 47%) was obtained as yellowish oil; R_f 0.92; n_D^{20} 1.4762.

Found: C, 47.67; H, 8.91, S. 13.50%. Calcd for $C_{10}H_{23}O_3PS$: C, 47.22; H, 9.12; S, 12.61%.

Formation of P^1,P^2-*di*-n-*Pentyl Pyrophosphate (**6f**).* A solution of *n*-pentyl 2-chloromethyl-4-nitrophenyl hydrogen phosphate (**1f**) (3.38 g, 0.01 mol) in 4 m*l* (0.05 mol) of pyridine was allowed to stand at room temperature for 2 days and further heated at 90°C for 6 hr. Ethanol (30 m*l*) was added to the solution. Pale yellowish precipitate, inner salt of 1-(2-hydroxy-5-nitrobenzyl)pyridinium hydroxide (2.25 g, 84%) separated and was filtered off. The filtrate was evaporated and the residue was dissolved in 30 m*l* of water. The solution was acidified with hydrochloric acid and extracted with four 30 m*l* portions of ether. The extracts were combined and dried over anhydrous sodium sulfate. After removal of ether, the residual oil was dissolved in 20 m*l* of ether and then 3.0 g of aniline was added. The mixture was kept standing in a refrigerator overnight. A white precipitate separated and was collected by filtration. The precipitate was recrystallized from a mixture of ethanol and acetone. Di-anilinium salt of P^1,P^2-di-*n*-pentyl pyrophosphate (**6f**) (0.93 g, 37%) was obtained as white prisms; mp 134°C; R_f 0.78.

Found: C, 51.78; H, 7.67; N, 5.57%. Calcd for $C_{22}H_{35}N_2O_7P_2$: C, 52.38; H, 7.59; N, 5.55%.

*Preparation of Dialkyl 2-Chloromethyl-4-nitrophenyl Phosphates (**11**).* *A Typical Procedure*: To a solution of 6.01 g (0.02 mol) of 2-chloromethyl-4-nitrophenyl phosphorodichloridate (**7**) in 30 m*l* of THF was added slowly a solution of cyclohexanol (2.00 g, 0.02 mol) and pyridine (1.60 g, 0.02 mol) in 20 m*l* of THF with stirring at a temperature below −10°C. The mixture was stirred for 4 hr and further at room tem-

perature for 2 hr. A solution of ethanol (2.33 m*l*, 0.04 mol) and pyridine (1.6 m*l*, 0.02 mol) in THF (20 m*l*) was then added under cooling. Stirring was continued for 2 hr and further at room temperature for 5 hr. After concentrating the mixture, the residue was poured into water (30 m*l*) and extracted with benzene (80 m*l*). The benzene was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the syrupy residue was passed through a column of Wakogel C-200 (100—200 mesh) (20 mm × 500 mm) by using benzene for elution. The eluent was concentrated to dryness. Ethyl cyclohexyl 2-chloromethyl-4-nitrophenyl phosphate (**11d**) (6.9 g, 91%) was obtained as a pale yellowish syrup. In a similar manner, the triesters (**11**), such as **11p**, **11b**, **11c**, and **11e** were obtained in high yields as shown in Table 2.

*Preparation of Dialkyl Hydrogen Phosphates (**5**) from Dialkyl 2-Chloromethyl-4-nitrophenyl Phosphates (**11**). A Typical Procedure*: A solution of *n*-pentyl cyclohexyl 2-chloromethyl-4-nitrophenyl phosphate (**11e**) (4.20 g, 0.01 mol) in 12 m*l* of aqueous pyridine (30% solution) was allowed to stand at room temperature for 2 days and then heated at 90°C for 3 hr. The reaction mixture was concentrated to dryness. Ethanol (30 m*l*) was added and pale yellowish precipitate, inner salt of 1-(2-hydroxy-5-nitrobenzyl)pyridinium hydroxide (2.35 g, 88%) separated and was filtered off. The filtrate was concentrated and the residue was dissolved in 30 m*l* of water. The aqueous solution was acidified with hydrochloric acid and extracted with three 30 m*l* portions of petroleum ether (bp 45—60°C). The extracts were combined and washed with three 10 m*l* portions of water and dried over anhydrous sodium sulfate. After removal of petroleum ether, *n*-pentyl cyclohexyl hydrogen phosphate (**5n**) (2.15 g, 86%) was obtained as colorless oil, R_f 0.85; n_D^{22} 1.4552.

Found: C, 53.30, H, 8.61%. Calcd for $C_{11}H_{23}O_4P$: C, 52.79; H, 9.26%.

In a similar manner, the other dialkyl hydrogen phosphate (**5**), such as **5p**, **5a**, **5b**, and **5c** were prepared as shown in Table 3.

*Isolation of an Intermediate 1-(2-Diethyl Phosphoroxy 5-Nitrobenzyl)pyridinium Chloride (**12p**).* A solution of diethyl 2-chloromethyl-4-nitrophenyl phosphate (**11p**) (3.24 g, 0.01 mol) in 8.0 m*l* of dry pyridine was allowed to stand at room temperature for 3 days. After addition of acetone (40 m*l*), yellowish precipitate, **12p** was separated and was collected by filtration. It was recrystallized from a mixture of ethanol (4 m*l*) and acetone (15 m*l*) to afford a pure sample (1.65 g, 43%) as pale yellowish prisms; mp 191°C dec., $\lambda_{max}^{H_2O}$ 262 mμ (ε: 10700), 267 mμ (ε: 10700), 289 mμ (ε: 10500); R_f 0.61.

Found: C, 50.03; H, 5.65; N, 7.46%. Calcd for $C_{16}H_{21}N_2O_7P$: C, 50.00; H, 5.51; N, 7.29%.

We wish to thank Mr. Masaru Koezuka for his help with elemental analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 235—239 (1971)

Synthesis and Elimination Reaction of *O*-Methyl Derivatives of Methyl (Methyl α-D-Glucopyranosido)uronate

Hironobu HASHIMOTO, Takeshi SEKIYAMA, Hideo SAKAI, and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 4, 1970)

Several methyl ethers [2,3,4-tri-*O*-methyl- (**1**), 4-*O*-methyl- (**2**), 3-*O*-methyl- (**3**), and 2-*O*-methyl- (**4**)] of methyl (methyl α-D-glucopyranosido)uronate were used as model compounds for the examination of β-elimination reaction. **1** was purely synthesized from methyl α-D-glucopyranoside and both **3** and **4** were newly synthesized *via* the corresponding methyl ethers of methyl α-D-glucopyranoside. The condition of β-elimination reaction was examined using **1** as a model compound. It was shown that β-elimination reaction occurred only when an alkoxide was used as a base. The yield of the unsaturated product, *i. e.*, methyl (methyl 4-deoxy-2,3-di-*O*-methyl-β-L-*threo*-hex-4-enopyranosido)uronate (**13**) was about 40—50% by sodium methoxide in methanol at 60—70°C, and 70—80% by potassium *t*-butoxide in *t*-butyl alcohol even at room temperature. In both cases the reaction was completed within several minutes. The β-elimination reaction was followed by UV spectra using the molecular extinction coefficient of purely isolated **13**, and the reaction products were examined by gas-liquid chromatography. The β-elimination product of **2** was also obtained in good yield, but that of **3** in very poor yield.

The selective cleavage of a certain glycosidic bond in heteropolysaccharides is essential for the sequential elucidation of compositional monosaccharides. For this the enzymatic cleavage is often used, but the desired enzyme is not easily available. The development of some chemical method has for long been a subject of interest.

Recently the selective cleavage of glycosidic bonds around uronic acid residues has been investigated in polyuronides and polysaccharides containing uronic acids. One investigation was carried out on the selective cleavage of glycosidic bonds by utilizing the β-elimination reaction in alkali.[1,2] Another was carried out on the selective cleavage of glycuronosyl bonds by acid hydrolysis after the Hofmann degradation of uronic

1) C. W. McCleary, D. A. Rees, J. W. B. Sammel, and I. W. Steele, *Carbohyd. Res.*, **5**, 492 (1967).

2) C. J. Lawson, C. W. McCleary, H. I. Nakada, D. A. Rees, I. W. Sutherland, and J. F. Wilkinson, *Biochem. J.*, **115**, 947 (1969).

acid amide residues, derived from uronic acid esters.[3]

It is well known that polyuronides such as pectin depolymerize in neutral or alkaline solution,[4] and this was applied to obtain a few depolymerized polysaccharides.[5] Thus, the β-elimination reaction seems to be useful for the structural analysis of naturally occurring uronic acid-containing polysaccharides. However, in aqueous solution the reaction proceeds only slightly owing to competing de-esterification, and the cleavage of the glycosidic bonds might occur only when they are 1→4 linkages to hexopyranuronoside structure.

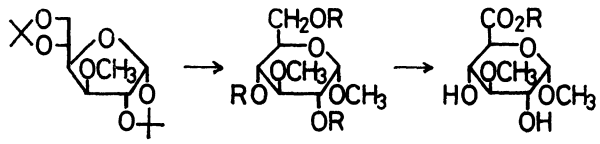
Heim and Neukom[6] reported that methyl (methyl α-D-galactopyranosido)uronate and methyl 4-*O*-(methyl α-D-galactopyranosyluronate)-(methyl α-D-galactopyranosido)uronate underwent the elimination reaction when treated with sodium methoxide in methanol, but details of the reaction were not presented. This reaction was applied by McCleary *et al.*[1] to partial depolymerization of 2-hydroxyethyl alginate, and recently by Lawson *et al.*[2] to structural analysis of colanic acid. On the other hand, Fujinaga and Matsushima[7] reported the degradation of methyl 4′,6′-*O*-ethylidene-β-pseudocellobiouronoside methyl ester by the treatment of hydrazine, conceivably due to β-elimination reaction.

For more efficient application of this β-elimination reaction to structural elucidation of uronic acid-containing polysaccharides, we examined the β-elimination reaction using several synthesized methyl ethers [2,3,4-tri-*O*-methyl- (**1**), 4-*O*-methyl- (**2**), 3-*O*-methyl- (**3**), and 2-*O*-methyl- (**4**)] of methyl (methyl α-D-glucopyranosido)uronate as model compounds. Possibility of a further cleavage of 1→2 glycosidic bond by δ-elimination reaction of once formed unsaturated compounds as shown in the case with picroclocin[8] was also examined.

Results and Discussion

Methyl (methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranosido)uronate (**1**) was synthesized by the method of Jones[9] from D-glucurono-6,3-lactone. This was fairly contaminated with β-anomer, which was ascertained by gas-liquid chromatography and NMR spectrum. **1** was synthesized purely from methyl α-D-glucopyranoside by catalytic oxidation and methylation in the usual manner.

Methyl (methyl 4-*O*-methyl-α-D-glucopyranosido)-uronate (**2**) was synthesized by the method of Wacek.[10] Methyl (methyl 3-*O*-methyl-α-D-glucopyranosido)uronate (**3**) newly synthesized as shown in Fig. 1. 1,2:



5 6, R = H 8, R = H
7, R = Ac 3, R = CH3

Ac=acetyl

Fig. 1

5,6-Di-*O*-isopropylidene-3-*O*-methyl-α-D-glucofuranose (**5**)[11] was converted to syrupy methyl 3-*O*-methyl-α-D-glucopyranoside (**6**) by refluxing in methanolic hydrogen chloride for 20 hr. In order to purify by distillation, acetylation of **6** was performed, and deacetylation and catalytic oxidation were carried out in one step.

Methyl (methyl 2-*O*-methyl-α-D-glucopyranosido)-uronate (**4**) was also newly synthesized from 3-*O*-benzyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose,[12] which was methanolized by refluxing in methanolic hydrogen chloride to give syrupy methyl 3-*O*-benzyl-α-D-glucopyranoside. This was converted to 4,6-*O*-benzylidene derivative (**9**), and then to 2-*O*-methyl derivative (**10**) in the usual manner. **10** was debenzylidenated and debenzylated by catalytic hydrogenolysis to give syrupy methyl 2-*O*-methyl-α-D-glucopyranoside (**11**),[13] and **11** gave methyl 2-*O*-methyl-α-D-glucopyranosidouronic acid (**12**) by catalytic oxidation, which was converted to its methyl ester (**4**) with diazomethane (Fig. 2). The

anomeric configuration of all synthesized *O*-methyl derivatives of methyl (methyl D-glucopyranosido)uronate was ascertained to be α by NMR spectra and optical rotations. However, in the case of **3** and **4** slight contamination with β-anomer was observed (*ca.* 10%), because the glycosidation products could not be crystallized.

First of all, the condition of the β-elimination reaction was examined using **1** as a model compound in some basic mediums, *i. e.*, aqueous solutions containing sodium hydroxide or sodium carbonate, or alcoholic solutions containing sodium hydroxide or sodium methoxide. The expected elimination reaction was observed only when sodium methoxide was used as a base. In other cases it was observed by thin-layer chromatography

that methyl uronate were converted to the corresponding sodium uronates and no elimination was observed.

The elimination reaction was followed by measurement of the NMR and UV spectra at suitable intervals. As the elimination reaction proceeded, in NMR spectra measured in CD_3ONa/CD_3OD a signal assigned to the vinyl proton appeared, whose intensity increased to a certain maximum value and then decreased slowly. This is attributed to the exchange between hydrogen and deuterium. Thus the intensity of the vinyl proton was unsuitable for quantitative discussion. In UV spectra, the absorption of α,β-unsaturated ester appeared at 235—240 mμ, and the optical density at this wavelength increased. The elimination reaction was followed by UV spectra in a suitable solvent.

In order to determine the molecular extinction coefficient of the elimination product, *i. e.*, methyl (methyl 4-deoxy-2,3-di-*O*-methyl-β-L-*threo*-hex-4-enopyranosido)uronate (**13**), its isolation was attempted. **1** was treated with sodium methoxide in methanol and refluxed for 45 min. The reaction mixture was treated with a strongly acidic resin (Amberlite IR-120 H-form) and evaporated to give a slightly yellowish syrup. **13** was obtained in about 35% yield by distillation of the syrup. The structure was ascertained by UV, IR and NMR spectra (Fig. 3).

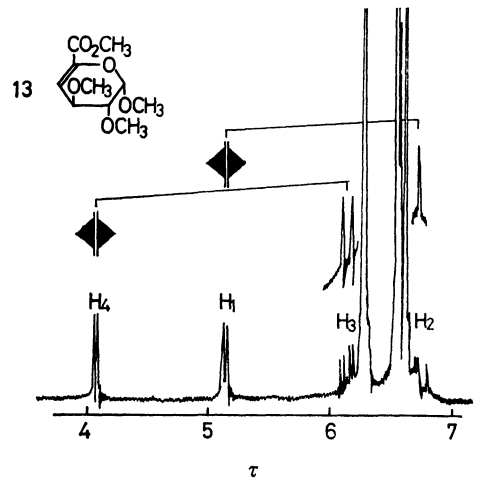

Fig. 3. NMR spectrum of **13** (100 MHz, in CCl_4).

The elimination reaction was carried out with sodium methoxide in methanol at 60—70°C and the optical density at 238 mμ was measured after partial neutralization of the reaction mixture with ethanolic hydrogen chloride. The amount of **13** was then calculated by using the molecular extinction coefficient of **13** (ε_{max}= 5500). Under these conditions the yield of **13** was about 40% (Fig. 4, curve 1). However, this increased to about 55% by direct addition of sodium to a methanol solution of **1** (Fig. 4, curve 2). The yield of the elimination product of **2** was also 50% under the same conditions (Fig. 4, curve 3). In these cases the reaction proceed to completion within 5 min. The yield could not be increased by elongation of the reaction time and elevation of the reaction temperature.

A more effective and moderate reaction condition was sought by using a stronger base, potassium *t*-

7: **13**, *t*-C_4H_9OK

butoxide. The reaction was carried out with freshly prepared potassium *t*-butoxide in freshly distilled *t*-butyl alcohol and the amount of **13** formed by the elimination reaction was determined by the optical density at 238 mμ after neutralization with ethanolic hydrogen chloride and dilution with ethanol. As shown in Fig. 4, the elimination reaction proceeded instantaneously even at room temperature and in a few minutes reached about 70—80% (curves 4 and 5). This reaction limit was not altered by elongation of the reaction time and heating. It is noteworthy that the yield decreased in about 40—50%, when stored *t*-butyl alcohol for a few days after distillation was used (curve 6). In order to investigate the nature of the reaction in detail, the reaction mixture was examined by gas-liquid chromatography after neutralization. As shown in Fig. 5, three peaks appeared in the chromatogram. The first and smallest peak was identified as the starting material (**1**),

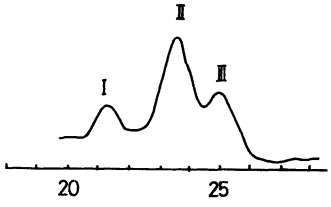

Fig. 5. Gas-liquid chromatogram of reaction mixture of **1**.

II: **13**

the second and largest one as a mixture of methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranosidouronic acid and methyl 4-deoxy-2,3-di-*O*-methyl-β-L-*threo*-hex-4-enopyranosidouronic acid (de-esterified **1** and **13**), and the last as **13**. It is remarkable that the ester groups of both the unchanged starting material and reaction product were partially hydrolyzed during the reaction. Comparing the result of the treatment of **13** with potassium *t*-butoxide in *t*-butyl alcohol (Fig. 6), it is suggested that the elimination reaction did not proceed completely, because of hydrolysis of a certain part of the starting material. Such hydrolysis took place probably by the moisture introduced during the operation.

No marked peak, other than the above mentioned three peaks, was detected, which suggests that the δ-elimination reaction did not occur. Both at room and elevated temperature no component other than **13** and its de-esterified derivative was detected in the reaction mixture by gas-liquid chromatography (Fig. 6). This was also ascertained by the fact that the optical density at 238 mμ of **13** was not altered by treatment with potassium *t*-butoxide (Fig. 4, straight line 7).

The elimination reaction of the synthesized model compound **2** and **3** was then attempted. It is predicted that water liberated as the reaction proceeds inhibits the elimination reaction by de-esterification. After treatment with potassium *t*-butoxide in *t*-butyl alcohol for 10 min at room temperature the reaction solution was passed through the column packed with an acidic resin. The syrup obtained by evaporation of the solvent was purified once or twice on an alumina column. However, a small amount of impurity detected in NMR spectra was involved in both products. Although methyl (methyl 4-deoxy-β-L-*threo*-hex-4-enopyranosido)uronate (**14**) was obtained from **2** in very good yield (80%), from **3** de-esterified methyl 4-deoxy-3-*O*-methyl-β-L-threo-hex-4-enopyranosidouronic acid (**15**) was obtained in every low yield (a few %). The low yield of **15** will be attributed to adsorption on the alumina column, since its formation in about 20—30% was estimated by UV spectra.

Experimental

Melting points are uncorrected. Specific rotations were measured with a Carl Zeiss LEP Al polarimeter and a 0.2 dm tube. The IR spectra were recorded with a Hitachi Model EPI-GS grating IR spectrophotometer. The NMR spectra were recorded at 100 MHz with a Japan Electron Optics JNM 4H-100 spectrometer for solutions in suitable solvents such as $CDCl_3$, CCl_4, and CD_3OD containing tetramethylsilane as the internal standard. The UV spectra were recorded with a Hitachi Perkin-Elmer 139 spectrophotometer and a Hitachi Model EPS-3T recording spectrophotometer. Thin-layer chromatography was performed with Wako gel G-O and the solvent system [A: ethyl acetate - acetic acid - formic acid - water (18 : 3 : 1 : 4), B: *n*-butanol - acetic acid - water (4 : 1 : 5), C: chloroform - methanol - acetic acid (9 : 1 : 1)]. Gas-liquid chromatography was performed with a Hitachi Model K-53 gaschromatograph using a column (1 m) packed with butanediol succinate (20%) on Chromosorb WAW (60—80 mesh) at 150—190°C.

General Method of Methylation. Methylation was carried out by the methods of Purdue and Irvine,[14] and Kuhn *et al.*[15] To a solution of starting material in chloroform or dimethylformamide was added silver oxide (1.2 parts), Drierite (15—20 g/100 m*l* of solvent), and finally methyl iodide dropwise under stirring and cooling in an ice-bath. Stirring was continued at room temperature for 2—4 days in the dark and the undissolved materials were filtered off. Evaporation of the filtrate gave methylated derivative.

General Method of Catalytic Oxidation. Into a suspended solution of starting material and the same amount of 10% platinum-charcoal or palladium-charcoal in water was bubbled oxygen (1.5—2.0 atm) at 80—100°C under vigorous stirring. The pH-value of the solution was maintained between 6 and 8 by addition of a sodium hydrogencarbonate solution during the reaction. After disappearance of the spot of the starting material on thin-layer chromatography, *i.e.*, after 20—30 hr, the catalyst was filtered off and the filtrate was evaporated to give the corresponding sodium uronate. The free uronic acid derivative was obtained by treatment of this salt on a column packed with Amberlite IR-120 or Dowex 50 W×8 (H-form).

Methyl (Methyl 2,3,4-Tri-O-methyl-α-D-glucopyranosido)uronate (1). *Method (A)*: This compound was synthesized by the method of Jones *et al.*[9] from D-glucurono-6,3-lactone. Bp 88—90°C/0.05 mmHg, $[\alpha]_D^{23}$ +87° (*c* 1.0, methanol); lit,[9] bp 120°C/0.02 mmHg, $[\alpha]_D$ +84° (*c* 1.0, methanol).

Method (B): Methyl α-D-glucopyranoside (12.4 g) was catalytically oxidized to give methyl α-D-glucopyranosidouronic acid, which was methylated by the method of Kuhn *et al.*[15] to give **1** in 35% yield (5.6 g). Bp 94—97°C/0.18 mmHg, $[\alpha]_D^{23}$ +140° (*c* 1.2, methanol).

Found: C, 50.33; H, 7.46%. Calcd for $C_{11}H_{20}O_7$: C, 49.99; H, 7.63%.

Methyl (Methyl 4-O-Methyl-α-D-glucopyranosido)uronate (2). This compound was synthesized by the method of Wacek.[10] Bp 140°C/0.15 mmHg, $[\alpha]_D^{23}$ +135° (*c* 1.0, methanol); lit,[10] bp 130—140°C/0.6 mmHg, $[\alpha]_D$ +145° (methanol).

Methyl (Methyl 3-O-Methyl-α-D-glucopyranosido)uronate (3). Methyl 2,4,6-tri-*O*-acetyl-3-*O*-methyl-α-D-glucopyranoside[16] (**7**, 5.0 g) was converted by catalytic oxidation to syrupy methyl 3-*O*-methyl-α-D-glucopyranosidouronic acid (**8**), which was treated with methanolic hydrogen chloride overnight. After evaporation of the solvent, the residual syrup was distilled to give **3** in 68% yield (2.4 g). Bp 137°C/0.07 mmHg,

$[\alpha]_D^{23}$ +98.5° (*c* 1.1, methanol).

Found: C, 45.97; H, 7.09%. Calcd for $C_9H_{16}O_7$: C, 45.76; H, 6.83%.

Methyl 3-O-Benzyl-4,6-O-benzylidene-α-D-glucopyranoside (9). 3-*O*-Benzyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose[12] (30 g) was dissolved in methanol containing 3% hydrogen chloride (200 m*l*) and the solution was refluxed for 20 hr. After neutralization with barium carbonate, undissolved material was filtered off and the filtrate was evaporated to dryness. The resulting syrup was benzylidenated with benzaldehyde and anhydrous zinc chloride in the usual manner. The crude product was crystallized from ethanol. Yield, 9.2 g (29%), mp 172—174°, $[\alpha]_D^{23}$ +30.4° (*c* 1.1, methanol).

Found: C, 67.55; H, 6.58%. Calcd for $C_{21}H_{24}O_6$: C, 67.73; H, 6.50%.

Methyl 3-O-Benzyl-4,6-O-benzylidene-2-O-methyl-α-D-glucopyranoside (10). **9** (9.0 g) was methylated by the method of Purdue and Irvine.[14] Yield, 7.8 g (83%), mp 103—104°C, $[\alpha]_D^{28}$ +16.7° (*c* 1.5, ethanol).

Found: C, 68.63; H, 7.00%. Calcd for $C_{22}H_{26}O_6$: C, 68.63; H, 6.78%.

Methyl (Methyl 2-O-Methyl-α-D-glucopyranosido)uronate (4). Methyl 2-*O*-methyl-α-D-glucopyranoside[13] (**11**, 4.4 g), which was obtained by catalytic hydrogenolysis of **10**, was catalytically oxidized in the presence of platinum-charcoal to give syrupy methyl 2-*O*-methyl-α-D-glucopyranosidouronic acid (**12**). **12** was esterified with diazomethane in ether - methanol. After evaporation of the solvent the residual syrup was distilled to give **4** in 33% yield (1.6 g). Bp 152°C/0.095 mmHg, $[\alpha]_D^{28}$ +98° (*c* 1.0, methanol).

Found: C, 45.17; H, 6.69%. Calcd for $C_9H_{16}O_7$: C, 45.76; H, 6.83%.

Methyl (Methyl 4-Deoxy-2,3-di-O-methyl-β-L-threo-hex-4-enopyranosido)uronate (13). **1** (5.2 g) was dissolved in methanol containing 1.5 N sodium methoxide (30 m*l*). After refluxing for 45 min the reaction mixture was treated with Amberlite IR-120 (H-form) and evaporated to dryness. The residual syrup was distilled to give **13** in 35% yield (1.6 g). Bp 75—82°C/0.03 mmHg, $[\alpha]_D^{28}$ +189° (*c* 1.0, methanol), IR (NaCl, cm^{-1}): 2940, 1725, 1645, UV (ethanol, mμ): 238 (ε=5500), NMR (CCl_4, τ): 4.07 (d, H_4), 5.13 (d, H_1), 6.13 (q, H_3), 6.68 (q, H_2), 6.27 (s, CO_2CH_3), 6.54, 6.55, 6.61 (three s, OCH_3), $J_{1,2}$ 2.0 Hz, $J_{2,3}$ 7.5 Hz, $J_{3,4}$ 2.5 Hz (see also Fig. 3).

Found: C, 51.24; H, 6.84%. Calcd for $C_{10}H_{16}O_6$: C, 51.72; H, 6.94%.

Methyl (Methyl 4-Deoxy-β-L-threo-hex-4-enopyranosido)uronate (14). To a solution of **2** (3 g) in *t*-butyl alcohol (20 m*l*) was added quickly potassium (680 mg) in *t*-butyl alcohol (50 m*l*) under nitrogen stream. After being shaken gently for 10 min the reaction mixture was neutralized with methanolic hydrogen chloride and evaporated under reduced pressure at room temperature. The residual syrup was dissolved in a small amount of methanol and evaporated. The resulting syrup was then dissolved in ethanol and undissolved potassium chloride was filtered off. Evaporation of the filtrate gave crude **14**. Purification was performed on an alumina column (30 g) by elution with petroleum ether - ethanol (95 : 5, 400 m*l*) and then with methanol - water (7 : 3, 50 m*l*). Evaporation of the latter eluate gave **14** in about 80% yield (2.2 g). $[\alpha]_D^{28}$ +184° (*c* 1.0, methanol), IR (NaCl, cm^{-1}): 3400, 1725, 1645, UV (ethanol, mμ): 238 (ε=4600), NMR ($CDCl_3$, τ): 3.97 (d, H_4), 4.97 (d, H_1), 6.22 (s, CO_2CH_3), 6.51 (s, OCH_3).

Found: C, 46.73; H, 6.14%. Calcd for $C_8H_{12}O_6$: C, 47.06; H, 5.92%.

Methyl 3-O-Methyl-4-deoxy-β-L-threo-hex-4-enopyranosidouronic Acid (15). To a solution of **3** (5 g) in *t*-butyl alcohol (20 m*l*) was added potassium (160 mg) in *t*-butyl alcohol (6 m*l*) under nitrogen stream. After standing at room temperature for 10 min the reaction mixture was treated with Amberlite IR-120 (H-form) to remove potassium ions. The syrup obtained by evaporation of the solvent was purified on an alumina column (100 g) by elution with petroleum ether - ethanol (95 : 5, 300 m*l*). Evaporation of the eluant gave crude **15** (40 mg), which was purified once more on the alumina column to give **15** in very low yield (22 mg). Elemental analysis could not be carried out but the structure was ascertained by spectral data. $[\alpha]_D^{28}$ +170° (*c* 1.0, ethanol), IR (NaCl, cm^{-1}): 3450, 1725, 1645, UV (ethanol, mμ): 238 (ε=4100), NMR ($CDCl_3$, τ): 3.97 (d, H_4), 5.03 (d, H_1), 6.42, 6.51 (two s, OCH_3).

Examination of β-Elimination Reaction in Some Basic Mediums. 1) By UV Spectra: The following three kinds of alkali solution of **1** were heated in sealed tubes at 60—95°C for about 1 hr. (a) 0.02N and 2.0N sodium carbonate aqueous solution, 0.02N, 0.5N and 2.0N sodium hydroxide aqueous solution, (b) 1.3N sodium hydroxide in ethanol, (c) 1.5N sodium methoxide in methanol. After neutralization with 1N hydrochloric acid or ethanolic hydrogen chloride the UV spectrum of the reaction solution was measured.

2) By NMR spectra: NMR spectrum was measured only in the case of (c). The reaction was carried out in an NMR measuring tube using CD_3ONa in CD_3OD as a base.

β-Elimination Reaction of 1. 1) By Sodium Methoxide in Methanol: The elimination reaction was carried out in two different ways. *Method (A)*: A solution of **1** (1.6×10^{-2}mol/*l*) and sodium methoxide (2.7N) in methanol were prepared separately. 1 m*l* of each solution was mixed in a glass tube and sealed quickly. After heating in a water bath at 70°C the tube was cooled with tap water and the reaction solution was acidified and diluted to exactly 5 m*l* with ethanolic hydrogen chloride (about 0.4N). The solution was centrifuged with 7000—8000 rpm for 10 min at 0°C and the optical density at 238 mμ was measured after dilution of the supernatant with ethanol (Fig. 4, curve 1).

Method (B): To 1 m*l* of a methanol solution of **1** (1.6×10^{-2} mol/*l*) in a glass tube (0.8×20 cm), which was previously heated at 60°C in a mantle heater, a piece of sodium (18 mg) was added. While the piece of sodium dissolved in the methanol, the reaction solution was refluxed. The reaction temperature was then maintained at 64°C by refluxing in an open tube or by heating in a sealed tube. The UV spectra were measured in the same manner as above mentioned.

2) By Potassium t-Butoxide in t-Butyl Alcohol: A solution of **1** and **13** (1.4×10^{-1} mol/*l*) and potassium *t*-butoxide (0.37N; curves 4, 6 and straight line 7 and 0.56N; curve 5) in *t*-butyl alcohol were prepared separately. The same amount of each solution was mixed as quickly as possible. 0.01 m*l* of the reaction solution was pipetted at suitable intervals and the UV spectra were measured after dilution with ethanolic hydrogen chloride to 5 m*l*.

The Ruthenium-Catalyzed Hydrogenation of Aromatic Amines Promoted by Lithium Hydroxide

Shigeo NISHIMURA, Yutaka KONO, Yoshiharu OTSUKI, and Yoshio FUKAYA

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei-shi, Tokyo

(Received August 6, 1970)

The effects of the addition of various alkaline substances on the ruthenium-catalyzed hydrogenation of aromatic amines have been investigated at raised temperature and pressure. The addition of lithium hydroxide was shown to be the most effective for rapid and selective hydrogenation of aromatic amines. The effect of various solvents on the hydrogenolysis of carbon-nitrogen bonds has also been studied in the hydrogenation of *m*-xylene-α,α′-diamine and *N*,*N*-dimethyl-*p*-phenylenediamine. Generally, the hydrogenation was fast and the amount of the hydrogenolysis was small in secondary alcohols. Typical examples of the syntheses of alicyclic amines are given.

It was previously shown that the ruthenium-catalyzed hydrogenation of aniline is promoted by the addition of small amounts of alkalies which not only depress the formation of dicyclohexylamine but also eliminate a strong inhibitory action of the ammonia produced along with the secondary amine.[1]

Subsequently, the effect of the addition of various alkaline substances has been compared in the hydrogenation of some aromatic amines over ruthenium catalysts, and it has been found that the addition of lithium hydroxide in fairly large amounts is the most effective for rapid and selective hydrogenation of aromatic amines. The effect of solvents on the hydrogenolysis of carbon-nitrogen bonds has also been studied in the hydrogenation of *m*-xylene-α,α′-diamine and *N*,*N*-dimethyl-*p*-phenylenediamine which are both known liable to the hydrogenolysis rather readily.[2,3]

Experimental

Materials. The aromatic amines hydrogenated were carefully purified by distillation at reduced pressure, if necessary, under the atmosphere of nitrogen. Aniline, bp 79°C/20 mmHg; *o*-toluidine, bp 90°C/18 mmHg; *N*,*N*-dimethylaniline, bp 85°C/19 mmHg; *N*,*N*-dimethyl-*p*-phenylenediamine, bp 143.5—144.5°C/21 mmHg, mp 36—37°C; *m*-xylene-α,α′-diamine, bp 130—131°C/4 mmHg, n_D^{20} 1.5707; *p*-xylene-α,α′-diamine, bp 157°C/21.5 mmHg, mp 52—54°C; 4,4′-methylenedianiline, bp 170—172°C/6 mmHg, mp 92—93°C. These amines were of commercial preparations except *p*-xylene-α,α′-diamine.

p-Xylene-α,α′-diamine was prepared by hydrogenation of terephthalonitrile (25 g) with rhodium hydroxide catalyst (0.3 g) and lithium hydroxide (0.4 g) in 100 m*l* ethanol at 85°C under the hydrogen pressure of 70—100 kg/cm² for 1.5 hr (70% yield).

Catalysts. The ruthenium hydroxide catalyst was prepared by adding a slight excess of lithium hydroxide solution to a hot aqueous ruthenium chloride. The ruthenium-carbon catalyst (5% Ru) was obtained from the Nippon Engelhard Co.

Hydrogenation. All hydrogenations were carried out in stainless steel bombs with stirrers driven magnetically. The catalyst, the additive, the substrate, and then the solvent, if necessary, were put into the bomb. Sodium and potasssium hydroxides were added in a 10% solution. The other alkaline substances were added in fine powder. The reaction temperature was controlled within 0.5°C by immersing the bomb in an oil bath maintained at a constant temperature.

Analysis of the Products. The hydrogenation product was analyzed directly by gas chromatography (column: PEG 6000-KOH on Chromosorb W). The product was also isolated by distillation after removing most of the catalyst by filtration, if necessary with addition of ether to the reaction mixture.

Results and Discussion

The effect of the addition of three alkalies is compared in Table 1 in the hydrogenation of aniline with ruthenium hydroxide catalyst. It is seen from the Table that aniline is hydrogenated most rapidly when lithium hydroxide was added in the amounts more than 30 mg (as monohydrate) to 65 mg of the catalyst. The stronger alkalies, sodium and potassium hydroxides, greatly depressed the rate of the hydrogenation even when added in the amount less than 10% of the weight of the catalyst. Aniline was hydrogenated fairly rapidly even when no alkali was added. This is probably due to the promotion by a small amount of the alkali which was contaminated into the catalyst during its preparation.[4]

Table 1. Effect of added alkalies on the hydrogenation of aniline[a]

Alkali added	mg	Reac. time (hr)	Aniline hydrogenated (%)
None	—	2.5	90
$LiOH \cdot H_2O$	10	2.5	94
$LiOH \cdot H_2O$	30	2.5	99
$LiOH \cdot H_2O$	50	2.5	100
$LiOH \cdot H_2O$	100	2.5	99
NaOH	3	2.5	90
NaOH	6	2.5	73
KOH	6	2.5	30

a) Aniline (65 g) was hydrogenated with 65 mg of the ruthenium hydroxide catalyst at 110°C under the hydrogen pressure of 70—100 kg/cm².

a) *o*-Toluidine (25 g) was hydrogenated at 110°C under the hydrogen pressure of 70—100 kg/cm².
b) Based on the *o*-toluidine converted.
c) The hydrogenation almost stopped.

In Table 2 the effects of the addition of alkali and alkaline-earth metal hydroxides and sodium carbonate are compared in the hydrogenation of *o*-toluidine where differences in the effect are more clearly seen than in the case of aniline. The hydrogenation was also the most rapid in the presence of lithium hydroxide. The addition of lithium hydroxide is also the most effective to suppress the formation of secondary amine and accordingly 2-methylcyclohexylamine is formed in the highest yield under the promotion of lithium hydroxide. When other bases or no base were added, it was difficult to complete the hydrogenation within a reasonable time and the formation of secondary amine increased. The addition of lithium hydroxide was also effective in the hydrogenation over a ruthenium-carbon catalyst as seen in Table 2.

a) *m*-Xylene-α,α′-diamine was hydrogenated with 30 mg of the ruthenium hydroxide catalyst in 10 m*l* of isopropyl alcohol at 120°C under the hydrogen pressure of 70—100 kg/cm².
b) Given by mol (*m*-methylbenzylamine + 1-aminomethyl-3-methylcyclohexane + 2 × *m*-xylene) × 100/mol (*m*-XD converted).

The effect of three alkalies added in various amounts on the hydrogenation of *m*-xylene-α,α′-diamine (*m*-XD) is shown in Table 3. In contrast to the hydrogenation of aniline and *o*-toluidine, the addition of a small amount of potassium hydroxide was more effective in this hydrogenation than the addition of sodium hydroxide. The same tendency was also observed in the hydrogenation of benzylamine.[5] Figure 1 illustrates the decrease in the rate during the course of hydrogenation of *m*-XD as a function of conversion, when each alkali was added in its optimum amount. It is clearly seen that the decrease in the rate is the least in the presence of lithium hydroxide. This result becomes important when the hydrogenation is performed in a larger substrate to catalyst ratio (see Expts. 14 and

and 15 in Table 3). The hydrogenation of *m*-XD may be accompanied by the hydrogenolysis of the benzyl-nitrogen bond, with formation of *m*-methylbenzylamine, 1-aminomethyl-3-methylcyclohexane and *m*-xylene.[2] The addition of alkalies was found also effective to suppress the hydrogenolysis as seen from the results shown in Table 3. In particular, the addition of lithium hydroxide is seen very effective for this purpose, since the amount of the hydrogenolysis was only 2.1% even in the hydrogenation of a larger amount of the substrate (Expt. 14 in Table 3). *N,N*-Dimethyl-*p*-phenylenediamine (DMP) is also known to be liable to an extensive hydrogenolysis of the dimethylamino group on hydrogenation.[3] Since the nature of the solvent may have a profound effect on the hydrogenolysis of a polar bond, as shown previously in the hydrogenation of *p*-anisidine,[6] the effect of various solvents on the hydrogenolysis of carbon-nitrogen bond has been studied on the hydrogenation of *m*-XD and DMP. The results are summarized in Table 4. It will be seen from the

c) Methylcyclohexane

results in the table that the proportion of the hydrogenolysis is smaller in higher primary alcohols, secondary and tertiary alcohols and methylcyclohexane. Among these solvents, secondary alcohols appear the most preferred ones, as the rate of hydrogenation is in most cases larger in secondary alcohols than in the other solvents mentioned. In Fig. 2 initial rates of the formation of hydrogenolysis products[6] in the hydrogenation of *m*-XD are plotted *versus* the reciprocal of the dielectric constant of the solvents in which hydrogenations were carried out. A similar dependence of the rates on the polarity of the solvents as observed in the hydrogenation of *p*-anisidine can be seen also in this hydrogenation, but the effect is much less pronounced than in the case of *p*-anisidine. Since differences in the rates of hydrogenolysis are rather small among the solvents, the proportion of hydrogenolysis seems to depend more on the variation of the rates of the hydrogenation with the solvents as shown in Fig. 3.

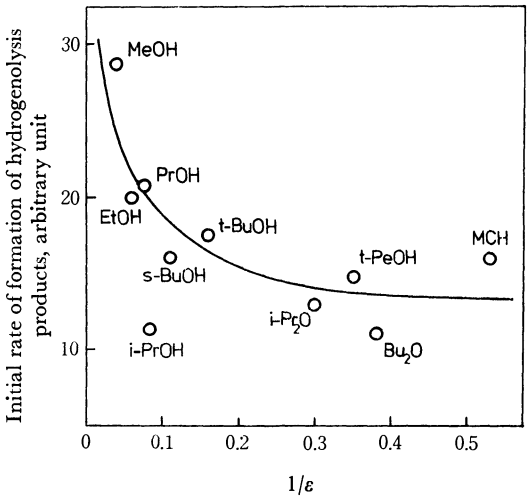

Fig. 2. Effect of solvents on the initial rates of formation of hydrogenolysis products as a function of the reciprocal of the dielectric constant of solvents (ε at 80°C) in the hydrogenation of *m*-xylene-α,α'-diamine with ruthenium hydroxide catalyst.

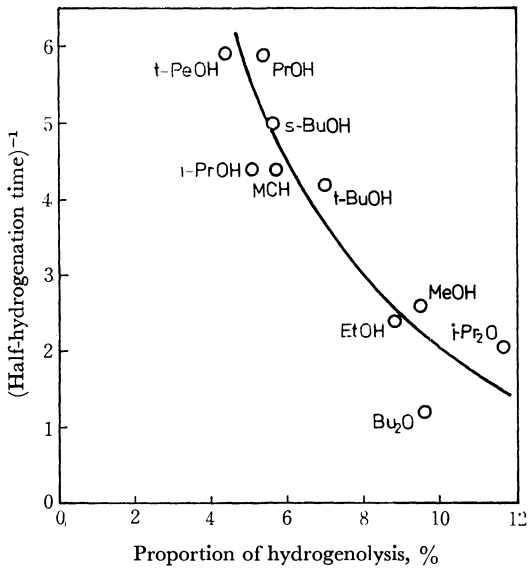

Fig. 3. Relation between proportion of hydrogenolysis and the rate of hydrogenation in the hydrogenation of *m*-xylene-α,α'-diamine with ruthenium hydroxide catalyst.

The results shown in Tables 1—3 and in Fig. 1 indicate that lithium hydroxide is the most effective promotor of the alkaline substances investigated in the ruthenium-catalyzed hydrogenation of aromatic amines. Since ruthenium is one of the most effective metals for the hydrogenation of aromatic amines,[7] the present im-

provement of the hydrogenation by the addition of lithium hydroxide offers a very useful general method of the synthesis of alicyclic amines from aromatic amines. Typical examples of the hydrogenation in preparative scales are listed in Table 5. It is seen that in most cases hydrogenations were completed within a few hours with use of only small portions of the catalyst to the substrate (0.1—0.7% as Ru hydroxide or 0.06—0.4% as Ru metal) and the corresponding alicyclic amines were obtained in excellent yields.[8)]

The authors are indebted to the Mitsubishi Chemical Industries Co., Ltd., for the analysis of the lithium in the catalyst and also for providing some of the aromatic amines and terephthalonitrile.

8) Lithium hydroxide added to or contained in the catalyst was shown also effective in the rhodium-catalyzed hydrogenation of nitriles and aromatic amines.[1,9,10)] However, the simple addition of lithium hydroxide appears not always effective as noticed in the hydrogenation of *p*-anisidine.[10)]

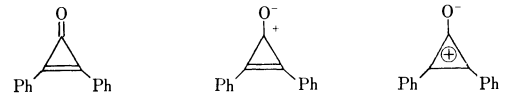
Cyclopropenones. IV. The Reactions of Diphenylcyclopropenone with Water, Carboxylic Acid, Phenol, and Amide

Fumio Toda, Toshiaki Kataoka, and Katsuhiko Akagi
Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama
(Received August 7, 1970)

The pyrolysis of diphenylcyclopropenone monohydrate (II) at 150°C afforded α-phenyl-*trans*-cinnamic anhydride (VI). It was proved that the reaction consists of two main steps, the nucleophilic attack of water on I to yield α-phenyl-*trans*-cinnamic acid (IV), and the reaction of I with IV, thus finally yielding VI. The same type of reaction as that of I with IV was also observed when I was heated in phenol to afford phenyl α-phenyl-*trans*-cinnamate (XII). The reaction of I with the weak nucleophilic reagent, α-phenyl-*trans*-cinnamamide (XIV), afforded a monoimino derivative of VI (XVI), which is believed to be produced by the nucleophilic attack of the amide-oxygen of XIV on the carbonyl-carbon of I.

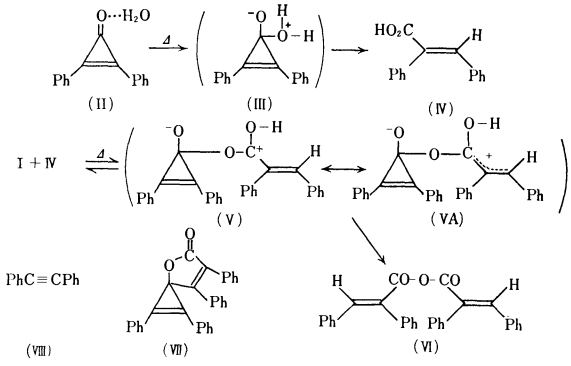
Since the first preparation of diphenylcyclopropenone (I) in 1959 by Breslow and his co-workers[1] and by Vol'pin and his co-workers,[2] independently, many reactions of I have been reported.[3] Because of the strongly polarized nature of the ketone,[4] to which the contribution of the IA and IB structures is considerable, the carbonyl carbon and the double bond of I cause a nucleophilic attack by various reagents. Although the reaction of I with a base such as aqueous sodium hydroxide,[4] hydroxylamine,[4] liquid ammonia,[5,6] aqueous ammonia,[7] primary amine,[6] aziridine,[8] and alkyllithium[9] has been reported, no reaction with acid has yet been done except the case in which I forms hydrobromide in crystalline forms.[2] The salt, however, can be decomposed by heating or by weak bases to give I again.[2]



(I) (IA) (IB)

We have found that I reacted with such acids as α-phenyl-*trans*-cinnamic acid (IV) and phenol at 150°C to give α-phenyl-*trans*-cinnamic anhydride (VI) and phenyl α-phenyl-*trans*-cinnamate (XII) respectively. We have also found that I reacted with a weak nucleophilic reagent, α-phenyl-*trans*-cinnamamide, and *N*-methylacetamide to afford a monoimino derivative of VI (XVI) and *N*-methyl-α-phenyl-*trans*-cinnamamide (XVII) respectively.

The heating of the monohydrate (II)[10] at 150°C for 32 hr afforded the anhydride VI, the cyclic dimer VII, and tolan (VIII) in 12.6, 14.1, and 23.9% yields respectively. The structure of VI (mp 117—118.5°C) was determined by a comparison of its electronic, infrared, and NMR spectral data with those reported in the literature for the anhydride (mp 113—117°C).[11] The spectral data of VII were identical with those recorded for the cyclic dimer[4] obtained in 40%, together with VIII (20%), by the pyrolysis of I at 145—150°C for 36 hr, to this dimer the structure VII has been assigned[4] provisionally. Since the heating of an equimolar mixture of I and IV at 150°C for 3 hr and 10 hr afforded VI in 25.4 and 55.5% yields respectively, IV must be the intermediate of the pyrolysis of II. The formation of IV from II can be interpreted in terms of the ketonization of the III initially produced by the attack of water on the carbonyl-carbon of I. The reaction of I with IV, of the same fashion as that of I and water, would give V as an intermediate.



Scheme 1

The ketonization and the ring-openning of V afford VI (Scheme 1). The contribution of the cation-delocalized structure (VA) to V, and the reversibility of the process of the formation of V from I and IV, are considerable, judging from the following observations. The heating of an equimolar mixture of I and α-phenyl-*cis*-cinnamic acid (IX) at 150°C for 27 hr afforded VI and the *trans*-acid IV in 35.4 and 31.6% yields respectively, but no recovered IX or *cis*-isomer of VI was detected. Since it is known that[12] the *trans*-acid

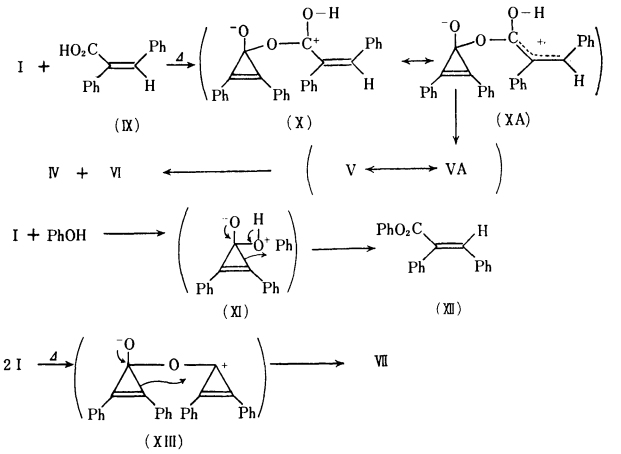
IV is more stable than *cis*-acid IX because of the much greater steric interaction between the phenyl and carboxylic group in IX than that between the two phenyls in IV, and since the heating of IX at 150°C for 34 hr gave recovered IX in almost a quantitative yield, the isomerization of IX into IV probably occurs during the course of the reaction of I and IX.

The above complete isomerization of the geometry around the carbon-carbon double bond both in the product, VI, and in the acid, IV, can be reasonably interpreted by assuming a reversible process and the contribution of the cation-delocalized structure (VA or XA), as has been described above. The intermediate, X, initially produced by the reaction of I and IX can be rearranged to V *via* the cation-delocalized structure, XA, in which a rotation around the carbon-carbon bond of the diphenylethylene part is possible for its increased single-bond nature, as is shown in Scheme 2.

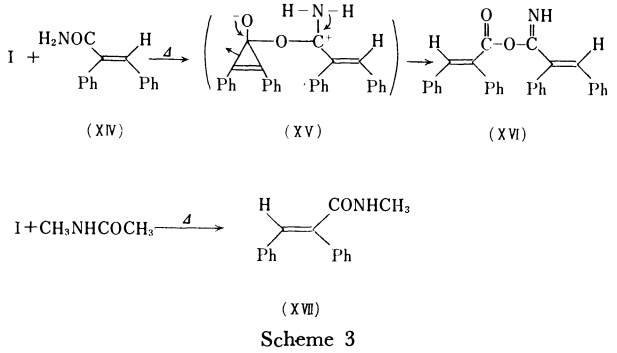


Scheme 2

The reaction of I with another carboxylic acid, such as *trans*-cinnamic acid or benzoic acid, gave no any acid anhydride. However, I reacted with phenol at 150°C for 26 hr to afford the ester XII in a 42% yield. The structure of XII was determined by a comparison of its spectral data with those of an authentic sample prepared according to the previously reported method.[13] The reaction probably proceeds *via* XI, which corresponds to V or X. Therefore, XIII is a possible intermediate of the thermal dimerization of I.

The observation that the oxygen of water, carboxylic acid (IV), and phenol react with I prompted us to investigate the reaction of I with several amides. Our attention was focussed on the question of which it was, the oxygen or the nitrogen of amide, which reacts with I. The heating of a mixture of I and an equimolar amount of the amide XIV at 150°C for 33 hr afforded XVI in a 4.2% yield, together with VIII (17.6%), recovered XIV (45%), and a small amount of an unidentified product, $C_{15}H_{13}ON$. The structure of XVI was determined by means of a study of the spectral data and by a base-catalyzed hydrolysis, which gave IV only. The electronic spectrum of XVI, 225 and 312 nm in ethanol, was comparable to that of VI, 223 and 300 nm in ethanol. The infrared spectrum of XVI in chloroform showed ν_{NH} $\nu_{C=O}$, and $\nu_{C=N}$ and/or $\nu_{C=C}$ at 3380, 1735, and 1615 cm^{-1} respectively, in addition to the strong ester absorption band at 1145 cm^{-1}. Since no absorption band of amide-II appeared in the 1600—1500 cm^{-1} region, and since the $\nu_{C=O}$ appeared at the field of frequencies higher than 1700 cm^{-1}, there is no possibility that XVI is amide or urea. The NMR spectral data, 1.88 (s, =CH, 1H), 2.10 (s, =CH, 1H), 2.86 (m, Ph, 20H), and 8.03 τ (s, =NH, 1H), which disappeared upon shaking with D_2O, also supported the structure of XVI.

The formation of XVI in the reaction of I with XIV shows that the reaction site of XIV is oxygen, not nitrogen, as is shown in Scheme 3. This result is reasonable, since the electron density on the oxygen of amide is higher than that of nitrogen because of the resonance, $-\overset{|}{N}-\overset{|}{C}=O \longleftrightarrow -\overset{|}{N}^{+}=\overset{|}{C}-O^{-}$. This result is also consistent with the fact that the protonation of amide in a solution occurs on its oxygen.[14-16] The *N*-alkyl derivative of XIV, however, did not react with I.



Scheme 3

Nevertheless, the reaction of I with *N*-methylacetamide under the same conditions as those employed for the above reaction showed a widely different mode, and the reaction product was *N*-methyl-α-phenyl-*trans*-cinnamamide (XVII). The structure of XVII was determined by a comparison of its spectral data with those of an authentic sample prepared from IV by the method described in the Experimental section. The product XVII can be derived formally by the attack of the methylamino group produced by the fission of the amide-bond of *N*-methylacetamide on I, in the same fashion as that shown in Schemes 1—3.

Experimental

All the melting points are uncorrected. The electronic spectra were measured on a Hitachi spectrophotometer, model 124. The infrared spectra were recorded on a spectrophotometer, IR-E, of the Japan Spectroscopic Co. The NMR spectra were recorded in deuteriochloroform on a Japan Electron Optics Laboratory H-100 spectrometer, TMS being used as the internal standard.

Materials. Diphenylcyclopropenone (I) was prepared according to the reported procedure;[4] mp 119—120°C (lit,[4] mp 119—121°C). Diphenylcyclopropenone monohydrate (II)

13) R. A. Nicolaus, *Ann. Chim. Applicata*, **39**, 542 (1949).

14) G. Fraenkel, A. Loewenstein, and S. Meiboom, *J. Phys. Chem.*, **65**, 700 (1961).

15) R. L. Gillespie and T. Birchall, *Can. J. Chem.*, **41**, 148 (1963).

16) S. J. Kuhn and J. S. Mclntyne, *ibid.*, **43**, 997 (1965).

was prepared according to the previously-reported method;[10] mp 87.5°C (lit,[10] mp 87.5°C). α-Phenyl-*trans*-cinnamic acid (IV) and α-phenyl-*cis*-cinnamic acid (IX) were prepared by the reported method.[12]

Pyrolysis of II. In an oil bath, II (2.2 g, 10 mmol) was heated at 150°C for 32 hr. After cooling, the crude product which had solidified was dissolved in ethanol (20 m*l*). An alcohol-insoluble crystalline solid was collected by filtration and recrystallized from ethanol to yield VI as colorless needles; yield, 0.27 g (12.6%); mp 117—118.5°C (lit,[11] mp 113—117°C). λ_{max}^{EtOH}: 223 (13400) and 300 nm (ε, 16000), IR (Nujol): 1715 and 1750 cm^{-1} (C=O), NMR: 2.23 (s, =CH, 2H) and 2.80 τ (m, Ph, 20H). The spectral data were identical with those reported for VI in the literature.[11]

The ethanol mother liquor remaining after the separation of VI was concentrated to dryness, and the residue was recrystallized from cyclohexane to afford VII; yield, 0.29 g (14.1%); mp 180—181°C (lit,[4] mp 181—182°C). The infrared and electronic spectra of VII thus obtained were identical with those of an authentic sample.[4] The evaporation of the solvent of the cyclohexane solution remaining after the removal of VII afforded tolan (yield, 0.45 g (23.9%)) after recrystallization from petroleum ether.

Reaction of I with IV. A mixture of I (0.5 g, 2.5 mmol) and IV (0.56 g, 2.5 mmol) was heated at 150°C for 3 hr. After cooling, the reaction mixture was recrystallized from ethanol to afford VI; yield, 0.28 g (25.4%). When the above mixture was heated at 150°C for 10 hr, 0.61 g (55.5%) of VI was isolated.

Reaction of I with IX. A mixture of I (0.7 g, 3.4 mmol) and IX (0.76 g, 3.4 mmol) was heated at 150°C for 27 hr. After cooling, the reaction mixture which had solidified was fractionated into the following two components by fractional recrystallization from ethanol: VI, 0.53 g (35.4%), and IV, 0.24 g (31.6%).

Reaction of I with Phenol. A mixture of I (2 g, 10 mmol) and phenol (2.8 g, 30 mmol) was heated at 150°C for 26 hr. After cooling, the crude product which had crystallized was recrystallized from cyclohexane to give XII; 1.68 % (42%); mp 138.5—139.5°C (lit,[13] mp 142—143°C). The infrared spectrum of the XII thus obtained in Nujol mull, 1725 (C=O), 1620 (C=C), and 1235, 1200, 1170, and 1155 cm^{-1} (ester), was identical with that of an authentic sample prepared according to the literature.[13]

Reaction of I with XIV. A mixture of I (3.0 g, 15 mmol) and XIV (3.36 g, 15 mmol) was heated at 150°C for 33 hr. After the mixture had cooled, cyclohexane (10 m*l*) was added. The crystals which separated out were collected by filtration and recrystallized from ethanol to afford XVI as colorless needles; 0.27 g (4.2%); mp 199—200°C. λ_{max}^{EtOH}: 225 (13000) and 312 nm (ε, 19500), IR ($CHCl_3$): 3380 (NH), 1736 (C=O), and 1145 cm^{-1} (ester), NMR: 1.88 (s, =CH, 1H), 2.10 (s, =CH, 1H), 2.86 (m, Ph, 20H), and 8.03 τ (s, =NH, 1H).

Found: C, 84.04; H, 5.34; N, 3.74%. Calcd for $C_{30}H_{23}O_2N$: C, 83.89; H, 5.40; N, 3.26%.

The heating of a solution of XVI in acetone-aqueous potassium hydroxide afforded IV.

The cyclohexane solution which remained after the removal of XVI was concentrated to dryness. Then the residue was chromatographed on alumina, using carbon tetrachloride as the solvent. From the fraction eluted with carbon tetrachloride, tolan (0.47 g (17.6%)) was obtained. From the fraction eluted with benzene, an unidentified product, $C_{15}H_{13}ON$, was isolated, 0.1 g; mp 161—163°C. From the fraction eluted with benzene - chloroform (1:1), XIV (1.51 g (45%)) was recovered.

Reaction of I with N-*Methylacetamide.* A mixture of I (1.5 g, 7.5 mmol) and *N*-methylacetamide (1.1 g, 15 mmol) was heated at 150°C for 40 hr. The crude product which solidified upon cooling was chromatographed on alumina, using carbon tetrachloride as the solvent. The fraction eluted with carbon tetrachloride was concentrated by distillation to afford tolan (0.38 g (28%)). From the fraction eluted with chloroform, XVII (0.14 g (7.9%)) was isolated, mp 166—167°C. λ_{max}^{EtOH}: 223 (8500) and 289 nm (ε, 12300), IR (Nujol): 1630 (C=O), 1610 (C=C), and 1540 cm^{-1} (amide-II), NMR: 2.68 (m, Ph, 10H), 3.13 (s, =CH, 1H), 4.06 (s, NH, 1H), and 7.23 τ (d, CH_3, 3H).

Found: C, 80.92; H, 6.30%. Calcd for $C_{16}H_{15}ON$: C, 80.98; H, 6.37%.

The spectral data of XVII were identical with those of an authentic sample (mp 165.5—167°C) prepared by the reaction of methylamine and α-phenyl-*trans*-cinnamoyl chloride derived from IV.

The authors wish to express their thanks to Mr. Kunio Ishibashi and Mr. Shoichi Kato for their elemental analyses, and to Miss Toshiko Matsutomo for her measurement of the electronic spectra.

Reactions of Metal Alkyl–Active Methylene Chelate Compounds with α,β-Unsaturated Carbonyl Compounds

Yusuke KAWAKAMI and Teiji TSURUTA

Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received August 10, 1970)

The method of the preparation of zinc (or aluminum) alkyl-active methylene chelate compounds was studied. The chelate compounds were identified mainly by NMR, IR, and component analysis. Zinc alkyl-active methylene chelate compounds were found to cause a Michael-type addition reaction with α,β-unsaturated esters or nitriles. Aluminum alkyl-active methylene chelate compounds exhibited lower reactivities than the zinc chelate compounds toward α,β-unsaturated carbonyl compounds. Kinetic studies of the addition reaction revealed that the reaction proceeded according to a first-order rate law with respect to both the metal compound and the α,β-unsaturated carbonyl compound. The effects of substituents on the metal atom as well as on the chelate ring were also studied. The intercorrelation among the chemical shift of the methine proton of the chelate ring, σ_p of the subsituents and the reactivity of metal alkyl-active methylene chelate compounds suggested that the rate of the addition reaction was governed mainly by the stability of the chelate ring.

In previous papers,[1-5] a series of studies of the reaction modes of metal alkyls, such as *n*-BuLi, *n*-BuMgBr, *n*-Bu_2Zn, and *n*-Bu_3Al, with α,β-unsaturated carbonyl compounds was reported. The reactivities of both metal alkyls and α,β-unsaturated carbonyl compounds were quantitatively determined. These studies were undertaken in order to elucidate the initiation mechanism in the anionic polymerization of α,β-unsaturated carbonyl compounds. In the course of our studies, we noticed some characteristic chemical behavior of the metal alkyl-active methylene compound system; this promoted us to study in more detail the structure and the reactivity of the metal alkyl-active methylene compound system in the reaction with α,β-unsaturated carbonyl compounds, and to compare them with those of simple metal alkyls in the reaction.

This paper will be concerned with studies of the method of the preparation of chelate compounds from the metal alkyls and active methylene compounds and of their structure identification, mainly by the use of nuclear magnetic resonance spectra (NMR) and infrared spectra (IR). The results of kinetic studies of the reactions between the metal alkyl-active methylene chelate compound and the α,β-unsaturated carbonyl compound are also included in this paper. Dimethyl malonate was mainly used as the active methylene component.

Experimental

Reagents. Benzene, *p*-cymene, and *n*-hexane were distilled over sodium wire.[6] Tetrahydrofuran was distilled after refluxing over potassium hydroxide, and again distilled over sodium wire.[6] Dimethyl malonate, dimethyl methylmalonate, dimethyl chloromalonate, ethyl acetoacetate, methyl cyanoacetate, and malononitrile were distilled after refluxing over calcium hydride. Methanol was dehydrated by magnesium methoxide.[6] Diethylamine was distilled after refluxing over potassium hydroxide and distilled again over calcium hydride.[6] *n*-Butyl mercaptan was distilled over calcium hydride.[6] Methyl isopropenyl ketone (MIPK) and methyl propenyl ketone (MNPK) were synthesized from the corresponding ketones and aldehydes[7,8] respectively. Commercial methyl acrylate (MA), methyl methacrylate (MMA), methyl crotonate (MCr), acrylonitrile (AN), and crotononitrile (CrN) were distilled over calcium hydride. Commercial methyl vinyl ketone (MVK) was dried by means of a molecular sieve and distilled. Methacrylonitrile (MAN) was synthesized according to the literature.[9] Di-*n*-butylzinc and triethylindium were synthesized according to the literature.[10,11] *n*-Butylzinc chloride was synthesized by Noltes' method[12] and was purified by recrystallization from *n*-hexane. Commercial triethylaluminum, triisobutylaluminum, and diethylaluminum chloride were distilled under reduced pressure.

Preparation of Metal Alkyl-Active Methylene Chelate Compounds. *n*-Butyl(dimethyl malonato)zinc was prepared by a hydrogen-abstraction reaction between *n*-Bu_2Zn and dimethyl malonate in the molar ratio of 1 : 1, in benzene and at room temperature. After the solvent had been dried up, *n*-butyl(dimethyl malonato)zinc was obtained in the form of a white solid. Diethyl(dimethyl malonato)aluminum was prepared from Et_3Al and dimethyl malonate in a malor ratio of 1 : 1, in benzene and at room temperature. It was distilled under reduced pressure after distilling off the solvent. Colorless liquid; bp 53°C/0.15 mmHg. Other metal alkyl-active methylene chelate compounds were prepared in a similar way. The preparation method is tabulated in Table 1.

The abbreviations of the names of the metal alkyl-active methylene chelate compounds are as follows:

n-Butyl(dimethyl malonato)zinc: *n*-BuZnDMM, (Dimethyl malonato)zinc chloride: ClZnDMM, (Dimethyl malonato)-

Analyses of Metal Alkyl-Active Methylene Chelate Compounds. The analyses of the metal alkyl-active methylene chelate compounds were performed by chelate titration, NMR, IR, and vapor-phase chromatography(VPC). The degree of association was measured in benzene by the cryoscopic method. The results obtained are shown in Tables 2—6 and in Figs. 1—5.

These results show that one alkyl group of every metal alkyl derivative, *e. g.*, RZnX, was quantitatively reacted with an active methylene compound, while alkane was eliminated, as follows:

$$RZnX + CH_2(CO_2Me)_2 \longrightarrow \underset{(XZnDMM)}{XZnCH(CO_2Me)_2} + RH$$

Procedure for Reactions with α,β-Unsaturated Carbonyl Compounds. Into a magnetic-stirred solution of a metal alkyl-active methylene chelate compound in a 30-m*l*, one-necked flask fitted with a three-way cock, an α,β-unsaturated carbonyl compound was added through the three-way cock from a syringe. After a given time interval, the reaction was stopped by adding acetic acid and the reaction products were determined by VPC. All the procedures described above were carried out under a dried nitrogen atmosphere. The NMR spectra were obtained by the use of a Japan Electron Optics Lab. Co., model C-60, high-resolution spectrometer using a 10 mol% benzene solution of a metal alkyl-active methylene chelate compound. The τ-values were determined by the use of tetramethylsilane as the internal standard. The IR spectra were obtained by the use of a Hitachi IR spectrometer, model EPI-G3, between KBr plates.

Results and Discussion

1. Structure of Meta Alkyl - Active Methylene Chelate Compounds. As is shown in Figs. 2—5 and in Tables 2, 3, and 6, each of the products from the metal alkyl - active methylene compound systems is a stoichiometric compound. The IR spectra of the carbonyl region is shown in Fig. 6.

The frequency of >C=O stretching is shifted to a region lower by 100—150 cm^{-1}, a fact which seems to indicate a chelating structure produced through the oxygen atom of the carbonyl group. Most of the chemical shifts of the methine proton in the NMR data are observed in the vicinity of 5.3 τ, which shows that the methine carbon is not linked directly with the metal atom. In order to elucidate the structure of the aluminum alkyl - active methylene chelate compound more clearly, the coupling constant, J^{13}_{C-H} at the methine proton was measured by using a neat sample. The results are shown in Table 7.

The value of J^{13}_{C-H} is regarded as a measure of the *s*-character of the carbon atom.[13] As is shown in the table, the value is about 170 cps for the aluminum

chelate, a fact which indicates that the central carbon of the active methylene compound in the aluminum chelate compound is in the sp^2 valence state. Kroll and Naegele[14] reported that diethyl(acetylacetonato)-aluminum has the following chelating structure:

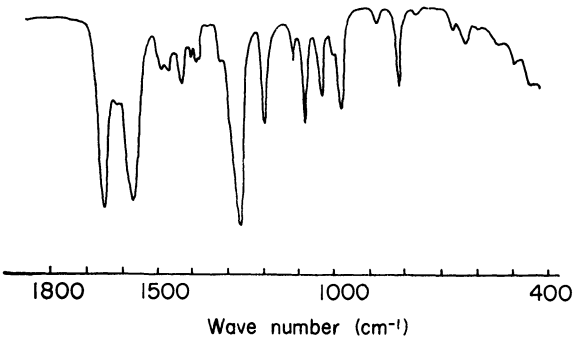

Fig. 7. IR spectrum of *n*-BuZnEAA.

Judging from Figs. 4—6 and Table 7, the products from aluminum alkyl-active methylene compound systems can reasonably be concluded to have a similar structure of the chelate ring.

Measurements of J^{13}_{C-H}, however, were not possible for the zinc alkyl-active methylene compound system, because all of the zinc compounds prepared, *e.g.*, XZnDMM, were solid. We may, though, suppose the structure of the zinc compound to be similar to the aluminum chelate from the NMR data (Figs. 2 and 3) as well as the IR data (Fig. 7).

2. Reaction Mode of Zinc (or Aluminum) Alkyl-Active Methylene Chelate Compounds with α,β-Unsaturated Carbonyl Compounds. In the reaction of *n*-BuZnDMM with methyl acrylate (MA), dimethyl malonate was found to decrease in the course of the reaction, ultimately almost disappearing, a fact which shows that no hydrogen abstraction by DMM occurred, and an addition product, $(MeOOC)_2CHCH_2CH_2CO_2Me$, of DMM to MA was detected by VPC. Since the formation of methanol in the reaction mixture was not detected, the possibility of the carbonyl addition reaction can be excluded. The addition product, fractionated by VPC, was identified by a comparison of its IR spectrum with that of an authentic sample.

These results show the only elementary reaction in this case to be a Michael-type 1,4 addition reaction. Reactions with α,β-unsaturated ketones and nitriles were also studied. The reactivity of the aluminum alkyl-active methylene chelate compound is rather lower than that of the zinc chelate, no addition reactions to α,β-unsaturated esters or nitriles being observed at 30°C

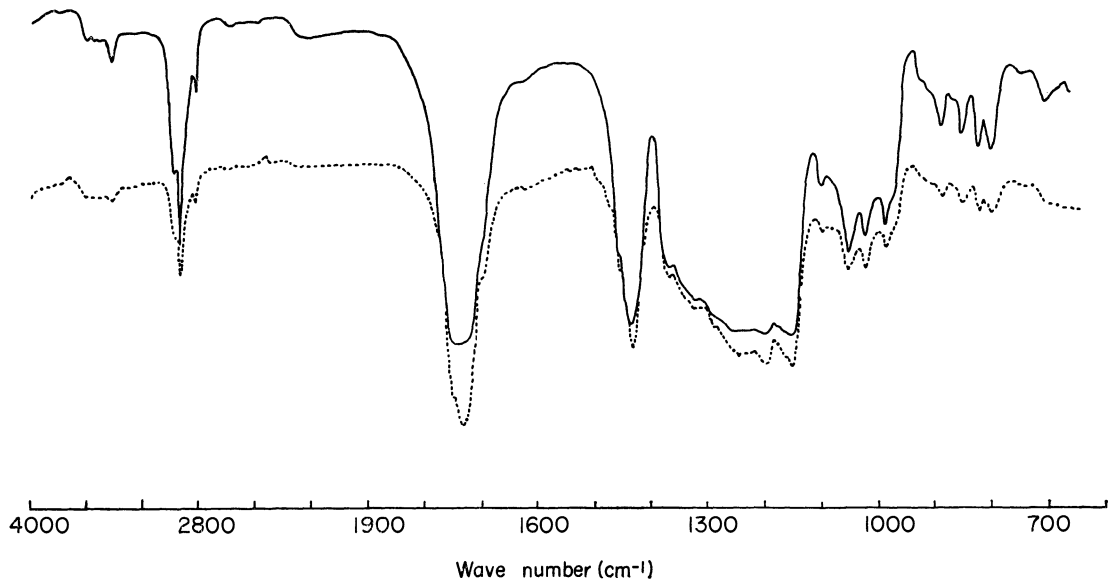

Fig. 8. IR spectra of the reaction products of BuZnDMM with MA and authentic sample (---).

□ [Zn]=0.20 mol/*l* ● [Zn]=0.10 mol/*l*

▲ [Zn]=0.12 mol/*l* ■ [Zn]=0.10 mol/*l*

in benzene. The reactivity of EtClAlDMM, however, was found to be high enough to add to the α,β-unsaturated ester or nitrile under the same conditions. The mode of the addition reaction was confirmed to be also a Michael-type reaction in the case of the aluminum chelate just as with the zinc-chelate compound.

3. Reaction-rate Analysis. The rate of the addition reaction was determined by measuring the quantities of dimethyl malonate recovered after the interruption of the reaction. To ascertain the effect of substituents on the metal atom, the reaction of XZnDMM (X=*n*-Bu, Cl, MeO, *n*-BuS, Et_2N) with MA was kinetically studied in detail. Substituent effects on the central carbon of DMM were also studied. Besides dimethyl malonate, ethyl acetoacetate, and methyl cyanoacetate were examined for the sake of comparison. In all

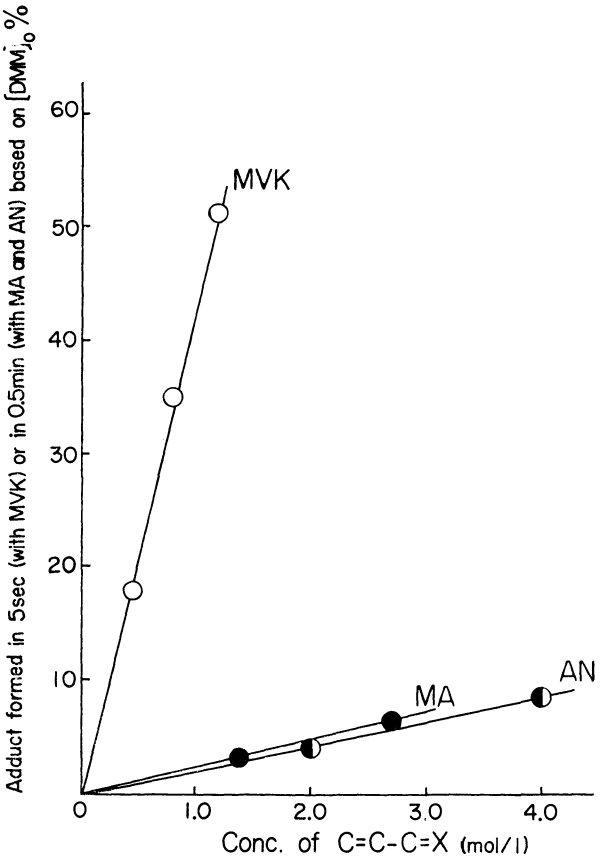

Fig. 10. Dependence of rate on the concentration of α,β-unsaturated carbonyl compound in the reaction with *n*-BuZnDMM (0.1 mol/*l*).

cases, the Michael-type addition of an active methylene compound to an α,β-unsaturated carbonyl compound was confirmed to take place. The results are tabulated in Tables 8, 9, 10, and 11.

The data in Tables 8—11 were found to fit the first-order rate law with respect to the metal alkyl-active methylene chelate compound. This was confirmed also by the further experiments shown in Fig. 9,

where [M] is the concentration of the metal compound. Equation (1) was found to be true for all the reactions examined between metal alkyl-active methylene chelate compounds and α,β-unsaturated carbonyl compounds. The rate constants of the second-order reaction are listed in Tables 12 and 13.

4. Reactivity of Metal Alkyl-Active Methylene Chelate Compounds. It can be seen from the preceding sections that RZnDMM exhibits much higher reactivity than ZnR_2 in the addition reaction to α,β-unsaturated esters or nitriles. As we reported previously, ZnR_2 or AlR_3 can add to α,β-unsaturated ketones,[5] but not to the unsaturated esters (*e. g.*, methyl acrylate, methyl methacrylate, and methyl crotonate) or nitriles (*e. g.*, acrylonitrile, methacrylonitrile, and crotononitrile). Contrary to RZnDMM, the reactivity of R_2AlDMM was not enough to result in the addition reaction with the unsaturated esters or nitriles, though the latter chelate compound adds easily to more reactive double bonds of α,β-unsaturated ketones.

Since significant effects were noticed in the reactivity of XZnDMM or EtXAlDMM (X: R, Cl, RO, RS, R_2N) in the addition reactions to α,β-unsaturated carbonyl compounds, systematical studies of the substituent effect were undertaken. From Tables 12 and 13, the main features of the reactions of metal alkyl-active methylene chelate compounds can be listed as follows:

i) The reactivity of XZnDMM or EtXAlDMM increases in the order, X: $Et_2N<$*n*-BuS$<$MeO$<$*n*-Bu(or Et)$\leqq$Cl, which is in accordance with the order of the methine proton chemical shift from a lower to a higher field.

ii) The more stable chelate ring seems to have a more diminished reactivity.

iii) The substituent effect on the central carbon atom of *n*-BuZn[$XC(CO_2Me)_2$] is the reverse of that of $Et_2Al[XC(CO_2Me)_2]$. The reactivity of *n*-BuZn-[$XC(CO_2Me)_2$] increases in the order; X: Cl$<$H$<CH_3$, while the reactivity of $Et_2Al[XC(CO_2Me)_2]$ decreases in this order.

An electron-withdrawing substituent, X, in EtXAl-DMM causes the chemical shift of the methine proton to a higher field. This could be interpreted in terms

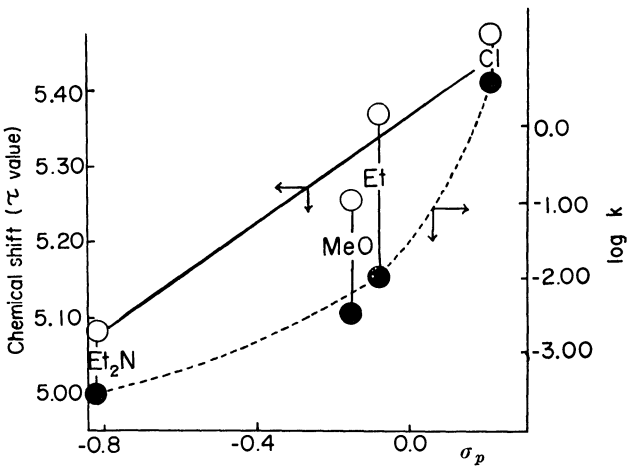

Fig. 11. Correlation among Hammett's σ_p, the chemical shift of methine proton in EtXAlDMM and reactivity.

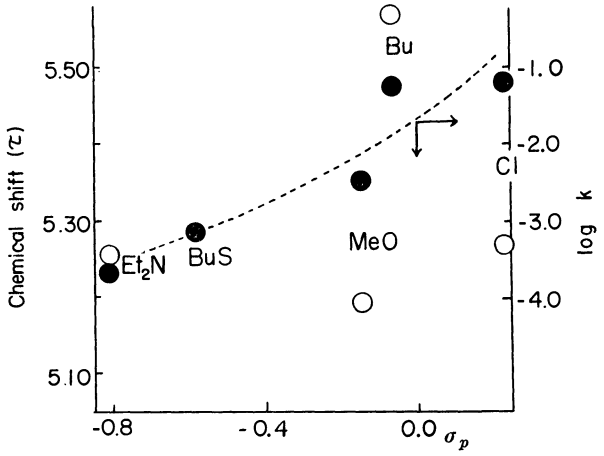

Fig. 12. Correlation among Hammett's σ_p, the chemical shift of methine proton in XZnDMM and reactivity.

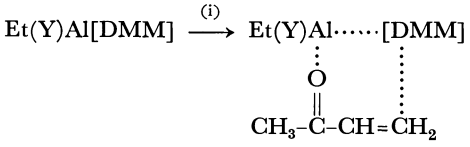
of the decrease in the ring current, because of the electron-withdrawing nature of X, in the pseudo-aromatic system of the aluminum chelate compound. A linear relationship is observed between Hammett's substituent constants, $\sigma_{p,x}$ and the chemical shift of the methine proton in EtXAlDMM, as is shown in Figs. 11 and 12. It is assumed from the above data that the reactivity of the EtXAlDMM system is governed by the stability of the chelate ring. For instance, an electron-withdrawing substituent, Cl, attached to methine or aluminum, decreases the electron density (or ring current) of the chelate ring, meaning the loss of the aromaticity of the chelate ring. Therefore, the more diminished ring current (or the lower aromaticity) is closely related to the higher reactivity of EtXAlDMM.

In the case of XZnDMM, no linear relationship was observed; between $\sigma_{p,x}$ and the chemical shift of methine proton in XZnDMM this might be ascribed at least partly to the association of the zinc compound or to the intrinsic nature of the zinc atom. The correlation between the reactivity, log *k*, and the σ_p of XZnDMM was, however, found to be similar to that in EtXAlDMM.

On the other hand, an electron-donating substituent (*e. g.*, CH_3), attached to the active methylene group, was found to increase the reactivity of *n*-BuZn[$XC(CO_2Me)_2$], a situation which is in contrast with the substituent effect in $Et_2Al[XC(CO_2Me)_2]$. An electron-withdrawing substituent such as halogen in *n*-BuZn-[$XC(CO_2Me)_2$] also exerts an effect opposite to that in $Et_2Al[XC(CO_2Me)_2]$.

It seems not to be easy to draw a consistent interpretation of the reactivities of the chelate complexes of aluminum and of zinc. We are inclined to consider, however, that the opposite substituent effects can be understood if we assume two steps [(i) and (ii)] in determining the rate of the addition reaction of the chelate complexes to the unsaturated carbonyl compounds.

For instance,



$$\xrightarrow{\text{(ii)}} \text{Et(Y)Al-O-}\overset{\overset{CH_3}{|}}{C}\text{=CH-CH}_2\text{-DMM}$$

The chelate ring is probably loosened (Step (i)) before the β-carbon atom of the unsaturated carbonyl compound is attacked by [DMM] at Step (ii). We have discussed the reactivity of $Et(Y)Al[C(X)(CO_2Me)_2]$ in terms of the stability of the chelate ring, which means the rate-determining step is probably Step (i).

In the light of the stability constants of metal acetylacetonates, according to Block *et al.*,[15-17] the chelate ring of the zinc alkyl complex system can be assumed to be much more unstable than the aluminum alkyl complex.

Table 14. Stability constants of metal acetylacetonates

Metal	Stability constant (log k)	Ion strength
Zn	9.11 (k_1)	75% dioxane[15]
	4.98 (k_1)	0[16]
	8.09 (k_2)	75% dioxane[15]
	3.83 (k_2)	0
Al	8.6 (k_1)	0[16]
	7.9 (k_2)	0[17]
	5.8 (k_3)	0[17]

Therefore, it is not unreasonable to deduce that the rate-determining step is Step (ii) with the zinc alkyl complex, the reactivity of which is governed, rather, by the reactivity of the active methylene component itself. For example, the chlorine substituent on the central carbon stabilized the [DMCM] anion, resulting in a decrease in the reactivity of the malonate anion. The methyl substituent has a reverse effect. It should be pointed out at this stage that the substituent effect in dimethyl malonato sodium in the Michael reaction[18] is in the same direction as with the zinc alkyl complex, a fact which is consistent with the above discussion, because the ability of chelate-ring formation should be extremely small in dimethyl malonato sodium in comparison with the case of the aluminum chelate.

5. *Vinyl Polymerization with Metal Alkyl - Active Methylene Chelate Compounds.* The possibility of polymerization was examined with several α,β-unsaturated carbonyl compounds by the use of the metal alkyl - active methylene chelate as the initiator, but high polymers were not formed in benzene at 30°C. When dimethyl sulfoxide or hexamethylphosphoric triamide was used as the solvent, MA was polymerized, as is shown in Table 15. When malononitrile was used instead of dimethyl malonate, the metal alkyl complex was also able to initiate the polymerization of MA. The anionic character of the polymerization was confirmed by the copolymerization method with styrene.

Table 15. Polymerization of α,β-unsaturated esters by the metal alkyl - active methylene chelate compound as catalyst

The Preparation of Fukinane, A New Skeletal Sesquiterpenic Hydrocarbon[1]

Keizo NAYA and Masakazu KOBAYASHI

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo

(Received August 12, 1970)

A novel skeletal sesquiterpenic hydrocarbon, fukinane (I), has been prepared by conversion from an eremophilane type, fukinone (VIII), *via* fukinan-8-ol (IX). A rearrangement of the fukinane skeleton into an eremophilane type through fukinan-8-ol tosylate (X) has been studied.

We have previously reported the isolation and stereochemistry of several new sesquiterpenoids with a fukinane (I) skeleton (fukinanolide (II),[2] fukinolide (III),[2] *S*-fukinolide (IV),[2] homofukinolide (V),[3] and dihydrofukinolide (VI))[3] from *Petasites japonicus* Maxim. The absolute configurations of these compounds were established by correlation with fukinone (VIII) through fukinan-8-ol (IX).[4] The absolute configuration of fukinone (VIII) had already been settled.[5]

Now we have an interest in preparing a new type of sesquiterpene hydrocarbon, fukinane (I); the present paper will report the results of the following three routes for synthesizing fukinane (I) from fukinan-8-ol (IX).

For the purpose of removing the oxygen function at C-8, we attempted the following three routes: (i) the reduction of fukinan-8-ol tosylate (X) with lithium aluminum hydride, (ii) the Wolff-Kishner reduction of fukinan-8-al semicarbazone (XVI), and (iii) the reduction of fukinan-8-al ethylene thioacetal (XVIII) with Raney nickel.

From Tosylate (X). Fukinan-8-ol (IX),[4] $C_{15}H_{28}O$, mp 38—39°C, was treated with three equivalents of tosyl chloride to give the tosylate (X) quantitatively. An attempt at the further purification of the tosylate (X) by chromatography on silica gel involved a Wagner-Meerwein-type rearrangement[6] to produce a mixture of hydrocarbons XI, XII and XIII. The glc pattern is illustrated in Fig. 2, while the relative ratio of the yield is shown in Table 1. The mixture reacted positively to a tetranitromethane-test and was exclusively converted to eremophilane (XIV) by hydrogenation with Adams' catalyst in acetic acid. Those facts suggest that the rearrangement proceeded stereoselectively, involving the migration of the C-9 methylene to the

electron-deficient C-8, but not to the C-6. Each hydrocarbon was isolated by preparative glc. The structures of the hydrocarbons XI, XII, and XIII, were determined as will be described below.

The NMR spectrum[7] of the compound XI shows a singlet at 5.03, suggesting a C=CH–C– grouping. The structure was settled as in formula XI from the MS fragmentation shown in Fig. 3.

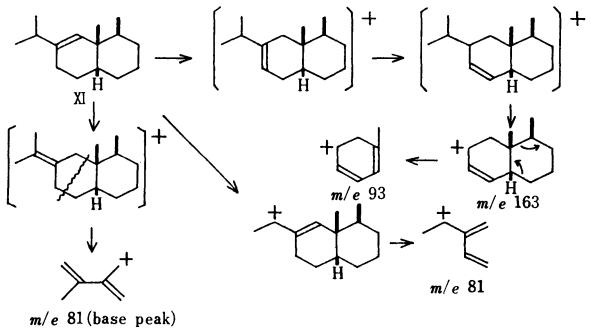

Fig. 3. Mass fragmentation of hydrocarbon XI.

The NMR spectrum of the compound XII shows a multiplet signal centered at 5.24 which was presumed to be the result of the long-range coupling between the vinyl proton at C-8 and the protons at C-6 and C-11. In the MS spectrum, the base peak at *m/e* 110 was derived from a retro-Diels-Alder rupture of the molecular ion. The structure was, then, represented by the stereoformula XII, based on the MS fragmentation, shown in Fig. 4.[8]

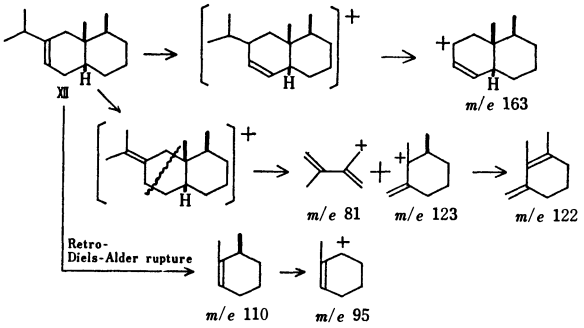

Fig. 4. Mass fragmentation of hydrocarbon XII.

The hydrocarbon XIII shows a singlet at 1.62 (6H) due to an isopropylidene group in its NMR spectrum. The structure XIII was established with the aid of the MS fragmentation shown in Fig. 5.[8]

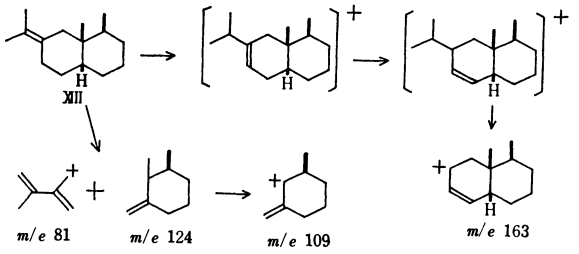

Fig. 5. Mass fragmentation of hydrocarbon XIII.

7) All NMR spectra were taken in CCl_4 on a JEOL C-60 spectrometer, otherwise mentioned, with TMS as an internal reference. The values are reported in ppm.

X

Fig. 6. The scheme of rearrangement of the tosylate (X).

The rearrangement should occur by means of the scheme shown in Fig. 6.

Because the tosylate (X) yielded predominantly migration products with an eremophilane sekeleton when submitted to chromatography over silica gel, the tosylate (X) was submitted to lithium aluminum hydride reduction without further purification. The glc pattern of the hydrocarbons obtained by the reduction is shown in Fig. 2. The products proved to include mainly the migration hydrocarbons, plus a small amount of fukinane (I).

From Fukinan-8-al Semicarbazone (XVI). Fukinan-8-al (XV) was obtained in a comparatively good yield by Jones' oxidation[9] under controlled conditions. The product XV was appreciably air-oxidized to the carboxylic acid (XVII), mp 125.5—126.0°C, by leaving it overnight in the air at room temperature, or by preparative tlc. The crude aldehyde (XV) was, therefore, quickly transformed to the semicarbazone (XVI). The product XVI was submitted to Wolff-Kishner reduction to afford fukinane (I) (10% yield; 3.7% overall yield from fukinan-8-ol). We turned to an alternate approach to produce fukinane (I) in a good yield.

From Fukinan-8-al Ethylene Thioacetal (XVIII). The third route involved the reduction of the ethylene thioacetal of fukinan-8-al (XVIII). The condensation of fukinan-8-al (XV) with ethanedithiol afforded the ethylene thioacetal (XVIII) in a 70.2% yield. Its reduction with Raney nickel proceeded readily to give fukinane (I) (yield, 79%), which was identical with the sample prepared by the other routes described

Table 2. Physical properties of fukinane (I)

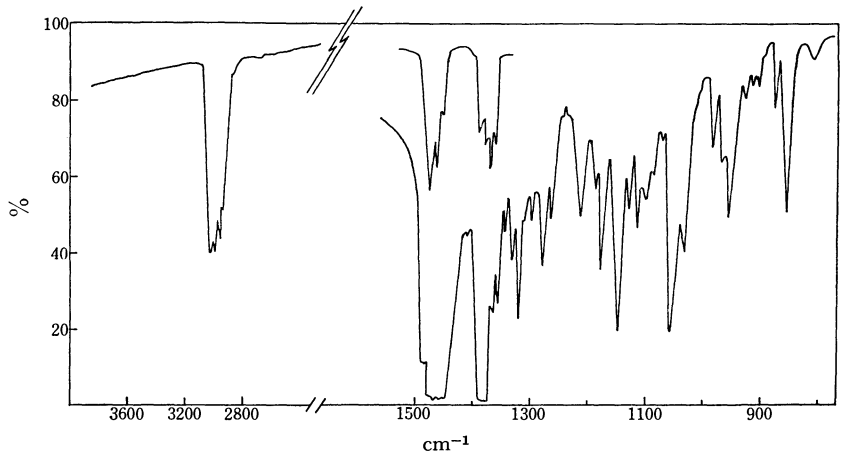

Fig. 8. IR spectrum of fukinane (I).

above. The physical properties of fukinane (I) are listed in Table 2. The MS spectrum is shown in Fig. 7, and the IR spectrum, in Fig. 8.

Experimental

All the melting points are uncorrected. The MS spectra were measured with a Hitachi RMU-6 MS spectrometer: ion-source temperature 250°C; evaporation temperature, 150°C. The IR spectra were recorded with a JASCO DS-402G spectrophotometer, and the optical rotations were measured with a Hitachi EPU-2A spectrophotometer. Glc was carried out using a Shimadzu GC-1C apparatus on a stainless steel column (ϕ=3 mm).

Fukinan-8-ol (IX)[4] was prepared from fukinolidol (VII),[2] which had been derived by alkaline hydrolysis from fukinolide (III),[2] *S*-fukinolide (IV),[2] homofukinolide (V),[3] and dihydrofukinolide (VI),[3] and also from fukinanolide (II)[2] and fukinone (VIII).[5]

Tosylate of Fukinan-8-ol (IX). To a solution of fukinan-8-ol (IX) (346 mg, 1.54 mmol) in dry pyridine (6.8 m*l*), was added tosyl chloride (909 mg, 4.8 mmol); the reaction mixture was then left at room temperature for 19 hr. Subsequent working up in the usual manner yielded the tosylate (X) (560 mg, yield 95.2%); almost one spot by tlc analysis with R_f=0.35 (light petroleum: benzene=3 : 1). IR (film): 1600, 1379, 1190, 1100, 960, 845, 820 cm^{-1} (characteristic of a tosylate).

Rearrangement of Tosylate (X) by Silica Gel. Fukinan-8-ol tosylate (X) (1.21 g, 3.45 mmol) was chromatographed on silica gel (30 g). The light petroleum-benzene (5 : 1) eluates were combined to give a mixture of the hydrocarbons XI, XII, and XIII (457 mg, 70%). Their pure specimens were furnished by preparative glc (PEG-20M on Celite 545; 2.6 m; H_2 37 m*l*/min; column temperature, 160°C).

Compound XI, $[\alpha]_D^{23}$ +23.1° (*c*, 0.91, CCl_4); n_D^{15} 1.4901; NMR: 0.78 (d, 3H, J=6 Hz), 0.86 (s, 3H), 1.02 ppm (d, 6H, J=6.6 Hz); MS: M$^+$ *m/e* 206, base peak *m/e* 81.

Found: C, 87.41; H, 12.54%. Calcd for $C_{15}H_{26}$: C, 87.30; H, 12.70%.

Compound XII, $[\alpha]_D^{23}$ −16.4° (*c*, 1.70, CCl_4); $n_D^{15.5}$ 1.4919; NMR: 0.85 (s, 3H), 0.89 (d, 3H, J=4.5 Hz), 0.98 (d, 6H, J=6.6 Hz), 5.24 ppm (br. s, 1H); MS: M$^+$ *m/e* 206, base peak *m/e* 110.

Compound XIII, $n_D^{15.5}$ 1.5060; NMR: 0.78 (d, 3H, J=6 Hz), 0.85 (s, 3H), 1.62 ppm (s, 6H); MS: M$^+$ *m/e* 206, base peak *m/e* 81.

Catalytic Reduction of the Hydrocarbons XI, XII, and XIII. A mixture of the hydrocarbons XI, XII, and XIII (99.4 mg) was hydrogenated in glacial acetic acid (3 m*l*) with Adams' catalyst (22 mg) at room temperature and at atmospheric pressure. After the hydrogen uptake had ceased, the catalyst was filtered. The filtrate was diluted with aqueous sodium hydrogen carbonate, and the product was extracted with benzene. The evaporation of the solvent *in vacuo* then gave a hydrocarbon (88 mg) which was found to be identical with eremophilane (XIV) in glc analysis; retention time, 6.1 min; PEG-6000 on Celite 545 (2.5 m, 60—80 mesh); carrier gas, H_2, flow rate, 120 m*l*/min; column temperature, 160°C.

Lithium Aluminum Hydride Reduction of Tosylate (X). To a stirred and refluxed mixture of lithium aluminum hydride (147 mg, 3.87 mmol) in absolute ether (10 m*l*), a solution of the tosylate (X) (289 mg, 0.76 mmol) in absolute ether (7 m*l*) was added, drop by drop over a 45 min period. The mixture was then maintained at that temperature for an additional 7 hr. After being cooled to room temperature, the reaction mixture was treated with moist ether and aqueous 10% hydrochloric acid, and then washed thoroughly with water. The ethereal extract was dried over anhydrous sodium sulfate. The evaporation of the solvent gave an oily residue (163 mg), which was then chromatographed over silica gel (7 g). Elution with light petroleum afforded a mixture of hydrocarbons (30 mg, 19%), which was proved by glc analysis to be a mixture of fukinane I, XI, XII, and XIII. Further elution with benzene-ethyl acetate (40 : 1) afforded fukinan-8-ol (IX) (104 mg; yield, 60%).

Semicarbazone of Fukinan-8-al (XV). Into a solution of fukinan-8-ol (IX) (334 mg, 1.5 mmol) in acetone (7.6 m*l*), 0.57 m*l* of Jones' reagent (containing 157 mg of chromium trioxide) was stirred in a single portion at −16°C. The mixture was kept for 30 min, methanol (4 m*l*) was added, and the solvent was removed under reduced pressure. The residue was then extracted with ether, and the ethereal extract was washed with aqueous sodium hydrogen carbonate and then with water. The ethereal solution was dried over anhydrous sodium sulfate, after which the solvent was evaporated to give a crude aldehyde, fukinan-8-al (XV); positive to tetrazolium test; IR (film): 1720 cm^{-1}. The residual oil was treated in ethanol (2 m*l*) with semicarbazide hydrochloride (400 mg) and freshly-fused sodium acetate (60 mg) as soon as possible. The reaction mixture was then left at room temperature for 16 hr to afford crystalline semicarbazone

(XVI) (208 mg, 49%); mp 189—190°C (decomp.). Recrystallization from aqueous methanol gave a pure semicarbazone; mp 206.0—206.5°C (decomp.); $[\alpha]_D^{23}$ +19.1° (*c*, 1.1, $CHCl_3$); IR (KBr disk): 3500, 3300 (sh), 3240, 3180, 1695, 1625 (sh), 1580, 1565 (sh), 1143, 1045, 1008, 948, 772 cm^{-1}; NMR:[10] 0.79 (d, 3H, J=6.1 Hz), 0.89 (d, 6H, J=6.0 Hz), 0.89 (s, 3H), 5.53 (br. s, 2H, $-CO-NH_2$), 7.01 (s, 1H, -CO-NH-N=), 8.96 ppm (s, 1H, -N=CH).

Found: C, 68.92; H, 10.42; N, 15.39%. Calcd for $C_{16}H_{29}N_3O$: C, 68.77; H, 10.46; N, 15.04%.

Wolff-Kishner Reduction of Semicarbazone (XVI). The semicarbazone (XVI) (325 mg, 1.17 mmol) and powdered potassium hydroxide (233 mg, 4.2 mmol) were heated under reflux for 9 min to give a brownish-yellow syrup. After being cooled, the reaction mixture was diluted with water and extracted with ether. Then the solvent was removed. The IR spectrum of the residue (219 mg) showed an absorption band at 1640 cm^{-1}, presumably due to the C=N group. The residual oil was heated under reflux again with potassium hydroxide (197 mg, 3.5 mmol). After the evolution of the gas had subsided, the solution was diluted with water and extracted with ether, and the ethereal solution was dried over anhydrous sodium sulfate. The evaporation of the solvent gave a crude oil (188 mg), which was then chromatographed on preparative tlc to give fukinane (I) (24 mg, 10%; total yield from IX, 4.9%).

Ethylene Thioacetal of Fukinan-8-al (XV). Fukinan-8-ol (IX) (574 mg, 2.6 mmol) was treated with 1.3 m*l* of Jones' reagent (containing 364 mg of chromium trioxide) at −13°C for 7 min to give a crude aldehyde (XV). After being dried throughly by azeotropic evaporation with dry benzene, the aldehyde (XV) was dissolved in ethanedithiol (1 m*l*) and to this a catalytic amount of BF_3-etherate was added. The reaction mixture was then left at room temperature for 1.5 hr. Methanol (2 m*l*) was added, and the mixture was diluted with 5% aqueous potassium hydroxide, extracted with ether, washed with water and dried over anhydrous sodium sulfate. The evaporation of the solvent gave an oil (1.24 g), which was chromatographed over silica gel (10 g) and eluted with light petroleum to afford fukinan-8-al ethylene thioacetal (XVIII) (536 mg, yield, 70.2%); $[\alpha]_D^{23}$ +22.5° (*c*, 1.1, CCl_4); $n_D^{18.5}$ 1.5544; IR (film): 1392, 1386, 1376, 1315, 1280, 1185, 1165, 1125, 1107, 1023, 944, 860, 840, 783 cm^{-1}; NMR; 0.78 (d, 3H, J=6 Hz), 0.92 (s, 3H), 0.99 (d, 6H, J=6.9 Hz), 3.11 (fine splitting, s, 4H, $-S-CH_2-CH_2-S-$), 4.81 ppm (s, 1H, -S-CH-S-); glc: retention time, 9 min; Thermol-3 (1.1 m) on Shimalite (60—80 mesh); carrier gas, H_2; flow rate, 200 m*l*/min; column temperature, 170°C.

Found: C, 68.72; H, 10.13: S, 21.30%. Calcd for $C_{17}H_{30}S_2$: C, 68.39; H, 10.13; S, 21.48%.

Raney Nickel Reduction of Ethylene Thioacetal (XVIII). A solution of the ethylene thioacetal (XVIII) (534 mg, 1.8 mmol) in ethyl acetate (3 m*l*) was stirred drop by drop into a suspension of Raney nickel (10 g) in ethyl acetate (10 m*l*) over a 12-min period. The reaction mixture was then refluxed for an additional hour, and subsequently filtered. The filtrate was evaporated *in vacuo* to give fukinane (I) (303 mg, 79%); single peak by glc analysis; retention time, 4.1 min; PEG-20M (2.6 m) on Celite 545 (60—80 mesh); carrier gas, H_2; flow rate, 37.3 m*l*/min; column temperature, 168°C. The pure specimen was obtained by preparative glc. MS: M^+ *m/e* 208, base peak *m/e* 109; NMR; 0.70—0.91 (15H, five methyls).

Found: C, 86.90; H, 13.26%. Calcd for $C_{15}H_{28}$: C, 86.46; H, 13.54%. The physical properties are listed in Table 2. The MS spectrum is shown in Fig. 7, and the IR spectrum, in Fig. 8.

The authors wish to thank the Shionogi Research Laboratory, Shionogi & Co., Ltd., for the microanalysis and the Institute of Food Chemistry for the measurements of the MS and NMR spectra.

Effects of *para*-Substituents on the Rates of Inversion of Biphenyl Derivatives. I. 5,7-Dihydrodibenzo[*c*,*e*]thiepins

Michinori Ōki, Hiizu Iwamura, and Gaku Yamamoto

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received August 22, 1970)

Several 3,9-disubstituted 5,7-dihydrodibenzo[*c*,*e*]thiepins were synthesized and temperature dependence of their NMR spectra was examined. All the substituted derivatives showed a lower energy barrier to inversion than the unsubstituted one. The effects of the substituents on the energy barrier may be interpreted in terms of resonance stabilization and/or out-of-plane bending of the axis bond at the transition state.

Many earlier works have revealed that the major part of the origin of energy barrier to inversion in biphenyl derivatives is the steric strain at the transition state due to non-bonded interactions between atoms or groups at the *ortho* positions.[1] Westheimer and his coworkers[2] successfully calculated the enthalpy of activation for racemization of 2,2′-dibromobiphenyl and 2,2′-diiodobiphenyl, assuming a planar transition state with deformation within the plane only and completely neglecting electronic factors.

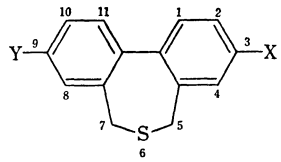
In contrast, the influence of electronic factors on the energy barrier has been left unclarified. The gain in resonance energy in the transition state may contribute in lowering the activation energy, but Westheimer's success in calculation can be taken as suggesting the existence of some compensating factors.

Although the assumption that the transition state is coaxial and coplanar has generally been accepted, some authors[3,4] suggested that bending of the axis bond out of plane of the benzene ring may decrease the non-bonded interactions and that the energy barrier to inversion is affected by the relative ease of the bending. Harris and Cheung King Ling[4] studied the racemization rates of optically active 4,4′-symmetrically substituted 2,2′-diiodobiphenyls and found that the energy barrier to inversion is considerably affected by the *para* substituents. They have claimed that in the transition state the two benzene rings are neither coaxial nor coplanar, but distorted out of the plane to each other, and the *para* substituents affect the ease of bending of the axis bond and thus the energy barrier. They also suggested that in this system *ortho* substituents are so bulky that even at the ground state it has a distorted non-coaxial conformation. It is then considered that with the extreme bulkiness of the *ortho* groups the biphenyl system experiences the distorted transition state.

From the above discussion, it will be interesting to known whether the out-of-plane bending of the axis bond is operating or not in biphenyl systems with less bulky *ortho* substituents. Such systems necessarily possess very low optical stability and polarimetric study may become impossible.

However, with dynamic NMR technique it is possible to obtain information on intramolecular motions with a specific rate of 1 to 10^3 sec^{-1}.[5] Energy barrier to inversion in several biphenyl systems has been studied by applying NMR technique.[6–10] Kurland and his coworkers[6] reported the temperature dependent NMR spectra of 5,7-dihydrodibenzo[*c*,*e*]thiepin (I). Methylene protons of I showed an AB quartet signal at low temperature, which coalesced at 43°C into a singlet. This change of spectra was correlated with the rate of inversion. The free energy of activation was calculated to be 16.1 kcal/mol with the entropy of activation less than 2 eu. This system seemed to be suitable for the present purpose because of synthetic ease and convenience in measurement and analysis of the NMR spectra.

Thus five 3,9-disubstituted derivatives of I (II—VI) were synthesized and their NMR spectra were measured over a wide range of temperature to find out the effects of substituents on the energy barrier to inversion.



I: X=Y=H
II: X=OCH_3, Y=NO_2
III: X=Y=OCH_3
IV: X=Y=F
V: X=Y=Br
VI: X=Y=CO_2CH_3

Results

Compounds II—VI were synthesized by benzylic bromination of 4,4′-substituted *o*,*o*′-bitolyl followed by ring closure with sodium sulfide (Scheme).

Table 2. Kinetic parameters of the inversion of 5,7-dihydrodibenzo[*c*,*e*]thiepins

Compound	Solvent	$\Delta G_c^{\ddagger}$ (kcal/mol)	$\Delta H^{\ddagger}$ (kcal/mol)	$\Delta S^{\ddagger}$ (eu)	Ref
I	CS_2	16.1±0.3		<2	6)
	$CDCl_3$	16.0			9)
II	$CHCl_2CHCl_2$	14.6±0.3	13.6±1.0	−3±4	a)
III	$CHCl_2CHCl_2$	15.2±0.3	13.1±1.0	−7±4	a)
IV	$CHCl_2CHCl_2$	16.1±0.3	16.0±0.5	0±2	a)

a) The present work.

In NMR spectra, the protons of each methylene group of compounds II, III and IV showed an AB quartet signal at low temperature due to the non-equivalence of protons, indicating slow inversion. The quartet signal coalesced into a single broad line at about room temperature, then gradually sharpened with increasing temperature. The obtained spectral parameters are summarized in Table 1. For compound II, two AB quartets due to 5- and 7-methylenes overlapped each other, and this made the determination of the coalescence temperature (T_c) somewhat inaccurate.[11]

The inversion rate k_c at T_c was calculated using the equation[10]

$$k_c = \frac{\pi}{\sqrt{2}}(\delta_{AB}^2 + 6J_{AB}^2)^{1/2} \quad (1)$$

From the line width W of the coalesced singlet, the approximate inversion rate k at various temperatures could be obtained by means of

$$k = \frac{\pi\delta_{AB}^2}{2(W - W_0)} \quad (2)$$

where W_0 is the extrapolated line width for $k=\infty$. Arrhenius plots gave parameters E_a and $\log A$. Eyring parameters, $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ could be derived from the following equations.

$$\Delta G^{\ddagger} = -RT\ln\frac{hk}{k_B T} \quad (3)$$

$$\Delta H^{\ddagger} = E_a - RT \quad (4)$$

$$\Delta S^{\ddagger} = \frac{\Delta H^{\ddagger} - \Delta G^{\ddagger}}{T} \quad (5)$$

The results are summarized in Table 2.

The methylene protons of V and VI were observed as a singlet down to the lowest attainable temperature (−50°C). Slight broadening was observed with lowering temperature. This seems to be due to the increased viscosity of the sample solution, because reference signals also showed broadening. Although this might be interpreted in terms of rapid inversion down to the lowest temperature, it is unreasonable to think that substitution at *para* positions caused such a large lowering of coalescence temperature. An alternative and more probable interpretation is that the lack of splitting is due to accidental magnetic equivalence of the methylene protons although the inversion is slow on the NMR time scale. Several examples have been reported in which diastereotopic protons show magnetic equivalence. Sometimes aromatic solvents give rise to magnetic non-equivalence of the protons which are equivalent in non-aromatic solvents such as chloroform and carbon tetrachloride. However, attempts to measure the NMR spectra of V and VI in pyridine and *o*-dichlorobenzene failed because of the low solubility of the samples in these solvents.

Discussion

The lack of full line shape analysis of the NMR spectra of these compounds and the essential tendency of the data of enthalpy and entropy of activation to include rather large systematic errors as pointed out by Gutowsky[12] prevent a direct comparison of the $\Delta H^{\ddagger}$ values obtained and the delicate quantitative discussions about the transition state of inversion. Qualitatively, however, we might conclude from these data (Table 2) that the barrier to inversion decreases in the order I≈IV>III≥II.

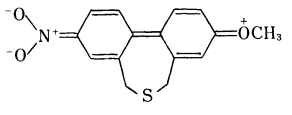
11) Theoretically two T_c's corresponding to the two kinds of methylene should exist, but could not be detected separately.

12) A. Allerhand, H. S. Gutowsky, J. Jones, and R. A. Meinzer, *J. Amer. Chem. Soc.*, **88**, 3185 (1966).

Fluorine atom is known to exert no large electronic effect on the *para* position, and it may be reasonable for compounds I and IV to have nearly the same value of activation parameters.

Several factors can be considered by which the substituents at *para* positions influence the energy barrier to inversion in this system. It may be reasonably assumed that the effects of the substituents on the ground state energy of this system are negligible, and only those on the transition state energy should be considered.

In 3,9-unsymmetrically substituted derivatives such as II with an electron-withdrawing group at one *para* position and an electron-releasing group at the other, resonance stabilization as represented by the canonical structure VII should contribute in lowering the energy level of the transition state. A farily large decrease in ΔH^* value of II agrees with this prediction.

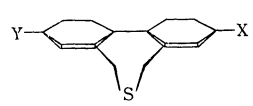


VII

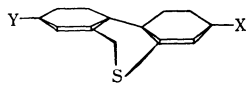
It has been suggested[13] that the large contribution of VII in the resonance hybrid would increase the double bond character of the axis bond, causing a shortening of the bond which would result in the increase of the nonbonded interaction. That is, the energy barrier would be heightened in contrast to the effect of the resonance stabilization. The present data show that the effect of bond shortening is rather unimportant. Here, the two benzene rings may be considered to be coaxial and coplanar at the transition state and the release of steric strain by the out-of-plane bending of the axis bond is much less important.

In 3,9-symmetrically substituted derivatives (III—VI), large resonance stabilization as observed in II can not be expected. Ultraviolet spectroscopic studies of 4,4′-disubstituted biphenyls[14] showed that all the substituents, irrespective of their nature, increase conjugation between the two rings to some extent. If such conjugation really contributes to stabilize the transition state for inversion, all the derivatives III—VI should have lower barriers than unsubstituted I.

In the coaxial and copolanar transition state (VIII), nonbonded interactions involving internal strains of the seven-membered ring would be the greatest, causing the barrier to inversion. These interactions would be considerably released if the axis bond could be bent out of the plane of the benzene rings as schematically shown in IX. The higher the π-electron density at the 1,1′-positions of the biphenyl skeleton, the easier will be the bending motion of the axis bond.[15]



VIII



IX

Derivative III, with methoxyl groups at 3- and 9-positions, shows a lower barrier to inversion than I, which can be explained by either of two factors. On one hand, the methoxyl group will lower the energy barrier because of the contribution of resonance structure through the two benzene rings. On the other hand, the same group will make it easy to take the transition state IX because of electron-releasing tendency.

The lack of data on the effect of electron-withdrawing substituents prevents us from determiniing which of these factors is more important. Considerable drop in ΔH^* value in III relative to I does not seem to be explained only in terms of resonance stabilization, and the out-of-plane bending is likely to contribute in lowering the barrier of III.

Further study is necessary for a definite conclusion on the ratio of contribution of these factors, but we may tentatively conclude as follows. In the case of compounds in which a strong resonance interaction is expected, the planar transition state is important, whereas in the case in which no strong resonance interaction is expected, both the planar and bent transition state must be considered.

Experimental

Spectra. The NMR spectra of II were obtained on a JNM 4H-100 spectrometer operating at 100 MHz, and those of III and IV on a JNM C-60H spectrometer at 60 MHz. Temperatures were read with methanol or ethylene glycol sample and are accurate to ± 2°C. Approximately 10% (w/w) solutions in 1,1,2,2-tetrachloroethane were employed.

Materials.[19] *4-Methoxy-4′-nitro-2,2′-bitolyl*: 2-Bromo-5-nitrotoluene[18] (43 g, 0.2 mol) and 2-iodo-5-methoxytoluene[17] (50 g, 0.2 mol) were heated with copper bronze (100 g) at 220—230°C over a period of 5 hr. The reaction mixture was extracted with acetone and distilled *in vacuo*. Repeated recrystallization of the fraction boiling at 158—163°C/1 mmHg from methanol gave yellowish white crystals; yield 3.2 g (6%), mp 91—92°C.

Found: C, 70.35; H, 5.88; N, 5.44%. Calcd for $C_{15}H_{15}O_3N$: C, 70.02; H, 5.88; N, 5.44%.

4,4′-Difluoro-2,2′-bitolyl: *m*-Tolidine hydrochloride (114 g, 0.4 mol), prepared according to Wenner's method[20] was suspended in 20% hydrochloric acid (400 m*l*) and tetrazotized with aqueous solution of sodium nitrite (61 g, 0.88 mol). The reaction mixture was filtered and treated with a saturated aqueous solution of sodium fluoroborate. The tetrazonium fluoroborate was filtered, washed with saturated solution of sodium fluoroborate and cold water, dried in a vacuum desiccator, pyrolyzed and distilled with steam. Yellow oil boiling at 100—102°C/1.2 mmHg was obtained, which crystallized on cooling; yield 25 g (29%), mp 25—26°C (from methanol).

14) B. Williamson and W. H. Rodebush, *J. Amer. Chem. Soc.*, **63**, 3018 (1941).
15) The correlation of the electron density and the ease of the out-of-plane bending has been observed. In IR spectra, the absorption due to out-of-plane bending of C–H bonds of monosubstituted benzenes appears in 750 cm^{-1} region and electron-withdrawing groups shift the absorption to higher wave number. These phenomena were interpreted in terms of "orbital following".[16]

4,4'-Dibromo-2,2'-bitolyl: Tetrazotization of *m*-tolidine hydrochloride (71 g, 0.25 mol) with 48% hydrobromic acid (350 m*l*) and sodium nitrite (39 g) followed by decomposition with copper bronze (5 g) gave an oil boiling at 170—175°C/3 mmHg. Recrystallization of the distillate from acetone - methanol (1 : 1) afforded white crystals; yield 11 g (13%), mp 57—58°C.

Found: C, 49.50; H, 3.47%. Calcd for $C_{14}H_{12}Br_2$: C, 49.45; H, 3.56%.

Dimethyl 2,2'-Bitolyl-4,4'-dicarboxylate: 4,4'-Dicyano-2,2'-bitolyl, propared according to the method of Theilacker[21] was hydrolyzed with alkali. The crude carboxylic acid was suspended in ether and treated with the ether solution of diazomethane. The solvent and excess diazomethane were evaporated and the residue was recrystallized from methanol affording white crystals, mp 98—99°C.

Found: C, 72.61; H, 6.07%. Calcd for $C_{18}H_{18}O_4$: C, 72.47; H, 6.08%.

2,2'-Bisbromomethyl-4-methoxy-4'-nitrobiphenyl: 4-Methoxy-4'-nitro-2,2'-bitolyl (5.1 g, 0.02 mol), *N*-bromosuccinimide (7.1 g, 0.04 mol) and benzoyl peroxide (0.2 g) were heated under reflux in carbon tetrachloride (150 m*l*) for 2.5 hr. Succinimide was filtered off and the filtrate was evaporated. Chromatography of the residual oil on alumina gave the desired compound by elution with petroleum ether - benzene (1 : 1); mp 115—116°C (from acetone - methanol (1 : 1)).

Found: C, 43.02; H, 3.22; N, 3.36%. Calcd for $C_{15}H_{13}O_3NBr_2$: C, 43.40; H, 3.16; N, 3.38%.

Elution of the column with benzene gave yellow crystals melting at 148—150°C, which were identified as 3-methoxy-9-nitro-5,7-dihydrodibenz[*c,e*]oxepin. The oxepin was inferred to be formed by the reaction of the dibromide with a trace of water existing in the column under the catalysis of alumina.

Found: C, 66.16; H, 4.97; N, 5.49%. Calcd for $C_{15}H_{13}O_4N$: C, 66.41; H, 4.83; N, 5.16%.

3-Methoxy-9-nitro-5,7-dihydrodibenzo[c,e]*thiepin (II)*: 2,2'-Bisbromomethyl-4-methoxy-4'-nitrobiphenyl (2.1 g, 0.005 mol) and sodium sulfide nonahydrate (1.4 g, 0.0055 mol) in methanol (300 m*l*) were heated under reflux for 10 hr. A major portion of the solvent was evaporated. The residue was poured into water and extracted with benzene. The combined extracts were dried with anhydrous sodium sulfate, evaporated and chromatographed on an alumina column. The eluate with petroleum ether - benzene (1 : 1) gave pale yellow crystals; mp 140—141°C (from methanol).

Found: C, 62.28; H, 4.72; N, 4.98%. Calcd for $C_{15}H_{13}O_3NS$: C, 62.70; H, 4.56; N, 4.88%.

3,9-Dimethoxy-5,7-dihydrodibenzo[c,e]*thiepin (III)*: 4,4'-Dimethoxy-2,2'-bitolyl[22] (9.7 g, 0.04 mol), *N*-bromosuccinimide (16.0 g, 0.09 mol) and benzyol peroxide (0.2 g) in carbon tetrachloride (200 m*l*) were heated under reflux for 2 hr. Filtration of succinimide and evaporation of the solvent gave an oily residue, which without purification was heated with sodium sulfide nonahydrate (10 g) in methanol for 8 hr. The product was recrystallized from acetone to afford white crystals, mp 141—142°C.

Found: C, 70.20; H, 6.38%. Calcd for $C_{16}H_{16}O_2S$: C, 70.55; H, 5.92%.

3,9-Difluoro-5,7-dihydrodibenzo[c,e]*thiepin (IV)*: 4,4'-Difluoro-2,2'-bitolyl was similarly treated with *N*-bromosuccinimide to give the dibromide which boiled at 155—156°C/1 mmHg and was heated with sodium sulfide. The product was distilled at 134—135°C/1.5 mmHg and recrystallized from methanol, affording colorless crystals melting at 88—89°C.

Found: C, 67.82; H, 4.13%. Calcd for $C_{14}H_{10}F_2S$: C, 67.72; H, 4.06%.

3,9-Dibromo-5,7-dihydrodibenzo[c,e]*thiepin (V)*: A similar treatment of 4,4'-dibromo-2,2'-bitolyl with *N*-bromosuccinimide and then with sodium sulfide afforded white crystals, mp 184.5—185°C (lit,[23] 191—192°C), after recrystallization from acetone.

Dimethyl 5,7-Dihydrodibenzo[c,e]*thiepin-3,9-dicarboxylate (VI)*. Dimethyl 2,2'-bitolyl-4,4'-dicarboxylate, treated similarly with *N*-bromosuccinimide followed by sodium sulfide, yielded the desired compound, mp 107—108°C, on recrystallization from ethanol - acetone (1 : 1).

Found: C, 65.77; H, 5.19%. Calcd for $C_{18}H_{16}O_4S$: C, 65.84; H, 4.91%.

Effects of *para*-Substituents on the Rates of Inversion of Biphenyl Derivatives. II. 2-Isopropyl-2′-methoxybiphenyls

Michinori Ōki and Gaku Yamamoto

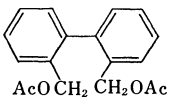
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received August 22, 1960)

Nine 4,4′-substituted 2-isopropyl-2′-methoxybiphenyls were synthesized and temperature dependence of the NMR spectra of these compounds was examined. The effects of the substituents on the energy barrier to inversion of the biphenyl skeleton can be interpreted in terms of both resonance stabilization and out-of-plane bending of the axis bond at the transition state. In the latter, an electron-donating substituent makes the bond bendig easier and lowers the barrier, whereas an electron-withdrawing group raises the barrier.

In a preceding paper[1] we reported that, in an *o,o′*-bridged biphenyl system where dynamic NMR technique (DNMR) could be applied, the energy barrier to inversion was really affected by the *para*-substituents. We postulated that the effects of the substituents on the barrier might be interpreted in terms of resonance stabilization and out-of-plane bending of the axis bond at the transition state. However, no definite conclusion could be given, because of the limited number of examples due to synthetic and other difficulties.

In this paper we wish to report on a study of the effects of *para*-substituents on the energy barrier to inversion of the non-bridged biphenyl system. There has been only one case where the energy barrier to inversion of non-bridged biphenyl is examined using DNMR. Meyer and Meyer[2] reported on the DNMR of 2,2′-bis(acetoxymethyl)biphenyl (I), where methylene protons showed AB quartet signal ($\delta_{AB}=3.5$, $J_{AB}=12.6$ Hz, in CS_2) at room temperature, and coalesced

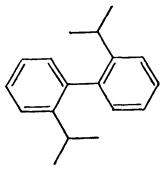


I

at 94°C into a singlet, the result indicating the activation energy of about 13 kcal/mol. A small chemical shift difference seemed to prevent precise line-shape analysis, hence this system did not seem suitable for our purpose.

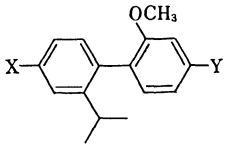
o,o′-Diisopropylbiphenyl (II), possessing geminal dimethyl groups instead of methylene groups in *ortho* positions, was considered. The NMR spectrum of II at room temperature showed double doublets corresponding to the methyl protons of isopropyl groups, indicating that the inversion is slow on the NMR time scale. That the double doublets neither broadened nor coalesced up to 180°C (in hexachloro-1,3-butadiene) indicated that the free energy of activation for rotation about the axis bond is higher than 27 kcal/mol, and that this system also was unsuitable for DNMR study.

2-Isopropyl-2′-methoxybiphenyl (III), derived by replacement of one of the isopropyl groups in II by a less bulky methoxyl group, was considered for study



II

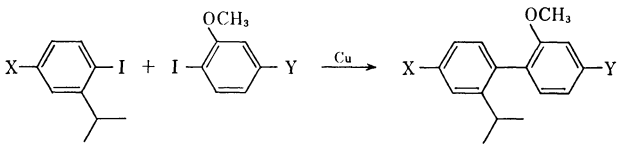
by means of DNMR. Replacement by methoxyl was chosen considering the synthetic ease. III and its 4,4′-substituted derivatives (IV—XI) were thus synthesized and their NMR spectra were examined over a wide range of temperature.



III: X=Y=H
IV: X=H, Y=OCH_3
V: X=H, Y=NO_2
VI: X=OCH_3, Y=H
VII: X=Y=OCH_3
VIII: X=OCH_3, Y=NO_2
IX: X=NO_2, Y=H
X: X=NO_2, Y=OCH_3
XI: X=Y=NO_2

Results and Discussion

Nine derivatives of 2-isopropyl-2′-methoxybiphenyl were synthesized by the Ullman reaction, *viz.*, the coupling of 2-iodocumenes (XII—XIV) and 2-iodoanisoles (XV—XVII) in the presence of copper bronze (Scheme 1).



XII: X=H
XIII: X=OCH_3
XIV: X=NO_2
XV: X=H
XVI: X=OCH_3
XVII: X=NO_2
III—XI

Scheme 1

The desired unsymmetrical biphenyls were isolated by distillation and/or column-chromatography. Nine biphenyls (III—XI) as well as two 2-iodocumenes (XIII and XIV) are new compounds. Elementary analyses and NMR spectra of these compounds were consistent with the expected ones.

5-Methoxy- (XIII) and 5-nitro-2-iodocumene (XIV)

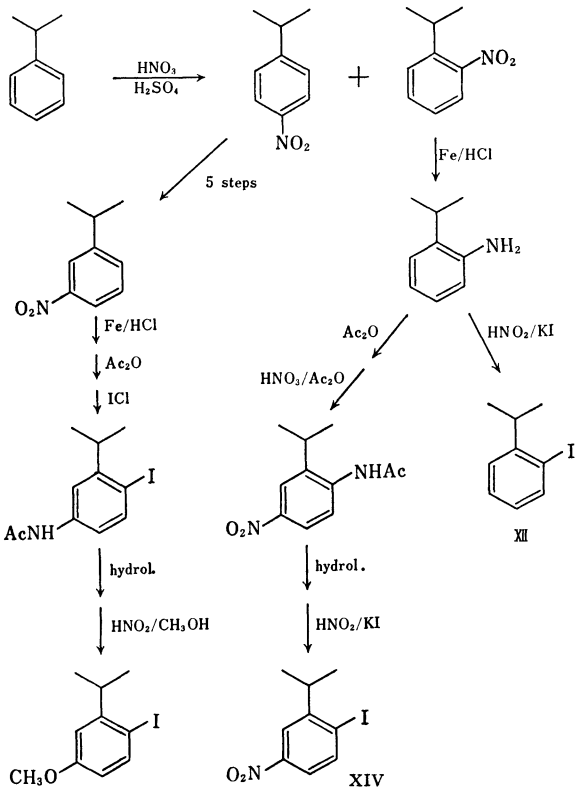
2) W. L. Meyer and R. B. Meyer, *J. Amer. Chem. Soc.*, **85**, 2170 (1963).



Scheme 2

were synthesized from cumene as described in Scheme 2. The positions of the introduced iodine in XIII and of the nitro group in XIV were confirmed by analysis of the aromatic proton signals in their NMR spectra, and further by comparison of the spectra with those of the corresponding toluene derivatives; XIII *vs.* 2-iodo-5-methoxytoluene and XIV *vs.* 2-iodo-5-nitrotoluene, each pair of spectra showing the same pattern of the aromatic proton signals.

The NMR spectra were measured as 15% solutions in 1,1,2,2-tetrachloroethane over a range from −10 to +150°C. Methyl protons of each compound showed a pair of doublets ($J\sim7$ Hz), with a separation of about 10 Hz at room temperature. This magnetic nonequivalence of the two methyls of the isopropyl groups indicated that inversion of the biphenyl skeleton is slow on the NMR time scale.

As the temperature was raised, the double doublet signal gradually broadened accompanying the gradual decrease in apparent chemical shift difference. The signal then became a broad single peak. The temperature at which this line shape was attained was regarded as the coalescence temperature T_c. With a further rise of temperature the signal split into two peaks, which gradually sharpened. At 150°C a sharp doublet was observed indicating fast inversion. A typical example, the case of V, is shown in Fig. 1.

The apparent chemical shift difference of the two methyl groups below T_c changed as shown in Fig. 2. The "intrinsic" chemical shift difference without exchange varied almost linearly with temperature. This phenomenon may be explained as follows. The "intrinsic" chemical shift difference is a weighed average of the chemical shift differences in conformations arising

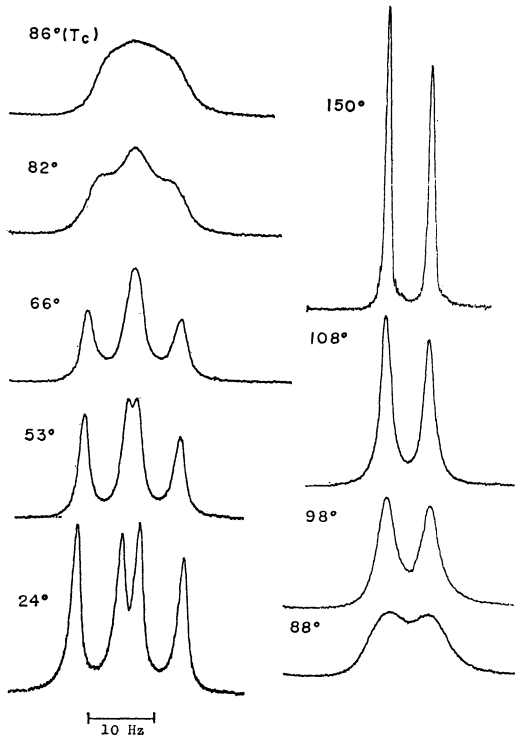


Fig. 1. The temperature dependence of the methyl proton signal of V.

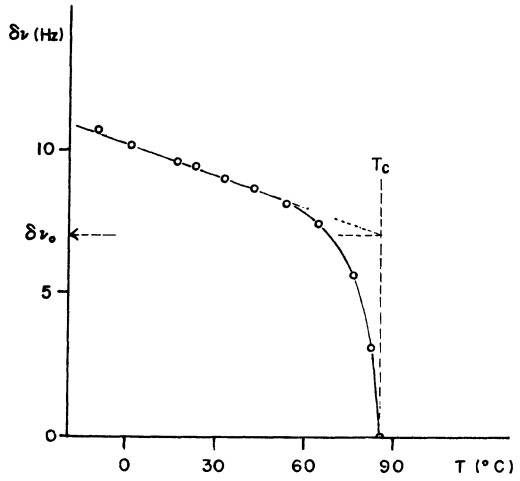

Fig. 2. The temperature dependence of the apparent chemical shift difference of the methyl protons of III.

from rotation about the bond between the isopropyl group and the benzene ring. The relative populations of these conformations may change with temperature because of the difference in potential energies, and this causes the observed change in chemical shift difference.

The same phenomenon was observed in the NMR spectra of *o,o′*-diisopropylbiphenyl (II). The methyl protons of II showed a chemical shift difference of 5.2, 4.9 and 4.5 Hz at 80, 120 and 180°C, respectively, at 60 MHz.

In order to obtain the kinetic parameters for inversion, these spectral changes were analyzed regarding them as two overlapping doublets, each coalescing into a singlet.

Inversion rate, k_c, at T_c was calculated using the

equation[3]

$$k_c = \frac{\pi\delta\nu_0}{\sqrt{2}} \quad (1)$$

where $\delta\nu_0$ represents the chemical shift difference of the two methyl groups without exchange. $\delta\nu_0$ was obtained by extrapolating the chemical shift differences at various temperatures to T_c.

Approximate inversion rate k at temperatures above T_c was calculated following the fast exchange approximation

$$k = \frac{\pi(\delta\nu_0)^2}{2(W - W_0)} \quad (2)$$

where W and W_0 are the signal width at half height at a given temperature and at a free exchange on the NMR time scale, respectively. W value at the highest temperature was used as W_0. The same numerical value as was used for the $\delta\nu_0$ in Eq. (1) was used for the $\delta\nu_0$ in Eq. (2). Uncertainty of the value inevitably gives rise to a considerably large error in k values.

The k values were plotted against the reciprocal temperature, which gave fairly good linearity. The inversion rate at 86°C was obtained graphically from this plot and $\Delta G_{86}^{\ddagger}$, the free energy of activation at 86°C, was calculated for each compound. The results are given in Table 1.

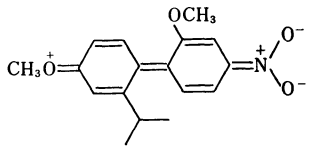
Table 1. Kinetic parameters of the inversion of 2-isopropyl-2′-methoxybiphenyls

Compound	X	Y	T_c (°C)	$\delta\nu_0$[a] (Hz)	$\Delta G_c^{\ddagger}$[b] (kcal/mol)	k_{86} (sec^{-1})	$\Delta G_{86}^{\ddagger}$[b] (kcal/mol)
III	H	H	86	7.2	19.2	16	19.2
IV	H	OCH_3	74	7.8	18.5	33	18.7
V	H	NO_2	86	7.1	19.2	16	19.2
VI	OCH_3	H	70	7.5	18.3	53	18.3
VII	OCH_3	OCH_3	61	7.3	17.9	82	18.0
VIII	OCH_3	NO_2	65	7.8	18.0	65	18.2
IX	NO_2	H	79	7.2	18.8	23	18.9
X	NO_2	OCH_3	58	8.0	17.6	80	18.0
XI	NO_2	NO_2	82	6.6	19.0	19	19.1

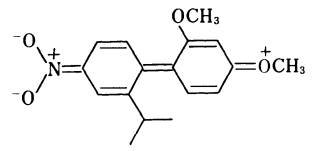
a) Extrapolated value to T_c.
b) The maximum errors for $\Delta G_c^{\ddagger}$ and $\Delta G_{86}^{\ddagger}$ are estimated to be ±0.1 and ±0.3 kcal/mol, respectively.

Enthalpy and entropy of activation derived from NMR line shape analysis, particularly by use of approximate equations were noted to involve serious errors.[4] Thus, in our case it seemed risky to discuss quantitatively using the obtained values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. We will rather discuss assuming that there is no large variation in $\Delta S^{\ddagger}$ values among the compounds in question, that is, the relative order of $\Delta G_{86}^{\ddagger}$ values corresponds to the relative order of the energy barrier to inversion. $\Delta G_{86}^{\ddagger}$ is considered to be reliable within the error of 0.3 kcal/mol.

Low barriers in 4-methoxy-4′-nitro- (VIII) and 4′-methoxy-4-nitro- (X) derivatives are in accordance with the results in 5,7-dihydrodibenzo[*c*,*e*]thiepin system[1] and may be explained in terms of resonance stabilization of the transition state, due to the contribution of canonical structures XVIII and XIX.



XVIII



XIX

Comparison of the data for compounds IV and V is of interest. The contribution of resonance stabilization by the through conjugation in these compounds is thought to be of the same order. The difference may then be attributed to the difference in the extent of release of steric interactions by the out-of-plane bending of the axis bond. The electron-donating methoxyl group increases the π-electron density at 1,1′-positions, and according to the orbital following theory[5] this makes the out-of-plane bending of the axis bond easier. This means that the steric interactions between the *ortho* positions in the coplanar transition state are more easily released and thus the energy barrier to inversion is lowered.

Decrease in the $\Delta G_{86}^{\ddagger}$ values for IV relative to that for III may be interpreted to be due to the sum of the small conjugation effect and the bond bending effect.

The ease of the bond bending is reasonably expected to increase with the increasing number of the methoxyl groups: 2′-(III)<2′,4′-(IV)<4,2′-(VI)<4,2′,4′-(VII). The obtained data clearly agree with this prediction. It is interesting that the 4,4′-dimethoxy derivative (VII) has almost the same barrier as the 4-methoxy-4′-nitro one (VIII), which indicates that the bond bending factor is as important as the resonance stabilization factor in lowering the barrier.

On the other hand, the orbital following theory predicts that the electron-withdrawing nitro group lowers the π-electron density at 1,1′-positions and makes the out-of-plane bending of the axis bond less easy. The reason why V has the same barrier as III is ascribed to two compensating factors, *viz.*, resonance stabilization and destabilization due to the difficulty of the out-of-plane bending at the transition state. A small decrease in the barrier for IX relative to that for III may be interpreted as the conjugation effect represented

XX

by the canonical structure XX exceeding the destabilization effect of the nitro group. It seems that an *o*-quinoid structure such as XX is much less important in stabilizing the transition state than *p*-quinoid structures such as XVIII and XIX. Increased double bond character of $C_{2'}$-O bond makes the in-plane bending of this bond difficult, which otherwise could release the non-bonded interactions at the transition state. In compound XI an almost complete compensation of the two factors is observed.

Of course, the bond bending factor may be operating also in compounds VIII and X, but here the resonance stabilization factor may be far more important in lowering the energy barrier.

Harris and Cheung King Ling[6] have proposed that the dependence of the racemization rates of optically active 2,2′-diiodobiphenyls on the *para*-substituents could be interpreted on the assumption that the axis bond bent out of the plane of the benzene rings at the transition state.

The possibility of such bond bending could be attributed to the extreme bulkiness of the *ortho* substituents. But the present study seems to show that out-of-plane bending of the axis bond contributes in lowering the energy barrier to inversion in biphenyl systems possessing as low a barrier as can be studied by DNMR.

Experimental

Spectra. NMR spectra were obtained on a JNM C-60H or a Hitachi R-20A spectrometer both operating at 60 MHz. The temperatures were read with ethylene glycol sample and are accurate to ±2C°. Approximately 15% (w/w) solutions in 1,1,2,2-tetrachloroethane were employed.

Materials.[7] o-*Iodocumene (XII)*: *o*-Isopropylaniline, prepared by reduction of *o*-nitrocumene, was diazotized and treated with potassium iodide. Slightly colored oil was obtained; bp 116—117°C/12 mmHg (lit,[8] 84—85°C/2 mmHg).

3-Isopropyl-4-iodoacetanilide: Freshly prepared iodine monochloride (16.2 g, 0.1 mol) in acetic acid (10 m*l*) was added to a stirred solution of *m*-isopropylacetanilide (13.5 g, 0.1 mol) in acetic acid (15 m*l*) at room temperature over a period of 1 hr. The reaction mixture was poured into water containing a small amount of sodium bisulfite. The solidified mass, after recrystallization from methanol - water (5 : 1), gave colorless plates; yield 20 g (60%), mp 130—131°C.

Found: C, 43.40; H, 4.58; N, 4.68%. Calcd for $C_{11}H_{14}ONI$: C, 43.58; H, 4.66; N, 4.62%.

3-Isopropyl-4-iodoanisole (XIII): 3-Isopropyl-4-iodoacetanilide (18.2 g, 0.06 mol) was hydrolyzed with alcoholic potassium hydroxide. The resulting aniline was dissolved in 100 m*l* methanol containing sulfuric acid (15 m*l*), diazotized with sodium nitrite (5 g) in minimal amount of water with ice-cooling. The diazotized solution was warmed on a water bath until boiling and finally heated under reflux for 15 min. After evaporation of the major portion of methanol, the residue was poured into water and extracted with ether. The ethereal solution was shaken with dilute sodium hydroxide solution to separate the phenol from the anisole. The aqueous layer was treated with dimethyl sulfate and the resulting oil was extracted with ether. The two ethereal solutions were combined, washed with dilute alkali and water, and dried with potassium carbonate. Vacuum distillation gave colorless oil; yield 14 g (80%), bp 110—111°C/2 mmHg.

Found: C, 43.36; H, 4.72%. Calcd for $C_{10}H_{13}OI$: C, 43.50; H, 4.74%.

2-Isopropyl-4-nitroacetanilide: *o*-Isopropylaniline (40.5 g, 0.3 mol), dissolved in acetic anhydride (300 m*l*), was cooled down to −50°C with dry ice-alcohol, and freshly distilled nitric acid (specific gravity 1.51) was added dropwise during the course of 3 hr. Stirring was continued further 4 hr during which period the temperature was kept below −40°C. The reaction mixture was poured onto ice-water affording an oil. Repeated recrystallizations from methanol gave colorless needles; yield 12 g (18%), mp 159—161°C.

Found: C, 59.28; H, 6.65; N, 12.74%. Calcd for $C_{11}H_{14}O_3N_2$: C, 59.45; H, 6.35; N, 12.60%.

2-Iodo-5-nitrocumene (XIV). 2-Isopropyl-4-nitroacetanilide (22.2 g, 0.1 mol) was heated under reflux with sulfuric acid (30 m*l*) in water (100 m*l*) for 3 hr. The solution was cooled with ice-bath, and diazotized with sodium nitrite (8 g) solution. After decomposition of excess nitrous acid with urea, aqueous potassium iodide (20 g, 0.12 mol) was added. The reaction mixture was kept at room temperature for 10 min, at 60°C for 15 min and cooled to room temperature. After extraction with ether, the ether layer was washed successively with sodium bisulfite solution, dilute sodium hydroxide solution and water and dried with potassium carbonate. Distillation gave 19.5 g (67%) of an oil, bp 128—129°C/2 mmHg.

Found: C, 37.21; H, 3.59; N, 4.82%. Calcd for $C_9H_{10}O_2NI$: C, 37.14; H, 3.46; N, 4.81%.

General Procedure of the Ullman Reaction. *o*-Iodocumene (or its 4-substituted derivative) and 1 to 5 molar equivalent of *o*-iodoanisole (or its 4-substituted derivative) were mixed and heated at 150°C. Approximately the same weight of copper bronze as the iodine compounds was added to the mixture, which was then gradually heated up to 220—250°C and kept for 1 to 2 hr. The reaction mixture was cooled to room temperature and extracted with acetone. The evaporated extract contained symmetrically substituted biphenyls, 2,2′-dimethoxybiphenyl and 2,2′-diisopropylbiphenyl, as well as the decomposition products of low molecular weight, in addition to the desired unsymmetrical biphenyl. In most cases the desired product was isolated by distillation under reduced pressure and/or column chromatography followed by repeated recrystallizations.

2-Isopropyl-2′-methoxybiphenyl (III) was obtained after recrystallization from methanol as colorless crystals, mp 36°C.

Found: C, 84.93; H, 8.31%. Calcd for $C_{16}H_{18}O$: C, 84.91; H, 8.02%.

2-Isopropyl-2′,4′-dimethoxybiphenyl (IV) was collected as a fraction boiling at 142—145°C/2 mmHg which resisted crystallization. Repeated distillation gave a colorless oil.

Found: C, 79.82; H, 7.65%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

2-Isopropyl-2′-methoxy-4′-nitrobiphenyl (V) was obtained as pale

yellow crystals, mp 101—102°C (from methanol).

Found: C, 70.98; H, 6.50; N, 5.04%. Calcd for $C_{16}H_{17}O_3N$: C, 70.83; H, 6.32; N, 5.16%.

2-Isopropyl-4,2'-dimethoxybiphenyl (VI) was obtained as a colorless oil, bp 142—145°C/2.5 mmHg.

Found: C, 79.70; H, 7.68%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

2-Isopropyl-4,2',4'-trimethoxybiphenyl (VII) crystallized from methanol as colorless granules, mp 56—57°C.

Found: C, 75.35; H, 7.95%. Calcd for $C_{18}H_{22}O_3$: C, 75.49; H, 7.74%.

2-Isopropyl-4,2'-dimethoxy-4'-nitrobiphenyl (VIII) was recrystallized from petroleum ether (bp 50—60°C) affording yellow orange granules, mp 73.5—74.5°C.

Found: C, 67.63; H, 6.40; N, 4.44%. Calcd for $C_{17}H_{19}O_2N$: C, 67.76; H, 6.36; N, 4.65%.

2-Isopropyl-2'-methoxy-4-nitrobiphenyl (IX) was obtained by recrystallization from methanol as pale yellow crystals, mp 72—73°C.

Found: C, 70.84; H, 6.61; N, 5.09%. Calcd for $C_{16}H_{17}O_3N$: C, 70.83; H, 6.32; N, 5.16%.

Chromatography of the reaction mixture also afforded 2,2'-diisopropyl-4,4'-dinitrobiphenyl as orange crystals, mp 172—174°C (from methanol).

Found: C, 65.93; H, 6.20; N, 8.45%. Calcd for $C_{18}H_{20}O_4N_2$: C, 65.84; H, 6.14; N, 8.53%.

2-Isopropyl-2',4'-dimethoxy-4-nitrobiphenyl (X) was obtained by repeated recrystallizations from ethanol as yellow crystals, mp 108—110°C.

Found: C, 68.06; H, 6.84; N, 4.66%. Calcd for $C_{17}H_{19}O_4N$: C, 67.76; H, 6.36; N, 4.65%.

2-Isopropyl-2'-methoxy-4,4'-dinitrobiphenyl (XI) was obtained by repeated recrystallizations from acetone as orange yellow plates, mp 139—140°C.

Found: C, 60.56; H, 5.25; N, 8.75%. Calcd for $C_{16}H_{16}O_5N_2$: C, 60.76; H, 5.10; N, 8.86%.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 271—272 (1971)

Studies of the *N*-Oxides of *N,N*-Dialkylamino Acids. IV. The Decarboxylation of *N,N*-Dimethylamino Acid *N*-Oxides with *p*-Toluenesulfonyl Chloride in Pyridine

Yoshikazu IKUTANI

Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka

(Received December 30, 1969)

Though many investigations have been made of the reactions between heteroaromatic tertiary amine *N*-oxides and acylating reagents, little attention has been paid to the similar reactions of aliphatic tertiary amine *N*-oxides especially *N,N*-dialkylamino acid *N*-oxides.

In the previous papers of this series, the preparations of *N*-oxides of *N,N*-dimethyl neutral amino acids,[1] *N,N*-dialkylglycine,[2] and *N,N*-dimethyl acidic amino acids[3] were investigated. In the present study, the decarboxylations of *N,N*-dimethylamino acid *N*-oxides with *p*-toluenesulfonyl chloride in pyridine and the hydrolysis of the reaction products have been investigated.

The evolution of carbon dioxide was observed immediately when *N,N*-dimethylamino acid *N*-oxide was treated with an equivalent amount of *p*-toluenesulfonyl chloride in pyridine at 5°C or below. The mixture, when allowed to stand for about a half an hour with shaking, turned a light red-brown. The carbon dioxide generated was collected as barium carbonate and weighed. The results thus obtained are shown in Table 1.

Table 1. The decarboxylation of *N,N*-dimethylamino acid *N*-oxide with *p*-toluenesulfonyl chloride in pyridine

Parent amino acid	Yields of carbon dioxide (%)
Gly	80
DL-Ala	33
DL-Val	16
L-Glu	57
L-Phe	74

In the reaction of *N,N*-dimethylglycine *N*-oxide with *p*-toluenesulfonyl chloride, the reaction mixture was concentrated to remove the excess pyridine; the residue was then treated with hot acetone to remove the pyridine hydrochloride and the pyridine hydro-*p*-toluenesulfonate. All attempts to obtain any crystalline product from the dark red-brownish sticky residue failed, but the following experiments confirmed the syrup to be a mixture of *N,N*-dimethyl-methyleneimmonium chloride and *p*-toluenesulfonate. The acid hydrolysis of the syrup gave formaldehyde and dimethylamine.

Further experiments with ion-exchange resin were performed in order to confirm the structure of the reaction product. The decarboxylation was performed much as has been described above, and the residue was dissolved in water. A half of the resulting solution was deposited on an ion-exchange column (Amberlite IRA-410, OH-form); it was then eluted with water. The eluate was hydrolysed much as has been described above. Formaldehyde as 2,4-dinitrophenylhydrazone and dimethylamine as *p*-toluenesulfonamide were obtained in almost quantitative yields. Another half of the resulting solution was deposited on an ion-exchange column (Amberlite IR-120, H-form), and subsequently eluted with water. The eluate included *p*-toluenesulfonic acid and hydrochloric acid. A part of the effluent was titrated directly, and another part was dried up in order to remove the hydrochloric acid, dissolved in water, and titrated. The value of the former was 2.02 equivalents of the corresponding *N*-oxide, while the value of the latter was 0.98. These results indicate that the formation of the immonium salts and the reaction mechanism shown in Fig. 1 may be postulated.

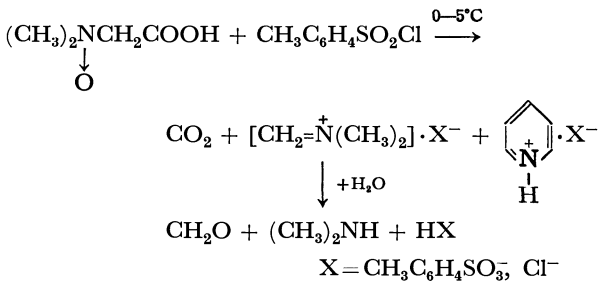

Fig. 1

Experimental

The Decarboxylation of N,N-*Dimethylglycine* N-*Oxide with* p-*Toluenesulfonyl Chloride in Pyridine.* In a flask, 3.5 g of *N,N*-dimethylglycine *N*-oxide were placed, the flask was cooled in an ice bath to 5°C or below, and then 5.7 g of *p*-toluenesulfonyl chloride in 20 m*l* of pyridine were added, drop by drop with shaking, over a period of approximately 15 min, after which the mixture was shaken for more than 15 min. At the end of the reaction, the evolution of carbon dioxide ceased. The carbon dioxide generated was led into

3) Y. Ikutani, *ibid.*, **43**, 3602 (1970).

a solution of barium hydroxide with nitrogen gas; 4.7 g of barium carbonate were thus obtained. The reaction mixture was concentrated under reduced pressure to remove the excess pyridine. The residue was then extracted with three 20 m*l* portions of hot acetone. The combined extract was concentrated under reduced pressure and stored in a refrigerator overnight. Pyridinium *p*-toluenesulfonate (5.1 g) was thus obtained as a precipitate. The filtrate was then dried up under reduced pressure; 1.2 g of pyridine hydrochloride were obtained. The extracted remnant was washed with ether several times and dried under reduced pressure. It was then dissolved in 100 m*l* of water, controlled to pH 2 with hydrochloric acid. To a half of the resulting solution, a mixture of 3.0 g of 2,4-dinitrophenylhydrazine, 15 g of concentrated sulfuric acid, 20 m*l* of water, and 70 m*l* of ethanol was added; the solution was then allowed to stand at room temperature for a few days. The yield of 2,4-dinitrophenylhydrazone of formaldehyde thus obtained was 3.1 g. To the other half of the solution, 15 m*l* of 2N hydrochloric acid were added, and the mixture was allowed to stand at room temperature for 5 days. To the resulting solution 5.0 g of *p*-toluenesulfonyl chloride were added, and then 2N aqueous sodium hydroxide was added with vigorous stirring to keep the mixture in a weak alkaline condition overnight. The precipitates were then collected by filtration, washed with water, and dried under reduced pressure to yield 2.2 g of *N*,*N*-dimethyl-*p*-toluenesulfonamide.

In another experiment, the decarboxylation of 2.4 g of *N*,*N*-dimethylglycine *N*-oxide and 3.8 g of *p*-toluenesulfonyl chloride in 15 m*l* of pyridine was performed in a manner similarly to that described above. After the completion of the reaction, 30 m*l* of water were added. A half of the resulting solution was deposited on an ion-exchange column of Amberlite IRA-410 (OH-form), and then eluted with water. The eluate was collected until it became neutral. To a half of the effluent, 25 m*l* of 2N hydrochloric acid, and then a mixture of 2.0 g of 2,4-dinitrophenylhydrazine, 10 g of concentrated sulfuric acid, 15 m*l* of water, and 50 m*l* of ethanol, were added. The mixture was allowed to stand at room temperature, and then it was heated at 80°C for 6 hr. 2,4-Dinitrophenylhydrazone of formaldehyde (1.0 g) was thus obtained. To one half of the effluent, 25 m*l* of 2N hydrochloric acid were added. When the mixture was treated much as has been described above, 0.90 g of *N*,*N*-dimethyl-*p*-toluenesulfonamide was obtained. The other half of the resulting solution was deposited on a column of Amberlite IR-120 (H-form) and then eluted with water. The effluent was diluted to 250 m*l* with water. The titration of 25 m*l* of the resulting solution with 0.1N (f=1.14) aqueous sodium hydroxide, using phenolphthalein as an indicator, required 17.93 m*l*. Another 25 m*l* portion of the resulting solution was dried up under reduced pressure and dissolved in 20 m*l* of water. The titration required 8.50 m*l* of 0.1N (f=1.14) aqueous sodium hydroxide.

The author is indebted to Professor Eizo Matsumura for his constant guidance in the course of the work, and to Professor Yoshiharu Izumi of Osaka University for his valuable advice and encouragement.

The Dipole Moment of the Trimethylamine-iodine Complex

Hiroaki MIHONO and Koichi TOYODA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received April 30, 1970)

One of the present authors[1] reported last year that his experimental measurements of the dipole moment of the triethylamine-iodine(Et_3N-I_2) complex confirmed the value, 5.5—5.7D, previously reported by Boule[2] in a cyclohexane solution. Furthermore, the dipole moment of the Et_3N-I_2 complex in a benzene solution was found to increase with the time after the two solutions had been mixed. These experimental values of the dipole moment show a much lower value than the value,[3] 12D, obtained in a dioxane solution. One of the present authors[3] has recently reported that his experimental dipole moment of the trimethylamine-iodine(Me_3N-I_2) complex shows the very large value, 10D, in a dioxane solution. We have reinvestigated the dipole moment of the Me_3N-I_2 complex in cyclohexane and in benzene; the importance of the complex as a typical example is so great that extra efforts to obtain accurate data are justified.

Experimental

The cyclohexane, benzene, and iodine were purified and stored by the method reported previously.[1] Trimethylamine generated from its aqueous solution by adding concentrated aqueous alkali was dried by potassium hydroxide. The dry trimethylamine thus obtained was led into cyclohexane to prepare the stock solution. The I_2 and Me_3N solutions were both made up by weight. The Me_3N solutions were prepared by the use of Le Fèvre's method.[4] The apparatus for the measurements of dielectric constants and the picnometer for the measurements of densities have been reported on previously.[1] The temperature was kept constant within 25.00 ± 0.05°C throughout the series of measurements. The dipole moment of nitrobenzene obtained by means of this apparatus was 4.06D in a benzene solution at 25°C. In each series of measurements, benzene or cyclohexane solutions containing a fixed concentration of Me_3N and various concentrations of iodine were used. The latter concentrations ranged from 0 to 8.0×10^{-3} mol/l in benzene solutions and from 0 to $3.5\times$

These straight lines are able to express
$\varepsilon_{123}=2.2763+13.3174W_3$, $d_{123}=0.87256+0.58852W_3$.

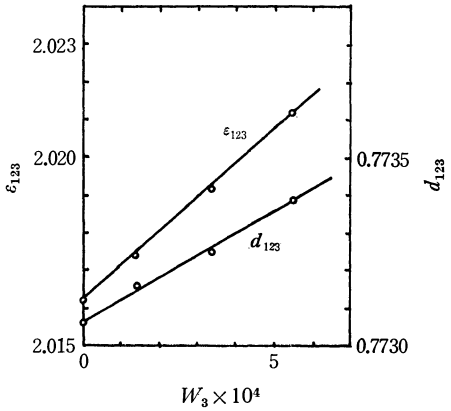

Fig. 2. In a cyclohexane solution, the relations between ε_{123} or d_{123} and W_3. These straight lines are able to express
$\varepsilon_{123}=2.0163+8.6538W_3$, $d_{123}=0.77308+0.57333W_3$.

10^{-3} mol/l in cyclohexane solutions; they never exceeded one-fifteenth that of amine in the solution. The dipole moments of the complex increased with an increase in the amine concentration in a mixed solvent containing benzene or cyclohexane and an amine. The dipole moments of the complexes were obtained by the use of the Kobinata-Nagakura method[5] as well as by that of a previous article.[1]

Results and Discussion

The Et_3N-I_2 complex was unstable in a benzene solution, but we have found that the Me_3N-I_2 complex is stable in a benzene solution. The relations between the experimentally-observed dielectric constants or the densities of the solutions and the weight fractions of the complexes for each series of measurements are shown in Fig. 1 for benzene solutions, and in Fig. 2 for cyclohexane solutions, as examples of the measurements. The dipole moments of the complex were calculated from the slopes of these straight lines by the use of only the first term of the Kobinata-Nagakura equation.[5] In a benzene solution, the experimental values of the dipole moment of the complex thus obtained are 6.31, 6.20, 6.12, 6.63, and 6.30D; in a cyclohexane solution, they are 5.31, 4.75, 5.42, 5.53, and 5.26D. We believe these values are reasonable as compared with the values of the Et_3N-I_2 complex in a benzene or cyclohexane solution. From the dipole moment thus obtained, the contribution of the dative structure in the present complex can be estimated at 29%.

An ESR Study of Radicals Produced in γ-Irradiated Allyl Alcohol Glass and Their Photochemical Reaction at 77°K

Shoji NODA, Keizo TORIMOTO, Kenji FUEKI, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received May 15, 1970)

The ESR spectrum of γ-irradiated allyl alcohol glass is a composite of four-line and five-line spectra.[1] The four-line spectrum has been assigned to the α-hydroxy allyl radical[1-3] (I), which disappears with UV-irradiation.[1] The five-line spectrum has been assigned to the allyl radical[1-3] (II). Neither coloration nor the ESR spectrum due to the trapped electron has been observed in this system, in contrast with the cases of γ-irradiated alkyl alcohol glasses.[4] In this work we have investigated the fate of the thermal electron, and also the photolysis and thermal behavior of the radicals in allyl alcohol glass.

Experimental

Allyl alcohol and triethylamine (TEA) were purified by fractional distillation. The γ-irradiation and ESR and optical measurements were described previously.[5] Thermal

annealing experiments were carried out at various temperatures in the range of 90—140°K by keeping the sample tube in a JES variable-temperature quartz Dewar insert. Photolysis experiments were performed with UV light from a high-pressure mercury lamp. Cut-off filters were employed if necessary.

Results and Discussion

The ESR spectrum of γ-irradiated allyl alcohol glass at 77°K is shown in Fig. 1. The trapped-electron

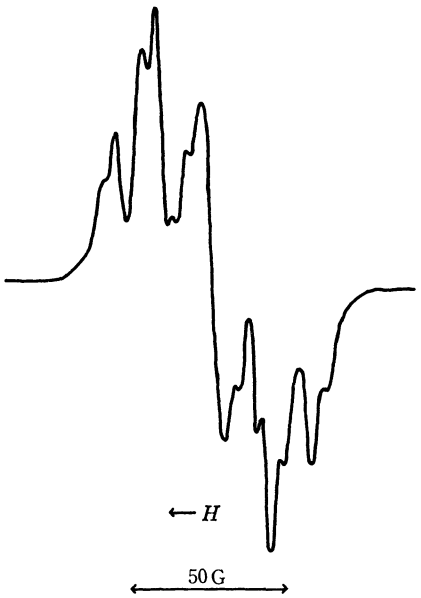

Fig. 1. ESR spectrum of γ-irradiated allyl alcohol glass at 77°K.

signal was not observed in this system, although ESR measurements were made at microwave powers low enough to avoid power saturation[6,7] and in the dark. Upon γ-irradiation, TEA glass produces a blue color and gives an ESR spectrum consisting of a sharp singlet due to the trapped electron and a broad unresolved signal due to the solvent radical.[7] The ESR spectrum of the γ-irradiated TEA containing 1 mol% of allyl alcohol is shown in Fig. 2a. The five-line spectrum appears with a decrease in the intensity of the central sharp singlet. The illumination of infrared light bleached the trapped-electron signal and increased the intensity of the five-line spectrum (see Fig. 2b). This five-line spectrum is ascribed to the radical(II) on the basis of its ESR parameters. These facts indicate that allyl alcohol reacts with the thermal electron dissociatively to produce the radical(II) and the hydroxy anion:

$$CH_2{=}CH{-}CH_2OH + e^- \longrightarrow CH_2{=}CH{-}\dot{C}H_2(II) + OH^-$$

Making use of the competitive reaction, the cross section, σ(R–OH), for electron capture by allyl alcohol relative to biphenyl was determined. Optical measurements were made in order to determine the yield of the

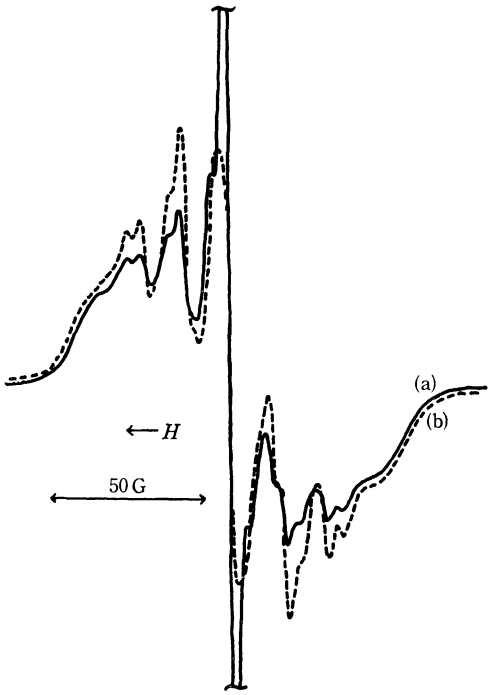

Fig. 2. ESR spectra of γ-irradiated TEA glass containing 1 mol% of allyl alcohol at 77°K, a) before bleaching, b) after bleaching with infrared light.

biphenyl anion (410 nm[8]). The observed ratio, σ(R–OH)/σ(biphenyl), was about 0.3. This agrees with that given by Habersbergerová *et al.*,[9] the ratio of the electron-capture efficiency of allyl alcohol to that of naphthalene in methanol glass being about 0.25. We have also found that other allylic compounds, such as allyl acetate, allyl formate, and allyl nitrile, react with thermal electron dissociatively to produce the radical(II) and the corresponding anion, although detailed studies on these compounds were not carried out.

When the γ-irradiated allyl alcohol glass was warmed to 118°K, the ESR spectrum changed to the pure four-line spectrum.[1] Moreover, UV-irradiation, following the γ-irradiation, caused the ESR spectrum of pure allyl alcohol glass to change from a composite of the four-line and five-line spectra into the five-line spectrum.[1] On warming this sample characterized by only a five-line spectrum, a weak four-line spectrum appeared with the decay of the five-line one. When the same sample was kept in the dark for a few days at 77°K, the spectrum changed to a composite of the four-line and five-line spectra. These facts seem to suggest that the radical(II) abstracts an α-H from allyl alcohol to produce the radical(I) at 77°K as well as at 118°K, but the evidence for this is not conclusive.[2]

Until now it has not been clear whether or not the radical(I) produces the radical(II) by UV-irradiation. The pure four-line spectrum remaining at 118°K was changed into a composite of the four-line and five-line spectra by UV-irradiation at 77°K, while prolonged UV-irradiation caused the composite spectrum to change completely into the five-line spectrum. The relative ESR peak heights of the four-line and five-line spectra are plotted against the UV-irradiation time in Fig. 3. From these results, it is apparent that the radical(I) decomposes upon UV-irradiation to produce the radical(II). As the mechanism of this photochemical conversion in allyl alcohol, the following process may be proposed:

$$CH_2{=}CH{-}CH_2OH + CH_2{=}CH{-}\dot{C}HOH\ (I) \xrightarrow{UV}$$
$$CH_2{=}CH{-}\dot{C}H_2\ (II) + CH_2{=}CHCOH + H_2O$$

A spot test[10] of the sample which had been UV-irradiated after γ-irradiation gave evidence of the presence of aldehyde, but we could not identify the aldehyde with acrolein because of the detection limit. Therefore, the scheme proposed above should be regarded as only tentative.

The relative primary yields of radicals in γ-irradiated allyl alcohol glass were obtained. The primary yield of the radical(II) was estimated to be about twice that of the radical(I). Since the radical yields of I and II must be the same if the ionic processes play an important role, the excitation process may also be concerned with the radiolysis of allyl alcohol glass. However, further product analysis is required for a complete understanding of the mechanism of the radiolysis and photolysis of allyl alcohol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 275—277 (1971)

Distribution of Aqueous Sodium Perchlorate into Some Polar Organic Solvents

Yuko HASEGAWA, Teruhiko ISHII, and Tatsuya SEKINE

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 3, 1970)

As sodium ions or perchlorate ions are usually believed to form only very weak complexes, sodium perchlorate has often been used in order to control the activity coefficients of ionic species in aqueous solutions.

However, in the systems where anionic species are extracted as ion pairs with sodium ions into an organic phase, the sodium concentration in the aqueous phase should be taken into account, and if the extracted ion pairs dissociate in the organic phase, the sodium-ion concentration in the organic phase is also important. In the extraction of mercury(II) complexes with halide or thiocyanate ions into polar solvents, some part of the complexes is assumed to consist of ion pairs of mercury(II) complex anions with sodium ions,[1] and the extraction of indium(III) halides or thiocyanate into polar solvents is very much effected by the aqueous sodium concentrations,[2] an effect which can also be explained in terms of the extraction of ion pairs of anionic indium complexes with sodium ions.

The present study has been carried out in order to obtain further, more detailed information about the liquid-liquid distribution behavior of sodium perchlorate as ion pairs.

Experimental

Reagents. The sodium-24 radioactive tracer was obtained as a sodium chloride solution. This was diluted with a large amount of water in order to prepare the stock tracer solution. The sodium perchlorate was prepared from perchloric acid and sodium carbonate and was recrystalized three times from water. The TBP(tributylphosphate), MIBK-(methylisobutylketone), methylisobutylcarbinol, and nitromethane were obtained from the Tokyo Kasei Co. They were washed with perchloric acid, water, and aqueous sodium hydroxide successively, and then several times with water. The hexane used was of a reagent grade and was used without further purification.

Procedures. All of the procedures were carried out in a thermostatted room at 25°C. Stoppered glass tubes (volume, 20 ml) were always used for the equilibration of the two phases. Sodium perchlorate solutions labelled by a radio-

1) T. Sekine and T. Ishii, This Bulletin, **43**, 2422 (1970).
2) Y. Hasegawa, H. Takeuchi, and T. Sekine, to be published.

active tracer and the organic solvent were placed in the tubes. The initial volume of the two phases was always 5 m*l*. The two phases were agitated mechanically for thirty minutes and then centrifuged. The γ-radioactivity of both phases was measured with a well-type (NaI) scintillation counter, and the distribution ratio of sodium was calculated as;

$$D = \frac{[\mathrm{Na(I)}]_{org,\ total}}{[\mathrm{Na(I)}]_{total}} = \frac{\gamma\text{-count rate per m}l\text{ of the org. phase}}{\gamma\text{-count rate per m}l\text{ of the aq. phase}}$$

Results and Discussion

In an aqueous phase, sodium salt could usually be assumed to dissociate. In an organic phase, on the other hand, the extracted ion pairs of the sodium ion and a large univalent anion, A^-, could dissociate completely or partially, or they could remain in the associated form. The distribution of sodium ion pairs from an aqueous phase to an organic phase can be described as:

$$Na^+ + A^- \rightleftarrows Na^+A^-(org) \quad (1)$$

$$K = \frac{[Na^+A^-]_{org}}{[Na^+][A^-]} \quad (2)$$

When the dissociation occurs in the organic phase:

$$Na^+A^-(org) \rightleftarrows Na^+(org) + A^-(org) \quad (3)$$

$$K^o_{diss} = \frac{[Na^+]_{org}[A^-]_{org}}{[Na^+A^-]_{org}} \quad (4)$$

The distribution ratio of sodium(I) can be described as:

$$D = \frac{[Na^+A^-]_{org} + [Na^+]_{org}}{[Na^+]} \quad (5)$$

When only one kind of sodium salt is present in the system, it is assumed that the concentration of the sodium ions is equal to that of the total number of anions, and that, consequently, $[Na^+]=[A^-]$ and $[Na^+]_{org}=[A^-]_{org}$. Then, by introducing Eqs. (2) and (4) into Eq. (5), the following equation is obtained:

$$D = K^{1/2}(K^{1/2}[Na^+] + (K^o_{diss})^{1/2}) \quad (6)$$

As no control of the activity of the chemical species in the two phases was made in the present study, only a qualitative discussion can be made of the results.

Figure 1 gives the distribution ratio of sodium between TBP, nitromethane, MIBK, or methylisobutylcarbinol and aqueous sodium perchlorate solutions as a function of the initial aqueous salt concentration. It was observed during the experiments with nitromethane that the organic volume decreases, and the aqueous volume increases remarkably, in the highest-salt-concentration region. In such systems, the aqueous salt concentration should decrease upon the volume change and also upon extraction. However, as the correction for these factors will not be easy, the sodium perchlorate concentration in the figures is given by their initial values. The extraction with these solvents is much higher than that with nitrobenzene ($D \simeq 10^{-4}$ at 0.1~5M $NaClO_4$[3]).

It may be seen from Fig. 1 that the distribution ratio of sodium in the nitromethane system is almost constant in the lower-salt-concentration region (below 1M). Equation (6) shows that if the extracted salt dissociates completely, the distribution ratio is independent of the concentration. As the activity coefficients in both the phases may be changed by the changes in the salt concentration, no definite conclusion should be introduced without information about the activities. However, it is probable that the extracted salt is almost dissociated in this organic solvent with a very high dielectric constant (ε=34.82 at 25°C[4]), at least when the salt concentration is low. However, as the extraction depends somewhat on the salt concentration in the other three solvents, the ions in them should associate to some extent. The increase in the distribution ratio in the higher-salt-concentration region (above 1M) could be due to the association of the sodium and perchlorate ions in the organic phase (*cf.* Eq. (6)) and/or to the change in the activity coefficients of the ionic species.

Figure 2 shows the extraction of sodium into undiluted, 50% (v/v), and 1M TBP in hexane as a function of the aqueous sodium perchlorate concentration. The decrease in the extraction upon the dilution of TBP is to be expected from the law of mass action, but it could also be due to the change in the nature of the organic phase (the polarity, the dielectric constants, the activity coefficients of TBP and ionic species, *etc.*).

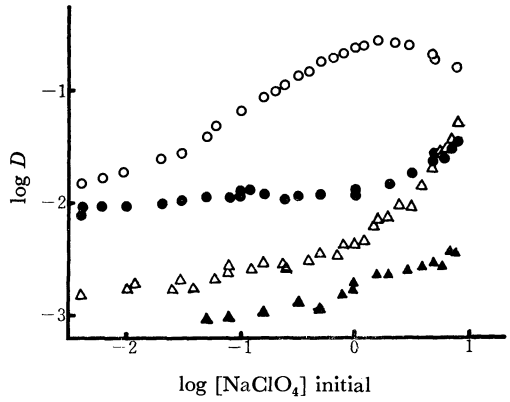

Fig. 1. Distribution of sodium(I) between TBP (○), nitromethane (●) MIBK (△) or methylisobutylcarbinol (▲) and aqueous sodium perchlorate solutions. The aqueous salt concentrations are the intial values.

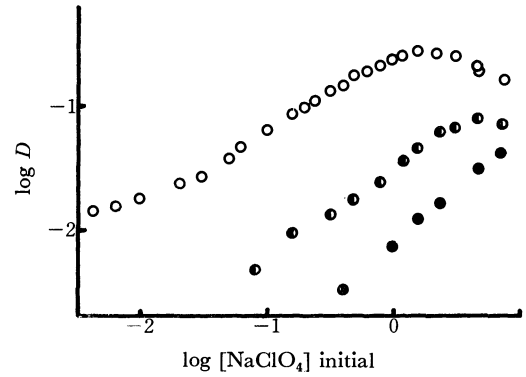

Fig. 2. Distribution of sodium(I) between undiluted TBP (○) 50% (v/v) TBP (◐) or 1M TBP (●) in hexane and aqueous sodium perchlorate solutions. The aqeuous concentrations are the initial values.

3) T. Sekine and D. Dyrssen, *Anal. Chem. Acta*, **45**, 433 (1969).
4) A. A. Maryott and E. A. Smith, "Table of Dielectric Constant of Pure Liquids" NBS Circular 514, Aug. 10, 1951.

It is remarkable that the shape of the extraction curve is changed by the dilution, as may be seen from Fig. 2.

The extractions of sodium perchlorate with these solvents are not very low; for example, when the aqueous phace is 1M Sodium perchlorate solution, 1—10 mM sodium perchlorate is present in all the organic solvents except TBP, and more than 0.1M is contained in TBP; as a dissociation of the extracted salt in the organic phase is assumed in these polar solvents, these organic phases can be regarded as constant ionic media for a small amount of other solutes in these organic phases, such as, for example, an aqueous sodium perchlorate solution at a constant concentration.

These facts should be taken into account when the extraction of ion pairs of sodium with anionic complexes occurs; they are especially important when the extracted ion pairs undergo dissociation in the organic phase.

Anion Radicals Produced by the Non-aqueous Polarographic Reduction of Several Benzonitrile *N*-Oxides[1]

Hiroshi MIYAZAKI, Koichi NISHIKIDA, and Tanekazu KUBOTA
Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received July 14, 1970)

Anion and cation free radicals and their structures, produced by the controlled potential electrolysis of heterocyclic amine *N*-oxides, have been extensively studied in our laboratory.[2] It has usually been found that the anion[2a-d] or cation[2e] free radical of the mother compound is produced at the first reduction or oxidation wave respectively. We have now extended this kind of study to several benzonitrile *N*-oxides whose electronic structures and physicochemical properties[3] have also been investigated in detail in comparison with such other amine oxides as pyridine *N*-oxide and nitrone. The experimental results obtained here, however, are somewhat different from those previously reported.[2] In this note we will report on the non-aqueous polarographic behaviour of the substituted benzonitrile *N*-oxides listed in Table 1, and on the electron-spin-resonance (ESR) spectra and their analyses of anion radicals produced by the controlled potential electrolysis of the nitrile *N*-oxides.

Of the samples, the 4-nitro-2,6-dimethyl-benzonitrile *N*-oxide (**5**) was prepared by the well-known Grundmann method[4] from 4-nitro-2,6-dimethylbenzoaldoxime and NaOBr, the corresponding nitrile (**10**) (see Table 1) being obtained by the deoxygenation of the above nitrile *N*-oxide with $(CH_3O)_3P$.[4] The other samples used and the experimental techniques were the same as those described in our previous papers.[2,5] As a typical example, in Fig. 1 we show the polarograms of 2,4,6-trimethylbenzonitrile *N*-oxide (**2**) and the corresponding nitrile (**7**) and the ESR spectrum obtained by electrolysis at the second wave of **2**. All the other experimental data are included in Table 1. We can see from Fig. 1 that the wave height of the first reduction wave of the DC polarogram of **2** is substantially larger than that of the second wave. For the case of the AC polaro-

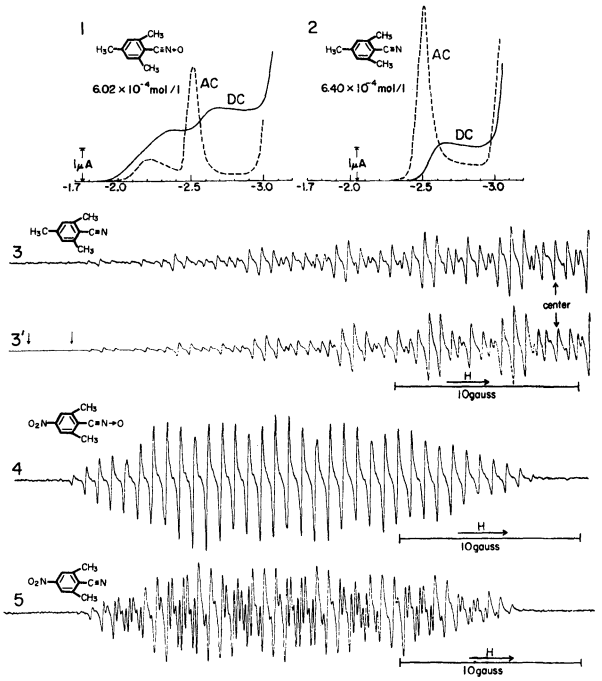

Fig. 1. ESR spectra of the anion radicals and non-aqueous polarograms of the compounds given in this figure. Simulated half spectrum for the observed one (3) is shown in the spectral number 3′ where vertical arrows indicate that the weak signals (1 : 2 : 1 triplet) also appear at these positions (hfc constant values used are listed in Table 1).

a) All measurements were made in dimethylformamide containing tetra-*n*-propylammonium perchlorate 0.1 mol/*l*. Here, Lingane's constant, I, was calculated by the equation $I(=607n\sqrt{D})=i_d/(cm^{2/3}t^{1/6})$, were i_d and c are wave height (μA) of diffusion current and sample concentration (mM), respectively. m (mg/sec) and t (sec/1 drop) are well-known characteristics of dropping mercury electrode. The t value was measured at the potential of diffusion current, but the m value in open circuit was approximately adopted.

b) The shape of the first wave is quite far from that of a normal one electron reduction wave as is seen in Fig. 1-1. Especially, for R=H the first wave seems to be divided into two waves. The former value is in this Table and the latter would be $E_{1/2}\approx-2.13$ V (0.90) and AC peak-height ≈6.

c) See discussions in the text.

gram, however, the above relationship between the first and second waves is just the reverse, the second peak height being considerably higher. In addition, the half-wave reduction potential values, $E_{1/2}$, of **2** and **7** are in almost the same order if a comparison is made between the second wave of **2** and the first wave of **7**. When controlled potential electrolysis has been made at the second reduction wave of **2**, one can obtain the well-resolved ESR spectrum shown in Fig. 1, which has the same pattern as that obtained by the electrolysis at the first wave of **7**. Therefore, we see that the anion radical of 2,4,6-trimethylbenzonitrile is produced there. On the other hand, no ESR signal was observed when the electrolysis was made at the first wave of **2**. Behaviour similar to the above was also found in the compound **1** (see Table 1).

All of the experimental facts mentioned above suggest the conclusion that the first wave of nitrile *N*-oxides is due to the deoxygenation process of the $-C\equiv N\rightarrow O$ group, which is behaviour similar to that observed in an aqueous medium,[2a] and that the second wave may be due to the anion-radical formation of the deoxygenated nitrile compound. This fact is quite different from the case of heterocyclic amine *N*-oxides, where the first reduction wave is due to the anion-radical formation of mother compounds, as is often the case. In the case of compound **3**, it was observed that the deoxygenation and debromination occur at the same time at the first reduction wave. The assignment of the hyperfine coupling (hfc) constants given in Table 1 is straightforward from the point of view of the molecular symmetry and the number of atoms which are in the same chemical environment, and seems to be reasonable in terms of theory.

The only exceptional compound in the present experiments is 2,6-dimethyl-4-nitrobenzonitrile *N*-oxide (**5**), whose anion radical was observed at the first reduction wave. The ESR spectrum obtained is well resolved, but is quite different from that of the anion radical of the corresponding nitrile (**10**). These spectra are shown in Fig. 1.[6] The fact that the oxygen atom of the nitrile-oxide group is very reactive[5,7] may be responsible for the deoxygenation process at the first wave. For the molecule **5**, however, the large intramolecular charge-transfer effect[3,5] from the nitrile-oxide group oxygen atom to the nitro group may stabilize the $\equiv N\rightarrow O$ bond more effectively; thus, the anion radical of the mother compound **5** is produced.

The authors wish to express their thanks to Professors Soichiro Musha and Makoto Munemori of the College of Engineering, University of Osaka Prefecture, for their useful discussions.

6) Detailed discussions of all the hfc constant values in this case (see Table 1) will be made in a separate paper, where they will be compared with the anion radical data of nitrones having a nitro group, *etc.*

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 279—280 (1971)

Non-aqueous Polarogrophic Behavior of the Anion Radical Itself of 4-Nitropyridine *N*-Oxide[1]

Hiroshi MIYAZAKI and Tanekazu KUBOTA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received July 16, 1970)

Although many reports have been published on the non-aqueous polarography of organic substances, there have been only a few reports on the polarographic behaviour of the anion radical itself, prepared macroscopically,[2] because of the instability of the radicals. However, a comparison of the non-aqueous polarogram for the neutral molecule (mother compound) with that of the anion radical formed from the mother compound also seems to be important in elucidating the reduction mechanism. From this point of view, we tried to make polarographic measurements of the anion radical itself of 4-nitropyridine *N*-oxide (4NPO) and of 4,4′-dinitrobiphenyl, whose polarograms usually show two waves: the first wave is due to the anion-radical formation of the mother compound,[3] while the second one may be caused by dianion formation.[3,4] In this note we would like to report our experimental results, and also our findings on the electrolysis cell, which may be very convenient for carrying out the measurement in a non-aqueous medium in which the contamination of water, *etc.* diffusing from the saturated calomel electrode (SCE) has been completely eliminated.

Experimental

The controlled potential electrolysis cell employed here is illustrated in Fig. 1. The cathode potential of either one of two electrolysis cells of almost the same size is controlled *versus* the SCE. The other cell is then in a parallel connection to the first one, as may be seen in Fig. 1. Now, it can easily be understood that the cathode potential of the second cell is also automatically controlled so as to operate at the cathode potential of the first cell. Since no reference cell is necessary for the second cell, any contamination originating from the reference cell is completely removed. Operation under a vacuum system or at a higher or a lower temperature is also very easy by making a little modification to satisfy this experimental purpose. In the present experiments, dimethylformamide was employed as the solvent, the supporting electrolyte being 0.1 mol/*l* tetra-*n*-propylammonium perchlorate. The capillary used for the dropping mercury

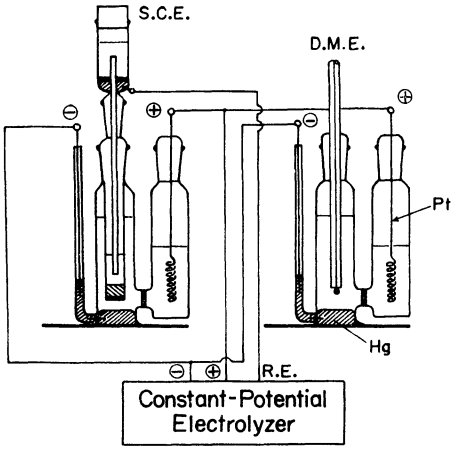

Fig. 1. Cells employed for recording the polarogram of anion radical itself (D.M.E.: dropping mercury electrode). The inlet part of N_2 gas for removing the dissolved oxygen is omitted in this figure for simplicity (see Fig. 1 of the reference 3a in text).

electrode had the following open circuit values in distilled water: $m=1.00$ mg/sec and $t=9.55$ sec at $h=70$ cm. When we measured the polarogram of the anion radical produced in the second cell, first the cell circuit was made free from the constant-potential electrolyzer, and then the anode of the cell (right-hand side in Fig. 1) was quickly replaced with SCE in a nitrogen atmosphere. The polarogram was subsequently recorded *versus* SCE. The other experimental procedure was just the same as in previous papers.[3,4]

Results and Discussion

The polarograms recorded for 4NPO are shown in Fig. 2 as typical examples. The observed constant values, such as the half reduction (or oxidation) potential, $E_{1/2}$, the DC wave height, i_{DC}, and the AC peak height, i_{AC}, are listed in Table 1. It was previously

4) T. Kubota, Y. Ōishi, K. Nishikida, and H. Miyazaki, This Bulletin, **43**, 1622 (1970).

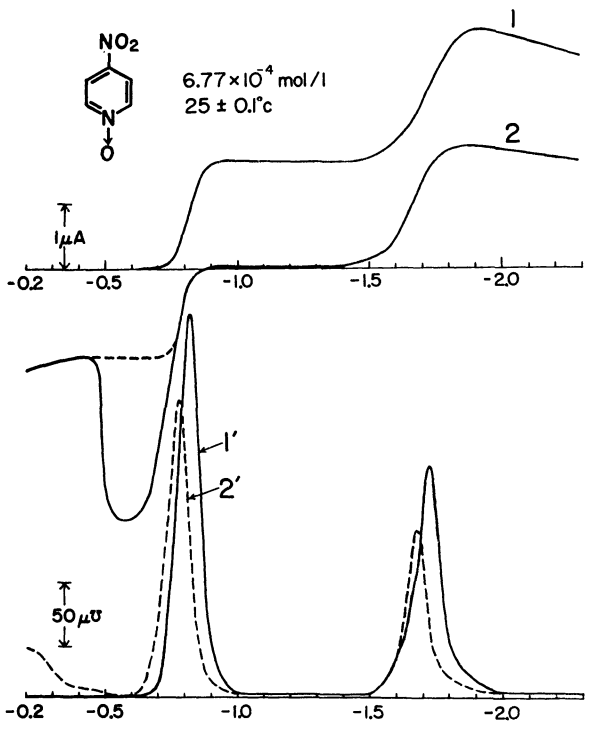

Fig. 2. DC (upper part) and AC (lower part) polarograms of 4-nitorpyridine *N*-oxide (1 and 1′) and its anion radical (2 and 2′).

shown that the first wave of the 4NPO neutral species is caused by the formation of the anion radical, which is quite stable,[5] and that the second wave may be due to the dianion formation, since: (i) DC wave-heights of the first and the second waves are almost the same and (ii) controlled potential electrolysis at the second wave gives the ESR signal of the 4NPO anion radical, perhaps because of a rapid electron exchange between neutral and dianion species. The results in Fig. 2 now give additional evidence for the interpretation of the reduction wave. That is, in the polarogram (curve 2) taken after reduction at -1.10 V for 60 min,[6] we see that the first wave disappears almost completely and that the oxidation wave appears at a potential close to that of the first wave of the polarogram 1.[7] In addition, (i) the second wave of the polarogram 1 decreases in wave height an amount corresponding to a one-electron reduction, so that the wave height of the polarogram 2 at ~ -2.0 V is almost the same as that of the first wave of the polarogram 1, and (ii) the AC peak-height (curve 2′) after reduction is also quite high in both the oxidation and reduction waves. These experimental results may indicate that the anion radical (A^-) formed at the first wave of the neutral species (N) is in an oxidation and reduction equilibrium like $N \rightleftarrows A^- \rightleftarrows A^=$, where $A^=$ stands for the dianion of the N species. Of course, the reversibility of the equilibrium between A^- and $A^=$ is less than that between N and A^-, since the reactivity of the $A^=$ species is quite high.[6] A polarographic behaviour of the anion radical similar to that described above was also observed in 4,4′-dinitrobiphenyl.[7]

In the case of 4-methylpyridine *N*-oxide, whose first reduction wave is not responsible for the anion radical formation, *i. e.*, in which the succeeding reaction also occurs at the first wave,[3a] no oxidation wave such as is seen in Fig. 2 could be observed in the polarogram of the substance produced after electrolysis at the first wave. This result seems to be reasonable because there is no good equilibrium between the A^- and N species.

The authors wish to express their thanks to Professors Soichiro Musha and Makoto Munemori of the College of Engineering, University of Osaka Prefecture, for their useful discussions.

5) K. Ezumi, H. Miyazaki, and T. Kubota, *J. Phys. Chem.*, **74**, 2397 (1970).

6) The color of the solution varied from pale yellow to pale blue→deep blue→and finally deep blue-greem, which again changed to pale yellow upon the introduction of dry air. In addition, polarographic measurements after reduction at -2.0 V (second wave: see Fig. 2) showed that the polarogram is somewhat complicated and time-dependent, indicating that the dianion generated macroscopically is not so stable as, and more reactive than, the monoanion radical.

7) Here, one remarkable point is that a quite strong maximum wave is superposed on the oxidation wave of the anion raidcal (see Fig. 2). This phenomenon seems to be generally observed in the experiments by us and by Bard *et al.*[2] The later authors explained it in terms of a pronounced streaming mechanism occurring on the dropping mercury electrode during the oxidation of the A^- species.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 281—283 (1971)

Direct and Sensitized Photoreactions of Allyl Phenyl Ether

Nakako SHIMAMURA and Akira SUGIMORI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo

(Received August 4, 1970)

It has been reported that UV irradiation of allyl phenyl ether gives rearrangement products (*o*- and *p*-allylphenol) and phenol.[1-4] Although the mechanism of the photo-rearrangement has been proposed,[4] little investigation has been carried out on the excited states responsible for the formation of photo-rearrangement products and phenol. The present work deals with the effects of solvents and additives (sensitizers and quenchers) for the elucidation of the character of the excited states in the photoreaction.

Results and Discussion

Unsensitized photoreaction of allyl phenyl ether in transparent solvents is explained by reaction paths a,b,c,d, and e in Scheme 1.

The formation of a radical pair in a solvent cage is concluded from the effect of the viscosity of the solvents. Cage reactions are dependent on the viscosity (η) of solvent. The following equation was presented:[5]

$$\frac{\phi_1 + \phi_2}{\phi_1} = K_1 + \frac{K_2}{\eta} \qquad (1)$$

where ϕ_1 and ϕ_2 are the quantum yields of the reaction within and outside a solvent cage, and K_1 and K_2 are constants. In the unsensitized photoreactions of allyl phenyl ether, the equation was satisfied when allylphenols and phenol were taken as the products within and outside a solvent cage, respectively (Fig. 1).

As shown in Table 1, the quantum yields of the reactions within and outside a cage were almost independent of the presence of 1,3-pentadiene (a triplet quencher). This suggests that the unsensitized photoreaction occurs *via* excited singlet state. Photo-Fries rearrangement has been reported to proceed from excited singlet state of aryl esters.[6,7]

In the photosensitized reaction it was observed that aromatic hydrocarbons acted as sensitizers in a different way from carbonyl compounds. The photoreaction of allyl phenyl ether in aromatic hydrocarbons such as benzene and toluene satisfies Equation (1) as shown in Fig. 1. Addition of naphthalene to the cyclohexane solution of ether slightly affected the ratio of the quantum yields of the reactions within and outside a solvent cage. The reaction in benzene solution was not quenched by the addition of 1,3-pentadiene. Thus, sensitization by aromatic hydrocarbons should proceed through singlet-singlet energy transfer.

In contrast to aromatic hydrocarbons, the presence of carbonyl sensitizers (benzaldehyde, acetophenone, benzophenone and substituted benzophenones) increased the formation of phenol.

Carbonyl compounds are photo-reactive and undergo photo-induced reactions such as hydrogen abstraction

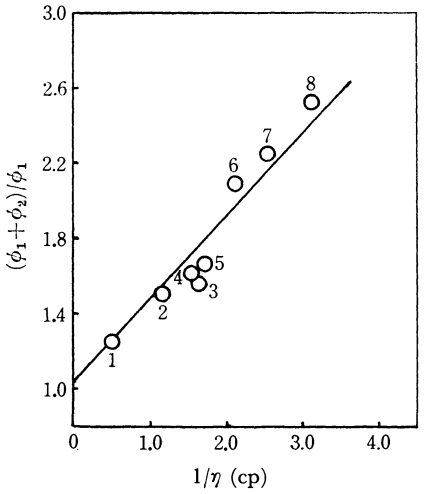

Fig. 1. Effect of viscosity on cage reaction $\phi_1=\phi_C+\phi_P$, $\phi_2=\phi_{PhOH}$. 1. 2-Propanol, 2. Cyclohexane, 3. Cyclohexene, 4. Benzene, 5. Toluene 6. Isooctane 7. *n*-Heptane, 8. *n*-Hexane

and oxetane formation. These reactions might induce phenol formation from allyl phenyl ether. (In this case the consumption of sensitizers is expected.) However, this sort of "sensitization" is not probable: (i) UV absorption and gas-chromatographic examination of the acetophenone and benzophenone sensitized reactions in benzene revealed that no sensitizer was consumed in the course of the reaction; (ii) sensitization was observed with Michler's ketone and *p*-hydroxybenzophenone which are known to be photo-unreactive; (iii) thermal decomposition of benzoyl peroxide in benzene containing allyl phenyl ether did not give allylphenols or phenol.

The results can be interpreted by the mechanism of energy transfer from *n*-π^* triplet state of carbonyl compounds to olefins proposed by Yang, Cohen, and Shani.[8] The mechanism consists of two steps: (i) addition of excited carbonyl compounds to olefinic double bonds; (ii) elimination of ground state carbonyl compounds to give excited olefins. This suggests that the triplet energy of carbonyl compounds can be transferred selectively to the double bond of allyl moiety rather than phenyl moiety of allyl phenyl ether, while the excess energy of aromatic hydrocarbons is transferred to phenyl moiety of the ether. Excitation of allylic double bond would bring about phenol formation, the mechanism of which is still unknown.

The photoreactions of allyl phenyl ether are summarized in Scheme 1.

8) N. C. Yang, J. I. Cohen, and A. Shani, *J. Amer. Chem. Soc.*, **90**, 3264 (1968).

Experimental

Materials. Ally phenyl ether was synthesized from phenol and allyl bromide and purified by distillation, bp 92°C/25 mmHg. The purity determined by gas-chromatography was 98.6%. Benzophenone, *p,p'*-dimethoxybenzophenone, 3,4-dimethylphenol (G.R. grade of Tokyo Kasei Co.), *p*-hydroxybenzophenone, Michler's ketone (E.P. grade of Tokyo Kasei Co.), naphthalene (E.P. grade of Showa Kagaku Co.), and benzoyl peroxide (T.G. grade of Wako Junyaku Co.) were used without further purification. Benzaldehyde, acetophenone (E.P. grade of Yoneyama Yakuhin Co.), and 1,3-pentadiene (T.G. grade of Tokyo Kasei Co.) were purified by distillation.

Solvents. Commercially available *n*-hexane, *n*-heptane, and isooctane of spectral quality (Dotite Spectrosol) were used without further purification. Benzene, toluene, and 2-propanol (each E.P. grade of Junsei Kagaku Co.) were purified by fractional distillation. Cyclohexane was purified by treatment with nitric acid, followed by treatment with a silica gel column. Cyclohexane, *n*-hexane, *n*-heptane, and isooctane used had no or a slight absorption at 254 nm.

UV Irradiation. Degassed 0.1 M solution of ally phenyl ether in a quartz tube was irradiated externally with a low pressure mercury lamp (16W spiral type lamp made by Taika Kogyo Co.) with or without sensitizers and quenchers. The solution was stirred with a magnetic stirrer. The reaction vessel and the mercury lamp were immersed in a thermostat kept at 25°C. Up to 5 hours the products increased nearly in proportion to irradiation time. Prolonged irradiation caused a decrease in the quantum yields of the products probably because of the contamination of the wall of the vessel by photolysis products.

Analysis of the Products. The reaction products were analyzed gas-chromatographically with Yanagimoto Gas Chromatograph Model GCG 550 F (column, 1.2 m, 20% Carbowax on Celite; temperature, 180°C).

In the experiment of photosensitization by carbonyl compounds, the quantities of carbonyl compounds after irradiation were estimated by UV absorption spectroscopy and gas-chromatography. Absorption of acetophenone at 320 nm and absorption of benzophenone at 345 nm were used for the estimation.

Actinometry. Actinometry was performed with potassium ferrioxalate actinometer.[9] In the reaction condition above, the intensity of light was 2.9×10^{17} quanta/sec for 20 m*l* of solution.

Asymmetric Reactions. V. Homogeneous Hydrogenation of Unsaturated Compounds Catalyzed by Bis-(dimethylglyoximato)cobalt(II)[1]

Yoshiaki OHGO, Seiji TAKEUCHI, and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received August 4, 1970)

Schrauzer and Windgassen[2] reported that stable metal-alkyl complexes are formed in the reaction of bis(dimethylglyoximato)cobalt(II) complex and certain olefines under hydrogen atmosphere, and that in some cases reduction products are obtained concurrently. Reductive methylation of amines and mercaptanes with formaldehyde and hydrogen catalyzed by bis(dimethylglyoximato)cobalt(II) was also reported by the same investigators.[3]

As a part of studies on the asymmetric reduction using optically active metal complexes,[4,5] we have tried to obtain a suitable metal-alkyl complex by the reaction of bis(dimethylglyoximato)cobalt(II) with several unsaturated compounds under hydrogen atmosphere. However, no metal-alkyl complex but the reduction product could be obtained.

We wish to report that bis(dimethylglyoximato)-cobalt(II) is a useful catalyst for reduction of activated olefines, unsaturated nitrogen compounds, α-diketones and α-keto acid esters.

Experiments were carried out under atmospheric pressure of hydrogen at room temperature, and the products were confirmed by mixed melting point and/or IR and NMR spectra. The results are summarized in Tables 1 and 2.

It can be considered that both steric and electronic

21	PhCOCOPh	10	35 min	 (99.5%)
22	$CH_3COCOCH_3$	10	24 hr	 [c]

a) S/Co: molar ratio of substrate to catalyst (Co).
b) Time required for the completion of reaction or for the reaction mixture to be left standing.
c) Biacetyl adsorbed a theoretical amount of hydrogen, but only a small amount of acetoin was obtained because of an unsuitable isolation procedure.

factors have an effect on the reactivity. As shown in Table 1, olefines which have electron defficient double bond were catalytically reduced by hydrogen. However, the olefines having no electron-withdrawing group were not reduced. Steric factors do not seem to be so important as electronic ones. From this viewpoint, methyl *p*-nitrocinnamate was considered to be catalytically reducible. However, it was found that the C–C double bond of this compound was not reduced, but the nitro group was reduced to give amino group contrary to anticipation (Table 2). Nitrobenzene was also reduced to give aniline and hydrazobenzene. Azobenzene and azoxybenzene gave hydrazobenzene, but a prolonged treatment for isolation and purification afforded azobenzene. This implies that hydrazobenzene is catalytically oxidized by oxygen during the course of isolation. Nitroalkanes were not reduced under mild conditions. α-Diketones and α-keto acid esters were also reduced easily. Studies on the reduction mechanism are now in progress.

Experimental

$CoCl_2 \cdot 6H_2O$ (0.708 g, 0.03 mol) was dissolved in 50 m*l* of methanol or ethanol, and to the solution was added 0.690 g of dimethylglyoxime (0.06 mol) with stirring under nitrogen atmosphere for 5 min. To this solution was added a solution of 0.28 g of sodium hydroxide (0.07 mol), pyridine (0.23 g)

and substrate (1—10 equivalent to cobalt) successively. Stirring was then stopped. The vessel containing the solution was purged with hydrogen, and the solution was again stirred under hydrogen atmosphere at room temperature. After absorption of the theoretical amount of hydrogen, the reaction mixture was diluted with water containing a small amount of acetic acid and extracted with ether or methylene chloride. The organic layer was washed with water, dried over anhydrous sodium sulfate and concentrated *in vacuo*. The resulting products were confirmed by mixed melting point (incase of crystals) and/or IR and NMR spectra. The results are shown in Tables 1 and 2.

Electronic Spectra of Amino-substituted Pteridines

Mamoru KAMIYA
Shizuoka College of Pharmacy, Oshika, Shizuoka

(Received August 26, 1970)

Several SCF-MO calculations have been reported for the π-electronic structure of pteridines, chiefly of the parent molecule,[1-6] but little is known about a systematic calculation for a series of substituted pteridines forming fundamental structures of complicated biopteridines. Here, the semiempirical VESCF-MO-CI[7-9] calculations on pteridines and all its monoamino derivatives and a few of its diamino derivatives have been performed in making a systematic survey of amino-substitution effects upon electronic spectra. The elements of the F matrix are usually evaluated by adopting the zero differential overlap approximation. On the basis of the atomic spectroscopic data reported by Pritchard and Skinner,[10] the equations representing

the parabolic dependence of the valence-state ionization potential (I_r) and one-center repulsion integral (γ_{rr}) upon the effective nuclear charge (Z_r) are taken to be as follows:

for =C– and –$\overset{|}{\text{N}}$– ($sxyz$, V_4)

$$I_r = 3.390Z_r^2 - 7.899Z_r + 1.157,$$
$$\gamma_{rr} = -0.432Z_r^2 + 9.164Z_r - 14.527,$$

for =N– (sx^2yz, V_3)

$$I_r = 3.455Z_r^2 - 10.594Z_r + 3.256,$$
$$\gamma_{rr} = -0.415Z_r^2 + 9.912Z_r - 19.435.$$

The two-center repulsion integrals (γ_{rs}) and the core-resonance integrals (β_{rs}) of all the atomic pairs were recalculated after each SCF iteration process according to the Pariser-Parr method[7] and the equation of $\beta_{rs} = -1/2S_{rs}(I_r + I_s)$, respectively. S_{rs} is the theoretically calculated overlap integral between the Slater-type atomic orbitals. The molecular orbitals became self-consistent to five-decimal places in fifteen interations, on the average. Full-configuration interaction is included between all singly-excited configurations. The molecular geometry of the pteridine ring is obtained from the X-ray analysis data by Hamor and Robertson,[16] and the bond-length of the C-NH_2 bond is assumed to be 1.34 Å and the direction of the bond is assumed to bisect the intra-ring angle around the substituted position. Actual numerical calculations were performed with the HITAC 5020-E computer at the University of Tokyo.

Table 1 shows that the two lowest transitions in the calculated spectrum of pteridine are polarized in agreement with the experimental data by Mason.[11] This fact suggests that the first and second π–π^* bands are polarized along the long-axis and the short-axis respectively. The calculated (observed) lowest π–π^* transition energy of the monoamino derivatives is in the increasing order of: $6 \leqq 2 < 7 < 4$ ($2 < 6 < 4 \leqq 7$). This indicates that the amino-group substituted parallel to the long-axis, especially to the 2- and/or 6-position, exerts a large bathochromic effect on this transition. The corresponding oscillator strength is in the increasing order of: $4 \leqq 7 < 2 < 6$, while the observed intensity is mostly enhanced by the 7-substitution. Furthermore, on all monoamino-substitutions except that to the 4-position, the polarization direction of the second π–π^* transition is also turned to the long-axis, and a weak theoretical transition appears between the two transitions correlated with the observed second and third π–π^* bands. The calculated spectra of the diamino derivatives are in fairly good agreement with those observed for the 2,4-, 4,6-, and 4,7-substituted derivatives. In this case also, it can be predicted that the substitution to the 7- and 4-positions causes the lowest π–π^* transition to be polarized quite close to the long-axis.

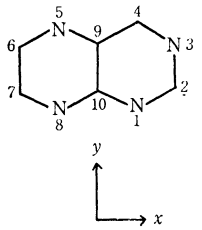

Fig. 1. The numbering of pteridine ring.

The Resolution of *t*-Butyloxycarbonyl-DL-α-phenylsarcosine

Hideki KINOSHITA, Masaki SHINTANI, Tomoo SAITO, and Hiroshi KOTAKE

Faculty of Science, Kanazawa University, Kanazawa

(Received August 26, 1970)

α-Phenylsarcosine was first found in nature by Sheehan *et al.* from the hydrolysate of etamycin and was proved to belong to the L-series.[1] Although Sheehan *et al.*[1] reported that the amino acid isolated from etamycin showed $[\alpha]_D^{31}$ +118° (in N hydrochloric acid), this value seemed to show not the actual value, but that of partially racemized α-phenylsarcosine. Since the actual specific rotation values of this amino acid has not yet been established as far as we know, we attempted to obtain optically pure components. In this paper the resolution of DL-α-phenylsarcosine using ephedrines is described. The usefulness of these substances for the resolution of amino acids has reported in a previous paper.[2]

t-Butyloxycarbonyl-DL-α-phenylsarcosine (I), which was prepared by the *t*-butyloxycarbonylation of DL-α-phenylsarcosine,[3] following a procedure of Sakakibara *et al.*,[4] was mixed with (−)-ephedrine (molar ratio 1:1.1) in benzene - hexane to give crystalline *t*-butyloxycarbonyl-L-α-phenylsarcosine·(−)-ephedrine salt (II).

2) K. Oki, K. Suzuki, S. Tuchida, T. Saito, and H. Kotake; This Bulletin **43**, 2554 (1970).

3) T. Araga, T. Saito, and H. Kotake, *Nippon Kagaku Zasshi*, **86**, 111 (1965).

4) S. Sakakibara, I. Honda, and K. Takada, This Bulletin, **42**, 809 (1969).

The filtrate from this salt was treated with (+)-ephedrine in benzene - hexane at room temperature to give *t*-butyloxycarbonyl-D-α-phenylsarcosine·(+)-ephedrine salt (III). The salt II was treated with hydrochloric acid to give *t*-butyloxycarbonyl-L-α-phenylsarcosine (IV) ($[\alpha]_D^{24}$ +134.8°), which was then treated with formic acid[5] to give L-α-phenylsarcosine (VI), $[\alpha]_D^{34}$ +169.3° (in N hydrochloric acid). By a similar procedure, III was converted to *t*-butyloxycarbonyl-D-α-phenylsarcosine (V)($[\alpha]_D^{29}$ −134.1°),which was then treated with formic acid to give D-α-phenylsarcosine (VII), $[\alpha]_D^{34}$ −170.7° (in N hydrochloric acid). These values of L- and D-phenylsarcosine were supported by the results of an alternative method of resolution. The resolution of benzyloxycarbonyl-DL-α-phenylsarcosine with brucine, followed by the removal of the benzyloxycarbonyl group by means of catalytic reduction, gave L-α-phenylsarcosine, $[\alpha]_D^{34}$+169.9° (in N hydrochloric acid).

Experimental

All the melting points are uncorrected. The optical rotation values were measured with a Jasco DIP-SL-type polarimeter.

t-Butyloxycarbonyl-DL-α-phenylsarcosine (I). A stock solution of *t*-butyl chloroformate was added to a solution of 7.59 g (0.03 mol) of DL-α-phenylsarcosine in ethanol containing 3.89 g of potassium hydroxide, and then 10 m*l* of dimethylformamide was added with stirring at 0—−3°C. The reaction mixture was agitated vigorously during the addition over a period of about half an hour. The stirring was continued for a further 2 hr at 0°C, and then for an additional hour at room temperature. The reaction mixture was subsequently adjusted to pH 2—3 with N hydrochloric acid, and the product was extracted with ethyl acetate. The ethyl acetate layer was washed with a saturated solution of sodium chloride and dried over anhydrous sodium sulfate. The ethyl acetate was evaporated to dryness to afford 4.4 g of *t*-butyloxycarbonyl-DL-α-phenylsarcosine (55.3%). Recrystallization from benzene-petroleum ether gave 4.0 g of I with a melting point of 122—123°C (50.2%).

Found: C, 63.30; H, 7.35; N, 5.26%. Calcd for $C_{14}H_{19}O_4N$: C, 63.38; H, 7.22; N, 5.28%.

t-Butyloxycarbonyl-L-α-phenylsarcosine·(−)-Ephedrine Salt (II) and t-Butyloxycarbonyl-D-α-phenylsarcosine·(+)-Ephedrine Salt (III). 1.060 g (0.004 mol) of I and (−)-ephedrine hemihydrate (750 mg, 0.0043 mol) were dissolved in 2 m*l* of hot benzene, and then 7 m*l* of hexane were added. The mixture was then allowed to stand for 24 hr at room temperature. The deposited crystals were filtered off and washed with 4 m*l* of benzene - hexane (1 : 3) to afford 830 mg (92.6%) of II, mp 84—88°C. Two recrystallizations from ethyl acetate-petroleum ether gave 680 mg (75.9%) of the pure material with a melting point of 91—93°C. $[\alpha]_D^{27}$ +65.2° (*c* 0.951; absolute ethanol).

Found: C, 64.23; H, 8.10; N, 6.37%. Calcd for $C_{24}H_{34}O_5N_2\cdot H_2O$: C, 64.26; H, 8.09; N, 6.25%.

The mother liquor obtained after the removal of II was evaporated to dryness to give an oily material. This oily material was dissolved in 6 m*l* of ethyl acetate, and the ethyl acetate layer was washed with 3 m*l* of N hydrochloric acid and water. The organic layer was dried over anhydrous sodium sulfate and then evaporated to dryness to give 530 mg of an oily product. This product and (+)-ephedrine hemihydrate (375 mg, 0.0022 mol) were dissolved in 1.3 m*l* of hot benzene, and then 7 m*l* of hexane were added. The deposited crystals were filtered off to afford 560 mg (65.2%, mp 84—89°C) of III. Two recrystallizations from ethyl acetate-petroleum ether gave 500 mg (55.8%) of an optically pure material with a melting point of 91—93°C. $[\alpha]_D^{28}$ −65.2° (*c* 0.605; absolute ethanol).

Found: C, 63.85; H, 8.17; N, 5.93%. Calcd for $C_{24}H_{34}O_5N_2\cdot H_2O$: C, 64.26; H, 8.09; N, 6.25%. A mixed-melting-point determination of (−) and (+) salt was depressed to 80—85°C.

t-Butyloxycarbonyl-L-α-phenylsarcosine (IV). To a suspension of 600 mg (0.0014 mol) of II in 7 m*l* of ethyl acetate, there were added 2.3 m*l* of N hydrochloric acid; the mixture was then shaken effectively in a separatory funnel. After washing with water (three 1-m*l* portions), the ethyl acetate layer was dried over anhydrous sodium sulfate. The ethyl acetate was evaporated to dryness to give 370 mg of crude crystals (quantitative, mp 110—112°C). Recrystallization from benzene-petroleum ether gave 312 mg (84.3%) of pure crystals with a melting point of 111.5—112.5°C. $[\alpha]_D^{24}$ +134.8° (*c* 0.804, absolute ethanol).

Found: C, 63.73; H, 7.23; N, 5.60%. Calcd for $C_{14}H_{19}O_4N$: C, 63.38; H, 7.22; N, 5.28%.

t-Butyloxycarbonyl-D-α-phenylsarcosine (V). Following the method used for the preparation of IV, from 600 mg (0.0014 mol) of III, 340 mg of crude crystals were obtained (91.9%, mp 110—111°C). Recrystallization from benzene-petroleum ether gave 300 mg (80.1%) of pure crystals with a melting point of 112—112.5°C. $[\alpha]_D^{29}$ −134.1° (*c* 0.682, absolute ethanol).

Found: C, 63.25; H, 7.32; N, 5.18%. Calcd for $C_{14}H_{19}O_4N$: C, 63.38; H, 7.22; N, 5.28%.

L-α-Phenylsarcosine (VI). 150 mg (0.566 mmol) of IV were dissolved in 7.5 m*l* of formic acid, and the mixture was allowed to stand for 1.5 hr at 22°C. The formic acid was evaporated to dryness at 22°C to afford 87 mg of VI (93.7%). Recrystallization from water - acetone gave 80 mg of a pure material (86.2%). $[\alpha]_D^{34}$ +169.3° (*c* 0.655, N hydrochloric acid), mp 245° (sublime).

Found: C, 65.45; H, 6.72; N, 8.18%. Calcd for $C_9H_{11}O_2N$: C, 65.44; H, 6.71; N, 8.43%.

D-α-Phenylsarcosine (VII). Following the method used for the preparation of L-α-phenylsarcosine, 88 mg of VII was obtained from 150 mg of V (94.8%). Recrystallization from water - acetone gave 80 mg of a pure material (86.2%). $[\alpha]_D^{34}$ −170.7° (*c* 0.571, N hydrochloric acid), mp 244°C (sublime).

Found: C, 65.68; H, 6.84; N, 8.34%. Calcd for $C_9H_{11}O_2N$: C, 65.44; H, 6.71; N, 8.43%.

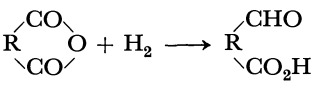
Hydrogenation of Acid Anhydrides with Cobalt Carbonyl Catalyst

Hachiro WAKAMATSU, Junko FURUKAWA, and Nobuyuki YAMAKAMI
Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

(Received August 31, 1970)

Various carboxylic acid derivatives such as acid chlorides, imidochlorides, *N*-alkylamides, thioesters, hydrazides, and nitriles are known to give aldehydes on hydrogenation. However, little is reported[1] on the selective hydrogenation of carboxylic acid anhydrides to give aldehydes. Carboxylic acid anhydrides were found to be catalytically hydrogenated to give corresponding aldehydes and acids. Intermolecular anhydrides gave acids and aldehydes in comparable amount, whereas intramolecular anhydrides gave aldehydic acids. The new hydrogenation reaction is catalyzed by cobalt carbonyl and takes place at elevated temperatures under pressure of hydrogen and carbon monoxide. No effort was made to improve yields of the aldehydes in the experiments. The results are given in Table 1. Benzoic, acrylic, and maleic anhydrides gave anomalous results.

$$(RCO)_2O + H_2 \longrightarrow RCO_2H + RCHO$$



The solvent effect is greater on the rate of reaction than on the hydroformylation of olefins. At 130°C, the reaction carried out in acetone gives pseudo first order rate constant five times larger than that in diethyl ether. The rate is about the same for the reaction in acetone at 130°C, that in acetic acid at 160°C, and that in benzene or cyclohexane at 175°C. When toluene was used as a solvent, the main products from acetic anhydride were reported to be acetic acid and ethyl acetate.[2] Addition of a catalytic amount of pyridine accelerates the hydrogenation reaction and thus makes the reaction possible at lower temperatures (~130°C) even in benzene and cyclohexane. Sodium iodide has an accelerating effect on the hydrogenation reaction in diethyl ether. The effect of partial pressure of carbon monoxide and hydrogen on the rate of hydrogenation of acetic anhydride is quite the same as that reported for hydroformylation and cobalt carbonyl catalyzed hydrogenation of aldehydes.[3]

When hydrogen cobalt tetracarbonyl was dissolved in acetic anhydride at −40°C and brought to −15°C, acetic acid, acetaldehyde and dicobalt octacarbonyl were obtained.

TABLE 1. HYDROGENATION OF ACID ANHYDRIDES

Acid anhydride	Reaction conditions	Product
Acetic anhydride 530 mmol	$Co_2(CO)_8$ 300 mg † H_2 100, CO 100 1 hr, 20 min	Acetic acid 225 mmol Acetaldehyde 180 mmol

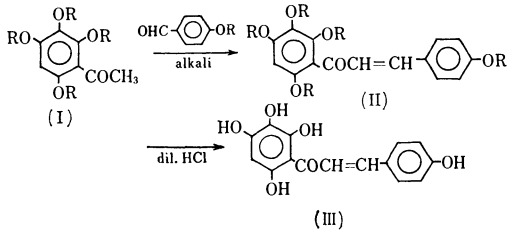
SHORT COMMUNICATIONS

The Synthesis of 2′,3′,4,4′,6′-Pentahydroxychalcone[1]

Heitaro OBARA, Jun-ichi ONODERA, and Yuji KURIHARA
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa
(Received September 21, 1970)

The structure of carthamin, the coloring matter of the flowers of *Carthamus tinctorius*, has been identified as a glucoside of 2′,3′,4,4′,6′-pentahydroxychalcone (III).[2,3]

The hydrolysis of carthamin gave the corresponding flavanones, *i. e.*, carthamidin and isocarthamidin. However, the aglycon (III) has not been isolated as a chalcone form because of its instability.[2] This uncertain behavior of III has prompted the present authors to attempt the synthesis of III according to the following scheme:



(R:CH_3OCH_2-)

The condensation of 2,3,4,6-tetrakis(methoxymethoxy)acetophenone (I), which had been prepared by the methoxymethylation of 2,3,4,6-tetrahydroxyacetophenone[4] with *p*-methoxymethoxybenzaldehyde, afforded 2′,3′,4,4′,6′-pentakis(methoxymethoxy)chalcone (II) as a pale yellow, viscous oil. The subsequent cautious hydrolysis of II with dilute hydrochloric acid in methanol gave III as yellow crystals; mp 180—182°C: UV; λ_{max}^{EtOH} 375 mμ (log ε=4.47).

The structure of this compound was identified by elemental analysis, by a study of the IR spectrum, and, furthermore, by its conversion into 2′,3′,4,4′,6′-pentamethoxychalcone, mp 92—93°C, which was identified by a comparison of the melting point and the UV and IR spectra with those of an authentic sample.[6]

The overall yield of III from 2,3,4,6-tetrahydroxyacetophenone was 25%. The IR spectrum of the new chalcone (III) is shown in Fig. 1.

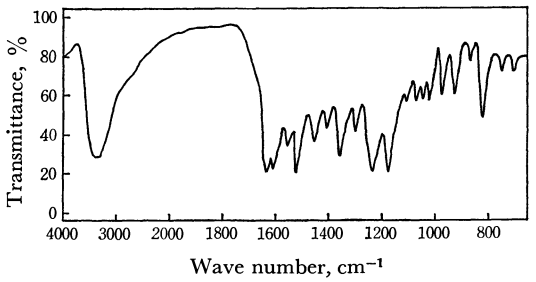


Fig. 1. The IR spectrum of 2′,3′,4,4′,6′-pentahydroxychalcone (III).

4) This compound was prepared from 1,2,3,5-tetrahydroxybenzene by a Hoesch reaction, mp 236—238°C (lit,[5] mp 204—205°C); tetramethylether, mp 55—56°C (lit,[2] mp 53—54°C).
5) M. Nierenstein, *J. Chem. Soc*, **1917**, 4.
6) This sample was prepared by the condensation of 2,3,4,6-tetramethoxyacetophenone with *p*-methoxybenzaldehyde according to Kuroda's method,[2] and the structure was confirmed by elemental analysis and by a study of the IR and NMR spectra; mp 92—93°C (lit,[2] mp 112°C).

Isopiestic Studies of Non-Aqueous Solutions of Quaternary Ammonium Halides. Comparison of the Degree of Solvations in Methanol and in Acetonitrile

Takeki MATSUI, Fumiyoshi YAMAUE, and Niichiro TOKURA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka
(Received April 13, 1970)

We wish to report on the result of an application of isopiestic vapor pressure method to estimate the relative stability of halide ions in non-aqueous solvents, methanol and acetonitrile, the former being hydroxylic and the latter a dipolar aprotic solvent. The static data is used to explain the solvent effects on the following equilibrium constant K.

$$CH_3Br + I^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} CH_3I + Br^- \qquad (I)$$

$$K = k_f/k_r$$

Two partially contrary views have been proposed with respect to the effects of solvents on both reactivities and nucleophilic activities for this type of reaction. The views are: (1) anions are "desolvated" in dipolar aportic solvents,[1] (2) small anions are also solvated in these solvents as in protic solvents.[2] A different set of extrathermodynamic assumptions may lead to this contrary conclusion. These assumptions have been used to determine the relative stability of single anions. We wished to provide a conclusion to the subject through an independent method.

For the isopiestic study tetra-*n*-butylammonium bromide and iodide were taken for their relatively large solubilities in the solvents. We used similar apparatus and procedure to those of Davies and Thomas.[3] The time required for an equilibration process was about ten days. The equilibrium concentrations of these two solutions result in the isopiestic ratio R which is here defined as the ratio of equilibrium molarity of iodide solution to that of bromide solution. Figure 1 shows the plot of R *vs.* equilibrium concentration of bromidesolution.

An attempt to correlate the static data with the rate or eqiulibrium data for reaction (I) is quantitatively made through the activity B coefficient according to the expression of activity coefficient. The difference in B values among two ions I^- and Br^- is obtained by the limiting derivative of R with respect to m, *viz.*,

$$\lim_{m\to 0} \partial R/\partial m = 2.303/2(B_{Br^-} - B_{I^-}) = 2.303/2\Delta B$$

Figure 1 gives the ΔB values of 0.76 and 0.04, in methanol and in acetonitrile, respectively. The rate

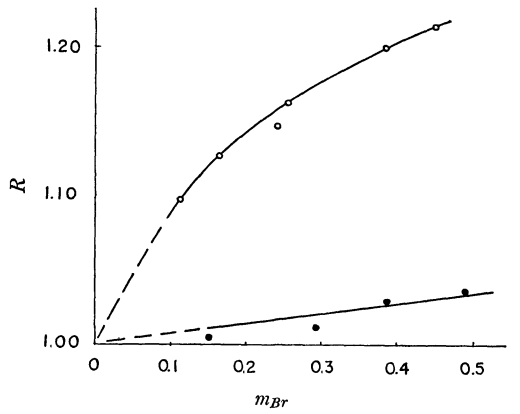

Fig. 1. Relationship between isopiestic ratio, R and molarity of bromide solution. ○, in methanol; ●, in acetonitrile

TABLE 1. RATE DATA FOR REACTION (I) AND STATIC DATA IN METHANOL AND IN ACETONITRILE AT 30°C

	in CH_3OH[a]	in CH_3CN[b]
k_f, $M^{-1}\cdot sec^{-1}$	13.7×10^{-4}	0.091
k_r, $M^{-1}\cdot sec^{-1}$	13.8×10^{-5}	0.292
K	9.9	0.31
ΔB, M^{-1}	0.76	0.04

a) The rate data are taken from E. A. Moelwyn-Hughes. *J. Chem. Soc.*, **1939**, 368.
b) The rate data are taken from K. Uosaki and N. Tokura, unpublished result.

data for reaction (I) are shown in Table 1 together with the ΔB values.

K is split into two terms, *i. e.*, intrinsic (denoted by superscript 0) and solvent-dependent terms, *viz.*,

$$\log K = \log K^0 + \log r_{I^-}/r_{Br^-}$$

where r_i is the solvent activity coefficient of i species. A plot of log K *vs.* ΔB for the changes in solvent results in the intrinsic nucleophilicity K^0. Log K^0 is obtained as the value on the ordinate of this plot at a point where $\Delta B=0$. The result shows that K^0 is smaller than 1.0, which in turn suggests the rate data in acetonitrile may reflect the intrinsic property of the reaction.

From the situations for ΔB and K we conclude as follows. The stability of halide ions is in the order $Br^- > I^-$ in both solvents, but these ions are more stabilized in protic solvents than in dipolar aprotic solvents. The latter explains the solvent effects on k_r or k_f.

Direct Observation of Catalytic Activity Change in Nickel Metal Deformed in Torsion During Reaction

Eizo MIYAZAKI, Takakazu FUKUSHIMA, Kiyoshi KAWASAKI, and Kazuo NAKADA
Department of Chemical Engineering, Niigata University, Nagaoka
(Received September 24, 1970)

There have been many experimental investigations on the role of defect structure in the catalytic activity of metals. Some investigations[1] show that the defect plays an important role in heterogeneous catalysis; others[2] show that the effect of defect is minimal. The former proposal is, however, based mainly on the parallelism between the change in catalytic activities of cold-worked, quenched and irradiated metals during annealing. The purpose of this paper is to show more explicitly the influence of the defect on catalytic activity by a method in which metal was *in situ* cold-worked during reaction.

The main parts of the apparatus consist of a reaction tube and a manometer. In the center of the reaction tube a nickel sheet (0.1 mm thick, 3 mm wide and 130 mm long), washed in acetone and subsequently annealed in hydrogen at 700°C, was fixed to a pyrex glass rod with one end connected to a ground glass joint. The sheet was treated afresh in hydrogen at 600°C in order to remove the oxidized layer on surface before reaction, and the sheet was deformed in torsion during reaction up to a definite number of turns with the aid of the joint. The reaction was followed by continuously recording the total pressure change with a newly-devised glass made manometer.[3] The small surface areas of the catalysts were measured by the BET method using xenon vapor at 78°K.[4] The surface areas before and after deformation in torsion up to 6 turns were 10.1 cm^2 and 13.1 cm^2 per catalyst, respectively. A full description of the apparatus will be given in a later publication.

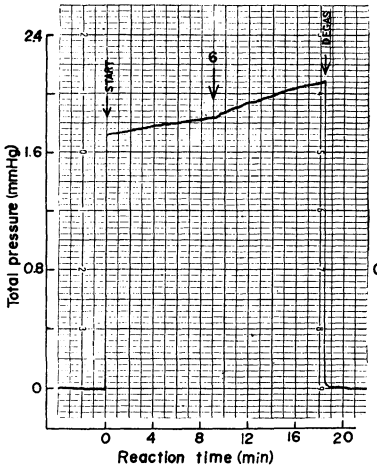

Fig. 1

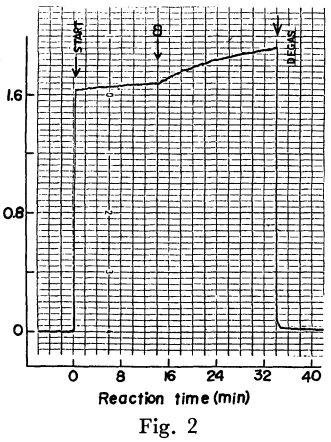

Fig. 2

Figs. 1 and 2. Changes in total pressure with reaction time at 194°C(Fig. 1) and 182°C (Fig. 2). Deformations in torsion were made at the points given by arrows up to 6 and 8 turns, respectively.

Figure 1 shows a typical curve obtained in the change of total pressure for the decomposition of formaldehyde ($H_2CO=CO+H_2$) over nickel sheet at 194°C, where deformation by torsion was carried out up to 6 turns at the point given by arrow. The discontinuity or sudden increase in total pressure was observed at the point of deformation, *i. e.*, deformation elevated the activity (slope of the curve). A similar result was obtained when the torsion was made up to 8 turns at 182°C as shown in Fig. 2, in which the increase in activity by deformation was found to be more drastic. However, such deformation-induced activities were found to practically disappear after the catalysts were annealed at 400°C. In addition, the reaction was confirmed to be kinetically first order with respect to formaldehyde pressure regardless of deformation range. Integral forms of the first order reaction before and after deformation during reaction are shown respectively as follows: $2.3\log(P_0/P)=kt$ and $2.3\log(P_0'/P)=k'(t-t_0')$, where k and k' are rate constants and P_0 or P_0' is formaldehyde pressure at $t=0$ or $t=t_0'$ (reaction time when deformation was made), respectively. The ratio of k' to k for the case shown in Fig. 1 was 2.1, *i. e.*, the activity was enhanced by 110% due to the deformation in torsion up to 6 turns during formaldehyde decomposition at 194°C. Increase in activity, however, might be due to the increase in surface area accompanying deformation in torsion. The actual surface areas were therefore measured for the catalysts only annealed and deformed in torsion up to 6 turns. The result was 29.8% increase; the residual increase in activity (110−30=80%) due to the deformation should be therefore attributed to other origins such as lattice imperfections which are known to be produced when nickel is subjected to deformation in torsion.[5] This can be also supported from the result of the annealing effect.

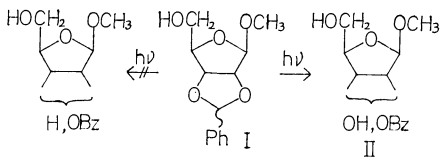
Synthetic Studies of Carbohydrate Derivatives with Photochemical Reaction. II.[1] Photochemistry of Benzylidene Sugar Derivatives

Kazuo MATSUURA, Sadao MAEDA, Younosuke ARAKI, and Yoshiharu ISHIDO
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received September 26, 1970)

The acetone-sensitized photochemical conversion of cyclic acetals to the corresponding carboxylic esters[2] suggests the possibility that the reaction may serve as an unique procedure for the preparation of deoxy sugars from cyclic acetals of sugars. A study on the photochemistry of sugar cyclic acetals has been carried out and part of the results will be described in the present communication.

A solution of methyl 2,3-*O*-benzylidene-β-D-ribofuranoside[3] (I)(0.02M) in a mixture of *t*-butyl alcohol and acetone (9:1) was irradiated[4] at room temperature under nitrogen atmosphere[5] for 60 hr, and the volatiles were evaporated *in vacuo*. The residue was subsequently chromatographed on a silica gel column by elution with benzene - acetone (95 : 5) to give I (recovery : 34%) as the first fraction and methyl 2(or 3)-*O*-benzoyl-β-D-ribofuranoside (II)[6] (58% yield) as the second



fraction. Contrary to expectation, the corresponding deoxy sugar was not produced. Variation of the molar concentration of I to 0.08 and 0.40 resulted in a stepwise decrease of the yield of II, and in an increase of that of recovered I. These results are summarized in Table 1. The correlation between the molar concentration of I and the results is now under investigation especially with respect to the effect of oxygen[7] which is slightly

Table 1. PHOTOCHEMICAL REACTION OF METHYL 2,3-*O*-BENZYLIDENE-β-D-RIBOFURANOSIDE (I)

Run	Conc. of I[a] (mol)	Recovery of I		Yield of II (%)
		Yield (%)	*exo*-H/*endo*-H	
1	0.02	34	0.25,[b] 0.20[c]	58[c]
2	0.08	67	0.27[c]	28[c]
3	0.40	100	0.75[c]	—

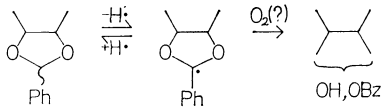
All the reactions were carried out in *t*-butyl alcohol - acetone (9 : 1) for 60 hr under irradiation.[4]

a) *exo*-H/*endo*-H of the isomers in the starting material was NMR spectroscopically 1.5, and gas chromatographically 2.0, and also refers to b and c.

b) Calcd by NMR[*exo*-H 4.29 τ, *endo*-H 4.03 τ ($CDCl_3$)]; These assignments were done by reference to 8).

c) Calcd by glc[Column: SE 30 1% on Chromosorb W, injection temp. 270°C, column temp. 200°C, carrier gas: N_2 150 ml/min, retention time (min): *exo*-H-I 5.2, *endo*-H-I 5.6 and II 9.8].

contained in commercial nitrogen. It is of interest that the content ratios of *endo*- and *exo*-benzylic proton isomers in each recovered I were considerably varied as compared with that of I applied as the starting material. This leads to the conclusion that *endo-exo* photoisomerization of the isomers actually took place along with the unexpected photooxygenation reaction of I. The reaction may be generalized to proceed *via* the benzylic radical(III) which is convertible into all the species mentioned above as follows:



III

A similar treatment of 3,5-*O*-benzylidene-1,2-*O*-isopropylidene-α-D-xylofuranose[6] also gave the corresponding 3- and 5-*O*-monobenzoate of 1,2-*O*-isopropylidene-α-D-xylofuranose[6] in good yield. Detailed results with other sugar derivatives will be published elswhere.

The Oxyhydration of Olefin over Transition Metal Oxide Catalysts

Yoshihiko MORO-OKA, Yusaku TAKITA, and Atsumu OZAKI
Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo
(Received October 9, 1970)

A number of catalytic oxidations of olefin have been developed on the transition metal oxide catalysts. Though the mechanisms of these oxidations have been extensively studied by the tracer technique with regard to the behavior of olefin,[1] little work has been done on the behavior of active oxygen. In this communication, we wish to report evidence which demonstrates that the oxygen atom is introduced into the oxidized product of olefin in two different ways, depending on the type of product. One is the case where the oxygen atom is introduced from molecular oxygen, and another is where the atom is introduced from the water molecule:

$$A + \frac{1}{2}O_2 \longrightarrow AO \quad (1)$$

$$A + \frac{1}{2}O_2 + H_2O^* \longrightarrow AO^* + H_2O \quad (2)$$

where A is the olefin to be oxidized.

TABLE 1. $H_2{}^{18}O$ TRACER IN THE OXIDATION OF PROPYLENE TO ACROLEIN OVER MoO_3–Bi_2O_3 CATALYST

2	385	4.35	65.5	3.84	0.00±0.2
3	433	9.45	55.0	3.73	0.16±0.2
4	460	14.80	51.0	3.40	0.18±0.2

a) Average of the values for input (4.00) and output gas.
GHSV: 600 m*l*-STP/m*l*-cat·hr
Gas composition; C_3H_6 20 vol%, O_2 30%, H_2O 30%, N_2 20%.

A typical example of Eq. (1) is the oxidation of propylene to acrolein over the MoO_3-Bi_2O_3 catalyst. The oxidation of propylene was done in the presence of the water vapor, 4% of which was $H_2{}^{18}O$. As can be seen in Table 1, the concentrations of ^{18}O in acrolein are far lower than those in water in the reactant gas. It can be concluded that the oxygen atom in acrolein comes from molecular oxygen, not from the water molecule, although it is well known that the presence of water vapor in the reactant gas mixture increases the selectivity to acrolein.

An example of Eq. (2) is the oxidation of propylene to acetone, which was previously reported by the present authors.[2] Propylene was oxidized to acetone in the presence of $H_2{}^{18}O$ vapor on the SnO_2-MnO_3 catalyst at two different temperatures. The experimental results are summarized in Table 2. As is shown in Table 2, the concentrations of ^{18}O in acetone are almost equal to those in water in the reactant gas. The exchange reaction of the oxygen atom between molecular oxygen and water:

$$^{16}O_2 + H_2{}^{18}O \rightleftarrows {}^{16}O{}^{18}O + H_2{}^{16}O \quad (3)$$

did not occur under the reaction conditions adopted in this experiment. These results clearly show that the oxygen atom in acetone comes from water, not from molecular oxygen. It has been suggested, regarding the mechanism of this oxidation, that acetone is formed *via* the hydration of propylene to form an alcoholic intermediate, followed by oxydehydrogenation.[3] The results obtained in this work present strong evidence for this proposed mechanism of acetone formation.

It has been proved that there are two different ways of oxygen introduction in the heterogeneous oxidations of olefin over metal oxide catalysts. It seems interesting that these two paths of the introduction of oxygen atoms to oxidized products correspond to two typical enzymatic oxidations, *i. e.*, oxidations by oxygenase[4] and oxidase.

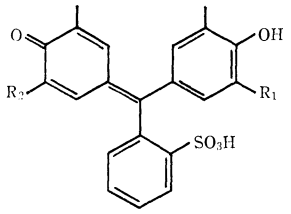
Separation of Semi-Xylenol Orange from Xylenol Orange by Thin-Layer Chromatography with Solvents Giving Stepwise pH Change on the Plate

Mutsuo YAMADA and Masatoshi FUJIMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received October 12, 1970)

Semi-Xylenol Orange (SXO) is a very suitable reagent as compared with Xylenol Orange (XO) for interpreting the kinetic behavior for complex formation. The *n*-butanol - water - acetic acid solvents reported for the separation of XO and SXO with a cellulose column[1,2] often cause serious tailing and cross-contamination. In the present communication we propose a new procedure with solvents giving stepwise pH change on the plate, whereby the clear-cut separation of SXO from XO is effectively performed by thin-layer chromatography with sandwich technique.



XO · $R_1 = R_2 = CH_2N(CH_2COOH)_2$
SXO · $R_1 = CH_2N(CH_2COOH)_2$, $R_2 = H$

A slurry for one plate (10×20 cm) was made by mixing 6 g of pretreated cellulose powder (Toyo, 300 mesh) with 18 m*l* of water. Developing solvents were prepared shortly before use from various amounts of 28% ammonia and 12 m*l* of *n*-butanol saturated with 10% acetic acid. The solvents formed regions I and II divided by a distinct boundary directly visible (Fig. 1). Region II gave an intense and uniform positive test with the Nessler reagent and a basic color (bluish green) with Bromothymol Blue (BTB), whereas region I showed an almost negative Nessler test and an acid color (orange) with BTB. Uniformity of the sensitive coloration indicates that the development with the given solvent automatically forms two distinct zones with different pH values, region I (*n*-butanol - acetic acid - water) and region II (*n*-butanol - ammonia - ammonium acetate - water).

In Fig. 1 the chromatograms for SXO and XO

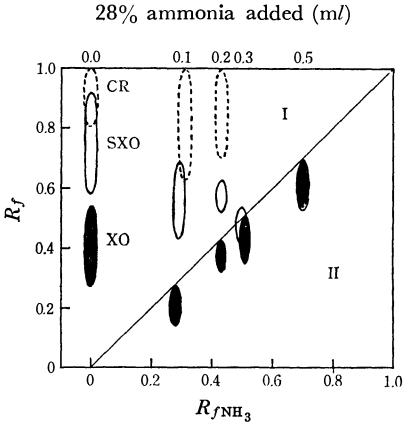


Fig. 1. Chromatograms for SXO and XO as a function of the R_{fNH_3}.
Spot solutions: 0.5 μl of 1×10^{-3} mol/*l* CR, SXO, or XO in *n*-BuOH satd. with 10% HOAc.
The straight line gives the ammonia front.

after 10 cm's development are plotted against R_{fNH_3}, the R_f values of the so-called ammonia front. XO lies always in region II beneath the boundary, whereas SXO is in region I for the R_{fNH_3} values lower than 0.5. When R_{fNH_3} is about 0.4, the cross-contamination of SXO and Cresol Red (CR), one of the raw materials, also disappears. In any case ammonia is very effective to prevent tailing. It is thus concluded that the solvent, 12 m*l* of *n*-butanol saturated with 10% acetic acid and 0.2 m*l* of 28% ammonia (R_{fNH_3}=0.43), gives the best separation of SXO from XO within only 1 hr. Preparative thin-layer chromatography for SXO of high purity using the present procedure is now in progress.

The solvent systems as mentioned above would be useful for the chromatographic separation of other series of substances of similar structure, where the subtle differences in charge type and its pH-dependence may be the primary factors for the sharp separation.[3] Further details for such systems will be reported elsewhere.

3) With the given solvents the disubstituted commercial specimen such as GCR, GTB, MTB, and MXB gave at least three distinct spots corresponding to the raw material, mono- and di-substituted derivatives.

Charge-Transfer Interaction between *N,N,N',N'*-Tetramethyl-*p*-phenylenediamine and Chloranil

Takashi NOGAMI, Keitaro YOSHIHARA, and Saburo NAGAKURA
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo
(Received October 12, 1970)

As an extension of a series of studies[1] of charge-transfer (CT) interactions between aromatic amines and chloranil, we measured temperature and concentration dependencies of an electronic absorption spectrum for a system including *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) and chloranil in an ethyl ether-isopropyl alcohol (3 : 1) mixed solvent.

The system showed spectra due to two different kinds of complexes. One is greenish yellow and exhibits an absorption peak at 830 mμ. This band was identified by Foster and Thomson[2] as the CT band of the outer complex. The other is reddish brown and has absorption peaks at 1100, 635, 520, and 434 mμ. The 1100 mμ band corresponds to a reverse CT band ($D \cdot A \leftarrow D^+A^-$) of the inner (ion-pair or ionic EDA) complex observed by Sato *et al.*[3] for the solid TMPD-chloranil. We studied the behaviors of these two specimens in the solution by measuring their absorption spectra at room temperature, 193°K and 77°K. In Table 1, the observed

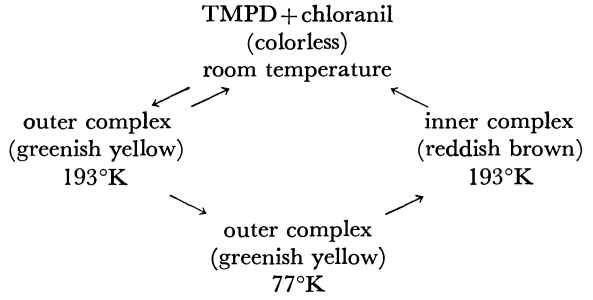
a) [D] and [A] are the concentrations (in the unit of 10^{-4} mol/*l*) of TMPD and chloranil, respectively.

results, A, B, C, D, and E denote the following phenomena. A: Immediately after mixing the TMPD and chloranil solutions at room temperature, the outer complex is formed and converted gradually into the inner complex. B: Only the outer complex is formed at room temperature, and the inner-complex formation starts by lowering the temperature of the solution to 193°K. C: Only the outer complex is formed in the temperature range from room temperature to 193°K, and the inner-complex formation starts at 77°K. D: The component molecules which are almost completely free at room temperature start to form the outer complex at 193°K. This process is reversible. By raising the solution temperature to 193°K after once having lowered it to 77°K, the inner complex is formed. By raising the temperature further, the solution returns to the initial stage at room temperature. E: Only the outer complex is formed in the range of 193°K to 77°K, and the inner complex is not formed.

The present results of the outer-complex formation are reasonable and can be explained by the equilibrium-shift toward the outer-complex formation caused by the lowering of temperature. The results concerning the inner complex, though rather complicated, suggest that its formation can not occur unless the outer-complex concentration exceeds some limited values. This seems to show that the inner-complex formation needs environmental cooperation; in particular, that there must be a clustering of donor-acceptor pairs before the inner-complex formation begins.[4] In this connection, phenomenon D is particularly interesting as showing the following color cycle with temperature:



The colorless solution at room temperature turns greenish yellow at 193°K and the color becomes deeper by decreasing the temperature to 77°K. The solution changes from greenish yellow to reddish brown by raising the temperature from 77°K to 193°K.[5] By raising further the temperature, the solution returns to the initial colorless state. The color cycle occurs regardless of the lowering and raising rates of temperature and can be repeated many times. Although the mechanism of the inner-complex formation in this cycle is not clear at the present stage, the phenomenon seems to support the opinion that the outer complex is a precursor to the inner-complex formation in the reaction path.

Electrophilic Substitutions on 8-Cyanoheptafulvene

Masaji ODA and Yoshio KITAHARA*
Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai
(Received October 26, 1970)

We wish to report here the first examples of electrophilic substitutions on 8-cyanoheptafulvene (**I**)[1] which is a moderately stable and the simplest derivative of heptafulvenes. The compound **I** is unstable to acids, however, basic conditions were found to be best for obtaining successful results.

Bromination. The addition of one equivalent of bromine to a solution of **I** and a small excess of triethylamine in methylene chloride at 0°C gave, by silica gel chromatography, 8-bromo-8-cyanoheptafulvene (**II**) as orange needles, mp ~50°C decomp., in a 87% yield. The compounds **II** is unstable and is liable to decompose at room temperature. When a mass of **II** was heated at *ca.* 40°C, it decomposed explosively and an evolution of hydrogen bromide was observed. Therefore, we could not obtain successful elemental analytic data. However, the structure was established by means of the spectral data given in the table.

Nitration. When **I** was treated with tetranitromethane in pyridine - ethanol at 10°C for one hour, it gave 8-cyano-8-nitroheptafulvene (**III**) as fine yellowish-brown needles, mp 168°C decomp., in a 16.5% yield. With other nitrating reagents, only polymeric materials were obtained.

Formylation. The Vilsmeyer reaction of **I** was successful in giving 8-cyano-8-formylheptafulvene (**IV**)[2] as red prisms, mp 181—182°C, in a 47% yield.

Trifluoroacetylation. The treatment of **I** with trifluoroacetic anhydride in methylene chloride at 4°C gave 8-cyano-8-trifluoroacetylheptafulvene (**V**) as orange red prisms, mp 213—214°C, in a 20% yield.

The structures of **III**, **IV**, and **V** were established by their elemental analyses and by their spectral data (see Table 1). The selectivity of the substitution position (C-8) is in accord with the polar character of **I**, which has a high electron density at C-8. The chemical shift of the ring protons of **II** (6.08 ppm) is close to that of **I** (6.13 ppm),[1] however, those of **III**, **IV**, and **V** are 1—1.5 ppm lower, suggesting their larger polar character because of the introduction of electron-withdrawing groups.

From these results, we can say that 8-cyanoheptafulvene (**I**) has an aromatic character.

Table 1. Spectral data

Compd.	ν_{max} (KBr) cm^{-1}			λ_{max} nm (log ε)		δ ppm (J Hz)[a]

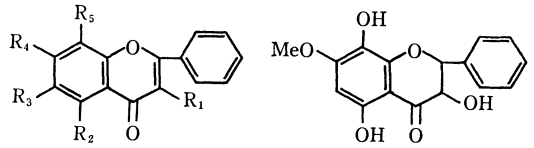
Four New Flavonoids Isolated from *Alnus sieboldiana*[1]

Yoshinori ASAKAWA, Fumihide GENJIDA, and Takayuki SUGA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima
(Received October 26, 1970)

Isolation of two new ketols having a phenyl-propane skeleton from *Alnus sieboldiana* has been reported.[2] We now wish to report the isolation of four new flavonoids with an unsubstituted B-ring from the phenolic portion of the benzene extract of the same plant. These substances were readily separated by their solubility difference in ether and methanol and purified by means of preparative thin-layer chromatography using a mixture of benzene, dioxane, and acetic acid.



R_1=R_2=R_4=OH R_3=OMe R_5=H (I) (IV)
R_1=R_3=R_4=OMe R_2=OH R_5=H (II)
R_1=H R_2=OH R_3=R_4=R_5=OMe (III)

3,5,7-Trihydroxy-6-methoxyflavone (I). Compound I (a main flavonoid of the plant), $C_{16}H_{12}O_6$, M+ 300, mp 239.0—241.0°C, exhibited positive coloration with $FeCl_3$ and Mg-HCl tests and the spectral properties as follows: *m/e* 285 (M-15), 282 (M-H_2O), 257 (M-43, base), 105, 77, 69; λ_{max}^{EtOH} mμ (log ε) 270 (4.25), 325 (4.26), 362$_{sh}$ (4.20), $\lambda_{max}^{EtOH+AcONa}$ 271 (4.39), 328 (4.15), 368 (4.20), $\lambda_{max}^{EtOH+AlCl_3}$ 278 (4.38), 350 (4.25), 415 (4.26); ν_{max}^{Nujol} 3350, 3300 (OH), 1640 (C=O), 762, 680 cm^{-1} (monosubst. benzene ring); $\delta_{ppm}^{CD_3COCD_3}$ (60 MHz) 3.89 (s, 3H, OMe), 6.68 (s, 1H, C_8-H), 7.60, 8.20 (m, 5H, B-ring), 9.25 (s, 1H, OH), 12.23 (s, 1H, C_5-OH). No bathochromic shifts in the UV spectrum on addition of H_3BO_3 and AcONa indicated the absence of *o*-dihydroxy group.[3] The results suggested that the structure of I is 3,5,7-trihydroxy-6-methoxy- or 3,5,7-trihydroxy-8-methoxyflavone. The strong fragment peak at *m/e* 285 (M-15) indicated the presence of the OMe group at C-6 position.[4] Methylation of I gave 3,5,6,7-tetramethoxyflavone[5] (mp 112.0—112.5°C), which was converted into benzoic acid and 2-hydroxy-ω,4,5,6-tetramethoxyacetophenone with alkali. Thus, compound I was determined to be 3,5,7-trihydroxy-6-methoxyflavone.

5-Hydroxy-3,6,7-trimethoxyflavone (II). Compound II possessed the following physical properties: mp 175.0—176.0°C; λ_{max}^{EtOH} 271 (4.30), 317 (4.09), $\lambda_{max}^{EtOH+AlCl_3}$ 286 (4.29), 337 (4.08), 392 (4.01); ν_{max}^{Nujol} 1660 (C=O), 765, 695 cm^{-1} (monosubst. benzene ring); $\delta_{ppm}^{CDCl_3}$ 3.89, 3.94, 3.97 (s, 9H, 3 OMe), 6.54 (s, 1H, C_8-H), 7.56, 8.10 (m, 5H, B-ring), 12.58 (s, 1H, C_5-OH). Methylation gave 3,5,6,7-tetramethoxyflavone. The results indicated the structure of II to be 5-hydroxy-3,6,7-trimethoxyflavone.

5-Hydroxy-6,7,8-trimethoxyflavone (III). Compound III, mp 100.0—101.0°C, showed the NMR signals at $\delta_{ppm}^{CDCl_3}$ 3.95, 3.97, 4.10, (s, 9H, 3 OMe), 6.69 (s, 1H, C_3-H), 7.56, 7.95 (m, 5H, B-ring), 12.45 (s, 1H, C_5-OH). Methylation gave 5,6,7,8-tetramethoxyflavone[6]: mp 112.0—113.0; λ_{max}^{EtOH} 270 (4.34), 305 (4.08); $\delta_{ppm}^{CDCl_3}$ 3.98 (s, 6H, 2 OMe), 4.04 (s, 3H, OMe), 4.10 (s, 3H, OMe), 6.70 (s, 1H, C_3-H), 7.57, 7.95 (m, 5H, B-ring). Thus, the structure of III was established to be 5-hydroxy-6,7,8-trimethoxyflavone.

3,5,8-Trihydroxy-7-methoxyflavone (IV). Compound IV, $C_{16}H_{14}O_6$, M+ 302, mp 175.0—177.0°C, showed positive coloration with $FeCl_3$, Mg-HCl, Zn-HCl, and Pachcós tests and the following spectral properties: *m/e* 273, 91 (M-CHO and 120-CHO, characteristic for flavanonol), 195, 183 (base), 167, 156, 120, 91, 77; λ_{max}^{EtOH} 215 (4.58), 226$_{sh}$ (4.48), 290 (3.87), $\lambda_{max}^{EtOH+AlCl_3}$ 313 (4.74), $\lambda_{max}^{EtOH+AcONa}$ and $\lambda_{max}^{EtOH+AcONa+H_3BO_3}$ no bathochromic shifts[2]; ν_{max}^{Nujol} 3480, 3460, 3340 (OH), 1635—1654 cm^{-1} (C=O); $\delta_{ppm}^{CDCl_3}$ 3.86 (s, 3H, OMe), 4.40, 4.97 (d, J= 12 Hz, C_3-H and C_2-H), 5.99 (s, 1H, C_6-H), 7.33 (s, 5H, B-ring), 11.34 (s, 1H, C_5-OH). The small fragment peak at *m/e* 301 (M-1) indicated the absence of OH and OMe groups at C_6 position.[4] The spectral data as well as the specific color reaction thus indicated that IV is 3,5,8-trihydroxy-7-methoxyflavone.

Molecular Complex between the Cation Radicals of Perylene and Tetracene

Tomoko YAMAZAKI and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo

(Received October 27, 1970)

A spectroscopic study of a molecular complex formed between two kinds of Würster's cations in solution has been reported by Takemoto *et al.*[1] Recently, Kimura *et al.*[2] have studied the reversible dimerizations of (perylene)$^+$ and (tetracene)$^+$ in concentrated sulfuric acid from an electronic-absorption study. In the present work, we have first established, spectroscopically, the existence of an interesting 1 : 1 complex between the cation radicals of cata-condensed hydrocarbons in concentrated sulfuric acid. The (perylene)$^+$-(tetracene)$^+$ complex may be one of the typical examples of radical-radical complexes.

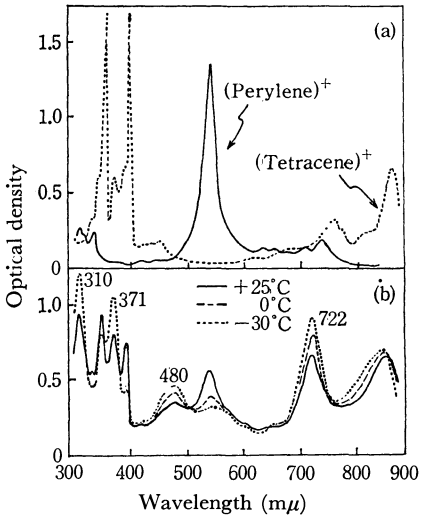

Fig. 1. (a) Electronic absorption spectra of (perylene)$^+$ (2.38×10^{-5}M) and (tetracene)$^+$ (2.21×10^{-5}M) in concentrated sulfuric acid at room temperature.
(b) Temperature dependent spectra of a mixed solution containing the two cations, whose concentrations are almost the same as above.

Perylene and tetracene are readily soluble in concentrated sulfuric acid; they thus form stable cation radical.[3] The absorption measurements were carried out under conditions in which none of the cations dimerized in a dilute concentrated-sulfuric acid solution. In Fig. 1, the electronic absorption spectra of the mixed solutions of (perylene)$^+$ and (tetracene)$^+$ measured at room temperature and also at lower temperatures are shown. Upon the mixing of the two cations, new several absorption bands appear at 264, 310, 371, 480, and 722 mμ, in addition to their own absorption bands, which become weak upon the mixing; several isosbestic points also exist.

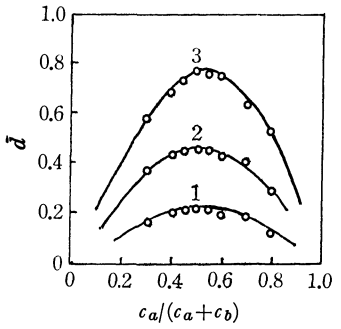

Fig. 2. Plots of $\bar{d}$ against $c_a/(c_a+c_b)$ in the continuous-variation method for different wavelengths.
Curve 1: 310 mμ, 2: 371 mμ, and 3: 538 mμ.
$c_a+c_b=5.0\times10^{-5}$M.

In order to identify this new species, we attempted to analyze the changes in the absorption intensity by using a method of continuous variation, in which concentrations of the two cations were selected so as to be constant. In Fig. 2, the increments of the optical densities, $\bar{d}=d-(c_a\varepsilon_a+c_b\varepsilon_b)$, are plotted aganst $c_a/(c_a+c_b)$ for three different wavelengths. Here, d is the optical density; c_a and c_b are the concentrations of (perylene)$^+$ and (tetracene)$^+$ respectively and ε_a and ε_b are the molar extinction coefficients of the absorption peaks of (perylene)$^+$ and (tetracene)$^+$ respectively. From Fig. 2 it can be seen that the maximum of each curve is located at 0.5. Therefore, it may reasonably be concluded that the (perylene)$^+$ and (tetracene)$^+$ in the solutions are in equilibrium with the 1:1 complex. This result was also supported by another analysis of the present absorption data by using the mole-ratio method, in which c_b was changed from 1.0×10^{-5} to 4.5×10^{-5}M, while c_a was kept constant (3.0×10^{-5}M). Furthermore, it was confirmed that the observed electronic absorption spectrum of the mixed solution can not be explained in terms of a mixture of (perylene)$^{2+}$ and tetracene, or of perylene and (tetracene)$^{2+}$; no absorption bands due to these species appear upon the mixing of the two cations.

The electronic absorption spectra were measured by a Cary Model 15 spectrophotometer, quartz cells with a pathlength of 1 cm being used. Commercial materials of perylene and tetracene were purified by vacuum sublimation. Concentrated sulfuric acid of a high purity ("Wako" 98.08%) was used without further purification.

On the Structure of *Trans* Ethyl Methyl Ether and the W Form of Diethyl Ether

Michiro HAYASHI, Hisae IMAISHI, Keiichi OHNO, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received November 4, 1970)

We have measured the microwave spectra of ethyl methyl ether and its isotopically substituted species. Since the measurements have not been finished for ^{18}O and one of ^{13}C species, the r_s structure can not be obtained at present.

We found many weak spectra around the expected regions for the spectra of the ^{18}O and one of three ^{13}C species. Some of these spectra may be assigned to those of the vibrationally excited states of the molecule. Since these spectra are confusing, it is preferable to assign them before the assignments of the spectra are undertaken for the ^{18}O and the ^{13}C species. However, we have tried to determine a tentative structure of *trans* ethyl methyl ether which reproduces the observed rotational constants for the parent and nine isotopic species.

In Table 1 are shown the observed rotational constants and the differences between the observed and the calculated rotational constants which were calculated using the obtained structural parameters given in Table 2. Work is in progress with respect to both the *trans* and the *gauche* isomers on the electric dipole moment, the internal rotation of the CH_3CH_2 and OCH_3 groups and the skeletal torsion and spectra due to the vibrationally excited states.

We have also tried to measure the microwave spectra of diethyl ether based on the trial calculation for the rotational constants of four possible molecular forms of diethyl ether using the structural parameters given in Table 2. We could find a set of spectra assigned to the W form (or the *trans-trans* form) of the molecule. In order to reproduce the observed rotational constants, we have adjusted only the structural parameters of the skeleton. The best agreement is obtained when we reduce the ∠COC angle by about 1° from the values for *trans* ethyl methyl ether. The results are given in Table 1.

TABLE 1. THE OBSERVED ROTATIONAL CONSTANTS (MHz) AND THE DIFFERENCES BETWEEN THE OBSERVED AND PREDICTED ROTATIONAL CONSTANTS

Species		$A(\Delta A)$[a]	$B(\Delta B)$[a]	$C(\Delta C)$[a]
trans ethyl methyl ether				
$CH_3CH_2OCH_3$		27992.03 (13.96)	4159.61 (4.61)	3891.11 (0.06)
$CH_3CH_2OCH_2D$	sym[b]	27218.96 (5.98)	3956.97 (4.21)	3699.99 (−0.74)
	asym[b]	26194.77 (0.52)	4009.66 (6.49)	3765.02 (2.23)
$CH_3CHDOCH_3$		25040.20 (10.71)	4131.86 (4.86)	3843.20 (0.18)
$CH_3CD_2OCH_3$		22669.17 (10.70)	4095.93 (5.23)	3804.65 (0.05)
$CH_2DCH_2OCH_3$	sym[b]	27505.31 (7.36)	3937.57 (−0.39)	3683.49 (0.02)
	asym[b]	26057.29 (18.57)	4008.84 (4.44)	3760.41 (0.20)
$CH_3CH_2OCD_3$		23838.31 (0.85)	3704.12 (7.48)	3491.59 (3.02)
$^{13}CH_3CH_2OCH_3$[c]		27951.36 (17.20)	4041.94 (6.71)	3787.16 (2.23)
$CH_3CH_2O^{13}CH_3$[c]		27978.56 (16.60)	4051.52 (6.66)	3796.06 (2.16)
the W form of diethyl ether				
$(CH_3CH_2)_2O$		17955.83 (6.87)[d]	2244.15 (2.71)[d]	2101.73 (0.12)[d]
		(−114.65)[e]	(−0.27)[e]	(−4.15)[e]

a) $\Delta R = R_{calctd} - R_{obsd}$, $R = A, B, C$

b) "sym" and "asym" refer to the symmetric and asymmetric forms, respectively with respect to the molecular plane.

c) Since the Q branches of the transitions have only been measured at present for two ^{13}C species, the rotational constants are determined on the assumption that the difference of $I_a+I_b-I_c$ between the parent and the isotopic species is the same as that found in CH_3CH_2Br and $(CH_3)_2O$, respectively.

d) The difference between the observed and predicted rotational constants calculated from the adjusted structural parameters.

e) The difference between the observed and predicted rotational constants calculated from the structural parameters obtained for *trans* ethyl methyl ether.

TABLE 2. STRUCTURAL PARAMETERS OBTAINED FOR *trans* ETHYL METHYL ETHER

CH_3O		CH_3C		CH_2		Skeleton

The Methylation of the Mercuric Ion by Methylcobaloximes

Jong-Yoon KIM, Nobumasa IMURA, Tyunoshin UKITA, and Takao KWAN
Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Tokyo
(Received November 7, 1970)

Cobaloximes and certain other cobalt complexes have recently been of interest as model compounds of vitamin B_{12}, and the chemistry involving the Co–C bond has been extensively investigated, particularly in connection with cobaloximes.[1]

It has been reported that Hg^{2+} is alkylated by alkylcobalamin, in the presence of a reducing agent, both enzymatically and nonenzymatically, to produce monoalkyl and dialkyl mercury.[2] Recently, Ukita *et al.*[3] found that the methylation of Hg^{2+} to afford monomethyl and/or dimethyl mercury took place by means of methylcobalamin in the absence of a reducing system. In view of the stability of the alkyl-cobalt bond,[4,5] the facile cleavage of the bond by Hg^{2+} to form alkyl mercurials is worthy of note.

Prompted also by the previous report that methylpentacyanocobalt complex can transfer its methyl group to Hg^{2+},[6] we were led to simulate the nonenzymatic reaction with methylcobaloximes and $HgCl_2$ in the absence of reducing agent and in a phosphate buffer solution. As a result, we found that the expected methylation took place although only methylmercuric chloride was formed.[7] The transmethylation may be represented by

$$CH_3\text{–(Co)–B} + HgCl_2 \xrightarrow[pH=7.0]{37^\circ, \text{dark}} CH_3HgCl + HO\text{–(Co)–B} + Cl^-$$

where (Co)-B denotes the cobaloxime moiety, with B representing an axial base such as H_2O or imidazole. Figure 1 shows the yield of the product with the time.

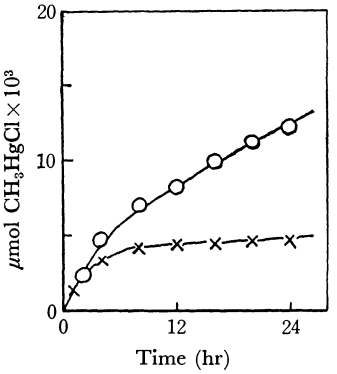

Fig. 1. The time course for the formation of CH_3HgCl in the dark at 37°C under an aerobic condition.
The reaction contained 0.1 μmol methylcobaloxime and 0.05 μmol $HgCl_2$ in 0.25M phosphate buffer at pH 7.0.
—○— methyl(imidazole)cobaloxime
—×— methyl(aquo)cobaloxime

It is apparent from Fig. 1 that the imidazole-coordinated cobaloxime is more reactive than the aquo-complex. This phenomenon is in accord with the kinetic data on the similar reaction between methylcobalamin or methylcobinamide and Hg^{2+}.[8] Also, it is to be noted that the methylcobaloxime is less reactive than the methylcobalamin, as is demonstrated by the formation of dimethyl mercury with the cobalamin. The difference in reactivity between the cobaloxime and the cobalamin is consistent with their electronic nature.[9] It is obvious, however, that the methylcobaloximes are reactive enough to methylate Hg^{2+} to yield monomethyl mercury.

Effect of Phase on the Primary Process of the Formation of Butyl Radicals in the Radiolysis of Solid Isobutane-2-d_1

Yoshiyuki SAITAKE, Terunobu WAKAYAMA, Toyoaki KIMURA, Tetsuo MIYAZAKI, Kenji FUEKI, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received November 10, 1970)

We have studied the radiolysis of organic compounds in the solid state and have proposed that two important problems must be solved in order to elucidate the mechanism of the solid-phase radiolysis. One is the problem of the extent to which the formation of an exciton plays an important role;[1] the other is how the condition of the solid matrix affects the reaction of the exciton.[2,3] It was recently reported that the i-C_4H_9 radical is formed in the radiolysis of isobutane in the crystalline state, while the t-C_4H_9 radical is formed in the glassy state.[2] The possibility that the phase effect may be attributed to an isomerization of butyl radicals, such as i-$C_4H_9 \rightleftarrows t$-$C_4H_9$, was not completely excluded in the previous study.

In order to determine whether or not the phase change affects the primary process of the C–H bond rupture or the isomerization of butyl radicals, the radiolysis of $(CH_3)_3CD$ has been investigated by ESR spectroscopy at 77°K. $(CH_3)_3CD$ was prepared by the reaction of t-butyl magnesium bromide with D_2O. The ESR spectrum of γ-irradiated isobutane, which is polycrystalline at 77°K, is shown in Fig. 1a. The spectrum can be assigned to the $(CH_3)_2CHCH_2\cdot$ radical. The ESR spectrum of γ-irradiated pure $(CH_3)_3CD$ in the polycrystalline state is shown in Fig. 1b. The spectrum in Fig. 1b is quite different from that in Fig. 1a; it consists of three broad lines, with a splitting constant of 22.7G. The splitting constants of the α-proton and the β-proton of the $(CH_3)_2CHCH_2\cdot$ radical have been reported to be 22 and 35 G respectively.[4] Since the splitting due to a deuteron is about 15% of that due to a proton, it is expected that the spectrum of the $(CH_3)_2CDCH_2\cdot$ radical is split into three lines by two α-protons, with a slitting constant of 22 G, and that each line is then split further into three lines by a β-deuteron with a splitting constant of 5 G. Since the splitting due to a deuteron is, however, very small, the poorly-resolved spectrum in the solid state may consist of three broad lines with a splitting constant of 22 G. Thus, the spectrum in Fig. 1b coincides well with the spectrum expected for the $(CH_3)_2CDCH_2\cdot$ radical. An $(CH_3)_3$-CD sample containing methylcyclohexane (5.7 mol%) can be frozen to a clear glass by rapid cooling at 77°K. Upon the γ-irradiation of the mixture in the glassy state, the ESR spectrum shown in Fig. 1c was obtained. The spectrum is the same as that[2] obtained in the radiolysis of isobutane in the glassy state at 77°K; it can be assigned to the $(CH_3)_3C\cdot$ radical. Therefore, the bond rupture in the radiolysis of $(CH_3)_3CD$ in the solid state may be represented as follows:

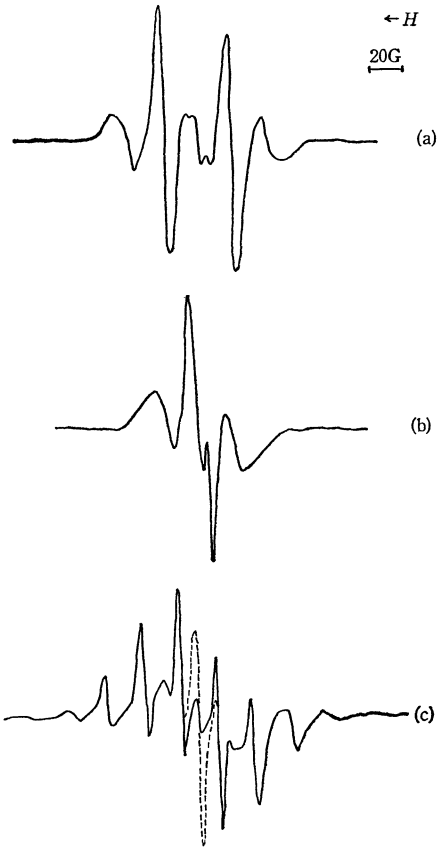

Fig. 1. (a) ESR spectrum of γ-irradiated i-C_4H_{10} in the polycrystalline state.
(b) ESR spectrum of γ-irradiated $(CH_3)_3CD$ in the polycrystalline state.
(c) ESR spectrum of γ-irradiated $(CH_3)_3CD$ containing methylcyclohexane (5.7 mol%) in the glassy state.
A dotted line represents the spectrum of trapped electron which is easily bleached by the illumination with visible light.
Irradiation dose: 2×10^5 rad.
Irradiation temperature: 77°K

$$(CH_3)_3CD \xrightarrow[\text{polycrystal}]{\sim\sim} (CH_3)_2CDCH_2\cdot + H \quad (1)$$

$$(CH_3)_3CD \xrightarrow[\text{glass}]{\sim\sim} (CH_3)_3C\cdot + D \quad (2)$$

It can be concluded that the phase change affects the primary process of the C–H bond rupture.

The Reduction of Enamines and the Reductive Alkylation of *sec*-Amines with Potassium Hydridotetracarbonylferrate

Take-aki MITSUDO, Yoshihisa WATANABE, Masato TANAKA,
Kazuo YAMAMOTO, and Yoshinobu TAKEGAMI
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto
(Received November 13, 1970)

Enamines have been recognized to have elegant and broad utility in organic synthesis.[1] On the other hand, little attention has been paid to the reactions of enamines with organotransition metal complexes. The present communication will deal with the reaction of enamines with potassium hydridotetracarbonylferrate, $KHFe(CO)_4$[2] (I), under carbon monoxide.

We have found that enamines react with the alcoholic ferrate (I) at 30°C, with a rapid absorption of carbon monoxide, to give the corresponding saturated amines.[3] No carbonylated product of the enamines was detected, however. The ferrate (I) also reacts with a binary system, consisting of a *s*-amine and a carbonyl compound, from which an enamine can be prepared, to give a *t*-amine in a fairly good yield.

The results of the typical reactions are shown in Table 1. To 11 mmol of the ferrate (I) in 50 m*l* of ethanol, was added 33 mmol of 1-morpholino-1-cyclohexene at 30°C under one atmosphere of carbon monoxide. Twenty mmol of carbon monoxide was absorbed in 1.5 hr, giving 15 mmol of *N*-cyclohexylmorpholine. The reaction also proceeded under nitrogen, but the yield of the product was lower. The yield of the *N*-cyclohexylmorpholine was improved by the addition of excess potassium hydroxide. 1-Piperidino-1-isobutene was readily reduced to the isobutane derivative. The ferrate (I) reacted with an equimolar mixture of morpholine and cyclohexanone, with a slow absorption of carbon monoxide, to give *N*-cyclohexylmorpholine. Neither morpholine and cyclohexanone, however, reacted separately with the ferrate (I). Pyrrolidine and acetophenone gave *N*-(1-phenylethyl)pyrrolidine. The iminium salt of 1-morphorino-1-cyclohexene, *N*-cyclohexylidenemorpholium perchlorate, also reacted with the ferrate (I) to give *N*-cyclohexylmorpholine.

The facts that iron pentacarbonyl is not effective for this type of reduction of enamines, and that the reductive alkylation of *s*-amines with a potassium hydroxide-carbon monoxide system is very slow, show that the ferrate (I) is essential for this reaction. Hydrogenation catalysts, such as Raney nickel[4] and derivativ of formic acid,[5] are effective for the reductive alkylation of amines, but both reactions require some more drastic reaction conditions than does the present reaction. It is plausible that the reduction of enamines and the reductive alkylation of *s*-amines with the ferrate (I) proceeds *via* iminium salt, which has been shown to be an intermediate in the reduction of enamines by formic acids.[6] Studies of the mechanism of this reaction and some of the extension fields of this system will be reported in more detail in the near future.

TABLE 1. THE REDUCTION OF ENAMINES AND REDUCTIVE ALKYLATION OF AMINES BY $KHFe(CO)_4$[a]

Exp. No.	Reagent[b]	Reaction time, hr	CO absorbed	Max. Rate of CO absorption	Product	Yield
1	1-Morpholino-1-cyclohexene	1.5	1.8[c]	13[d]	*N*-Cyclohexylmorpholine	1.4[c]
2	1-Morpholino-1-cyclohexene	1.5	—[e]	—	*N*-Cyclohexylmorpholine	0.9
3[f]	1-Morpholino-1-cyclohexene	5.0	2.0	10	*N*-Cyclohexylmorpholine	2.4
4	1-Piperidino-1-isobutene	48	1.9	0.8	*N*-Isobutylpiperidine	1.5
5	Morpholine-Cyclohexanone	48	1.7	1.0	*N*-Cyclohexylmorpholine	1.4
6	Pyrrolidine-Acetophenone	48	1.5	1.0	*N*-(1-Phenylethyl)pyrrolidine	1.1

a) $KHFe(CO)_4$ 11 mmol in 50 m*l* ethanol, at 30°C.
b) 3.0 mol/mol-$KHFe(CO)_4$ of reagent was used.

Anomalous Products Obtained by Nitration of Some Polyalkylnaphthalenes

Hitomi SUZUKI and Kiyomi NAKAMURA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received November 16, 1970)

Polyalkylbenzenes react with fuming nitric acid in an unusual way to yield benzyl nitrate as the main product. The reaction has an electrophilic feature and is characterized for its peculiar orientation and high positional selectivity.[1] Our studies on the anomalous nitration are now extended to include naphthalene series. Among various polyalkylnaphthalenes investigated, anomaly was observed only with those systems in which both 1 and 4 positions were occupied by alkyl groups. In contrast to the results obtained with polyalkylbenzene derivatives, the major product in this case was not nitrooxymethylnaphthalene but nitromethylnaphthalene.

1,4-Dimethylnaphthalene (I) was treated with fuming nitric acid in dilute methylene chloride solution at −5—0°C for 0.5 hr to give a pale yellow oily mixture, which was found to contain besides 4-methyl-1-nitromethylnaphthalene (V) some amounts of a methylene compound, presumably 1-methylene-4-nitro-4-methyl-1,4-dihydronaphthalene (III), and addition products on the basis of infrared, ultraviolet and PMR spectra as well as by spectral comparison with the anomalous nitration product from 9,10-dimethylanthracene.[2] Our result differs somewhat from both an earlier report by Robinson and Thompson[3] who isolated V, and from the recent comment by Davies and Warren[4] who obtained 1,4-dimethyl-5-nitronaphthalene (VI).

With the use of excess of nitric acid, 1,2,4-trimethylnaphthalene readily underwent side-chain nitration at less hindered methyl group to give 3,4-dimethyl-1-nitromethylnaphthalene (mp 92—95°C) as the principal product. However, 1,2,3-trimethylnaphthalene was only nitrated at ring position to give 1,2,3-trimethyl-4-nitronaphthalene (mp 148—149°C) in good yield. No side-chain attack was observed. 1,2,3,4-Tetramethylnaphthalene showed a similar anomaly to give 2,3,4-trimethyl-1-nitromethylnaphthalene (mp 99.5—101.5°C). The orientation of these side-chain substituted products has been established by treatment of the corresponding polymethylnaphthylmethyl chlorides with silver nitrite in acetonitrile, followed by purification of the resulting nitro compounds through repeated precipitations from alkaline solution.

Davies and Warren[4] recently suggested that the nitromethyl compound V can be derived from an acid-catalysed rearrangement of VI. Although the nitro group at the hindered position is known to be subjected to migration in some cases,[5] there seems so far to be no analogy of such rearrangement. More probable reaction sequences which account for side-chain nitration might be as shown in Scheme 1

Nitronium ion attaches to 1-position of the higher alkylated ring to form arenonium ion II, in which steric strain due to the interaction between alkyl group and peri-hydrogen is partly relieved and the positive charge is more effectively delocalized when the alkyl groups are located at 1- and 4-positions. Loss of proton from the alkyl side-chain, followed by electrophilic attack of nitronium ion at the terminal methylene group of III, redistribution of electrons to regain the naphthalene ring system, and the concomitant departure of the nitro group from the ring will lead to the formation of side-chain nitro compound. An alternative reaction scheme involves intermediate formation of addition product. The methylene compound III may undergo 1,4-addition of dinitrogen pentoxide to form IV which, on further removal of dinitrogen pentoxide from the ring, will lead to side-chain nitration.

Photosensitized Electrolytic Oxidation of Iodide Ions on Cadmium Sulfide Single Crystal Electrode[1]

Akira FUJISHIMA, Eiichi SUGIYAMA, and Kenichi HONDA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 2, 1970)

The semiconductor electrode reactions have been studied by a number of research workers[2]; they exhibit interesting behavior different from that of metal electrodes. The present authors[3] have studied mainly the effect of the irradiation with light on the semiconductor electrode reactions and have learned that the oxidation reactions, such as oxygen evolution from water or the oxidation of halogen ions, occur at more negative potentials than the standard oxidation potential on a TiO_2 or ZnO single crystal electrode.[4]

The behavior of the CdS semiconductor electrode, which has a band gap of 2.4 eV, has been reported only by Williams,[5] who especially studied the mechanism of its photo-voltaic effect.

In the present paper, it is concluded that the photosensitized electrolytic oxidation does occur on the CdS electrode in the same way as on the TiO_2 and ZnO electrodes. It will also be reported that the mechanism of this photosensitized electrolytic reaction can be determined by using the method of a rotating ring-disk electrode, in which the disk electrode consists of a cadmium sulfide single crystal and the ring electrode gold or amalgamated gold.

The anodic current of the CdS electrode does not flow in the dark, but under irradiation it flows in proportion to the intensity of light at potentials more positive than -0.68 V (*vs.* SCE) and depends on the wavelength of light (the greatest anodic current is found to flow at 520 mμ, *i.e.*, 2.4 eV). The anodic reaction is related to the holes formed by the irradiation in the valence band and is rate-controlled by the supply of the holes to the surface of the electrode.

When the anodic reaction occurs on the CdS disk electrode, the reduction current on the ring amalgamated electrode is found to begin to flow from -0.6 V towards the negative potential and then to appear in the limiting reduction current region. The half-wave potential of this reduction corresponds to the reduction of Cd^{2+} to Cd. The ratio of the disk electrode current to the ring electrode current nearly agrees with the calculated collection efficiency. After the anodic disk current flows for several minutes, the surface of CdS is observed to become white-yellow because of some adhered substance, which is found to be sulfur from its high solubility into CS_2. These facts indicate that the anodic reaction of the CdS electrode under irradiation is the anodic dissolution of the electrode, as expressed by the following reaction (1):

$$CdS + 2p^+ \rightarrow Cd^{2+} + S. \quad (1)$$

When the electrolyte solution contains iodide ions, the apparent anodic behavior is similar to that in the electrolyte not containing iodide ions from the viewpoint of the current-voltage curves of the CdS electrode. However, the anodic current can be attributed to the oxidation of iodide ions:

$$2I^- + 2p^+ \rightarrow I_2 \quad (2)$$

as revealed from the behavior of the ring electrode, which shows an increase of the reduction current at a more negative potential than 0.3 V, indicating the formation of iodine on the CdS surface. In this case, the change of the CdS surface can scarcely be detected after the anodic oxidation.

The fact that the starting potential of the oxidation of iodide ions is -0.68 V, which is much more negative than its reversible potential, indicates that photosensitized electrolytic oxidation occurs even on CdS.

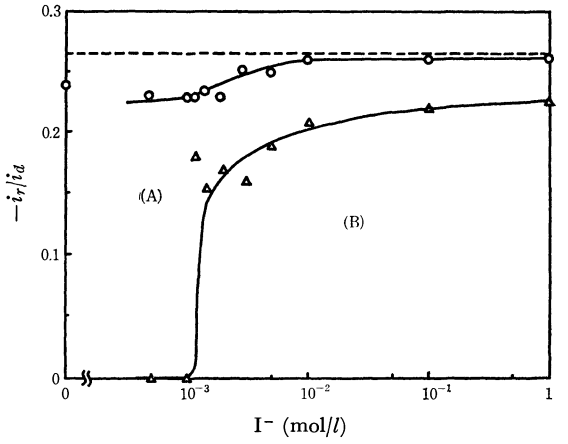

Fig. 1. Competition between dissolution of CdS and oxidation of iodide ions against the concentration of iodide ions.
Potential of the disk electrode (V_d): 1.0 V
△: Potential of the ring electrode, -0.40 V, at which iodine can be detected.
○: Potential of the ring electrode, -1.00 V, at which both iodine and cadmium ions can be detected.

In Fig. 1, the ratio of the current of the amalgamated ring electrode to the disk current against the concentration of iodide ions is shown. The collection efficiency of this electrode is calculated to be 0.265 from the geometric dimensions of the electrode. When the concentration of iodide ions is lower than 10^{-3} mol/l, the dissolution of CdS occurs ((A) in Fig.1); on the other hand, when it is higher than 10^{-3} mol/l, the oxidation of iodide ions occurs in competition with the dissolution of CdS ((B)). The degree of the competition between the reaction (1) and (2) may depend on the amount of iodide ions adsorbed on the CdS surface.

The results will be reported in detail in due course.

The Separation of Copper Isotopes by Ion-exchange Chromatography

Tadao KANZAKI[1] and Hidetake KAKIHANA

Research Laboratory of Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 14, 1970)

A break-through experiment on the separation of copper isotopes was carried out through the use of a cation-exchange resin column. By analysing the experimental results, the approximate values of the single-stage (elementary) separation factors, S^{63}_{65}, were determined. The copper sulphate and copper chloride systems gave significant separation factors ($S^{63}_{65}=1.0000_3-1.0004_2$), but the copper nitrate system gave no isotope separation. These data were analysed in terms of the theory of the two-phase distribution of isotopes previously proposed by one of the present authors (Kakihana). The equilibrium coefficient for isotopic-exchange reaction by complex formation in an external solution ($K_1=1.0001_5$ for the copper sulphate system, and $K_1=1.0005$ for the copper chloride systems) was estimated.

Since the first experiment on isotope separation by ion-exchange chromatography was carried out by Taylor and Urey[2] in 1938, many experiments have been done on the separation of isotopes using the same method. Some results, especially these for nitrogen[3–5] and uranium[6–8] isotopes, were not, however, the results of a simple ion-exchange reaction, but those of the effects combining with some other chemical reactions, *e.g.*, complex formation and an electron-exchange reaction.

In order to explain these results, the theory of the two-phase distribution of isotopes was proposed by one of the present authors (Kakihana);[8–12] the isotope effects caused by complex formation and electron-exchange reaction have been analysed using this theory in connection with experiments on lithium,[8,13] nitrogen,[8] and uranium[7,8] isotopes.

In this paper, for the further extension of these studies, copper, which forms various well-known complexes, was selected and studied.

Experimental

The 0.1 M copper solutions shown in Table 1 were passed very slowly through an ion-exchange column of Dowex 50W-X12 in the H^+ form (100—200 mesh) (about 100 cm in height and 1 cm in diameter). In the case of the experiments IV, V, VI, and VII, an acetone-water mixed solvent of the same acid concentration and acetone content as the copper solution had been passed through the column beforehand. Each fraction of the effluent copper solutions from the column was collected and analysed in the following way.

The copper concentrations were determined by chelatometric titration with ethylenediaminetetraacetic acid (EDTA).[14]

The abundance ratios of the copper isotopes were determined on a copper nitrate sample by means of a Nier-type 60° mass spectrometer, Atlas CH 4, using the surface ionization method.[15] Copper nitrate samples were obtained from the effluent by the following procedure. For the experiment I, the effluent copper solutions were evaporated to dryness directly. For the other experiments, a small amount of 2 M hydrochloric acid was added to the effluent solution (for the experiments VI and VII, the effluents were evaporated to dryness to remove the acetone before the addition of the hydrochloric acid), the copper was deposited from the unstirred solution onto a small platinum electrode by adjusting the voltage so that the current was 0.2 to 0.3 A and by allowing the electrolysis to continue more than 8 hr (the yield of copper was above 99.9%). After the cathode had been rinsed with deionized water, the copper was stripped from the electrode with dilute nitric acid; the copper nitrate sample was then obtained by the evaporation of the solution. The reagents used in this experiments were all of an analytical grade except for the copper reagent. Copper nitrate was prepared by dissolving copper metal of a high purity (above 99.99%) with dilute nitric acid and then recrystallizing it. Copper chloride and copper sulphate were prepared by passing the copper nitrate solution through a column of the cation-exchange resin, Dowex 50W-X12, in the H^+ form, and by eluting the copper ions adsorbed on the column using dilute hydrochloric acid or sulfuric acid, and by recrystallizing them.

Results

The elution curves obtained for each experiment are shown in Fig. 1-1—1-7. Sample numbers of the mass-spectrometric analysis are also shown in Fig. 1. The total amounts of copper isotopes adsorbed in the ion-exchanger, Q, were estimated from these curves (Table 2).

The results of the mass-spectrometric analysis are given in Table 3. In Table 3, the significant values are underlined (the accuracy of the mass-spectrometric analysis is within ±0.0007 for the R_o–R_t value). The

VII	$CuCl_2$	40 vol% acetone	0.100_4	$0.007^{a)}$	14.6

a) For prevention of hydrolysis of copper salt a small amounts of hydrochloric acid was added to the solution

TABLE 2. TOTAL AMOUNTS OF COPPER ISOTOPES ADSORBED IN THE ION-EXCHANGER, Q

Experiment No.	Q mol
I	0.0917_3
II	0.0937_0
III	0.0877_0
IV	0.0556_0
V	0.0335_1
VI	0.0875_3
VII	0.0845_0

Total capacity of ion-exchanger is 0.198 equivalent in all experiments.

D values were calculated from these values by a method which will be described below.

Discussion

The single-stage (elementary) separation factors can be calculated from the results in Tables 2, and 3 by means of the following equation:[16]

$$S_{65}^{63} = \frac{\text{Total amount of } {}^{63}\text{Cu in the ion-exchanger phase}}{\text{Total amount of } {}^{65}\text{Cu in the ion-exchanger phase}} \times \frac{\text{Total amount of } {}^{65}\text{Cu in the external solution phase}}{\text{Tatal amount of } {}^{63}\text{Cu in the external solution phase}} = 1 + \frac{D}{Q-D} \cdot \frac{1}{R_o} \quad (1)$$

where Q is the total amount of copper isotopes adsorbed in the ion-exchanger (mol), R_0 is the mole fraction of the ^{63}Cu isotope in the feed solution, and D is the amount of the ^{63}Cu isotope enriched in the ion-exchanger (mol).

$$D = \frac{1}{(1-R_o)} \sum_{i=1}^{n} (R_o - R_i) \cdot f_i \quad (2)$$

where f_i and R_i denote the sum of the copper isotopes, ^{63}Cu and ^{65}Cu (mol), and the mole fraction of the ^{63}Cu isotope in the effluent fraction i, respectively.

The results calculated by means of Eq. (1) are given in Table 4; they lead to the following conclusions:

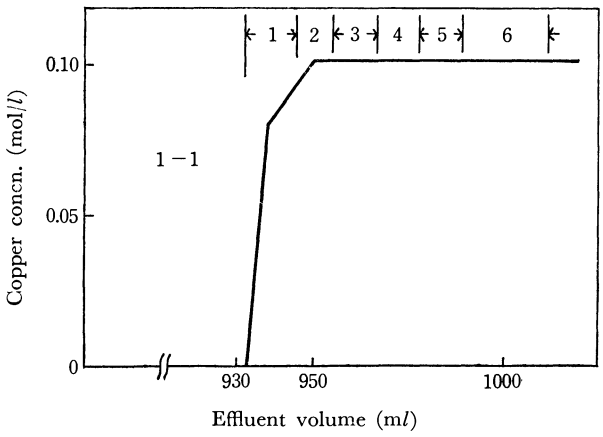
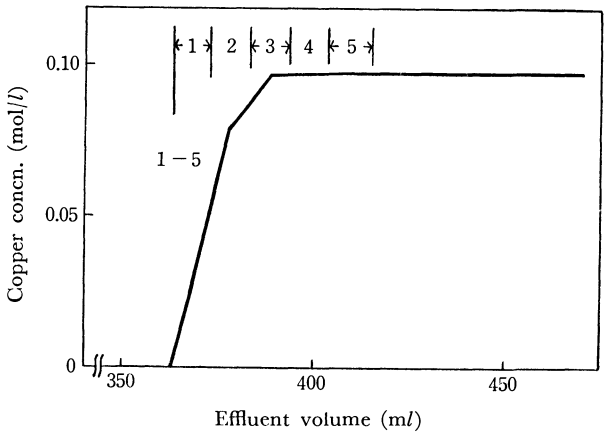
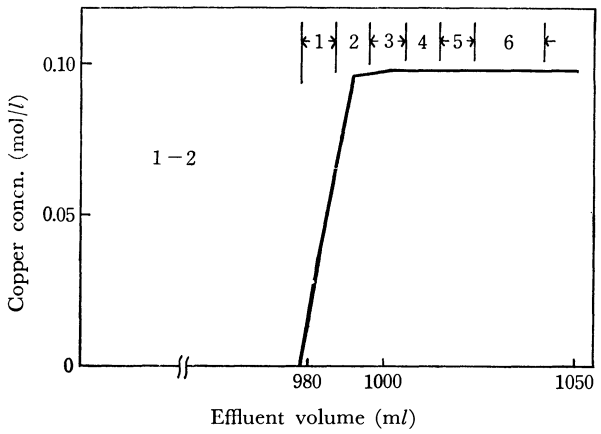
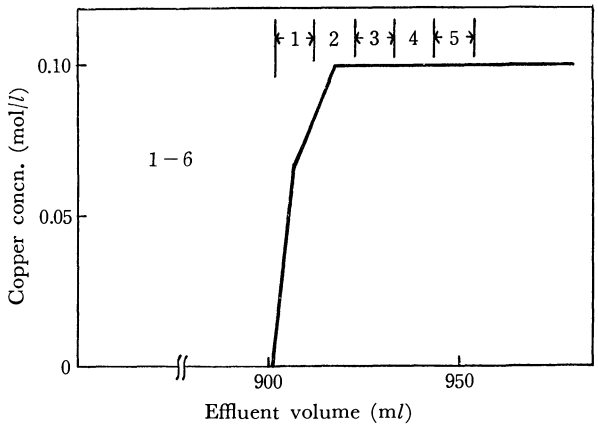
a) Mole fraction of lighter isotope, ^{63}Cu in the feed solution: 0.692_0.

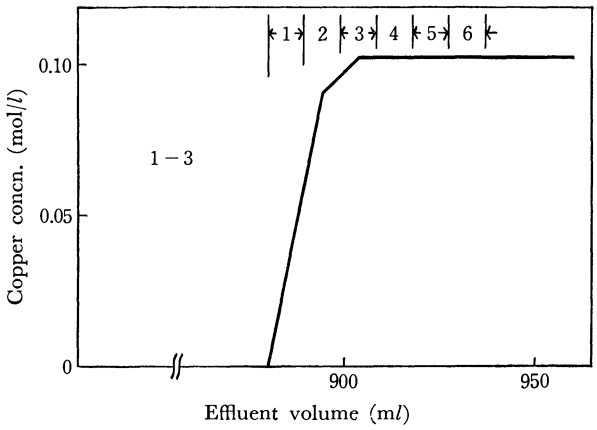
b) Amounts of isotope, ^{63}Cu enriched in the ion-exchanger.

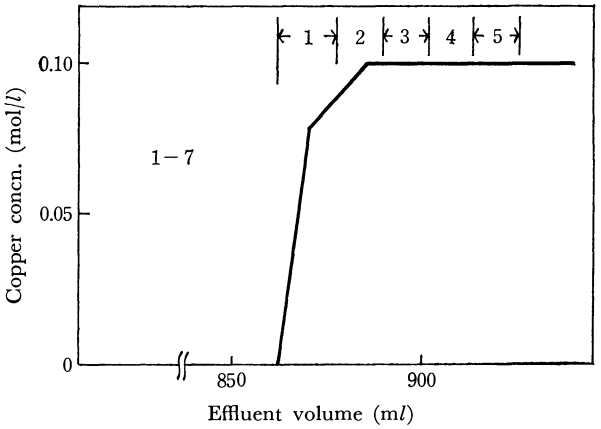












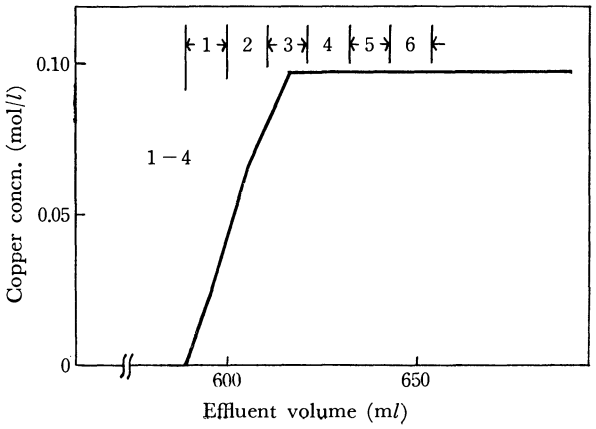


Fig. 1. Elution curves.
1—1. Experiment I. 1—2. Experiment II. 1—3. Experiment III. 1-4. Experiment IV. 1—5. Experiment V. 1—6. Experiment VI. 1—7. Experiment VII.

(a) For all systems, the lighter isotope, ^{63}Cu, is enriched in the ion-exchanger.

(b) For the copper nitrate system (experiment I), scarcely no isotope effect is found within our limits of experimental accuracy, while for the copper sulphate and copper chloride systems, significant isotope effects are found.

(c) The value of the single-stage (elementary) separation factor obtained for the $CuSO_4$-water system (experiment II) is larger than that for the $CuCl_2$-water (experiment III).

TABLE 4. SINGLE STAGE (ELEMENTARY) SEPARATION FACTOR, S_{65}^{63}

Experiment No.	Copper salt	Solvent	S_{65}^{63}
I	$Cu(NO_3)_2$	water	1.0000_0
II	$CuSO_4$	water	1.0001_2
III	$CuCl_2$	water	1.0000_3
IV	$CuCl_2$	0.5 M HCl	1.0001_7
V	$CuCl_2$	1.0 M HCl	1.0004_2
VI	$CuCl_2$	20 vol% acetone	1.0001_6
VII	$CuCl_2$	40 vol% acetone	1.0002_2

(d) For the $CuCl_2$–HCl system, the values of the single-stage separation factor become larger with an increase in the concentration of hydrochloric acid.

(e) For the $CuCl_2$-acetone-water mixed solvent system, the values of the single-stage separation factor become slightly larger with an increase in the acetone content.

The four facts (b), (c), (d), and (e) can be explained by the isotope effects in complex-formation reactions.

Since copper nitrate dissociates nearly completely in an aqueous solution, the isotope effects for the $Cu(NO_3)_2$-water system can be said to result from a simple ion-exchange reaction only: that is, they represent the isotope difference in the hydrated copper ion between the aqueous-solution and the ion-exchanger phases.[17]

On the other hand, in the cases of the $CuSO_4$ and $CuCl_2$ systems, such complexes as $(CuSO_4)$, $(CuCl^+)$, and $(CuCl_2)$ are formed in the solution. Therefore, the isotope effects of the systems result from the combination of these complex formation reactions with the simple ion-exchange reaction. It has been suggested by Kakihana, in his theory of the two-phase distribution of isotopes, that, for the cation exchange system, the greater the amounts of complex species formed in the external solution, the larger the single-stage separation factors obtained. The four experimental facts, (b), (c), (d), and (e) agree with this suggestion, as will be described below. As will be discussed below, in an aqueous solution the amount of the copper sulphate complex $(CuSO_4)$ is one hundred times as much as that of the chlorocomplexes of copper $(CuCl^+)$, $(CuCl_2)$. This may be the reason why the isotope effect of the copper sulphate system (experiment II) is higher than that of the copper chloride system (experiment III). In the hydrochloric acid solution, the amounts of the chlorocomplexes increase with the increase in the concentration of hydrochloric acid, which has a higher isotope effect in a higher hydrochloric acid system (experiment V) than in a dilute hydrochloric acid system (experiment IV) or in an aqueous solution system (experiment III). In the acetone-water mixed solution, the amount of the chlorocomplexes is much more than in the aqueous solution because of the decrease in the dielectric constant of the solvent. This gives the higher isotope effect in the acetone-water mixed systems (experiments VI and VII).

From the results in Table 4, we can estimate the equilibrium coefficients for the isotopic-exchange reactions involved in the external solution by applying the theory of the two-phase distribution of isotopes.

The single-stage separation factors, S, obtained from the abundance ratios of copper isotopes in the two phases (external-solution and ion-exchanger phases) can be expressed by the following equation:

$$\begin{aligned}\ln S_A^B = {} & \ln {}_A^B K_z \\ & - \ln \Big[1 + \sum_{n=0}^{z-1}\sum_{t=0}^{T} x_{nt}\Big(\prod_{n+1}^{z} K_n \cdot \prod_{1}^{t} K_{nt}^{-1} - 1\Big) \\ & \quad + \sum_{n=z}^{r}\sum_{t=0}^{T} x_{nt}\Big(\prod_{z+1}^{n} K_n^{-1} \cdot \prod_{1}^{t} K_{nt}^{-1} - 1\Big)\Big] \\ & + \ln \Big[1 + \sum_{n=0}^{z-1}\sum_{s=0}^{S} \bar{x}_{ns}\Big(\prod_{n+1}^{z} \bar{K}_n \cdot \prod_{1}^{S} \bar{K}_{ns}^{-1} - 1\Big) \\ & \quad + \sum_{n=z}^{r}\sum_{s=0}^{S} \bar{x}_{ns}\Big(\prod_{z+1}^{n} \bar{K}_n^{-1} \cdot \prod_{1}^{S} \bar{K}_{ns}^{-1} - 1\Big)\Big] \qquad (3)^{12)}\end{aligned}$$

Since only one ligand, Cl^- or SO_4^{2-} in our case, exists, Eq. (3) can be reduced to:

$$\begin{aligned}\ln S_{65}^{63} = {} & \ln {}_{65}^{63}K_z - \ln\Big[1 + \sum_{n=0}^{z-1} x_n\Big(\prod_{n+1}^{z} K_n - 1\Big) + \sum_{n=z}^{r} x_n\Big(\prod_{z+1}^{n} K_n^{-1} - 1\Big)\Big] \\ & + \ln\Big[1 - \sum_{n=0}^{z-1} \bar{x}_n\Big(\prod_{n+1}^{z} \bar{K}_n - 1\Big) + \sum_{n=z}^{r} \bar{x}_n\Big(\prod_{z+1}^{n} \bar{K}_n^{-1} - 1\Big)\Big]\end{aligned} \qquad (4)$$

where x and $\bar{x}$ are the mole fraction of each chemical species in the external-solution phase and in the ion-exchanger phase respectively. ${}_{65}^{63}K_z$ is the equilibrium coefficient for an isotopic exchange reaction between the two phases (the external-solution and ion-exchanger phases) of the chemical species, CuX_z, which are contained in both phases (X is the ligand). K_n and $\bar{K}_n$ are the equilibrium coefficients for an isotopic-exchange reaction by complex formation in the external-solution and the ion-exchanger phases respectively, and $\prod_1^0 K_n = 1$.

The equations for the copper sulphate and copper chloride systems are derived from Eq. (4) as follows.

Copper Sulphate System (Experiment II). In this system, the chemical species existing in the external solution are Cu^{2+} and $CuSO_4$, and in the cation-exchange resin only Cu^{2+} can be adsorbed in appreciable amounts. These facts indicate that, in Eq. (4), z is zero (which means that Cu^{2+} exists in both phases), $r=1$ (which means that only Cu^{2+} and $CuSO_4$ exist in the external solution) and $\bar{x}_0=1$ (which means that only Cu^{2+}, not $CuSO_4$, is adsorbed in the cation-exchange resin). Therefore, Eq. (4) becomes:

$$\begin{aligned}\ln S_{65}^{63} = {} & \ln {}_{65}^{63}K_0 - \ln\Big[1 + x_0\Big(\prod_{1}^{0} K_n^{-1} - 1\Big) + x_1(K_1^{-1} - 1)\Big] \\ & + \ln\Big[1 + \bar{x}_0\Big(\prod_{1}^{0} \bar{K}_n^{-1} - 1\Big)\Big],\end{aligned} \qquad (5)$$

where $\prod_1^0 K_n^{-1}$ equals to 1 in our definition, and:

17) H. Kakihana, T. Nomura, H. Fukutomi, H. Ōtaki, and K. Yamazaki, *J. Atomic Energy Soc. Japan*, **1**, 46 (1959).

$$\ln S_{65}^{63} = \ln {}_{65}^{63}K_0 - \ln [1+x_1(K_1^{-1}-1)] . \quad (6)$$

K_1 is the equilibrium coefficient for isotopic-exchange reaction by complex formation in the external solution:

$$^{65}Cu^{2+} + {}^{63}CuSO_4 \overset{K_1}{\rightleftarrows} {}^{65}CuSO_4 + {}^{63}Cu^{2+}, \quad (7)$$

or the ratio of the stability constants of the sulphate complexes of isotopes:

$$^{65}Cu^{2+} + SO_4^{2-} \overset{\beta^{65}}{\rightleftarrows} {}^{65}CuSO_4 \quad (8)$$

$$^{63}Cu^{2+} + SO_4^{2-} \overset{\beta^{63}}{\rightleftarrows} {}^{63}CuSO_4 \quad (9)$$

and:

$$K_1 = \frac{\beta^{65}}{\beta^{63}} . \quad (10)$$

Copper Chloride System (Experiments III, IV, V, VI, and VII). In these systems, the chemical species existing in the external solution are Cu^{2+}, $(CuCl^+)$, and $(CuCl_2)$, and in the cation-exchange resin only Cu^{2+} can be adsorbed in appreciable amounts. Therefore, in Eq. (4), $z=0$, $r=2$, $\bar{x}_0=1$, and:

$$\ln S_{65}^{63} = \ln {}_{65}^{63}K_0 - \ln [1+x_1(K_1^{-1}-1)+x_2(K_1^{-1}\cdot K_2^{-1}-1)], \quad (11)$$

where x_1 and x_2 are the mole fractions of the $(CuCl^+)$ and $(CuCl_2)$ complexes respectively in the external solution. K_1 and K_2 are the equilibrium coefficients for an isotopic-exchange reaction by complex formation:

$$^{65}Cu^{2+} + {}^{63}CuCl^+ \overset{K_1}{\rightleftarrows} {}^{65}CuCl^+ + {}^{63}Cu^{2+} \quad (12)$$

$$^{65}CuCl^+ + {}^{63}CuCl_2 \overset{K_2}{\rightleftarrows} {}^{65}CuCl_2 + {}^{63}CuCl^+ \quad (13)$$

or the ratios of the stability constants chlorocomplexes of isotopes:

$$^{65}Cu^{2+} + Cl^- \overset{\beta_1^{65}}{\rightleftarrows} {}^{65}CuCl^+ \quad (14)$$

$$^{63}Cu^{2+} + Cl^- \overset{\beta_1^{63}}{\rightleftarrows} {}^{63}CuCl^+ \quad (15)$$

$$^{65}CuCl^+ + Cl^- \overset{\beta_2^{65}}{\rightleftarrows} {}^{65}CuCl_2 \quad (16)$$

$$^{63}CuCl^+ + Cl^- \overset{\beta_2^{63}}{\rightleftarrows} {}^{63}CuCl_2 \quad (17)$$

and:

$$K_1 = \frac{\beta_1^{65}}{\beta_1^{63}}, \quad K_2 = \frac{\beta_2^{65}}{\beta_2^{63}} . \quad (18)$$

The values of the stability constants of copper sulphate and chloride complexes in an aqueous solution obtained by Davies and McConnell are shown in Table 5. Since the stability constants of copper chloride complexes have not yet been measured in an acetone-water mixture, the values are approximately estimated by assuming that the logarithm of the stability constants is proportional to the reciprocal of the dielectric constant of the solution. Two sets of values of the stability constants are used for the calculation on the monochlorocopper complex: (a) the stability constants in pure water[19] and in pure acetone,[20] and (b) the stability constants in pure water and in a 5 vol% acetone-water mixture which has previously been measured by the present authors by means of spectrophotometry[19] using an EPS-3T type Hitachi Automatic Recording spectrophotometer with a quartz cell 1 mm thick. The values obtained by the use of these two bases are shown in Table 5. In the case of the dichlorocopper complex, only the first set of stability constants is used because of the insufficient accuracy of our stability constants.

Table 5. Stability constant (25°C)

Copper salt	Solvent	Logarithm of stability constant		
		$\log\beta$	$\log\beta_1$	$\log\beta_2$
$CuSO_4$	Water	2.3[18],*		
$CuCl_2$	Water (contains HCl)		0.11[19],**	−0.64[19],**
	20 vol%		0.30[a],**	−0.45[a],**

a) and b) correspond to a) and b) in Table 5, respectively.

18) C. W. Davies, *J. Chem. Soc.*, **1938**, 2093.
19) H. McConnell and N. Davidson, *J. Amer. Chem. Soc.*, **72**, 3164 (1950).
20) J. Gažo, *Chem. Zvesti.*, **10**, 509 (1956).

The mole fractions of copper complexes in the external solution (x_n) were estimated by using the values of the total concentration of copper described in Table 1 and the stability constants described in Table 5; they are shown in Table 6. The values of the equilibrium coefficients for an isotopic-exchange reaction (K_1, K_2) were estimated by means of Eqs. (6) and (11) (Table 7). The values in Table 6 were used for x_1 and x_2 in Eqs. (6) and (11), while the value for S_{65}^{63} of the copper nitrate system (no complex formation) in Table 4 was used for ${}_{65}^{63}K_0$ in Eqs. (6) and (11). In the cases of the experiments III, IV, VI, and VII, the values of x_2, the mole fraction of the $CuCl_2$ complex in the external solution, were so small that it was impossible to estimate the values for K_2. However, the values for K_1 could be calculated with good accuracy. In the case of the experiment V, the value of K_2 was estimated by means of Eq. (11) using with the mean value of K_1 obtained in the experiments IV, VI, and VII. The results in Table 7 indicate that the values of the equilibrium coefficient for isotopic-exchange reactions by complex formation for copper chloride systems are larger than the value for the copper sulphate system, and that there is a good agreement of the values of K_1 for all the copper chloride systems except in experiment III.

Conclusion

The conclusions of our break-through experiment on the separation of copper isotopes and for our analysis based on the theory of the two-phase distribution of isotopes are as follows:

(a) The ion-exchange chromatography through a cation-exchange resin column proves that the lighter isotope, ^{63}Cu, is enriched in the ion-exchanger phase.

(b) The isotope effect caused by the simple ion-exchange reaction, that is, by the distribution of the hydrated copper ion between the external solution and the ion-exchanger phase, is very small (experiment I).

(c) Significant isotope effects ($S_{65}^{63}-1.0000_3$—1.0004_2) were found for the systems with the complex formation in the external solution. Moreover, the values of the equilibrium coefficient for isotopic-exchange reaction by the complex formation of copper, $K_1=1.0001_5$ for the copper sulphate system and $K_1 \fallingdotseq 1.0005$ for the copper chloride systems, were estimated. These values are the first ones obtained for the equilibrium coefficients for isotopic-exchange reactions by means of the complex formation of copper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 310—312 (1971)

Group Interactions in Polyelectrolytes. IV. Kinetics of the Alkaline Hydrolysis of Polymethyl Acrylate (Part II)

Hiroshi KAWABE and Masaya YANAGITA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received May, 28 1970)

Rate equations which express the over-all kinetics of the alkaline hydrolysis of polymethyl acrylate in the presence of a large excess of alkali were derived. The over-all course of this reaction was calculated by using the rate constants given in the previous paper, which were derived from the kinetic data obtained by the reaction in a 29% (*v*/*v*) aqueous acetone solution with a slight excess of sodium hydroxide at 55°C. The partially-hydrolyzed polymethyl acrylate (30.6% hydrolyzed) was hydrolyzed by the addition of about sixteen times as much sodium hydroxide as the amount of the ester group; the kinetic data thus obtained were found to be in good agreement with the calculated values.

In the previous study,[1] the rate equations of a polymer reaction which proceeds in more than two steps were derived and applied to the alkaline hydrolysis of polymethyl acrylate. Upon the examination of the published kinetic data,[2] the reaction in a 29% (*v*/*v*) aqueous acetone solution with a slight excess of sodium hydroxide was found to proceed in four steps, and the corresponding four rate constants were determined.

In the present study, rate equations which express the over-all kinetics have been derived in a simple case; that is, the over-all rate of a reaction with a large excess of alkali has been calculated by using the rate constants at 55°C given previously. It is the purpose of the present study to confirm the validity of the assumptions, adopted in the derivation of these rate equations, by comparing the calculated values with the experimental values. For this reason, the alkaline hydrolysis of polymethyl acrylate in the presence of a large excess of sodium hydroxide has been carried out in a 29% aqueous acetone solution at 55°C.

Experimental

Materials. Polymethyl acrylate was prepared and purified as previously.[1] It was dissolved in acetone and partially hydrolyzed by carefully adding a limited amount of an aqueous sodium hydroxide solution over a long period so as to keep the solution homogeneous. The volume ratio of acetone to water in the solution was finally adjusted to 2/5. The solution was kept at 40°C until the alkalinity of the solution almost disappeared; this solution was then used for the kinetic measuremtns. The degree of hydrolysis was deter-

1) H. Kawabe and M. Yanagita, This Bulletin, **42**, 3109 (1969).
2) I. Sakurada, Y. Sakaguchi, and S. Fukui, *Kobunshi Kagaku*, **13**, 355, 361, 408 (1956).

mined by the usual titration method; it was found to be 30.6%.

Determination of the Degree of Hydrolysis. Partial and complete hydrolyses of polymethyl acrylate were carried out in aqueous acetone solutions containing the necessary amount and a slight excess of sodium hydroxide respectively. The degree of hydrolysis was determined by pouring an aliquot of the solutions into water containing an excess of hydrochloric acid and by then titrating the mixture with 0.1 N sodium hydroxide. In kinetic runs, since a large excess of sodium hydroxide (about sixteen times as much as the moles of the ester group) was used, it was necessary before titration to remove sodium ions in the solution by Dowex-50. This method has already been described with respect to low-molecular esters;[1] also in the present study it was found to be effective for polymethyl acrylate. Five grams of Dowex-50 (X-8, 50—100 mesh), which had previously been half-neutralized and which had an effective capacity of 0.668 meq/g-wet, were added to a 50-m*l* aqueous solution containing 0.104 meq of polyacrylic acid and 1.074 meq of sodium hydroxide. The mixture was stirred, and its pH was measured by the use of Beckman's model G pH meter. The results are shown in Table 1. After removing the resin, the solution was titrated with 0.1 N sodium hydroxide in the presence of sodium chloride in order to determine the original amount of polyacrylic acid.

Table 1. Removal of sodium ions from an aqueous solution containing polyacrylic acid and sodium hydroxide by dowex 50

Time, sec	0	30	45	60	600
pH	12.39	4.91	3.95	3.92	3.99

Kinetic Measurement. The alkaline hydrolysis of the 30.6% hydrolyzed polymethyl acrylate was carried out in an aqueous acetone solution (acetone/water=2/5) containing a large excess of sodium hydroxide. During the course of this reaction, the temperature was kept at 55±0.1°C. The total concentration of sodium hydroxide in the solution, including that used for preliminary partial hydrolysis, was 0.0905 mol/*l*, and the concentration of the total carboxylate groups was 0.0055 mol/*l*. At appropriate intervals, aliquots of the solution were taken out and poured into water containing Dowex-50, after which the mixture was stirred for a few minutes in order to remove sodium ions. After removing the resin, the carboxylic acid content was determined by titration.

Rate Equations

In the previous paper,[1] the rate equations for a polymer reaction which proceeds in σ steps was derived on the model of the reaction of a low-molecular compounds containing σ groups whose reactivity altered when one of the groups was changed.

$$X_{n-1}Y_{\sigma-(n-1)} \xrightarrow{k_n} X_nY_{\sigma-n} \xrightarrow{k_{n+1}} X_{n+1}Y_{\sigma-(n+1)}$$

where X represents a changed group in a compound; Y, an unchanged one; n, the number of the changed group, and σ, the total number of groups. The over-all kinetics in the presence of a large excess of reagent was also expressed by a pair of rate equations in the case when $\sigma=3$. The derivation of the equations was based on the assumption that the reaction at nth and $(n+1)$th steps was controlled by the two rate constants, k_n and k_{n+1}.

When $\sigma=4$, the corresponding equations can similarly be derived on the same assumption. When $n=1$, the rate is thus controlled by k_1 and k_2 in the range of fractional conversion (β) from 0 to 1/2 and can be expressed by the following equation:

$$dx/dt = a[k_1b - (4k_1 - 6k_2)x_1 - 3k_2x] \quad (1)$$

where a and b are the initial concentration of a reagent and that of the group in the compound respectively, and where x_1 and x are the concentration of the first changed group and that of the total changed groups in the compound, again respectively, at the time t. Moreover, x_1 is given by:

$$x_1 = (1 - e^{-4k_1at})b/4 \quad (2)$$

Upon integration, Eq. (1) becomes:

$$\beta = \frac{1}{2} - \frac{2k_1 - 3k_2}{2(4k_1 - 3k_2)}e^{-4k_1at} - \frac{k_1}{4k_1 - 3k_2}e^{-3k_2at} \quad (3)$$

where $\beta=x/b$. When $n=2$, the rate, which is controlled by k_2 and k_3 in the 1/4—3/4 range of β, is given by:

$$dx/dt = a[(3k_2 + 2k_3)b/4 - (3k_2 - 4k_3)x_2 - 2k_3x] \quad (4)$$

where x_2 is the concentration of the secondly-changed group in the compound and is given by:

$$x_2 = (1 - e^{-3k_2a(t-t_{1/4})})b/4 \quad (5)$$

Upon integration, Eq. (4) yields:

$$\beta = \frac{3}{4} - \frac{3k_2 - 4k_3}{4(3k_2 - 2k_3)}e^{-3k_2(t-t_{1/4})} - \frac{3k_2}{4(3k_2 - 2k_3)}e^{-2k_3a(t-t_{1/4})} \quad (6)$$

where $t_{1/4}$ is the time where β is 1/4. Similarly, when $n=3$, the following equations can be derived in the β range from 1/2 to 1:

$$dx/dt = a[(k_3 + k_4)b/2 - 2(k_3 - k_4)x_3 - k_4x] \quad (7)$$

$$x_3 = (1 - e^{-2k_3a(t-t_{1/2})})b/4 \quad (8)$$

where x_3 is the concentration of the thirdly-changed group in the compound and where $t_{1/2}$ is the time when β is 1/2. Upon integration, Eq. (7) becomes:

$$\beta = 1 - \frac{k_3 - k_4}{2(2k_3 - k_4)}e^{-2k_3a(t-t_{1/2})} - \frac{k_3}{2(2k_3 - k_4)}e^{-k_4a(t-t_{1/2})} \quad (9)$$

Results and Discussion

The alkaline hydrolysis of the partially-hydrolyzed polymethyl acrylate (30.6% hydrolyzed) was carried out in a 29% aqueous acetone solution at 55°C. Since a large excess of sodium hydroxide was used in this experiment (a=0.0905 mol/*l*, b=0.0055 mol/*l*, and a/b=16.5), the over-all course of the reaction is given by Eqs. (3), (6), and (9). In the previous paper,[1] the rate constants were given on the basis of Sakurada's data[2] for the reaction in a 29% aqueous acetone solution containing a slight excess of sodium hydroxide at 55°C. They were $k_1=8.02\times10^{-1}$, $k_2=1.66\times10^{-1}$, $k_3=4.04\times10^{-2}$, and $k_4=3.31\times10^{-3}$ *l*/mol min. The values of β were first computed on the basis of Eq. (3) and plotted against t as is shown by the full line in Fig. 1 (Curve I), from which $t_{1/4}$ was determined to be 6.5 min. The plots obtained by means of Eq. (6)

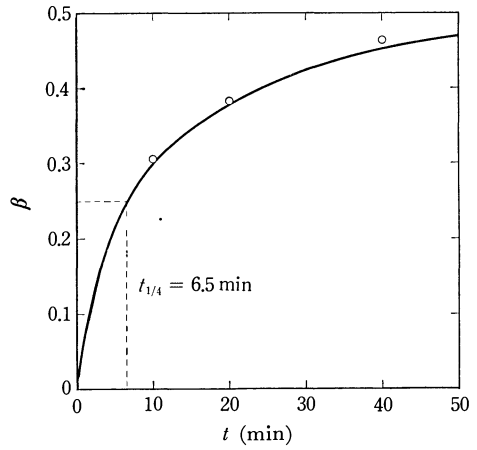

Fig. 1. Alkaline hydrolysis of polymethyl acrylate. Calculated curve I.

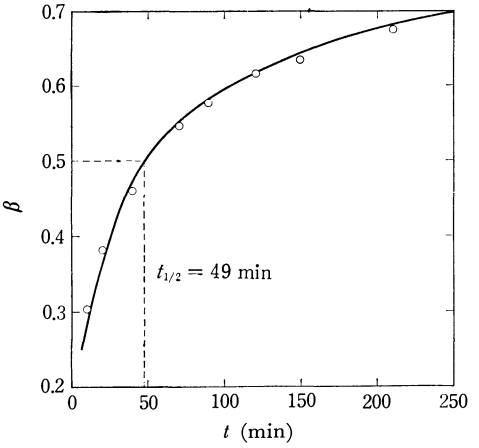

Fig. 2. Alkaline hydrolysis of polymethyl acrylate. Calculated curve II.

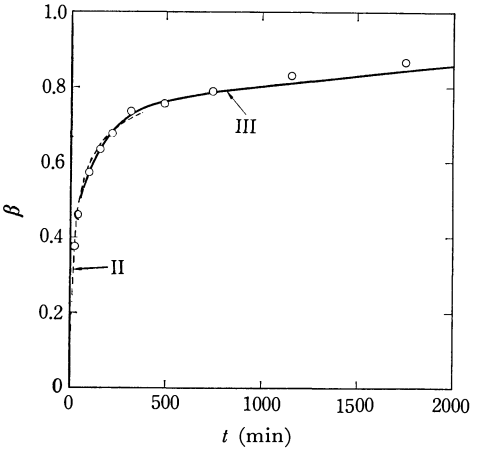

Fig. 3. Alkaline hydrolysis of polymethyl acrylate. Calculated curves II and III.

are shown in Fig. 2 (Curve II); $t_{1/2}$ was determined to be 49 min. Finally, the plots fitting Eq. (9) are shown in Fig. 3 (Curve III).

In Figs. 1, 2, and 3, the white circles indicate the values observed in the present experiment. Since polymethyl acrylate used in this experiment was preliminarily 30.6% hydrolyzed, and since this value of β corresponds to the reaction time of 10 min, as may be seen in Figs. 1 and 2, the observed values of β are plotted against the corrected time, namely, the actual reaction time plus 10 min. A fairly good agreement is shown between the calculated and observed values. Although the conditions in this experiment and those in Sakuradas' are different except for the temperature and the composition of the medium, the agreement is remarkable; this justifies deriving the rate equations on the basis of the assumption adopted in the previous paper, the assumption that the reactivity of ester groups in a polymethyl acrylate molecule is electrostatically affected mainly by the first and second neighboring groups when the reaction is carried out in a water-rich system.

In the previous paper, it was also shown that the plot of the logarithmic term of the simple second-order rate equation (Eq. (10)) against the time could be divided into four lines:

$$k_{\mathrm{app}} = \frac{1}{(a-b)t} \ln \frac{b(a-x)}{a(b-x)} \tag{10}$$

where k_{app} is the apparent rate constant. This is also true of the present experiment, as is shown in Fig. 4,

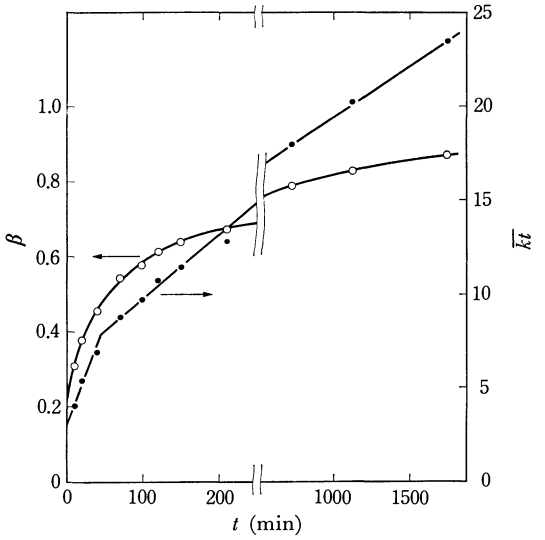

Fig. 4. Plot of $\overline{kt}$ *viz.* t in the alkaline hydrolysis of polymethyl acrylate.

where $\overline{kt} \equiv [1/(a-b)]\ln[b(a-x)/a(b-x)]$, and where the white and black circles represent the observed values of β and $\overline{kt}$ respectively. The approximate value of the rate constant, k_n', as estimated in terms of the slope, can be expressed thus:

$$k_n' = \Delta\overline{kt}/\Delta t \tag{11}$$

The values are shown in Table 2, in which those values obtained from Sakurada's data in the previous paper are also given for comparison.

TABLE 2. APPROXIMATE VALUES OF THE RATE CONSTANTS

n	k_n' (l/mol min)	
	present experiment	Sakurada's data
1		3.99×10^{-1}
2	1.10×10^{-1}	1.40×10^{-1}
3	2.75×10^{-2}	3.07×10^{-2}
4	5.40×10^{-3}	3.31×10^{-3}

The authors wish to express their thanks to Mr. N. Sato and Mr. M. Hayashi for their helpful assistance in preparing the sample and in carrying out the measurements.

The N-H Stretching Absorption Band Intensities in Secondary Amides, Secondary Thioamides, and Anilides

P. Usha BAI

Department of Physics, College of Science, Osmania University, Hyderabad-7, India

and K. Venkata RAMIAH

Department of Physics, Post-Graduate Centre, Osmania University, Warangal (A. P.), India

(Received January 5, 1970)

The intensities of the N–H stretching absorption bands of a number of *N*-methylamides, *N*-methylthioamides and anilides have been measured in a solution of carbon tetrachloride. It was observed that the intensities of the N–H stretching absorption bands of *N*-methylacetamide and *N*-methylpropionamide are considerably higher than those of the same band in the corresponding anilides. On the other hand, the intensity of the N–H stretching absorption band of *N*-methylformamide is of the same order as that of formanilide. The pattern of variation of the intensity of the N–H streching absorption bands in these compounds is similar to that of the C=O stretching absorption bands of the same compounds, but the variation in their frequencies is different. It was also observed that the intensities of the N–H stretching bands of *N*-methylthioamides are considerably higher and their frequencies are lower than those of the corresponding secondary amides.

Variations in the position and integrated absorption intensities of the carbonyl band in aldehydes, ketones, esters, and amides have received considerable attention.[1-8] They have been generally interpreted in terms of changes in resonance contribution or the variation in the interaction of the orbitals in these molecules.[7,8] Some authors[3,6] have taken the mesomeric, inductive, and steric effects as well as the environmental factors into consideration to account for the variation in the integrated intensities of the carbonyl band. Huggins and Pimentel[9] measured the intensities of OH and NH stretching absorption bands of methanol, phenol, and pyrrole and found that the intensity of the OH stretching band in phenol is considerably higher than that of methanol. Stone and Thompson[10] discussed the variation in frequencies and intensities of the OH stretching bands of phenols with the electron-withdrawing or electron-donating substituents. Elliott and Mason[11] have shown that the frequencies and the intensities of the N–H stretching bands, the HNH bond angle and the N–H bond dipole gradient increase in monocyclic *N*-heteroaromatic amines relative to the values for aniline. Russel and Thompson,[12] and Kreuger and Thompson[13] measured the intensities of several characteristic absorption bands including those of O–H and N–H stretching absorption bands. From the studies of the position of the N–H stretching absorption bands of anilides and thioanilides Suzuki *et al.*[14] discussed the nature of *cis* or *trans* structure of the molecules. The authors report in this paper the intensities of N–H stretching absorption bands of a number of secondary amides, secondary thioamides, and anilides and correlate the results with those of C=O stretching absorption bands of some of the same compounds measured by earlier workers.[8]

Experimental

The infrared spectra of the N–H stretching absorption bands of the amides and the anilides were recorded with Perkin Elmer Model 221 infrared spectrophotometer using matched quartz cells of 3 cm thickness. The gear combinations were so chosen as to spread the spectrum to 100 cm^{-1}=10 cm^{-1}. The operating conditions of the spectrophotometer were: slit programme=947, gain=2.3, attenuator speed=1100, expansion=XI and scale factor 4. *N*-methylthioacetamide was synthesised. The rest of the chemicals used were of British Drug Houe and Eastman Organic Chemicals. They were purified by conventional methods and dried before use. The functional groups responsible for H bond in amides, anilides and thioamides are the N–H and the C=O or C=S bond and therefore very dilute solutions of these amides and anilides in solutions of CCl_4 were used so as to eliminate intermolecular association. This is indicated by the presence of only one absorption band in the region of 3450 cm^{-1} arising from the stretching vibration of free N–H group in all compounds except for formanilide wherein one observes two absorption bands with a difference of about 20 cm^{-1} as shown in Fig. 1. On the other hand, the N–H stretching absorption band in acetanilide and the *N*-methylthioamides is a single absorption band as shown in Figs. 2 and 3. The concentrations of the amides and the anilides chosen were such that Beer's Law holds as given in Fig. 4 by the linear relationship between the absorbance and the corresponding molar concentration.

coefficient ε of the band was made at intervals of 5—10 cm^{-1} and plotted against ν in cm^{-1}. The area under the curve was measured for an interval of $\nu-\nu_m=60$ cm^{-1} on either side of the band maximum by planimeter. ν_m is the frequency at the maximum absorption. As there is some overlapping of the two N–H stretching absorption bands in formanilide (Fig. 1), the total area of the two bands has been obtained by drawing symmetrical curves with respect to the maximum absorption of each curve and then substracting the area common to both the absorption bands from the sum of the two areas. The intensity of the bands for each compound was measured at three to four concentrations and the average values were calculated. The halfband width of all these absorption bands is in the neighbourhood of 15 cm^{-1}. Wings correction was not applied.

Results

The intensities of the N–H stretching absorption bands of the secondary amides, secondary thioamides, and anilides measured in the solution of carbon tetrachloride are given in Table 1. The integrated intensities of the carbonyl band of some of these compounds obtained by the earlier workers[8] are also given in Table 1 for comparison. The existence of two bands in the N–H stretching region of formanilide is due to the co-existence of *trans* and *cis* structures because of the steric repulsion between the carbonyl group and phenyl group of *trans* form of formanilide. This makes the *trans* structure in formanilide less stable compared to that in the other anilides, since the steric repulsion is overcome by strong repulsion between the CH_3 group and the phenyl group in an anilide like acetanilide.

It is seen from Table 1 that as in the case of C=O stretching absorption bands, the intensities of the N–H stretching absorption bands of *N*-methylacetamide and *N*-methylpropionamide are higher than those of the corresponding anilides, whereas the intensity of the same band of *N*-methylformamide is of the same order as that of formanilide (in case of formanilide, the intensity given is the sum of the intesnsities of the N–H stretching absorptions of *trans* and *cis* structures). The result is similar to that obtained by the earlier workers[8]

Table 1. Integrated intensities of the N–H and C=O stretching absorption bands in secondary amides and anilides

Amide or anilide	N–H Stretching absorption band		C=O Stretching absorption band	
	Frequency	Intensity A ($mol^{-1} \cdot l \cdot cm^{-2} \times 10^4$ in solution of CCl_4)	Frequency	Integrated absorption intensity A ($mol^{-1} \cdot l \cdot cm^{-2} \times 10^4$ in solution of CCl_4)
N-Methylacetamide	3470	0.52	1691	3.5
Acetanilide	3440	0.42	1710	2.6
N-Methylpropionamide	3467	0.55	1688	3.6
Propionilide	3436	0.32	1701	2.4
N-Methylformamide	3460	0.55	1698	3.9
Formanilide	3420 3400	0.58	1704 (a doublet with a frequency difference of 5 cm^{-1})	4.0
N-Methylthioacetamide	3408	0.73	—	—
N-Methylthiopropionamide	3407	0.73	—	—

as regards the integrated intensities of the carbonyl band of the same compounds as shown in Table 1. The pattern of variation in intensities of N–H and C=O stretching bands of these compounds is similar, but it is different with respect to their frequencies. While the frequencies of the carbonyl bands of anilides are higher than those of the corresponding *N*-methylamides, the frequencies of the N–H stretching absorption bands of the same anilides are lower than those of the corresponding secondary amides. It is also seen from Table 1 that the intensities of the N–H stretching absorption bands of *N*-methylthioacetamide and *N*-methylthiopropionamide are considerably higher than those of *N*-methylacetamide and *N*-methylpropionamide. On the other hand, the frequencies of the N–H stretching absorption bands of the same secondary thioamides are lower than those of the corresponding ordinary secondary amides.

Discussion

In amides and anilides, no single valence bond structure is consistent with all their properties. Two possible structures contribute to the resonance hybrid in the molecules, with the dipolar resonance structure making substantial contribution to the ground state of the molecules giving partial single and double bond characters to the C=O and C–N linkages. Cannon[15,16] discussed this problem in terms of interaction and mixing of the π orbitals of C=O group and $2P_z$ orbitals of nitrogen atom in the sp^2 hybrid configuration. The π–p orbitals mixing lengthens the bond length of C=O and shortens that of C–N bond relative to the normal valence bond structure. This may explain the high values of the intensities of N–H stretching absorption bands of secondary amides and anilides compared to those of amines reported by Elliott and Mason.[11] The important factor responsible for the difference in the positions and intensities of the N–H stretching absorption bands of *N*-methylamides and anilides may be due to the delocalisation of the lone pair of electrons of the amino group over the aromatic nucleus of the anilides.

The C–N stretching frequencies of primary and tertiary amides and thioamides and the stretching frequencies of the amide III bands in secondary amides and secondary thioamides are given in Table 2.

Table 2

Amide	Mode of vibration and Frequencies (in cm^{-1})	
	Mode	(Frequency in cm^{-1})
Formamide	ν (C–N)	1309
Thioformamide	ν (C–N)	1325
N-Methylformamide	Amide III	1248
N-Methylthioformamide	Amide III	1297
N-Methlacetamide	Amide III	1300
N-Methylthioacetamide	Amide III	1360
Dimethylformamide	ν (C–N)	1502
Dimethylthioformamide	ν (C–N)	1540
Dimethylacetamide	ν (C–N)	1494
Dimethylthioacetamide	ν (C–N)	1510

As seen from Table 2, the C–N stretching frequencies of primary and tertiary thioamides are higher than those of the corresponding ordinary amides. Similarly the frequencies of the amide III band in secondary thioamides, to which the contribution of C–N stretch is considerable, have higher values than those in the corresponding secondary amides. The higher values of the C–N stretching frequencies in the thioamides may thus be due to (i) the difference in the contribution of various modes of vibrations to this absorption frequency and/or (ii) higher double bond character of the C–N bond with the dipolar resonance structure making greater contribution to the ground state of the molecules than in the case of ordinary amides. These factors may be responsible for the high values of the intensity of the N–H stretching absorption bands in *N*-methylthioamides.

One of us (P. U. B.) expresses her sincere thanks to the University Grants Commission for financial assistance.

Infrared Spectra and Normal Vibrations of *N,N*-Dimethylformamide and *N,N*-Dimethylthioformamide*

G. DURGAPRASAD, D. N. SATHYANARAYANA, and C. C. PATEL

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-12, India

(Received May 27, 1970)

The infrared spectra of *N,N*-dimethylformamide (DMF) and *N,N*-dimethylthioformamide (DMTF) have been investigated in the range 4000—250 cm^{-1}. Assignment of the frequencies of DMF has been made on the basis of normal coordinate analysis for DMF, DMF-^{15}N, and DMF-d_7 using Urey-Bradly, modified Urey-Bradley, and symmetrized valence force fields. Calculations have been extended to *N,N*-dimethylthioformamide and *N,N*-dimethylselenoformamide, using the Urey-Bradley and symmetrized valence force fields. The assignments for DMF from the modified Urey-Bradley field are found to be more satisfactory. The frequency shifts on isotopic substitution and on complexation have been explained. The results of the calculations are discussed in comparison with other related molecules.

The infrared spectra of amides have been subjected to many studies.[1-5] Detailed assignments are available in literatures for primary and secondary amides.[1-4,6-8] In these amides, the characteristic infrared frequencies are due to highly coupled vibrations and the N–H bending mode is mixed extensively with the other vibrations. However, in the case of tertiary amides, the C–N stretching mode appears in the region of C–H bending vibration, rendering its identification difficult.

The simplest tertiary amide is *N,N*-dimethylformamide (DMF). While there has been no difficulty in assigning some of its frequencies, a satisfactory and complete assignment of the infrared spectrum has not been possible. The valence bond approach to assign a few important bands from the frequency changes in metal complexes of DMF has not been helpful. The different earlier assignments for a few important bands have been summarized by Randall *et al.*[9]

Kaufman and Leroy[10] have carried out a force constant calculation for DMF and made assignments which follow largely those of *N*-methylformamide by Suzuki[2] and those of DMF by Jones.[3] Chalapathi and Ramaiah[11] have made a normal vibration calculation for the DMF skeleton. Their assignments comply generally to the earlier assignments. The different assignments[9-11] for DMF have not been substantiated and doubts regarding the assignment of some of the bands still exist. For example, the band at 1395 cm^{-1} in DMF has been assigned to C–H bending vibration, which appears to be incorrect, since the same band is present in DMF-d_1.[12] Moreover, the frequency shifts are now available from the spectrum of DMF-^{15}N which could be used to test the validity of a potential field employed. This tempted us to undertake a fresh normal coordinate treatment to make a reasonable and complete assignment for DMF. As the assignments are known to be somewhat sensitive to the force fields, the three commonly employed potential fields were tried. The study includes related *N,N*-dimethylthioformamide (DMTF) and *N,N*-dimethylselenoformamide (DMSeF) for understanding the nature of the vibrations in the simplest thioamides and selenoamides.

Experimental

Dimethylformamide used was a product of Riedel De Haen AG which was redistilled at reduced pressure, after keeping over KOH pellets for four days. Dimethylthioformamide was obtained through the courtesy of Prof. W. Walter, Institute of Organic Chemistry, Hamburg.

The infrared spectra of DMF and DMTF as thin films were recorded on a Carl-Zeiss UR 10 Spectrophotometer in the range 4000—400 cm^{-1} and on a Perkin-Elmer 521 Grating Spectrophotometer in the range 400—250 cm^{-1}. The spectra in the range 400—1800 cm^{-1} are given in Fig. 1. The infrared spectra of DMF-d_7 and DMF-^{15}N were kindly supplied by Dr. T. H. Siddall, III,[13] Savannah River Laboratory, E. I. du Pont de Nemours & Co., Aiken, South Carolina and Dr. J. J. Zuckerman,[9] Department of Chemistry, State University of New York at Albany, respectively.

Normal Coordinate Treatment

The vibrational problem was set up in internal coordinates, using GF matrix method.[14] The secular

equation was solved using Miyazawa's method[15,16] on a National Elliott 803 computer. The least squares adjustment of the frequencies has not been made because of the small computer at hand. The high frequency C–H stretching modes were split off from the lower vibrations for the same reason.

Dimethylformamide belongs to the point group C_S and its 30 fundamental vibrations are split into $19A'$ and $11A''$ vibrations. The calculations have been made for the A' vibrations only, since the assignment of frequencies in question belong to this species. The internal coordinates are defined in Fig. 2 and the symmetry coordinates are given in Table 1.

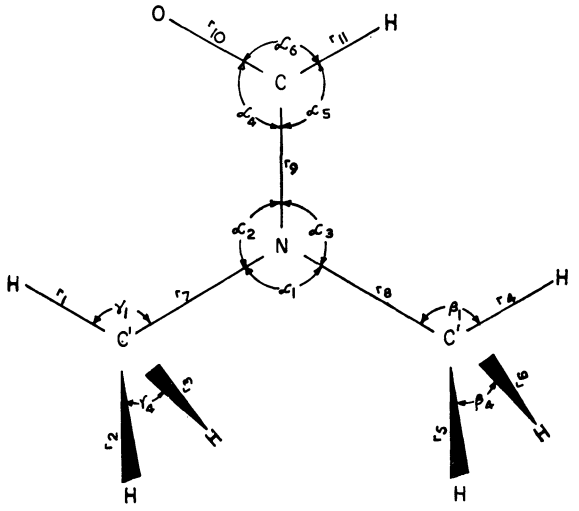

Fig. 2. Internal coordinates for DMF.

The structural parameters of DMF are taken from the electron diffraction data,[17] except for the angles around carbonyl carbon which are from the microwave data of formamide.[18] The C=S bond length is taken as in thioformamide[2] while C=Se distance is from the covalent radii. The other parameters for DMTF and DMSeF are the same as those of DMF. The structural parameters are listed in Table 2.

The final sets of force constants, for DMF and DMTF, obtained after several trials, are given in Tables 3 and

4, respectively. The observed and calculated frequencies for DMF, DMF-^{15}N and DMF-d_7 along with their assignments from the modified Urey-Bradley field (MUBF) are given in Table 5. The frequencies for DMTF and their assignments from Urey-Bradley field (UBF) are given in Table 6. Finally, the present assignments for DMF are compared with the previous assignments in Table 7.

Results and Discussion

Dimethylformamide. Lower Vibrations: The lowest frequency in the spectrum at 319 cm^{-1} is assigned to C'NC' rocking vibration, instead of a band at 350 cm^{-1} as assigned by Kaufman and Leroy.[10] Katon *et al.*[4] favour the band near 350 cm^{-1} to a similar wagging mode in amides. The 350 cm^{-1} band may, therefore, be assigned to C'NC' wagging vibration. The bands at 405 and 660 cm^{-1} need no comment since their

b) spectrum in this region was not obtained.

assignments are undoubted.

Methyl Rocking Vibrations: The bands at 1067 and 1099 cm^{-1} are assigned to methyl rocking vibrations of the *A'* type while the methyl rocking mode of the *A''* type is observed as a weak band at 1150 cm^{-1}. The 1099 cm^{-1} band in DMF increases by about 25 cm^{-1} in metal complexes and was assigned to C–N stretching mode since the double bond character of C–N is expected in increase on theoretical grounds with the decreasing bond order of C=O in metal complexes.[9] However, that this correlation is misleading may be judged from: (a) the infrared spectra of compounds containing gem dimethyl groups [includes $-N(CH_3)_2$] show strong bands in the region 1000—1200 cm^{-1} for CH_3 rocking modes,[19-23] and hence the assignment of frequencies at 1067, 1099, and 1150 cm^{-1}

a) Spectrum was not scanned in this region.

to CH_3 rocking vibrations is reasonable, (b) rocking frequencies are sensitive and are known to shift on complex formation[22]; thus the frequency rise of the CH_3 rocking mode in DMF metal complexes is not unexpected, and (c) the 1099 cm^{-1} band does not show any change in the infrared spectrum[9] of DMF-^{15}N, thus ruling out any major C–N stretching contribution in the 1099 cm^{-1} band. Only about 10% C–N character is indicated by the calculation. The assignment of 1099 cm^{-1} to methyl rocking mode is in accord with these facts.

C=O *and* C'–N *Stretching Vibrations*: There is complete agreement over the assignment of the bands at 1685, 1268, and 870 cm^{-1} to C=O stretching, C'–N asymmetric and symmetric stretching vibrations, respectively. The carbonyl band has contributions from C–N stretching and C–H bending modes, as also expected by others.[10,11] From the band shapes of the vapor phase spectrum, Jones[3] has supported the assignment of C'–N symmetric and asymmetric stretching, OCN bending and CH_3 rocking vibrations and these agree with the present assignments.

C–N *Stretching Vibration*: The weak to medium band at 1512 cm^{-1} is a highly coupled vibration and has a complex character. This band is due to a CH_3 deformation vibration with contributions from CH_3 rocking and C–N stretching vibrations. The mixing of CH_3 deformation modes with skeletal vibrations has been found in other similar molecules containing gem dimethyl groups.[20,23] The 1512 cm^{-1} band of DMF is absent in diethylformamide (DEF).[5] It could, therefore, be expected that the coupling of CH_3 deformation vibrations with C–N stretching mode, present in DMF, does not occur in DEF. The band assignable to C–N stretching motion in DEF appears in the region 1420—1370 cm^{-1}.

The 1512 cm^{-1} band hardly shifts by 5 cm^{-1} in metal complexes. In the spectrum of DMF-^{15}N, the 1512 cm^{-1} band is lowered by 7 cm^{-1}, while the calculated shifts are -11 to -12 cm^{-1}.

C–H *Bending and* CH_3 *Deformation Vibrations*: The assignments in the region 1395—1450 cm^{-1} were found to be very sensitive to the force fields employed. In the UBF, the 1397, 1414, and 1418 cm^{-1} and in the symmetrized valence field (SVF), the 1397, 1409, and 1406 cm^{-1} bands have approximately the same assignments as the bands at 1409, 1430, and 1376 cm^{-1} in the MUBF (Table 5).

The MUBF calculations indicate that the 1376 and 1430 cm^{-1} bands are due to CH_3 symmetric deformation vibrations, and the band at 1409 cm^{-1} to C–H

bending vibration. The CH_3 asymmetric deformation vibrations are easily located at 1450 and 1460 cm^{-1}.

The 1395 cm^{-1} band is a coupled vibration with major contributions from CH_3 deformation (~35%) and C–N stretching (~24%) modes. It is lowered by 20 to 40 cm^{-1} in metal complexes and this shift may be understood from the major components of the band. It is also known that the CH_3 symmetric deformation vibration is more sensitive to the atom adjacent to the methyl group than the asymmetric vibration.[22]

The 1395 cm^{-1} band in DMF was observed to shift by −13 cm^{-1} in the spectrum[9] of DMF-^{15}N, which is in good agreement with the calculated value of −14 cm^{-1} in the MUBF. It should be noted that the calculated frequencies for DMF-^{15}N in the UBF and SVF indicate no shift for 1395 cm^{-1} band, which is contradictory to the experimental data. On the other hand, the calculations showed shifts for 1432 cm^{-1} frequency in the UBF and 1406 and 1435 cm^{-1} frequencies in the SVF, which is again contradictory to the observed data, since these bands remain unaffected in the infrared spectrum of DMF-^{15}N. This piece of evidence suggests that the assignments from the MUBF are to be preferred.

Some of the earlier investigators had favoured the assignment of the 1395 cm^{-1} band to C–H bending mode.[3,10,11] That this band is not due to C–H bending vibration also finds support from the spectrum of DMF-d_1.[24] Castelli and Cragle[12] have recorded the infrared spectra of DMF and DMF-d_1 as liquids. It is found that (a) a shoulder at 1400 cm^{-1} in DMF (corresponding to 1410 cm^{-1} of the present work) is absent in the spectrum of DMF-d_1, and is observed at ~1010 cm^{-1} as expected with the replacement of hydrogen by deuterium, indicating that this band can be assigned to C–H bending vibration, and (b) the band at 1380 cm^{-1} (this work, 1395 cm^{-1}) is present both in DMF and DMF-d_1, showing that this band is not due to aldehydic C–H bending vibration. These expected assignments are realised only in the results of MUBF. Notably, the 1395 cm^{-1} band has the assignment as C–H bending vibration in UBF and SVF, which is incorrect as discussed above.

Out-of-plane Vibrations: A brief mention is made here of the out-of-plane vibrations for completeness, although no calculations were made to aid the assignments. In the region under study, seven A'' vibrations are expected. Since the spectrum is of the liquid, some of the methyl group modes may overlap. Further, since some of the out-of-plane vibrations are weak, it may not be possible to observe them.

The band at 350 cm^{-1} is assigned to C'NC' wagging mode (may also be associated with C–N torsional mode). The C=O wagging vibration is expected near 550—600 cm^{-1}; but no band is observed in this region. Similarly, the C–H wagging mode expected at 900—1100 cm^{-1} is not observed. The intensities of these bands are probably too weak to be observed or the bands might have merged with the neighbouring absorptions. The weak band at 1150 cm^{-1} is assigned to CH_3 wagging mode.[3] Another out-of-plane rocking mode expected for A'' species may be too weak to be observed or may be taken to have merged with 1067 cm^{-1} band belonging to A' vibrations.[10] The CH_3 deformation vibrations may be taken to have overlapped with 1460 and 1410 cm^{-1} bands of the A' vibrations. These features are commonly encountered in other similar molecules.[19,20,23]

Dimethylformamide-^{15}N. The observed and calculated frequencies for DMF-^{15}N are given in Table 5 along with their assignments. It is interesting to observe the changes in the assignments as compared to those of DMF, particularly with respect to C–N stretching mode.

Dimethylformamide-d_7. The calculated frequencies obtained for DMF-d_7 using the same force constants as those of DMF are given in Table 5 along with the observed frequencies. Two points worth noting are: the absence of 1512 cm^{-1} frequency in the infrared spectrum of DMF-d_7 and the appearance of pure C–N stretching vibration at 1385 cm^{-1}. A detailed picture of the changes due to complete deuteration of DMF can be obtained from the same Table .

Force Fields. The UBF force constants of formamide and *N*-methylformamide,[2] and MUBF force constants of *N*-methylacetamide[24] formed the starting point for UBF and MUBF calculations of DMF.

There is considerable difference between the observed and the calculated frequencies due to methyl rocking modes in the UBF. The difficulties of reproducing the rocking frequencies in this force field are well known.[2,23] Some unacceptable assignments in the UBF and SVF (where a number of interaction constants are neglected) may reflect upon the inadequacies of these force fields. The frequency-fit alone cannot be a criterion in judging the suitability of a force field and therefore, while making a choice among the force fields, the reproducibility of the data from the frequency shifts in isotopic molecules should be kept in view. Such data could be useful in making correct assignments.[25] The results of the MUBF for DMF are in good agreement, as discussed before, with the frequency shifts from the isotopic species, DMF-^{15}N, DMF-d_1 and DMF-d_7; whereas the results from the other two force fields are not. Only the assignments from MUBF are, therefore, given (Table 5).

Dimethylthioformamide. The UBF force constants for DMTF are transferred from thioformamide,[2] *N*-methylthioformamide[2] and DMF. The appropriate SVF force constants are taken from DMF. The assignments for DMTF are very nearly the same both in UBF and SVF. Frequency shifts from isotopic substitution are not available for DMTF to test the validity of the force fields, and the MUBF was not attempted in this case.

The assignments from the calculations are discussed here briefly. The symmetric and asymmetric C'–N stretching at 828 and 1212 cm^{-1} compare well with

24) The authors are not in possession of the spectrum of DMF-d_1.

25) J. Jakes and B. Schneider, *Coll. Czech. Chem. Commun.*, **33**, 643 (1968).

26) L. H. Jones, L. B. Asprey, and R. R. Ryan, *J. Chem. Phys.*, **47**, 3371 (1967).

those of DMF. In DMTF complexes of cobalt(II) and nickel(II) chlorides,[27] the bands at 1560 and 521 cm^{-1} in DMTF shift to higher frequencies to around 1580 and 535 cm^{-1}, respectively and the band at 975 cm^{-1} shifts to lower frequencies to 950 cm^{-1}. These shifts agree with the assignments made for the bands at 1560, 521, and 975 cm^{-1} to C–N stretching, coupled C=S bending and C=S stretcing vibrations, respectively. The band at 1130 cm^{-1} is due to a CH_3 rocking vibration coupled with C=S and C–N stretching vibrations. This mode, being sensitive, shifts to higher frequencies in metal complexes and on *S*-methylation.[28]

Jensen and Nielsen[28] have studied the infrared absorption bands of a series of thioamides and located the characteristic bands. Recently, Indirachary and Ramaiah[29] have made a normal coordinate analysis of DMTF, treating the methyl groups as point masses. In particular, the bands at 970, 915, and 518 cm^{-1} have been assigned to C–H out-of-plane bending, C=S stretching and C'NC' bending vibrations, respectively.[29] These assignments differ from the present ones. The band at 922 cm^{-1} can be assigned to the out-of-plane bending mode of C–H.

Dimethylselenoformamide. In a series of thioamides and related selenoamides, Jensen and Nielsen[28] observed that the substitution of sulphur with selenium behaves like 'isotopic substitution' and shifts the C=S stretching by 30—100 cm^{-1} towards lower frequencies, while the other frequencies are generally unaltered. Employing the force constants of DMTF, approximate calculations have been made for DMSeF. The calculated frequencies show the expected trend. The C=Se stretching and bending are expected around 930 and 497 cm^{-1} respectively, according to the present calculations.

The authors wish to thank Professor M. R. A. Rao for his keen interest in the work.

Dielectric Relaxation of 1,2-Dichloroethane and 1,2-Dibromoethane in the Liquid State

Abul HASAN, Arati PAL, and Alpana GHATAK

Optics Department, Indian Association for the Cultivation of Science, Calcutta 32, India

(Received July 14, 1970)

The activation energies for dielectric relaxation (ΔH_τ) of the gauche rotational isomers of 1,2-dichloroethane and 1,2-dibromoethane in the liquid state have been determined from the dielectric relaxation data obtained from the absorption in 1.62 cm and 3.20 cm microwave regions at different temperatures. The activation energies (ΔH_τ) in both the liquids obtained in the present investigation agree fairly well with the values of electrostatic self energy of the polar isomers in the liquid state calculated theoretically by Wada.

It is well known that the energy differences between the *trans*- and *gauche*-rotational isomers of the molecules of 1,2-dichloro- and 1,2-dibromoethanes in the gaseous state are 1.27 kcal/mol and 1.7 kcal/mol respectively and in the liquid state this energy difference in the former molecules is almost zero while in the latter molecules about 800 cal/mol.[1-3]

Wada[4] explained the observed decrease in the values of energy difference in the pure liquids to be due to the electrostatic energy of the polar gauche molecules embedded in a continuous dielectric medium and the results of his calculations seem to agree with the experimental results.

Since measurements on the temperature dependence of relaxation times of the molecules of polar liquids afford a method for determining the activation energy of the molecules *i. e.* the potential energy of the molecules in the liquid state due to the various intermolecular forces in the liquid, it was intended to study the relaxation times of 1,2-dichloroethane and 1,2-dibromoethane molecules in the liquid state at different temperatures by the method of microwave absorption.

The experimental results and discussions of the results are presented in this paper.

Experimental

Chemically pure samples of 1,2-dichloroethane and 1,2-dibromoethane obtained from E. Merck were first dehydrated with fused calcium chloride and then fractionated. The proper fractions were then distilled under reduced pressure and used in the experiment.

The dielectric constant (ε') and dielectric loss (ε'') values of the two liquids at different temperature were measured by

Surber's method[5] at 1.62-cm and by Poley's method[6] at 3.2-cm microwaves. The values of the static dielectric constants (ε_0) were determined at 1 MHz while the refractive indices (n) were measured with an Abbe Refractometer. The temperature in all the measurements were kept constant within $\pm 1/2$°C by means of a thermostat.

Results

The values of ε' and ε'' determined experimentally at different temperatures and at the two microwave frequencies in the case of liquid 1,2-dichloroethane and 1,2-dibromoethane are given in Tables 1 and 2. Each of the tables also contains the measured values of ε_0 and n at the corresponding temperatures.

Table 1. Values of ε', ε'', ε_0, and n of 1,2-dichloroethane at different temperatures

Temp. °C	$\lambda=1.62$ cm		$\lambda=3.20$ cm		ε_0	n
	ε'	ε''	ε'	ε''		
31.5	7.01	3.19	8.65	2.50	9.80	1.437
50	7.11	2.74	8.31	2.23	9.35	1.428
65	7.17	2.42	7.94	1.82	8.55	1.420

Table 2. Values of ε', ε'', ε_0, and n of 1,2-dibromoethane at different temperatures

Temp. °C	$\lambda=1.62$ cm		$\lambda=3.20$ cm		ε_0	n
	ε'	ε''	ε'	ε''		
30	3.44	0.802	4.01	0.185	4.67	1.533
50	3.53	0.869	4.16	0.805	4.65	1.520
65	3.64	0.922	4.21	0.712	4.62	1.512
80	3.76	0.873	4.25	0.656	4.55	1.511

The values of ε' and ε'' for the two liquids at different temperatures have been fitted into the Cole-Cole arc plots, some of which are shown in Figs. 1 and 2. The values of τ, ε_∞ and the distribution parameters α determined from these plots are shown in Tables 3

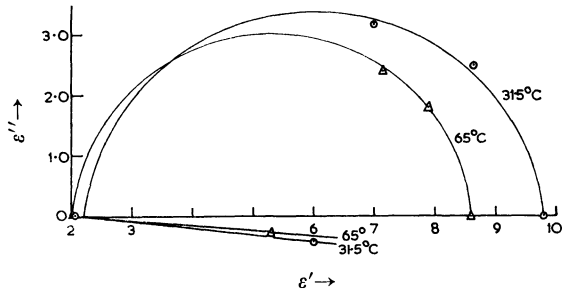

Fig. 1. Cole-Cole arc plot of 1,2-dichloroethane at 31.5°C and 65°C.

Table 3. Relaxtion time τ, Cole-Cole parameter α, ε_∞, and activation energies of 1,2-dichloroethane

Temp. °C	$\tau\times10^{12}$ sec	α	ε_∞	ΔH_τ kcal/mol	ΔH_η kcal/mol

Discussions

It is seen from Tables 3 and 4 that the relaxation time of 1,2-dibromoethane at any temperature is larger than that of 1,2-dichloroethane which is consistent with the larger size of the former molecule. The τ value 6.15 p·sec of 1,2-dichloroethane at 31°C is compatible with the value 5.6 p·sec at 25°C for a solution of 1,2-dichloroethane in *p*-xylene as reported by Crossley and Walker[8] but is somewhat larger than the value 4.53 p·sec for the same solution at 20°C given by Chitoku and Higasi.[9] However the value of relaxation time for the pure liquid has not been apparently reported in the literature. In this connection it may be noted that from the measurements of spin-lattice relaxation of a solution of 1,2-dichloroethane in 1,2-dichloroethane-d_4 Bock and Tomchuk[10] derived a value of 8.62 p·sec for the relaxation time of 1,2-dichloroethane at 20°C. This value seems to be slightly higher than the value obtained in the present investigation.

The value of 0.07 for the distribution parameter (α) obtained in this investigation for the pure liquid at 31°C is near the value of 0.08 reported by Crossley and Walker[8] and is much smaller than the value 0.19 obtained by Chitoku and Higasi.[9] It is seen from Table 3 that the α-values for the pure liquid decreases with the increase of temperature as is generally observed. The α value for 1,2-dibromoethane (Table 4) is somewhat larger than that of 1,2-dichloroethane and also decreases with increasing temperature as in the case of 1,2-dichloroethane.

It is seen from Tables 3 and 4 that the values for the activation energy for dielectric relaxation (ΔH_τ) of 1,2-dichloroethane and 1,2-dibromoethane are both smaller than the respective values of the activation energy for viscous flow (ΔH_η) for both the liquids as are generally observed with other polar liquids.

The activation energy (ΔH_τ) of 1.3 kcal/mol in the case of 1,2-dichloroethane in liquid state as determined in the present investigation is almost equal to Wada's calculated value 1.22 kcal/mol[4] representing the electrostatic self energy of the polar gauche molecule in the liquid state. In the case of 1,2-dibromoethane in the liquid state the activation energy (ΔH_τ) is found to be 1.09 kcal/mol while according to Wada's calculation[4] the electrostatic self energy in this case is about 800 cal/mol.

Thus though the observed value of ΔH_τ in the case of 1,2-dichloroethane closely agrees with the value calculated by Wada, in the case of 1,2-dibromoethane the calculated value is somewhat lower than the observed one. It need be noted that Wada considered only the electrostatic energy of the polar gauche molecules in the liquid but did not take into account other types of intermolecular forces within the liquid which will further lower the energy of the gauche isomers. The small difference in ΔH_τ in the case of 1,2-dibromoethane may arise from this cause.

Considering the accuracy of the determination of the τ-values in the present investigation it may be concluded that the values of the activation energy determined experimentally are in agreement with the values calculated by Wada and that the greater part of the potential energy of the gauche isomers of the molecules of 1,2-dichloroethane and 1,2-dibromoethane in the liquid state arises from the electrostatic self energy of the polar molecules.

The authors are grateful to Dr. S. B. Roy for his guidance and to Professor G. S. Kastha, D. Sc. for his continued interest during the progress of the work.

The Hydrogenation of Aniline over Supported Rhodium-Palladium Alloy Catalysts

Kazue IKEDATE and Sadao SUZUKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 3, 1970)

The hydrogenation of aniline was investigated in the temperature range from 30° to 50°C over Rh-Pd alloy catalysts supported on activated carbon. The reactions were mainly carried out in acetic acid at an atmospheric pressure of hydrogen. The activity per unit weight of the catalysts was measured and plotted for the alloy composition. It showed a maximum at 75—85 wt% Rh. However, the activity per unit of surface area showed a maximum at about 25 wt% Rh, and the minimum activation energy of this reaction was observed at the same composition. The relationship between the selectivity and the alloy composition was also studied. The maximum selectivity to dicyclohexylamine was observed at 20—30% Rh, while the maximum formation of *N*-phenylcyclohexylamine appeared at 50—60% Rh. However, the selectivity to cyclohexylamine showed a minimum at about 25% Rh. The initial rates of the formation of cyclohexylamine and *N*-phenylcyclohexylamine were measured and plotted for the catalyst composition. The maximum activity was observed at about 85 wt% Rh for the formation of cyclohexylamine and at 50—60% Rh for the formation of *N*-phenylcyclohexylamine. Then the ratios of the two simple reaction rates were calculated. At a higher Rh content, (above about 25% Rh), the selectivity increased as the ratio increased. The reaction over the catalysts prepared by different methods and the hydrogenation of aniline in cyclohexane were also investigated.

Recently some interesting work with respect to the binary alloy catalysts of the platinum group metals have been reported.[1-7] However, there have been only a few reports on the Rh-Pd alloy system, and, moreover, these reports have shown two different tendencies for the catalytic activity change in this alloy series; on the one hand, a maximum activity was found for the hydrogenation of nitrobenzene and ethyl methyl ketone[4] at each certain Rh content, and on the other hand, the activity for CH_4+D_2 exchange and propane cracking [3a] changed smoothly with an increase in the Rh content.

Then we investigated the activity change for the hydrogenation of aniline with Rh-Pd alloy catalysts supported on activated carbon, in order to consider the contribution of any unpaired *d* electrons present in the metal and concerned with its magnetic susceptibility. The structure of the catalyst was studied by X-ray diffraction, and the surface area of the metal on the catalyst was measured by the CO adsorption method. The selectivity change in this series was of as much interest as the activity change. However, this subject was scarcely investigated. There has been one report showing that on Rh-Pt alloys of the Adams type, the catalysts containing 70 to 90 wt% Rh were the most active and selective for the hydrogenation of acetophenon.[1] In that report, however, the selectivity was not referred to any detail beyond the above description. Therefore in this report the selectivity change for the hydrogenation of aniline and the relationship between the selectivity and the activity were investigated with respect to the composition of the binary alloy catalyst.

Moreover, we studied how the activity and selectivity depended upon the catalysts obtained by the different method of preparation. The hydrogenation of aniline in a cyclohexane solvent with Rh-Pd alloy catalysts was also investigated.

Experimental

Procedure of Catalyst Preparation. The catalysts were prepared by the reduction of a solution of mixed Rh and Pd chlorides with formaldehyde, and by co-precipitation followed by reduction with hydrogen gas. Activated carbon was used as the carrier, and 5 wt% metal was supported on it.

Catalyst Preparation by Reduction with Formaldehyde: The method used as almost the same as that proporsed by Willstätter.[8] A given amount of the solution of mixed metal chlorides was added to the activated carbon. Then the metal chlorides were reduced with formaldehyde and sodium hydroxide at room temperature for 30 min and next at 100°C for 1 hr. It was left to stand overnight and then, after filtration, dilute hydrochloric acid was added until the pH of the solution went below about 3. After one day, it was washed fully with ion-exchanged water; a catalyst dried in the vacuum system was used directly for the reaction.

Catalyst Preparation by Co-precipitation: A given amount of the solution of the mixed metal chlorides was added at a stretch to the activated carbon, which was stirred at 40°C in a solution containing the calculated amount of sodium hydroxide. Then the metal hydroxide co-precipitated on the carrier was reduced to the metal by bubbling hydrogen gas into the solution and washed fully with ion-exchanged water. The dried catalyst in the vacuum system was used directly for the reaction.

Hydrogenation of Aniline. The hydrogenation experi-

ments were carried out in the liquid phase at an atmospheric pressure of hydrogen in the apparatus described in a previous paper.[9] The rates of the hydrogenation of aniline were measured 2 or 3 times. When almost the same value was obtained in two measurements, that value was taken as the activity of the used catalyst. The method of the analysis of the reaction samples was the same as that already reported.[10] The surface area of the metal on the carrier was measured by the ordinary CO adsorption method.

Results and Discussion

X-Ray Diffraction of Rh-Pd Alloy Series. In order to examine whether or not, the catalysts prepared by reduction with formaldehyde were homogeneous, they were subjected to a X-ray diffraction. The X-ray diffraction angles observed for the Rh-Pd alloy catalysts are shown in Fig. 1. Since a linear relationship between these angles and the composition was observed, we considered that the catalysts prepared by this method formed homogeneous alloys.

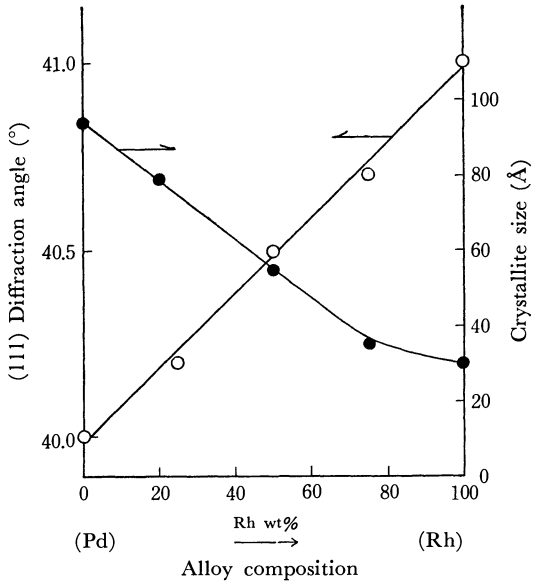

Fig. 1. X-ray diffraction angle and crystallite size of Rh-Pd supported on activated carbon.

The particle size, which was calcuated by the X-ray line-broaden method, changed smoothly in the range of about 30—100 Å. These catalysts were then used for the hydrogenation of aniline.

Hydrogenation of Aniline in Acetic Acid. The reaction was carried out in acetic acid at an atmospheric pressure of hydrogen in the temperature range from 30° to 50°C. The hydrogenation of aniline in this solvent over palladium supported on activated carbon, as has already been reported,[9] proceeded under a zero order of aniline concentration and one order of hydrogen pressure.

The influences of the hydrogen pressure on the reaction rates were investigated over a catalyst with a 15 wt% Rh content and over one with a 100% Rh content. The results are shown in Fig. 2. From this figure, it may be seen that over these catalysts the

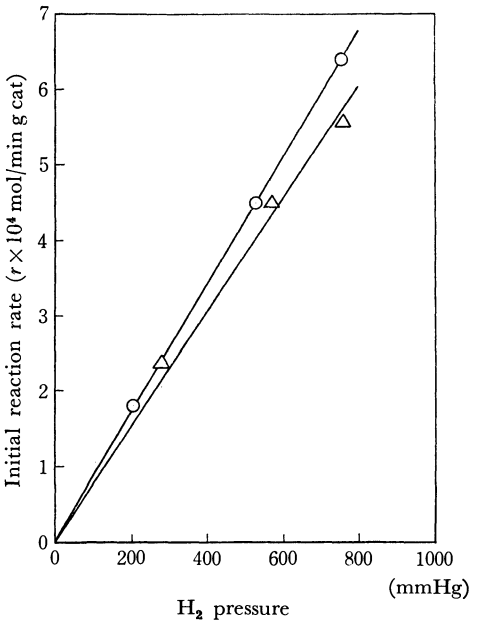

Fig. 2. Influence of the hydrogen pressure to the initial reaction rate.
—○— 15% Rh (at 50°C) —△— 100% Rh (at 40°C)

initial reaction rate was first order with respect to the hydrogen pressure. Since, in an initial reaction period, the aniline was consumed almost lineary for the reaction time, we consider that the reaction proceeds with zero order of the aniline concentration. Hence, we concluded that, over the Rh-Pd alloy series, the initial reaction rate may be expressed by the following equation, as on the Pd catalyst, when the constant weight of the catalyst is used: $V=kP_{H_2}$ Here, k denotes the rate constant.

Then the initial reaction rate of the hydrogenation

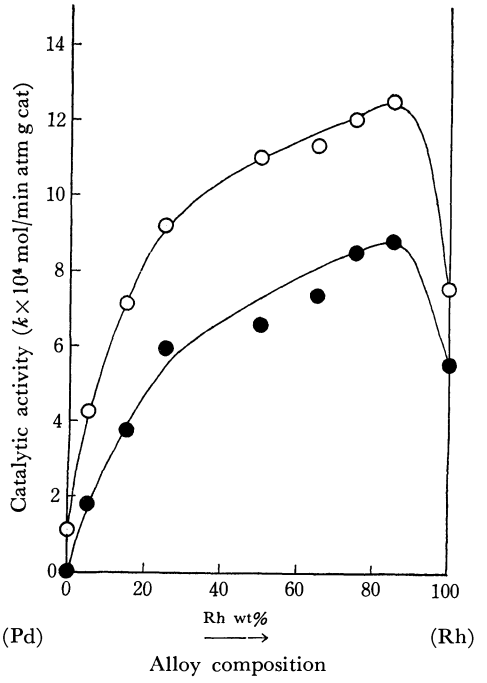

Fig. 3. Catalytic activity per g catalyst for the hydrogenation of aniline in acetic acid.
—○— at 50°C —●— at 40°C

10) K. Ikedate, T. Suzuki, and S. Suzuki, *Nippon Kagaku Zasshi*, **89**, 304 (1964).

was measured; the rate constant as a function of the alloy composition is shown in Fig. 3. In this alloy series the activity per unit of weight of the catalyst has a maximum at a 75—85% Rh content.

Since, in the last section, it was shown that the particle size of the metal on the carrier varied with the composition of the catalysts, it can be easily presumed that the active surface areas of the catalysts also vary with the composition. Therefore, the metal surface area on the carrier was measured by the CO adsorption method and the catalytic activity per unit surface area of the metal was calculated. The results, plotted in Fig. 4, show that the catalytic activity curve changed. The maximum of the activity shifted to about a 25 wt% Rh content, at that point the activation energy observed for this reaction had its minimum value.

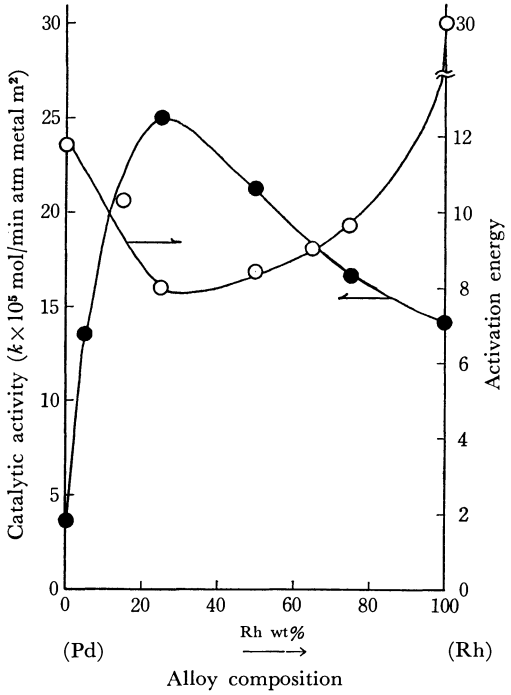

Fig. 4. Catalytic activity per unit surface area of metal on the carrier —●— and activation energy —○—.

Since the magnetic susceptibility of the Rh-Pd alloys has a maximum value at 5 atm% Rh, as has been reported in the literature,[11,12] we considered that the unpaired *d* electrons concerned with the magnetic susceptibility might influence the activity of the catalysts, as Yoshida also pointed out in his report[5,13] on Rh-Pt catalysts. However, the composition at the maximum in the magnetic susceptibility of the Rh-Pd alloy series did not completely agree with that at the maximum activity observed in this reaction, and also in his data,[5] the composition at the maximum of the magnetic susceptibility of the Rh-Pt alloy series does not coincide exactly with that at the catalytic activity maximum based on the unit of the metal surface area for the hydrogenation of phenol and benzoic acid. Therefore, it may be considered that the catalytic activity could not be explained only in terms of the magnetic susceptibility of the metal used as the catalyst.

The Reaction Mechanism on Rh-Pd Alloys in Acetic Acid. Over the catalysts of the platinum-group metals, the hydrogenation of aniline proceeds through the reaction mechanism illustrated in Fig. 5, as has been shown in our previous reports.[10,14] When acetic acid was used as the solvent, over the Rh-Pd alloy catalysts dicyclohexylamine was formed from *N*-phenylcyclohexylamine (hereafter descrived as NPC) much as over other platinum metals,[14] and the hydrogenation of the NPC formed did not occur at the same time the hydrogenation of aniline was progressing. The hydrogenation of NPC began when almost all the aniline had been consumed. In acetic acid, then, the selectivity for the formation of cyclohexylamine in the hydrogenation of aniline was influenced by two steps in the reaction mechanism: namely by k_2 and k_3, and by k_5 and k_6. The former is named the first step, and the latter, the second step (Fig. 5).

Selectivity. The reaction was investigated in acetic acid at 50°C. Since the hydrogenation of aniline was finished, the yields of the cyclohexylamine and dicyclohexylamine formed express the selectivities for the respective amines. The selectivities at the end point of the reaction are plotted as a function of the alloy composition in Fig. 6. The maximum yield of the NPC formed, an intermediate, in the course of the reaction is also plotted. In this experiment the Pd-C catalyst prepared by the adsorption method reported previously[10] was used, because the palladium catalyst which was prepared by the reduction with formaldehyde was almost inactive and so, on this catalyst, the reaction proceeds scarcely not at all. A maximum of the formation of dicyclohexylamine was shown at 20—30

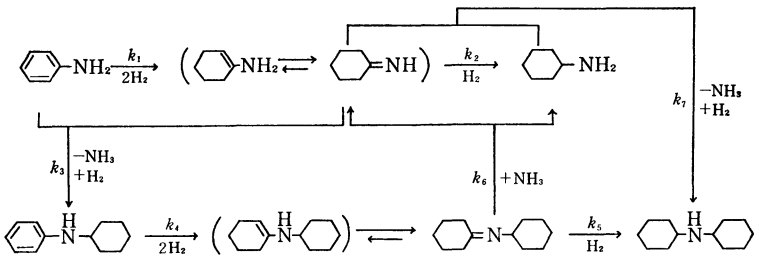

Fig. 5. Mechanism of the hydrogenation of aniline.[10]

wt% Rh. Then it greatly decreased beyond about 50% Rh. The formation curve of NPC showed a maximum at 50—60% Rh, but in the formation curve of cyclohexylamine a maximum was not found, while a minimum was shown at about 25% Rh.

The quantity of dicyclohexylamine formed was somewhat decreased when the reaction temperature went down. However, the formation curve observed at 40°C had a maximum at 20—30% Rh and showed almost the same shape as that observed at 50°C. Of course, the selectivity of the catalyst is influenced by the reaction temperature, but the formation curves may show almost the same tendency near 50°C.

From Fig. 6 it may be considered that the deviation between the curve of dicyclohexylamine and NPC shows the variety in the activity of each catalyst for the hydrogenating decomposition of NPC. This activity of the catalyst contributes to the second step and influences the selectivity. However, the change in the selectivity to cyclohexylamine can not be explained only this deviation.

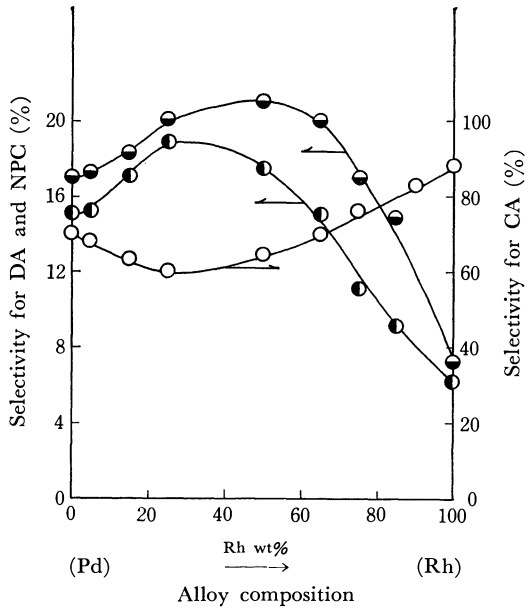

Fig. 6. Selectivity change for cyclohexylamine (CA) —○—, dicyclohexylamine (DA) —◑—, *N*-phenylcyclohexylamine (NPC) —◒— in acetic acid at 50°C.

The rates of the formation of cyclohexylamine and NPC, which influenced the first step, were measured. They are plotted in Fig. 7. The activity per unit weight of the catalyst for cyclohexylamine formation showed a sharp peak at about 85% Rh, while the activity for NPC formation showed a peak near 60% Rh and decreased in the region of Rh contents more than 75—85%. The activity per unit of weight of the catalyst for aniline had a maximum at 75—85% Rh, and it almost coincided with the maximum activity per unit of weight for the cyclohexylamine formation. Therefore, it was considered that, in this system, the total activity of this reaction depended mainly on the activity of the direct hydrogenation of aniline to cyclo-

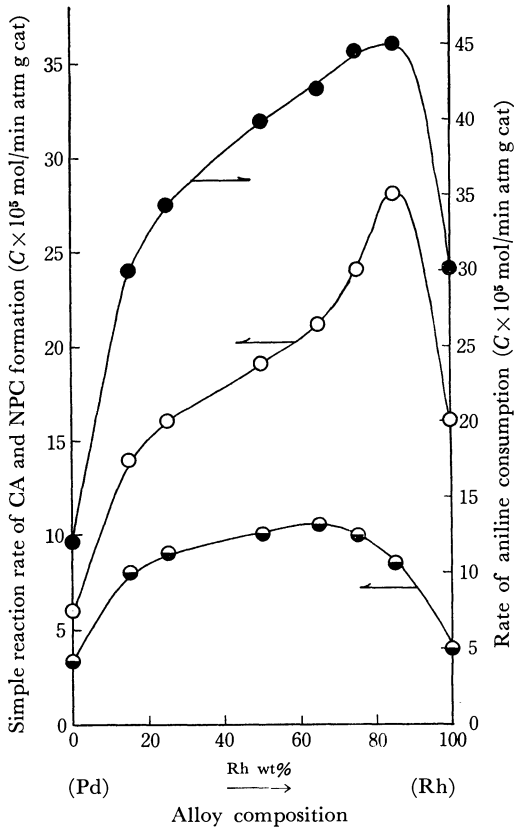

Fig. 7. Simple reaction rates of formation of cyclohexylamine —○—, *N*-phenylcyclohexylamine —◒—, and rate of aniline consumption —●— at 50°C, in acetic acid.

b) A: aniline

hexylamine.

In the Rh-Pd alloy series the selectivity to cyclohexylamine did not have a maximum and showed a minimum at about 25% Rh, as is shown in Fig. 6. Here, the selectivity can not be interpreted only on the basis of the activity of the catalyst. The ratios between the simple reaction rate of cyclohexylamine formation and that of NPC were then calculated; they are collected in Table 1. In Table 1 the rate of the formation of each substance is shown as an activity per unit of weight of the catalyst, but the ratio between the simple reaction rates does not have an order with respect to the catalyst. Therefore, it should be the same if it is obtained from the rates per unit of the surface area of the metal on the catalyst.

Beyond 25% Rh to 100% Rh the value of this ratio increased gradually with the increase in the Rh content. Between the selectivity to cyclohexylamine and this ratio, a good proportional relationship was observed. It was considered that, on these catalysts, the selectivity to cyclohexylamine was governed mainly by the first step under the present reaction conditions. For example, in spite of the lower activity over 100% Rh than over the other alloy catalyst, a better selectivity to cyclohexylamine was shown at 100% Rh. This can be explained on the basis of the fact that in the first step, the ratio for rhodium is the largest in the Rh-Pd alloy series. Therefore, it is clear that the selectivity did not depend only on the simple catalytic activity for the hydrogenation, but was also determined by the relative activity for the simple reactions which were concerned with the selectivity.

From 0% Rh (*viz.*, 100% Pd) to 25% Rh, the ratios between the rate of cyclohexylamine and NPC formation were almost constant. This signifies that, over catalyst in this composition range, the rate of the formation of cyclohexylamine increased to the same degree as that of NPC. However, the selectivity to cyclohexylamine decreased. Hence, it was considered that, in this composition range, the catalytic activity which was connected with the second step, mainly influenced the selectivity.

Influence of the Different Method of Catalyst Preparation. Changes in the selectivity and the activity were investigated over Rh-Pd catalysts prepared by two different methods: one was prepared by reduction with formaldehyde, and the other by the co-precipitation of these metals. A catalyst with a 25% Rh content was used, and the reaction carried out under the conditions described above.

The results are shown in Table 2. The total activity of the catalyst prepared by reduction with formaldehyde for the hydrogenation of aniline was higher than that of the catalyst prepared by the co-precipitation. Further, the activity for the hydrogenation of benzene had the same tendency as that described above. Hence, we expected that the former catalyst would have the higher activity for the benzene nucleous of aniline and would give the better selectivity to cyclohexylamine. However, the amount of NPC formed was almost the same in both cases; if anything, that of cyclohexylamine was somewhat lower on the former than on the latter. That the same amount of NPC was formed shows that, in the first step, the ratio between the simple reaction rates (*viz.*, k_2 and k_3) was almost the same over both the catalysts. Judging from the small difference in the amount of dicyclohexylamine formed, it was considered that, in this case, the preparation of the catalyst influenced the hydrogenating decomposition rate of NPC, although the difference between them in the amount of cyclohexylamine formed was not very large (about 6%).

Therefore, it may be said that the selectivity of the catalyst does not differ much when the composition of the catalyst is the same. That is, this suggests that,

at a given composition of the catalyst, the ratios of the simple reaction rates are almost the same.

Hydrogenation of Aniline in a Cyclohexane Solvent. With the intention of considering the hydrogenation of free aniline over Rh-Pd catalysts, the reaction was carried out in a cyclohexane solvent. The results are shown in Fig. 8. The catalyst prepared by the reduction with formaldehyde was used. The catalysts were inhibited rapidly by the amine formed in the hydrogenation. The catalytic activity was then obtained from the initial reaction rate. The activity per g of catalyst showed a maximum at 75—85% Rh, the same composition as that observed in acetic acid.

The curves of the selectivity to dicyclohexylamine and cyclohexylamine in the non-polar solvent were different from those in acetic acid. The selectivity to dicyclohexylamine showed a maximum at the activity maximum. On the whole, the formation of dicyclohexylamine in cyclohexane was higher than that in acetic acid.

On the other hand, in a cyclohexane solvent the formation of NPC was extremely small as compared with that in an acetic acid solvent; at 15% Rh, the NPC formed was about 5 mol% of the material; at 85% Rh, NPC was barely perceived by gas chromatography with a thermal conductivity detector, and, as was reported in a previous paper,[14] at 100% Rh it was not found at all. Hence, it was clear that, in the hydrogenation of free aniline, dicyclohexylamine was formed mainly by the combination of imine and cyclohexylamine; this process is shown as k_7 in Fig. 5.

Thus, over the Rh-Pd alloy catalysts the process of the formation of dicyclohexylamine in cyclohexane was different from that in acetic acid. Therefore, the curves of the selectivity to dicyclohexylamine are different in the two solvents. From this, it was considered that the amine and imine which were formed in the hydrogenation, were in different adsorption states over the catalysts in the two solvents.

A Nuclear Magnetic Relaxation of ^{139}La in Ionic Aqueous Solutions

Keikichi NAKAMURA and Kazutaka KAWAMURA

National Research Institute for Metals, Nakameguro, Meguro-ku, Tokyo

(Received July 7, 1970)

The nuclear magnetic relaxation rates of the ^{139}La ion in aqueous solutions of halides, nitrate, sulfate, and perchlorate have been measured. The observed relaxation rates increased as the concentration of the salts increased. However, in the low concentration range, the relaxation rate divided by the relative viscosity, $\Delta\nu/\eta_r$, increased only in the cases of nitrate and sulfate, while it decreased in the cases of halides and perchlorate. It was found that the formation of inner-sphere complexes is a satisfactory explanation of the increase in the $\Delta\nu/\eta_r$ of nitrate and sulfate solutions in the low to middle concentration range. With the fact, proved by various authors, that the lanthanide ions have several coordination numbers, the decrease in the $\Delta\nu/\eta_r$ of halide and perchlorate solutions in the same concentration range can be explained in terms of the existence of an equilibrium between two hydrated species, such as:

$$La(H_2O)_9^{3+} \rightleftharpoons La(H_2O)_8^{3+} + H_2O$$

and the symmetrical species, $La(H_2O)_8^{3+}$, contributes to the decrease in $\Delta\nu/\eta_r$. At a high nitrate concentration, after reaching the maximum value $\Delta\nu/\eta_r$ decreases, demonstrating that a symmetrical trinitrato species may be formed in the solution.

It has been shown that, in solution, lanthanide ions have no definite coordination number, being in an equilibrium between several possible coordination numbers.[1-4] The coordination numbers for the lanthanides vary through the lanthanide series, a higher coordination number is favourable for the lighter lanthanides, while a lower coordination number is favourable for the heavier lanthanides. Because ^{139}La ($I=7/2$) is diamagnetic and has a relatively large quadrupole moment (0.5×10^{-24} cm^2), which interacts with the electric field gradient, a nuclear magnetic relaxation study of ^{139}La should provide various information concerning the symmetry of the molecule and the distribution of anions outside the first coordination sphere.

Abragam[5] has derived the following relation for the relaxation of a quadrupole nucleus in solution:

$$T_1^{-1} = \frac{3\cdot(2I+3)}{40I^2\cdot(2I+1)}\cdot\left(1+\frac{1}{3}\xi\right)\cdot\left(\frac{e^2qQ}{\hbar}\right)^2\tau_c \qquad (1)$$

where eQ is the nuclear quadrupole moment, where eq

is the z principal component of the electric field gradient tensor, where ξ is the assymmetry parameter, and where τ_c is the correlation time for the quadrupole interaction and is given by:[6]

$$\tau_c = \frac{4\pi a^3}{3KT}\eta \qquad (2)$$

assuming that the molecule can be regarded as a rigid sphere with a radium of a.

However, to evaluate eq and τ_c in ionic solutions, two different models can be used. One is that the water molecules or anions in the first coordination sphere move uncorrelatively; *i.e.*, the correlation time for the individual motion of water or an anion is shorter than the correlation time for the Brownian motion of the entire water-metal or metal-anion complex. In this case, the observed relaxation rate[7] is z (z: coordination number) times the relaxation rate for the quadrupole interaction due to the fluctuating field of one water molecule or one anion coordinated to the metal ion. Moreover, the observed relaxation rate will increase monotonously as the concentration of the salts increases. This is because of the additional electric field gradient due to ions.

However, when the mean resident time of water molecules or anions in the first coordination sphere is sufficiently longer than the correlation time for the entire complex motion, the field gradient at the metal ion will depend strongly on the symmetry of the molecule. In this case, the observed relaxation rate will not increase monotonously with the concentration increase, but will strongly depend on the kind of species existing in the solution. If the coordination fluctuates between different configurations, the observed relaxation rate will be a weighted average of the relaxation rates of different configurations.

The purpose of this paper is to obtain information on the hydration number change and the complex formation with the anion through the quadrupole interaction of ^{139}La.

Experimental

The NMR spectra were obtained with a Varian VF-16 wide-line spectrometer operating at 6.012 MHz. The magnetic fields were controlled with a "Fieldial Mark II" with a stability of 5×10^{-7}. The frequency were monitored with a Matsushita VP-437 A electronic counter. Distortion due to the finite modulation width were corrected by using different modulation widths and by extrapolating to zero amplitude. Since the observed line shape is Lorenzian, the line width (cycles/sec) is related to the relaxation time thus;

$$T_1^{-1} = \sqrt{3}\pi\Delta\nu \qquad (3)$$

The relative viscosities were measured by using an Ostwald-type viscometer in a thermostat bath at 23.0±0.1°C. To check the accuracy of the method used, the relative viscosities of the $LaCl_3$ solutions were compared with the literature value[2] and found to agree within ±1%.

Reagent. The lanthanum nitrate, sulfate, perchlorate, and halide solutions were obtained by dissolving lanthanum oxide (99.95%) purchased from Michigan Chemical Corporation with these acids. All these acids were of a reagent grade and were used without further purification.

Results and Discussion

The concentration dependence of the line width can be separated into two contributions. One is the correlation time, which increases with the viscosity increase of the solution according to Eq. (2). Spedding *et al.*[2] have shown that the concentration dependence of the relative viscosity of a lanthanide chloride solution at a moderate or high concentration can be described in terms of a modification of Vand's equation in this form:

$$\ln(\eta/\eta_0) = A_3C/(1 - Q''C) \qquad (4)$$

where $\eta/\eta_0=\eta_r$ is the relative viscosity of the solution, where C is the molar concentration, and where A_3 and Q'' are adjustable parameters. According to Spedding, the success of Eq. (3) suggests that the major contribution of a lanthanide chloride solution at a moderate or high concentration arises from the interference of large hydrated ions with the stream of the solvent. This implies that the lanthanide ions are firmly coordinated with one row of water molecules; *i.e.*, the correlation time for the reorientational motion of the hydrated lanthanide ion is sufficiently short compared with the mean resident time of water molecules in the first coordination sphere.

Another is the change in the field gradient due to the changes in the molecular environment. These changes may involve both the change in the first hydration sphere and the change in the charge distribution around it. Figure 1 shows the concentration dependence of the ^{139}La line widths. An examination of the figure

will show that the line widths increase with the concentration increase in the salts due to the increase in the viscosity and the change in the molecular environment. However, to ascertain the change in the molecular environment, it is necessary to divide the line width by the relative viscosity of the solution.[8] The results are shown in Fig. 2, which shows a marked difference in the concentration dependence.

Line Width at an Infinite Dilution. Since the electric field gradient at an infinite dilution is solely determined by the water molecules, the line widths at an infinite dilution are independent of as the anions, as is shown in Figs. 1 and 2. To discuss the line width at an infinite dilution, it is necessary to know the mean resident time of the coordinated water molecules, the coordination number, and the symmetry of the entire lanthanum-water complex.

As has been described previously, a relative viscosity of the $LaCl_3$ solution has shown the existence of a firmly-coordinated lanthanum ion. Recently, Reuben and Fiat[9] have calculated the water-exchange rate constants from ^{17}O NMR. Their calculated rates ranged from 2.6×10^7 to 3×10^6 sec^{-1} as the ionic-radii change from Tb to Tm. If we extraporate these rate constants to the ionic radius of La^{3+}, we obtain 2×10^9 sec^{-1}. This rate is about one-tenth of the reciprocal of the correlation time for the reorientational motion of the hydrated lanthanum ion;[10] moreover, this rate is considerably larger than the observed relaxation rates (100—1000 cps) and the chemical shift (<100 cps).[11]

The coordination numbers of hydrated lanthanide ions have been investigated by various authors. Proton NMR study[1] has shown that the coordination numbers vary in the lanthanide series, being 9 for lighter lanthanides and 6 for heavier lanthanides. On the other hand, the apparent molar volume, the heat capacity, the heat of dilution, and relative viscosity studies[2] have shown that the lanthanide ions in water exist in an equilibrium between two possible coordination numbers; *i.e.*, the coordination number of 9 is favourable for from La^{3+} to Nd^{3+}, while 8 is favourable for from Tb^{3+} to Yb^{3+}. Karraker's spectrometric study[3] of an Nd^{3+} aqueous solution supports this conclusion. He concluded that Nd^{3+} has two coordination numbers, 9 for a dilute and 8 for a concentrated aqueous solution.

The mean resident time and the existence of the two coordination numbers mentioned above indicate that the observed line width is determined by the rapid exchange condition[12] according to:

$$\Delta\nu/\eta_r = P_9\Delta\nu_9^0 + P_8\Delta\nu_8^0 \quad (5)$$

where P_9 and P_8 are the fractional populations of the species and where $\Delta\nu_9^0$ and $\Delta\nu_8^0$ are the line widths of $La(H_2O)_9^{3+}$ and $La(H_2O)_8^{3+}$ respectively at $\eta_r=1$. When 8 coordinated species is symmetrical, the observed line width will be determined only by the fraction of the 9 coordinated species by;

$$\Delta\nu/\eta_r = P_9\Delta\nu_9^0 \quad (6)$$

Effect of Anion Concentration. The change in $\Delta\nu/\eta_r$ due to the anion concentration increase may be interpreted in terms of the following several reasons:

1) Some kinds of the anions can replace the water molecules in the first coordination sphere of La^{3+}. This changes the symmetry of the molecule and, hence, the field gradient.

2) The activity of water decreases as the anion concentration increases. This has the effect of reducing the coordination number.

3) So far as the ions outside the first coordination sphere can be treated as point charges, fluctuations from a spherical Debye-Hückel charge distribution also contribute to the relaxation process.

Among the above three reasons, 2) and 3) do not depend strongly upon the difference in the anions of the same charge. At least, they can be considered to have similar concentration dependences. Therefore, the large difference in the concentration dependence between NO_3^- and X^- ions shown in Figs. 1 and 2 is caused primarly by 1).

Only a few studies have been made of the formation constants of lanthanum halide and nitrate. Spectrometric study[13] has shown that K_1 for $LaCl^{2+}$ is −0.2, while that for $La(NO_3)^{2+}$ is 0.26, which is smaller than that for $LaCl^{2+}$. On the other hand, ion-exchange study[14] has shown that K_1 and K_2 for $La(NO_3)^{2+}$ and $La(NO_3)_2^{1+}$ are 0.25 and 0.18 respectively. Depending on the experimetal method used, these values differ. However, even if we compare the formation constants derived from the same method, the large difference between the $\Delta\nu/\eta_r$ of nitrate and

halides can not be explained. Two probable explanations for the above discrepancy are that NO_3^- acts as a bidentate ligand[15] and that halide ions can not form an inner-sphere complex.[16]

If the line width of each species were known, the successive formation constants could be obtained by successive approximation and least-square fitting, using the observed line width, the total metal amount, and the anion concentration. Unfortunately, we have obtained no information about the line widths except for the line width at an infinite dilution. However, at a very low concentration where only the mononitrato complex is a dominant species, the $\Delta\nu/\eta_r$ for the mononitrato complex can be obtained by using the K_1 value (0.25) and the line width at an infinite dilution (141 cps$\cdot\eta_r^{-1}$). The calculated value for $La(NO_3)^{2+}$ is about 600 cps$\cdot\eta_r^{-1}$. It is confirmed that the highest $\Delta\nu/\eta_r$ is about 600 cps$\cdot\eta_r^{-1}$ at 1.9 M $La(NO_3)_3$ and that $\Delta\nu/\eta_r$ decreases above this concentration. Assuming that it is capable of forming an inner-sphere complex up to three NO_3^- ions, and considering the above confirmation, it may be concluded that the $\Delta\nu/\eta_r$ of $La(NO_3)_2^{1+}$ is above 600 cps$\cdot\eta_r^{-1}$, while that of $La(NO_3)_3$ is smaller than that of $La(NO_3)_2^{1+}$ due to the symmetrical configuration of the complex.

Effect of Coordination-number Change.[17] It has been shown in coordination chemistry that perchlorate ions do not form any complexes with metal ions in the low-concentration range. The ^{17}O NMR study[9] also supports this fact. As has been described previously, halide ions also form no inner-sphere complexes with lanthanide ions in the low-concentration range. Therefore, the decrease in the $\Delta\nu/\eta_r$ values of these salts can be explained in terms of the change in the hydration number of the lanthanum ion according to the following equilibrium:

$$La(H_2O)_9^{3+} \rightleftharpoons La(H_2O)_8^{3+} + H_2O \qquad (7)$$

The thermodynamic stability constant can be expressed as:

$$^tK_{8,9} = \frac{a_9}{a_8 \cdot a_{H_2O}} = \frac{y_9}{y_8 \cdot y_{H_2O}} \cdot {}^cK_{8,9} \qquad (8)$$

$$\left({}^cK_{8,9} = \frac{C_9}{C_8 \cdot C_{H_2O}}\right)$$

where the subscripts 9 and 8 indicate $La(H_2O)_9^{3+}$ and $La(H_2O)_8^{3+}$ species and where a, y, and C mean the activity, the molar activity coefficient, and the molar concentration respectively. The activity coefficient of H_2O in a ionic solution is measurable. However, the meaning of the activity coefficient of $La(H_2O)_9^{3+}$ and $La(H_2O)_8^{3+}$ is not known. The measured activity coefficient may be the averaged value of these two species.

If we assume that the 8 coordinated species is a symmetrical species and has a zero field gradient, the observed line width can be, from Eqs. (5) and (7), expressed as;

$$\Delta\nu = P_9 \cdot \Delta\nu_9 = {}^tK_{8,9} \cdot \frac{y_8 \cdot y_{H_2O}}{y_9} C_{H_2O} \Big/ \left(1 + {}^tK_{8,9} \frac{y_8 \cdot y_{H_2O}}{y_9} \cdot C_{H_2O}\right) \qquad (9)$$

Figure 3 shows the calculated concentration dependence of $\Delta\nu/\eta_r$ for various values of ${}^cK_{8,9}$ assuming a constant activity coefficient. However, this assumption is a very rough approximation; the activity coefficient ratio, $y_8 \cdot y_{H_2O}/y_9$ may strongly depend on the lanthanum salt concentration.

The observed concentration dependence of $\Delta\nu/\eta_r$ for $LaCl_3$ △ and $La(ClO_4)_3$ ○ are also shown in the figure.

Figure 4 shows the concentration dependence of the fraction of $La(H_2O)_9^{3+}$ for various values of ${}^cK_{8,9}$. $\Delta\nu/\eta_r$ values calculated by using Eq. (8) are also given in the figure. The calculated $\Delta\nu/\eta_r$ values range from 140 to 25700 cps$\cdot\eta_r^{-1}$ as ${}^cK_{8,9}$ changes from 1 to 0.0001. However, considering the experimental facts that the highest $\Delta\nu/\eta_r$ observed in this experimental series is about 1000 cps$\cdot\eta_r^{-1}$ and that the change to 8 coordination takes place in the high-concentration range, such low formation constants as 0.01 to 0.0001 and such high formation constants as 1.0 are thought to be unlikely.

Even if we take the values of ${}^cK_{8,9}$ ranging from 0.1 to 0.01, as plausible constants, there are still large deviations from the observed values. However, these deviations may be compensated for if we take into account errors due to the decrease in y_{H_2O} with the concentration increase and due to the change in y_8/y_9. The differences in the kind of anions shown in Fig. 4 may come from the different dependencies of $y_8 \cdot y_{H_2O}/y_9$ on the salt concentration.

Effect of an Additional Electric Field due to Ions. $\Delta\nu/\eta_r$ values for the halides and perchlorate, after reaching the minimum value, increase in the middle to high concentration range. According to Hertz,[7] these increases can be explained as the result of an

additional electric field due to other ions which are spherically distributed around the central ion. He treated ions as point charges which are in a uniform distribution outside of the central ion with a radius of a. However, in strongly dissociated dilute electrolytes, the Debye-Hückel charge distribution is valid. Eisenstadt and Friedman[18] treated them by means of this distribution. In either case, such a relaxation mechanism due to the additional electric field is considered to be the same for both anions and cations. The ratio of the relaxation rate of the cation to that of the anion is, from by modifying Eqs. (31)—(36) of Ref. 7 and Eq. (5.11) of Ref. 18, approximately given by:

$$\frac{\Delta\nu_{\text{anion}}^{\text{ion-ion}}}{\Delta\nu_{\text{cation}}^{\text{ion-ion}}} = A\left(\frac{Q_{\text{anion}}}{Q_{\text{cation}}}\right)^2\left(\frac{(1-\gamma_\infty)_{\text{anion}}}{(1-\gamma_\infty)_{\text{cation}}}\right)^2 \qquad (10)$$

where A is $((2I+3)/I^2(2I+1))_{\text{anion}}/((2I+3)/I^2(2I+1))_{\text{cation}}$, where $(1-\gamma_\infty)$ is the Sternheimer antishielding factor.

To understand whether the relaxation mechanism proposed by Hertz is predominant in this case for both ions, the relaxation rate for ${}^{79}Br$ in the $LaBr_3$ solution has been measured and compared with the theoretical value calculated by using Eq. (10). With the value of $eQ_{La}=0.5e\times10^{-24}$ cm^2, $eQ_{Br}=0.34e\times10^{-24}$ cm^2, $(1-\gamma_\infty)_{La}=69.0$,[19] $(1-\gamma_\infty)_{Br}=98.0$,[20] and A=9.8,

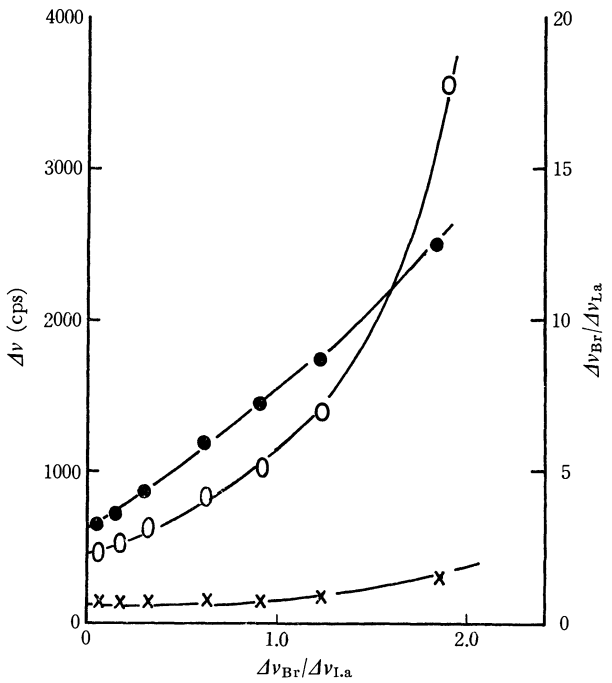

Fig. 5. The concentration dependence of ${}^{139}La$ and ${}^{79}Br$ line widths and $\Delta\nu_{Br}/\Delta\nu_{La}$.
○ ${}^{79}Br$, × ${}^{139}La$, ● $\Delta\nu_{Br}/\Delta\nu_{La}$

the calculated value of Eq. (10) is 10.9. However, it is very hard to obtain an accurate $\Delta\nu_{Br}^{\text{ion-ion}}/\Delta\nu_{La}^{\text{ion-ion}}$ ratio experimentally, since the observed relaxation rate of ${}^{139}La$ consists of two parts:

$$\Delta\nu_{Br}/\eta_r = \Delta\nu^0{}_{Br} + \Delta\nu_{Br}^{\text{ion-ion}} \qquad (11)$$

$$\Delta\nu_{La}/\eta_r = P_8\Delta\nu_8{}^0 + P_9\Delta\nu_9{}^0 + \Delta\nu_{La}^{\text{ion-ion}} \qquad (12)$$

where $\Delta\nu^0{}_{Br}$ is the line width of ${}^{79}Br$ at an infinite dilution. To obtain an accurate $\Delta\nu_{Br}^{\text{ion-ion}}/\Delta\nu_{La}^{\text{ion-ion}}$ ratio experimentally by using Eqs. (11) and (12), it is necessary to ascertain the value of $P_8\Delta\nu_8{}^0+P_9\Delta\nu_9{}^0$; however, this can not be obtained accurately in the present investigation.

Conclusions. Through the study of the ${}^{139}La$ relaxation times, we can draw the following conclusion: a) The line width at an infinite dilution is determined by the rapid exchange of two hydrated species; symmetrical $La(H_2O)_8{}^{3+}$ and unsymmetrical $La(H_2O)_9{}^{3+}$ are the most probable in the solution;
b) In the solutions of nitrate and sulfate, the formation of inner-sphere complexes is thought to be a main reason for the increase in $\Delta\nu/\eta_r$. This explanation is consistent with the result of ${}^{17}O$ NMR study of lanthanide aqueous solutions;[9]
c) The change in the hydration number is found to be the most probable explanation for the decrese in the $\Delta\nu/\eta_r$ of halide and perchlorate solutions, and
d) The effect of an additional electric field gradient due to anions is found to be present, but to be less effective than the other relaxation mechanisms.

The authors wish to express their deep gratitude to Professors Shizuo Fujiwara and Yoji Arata of the University of Tokyo and to Dr. Tadashi Yanagihara for their interest and encouragement during this work.

Four Radical Species Produced Photochemically in the Solid Mixture of Acridine and Acridan

Shigeya NIIZUMA, Hiroshi KOKUBUN, and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received August 11, 1970)

It has been established from measurement of the fusion curve that a 1 : 1 complex of acridine and acridan is formed in the solid state. The complex has an absorption band at 400—500 nm and is considered to be of C-T character although hydrogen bonding plays a role in complexing. Excitation of this complex gives rise to four radical species which display the corresponding characteristic ESR signals *a*, *b*, *c*, and *d*. The line width of *a* (α) and the line separations of *b*, *c*, *d* (β, γ, δ) are $\alpha=18.0\pm3.5$, $\beta=112\pm2$, $\gamma=137\pm5$, $\delta=212\pm6$ gauss. Studies on the dependence of the relative intensities of *a*, *b*, *c*, and *d* upon the acridine-acridan ratio and upon the length of irradiation have led to the conclusion that *a* and *b* are due to C- and N-radicals (the latter, triplet with separation of 44 gauss) and *c* and *d* are two kinds of radical pair. Detection of $\Delta M=\pm2$ transition at 1670 gauss (with 9337.4 MHz) also confirmed the above assignment of *c* and *d*. It is likely that the mutual transformation occurs only during irradiation. It is concluded that C-radical is more stable than N-radical in agreement with the result in fluid state. An interesting decay feature of signal *a* was found and was given a plausible interpretation.

The photoreduction of acridine in the fluid state has been extensively investigated and four main features in the reaction have been elucidated. 1) Photoreduction in alcohols occurs mainly at singlet excited state but a higher $T(n\text{-}\pi^*)$ can participate in the reaction to some extent in methanol and to a very little extent in ethanol.[1-3] 2) Although the lowest $T(\pi\text{-}\pi^*)$is not a reactive state in alcohol, it can be in some cases, for example in tetrahydrofuran.[7] 3) Reaction occurs in general *via* two mechanisms; *viz.*, a molecular mechanism in which no intermediate can be detected by the usual flash technique, and a radical one in which half reduced radical can be captured in a free state.[1,2,8] 4) Two types of radical are produced generally,[9,10] *i.e.*, C-radical and N-radical, with an unpaired electron on 9-C-atom and on N-atom, respectively. Only C-radical is produced in the photoreduction in alcohols,[9]while in the reaction between acridine and acridan, the former yields C-radical and the latter, N-radical. We have been continuing ESR studies on the radical anions[12] and neutral radical species[14] related to acridine and acridan. However, the information obtained on the neutral radical species is still very scanty. We have only succeeded in detecting an ESR spectrum of radical species originating from acridine or acridan in the crystalline medium of benzene, tetrahydrofuran or of t-butanol at 77°K. In these media, the ESR spectrum appeared upon irradiation of acridan (except benzene) or by excitation of acridine in the acridine-acridan mixture. During the course of this work, we found that the mixture of acridine and acridan is colored yellow at 77°K, suggesting the formation of a certain molecular complex.

The present paper deals with an extension of the above work. By irradiating at 430—600 nm, the mixture of acridine and acridan in crystalline benzene medium at 77°K, or by irradiating the mixture with no medium, obtained either by distilling off the solvent or by fusing the mixture of two components, we could detect four types of ESR signal, two of which are due to radicals in the free state, most likely C- and N-radical, and the other two kinds of radical pair. The study on the fused sample was particularly successful and it has been established that a molecular complex, perhaps of C-T type, consisting of 1 acridine and 1 acridan is formed in the solid state having an absorption band ~450 nm. The excitation in this band region produced four different radical species, the behavior of which was studied under various conditions.

Experimental

Materials. Acridine, ethanol, and tetrahydrofuran were purified as described previously.[13] Preparation and purification of acridan were carried out in the same way. Benzene of Wako Junyaku G.R. was used without further purification. *N*-methylacridan was prepared by reducing *N*-methylacridinium iodide (obtained from acridine and

3) According to Kellmann and Dobois,[4] singlet excited state and $T(n-\pi^*)$ are reactive in methanol, while Vander Donkt and Porter[5] concluded that only singlet excited state is reactive in isopropanol. Wilkinson and Dubois[6] claimed that singlet excited state mainly participates in the reaction in ethanol. All these statements are essentially consistent with our data.

methyliodide) by $NaBH_4$. It was recrystallized from ethanol. mp 94.5—95.5°C.

Apparatus and Procedures. As a light source for UV irradiation, an Ushio USH-500 mercury lamp or a Toshiba SHL-100 UV was used and for the visible light irradiation, a tungsten lamp of Kondo 1 kW or 500 W was used. The filters used for visible light, $CuSO_4$ aq. solution—Toshiba VY-43 (or VY-45 or VY-48), for the UV irradiation, Hoya crystal U-2—Toshiba L-1A—water, 1 cm. The former transmits 430 (or 450 or 480) ~600 nm while the latter only 365 nm. In the case of irradiation at shorter wavelengths, the light from a mercury lamp was passed through 1 cm layer of water. Samples were prepared as follows. Removal of the solvent from benzene or tetrahydrofuran solution of acridine and acridan, was performed in a sample tube for ESR by distillation *in vacuo*. The fused sample was prepared by keeping a ESR capillary cell containing a mixture of acridine and acridan in an electric furnace, after having been evacuated and sealed, at temperatures higher than melting point by 5—15°C for 1—5 min. It was then cooled rapidly with water. A JEOL P-10-type ESR spectrometer (X-band 100 Kc modulation) was used for the measurement of $\Delta M=\pm 1$ transition, and a Hitachi Model 771-ESR spectrometer for that of $\Delta M=\pm 2$.[15] Electronic spectra were taken with a Hitachi EPS-3T spectrophotometer.

Results and Assignment of Radical Species

Experiment Using a Sample in a Benzene Medium. A solution of acridine and acridan in benzene colored yellow when frozen. Upon irradiation by 365 nm at 77°K, it turned brown and gave an ESR spectrum. The signal intensity grew rapidly in a few minutes irradiation and then the increase became much more gradual. Figures 1a and b give two examples of ESR signals for acridine: acridan=1 : 2 and 1 : 5, respectively. All the spectra are characterized by four peaks (or shoulders) *a*, *b*, *c*, *d* as shown in the figure. The line width of *a* (ΔH_{msl}) and the line separations of *b*, *c*, and *d* are denoted by α, β, γ, and δ, respectively. Although the relative intensities

15) Thanks are due to Dr. Y. Ikegami and Dr. M. Iwaizumi of Chem. Res. Inst. of Non-Aqueous Solution for use of their instrument.

a, *b*, *c*, and *d* varied according to experimental conditions (for instance, *b* which exists as a shoulder in this figure becomes a peak in some other cases), the values of α, β, γ, and δ remained almost the same. The mean values determined from a number of experiments are

$$\left.\begin{aligned}\alpha &= 18.0 \pm 3.5 \text{ gauss}\\ \beta &= 106 \pm 2 \text{ gauss}\\ \gamma &= 135 \pm 2 \text{ gauss}\\ \delta &= 226 \pm 9 \text{ gauss}\end{aligned}\right\} \quad (1)$$

The g-value of peak *a* was 2.004. As a general tendency, peak *a* becomes stronger with the increase in the mole ratio of acridine to acridan, $[A]/[AH_2]$. An over-all survey of the results leads us to the conclusion that these four peaks (or shoulders) are ascribed to different radical species.

Figure 2 shows the effect of irradiation time upon the intensity ratio (evaluated from the peak to peak height of the differential curve) of *a* and *c* for a sample for which $[A]/[AH_2]=1$.[16] A remarkable change in

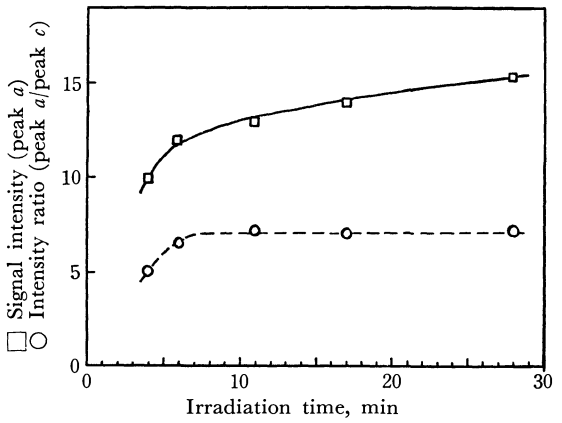

Fig. 2. Effect of irradiation time upon intensity ratio of *a* to *c*. ($[A]/[AH_2]=1$).

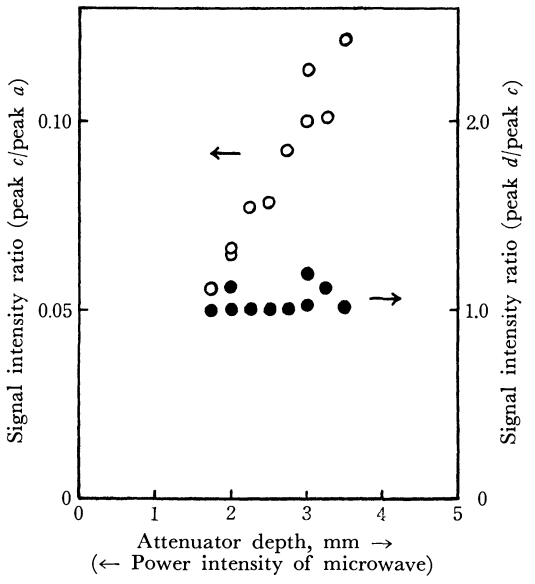

Fig. 3. Effect of microwave intensity upon intensity ratio of *c* to *a* and that of *d* to *c*.

16) It is thought that *b* contributes to the intensity of *c* to some extent.

this ratio during the first seven minutes clearly indicates that *a* and *c* are different species. Figure 3 shows the effect of microwave intensity upon the intensity ratio of *c* and *a* and that of *c* and *d* for the sample, $[A]/[AH_2]=1/2$. It is evident that the former changes remarkably while the latter remains almost constant. This again shows that *a* and *c* are different species.

Although at 77°K the signals are quite stable and the intensity scarcely decreases after being kept for a night in the dark, they decay more rapidly with rising temperature. The temperature effecton the signal shape and the decay rate was examined from −27 to −158°C using the sample for which $[A]/[AH_2]=1$. Since the signal intensities are so weak at higher temperatures that the peaks other than *a* are almost comparable with the noise, the decay could be measured only at peak *a*. It is remarkable that all the decays in the whole temperature region could be analysed as a sum of two first order terms. As an example a decay at −57°C is shown Fig. 4. Furthermore, moderately good Arrhenius plots were obtained for the two rate constants k_S (short lived species) and k_L (long lived species) as shown in Fig. 5. The activation energies obtained are for the former 3.3 and for the latter 3.9 kcal/mol. The values of k_S and k_L at various temperatures are listed in Table 1. It should be noted that the point at 114°K deviates a great deal from the linear plot. Since the second order transition point of benzene exists at 110°K[17] the above anomaly can be ascribed to the different state of benzene medium, if the error in temperature measurement is taken into account. The ratios of the quantity of short lived and long lived species immediately after the interruption of irradiation, which were evaluated by extrapolating the linear part in the later stage (decay of a long lived species), to the time origin, are plotted against the temperature in Fig. 6. There is a clear tendency for a relative yield of short lived species to increase with the rise of temperature. The temperature effect strongly suggests that there are two independent species (or states) with different stability and that the four radical species do not mutually transform thermally. If this were to occur such a simple behavior as obtained would not be expected.

Table 1. Decay constants of short-lived (k_S) and long-lived species (k_L) at various temperatures

Temp., °C	Irrad. time	k_S (sec^{-1})	k_L (sec^{-1})
−158—−160	12 min 4 sec	5×10^{-4}	$2.2_2 \times 10^{-5}$
−131—−134	24 min 40 sec	5.5×10^{-4}	$2.5_0 \times 10^{-5}$
−95— −97	26 min 20 sec	$2.2_4 \times 10^{-3}$	$1.6_7 \times 10^{-4}$
−95	ten several min	6.17×10^{-3}	$5.2_4 \times 10^{-4}$
−89— −92	5 min 35 sec	4.21×10^{-3}	1.02×10^{-4}
−85— −89	15 min 11 sec	4.16×10^{-3}	1.29×10^{-4}
−57	several min	2.50×10^{-2}	1.67×10^{-3}
−27	several min	4.17×10^{-2}	$2.1_7 \times 10^{-3}$

The results obtained for the solid mixture of acridine and acridan prepared by evaporating the solvent (benzene or tetrahydrofuran) were essentially the same as above. The sample was deep yellow at room temperature, suggesting again the strong interaction between the two components. The ESR signals obtained upon 365 nm irradiation at 77°K showed similar spectral feature and spectral change during irradiation.

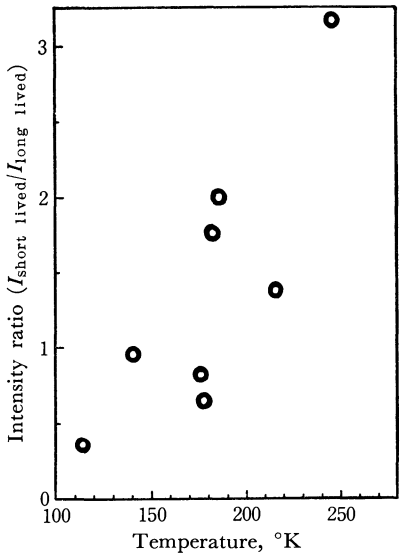

Fig. 6. Ratio of the quantity of short lived and long lived species plotted against temperature.

Experiments Using the Solid Sample prepared by Fusing the Mixture of Acridine and Acridan. The ESR signals obtained in this sample had better S/N ratios than the preceeding ones and the spectral feature could be studied more satisfactorily.

First, the electronic spectrum of the sample was taken by the following procedure. A mixture of acridine and acridan 1 : 1 in ratio was placed between two cover glasses (for melting point determination), and was fused on a hot plate. The liquefied deep yellow mixture spread as a thin film and remained almost transparent after being solidified. The spectrum obtained is shown in Fig. 7. An acridine film prepared similarly as above is shown by a broken line and the two cover glasses by a dotted line. An absorption band is clearly observed in the region 400—500 nm.

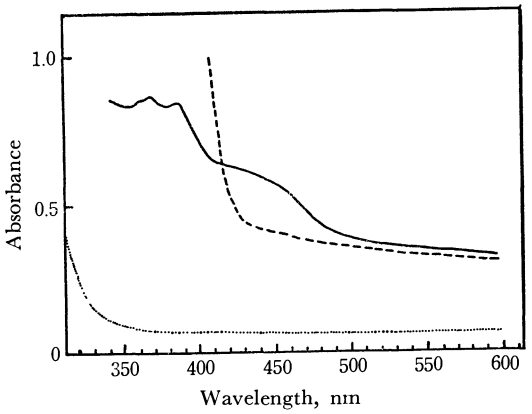

Fig. 7. Absorption spectrum of the mixture of acridine and acridan, 1 : 1 in ratio.

In order to confirm the existence of a molecular complex if any, and determine its composition, melting points of the mixture of acridine (mp 110°C) and acridan (mp 172°C) in various composition were measured. The phase diagram obtained is given in Fig. 8. It is seen that a clear peak exists at a mole fraction of

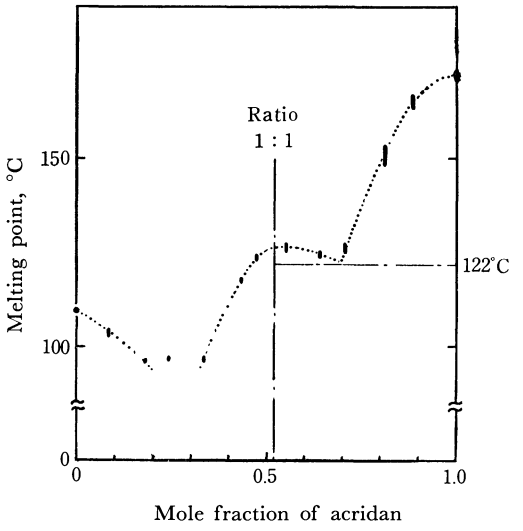

Fig. 8. Fusion curve for the mixture of acridine and acridan.

~0.52 corresponding to 1 : 1 complex. It appears that another peak exists near 0.25 which suggests the formation of 3 : 1 complex.

The ESR signals obtained upon irradiation were found to change considerably in their spectral shape according to the composition, and the assignment of the four species could be made on the basis of these spectral changes. In spite of the change in shape, the values of parameters β, γ, and δ were almost the same as those obtained for the sample in a benzene medium.

$$\left.\begin{aligned}\beta &= 112 \pm 2 \text{ gauss}\\ \gamma &= 137 \pm 5 \text{ gauss}\\ \delta &= 212 \pm 6 \text{ gauss}\end{aligned}\right\} \quad (2)$$

Figure 9 shows a typical example of the spectral change depending on the composition. Mixing ratio [A]/[AH_2] is written on the left, and the exciting light and irradiation time on the right side. Similar signals were obtained by 365 nm- and 480—600 nm-irradiations. From a number of experiments, we could conclude as follows. 1) The relative intensity of peak *a* compared with other peaks increases with [A]/[AH_2]. 2) It increases with the length of irradiation time. 3) The intensity ratio of peak *d* to *c* is scarcely affected by the irradiation time and depends largely on the composition. As a general tendency, it increases with [A]/[AH_2]. 4) Generally the sum of *c* and *d* is relatively large in the low [A]/[AH_2] region and becomes quite small in the high region. Hence in the former case, peak *b* tends to be hidden in peak *c*, while in the latter case it becomes difficult to be observed. 5) The resolution of peak *a* becomes worse whenever peak *b* is prominent.

From 3), there is no doubt that *c* and *d* are due to different species and the spectral shape of *c* and *d* have been made quite clear from (a)—(c) in Fig. 9. If separately drawn, they are certainly of types C and D in Fig. 10. From the line shapes and large line separations, there is scarcely any doubt that they are due to $\Delta M = \pm 1$ transitions of certain radical pairs. If so, the signal due to transition $\Delta M = \pm 2$ should exist at the magnetic field of about half strength. In fact,

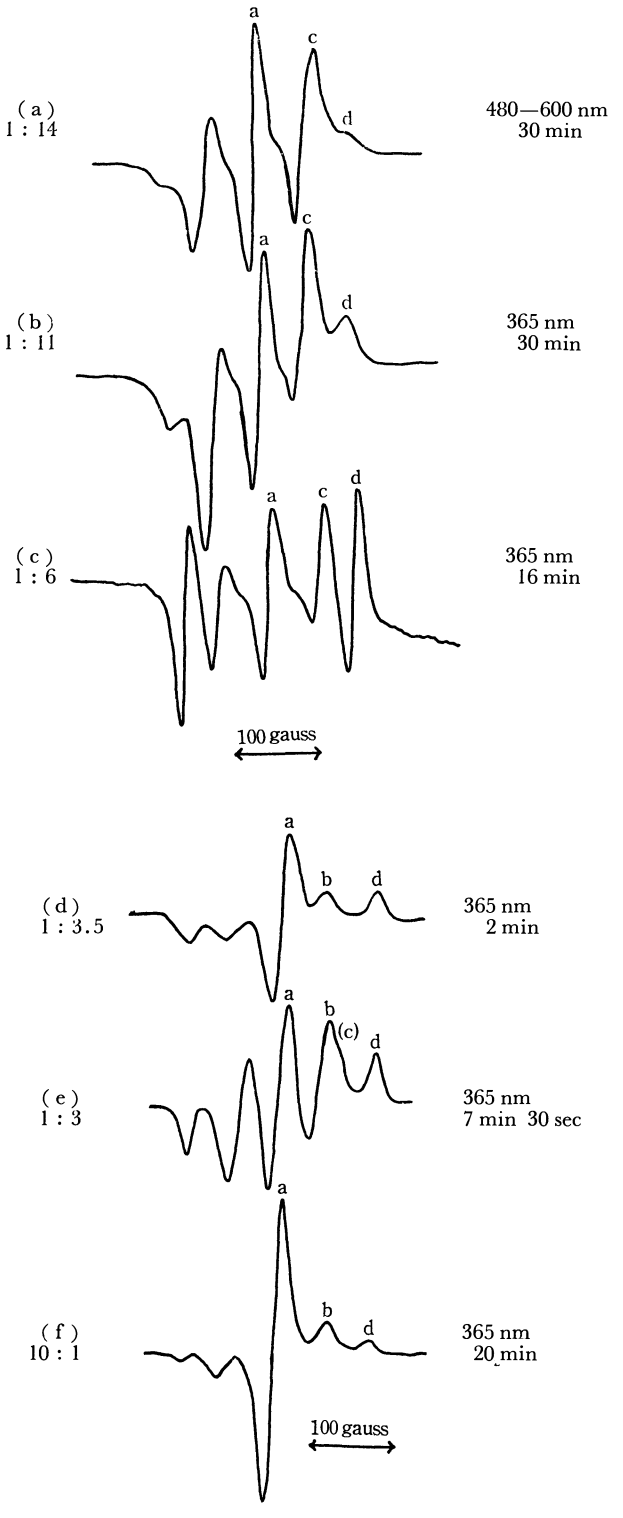

Fig. 9. Some examples of ESR spectrum.

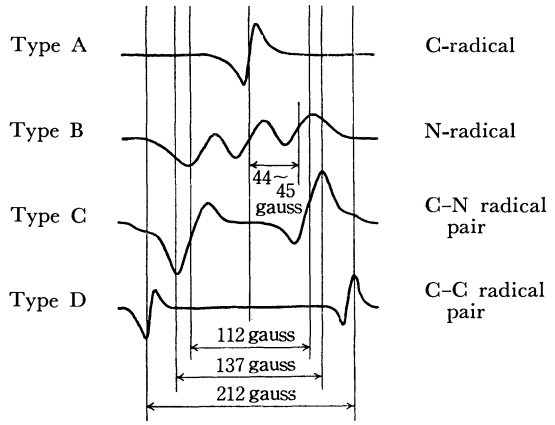

Fig. 10. ESR signal for each radical species.

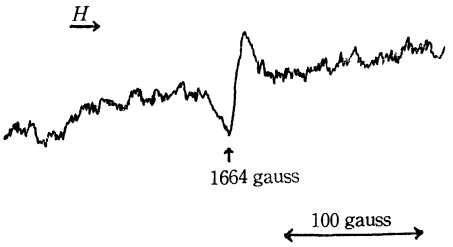

Fig. 11. ESR signal of radical pair due to $\Delta M = \pm 2$ transition.

we could succeed in detecting a signal at 1670 gauss (with 9337.4 MHz) as shown in Fig. 11. The sample composition was acridine : acridan=1 : 5.4. The irradiation was performed for 50 min with no filter, using a 1 kW superhigh pressure mercury lamp. The signals at higher magnetic field in this sample, consisted of peaks *a*, *b*, and *d*. Peak *c* was observable only in a certain period of irradiation. For the measurement of $\Delta M = \pm 2$ transition, the sensitivity was raised 22 times that for the $\Delta M = \pm 1$ measurement. In spite of the above success, it is not certain whether this signal corresponds to type C or D. However, if the two species were to be captured at the same time, they would appear at about the same position and could not be discriminated.

c- and *d*-species now having been identified as radical pairs, unpaired electron distances for *c*- and *d*-species were evaluated by the usual method[18] as 6.0 and 5.1 Å, respectively, from the zero field splitting constant $D=$ 137 and 212 gauss (assuming $E=0$).

a- and *b*-species were assigned as follows. From 5), it can be judged that peak *b* has its component in peak *a*. That the decay for the sample in a benzene medium consists of two first order terms also supports the superposition of the two species. Hence the spectral shape of A and B can be drawn as shown in Fig. 1 . Type A with g=2.004 and $\Delta H_{msl}=18$ gauss always appears under various conditions. Type B is a triplet with a separation of 44 gauss and is easily observed in the high $[A]/[AH_2]$ region. There is scarcely any doubt that *a* and *b* are due to C- and N-radical, respectively, the existence of which has already been fully established in the previous works.[9,11,19] The value of coupling constant 44 gauss is reasonable for ^{14}N taking anisotropy into account.[20]

20) Isotropic and anisotropic hyperfine coupling constants of N-radical in *t*-butyl chloride are (private communication from Dr. T. Shida) $A_{iso}=34.6$ $A_{aniso}=6.80$ gauss.

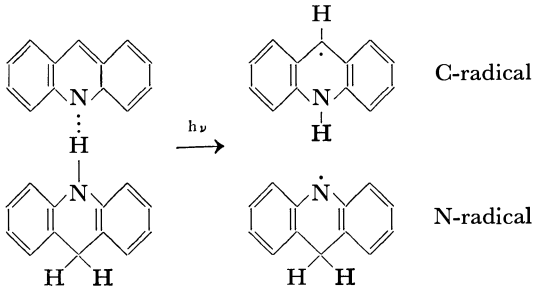
Discussion

Now that the ESR signals of the solid mixture of acridine and acridan have been successfully analysed and the four radical species, N-radical, C-radical and two kinds of radical pair have been identified, the problems to be considered are 1) the primary step for the formation of these species and 2) the nature and behavior of these radical species. They may be answered to some extent on the ground of the present results.

It is most likely that the molecules of acridine and acridan in a solid state interact in such a way that a molecular complex is formed by hydrogen bonding and that the formation of radical species is intimately connected with it. The formation of 1 : 1 complex in a solid state has been fully established by the L-S phase diagram of acridine and acridan in addition to a new band observed in the region 400—500 nm. That the hydrogen bond plays a role in this complex formation, is supported by the following facts. The formation of a similar 1 : 1 complex takes place between 9,9-dimethylacridan having N-H hydrogen and acridine (or 9-methylacridine),[21] whereas according to our experiment, *N*-methylacridine is not colored when it is fused with acridine, and furthermore, a mixture of various compositions (deaerated) never gives the ESR signal upon irradiation at 365 nm at 77°K. Thus it is reasonable to say that the hydrogen bond of N···H-N type is involved in the complex formation.

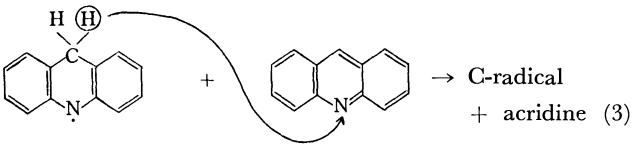
It is well known, however, that in a fluid state acridine and acridan show no sign of such hydrogen bonding. For instance, the electronic spectrum of a mixture of acridine and acridan is a mere superposition of the spectrum of two separated components.[22] In addition, it has been established from the fluorescence quenching experiment that acridan does not form a hydrogen bond with triethylamine which is a most powerful H-acceptor. In view of these facts, the hydrogen bond between acridine and acridan in a solid state must be very weak. Furthermore, the appearance of a new band at 400—500 nm strongly suggests the C-T character of the complex.

The formation of radical species was achieved only by irradiation, but the fact that the light of 480—600 nm is as equally effective as 365 nm implies that excitation of the complex leads to the radical formation in question. Thus we have schematically

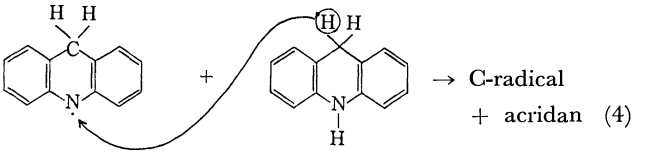


The radical species primarily produced are considered to be a radical pair consisting of C-radical and N-radical and also the equimolar separated C- and N-radicals. During the course of irradiation, however, mutual transformation occurs, and this is the reason why the spectral shape varies according to the experimental conditions.

For the nature and behavior of radical species, we have to be content with a speculative discussion in present stage. Generally the formation of radical pair is considered to depend on the diffusibility of the produced radicals, which in turn is determined by the magnitude of kinetic energy associated with the radicals and also by the rigidity of the medium. In the present case, however, we are tempted to consider the problem in terms of C- and N-radical. Assuming that the mutual transformation occurs only during irradiation, the increase in the yield of C-radical (*a*-species) and also the increase in the ratio of C-radical (*a*-species) to *c*-species both with the increase in irradiation time (finding 2) and Fig. 2) indicates that C-radical is produced efficiently from other species photochemically. The finding 1) that the yield of C-radical increases with the higher $[A]/[AH_2]$ may then be interpreted to be due to the fact that the reaction



occurs photochemically not but the reaction



This is reasonable from the thermodynamic stability of acridine and acridan.

Finding 4) (the yield of N-radical (*b*-species) is small when $[A]/[AH_2]$ is very small) can be interpreted that under such a condition it is difficult for process (3) to occur, and N-radical chiefly exists as a radical pair. This will be supported again from another point of view. The above statements are consistent with Zanker's view as well as ours, *i.e.*, C-radical is more stable than N-radical in the fluid state[7] or in the rigid solvents.[11]

It is most remarkable that the decay of *a* species is reproduced by the superposition of the two first order processes. Since the disappearance of radical occurs only by recombination or disproportionation process, the first order decay may require that radicals exist in pairs and in such neighborhood to each other that mutual attraction favors their encounter but not close enough for the ESR signal of the radical pairs to become observable. As such radical pairs lying apart, the following two are conceivable, *i.e.*, C-C radical pair (apart) and C-N radical pair (apart) (N-N radical pair does not exist appreciably since N-radical cannot exist in excess). If such a hypothesis be admitted,

21) W. L. Semon and D. C. Craig, *J. Amer. Chem. Soc.*, **58**, 1278 (1936); D. C. Craig, *ibid.*, **60**, 1458 (1938).

22) S. Niizuma, Y. Ikeda, and M. Koizumi, This Bulletin, **40**, 2249 (1967).

then a short-lived species may be assigned as C-C radical pair (apart) and long-lived species as C-N radical pair (apart). The higher yield of a short-lived species at higher temperatures is consistent with this assignment, because the N-radical→C-radical process may more easily occur at higher temperatures.

Finally the radical pairs *c* and *d* may be assigned as follows. From the finding that *d* increases with the larger $[A]/[AH_2]$ as compared with *c*, *d*-species may be assigned as C-C radical pair and in consequence *c*-species as C-N radical pair. Finding 4) (*c*-species mainly exists in very low $[A]/[AH_2]$ and the non-appearance of N-radical in this region, *cf. a*, *b*, and *c* in Fig. 9) can be understood by the above assignment, because it is difficult for reaction (3) to occur under such a condition.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 341—347 (1971)

Mechanistic Studies on the Photochemical Oxidation of Phenothiazine with Oxygen in Ethanol

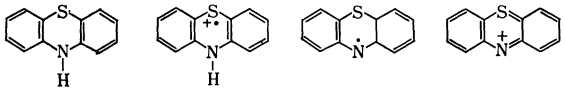
Teiki IWAOKA, Hiroshi KOKUBUN, and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received September 3, 1970)

It has been established that phenothiazine (PTH) undergoes photooxidation, $PTH+O_2 \xrightarrow{h\nu} PT\cdot+HO_2$ in the aerated ethanol (dehydrated!) yielding a neutral radical as a stable product. The reaction is a one photon process and the reactive state is triplet PTH. It has further been established that the reaction occurs *via* a molecular complex (PTH-O_2) most likely of C-T type, which has the absorption at ~385 nm and decays with the first order rate constant of 1.6×10^2 sec^{-1}. A similar transient C-T complex has been found to be produced from triplet PTH and dimethylisophthalate (weak electron acceptor) (absorption ~385 nm, decay constant 2×10^3 sec^{-1}) with almost the diffusion controlled rate constant, although the eventual reaction does not occur. Thus in case of (PTH-O_2), reaction (PTH-O_2)→PT·+HO_2 occurs while in case of (PTH-DMIP), the analogous reaction does not. Behavior of radical species (containing radical cation and (PTH-O_2)) produced in the rigid aerated ethanol at 77°K has also been studied. The present C-T complex is interesting in the point that it is produced *via* triplet state of donor and has a rather long lifetime.

The oxidation reaction of phenothiazine has long been attracting much attention owing to the interest in the pharmacological properties of its substituted derivatives. As Lhoste *et al.* have pointed out,[1] this compound having π-electrons in number differing from $4n+2$ as a result of two heteroatoms in the central ring, is very liable to be oxidized photochemically as well as chemically. It is seen in literature that phenothiazine (PTH) (I) converts by one step oxidation to radical cation (II) or neutral radical (III) according to the experimental conditions, and by the additional oxidation to diamagnetic phenazothionium ion (IV).



(I) (II) (III) (IV)

Shine and Mach[2] who have made systematic studies on the related compounds, observed that I in the aqueous acetic acid transforms to II photochemically but they proposed on the ground of the difference in ESR signals that in 95% aqueous ethanol, III instead of II is produced photochemically. Gilbert *et al.*[3] reported on the other hand, that by oxidation with perchlorate in acetonitrile, II is produced as a perchlorate salt, and in the reaction of II with water in acetonitrile, III is produced as a primay product. According to them, III is also obtained from II by treating it with triethylamine or D_2O. Although it is possible to capture IV electrochemically, for instance by anodic oxidation of I in acetonitrile,[4] II and III are extremely stable under the ordinary conditions. However, reactions of these species have been reported in some systems, for instance, III produced in DMSO-Ac_2O mixture (deaerated) gradually converts to two types of dimer and certain higher polymers.[5] Even at liquid nitrogen temperature, PTH is photooxidized rather easily. For instance, Kasha[6] reported that upon irradiation of PTH in EPA (perhaps aerated), a new absorption peak at 19300 cm^{-1} with another weak band ~22900 cm^{-1} appeared, indicating the formation of II. In addition, ESR studies on II were reported by Odiot and Tonnard,[7] and those of II and III by Shine *et al.*[2] and also by Gilbert *et al.*[3]

In spite of all these observations, there is still no detailed kinetic work made on this photooxidation reaction as far as we know. The purpose of the present investigation is to confirm that the photochemical

oxidation of phenothiazine with oxygen yields III in *pure et hanol* and to elucidate the detailed mechanism of the reaction, by the steady light experiment and by the flash technique. ESR studies on the radical species produced at 77°K have also been made.

Experimental

Materials. Phenothiazine of Tokyo Kasei E.P. grade was recrystallized two times from ethanol. Ethanol of Wako Junyaku G.R. grade was used without further purification unless otherwise described. DMIP of Tokyo Kasei E.P. grade was purified by recrystallization from ethanol, carbon tetrachloride and finally from G.R. grade ethanol. It was then dried *in vacuo* for one day.

Procedures and Apparatus. The 253.7 nm irradiation was made using a Toshiba 6 W low pressure germicidal lamp and the 313 nm irradiation by a Toshiba 100W high pressure mercury lamp using, as a filter, potassium chromate 1×10^{-3} M, 0.05 N NaOH in a quartz cell of 5 mm thickness. The reaction was followed by a Hitachi EPS-3T spectrophotometer. A JEOL P-10-type ESR spectrometer (X-band, 100 kc modulation) was used for the ESR measurement. Apparatus and procedures for the flash experiment are the usual ones employed in our laboratory.

Results and Discussion

Steady Light Experiments. General Feature of the Steady Light Photooxidation: When the aerated solution of PTH in ethanol was irradiated by 253.7 nm or 313 nm, photoreaction of a simple type occurred as shown in Fig. 1. Isosbestic points are observed clearly at 241

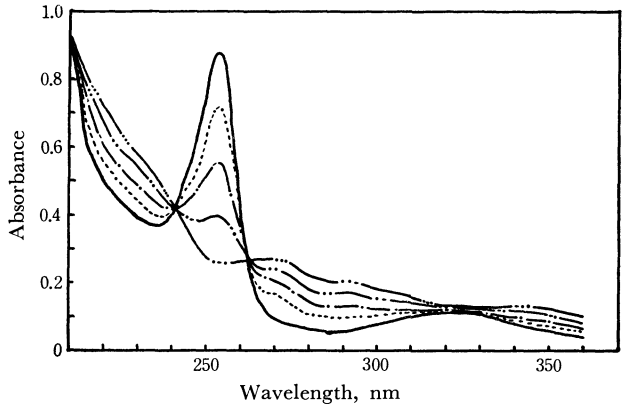

Fig. 1. Spectral change upon illumination (253.7 nm) of the phenothiazine solution in the aerated ethanol; —— 0 sec, ---- 75 sec, —·— 184 sec, —··— 340 sec, —···— 700 sec.
[PTH] = 2.6×10^{-5} M

and 263 nm. The spectrum obtained ultimately kept its shape for a few days. When the solution was degassed, practically no reaction occurred; irradiation for more than an hour caused the decrease of only 0.5% or so in optical density. It was checked that there is no essential spectral difference between the deaerated and aerated solution. The photoproduct was identified as a neutral radical by taking its ESR spectrum; thus the spectrum obtained was almost the same as that of a neutral radical reported by Gilbert *et al.*[3] and was quite different from that of radical cation which for the purpose of comparison, was produced in the concentrated sulfuric acid. It was ascertained further, that the hfs constants obtained by a simulation method agrees aproximately with those reported by Gilbert *et al.*[3] Thus our results have reconfirmed Shine and Mach's statement[2] and that reaction,

$$PTH + O_2 \xrightarrow{h\nu} PT\cdot + HO_2 \qquad (1)$$

occurs in ethanol. We thought however, that it is necessary to examine the effect of the presence of a small quantity of water in view of the experimental conditions employed by the previous workers. For instance, Shine and Mech[2] used 95% aqueous ethanol while Gilbert *et al.*[3] prepared a neutral radical by treating a radical cation (obtained by oxidizing PTH with perchloric acid in acetonitrile) with the buffered aqueous solution of pH 7. We therefore purified ethanol and removed a trace of water with much care and repeated the experiment with the so purified ethanol. The result was essentially the same, except that the kinetic feature of the reaction became a bit simpler (see below) and the quantum yield became a little larger. This may be due to the removal of impurities of aldehyde type, and the possibility of the scheme

$$\left.\begin{aligned} PTH + O_2 &\rightarrow PTH\cdot^+ + O_2^- \\ PTH\cdot^+ + H_2O &\rightarrow PT\cdot + H_3O^+ \end{aligned}\right\} \qquad (2)$$

is rejected.

Effect of Light Intensity: The runs for reaction were satisfactorily reproduced by linear $\ln(e^{\alpha cd}-1)$ *vs.* t plots when the inner-filter effect of photoproduct was taken into account.[8] It is to be noted that purification of ethanol does not alter the feature of the run except a little better linearity of the plot with a little larger slope. As is shown in Fig. 2, the rate of disappearance of PTH (evaluated from the initial slope of the run) is proportional to the light intensity. Thus the main reaction is a one photon process.

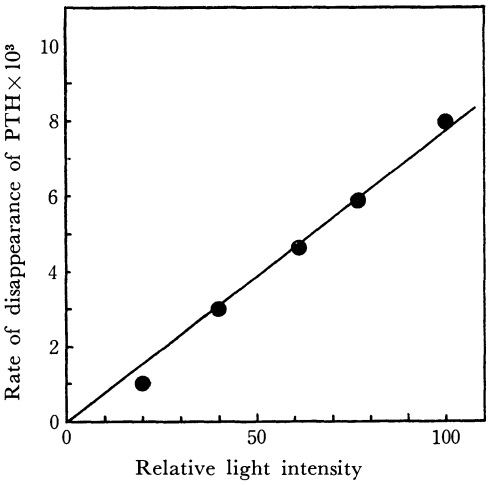

Fig. 2. Dependence of the rate of disappearance of phenothiazine on the light intensity; relative light intensity 100 corresponds to 8.8×10^{-9} M/cm² sec.

8) T. Iwaoka, S. Niizuma, and M. Koizumi, This Bulletin, **43**, 2786 (1970).

The Effect of Oxygen Concentration on the Rate: The overall reaction having been established (except for the reactions induced by HO_2) as

$$PTH + O_2 \rightarrow PT\cdot + HO_2 \quad (1)$$

the effect of oxygen concentration on the rate was examined in order to know the reactive state of PTH. For the system containing $\sim 10^{-6}$ M of oxygen, the rate decreased gradually but recovered by redissolving the oxygen through shaking the sample cell. It is to

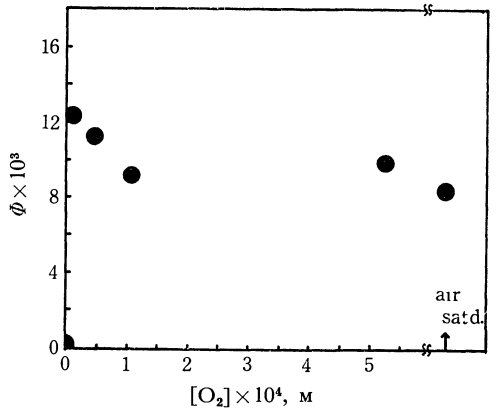

Fig. 3. Effect of oxygen concentration on the quantum yield of phenothiazine disappearance in ethanol; [PTH]= 3×10^{-5} M.

be added that a slight recovery of absorption was observed when the irradiation was stopped. This suggests the existence of very long lived intermediate (see below). Figure 3 gives the plot of quantum yield *vs.* the oxygen concentration. Although a little larger values were obtained at lower concentrations of oxygen, the reason for which is unknown, the quantum yields were almost constant when the concentration of oxygen was larger than 10^{-4} M. This strongly suggests that the triplet state is a reactive one.

The Effect of PTH Concentration on the Quantum Yield: Table 1 gives the quantum yields at various PTH concentrations. Since there is no concentration effect, we may conclude that the participation of the ground state PTH in the later stage of reaction does not occur in any sense.

Table 1. The effect of PTH concentration on the quantum yield, Φ

Studies on the Reaction Mechanism by the Flash Technique. Now that the overall reaction has been established to be very simple, the next problem is to make clear whether the reaction occurs as a real simple reaction or a complex one, and in the latter case to know the composing processes, in particular the primary one. Reasonable schemes other than a simple reaction are

$$\left.\begin{aligned} &PTH + O_2 \rightarrow PTH\cdot^+ + O_2^- \text{ (electron transfer)} \\ &PTH\cdot^+ + O_2^- \rightarrow PT\cdot + HO_2 \end{aligned}\right\} \quad (3)$$

$$\left.\begin{aligned} &PTH + O_2 \rightarrow (PTH\text{-}O_2) \text{ (formation of molecular complex)} \\ &(PTH\text{-}O_2) \rightarrow PT\cdot + HO_2 \end{aligned}\right\} \quad (4)$$

To solve the problem, the behaviors of transient species have been studied by the flash technique.

The Behaviors of Transient Species Produced in a PTH-O_2 System. Figure 4 shows the transient spectra for degassed PTH solutions in ethanol. These are assigned as T–T absorption on the ground that the peak (465

a: 82 μsec, b: 150 μsec, c: 780 μsec after flashing. d is a transient absorption at 82 μsec taken with a panchromatic plate.

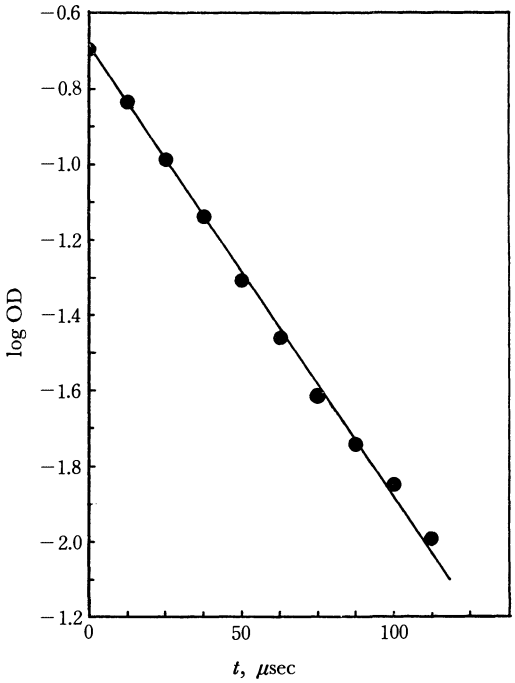

Fig. 5. First order decay of phenothiazine triplet state in deaerated ethanol (470 nm); [PTH] = 1.1×10^{-4} M.

nm) agrees with the peak of T–T absorption (467 nm) (77°K, EPA) reported by Kasha and Henry[6] and that the decay is first order with the rate constant of $1.5\pm 0.4\times10^{4}$ sec^{-1}. This is shown in Fig. 5. The decay curve suggests the existence of a small amount of another long lived species ($\tau_{1/2}$ a few sec) which might be a PTH$\cdot^{+}$ the reason for which will be described later.

In the aerated solutions, the T–T absorption did not appear at all and a new absorption band of small intensity was observed near 385 nm. A principal photoproduct obtained after several flashings was identified as a neutral PT$\cdot$, because the spectral shape was similar to that obtained by the steady light irradiation. A slight difference might be due to the reaction product originating from radical cation. This band (hereafter designated as a X-band and a species giving rise to this band as X-species) decays as a first order process with the rate constant of 1.6×10^{2} sec^{-1}. Figure 6 gives the spectrum drawn from the decay curves at different wavelengths. In parallel with the decay at 385 nm, the absorption increased at 290 nm where the absorption of both photoproduct and the initial PTH exist. This indicates that X-intermediate converts to PT$\cdot$ or reconverts to PTH. When 0.1 N HCl was added to the solution, X-band did not appear and a new band was observed near 510 nm (perhaps radical cation, see below). Thus there is no doubt that X-intermediate is a precursor of reaction PTH$+O_2\rightarrow$ PT$\cdot+HO_2$.

b, 5 msec after flashing

Experiment using DMIP as an Electron Acceptor. We have now reached to the step to elucidate the nature of X-species. To confirm more definitely that it is a molecular complex with oxygen, we have studied the transient species when DMIP instead of oxygen was used as an acceptor. DMIP is a weak electron acceptor[9] and it was expected to act just like oxygen as far as electron transfer is concerned, but not to produce a stable neutral radical because reaction (PTH^{+}-DMIP^{-})$\rightarrow$PT$\cdot+$DMIPH$\cdot$ is not likely to occur. Another reason for performing such an experiment was that the intensity of X-band in the case of oxygen was considered to be too weak to make accurate quantitative studies. This way of attacking the problem has proved to be very successful.

The transient spectra were measured varying the concentrations of DMIP from 10^{-6} to 10^{-2} M at a fixed PTH concentration of 1.14×10^{-4} M. It was established that the eventual reaction does not occur by a number of flashing. As Fig. 7 shows, the transient spectrum

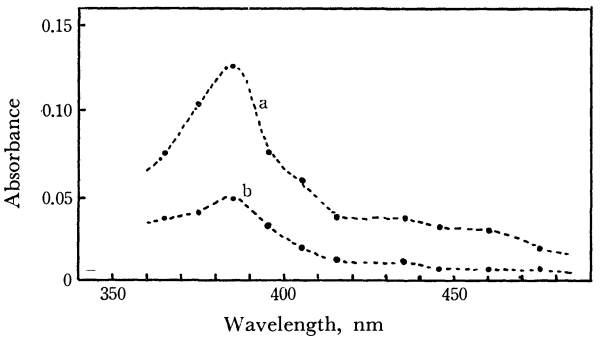

Fig. 7. Transient absorption spectra obtained upon flashing the degassed ethanol solutions of PTH-DMIP; [PTH]$=1.1\times10^{-4}$ M, [DMIP]$=1\times10^{-2}$ M.
a, immediately after flashing
b, 5 msec after flashing

is very much like X-band in the case of oxygen. The decay is first order and the rate constant obtained is 1.7×10^{3} sec^{-1} independent of wavelengths. When the concentration of DMIP was lower than 5×10^{-5} M, T–T absorption of PTH was observed at 420—470 nm. The triplet PTH decayed faster with the increasing DMIP concentration. Figure 8 gives the plot of the

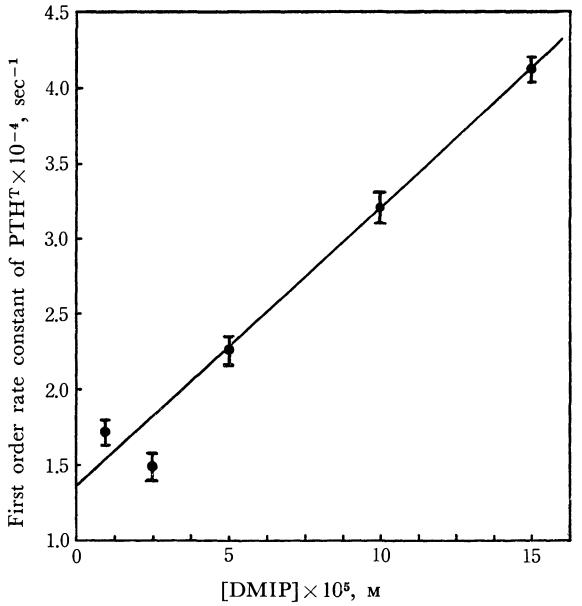

Fig. 8. Dependence of the apparent first order rate constant of phenothiazine triplet state upon the concentration of dimethylisophthalate; [PTH]$=1.1\times10^{-4}$ M.

apparent first order decay constant against [DMIP]. From the slope, the second order rate constant for the disappearance reaction of PTH^{T}, PTH$^{T}+$DMIP$\rightarrow$ was evaluated as 1.9×10^{9} M^{-1}sec^{-1}. The yield of X-intermediate increases with the increases in [DMIP]. Assuming that the interaction between triplet PTH

9) M. Koizumi and H. Yamashita, *Z. Physik. Chem. N. F.*, **57**, 103 (1968); H. Yamashita, H. Kokubun, and M. Koizumi, This Bulletin, **41**, 2312 (1968).

and DMIP consists only of reaction $PTH^T + A \xrightarrow{k_r} X$ (A stands for DMIP), the following equation can easily be derived.

$$[OD_{PTH^T}]_0/[OD_X]_\infty = (\varepsilon_{PTH^T}/\varepsilon_X)(1 + k_d/k_r[A]) \quad (5)$$

where $[OD_{PTH^T}]_0$, optical density of triplet PTH immediately after flashing, $[OD_X]_\infty$, optical density of X immediately after disappearance of PTH^T, and k_d, the decay constant of triplet PTH.

As shown in Fig. 9 the plot of $[OD_{PTH^T}]_0/[OD_X]_\infty$ against 1/[DMIP] gives a straight line as is expected from (5). The rate constant k_r as evaluated from the slope and the intercept, is 1.3×10^9 M^{-1}sec^{-1}. Thus

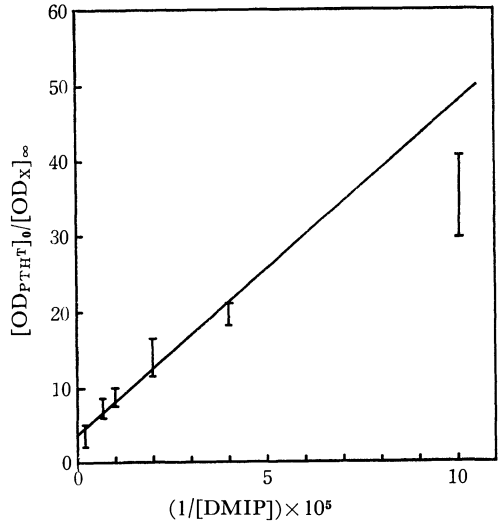

Fig. 9. Plot of $[OD_{PTH^T}]_0/[OD_X]_\infty$ against 1/[DMIP], as obtained at 470 nm; $[PTH] = 1.1 \times 10^{-4}$ M.

it has been verified that the reaction between triplet PTH and DMIP occurs with an almost diffusion controlled rate and produces intermediate X.

Intermediate X in the present system also decays as first order independent of the concentration of DMIP. Table 2 gives the results. It is to be added that a small quantity of a very long lived species ($\tau \sim$sec) is suspected to exist from the decay feature of X. This species appears to decay as second order and may perhaps be a radical cation.

Figure 10 shows the transient spectrum for the PTH solution in the degassed acidic ethanol (0.1 N HCl) containing 2.5×10^{-6} M of DMIP. This agrees with the spectrum of cation radical obtained in *s*-butylchloride by γ-radiolysis[10] and that in H_2SO_4 reported by Shine and Mach.[2] There is no sign of X-band. The decay is second order with the rate constant of $k/\varepsilon = 2.8 \times 10^5$. Thus in an acidic medium intermediate X is not produced and only the formation of radical cation occurs.

We may now conclude that X-species is a molecular compound most likely of C–T character. Although there is a possibility that this is a triplet exciplex, it may perhaps be a C–T complex in the ground state which is unstable as compared with the two separated components. If this is true, the peak position of X-band should be well related with those of other stable complexes. It is well known that the wave number of C–T absorption is linearly related with the electron affinity of the acceptor. Phenothiazine with very low ionization potential of 6.96 eV,[11] forms stable

C–T complexes with a large number of electron acceptors. According to Foster and Hanson,[12] a good linear relation exists between $\tilde{\nu}_{CT}$ and the electron affinity of acceptor. This is shown in Fig. 11. The electron affinity of oxygen is 0.7—0.9 eV and that of DMIP is considered to be a little less than 1.5 eV (the value for phthalic anhydride). The peak position of 385 nm for oxygen and DMIP does not appear to deviate so much from the linear relation of Foster and Hanson as shown in Fig. 11.

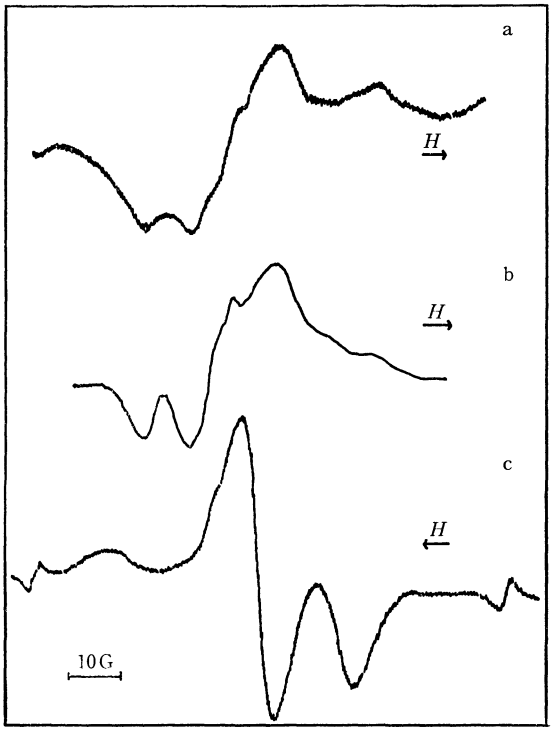

Fig. 12. ESR spectra at 77°K for a) photoproduct obtained upon illumination of the aerated ethanol solution of phenothiazine, b) phenothiazine radical cation in concentrated H_2SO_4, and c) phenothiazine neutral radical produced at room temperature.

Behavior of the Radical Species Produced when the Aerated Solution of PTH in Ethanol was Irradiated at 77°K. To get further information on the radical species related to the present reaction, ESR studies have been made on the photoproduct obtained by irradiation at 77°K. Upon irradiation of the PTH solution in ethanol at 77°K by the light 250—400 or >340 nm, the solution gradually colored from yellow to light brown and the absorption spectrum of the resultant rigid solution displayed peaks at 385 and ~520 nm. This implies that both X-intermediate and the radical cation are formed at 77°K. The ESR spectra observed were of a simple shape independent of the exciting wavelength. Figure 12 shows the ESR spectra for a) the photoproduct, b) the radical cation produced in a concentrated sulfuric acid solution and c) the neutral radical produced at room temperature, all measured at 77°K. The agreement of a) and b) leads to the conclusion that the main radical species produced at 77°K is the radical cation. The colors of the solution for a) and b) were both light brown while that for c) colored pink with a tint of violet. This also supports the above assignment. The formation of the radical cation at 77°K agrees with the observation of Henry and Kasha[6] in EPA. From the above findings, we may conclude that X-intermediate is diamagnetic and reaction (PTH^+-O_2^-)→$PT\cdot+HO_2$ does not occur photochemically.

It is to be added that in the degassed medium, 313 or 365 nm irradiation produces mainly ethanol radical which could be identified by comparing the ESR signals with those reported by Niizuma and Koizumi.[13]

Next, the sample irradiated at 77°K was brought to room temperature. The ESR spectrum showed a complicated structure and was quite different from that of the neutral radical. This sample upon cooling to 77°K, showed the ESR spectrum which clearly showed the coexistence of the neutral and cation radicals. This is very natural since X-species converts quickly to the neutral radical at room temperature. An interesting conclusion which we can draw from this experiment is that the radical cation is rather stable and can coexist with the neutral radical, because it took more than an hour to carry through the above experiment. The radical cation once formed does not seem to transform to the neutral radical so easily.

The results obtained by further irradiation are also interesting. Irradiation by 395 nm for more than two hours at 77°K caused very little formation of the neutral radical. This again indicates the stability of X-species against irradiation. When the radical cation obtained at 77°K was brought to room temperature and was irradiated by the $\lambda>395$ nm light, then the color turned from light brown to pink violet. The ESR spectrum at room temperature clearly showed three peaks due to ^{14}N and at 77°K it consisted mainly of the neutral radical (with a very small contribution of the radical cation). We may conclude that the radical cation when excited, transforms to the neutral radical while the neutral radical is rather stable against irradiation.

General Discussion and Some Future Problems. The present work has established that the final photoproduct for the aerated PTH solution in ethanol at room temperature, is the neutral radical III. On the other hand, a large quantity of radical cation II was produced in the rigid ethanol at 77°K. The reason for this difference may be as follows. The formation of C–T type X-species may require the reorientation of the solvent molecules surrounding donor and acceptor to a higher extent, which is easy to occur at room temperature but not at 77°K. For radical cation II to be formed on the other hand, a pair of radical ions produced, must diffuse apart from each other utilizing the excess energy as the kinetic one of the two components prior to its dissipation to the surrounding medium. This may be more feasible in the rigid medium. The formation of II or III may also depend upon the solvent polarity and also on the acidity and basicity of the medium. For instance, the formation of II may be fovored by the high polarity of the solvent.

12) R. Foster and P. Hanson, *Biochem. Biophys. Acta*, **112**, 482 (1966).

13) S. Niizuma and M. Koizumi, This Bulletin, **41**, 1090 (1968).

As to the stability of radical species, it is easy to understand that III is stable, because the HO_2 radical produced by reaction, $PTH+O_2 \rightarrow PT\cdot+HO_2$ may quickly disappear in the succeeding reactions leaving only PT·. But the finding that radical cation II produced at 77°K can coexist with III for more than an hour, seems somewhat curious; O_2^- produced by reaction, $PTH+O_2 \rightarrow PTH\cdot^+ + O_2^-$ is expected to react according to $PTH\cdot^+ + O_2^- \rightarrow PT\cdot + HO_2$, if HO_2 is more stable than O_2^- in pure ethanol. That II remains stable might be due to reaction $O_2^- + H_3O^+ \rightarrow HO_2 + H_2O$, because the experiment was not performed in the purified ethanol.

Turning to the mechanism for the formation of III, it has been established on the basis of the experiments on PTH-O_2 and PTH-DMIP systems that intermediate X of C–T type is a precursor of the reaction. Further it has been concluded that X reacts as follows in the aerated solution,

$$(PTH^+\text{-}O_2^-) \begin{cases} \nearrow PTH + O_2 \\ \searrow PT\cdot + HO_2 \end{cases}$$

HO_2 disappearing in the succeeding reactions and thus leaving PT· as a stable radical. The reason why DMIP does not give the neutral radical is that reaction

$$(PTH^+\text{-}DMIP^-) \rightarrow PT\cdot + DMIPH\cdot$$

does not eventually occur, because even if it occurs the backward reaction $PT\cdot + DMIPH\cdot \rightarrow PTH + DMIP$ will soon ensue. The effect of environmental medium on the stability of this complex is again an interesting problem. By the analogy of exciplex, the stability may perhaps increase from nonpolar to weakly polar solvents and further, the molecular compound might gradually turn into the ion pair and finally to the separated ions as the solvent becomes from medium to highly polar. In this respect, we have made some preliminary experiments using acetonitrile and cyclohexane as solvents. In these solvents the photooxidation of PTH with oxygen occurred in the same way as in ethanol, $PTH+O_2 \rightarrow PT\cdot+HO_2$, and the transient spectra observed were very much like that of X in ethanol. Table 3 gives the comparison of the quantum yields of reaction (Φ) and the first order rate constant for the disappearance of X-spesies (k) in the three solvents. The results are understandable from the general nature of C–T complex. Thus in moderately polar solvents the complex becomes more stable than in nonpolar solvents. In addition, reaction $(PTH^+\text{-}O_2^-) \rightarrow PT\cdot + HO_2$ may occur more easily in nonpolar solvents. This causes the increase in Φ and may contribute to the increase in the k-value for cyclohexane.

Table 3.

	DK	Φ	k
Ethanol	24.3	6.5×10^{-3}	1.6×10^{2}
Acetonitrile	37.5	1.4×10^{-3}	1.4×10^{2}
Cyclohexane	2.02	2.4×10^{-2}	too fast to be measured

Studies on the solvent effects in the wider scope are desirable.

Studies on the present C–T type molecular complex from various view points will be interesting. Although X-species is most likely a C–T complex in the ground state, still a possibility of triplet exciplex may not be excluded altogether. It is desirable to develop the similar studies using acceptors of various strength including those constituting stable C–T complexes and to investigate their absorption and emission spectra (if any).

Admitting that the present C–T complex is an unstable ground state one, it can be said that it is a very novel type of reaction intermediate. A few years ago we proposed the formation of a somewhat similar molecular complex between eosine and oxygen in the aqueous solution,[14] but it was considered to be a solvent-shared ion pair ($D^+\cdots O_2^-$) having almost the same absorption band as that of free D^+. The present complex is produced in moderately polar solvents and has a quite different absorption band from that of free cation. Moreover, it has quite a long lifetime of more than msec. We believe that this is the first example of a molecular complex in the points that it is produced *via* triplet donor and acceptor and has such significant characteristics. It will be instructive to investigate the general nature of the intermediate of this type.

The Electronic Structure of Zeise's Salt, $[PtCl_3C_2H_4]^-$

Hajime KATÔ

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe

(Received August 13, 1970)

A semiempirical SCF MO method including all the valence electrons in a molecule has been applied to Zeise's salt, which is one of the most simple metal-olefin π-complexes. The electron-repulsion integrals are included explicitly in the present method. The results agree well with the available experimental data, indicating that the C-C bond order is equal to 1.545 and that the ethylene is tightly bound to platinum. An attempt to assign the observed bands to particular electron transitions has been made on the basis of a calculation of the transition energies and transition moments. We identify the band at 40700 cm^{-1} as the charge-transfer band corresponding to the electronic transition from ethylene to platinum. Several properties of Zeise's salt are calculated, and much information on the bonding is obtained.

Since Zeise isolated the first olefin complex, $K^+[PtCl_3(C_2H_4)]^-\cdot H_2O$, known as Zeise's salt,[1,2] a very large number of olefin complexes of platinum and other metals have been reported. Many reviews of the research of metal-olefin complexes have been reported by many investigators.[3–6] Zeise's salt is one of the most simple metal-olefin π-complexes. The research into the structure and bonding mechanism is interesting and important. The X-ray structure determination has shown that the ethylene molecule forms an approximately symmetrical π-type bond with the platinum atom and that the C–C bond length is 1.44(3) Å.[7] Infrared studies of Zeise's salt have been reported by many investigators.[8–14] Recently, Raman and infrared spectra have been obtained by Hiraishi.[15] He identified the C–C stretching frequency as a strong, polarized Raman line at 1243 cm^{-1}, while the two Pt-C stretches were thought to be at 405 cm^{-1} (symmetric) and 493 cm^{-1} (antisymmetric). He concluded that the C_2H_4 group has many similarities to the C_2H_4 group in ethylene oxide and that the ethylene is tightly bound to the Pt(II) atom.

Various electronic structures have been proposed to explain the bonding scheme between the ethylene molecule and platinum, but that scheme was not satisfactorily explained until 1953. Chatt and Duncanson[8] then applied Dewar's description[16] of the bonding in silver-olefin complexes to Zeise's salt. The σ-type bond is formed by the overlap of a $5d6s6p^2$ hydrid orbital of the platinum atom with the filled π-orbital of the ethylene molecule. The π-type bond is formed by the overlap of a $5d6p$-hydrid orbital of the platinum atom with the vacant anti-bonding π-orbital of the ethylene molecule; this is referred to as "back-bonding." This interpretation of the bonding is now generally accepted for metal-olefin π-complexes.[5]

This paper will describe the results of a molecular orbital investigation of the electronic structure and bonding mechanism in Zeise's salt. The electronic spectra of Zeise's salt have been reported,[17–21] and three attempts have been made to assign the observed bands to particular transitions,[19–21] but in their molecular orbital treatment the electron repulsion integrals have not been considered explicitly. The electron-repulsion integrals are considered explicitly in the present semiempirical self-consistent molecular orbital calculation for all the valence electron systems. A new assignment based on the calculation of the excitation energies and on the calculation of the transition moments is proposed in this article. The C–C bond order, the dipole moments, and H-^{195}Pt coupling constant are also discussed.

Method of Calculation

A semiempirical LCAO-MO-SCF method including electron repulsion for all valence electrons is presented. The valence electrons are represented by LCAO molecular orbitals, as given by:

$$\Phi_i = \sum_\nu C_{i\nu}\chi_\nu \qquad (1)$$

where χ_ν's are valence atomic orbitals. We take as a χ_ν Slater-type AO (atomic orbital)[22] centered on each atom:

$$\chi_\nu(n, l, m) = Nr^{n-1}\exp(-\zeta r)\, Y_l^m(\theta, \varphi) \qquad (2)$$

where n is the principal quantum number. We use orbital exponents, ζ's which have been preferably

determined by a variational procedure.[23] For a molecule with a closed-shell configuration, the variational treatment of the orbital coefficients, $C_{\nu i}$, leads to the Roothaan equations:[24]

$$\sum_{\nu} F_{\mu\nu}C_{i\nu} = E_i C_{i\mu}$$

where $F_{\mu\nu}$ are matrix elements of the Hartree-Fock Hamiltonian. The eigenvalues, E_i, are roots of the secular equation:

$$|F_{\mu\nu} - E\delta_{\mu\nu}| = 0$$

Using zero differential overlap approximation, we approximate the matrix elements, $F_{\mu\nu}$, as:

$$F_{\mu\mu} = H_{\mu\mu}^{\text{core}} - 1/2P_{\mu\mu}(\mu\mu|\mu\mu) + \sum_{\nu} P_{\nu\nu}(\mu\mu|\nu\nu), \quad (3)$$

$$F_{\mu\nu(\mu\neq\nu)} = H_{\mu\nu}^{\text{core}} - 1/2P_{\mu\nu}(\mu\mu|\nu\nu), \quad (4)$$

$$H_{\mu\mu}^{\text{core}} = -I_p(\mu) - (N_\mu - 1)(\mu\mu|\mu\mu) - \sum_{\nu(\neq\mu)} N_\nu(\mu\mu|\nu\nu), \quad (5)$$

$$H_{\mu\nu(\mu\neq\nu)}^{\text{core}} = 0.25S_{\mu\nu}[2(\mu\mu|\nu\nu) - (\mu\mu|\mu\mu) - (\nu\nu|\nu\nu) + (\mu|\nu\nu) + (\nu|\mu\mu) - (\mu|\mu\mu) - (\nu|\nu\nu)] \quad (6)$$

where I_p is the valence-state ionization potential, where N_μ is the number of valence electrons occupying χ_μ, where $S_{\mu\nu}$ is the overlap integral between χ_μ and χ_ν, and where $P_{\mu\nu}$ is the charge-density and bond-order matrix:

$$P_{\mu\nu} = 2\sum_{i}^{occ} C_{i\mu}C_{i\nu} \quad (7)$$

The one-center Coulomb repulsion integrals $(\mu\mu|\mu\mu)$ are semiempirically estimated by:

$$(\mu\mu|\mu\mu) = I_p(\mu) - E_A(\mu) \quad (8)$$

The valence-state electron affinities, E_A, are assumed to be equal to the experimental values, and the valence-state ionization potential, I_p, is assumed to be equal to the values of the valence orbital ionization potential (VOIP).[25,26] The required term energies and ionization potentials are taken from Moore's table.[27] The values of I_p and E_A are summarized in Table 1.

Table 1. Valence orbital ionization potential (I_p) and valence state electron affinity (E_A) of AO's

The one-center and two-center Coulomb repulsion integrals are calculated by:[28]

$$(\mu\mu|\nu\nu) = \frac{14.3986}{R + a} \quad (9)$$

$$a = \frac{28.7972}{(\mu\mu|\mu\mu) + (\nu\nu|\nu\nu)} \quad (10)$$

where R is the distance between the centers, μ and ν, with R represented in Å units, and $(\mu\mu|\nu\nu)$, in eV's. The molecular integrals, $(\mu|\nu\nu)$, are evaluated by means of the product of the effective nuclear charge and $(\mu\mu|\nu\nu)$.

The calculated results obtained by this procedure do not vary with respect to an orthogonal transformation of the atomic orbital basis function. This can easily be proved by the invariance of the F-matrix under the unitary transformation.

The molecular dipole moments, μ_{total}, are obtained as a sum of two parts:[29]

(1) A contribution from the net atomic charge densities, Q_A,

$$\mu_{point}(\text{debyes}) = 4.803 \sum_{A}^{atom} Q_A r_A \quad (11)$$

(2) A contribution from atomic polarizations, μ_{atom}(debyes)

$$= 4.803 \sum_{A}^{atom} P_{ns(A),np(A)} \int \chi^A{}_{ns} \boldsymbol{r} \chi^A{}_{np} d\tau \quad (12)$$

where $\boldsymbol{r}$ is the vector of the appropriate cartesian coordinate in units of Å.

Calculations on the $[PtCl_3C_2H_4]^-$ Ion and Results

In order to apply this method of calculation, it is necessary to know the coordinates of the atoms in the molecule. The molecular structure of Zeise's salt in the crystal was determined by X-ray diffraction;[7] it was found that the deviations from ideal symmetry (C_{2v}) are small. The Raman and infrared spectra of an aqueous solution of $K^+[PtCl_3(C_2H_4)]^-$.

H_2O[15] were measured, and it was concluded that the $[PtCl_3C_2H_4]^-$ ion has C_{2v} symmetry, whether the C_2H_4 group is planar or whether the CH_2's are bent

symmetrically toward or away from the Pt atom. The high-resolution proton magnetic resonance spectrum[10] of the $[PtCl_3C_2H_4]^-$ ion in deuterium oxide is in agreement with a symmetrically-co-ordinated ethylene molecule. On the basis of these results, it is reasonable to assume the C_{2v} symmetry for the $[PtCl_3C_2H_4]^-$ ion as the base of the molecular orbital calculations. The spatial arrangement is taken to be as is shown in Fig. 1. The C_2H_4 group is assumed to be planar, and the C–H bond distance and ∠HCH-bond angle are assumed to be equal to that of the free ethylene molecule.

The values of VOIP used in this calculation are as follows, in units of eV: 13.595 for $(1s)_H$, 23.384 for

The calculated orbital energies and the orbital symmetry representations in C_{2v} symmetry are given in Table 2, while the molecular orbitals are given in Table 3*a* and 3*b*.

We present, in Table 4, the valence electron distributions on each atomic orbital and on each atom in the $[PtCl_3C_2H_4]^-$ ion. In order to show the bonding mechanism between platinum and ethylene, we present in Table 5 the overlap integrals and the bond orders between the ethylene π-orbital and the Pt atomic orbitals, as well as those between the π-atomic orbital in 1C and that of in 2C.

Ultraviolet and visible spectra have been reported for the solution and the crystal of Zeise's salt,[17-20] and molecular orbital calculations have been carried out in an attempt to assign the observed bands to particular electronic transitions within the complex.[19-21] In our molecular orbital calculations, the excitation of an electron from the MO Φ_i to the MO Φ_j give rise to the excitation energies, δE_{i-j}, relative to the ground state. These energies are given by:

$$\delta E_{i-j}=\varepsilon_j-\varepsilon_i-J_{ij}+2K_{ij} \quad (13)$$

where ε_i is the orbital energy of Φ_i, and the J_{ij} and K_{ij} are the Coulomb and exchange integrals respec-

tively. The calculated excitation energies and oscillator strengths are given in Table 6.

Calculation of H-^{195}Pt Nuclear Spin-spin Coupling Constant

The high-resolution proton magnetic resonance spectrum of the $[PtCl_3C_2H_4]^-$ ion in deuterium oxide[10] shows a strong singlet attributed to the ethylenic protons with a weak side band, 34 Hz apart, produced by the spin-spin coupling with ^{195}Pt.[30] The most important term giving nuclear spin-spin coupling is the term due to the Fermi contact interaction.[31,32] The Fermi contact coupling is also likely to be the principal contributor to the coupling constant between the hydrogen atom and ^{195}Pt in Zeise's salt, because the electrons on a hydrogen atom are represented by a 1s atomic orbital. By substituting the LCAO MO wave functions in the general Ramsey formulae, the following molecular orbital expression for the Fermi contact spin-spin coupling constant between a particular pair of nuclei, N and N', has been given by Pople and Santry:[33]

$$J_{NN'} = -\frac{64}{9}h\gamma_N\gamma_{N'}\beta^2\sum_i^{occ}\sum_j^{vac}({}^3\delta E_{i\to j})^{-1} \sum_{\lambda\mu\nu\sigma} C_{i\lambda}C_{j\mu}C_{j\nu}C_{i\sigma}\langle\chi_\lambda|\delta(\boldsymbol{r}_N)|\chi_\mu\rangle\langle\chi_\nu|\delta(\boldsymbol{r}_{N'})|\chi_\sigma\rangle \quad (14)$$

where γ_N and $\gamma_{N'}$ are the nuclear magnetic ratios, where β is the Bohr magneton, and where the other notations are in accordance with those in Ref. 32.

Using the results of the above MO calculations, we have calculated the H-^{195}Pt coupling constant on the basis of Eq. (14). The formula involves the value of the valence $(6s)_{Pt}$ atomic orbital at platinum: the magnitude at the center is important in the calculation of the H-^{195}Pt coupling constant. Accordingly, it is necessary to use a $(6s)_{Pt}$ atomic orbital accurate at the center of platinum in order properly to evaluate the molecular integrals, $\langle x_\nu|\delta(\boldsymbol{r}_N)|x_\mu\rangle$. The analytical wavefunctions accurate at the inner part have been calculated for a number of atoms.[34-36] However, so far these calculations have not been reported for platinum. Accordingly, we have employed an approximate analytical (6s) wavefunction for radon as (6s). The values of the atomic orbitals at platinum and at the proton (1H) are given in Table 7. It can easily be seen that the values of $\langle(1s)_H|\delta(\boldsymbol{r}_H)|(1s)_H\rangle$ and $\langle(6s)_{Pt}|\delta(\boldsymbol{r}_{Pt})|(6s)_{Pt}\rangle$ are dominant over the other molecular integrals, $\langle\chi_\lambda|\delta(\boldsymbol{r}_H)|\chi_\mu\rangle$ and $\langle\chi_\nu|\delta(\boldsymbol{r}_{Pt})|\chi_\sigma\rangle$ respectively. Thus, we have obtained -40.4 Hz as the calculated value of the H-^{195}Pt coupling constant; this indicates that the ethylene is firmly bound to

platinum. This calculated value is in very good agreement with the observed value of 34 Hz. The sign of the experimental coupling constant is not known, but the theoretical calculation shows it to be negative.

Discussion

The signs and magnitudes of molecular orbital coefficients (Table 2*a* and 2*b*) indicate that the ethylene π^*(anti-bonding) orbital is included in the highest occupied orbital, Φ_{22}. This is consistent with the π-type bond which is referred to as "back-bonding." The ethylene π(bonding) orbital is included in the Φ_{15} and Φ_{19} orbitals. This is consistent with the σ-type bond.[8] The form of the molecular orbitals, Φ_{22} and Φ_{15}, are shown schematically in Figs. 2 and 3. These results show essentially the same bonding mechanism as when Chatt and Duncanson[8] applied Dewar's[16] description to Zeise's salt, but it should be pointed out that the mixing of the ligand chlorine atomic orbitals with these molecular orbitals is considerably large. It should also be pointed out that the ethylene π^* orbital is included in the vacant molecular orbital, Φ_{28}.

The importance of the *trans*-effect caused by ethylene should also be noted. A review[37] of the *trans*-effect favored the π-bonding mechanism for the *trans*-effect of olefins,[38] in which a ligand olefin which can form π-bonds will with draw some of the electron density of the d_{yz} orbital from the ligand in the *trans* position. Moreover, it was pointed out that this should weaken the Pt-X(*trans*) bond. Certainly it does (see Fig. 2) but we should also note that the σ-type bonding (see Fig. 3) strengthens the Pt-Cl(*cis*) bond, but not the Pt-Cl(*trans*) bond.

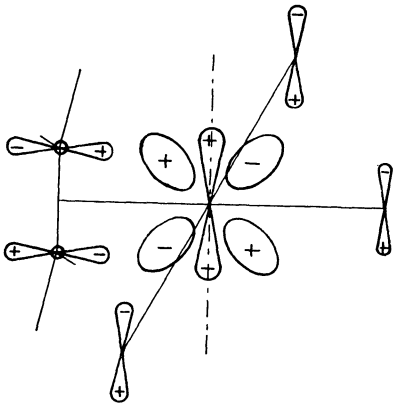

Fig. 2. Shematic scheme of MO Φ_{22}, illustrating the π-type bonding.

The ionization potential of a molecule should, according to Koopmans' theorem,[39] be approximately equal to the calculated orbital energy of the highest occupied orbital multiplied by -1. We can see in Table 1 that the calculated ionization potential of the $[PtCl_3C_2H_4]^-$ ion is equal to 6.40 eV. The experimental ionization potential of this salt has not been reported, but this calculated value seems to be reasonable with respect to the ionization potential of platinum. The orbital energy of the lowest vacant orbital, Φ_{23}, is slightly negative. Nevertheless, the over-all picture of orbital energies is very encouraging in comparison with the negative values of the vacant molecular orbitals in the calculation of many sorts of metallic compounds.[40-42]

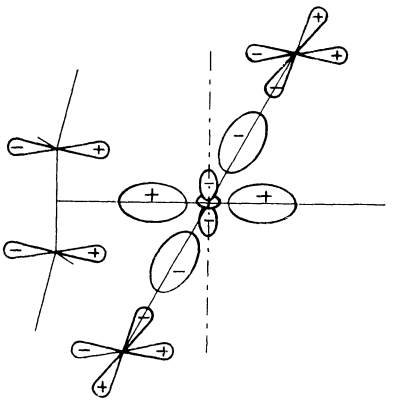

Fig. 3. Shematic scheme of MO Φ_{15}, illustrating the σ-type bonding.

Let us now consider the valence electron distributions obtained from the calculations (Table 3). The electrons of the protons in ethylene are redistributed to the carbons. The excess charge, (-e), is redistributed to platinum and chlorines. It should be noted that the electrons in the 5*d* orbitals in platinum are largely redistributed to the 6*p* orbitals. This redistribution can be considered to be due to the large contribution of 6*p* orbitals to the bonding of platinum with the ethylene molecule, as can easily be seen from the form of the molecular orbitals in Tables 2*a* and 2*b*. Our method predicts the dipole moment of $\mu_{total}=2.772$ debyes for the $[PtCl_3C_2H_4]^-$ ion, where $\mu_{point}=2.035$ debyes and $\mu_{atom}=0.737$ debyes. From the experimental dipole moments of compounds of the C_2H_4, amine, $PtCl_2$ type, Chatt and Duncanson[8] estimated that the dipole moment of the C_2H_4-Pt bond has a value of about 4 debyes. Our calculated result is in good agreement with their estimated value.

Let us next consider the data on the overlap integrals and bond orders between the ethylene π-orbital and platinum atomic orbitals (Table 4). From the signs and magnitudes of the overlap integrals and bond orders, we can understand the bonding mechanism due to the formation of the σ-type bond and the π-type bond. As can easily be seen, the total σ-type bond order is equal to 0.833, while the total π-type bond order is equal to 0.777. Accordingly, the bonding between ethylene and platinum is found to be through both the σ- and the π-type bonds. The calculated

ethylene π-bond order is reduced from 1.0 to 0.545 by forming a bond with $PtCl_3$. Thus, the C–C bond order is reduced from 2.0 to 1.5. This is consistent with the experimental results.

Let us now consider the assignment of the electronic spectra. We will not, in contrast to previous authors,[19,20] discuss the assignment on the basis only of the arrangement of the electronic energy levels (see Eq. (13)). Since the $[PtCl_3C_2H_4]$ ion is a molecule of low symmetry (C_{2v}), there are many group theoretically-allowed transitions. In spite of this fact, the number of probable transitions is reduced to a relatively small number by calculating the transition moments and neglecting the small ones. The transitions given in Table 5 are those which satisfy the following conditions: 1) the calculated oscillator strength (f) is larger than 10^{-3}, and

2) the excitation energy is smaller than 50000 cm^{-1}. Considering the intensities of the absorption spectrum and the calculated oscillator strengths, we can identify the band at 40700 cm^{-1} as $\Phi_{18a_1}-\Phi_{23b_1}$ ($^1A_1-^1B_1$), that is, the charge-transfer band corresponding to the transition from ethylene to platinum. The band at 37450 cm^{-1} may also be identified as $\Phi_{22b_1}-\Phi_{26b_1}$ ($^1A_1-^1A_1$) and the band at 33450 cm^{-1}, as $\Phi_{20a_1}-\Phi_{24b_1}$ ($^1A_1-^1B_1$). The calculated excitation energies for these transitions are 44448 cm^{-1}, 35018 cm^{-1}, and 34784 cm^{-1} respectively, showing good agreement with the experimental results. Previously, three attempts[19,20] have been made to assign the observed bands to particular electron transitions within the complex, but the three assignments are different. The present assignment is also different from previous ones and indicates that there is considerable mixing of the component atomic orbitals.

The magnitude of the spin-orbit interaction is given by ζ.[43] For the platinum $(5d)^9(6s)^1-^3D$ multiplet, the ζ-value is calculated to be [27] $\zeta=388$ cm^{-1}. In this molecular orbital treatment we do not consider the effect of spin-orbit coupling, although this effect is indefinably included through the evaluation of the VOIP's. However, this effect should be precisely considered if one wants to assign the small intensity bands of the polarized spectrum of crystal Zeise's salt.

The author wishes to thank Professor Hiroshi Kato for a very instructive discussion of this article. He also wishes to thank Professor Teijiro Yonezawa for his generous support of this work.

ESR and Optical Studies on the EDA Complexes of Di-*t*-butyl-*N*-oxide Radical

Yoshifumi MURATA and Noboru MATAGA[1]

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received August 20, 1970)

It has been confirmed that di-*t*-butyl-*N*-oxide (DTBNO) forms EDA complexes with various electron acceptors, and the resulting complexes show CT (charge transfer) absorption bands. Wave-numbers of the CT bands agreed satisfactorily with theory. Charge distributions in the EDA complexes of DTBNO, including hydrogen bonded complexes with proton donors, have been investigated by means of ESR. From the effect of the EDA complex formation upon the hyperfine coupling constant of ^{14}N of DTBNO, contribution of electrostatic forces to complex formation has been demonstrated. However, in the case of complexes with strong acceptors such as tetracyanoethylene, the values of the hyperfine coupling constant have indicated a significant contribution of CT interaction to complex formation.

The structures and properties of the EDA complexes have been studied extensively and are being subjected to active investigation. Among organic molecular complexes, there are numerous EDA complexes consisting of molecules with closed shell ground state.[2] However, little investigation has been carried out on the complexes in solution which have unpaired spins in the electronic ground state.

Studies on the ground state of molecular complexes have supported the CT theory,[2] but there are still some questions concerning the extent to which the classical electrostatic forces contribute to the binding energy and dipole moments of EDA complexes, especially in the case of weak complexes.[3-5] For example, Hanna[4] has shown that quadrupole-induced dipole forces may be comparable to CT forces in importance in explaining the stability of benzene-iodine and of similar complexes. Other authors have also insisted that the multipole-multipole and multipole-induced multipole interactions are important for the stability of π–π type EDA complexes.[3] Nevertheless, it seems

that there is no direct evidence for the predominant contributions of the electrostatic forces to the interactions in the complexes.

Elucidation of the above problem and CT interactions can be achieved by measurement of the ESR spectra of complexes which have unpaired spins in the ground state.

Since almost all radicals with doublet ground state are unstable, ESR studies are possible only for some complexes involving exceptionally stable radicals. We have found that DTBNO forms stable complexes with some electron acceptors, and studied the complexes by means of optical as well as ESR spectral measurements.

Experimental

The absorption spectra were measured with a Cary 15 spectrometer and a Shimadzu MPS-50L spectrophotometer. ESR spectra were recorded by a JES-3BX spectrometer of Japan Electron Optics using X-band.

DTBNO was synthesized according to the method given in literature,[6] and was purified by repeated distillation under reduced pressure. The purified sample was distilled in a vacuum and sealed off in parts. Tetracyanoethylene (TCNE) was recrystallized several times from monochlorobenzene and was sublimed in vacuum. Purified sample of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) was kindly supplied by Dr. Y. Sato of this institute. Chloranil was recrystallized twice from benzene. 2,5-Dichloro-*p*-benzoquinone (DQ) and phthalic anhydride (PA) were sublimed under reduced pressure. Phenol was carefully distilled. Pyromellitic dianhydride (PMDA) was recrystallized twice from ethylacetate. *s*-Tetracyanobenzene (TCNB) was the same sample as used before.[7] It was recrystallized several times from ethanol and sublimed in a vacuum before use.

Cyclohexane and *n*-hexane were passed through a column of activated silica gel twice, dried over metallic sodium, and distilled. Toluene and benzene were shaken with sulfuric acid, neutralized, and distilled. The distillate was passed through a column of activated silica gel, dried over metallic sodium and distilled. Tetrahydrofurane (THF) was refluxed over metallic sodium fifty hours, and distilled. Other solvents were purified by the methods described in literature.[8]

For ESR measurements, solutions in the sample tube were carefully deaerated by an ordinary procedure with an evacuating system equipped with a rotary and oil diffusion pump.

Results and Discussion

A. Optical Absorption Spectra. The visible absorption spectrum of DTBNO in *n*-hexane is given in Fig. 1. This absorption band can be assigned to the n–π^* transition.[9] When amines which can act as electron donors in the complex formation, are added to the solution of DTBNO, or when they are used as solvents for DTBNO, the absorption spectrum of DTBNO does not change. As will be discussed later in detail, the hyperfine coupling (hfc) constant due to

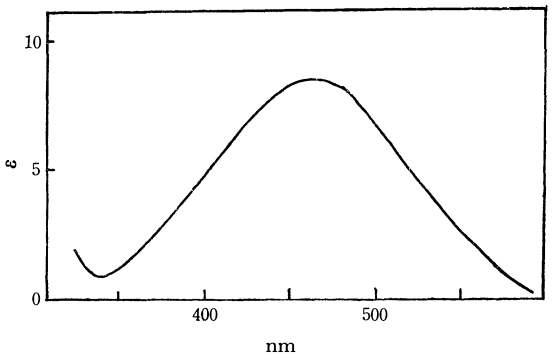

Fig. 1. Visible absorption spectrum of DTBNO in *n*-hexane at room temperature (~23°C).

the nitrogen atom of DTBNO dissolved in *N,N*-dimethylaniline (DMA) is almost the same as when it is dissolved in monochlorobenzene. The ionization potential of DMA is much smaller than that of monochlorobenzene while their dipolemoments or static dielectric constants are almost equal. Thus, it seems certain that DTBNO hardly works as an electron acceptor.

On the other hand, when a strong electron acceptor such as TCNE or DDQ is added to the DTBNO solution, we can observe a new absorption band as indicated in Fig. 2. In a sufficiently polar solvent such as acetonitrile, we can observe clearly that the DTBNO-TCNE

system undergoes ionic dissociation and there arises the anion radical of TCNE (Fig. 3). The reaction of ion radical formation is not very rapid, and the produced TCNE anion is fairly stable even in the air.

We have examined the origin of the new absorption band in Fig. 2 by the method frequently used for usual EDA complexes. Application of the Benesi-Hildebrand equation[10] to the three component system, TCNE-DTBNO-diethylether, gives a good linear relation as shown in Fig. 4, from which the equilibrium constant for the complex formation has been evaluated to be 4.0 *l*/mol. Thus it is certain that DTBNO forms 1 : 1 complex with TCNE.

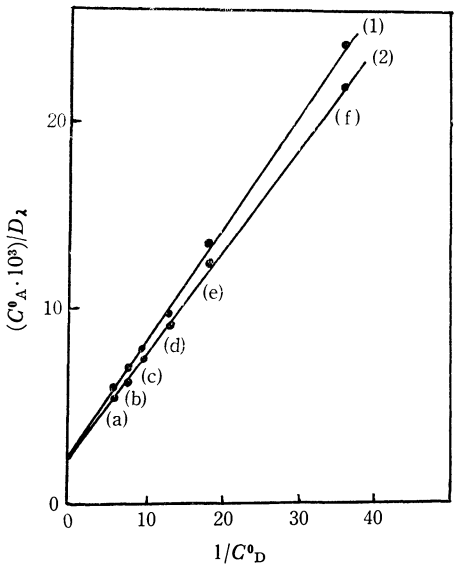

Fig. 4. Benesi-Hildebrand plot for DTBNO-TCNE system in ether at room temperature (~23°C). C^0_A and C^0_D are analytical concentrations of TCNE and DTBNO, respectively.
$C^0_A = 2.57 \times 10^{-3}$ M.
C^0_D: (a) 1.6×10^{-1} M, (b) 1.3×10^{-1} M, (c) 1.0×10^{-1} M, (d) 7.7×10^{-2} M, (e) 5.6×10^{-2} M, (f) 2.8×10^{-2} M.
1. at 850 nm, 2. at 790 nm.

The wavelengths of the new absorption bands which appeared when various electron acceptors are added to the solution are listed in Table 1. We see that the

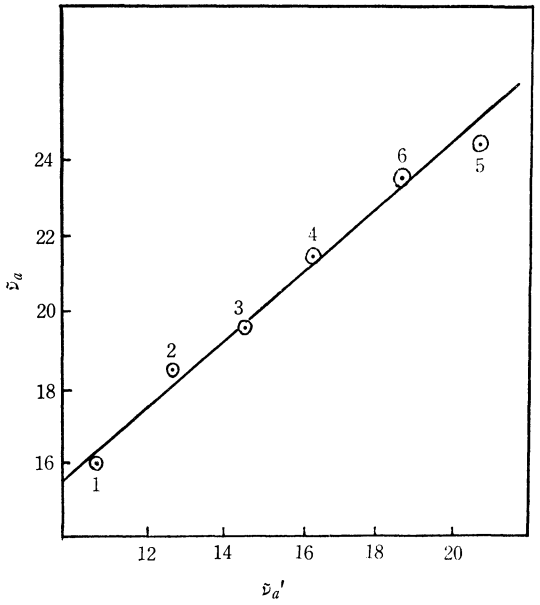

Fig. 5. Relation between the band maxima of the hexamethylbenzene complexes ($\tilde{\nu}_a$) and those of the DTBNO complexes ($\tilde{\nu}'_a$) for the common acceptors. See Table 1 for the numbering of the points in the figure.

larger the electron affinity of the acceptor, the longer the wavelength of the absorption band. Furthermore, we have compared the wavenumbers of the absorption bands of DTBNO-acceptor systems with those of the CT absorption bands of hexamethylbenzene complexes with the same acceptors. As shown in Fig. 5, we have a linear relation which can be written approximately as

$$\tilde{\nu}'_a = \tilde{\nu}_a + \text{Const.} \quad (1)$$

For ordinary EDA complexes, the energy of the CT absorption band is approximately given by

$$h\nu_{CT} = I_D - E_A + C \quad (2)$$

where I_D, E_A, and C are ionization potential of the donor, electron affinity of the acceptor, and the interaction term including the coulomb energy between the ion-pair, respectively. The corresponding equation for the DTBNO complexes may be written as

$$h\nu_{CT}' = I_D' - E_A + C' \quad (3)$$

where I_D' is the ionization potential of DTBNO. Thus we have

$$\tilde{\nu}'_{CT} \approx \tilde{\nu}_{CT} + \text{Const.} \quad (4)$$

From the above arguments, it has been confirmed that DTBNO forms EDA complexes with various electron acceptors and the new absorption band due to the complex can be ascribed to the CT transition.

In connection with the CT interaction, we have examined the hydrogen bonding of DTBNO with several proton donors. The solvent effect upon the wave number of the visible absorption band of DTBNO is indicated in Table 2 and Fig. 6. In Fig. 6, the wave number is plotted against the factor $[(\varepsilon-1)/(\varepsilon+2)-(n^2-1)/(n^2+2)]$, where ε and n are the static dielectric constant and the refractive index of the solvent, respectively. The solvent shift of the electronic spectrum, when the short range interactions such as molecular complex formations are absent, can be given as a function of ε and n. As an example, the equation given by McRae[11] is

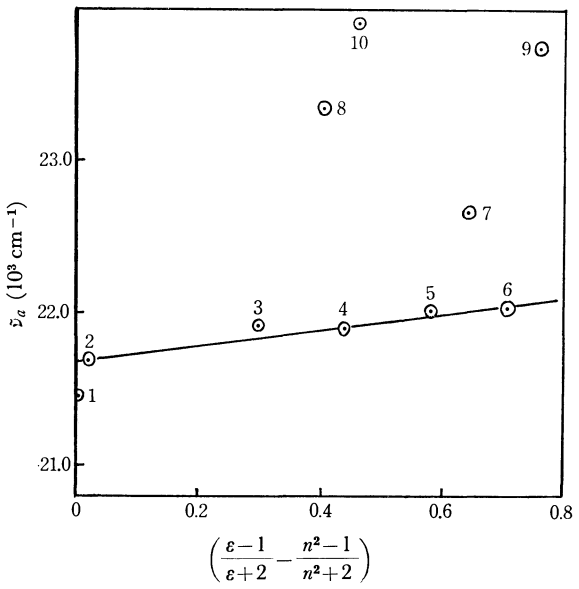

Fig. 6. Solvent shift of the absorption band of DTBNO. See Table 2 for the numbering of the points.

$$hc\Delta\tilde{\nu}_a \approx (AL_0+B)\frac{(n^2-1)}{(2n^2+1)} + C\left(\frac{\varepsilon-1}{\varepsilon+2}-\frac{n^2-1}{n^2+2}\right) + D\left(\frac{\varepsilon-1}{\varepsilon+2}-\frac{n^2-1}{n^2+2}\right)^2 \quad (5)$$

The second term on the right hand side of Eq. (5) comes from the permanent dipole-permanent dipole interaction between the solute and solvent molecules. The contribution of this term will be predominant in the present case, since DTBNO has a large dipolement (3.08D) in the ground state. As we see from Fig. 6, $\tilde{\nu}_a$ is approximately linear with respect to $[(\varepsilon-1)/(\varepsilon+2)-(n^2-1)/((n^2+2)]$ when the solvent is not likely to form the hydrogen bond with DTBNO (from this linear relationship, we have estimated the dipole-moment of DTBNO in the lowest excited state to be 2.6D.). In the case of the solvent which seems to form hydrogen bond with DTBNO, the blue shift of the spectrum is large and the deviation from the linear relation is remarkable. The spectral behaviors in the hydrogen bonding solvents are quite similar to those of the n–π^* transitions of ordinary closed shell molecules. Of course, the hydrogen bonding interaction may also affect the distribution of the unpaired electron of DTBNO.

11) E. G. McRae, *J. Phys. Chem.*, **61**, 562 (1957).

In order to make a more detailed study of the hydrogen bonding effect on the absorption spectrum, we have examined the three component system DTBNO-phenol in toluene. It is evident from Fig. 7 that there arises 1 : 1 hydrogen complex. We have evaluated equilibrium constant to be 6.4 *l*/mol at room temperature.

When trifluoroacetic acid, a strong proton donor, was added to the benzene solution of DTBNO, the visible absorption band of DTBNO vanished completely and a new absorption band with a maximum at *ca.* 700 nm appeared. In contrast to the case of DTBNO-phenol-toluene system, this benzene solution showing the new absorption band does not show any ESR signal. We have observed the absorption band at 700 nm also for the acetic acid solution of DTBNO when a small amount of concd. sulfuric acid is added to the solution. Although the origin of this long wavelength absorption band is not clear, it may be due to some product of unknown reaction occurring in a strongly acidic media.

B. ESR Spectra. The ESR spectrum of DTBNO in toluene solution at room temperature is shown in Fig. 8. It is possible that, in a highly concentrated

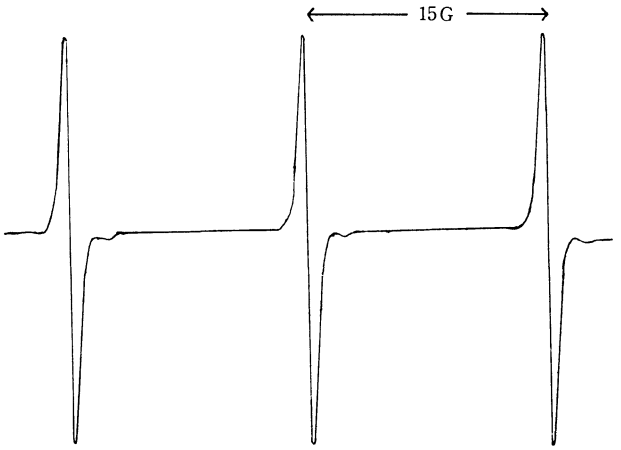

Fig. 8. ESR spectrum of DTBNO in toluene. Concentration of DTBNO: 10^{-4} M.

solution, DTBNO forms a cluster which has a spin multiplicity greater than doublet. However, the ESR spectrum due to triplet or higher multiplet state could not be observed at room temperature. At 77°K the mixtures of DTBNO and cyclohexane (volume ratio 1 : 1 and 1 : 10) showed ESR spectrum due to triplet state ($\Delta m=2$ transition). From the spectrum we can evaluate the dipole-dipole interaction parameter D, which is directly related to the separation between two unpaired electrons. D/hc was found to be 0.0370 $cm.^{-1}$ By using the equation[12]

$$\tilde{r}_{12}=(2|D|/3\,g^2\beta^2)^{1/3} \tag{6}$$

the average separation $\tilde{r}_{12}$ between two unpaired electrons was evaluated as 4.2 Å.

Hirota[12] measured D/hc and $\tilde{r}_{12}$ for some ion radical pairs. For the anion radical of hexamethylacetone with lithium cation as gegen ion: $D/hc=0.0210$ cm^{-1} and $\tilde{r}_{12}=5.0$ Å. For the same radical with sodium cation: $D/hc=0.0155$ cm^{-1} and $\tilde{r}_{12}=5.6$ Å. Since these radical pairs are ion-pair dimers, *i.e.* the gegen ion is placed between the two radical ions, their $\tilde{r}_{12}$ values are a little larger than that of DTBNO dimer. Though DTBNO molecules have bulky *t*-butyl groups which can more or less hinder the interactions between unpaired electrons, they can approach each other to form a triplet state dimer.

Let us examine the effect of the EDA complex formation on the ESR spectrum.

$$A + \dot{D} \rightleftarrows (A\dot{D}) \tag{7}$$

According to Gendell *et al.*,[13] when the complex formation and dissociation reaction of Eq. (7) is very rapid, the observable hfc constant $\bar{a}$ is given by

$$\bar{a}=\frac{1}{2}(a_D+a_{AD})+\frac{1}{2}(K[A]-1)/(K[A]+1)\,(a_{AD}-a_D) \tag{8}$$

where a_D and a_{AD} are the coupling constants of $\dot{D}$ and $A\dot{D}$, respectively, and K is the equilibrium constant of complex formation.

Equation (8) can be rewritten as[13]

$$\bar{a}=a_{AD}-\left(\frac{1}{K}\right)(\bar{a}-a_D)/[A]. \tag{9}$$

Validity of Eqs. (8) and (9) for the hydrogen bonded complex formation has been examined by several workers and it has been proved that these equations

are useful.[14,15] We have applied Eq. (9) to our systems, since the interactions between the partners are rather weak leading to rapid formation and dissociation reactions.

The results of measurements are given in Fig. 9 and Table 3. Since [A] is much larger than the concentration of DTBNO in our present systems, we can use the analytical concentration $[A]_0$ instead of [A], and we can evaluate K and a_{AD} from the plot of $\bar{a}$ against $(\bar{a}-a_D)/[A]_0$. As can be seen from Table 3, agreement between the K value obtained by optical spectral measurement and that estimated by ESR measurement is satisfactory. For some systems where optical measurement was not possible, K values were determined by means of ESR.

The interactions between the halves in the EDA complexes, which seem to affect the ESR spectra, will be the CT interaction and the electrostatic one, because both can affect the spin densities on DTBNO.

According to the theory of Karplus and Frenkel,[16] the hfc constant of DTBNO nitrogen can be written as

$$a_N = Q_1\rho_N + Q_2\rho_O \quad (10)$$

in terms of the spin densities on nitrogen and oxygen. As an example, Ayscough and Sargent[17] show that, for diphenyl-*N*-oxide, $a_N = 36.65\rho_N + 1.38\rho_O$ when Hückel MO was used for the spin density calculation, and $a_N = 35.61\rho_N - 0.93\rho_O$ if the McLachlan spin densities were used. Furthermore, Vasserman and Buchechenko[18] have used the formula $a_N = Q\rho_N$ for some nitric oxide derivatives. According to the SCF calculation by Kikuchi[19] with CNDO/2 approximation, the unpaired electron is almost completely localized on the $2p\pi$ AO's of nitrogen and oxygen of nitric oxide derivatives.

In the case of CT interaction with an electron acceptor, both of ρ_N and ρ_O of DTBNO will decrease. Since $|Q_1| \gg |Q_2|$ and $Q_1 > 0$ in Eq. (10), the CT interaction may cause the decrease of a_N.

The electrostatic interaction seems to polarize the charge distribution on the NO group, thus affecting the densities. Namely, when DTBNO is put in a polar environment or if some polar group approaches the NO group, the polarization in the sense $>N^{+\delta}-O^{-\delta}$ will occur, leading to the enhancement of the spin density on nitrogen. We assume that the spin densities change respectively to $\rho_N + \delta\rho_N$ and $\rho_O - \delta\rho_O$ by electrostatic interaction. Thus, the change of a_N can be written as $\Delta a_N = Q_1\delta\rho_N + Q_2\delta\rho_O$. As $\delta\rho_N - \delta\rho_O = 0$ (no intermolecular charge transfer), $\Delta a_N = (Q_1 - Q_2)\delta\rho_N = (Q_2 - Q_1)\delta\rho_O$. Since $\delta\rho_N > 0$ and $Q_1 \gg Q_2$ as mentioned above, a_N may increase by electrostatic interaction.

In the case of the hydrogen bonding interaction with proton donors such as ethanol and phenol, the σ-type lone pair electrons on oxygen of DTBNO will be mainly concerned with the bonding. Owing to the short range interaction, the electrostatic polarization $>N^{+\delta}-O^{-\delta}$ will be more extensive in the hydrogen bonding interaction than in the case of the non-hydro-

gen-bonding electrostatic interaction. Moreover, the electron delocalization in the hydrogen bond as indicated by $>N^{+}-O-H\cdots O^{-}-$ will contribute to the enhancement of the spin density on nitrogen. Thus, the hydrogen bonding interaction will increase a_N a great deal.

Summarizing the above arguments, the hfc constant of nitrogen decreases by the charge transfer from the highest occupied π-orbital of DTBNO in the EDA complex formation, while it increases by the non-hydrogen-bonding electrostatic interaction as well as by the hydrogen bonding interaction.

Deguchi[20] pointed out that the increase of the hfc constant of some stable radicals in non-hydrogen-bonding polar solvents was approximately proportional to the dipole moment μ of the solvent molecule. The solvent effects on the hfc constant of DTBNO nitrogen is shown in Fig. 10 and Table 4. We see from Fig. 10, that there is an approximately linear relation between the a_N value of DTBNO and the μ value of the non-hydrogen-bonding solvent. The relation between a_N and μ values might be ascribed to the fact that the

ESR spectra reflect the short range molecular interactions more sensitively than the optical spectra.

The a_N value of the DTBNO-phenol hydrogen bonded complex in toluene and that of DTBNO in ethanol are given in Fig. 10. The a_N values are much larger than those expected from the $a_N \sim \mu$ linear relation in the non-hydrogen-bonding solvents. This is in accordance with the above argument.

It can be seen from Tables 3 and 4 that the EDA complex formation of DTBNO with electron acceptors such as TCNE, PMDA, and PA leads to the increase of a_N. Several workers argued that electrostatic interaction between the partners in the EDA complex seems to make an important contribution to the stability of the complex, particularly in the case of weak π-π complexes. Our results indicate that the electrostatic forces play important roles also in the case of π–π complexes of DTBNO. Although TCNE as well as PMDA molecules do not have dipole moment as a whole, they have large local dipole moment. The local electric moment seems to cause the increase of a_N in the molecular complex formation. However, we cannot conclude even for these weak π–π complexes that the electrostatic interaction is predominant (or exclusive) in the ground state. If the electrostatic interaction is predominant, we can expect that the a_N value of TCNE-DTBNO complex is larger than or at least nearly equal to that of PMDA-DTBNO complex, since TCNE seems to have larger local dipole moments than those of PMDA. Contrary to this, the observed a_N value of the former complex is significantly smaller than the value of the latter. Thus, in the case of the TCNE-DTBNO complex, the CT interaction seems to play an important role. This is in accordance with the ordinary CT concept in view of the fact that the electron affinity of TCNE is 1.8 eV compared with 0.8 eV of PMDA.

The authors express their cordial thanks to Dr. T. Kubota of Shionogi Research Laboratory for his helpful discussions.

Diffuse Reflection Spectra of Filter Papers Dyed with 1-Arylazo-2-naphthols

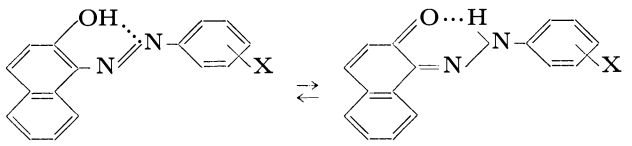
Yoshio MATSUNAGA and Nobuhiko MIYAJIMA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 21, 1970)

The diffuse reflection spectra of filter papers dyed with sixteen 1-arylazo-2-naphthols were examined in the range from 350 to 700 mμ. The absorption bands due to both the azo and hydrazone tautomers were observed in this state. Appreciable changes in the hue of the dyed papers caused by moisture were attributed to the deviation from the Kubelka-Munk theory due to the increased regular reflection; however, the movement of the tautomeric equilibrium caused by moisture was also clearly demonstrated in many cases. The direction was found to depend upon the kind and position of the substituents, *e.g.*, towards the azo tautomer in the case of the *p*-Cl and *o*-NO_2 derivatives and towards the hydrazone tautomer in the case of the *m*-Cl and *o*-MeO derivatives.

Spectroscopic studies of 1-arylazo-2-naphthols have indicated that these compounds exist in solution and also in the solid state as mixtures of the azo and hydrazone tautomers, I and II.[1-5]



(I) (II)

In a previous paper, we demonstrated that diffuse reflection spectra of 1-phenylazo-2-naphthol and its fifteen derivatives diluted with sodium chloride consist of absorption bands which can be assigned to both the azo and hydrazone tautomers.[6] In addition, we disclosed that the equilibrium moves by dilution towards the hydrazone tautomer, regardless of the kind and position of the substituents. As the compounds are prototypes of azo dyestuffs, it seemed that it would be interesting to examine the possible tautomerism in the compounds deposited on various substrates, *e.g.*, cotton, silk, wool *etc.*, by the same technique. We wish to report in this paper, the first of our attempts along this line, the results of our spectral measurements of filter papers dyed with 1-arylazo-2-naphthols. As we noticed that the hue of the dyed papers is sensitive to moisture, the effects of this on the spectra were also studied.

Experimental

Materials. The samples of 1-arylazo-2-naphthols were the same as those used in our previous work.[6] The derivatives carried one of the following substituents in the *o*-, *m*-, and *p*-positions on the phenyl ring: methyl, chloro, hydroxy, methoxy, and nitro.

Measurements. Toyo filter papers, No. 2, 5.5 cm in diameter, were wetted as uniformly as possible with an acetone solution of one of the 1-arylazo-2-naphthols, dropped from a 1-m*l* pipette with graduations. The concentration and volume were adjusted to achieve 3—6 μg of the dye per cm^2 of the paper. After the solvent had been evaporated at room temperature, the papers were dried at 100°C for 10 min and then cooled in a desiccator over silica gel. The difference in reflectance between the filter paper and the dyed paper, which is generally in the range from 0 to 60%, was recorded in the visible region by means of a Beckman DK 2A spectroreflectometer. When this measurement was finished, both the dyed paper and the reference were left overnight in a desiccator containing distilled water; then the difference in reflectance was measured in order to obtain the spectrum affected by moisture. To check the reproducibility, the papers were dried again and the measurements were repeated. The spectra were plotted using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance. The absorption spectra of the 1-arylazo-2-naphthols dissolved in *n*-hexane, ethanol, and chloroform were measured by means of a Beckman DK 2A spectrophotometer. The concentrations were in the order of 10^{-5} mol/*l*. In all the figures in this paper, the reflection and absorption spectra are plotted taking the maxima arbitrarily as 1.00.

Results and Discussion

1-Phenylazo-2-naphthol (Figs. 1 and 2). As is shown in Fig. 1, the spectrum of the dried dyed paper consists of a broad band located in the region between 350 and 440 mμ and a sharp strong band with a maximum at 490 mμ. This spectrum closely resembles that measured in the chloroform solution (see curve *c* in Fig. 2). The former band, which dominates in the spectrum observed in a hexane solution, has been assigned to the azo tautomer, and the latter, to the hydrazone tautomer.[1] When the dyed paper is moistened, the relative intensity in the region from 350 to 440 mμ is much increased. However, the correlation between the spectral change and the movement of the equilibrium is not straightforward. Examining the solution spectra presented in Fig. 2, we reach the conclusion that the movement of the equilibrium towards the azo tautomer is probably not accompanied by an increase in the relative intensity in the region above 500 mμ. This is in serious disagreement with the finding in Fig. 1. The apparent change of the spectrum by moisture may be mostly caused by the deviation from the Kubelka-Munk theory due to the increased regular reflection. In accordance with this view, the absolute intensity at the absorption maximum

observed with the moist dyed paper is only one eighth of that observed with the dried paper.

1-Tolylazo-2-naphthols (Fig. 1). When the papers are dried, all the Me derivatives show essentially the same spectrum. In the case of the *o*-Me derivative shown in Fig. 1, the spectrum is only slightly flattened by moisture (see Table 1). It is easy to see that the relative intensity decreases in the region from 350 to 490 mμ and increases in the region from 520 to 580 mμ upon this treatment. A shoulder due to the hydrazone tautomer can be clearly seen around 530 mμ. As the azo tautomer has an absorption maximum around 430 mμ, the whole change may be considered as an indication of a slight movement of the equilibrium towards the hydrazone tautomer. In the other two derivatives, marked decreases in the absolute intensity were observed upon moistening; however, no movement of the equilibrium could be detected. The relative intensity in the region from 350 to 450 mμ, which has been considered a measure of the amount of the azo tautomer by Burawoy and also by Bansho, increases in the order of substituents: *o*-Me<*m*-Me≲H≲*p*-Me. This is in accordance with the order found

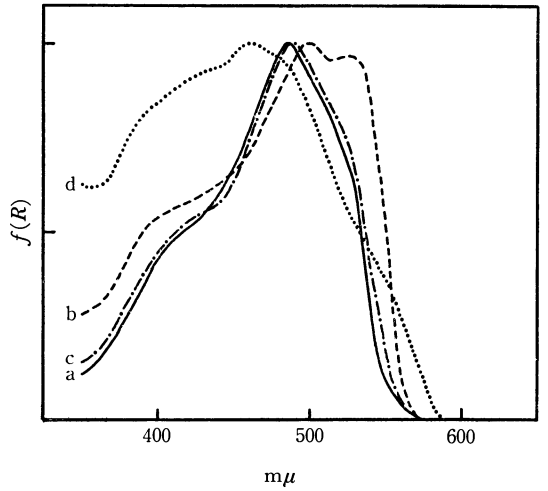

Fig. 3. Spectra of filter papers dyed with 1-(*m*-chlorophenylazo)-2-naphthol; (a) dried and (b) moistened, and with 1-(*p*-chlorophenylazo)-2-naphthol; (c) dried and (d) moistened.

in an ethanolic solution by Burawoy *et al.*

1-Chlorophenylazo-2-naphthols (Fig. 3). The spectra of the dried papers dyed with these derivatives are very close to each other; however, large differences can be found when they are moistened. The spectrum of the *o*-Cl derivative is least affected by moisture. A relatively slight flattening and the appearance of a shoulder around 525 mμ can be noted. The spectrum of the moistened paper dyed with the *m*-Cl derivative presented in Fig. 3 has a well-resolved doublet, located at 500 and 525 mμ, indicating the movement of the equilibrium towards the hydrazone tautomer. This spectrum is similar to that of the same compound highly diluted with sodium chloride.[6] Not only a flattening by a factor of ten by moisture, but also a drastic change in the spectrum, was observed in the case of the *p*-Cl derivative. The relative intensity is very much increased in the region from 350 to 480 mμ and is decreased in the region from 490 to 540 mμ. This change may be attributed to the movement of the equilibrium towards the azo tautomer. It may be pointed out that the spectrum thus obtained looks like the spectrum of the same compound diluted with sodium chloride at a concentration of 1%.[6] As may be noticed in Fig. 3, the relative intensities in the region from 350 to 450 mμ are little different from each other in the dry state.

1-Hydroxyphenylazo-2-naphthols (Figs. 4 and 5). When the dyed papers are dry, the *o*-OH and *m*-OH derivatives exhibit spectra similar to that of 1-phenylazo-2-naphthol. Upon moistening, the spectrum of the *o*-OH derivative shows a decrease in its relative intensity in the region between 500 and 550 mμ. As a result, a shoulder appears around 550 mμ. The equilibrium seems to move a little towards the azo tautomer upon the addition of moisture. As is shown in Fig. 4, the effect of moisture on the spectrum of the *m*-OH derivative is somewhat strange. The whole spectrum seems to be simply shifted to wavelengths shorter by 30 mμ. However, from a comparison with the spectra measured in various solvents shown in Fig. 5, we may conclude that the observed change arises from

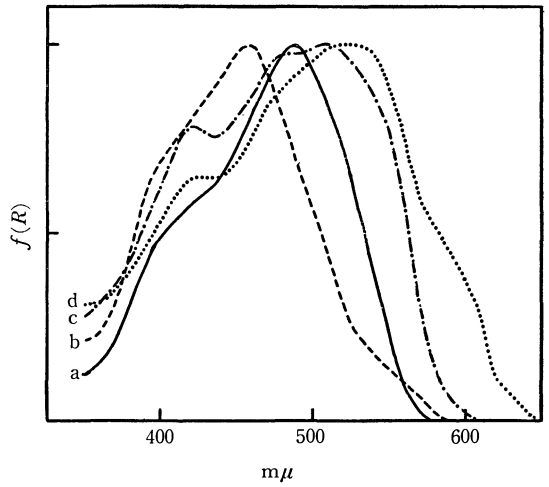

Fig. 4. Spectra of filter papers dyed with 1-(*m*-hydroxyphenylazo)-2-naphthol; (a) dried and (b) moistened, and with 1-(*p*-hydroxyphenylazo)-2-naphthol; (c) dried and (d) moistened.

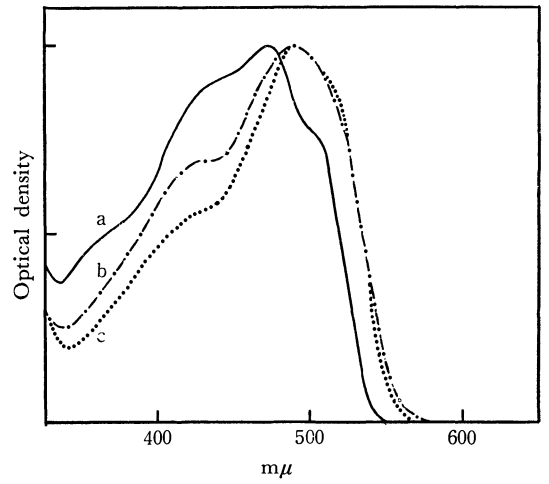

Fig. 5. Spectra of 1-(*m*-hydroxyphenylazo)-2-naphthol dissolved in (a) *n*-hexane, (b) ethanol, and (c) chloroform.

the movement of the equilibrium towards the azo tautomer. The *p*-OH derivative shows a spectrum very different from those of the other two, even in the dry state. The high relative intensity of the absorption around 420 mμ indicates that a fairly large amount of the azo tautomer is present. The spectral change caused by moisture may be attributed to an increase in the amount of the hydrazone tautomer.

1-Anisylazo-2-naphthols (Fig. 6). The spectra of the *o*-MeO and *m*-MeO derivatives are of the same kind. The only difference is in the relative intensity in the region from 350 to 450 mμ; it is much higher in the *m*-MeO derivative than in the *o*-MeO derivative. The same tendency is also observed in various solvents. Both of them are flattened by moisture. The doublet appearing at 525 and 560 mμ and assignable to the hydrazone tautomer can be distinctly seen in the case of the *o*-MeO derivative. The spectral change caused by moisture found in the case of the *m*-MeO derivative is less pronounced here. Nevertheless, the appearance of a shoulder at 525 mμ is undoubtedly a sign of the movement of the equilibrium towards

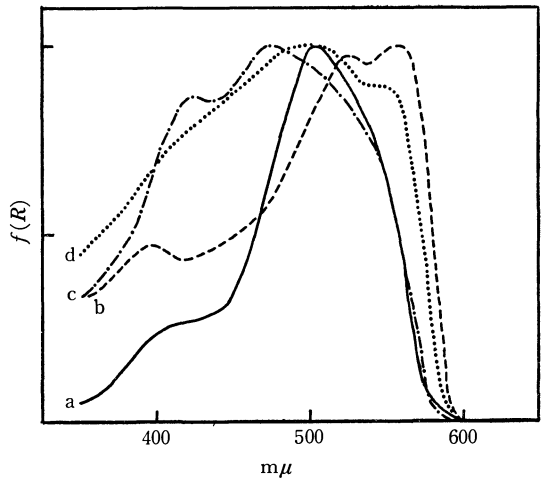

Fig. 6. Spectra of filter papers dyed with 1-(*o*-anisylazo)-2-naphthol; (a) dried and (b) moistened, and with 1-(*p*-anisylazo)-2-naphthol; (c) dried and (d) moistened.

the hydrazone tautomer. The spectrum of the *p*-MeO derivative is rather similar to that of the *p*-OH derivative. For these two compounds, the equilibria in solution very much favor the azo tautomer. The presence of strong maxima at 420 and 480 mμ to be assigned to the azo and hydrazone tautomers respectively indicates that the amounts of the two are comparable in the dry state. When the dyed paper is moistened, the above-mentioned maxima are replaced by those at 500 and 550 mμ assignable to the hydrazone tautomer. The former maximum apparently corresponds to the one at 480 mμ in the dry state. The relative intensities in the region from 350 to 450 mμ are in the order: *o*-MeO<*m*-MeO<H<*p*-MeO; this order is in good agreement with the order found in ethanolic solutions.[1)]

1-Nitrophenylazo-2-naphthols (Figs. 7 and 8). Although the spectra of these derivatives look alike in the dry state, the effects of moisture are not the same. In the case of the *o*-NO_2 derivative, the sharp peak at 490 mμ disappears and a broad band with a maximum at 440 mμ becomes dominant. The tautomeric

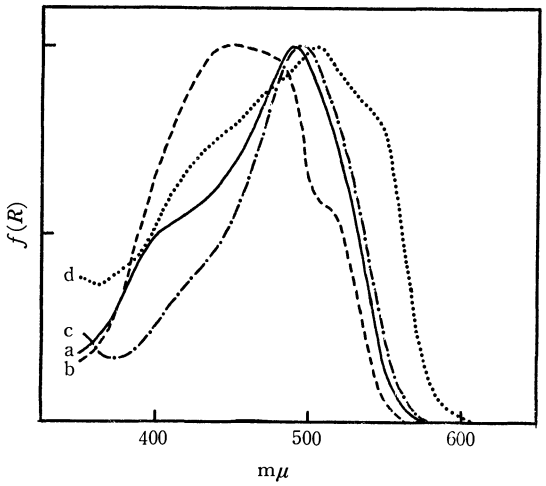

Fig. 7. Spectra of filter papers dyed with 1-(*o*-nitrophenylazo)-2-naphthol; (a) dried and (b) moistened, and with 1-(*p*-nitrophenylazo)-2-naphthol; (c) dried and (d) moistened.

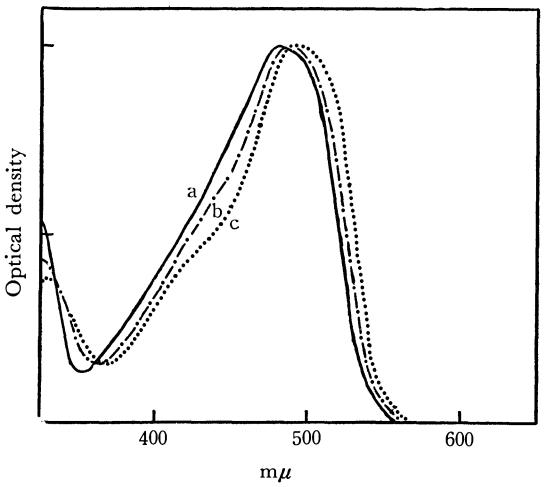

Fig. 8. Spectra of 1-(*p*-nitrophenylazo)-2-naphthol dissolved in (a) *n*-hexane, (b) ethanol, and (c) chloroform.

equilibrium moves drastically towards the azo tautomer. The spectrum of the *m*-NO_2 derivative is most flattened by moistening; nonetheless, the movement of the equilibrium is clear. The sharp peak at 480 mμ observed in the dry state is replaced by a broad one at 510 mμ on moistening. It must be added that these absorption bands are shifted to wavelengths longer by 50 mμ compared to those observed in solution.

Although the spectrum of the *p*-NO_2 derivative looks similar to those of the other two, comparison with the spectra observed in the solid, two-component system with sodium chloride suggests that the peak located at 495 mμ is due to the azo tautomer. The shoulder appearing at 540 mμ on moistening is to be assigned to the hydrazone tautomer. These assignments are supported by our measurements of the absorption spectra. This compound has been considered to exist nearly exclusively as a hydrazone tautomer in solution; however, a close examination of the spectra presented in Fig. 8 shows that the two tautomers exhibit absorption maxima only 40—50 mμ apart. Compared to these spectra, the bands in the spectrum of the dyed paper appear to be shifted by as much as 70 mμ.

General Remarks. On the basis of the spectrum, we may conclude that 1-arylazo-2-naphthol exists, in general, as a mixture of the azo and hydrazone tautomers when deposited on filter paper. As is summarized in Table 1, the spectrum plotted using the Kubelka-Munk function is flattened by moisture, mostly by a factor between two and ten. This phenomenon, attributed to the deviation from the theory due to the increased regular reflection, suggests a drastic change in the state of the dispersion of the dye molecules caused by moisture. As cellulose, the substrate in the present work, is a kind of polyhydric alcohol, and as the dyestuff is less soluble in water than in alcohol, it is very likely that the molecules of the dyestuff deposited on filter paper are segregated on moistening. Of course,

Table 1. The intensity ratio of the absorption maximum in the spectrum of moistened dyed paper to that in the spectrum of the corresponding dried paper and the direction of the movement of the equilibrium by moisture; towards the azo tautomer (+) or the hydrazone tautomer (−)

Substituent	Position		
	ortho	*meta*	*para*
None		0.12 (±)	
Methyl	0.8 (−)	0.1 (±)	0.2 (±)
Chloro	0.45 (−)	0.3 (−−)	0.1 (++)
Hydroxy	0.3 (+)	0.5 (+)	0.5 (−)
Methoxy	0.25 (−−)	0.35 (−)	0.2 (−)
Nitro	0.4 (++)	0.2 (−)	0.3 (−)

the extent of the segregation may depend upon the strength of the interaction between the dye molecule and the substrate, which, in turn, depends upon the nature of the substituent carried on the dye molecule.

It has been noted by Burawoy *et al.* that the relative stabilities of the hydrazone tautomer increase in this order of the solvents: hexane<alcohol<chloroform<water.[1] Therefore, the movement of the equilibrium of the dyestuff deposited on filter paper towards the hydrazone tautomer on moistening is reasonable if we consider the chemical constitution of cellulose. However, our observations, summarized in Table 1, indicate that this is not necessarily the case. Such a disagreement may be accounted for if we take into consideration the effect of moisture on the state of dispersion. In our previous work on the dyestuff-sodium chloride system, the spectral changes by dilution were attributed, at least in part, to the movement of the equilibrium towards the hydrazone tautomer.[6] The segregation of dye molecules deposited on filter paper by moisture must, therefore, favor the azo tautomer. These two effects of moisture oppose each other, but their magnitudes appear to be comparable. As is observed in our present study, the total effects depend on the kind and position of the substituent carried on the phenyl ring. As a matter of fact, the *o*-NO_2 derivative, which exhibits an exceptionally pronounced spectral change caused by moisture, is known to be one of those compounds which have solid-state spectra dominated by the absorption which is to be assigned to the azo tautomer.[6] In conclusion, the whole phenomenon is determined not only by the nature of the dyestuff itself, but also by the interaction between the dye molecule and the substrate. The results of the spectral measurements of the same compounds deposited on various fabrics made of both natural and synthetic fibers are in good accordance with this conclusion; the semeasurements will be the subject of forthcoming papers.

Infrared Absorption Spectra and Normal Coordinate Analysis of Metal-DL-α-Serine Chelates

Yoshie INOMATA, Tadaaki INOMATA, and Takao MORIWAKI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo

(Received September 1, 1970)

The infrared absorption spectra of DL-α-serine and four metal-DL-α-serine chelates have been investigated from 4000 to 200 cm^{-1}. A normal coordinate analysis has been accomplished for the metal chelates as a 27-body problem and an approximate description of the vibrational mode has been assigned to the observed frequencies. The frequency separation between carboxylate antisymmetric and symmetric stretching vibrations and values of the bond-stretching force constants for the metal-nitrogen bonds have been found to decrease in the order Pt(II)>Pd(II)>Cu(II)>Ni(II). These facts show that the hydroxy group in the β-position of DL-α-serine has no influence on the order of metal-ligand bond strength, which order has been already found in aliphatic α-amino acids chelates having no hydroxy group in the β-position. Two species of copper chelates have been prepared. Though the infrared spectrum of one of them is similar to that of the nickel(II) chelate, that of the other species is different. This fact may be explained by assuming that the copper ion has been coordinated with the hydroxy group in the latter.

The infrared absorption spectra and the normal coordinate analysis for aliphatic α-amino acid chelates have already been studied by Lane[1] and Walter[2-4]. However, DL-α-serine having hydroxy group in the β-position and its metal-chelates have not been studied yet in detail. Nakamura[5] has made some empirical assignments for DL-α-serine copper(II) chelate in the region 1700 to 400 cm^{-1}. Nakamoto[6] have demonstrated that in amino acid chelates the frequency separation between carboxylate stretching vibrations increases in the order Ni(II)<Cu(II)<Pd(II)<Pt(II) regardless of the nature of the ligand, if the comparison is made in the same physical state. They have concluded that this fact is based on the increase of the covalent character in metal-oxygen bond. Nakagawa *et al.*[2] showed in DL-α-valine chelates that the metal-nitrogen bond-stretching force constants vary in the order Ni(II)<Cu(II)<Pd(II)<Pt(II) which indicates a relative strength of the interaction of metal-nitrogen bond and that the NH_2 stretching and the NH_2 rocking frequencies follow the same order.

In this investigation, the infrared spectra of four metal-serine chelates have been studied. The bond-stretching force constants for the metal-nitrogen bond have been calculated. In addition, we discuss how the hydroxy group in β-position influences the relation mentioned above. The problem of whether the hydroxy group coordinates with metal ion or not is also taken up.

Experimental

Preparation of Compounds. Bis(DL-α-serino)-platinum-(II) was prepared by stirring 2.6 g (0.025 mol) of DL-α-serine and 1.3 g (0.0031 mol) of potassium tetrachloroplatinate(II) in water (50—100 m*l*) at room temperature for several days. The white crystals separated were recrystallized from hot water and dried at room temperature *in vacuo* for several hours.

Found: C, 18.13; H, 2.85; N, 6.80%. Calcd for Pt-$C_6H_{12}N_2O_6$: C, 17.87; H, 3.00; N, 6.95%.

Bis(DL-α-serino)-palladium(II) was prepared by employing essentially the same procedure as that used above for the platinum(II) chelate.

Found: C, 22.38; H, 3.68; N, 8.75%. Calcd for Pd-$C_6H_{12}N_2O_6$: C, 22.91; H, 3.85; N, 8.91%.

Two species of Bis(DL-α-serino)-copper(II) were prepared. Elementary analysis of each of these two species gives the same results, but the absorption spectra and the color of these two chelates are different. One of them which gives a similar spectrum to the nickel(II) chelate was named "A chelate" and the other was named "B chelate".

The A chelate was prepared by stirring 5.3 g (0.05 mol) DL-α-serine and 2.8 g (0.013 mol) of basic copper carbonate in hot water at 70°C for 15 min, then condensing the filtrate to 25 m*l* after filtering. The blue crystal formed was filtered at hot stage. By cooling the filtrate, the sky blue B chelate was obtained. Both precipitates were washed by water and dried for several hours at 50°C *in vacuo*.

These chelates will be discussed in detail below.

A chelate. Found: C, 26.81; H, 4.23; N, 10.29%. Calcd for $CuC_6H_{12}N_2O_6$: C, 26.52; H, 4.45; N, 10.31%.

B chelate. Found: C, 26.89; H, 4.29; N, 10.30%. Calcd for $CuC_6H_{12}N_2O_6$: C, 26.52; H, 4.45; N, 10.31%.

Bis(DL-α-serino)-nickel(II) was prepared from 5.3 g (0.05 mol) of DL-α-serine and 3.0 g (0.008 mol) of nickel carbonate by the same procedure used above for the copper A chelate.

Found: C, 23.74; H, 5.39; N, 9.29%. Calcd for Ni-$C_6H_{12}N_2O_6 \cdot 2H_2O$: C, 23.79; H, 5.32; N, 9.25%.

Deuteration of Compounds. The deuterated DL-α-serine and metal chelates were prepared by dissolving the DL-α-serine and each chelate in 99.75 atom% deuterium oxide at 80°C and drying them *in vacuo*. The NH and OH groups were deuterated by this method.

Thermal Analysis of Chelates. Thermal analysis was performed with Rigaku Denki DTA-8001 from room temperature to 400°C in air and at the same time, the decrease of weight accompanying an endothermic reaction was measured. It was found that only the nickel(II) chelate had two molecules of water.

Absorption Measurement. The infrared absorption spectra from 4000 to 200 cm^{-1} were obtained with Hitachi EPI-G_2 and EPI-L spectrophotometers and were calibrated with polystylene, 1.2.4-trichlorobenzene and atmospheric water vapor. Samples were prepared as potassium bromide discs and nujol mulls. The spectra are shown in Figs. 1 and 2. The observed absorption frequencies and assignments for DL-α-serine and the metal chelates are listed in Table 1.

Discussion

The assignments of observed frequencies were made by comparison with metal-glycine,[1] -valine,[2] -leucine,[3] and -alanine[4] chelates and DL-α-amino-*n*-butyric acid[7] which had been thoroughly studied.

The spectra of DL-α-serine chelates are similar to the spectra of those which have *trans* configurations. The observed frequencies of DL-α-serine chelates have been reasonably assigned.

Assignment of Observed Frequencies. *DL-α-serine*: The spectrum of DL-α-serine shows the bands of NH_3^+ and COO^- which are characteristic of a zwitter ion as shown in Fig. 1. The strong broad bands at about 2900 cm^{-1} are assigned to the OH, CH and NH_3^+ stretching vibrations. On deuteration, the CH stretching vibration band is not shifted and is assigned easily.

The bands at 1662, 1633, 1513 and 1166 cm^{-1} which shift on deuteration are due to NH_3^+ deformation vibrations, since no corresponding bands appear in the metal chelates.

In addition there are bands at 1250 and 729 cm^{-1} which disappear on deuteration. Primary alcohols in the bonded state have diffuse association bands near 1420 and 1330 cm^{-1} (OH deformation and CH_2 wagging).[8] All alcohols show very broad bands in the range 750—650 cm^{-1}, which are assigned to out-of-plane bonded OH deformation vibrations.[9] It has been generally known that the frequencies of OH deformation vibrations can be affected by structures and hydrogen bond.[9] Therefore, it is reasonable to assign these two bands respectively to the OH in plane and out-of-plane deformation vibrations, considering that these bands appear at the same region also in the metal chelates and that the force constants of OH deformation vibrations calculated by normal coordinate analysis are approximately equal to that already reported for alcohol.

The assignments for COO^- stretching and deformation vibrations and CH and CH_2 deformation vibrations are easily made as shown in Table 1. The bands of CH and CH_2 deformation vibrations appear in the same region as DL-α-amino-*n*-butyric acid.[7] The hydroxy group is thought not to have affected these deformation vibrations. CN and CC stretching and skeletal deformation vibrations are assigned by comparison with the spectra of the metal chelates. The band at 1030 cm^{-1} is assigned to CO stretching vibration as in methyl alcohol.[9]

Metal-chelates: The spectra of the metal chelates shown in Figs. 1 and 2 are similar to each other except for that of copper(II) B chelate.

3400 to 2800 cm^{-1}: Although the bands above 3000 cm^{-1} are due to NH_2 antisymmetric and symmetric stretching and OH stretching vibrations, it is difficult to assign them separately, since all bands shift on deuteration.

1700 to 500 cm^{-1}: In this region the NH_2 deformation vibration appears instead of NH_3^+ deformation vibration of the ligand. They are assigned in view of the shift in deuterated compounds. The COO^- antisymmetric stretching vibration is observed in higher frequencies and deformation vibrations are at lower frequencies than those of the ligand. The OH in plane deformation vibration occurs at the same region (1250 cm^{-1}) as in the ligand and the OH out-of-plane

deformation vibration shifts to lower frequencies.

500 to 200 cm^{-1}: In this region the absorption bands which cannot be observed in the ligand appear at 404 cm^{-1} for platinum(II) chelate, 407 cm^{-1} for palladium(II) chelate, 373 cm^{-1} for copper(II) A chelate, 394 cm^{-1} for copper(II) B chelate and 350 cm^{-1} for nickel(II) chelate. They are assigned to metal-nitrogen stretching vibration. The bands at 217 cm^{-1} for platinum(II) chelate and 218 cm^{-1} for palladium(II) chelate are assigned to metal-oxygen stretching vibration. Nakamura[5] has assigned the bands at 588 cm^{-1} for DL-α-serine copper(II) chelate and 581 cm^{-1} for DL-α-alanine copper(II) chelate to copper-nitrogen stretching vibration, and the bands at about 420 cm^{-1} to COO^- rocking vibration. These assignments are different from ours. If the band at about 590 cm^{-1} is assigned to metal-nitrogen stretching vibration, the force constant of metal-nitrogen stretching vibration has the value of 1.8—2.0 mdyn/Å by the calculation, which is much larger than that for glycine[1] and valine[2] chelates. In addition NH_2 vibrations for serine chelate are at the same region as those for valine chelate.[2] Therefore it is doubtful to assign the band at about 590 cm^{-1} to metal-nitrogen stretching vibration. The metal-nitrogen stretching vibration was observed in the region from 400 to 360 cm^{-1} and the NH_2 stretching vibration in the region from 3300 to 3100 cm^{-1} for valine chelate, for which the covalent character of the metal-nitrogen bond has been established.[2] Since the NH_2 stretching vibrations for the serine chelates are observed in the same region as those for valine chelates, the metal-nitrogen bonds of serine chelates must be fairly covalent and metal-nitrogen stretching vibrations for serine chelates should be in the region 400 to 360 cm^{-1}. Therefore the bands in this region of the chelates can be assigned to metal-nitrogen stretching vibration.

The carboxylate stretching vibrations are not shifted considerably on chelation, which indicates that the covalent character of metal-oxygen bond is weak. Consequently, metal-oxygen stretching vibration should be in the lower region than metal-nitrogen stretching vibration. Therefore the new bands at 217 cm^{-1} for platinum(II) chelate and 218 cm^{-1} for palladium(II) chelate can be assigned to metal-oxygen stretching vibration.

The skeletal deformation vibrations are assigned to the same range as those in the ligand by comparison with DL-α-leucine chelates.[3]

Copper Chelate. The spectra of the two species differ in many points as shown in Figs. 1 and 2. The principal difference is that the bands at 1250 and 686 cm^{-1} assigned to OH in plane and out-of-plane deformation vibrations respectively in copper(II) A chelate and in the ligand, disappear in copper(II) B chelate. In the far infrared region, the spectrum of B chelate is not similar to either those of A chelate or of any metal chelate. The copper(II) chelate studied by Nakamura[5] has no band to be assigned to OH deformation vibrations like the copper(II) B chelate. In addition, the X-ray spectra of copper(II) A chelate and copper (II) B chelate are different from each other. The infrared spectrum of the copper(II) chelate prepared from L-α-serine or D-α-serine does not coincide with either those of copper(II) A chelate or of copper(II) B chelate of DL-α-serine. It has been frequently discussed that the hydroxy group is coordinated with metal without changing its shape. The stability constants of metal-amino polycarboxylic acids chelates with hydroxy groups are higher than those without hydroxy groups. From this result it has been concluded that the hydroxy groups are coordinated to metals by forming chelate rings and that the chelates become stable.[10]

In the copper(II) B chelate, it may be assumed that the hydroxy group is coordinated with copper ion and becomes stable, since the basic character of the nitrogen atom of the amino group decreases from the inductive effect of the hydroxy group and since the copper ion can take on a distorted octahedral structure. Because the results of elementary analysis show the same values for both copper(II) A and copper(II) B chelates, it is doubtful whether the hydroxy group is coordinated to metal removing its hydrogen atom. In addition, it is hardly possible for the copper(II) B chelate to take the structure in which the hydroxy group forms a chelate ring, considering the bond distances and the bond angles of DL-α-serine studied by X-ray diffraction method.[11] Therefore copper(II) B chelate probably has the structure in which the hydroxy group bonds to another copper ion.

Thus, DL-α-serine chelates are found to be coordinated with metal through nitrogen and oxygen as well as other aliphatic α-amino acids, and the hydroxy group

probably does not participate in coordination except in the case of copper(II) B chelate.

Normal Coordinate Analysis. A normal coordinate analysis for a metal chelate was performed as a 27-body problem using the model illustrated in Fig. 3. The calculations were carried out on HITAC 5020E[12] and IBM 1130 computers.

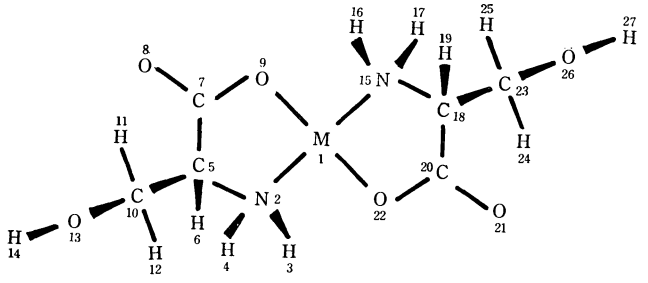

Fig. 3. Structure of DL-α-serine chelates.

The model adopted has M_1 as a center of symmetry. In the left side of the model, M_1, N_2, C_5, C_7, and O_9 form a planar five membered chelate ring and O_8 is on the same plane. The atoms C_5, C_{10}, O_{13}, and H_{14} are on the same plane which is perpendicular to this chelate ring and H_{11}, C_{10}, and H_{12} are on the same plane which is parallel to this chelate ring. Since no X-ray data for metal-DL-α-serine chelate is available, the bond lengths and bond angles listed in Table 2 were used in the calculation. They were taken from Refs. 4, 11, and 13.

Table 2. Bond lengths and bond angles used in the calculation for DL-α-serine chelate

Bond lengths (Å)					
1.	M_1–N_2	1.86	8.	O_9–M_1	1.916223

C_5–C_7–O_9		120			

θ: 190°28′

All other angles are assumed to be 109°28′. The same bond lengths and bond angles are used for second chelate ring.

The frequencies of infrared active species were calculated using the symmetry coordinates listed in Table 3. Wilson's *GF* matrix method[14] was used and all results were obtained using FORTRAN program designed by Shimanouchi.[15] The potential field employed was the following modified Uray-Bradley type,

$$2V = \sum_i \boldsymbol{K}_i(\Delta r_i)^2 + \sum_{i<j} \boldsymbol{H}_{ij}(r_0\Delta\alpha_{ij})^2 + \sum_{i<j} \boldsymbol{F}_{ij}(\Delta q_{ij})^2 + \sum_{i<j} \boldsymbol{F'}_{ij}\mathbf{Y} + \boldsymbol{P}(\Delta\omega)^2 + \sum_{i<j} \boldsymbol{T}_{ij}(\Delta\tau_{ij})^2$$

$$\Delta q_{ij} = S_{ij}\Delta r_i + S_{ji}\Delta r_j + (t_{ij}t_{ji})^{1/2}(r_0\Delta\alpha_{ij})^2$$

$$\mathbf{Y} = t_{ij}{}^2(\Delta r_i)^2 + t_{ji}{}^2(\Delta r_j)^2 - S_{ij}S_{ji}(r_0\Delta\alpha_{ij})^2 - 2t_{ij}t_{ji}(\Delta r_i)(\Delta r_j) + 2t_{ij}S_{ji}r_i(\Delta r_i)(\Delta\alpha_{ij}) + 2t_{ji}S_{ij}r_i(\Delta r_j)(\Delta\alpha_{ij})$$

$$r_0 = (r_ir_j)^{1/2}, \quad S_{ij} = (r_i - r_j\cos\alpha_{ij})/q_{ij},$$

$$t_{ij} = r_j\sin\alpha_{ij}/q_{ij}$$

where r_i is a bond length and α_{ij} is the angle between bonds r_i and r_j at an equilibrium position. q_{ij} is the distance between atoms i and j which are bonded to a common atom. ω is the angle between the C–C-(ring) bond and the COO^- plane. τ_{ij} is the torsion about the axis connecting atoms i and j. These torsions are C–C(ring), C–C, and C–OH.

The force constants are given by $\boldsymbol{K}$(stretching), $\boldsymbol{H}$ (bending), $\boldsymbol{F}$(repusion), $\boldsymbol{P}$(out-of-plane wagging) and $\boldsymbol{T}$(torsion). $\boldsymbol{F'}$ is introduced as a force constant associated with the linear terms of the repulsion energy and remains in this equation as an internal tension. The value of $\boldsymbol{F'}$ is estimated to be $-0.1\boldsymbol{F}$. Table 4 shows the observed and calculated frequencies, poten-

tial energy distributions to symmetry coordinates and force constants with an approximate description of the vibrational mode for the platinum(II) chelate. The force constants used in this calculation are listed in Table 5. They were evaluated so as to obtain the best fit between the calculated and the observed frequencies by a trial and error method guided by the values of a Jacobian matrix.

Metal-ligand Bonds. A similar calculation was accomplished for the palladium(II), copper(II) A, and nickel(II) chelates and good agreement was obtained between the observed and calculated frequencies for these chelates as well as for those of the platinum(II) chelate. In Table 6 the important frequencies related to the metal-ligand bonds are summarized for each chelate. The force constants used in these calculations are given in Table 7.

As seen in Table 6, the frequency separation of COO^- antisymmetric and symmetric stretching vibrations increases from the nickel(II) chelate to the platinum (II) chelate except for the copper(II) B chelate. The values of $\boldsymbol{F}_{dia}$(M-O) and $\boldsymbol{K}$(M-O) for platinum(II) chelate are larger than those of palladium(II) chelate as seen in Table 7. Therefore, the covalent character of the metal-oxygen bond can be considered to increase in the order Ni(II)<Cu(II)<Pd(II)<Pt(II). This same order has already been reported for glycine,[1] alanine,[4] and other aliphatic α-amino acids chelates.[2,3] A similar trend is observed in the COO^- rocking vibration. Although the metal-nitrogen stretching frequencies increase in the order Ni(II)< Cu(II)<Pt(II)<Pd(II), the force constants of the metal-nitrogen stretching vibration and the frequencies of the NH_2 scissors increase in the order Ni(II)<

F_{dia}=the diagonal elements of the symmetrized F matrix

Cu(II)<Pd(II)<Pt(II). The frequencies of the NH_2 wagging vibration show a slightly different trend. This fact can be explained by considering how little the metals affect this vibration, since the NH_2 wagging vibration is closely coupled with other vibrations as seen in Table 4. The calculated frequency of metal-nitrogen stretching vibration agrees fairly well with the observed frequency, and the force constant takes a reasonable value for each chelate. Therefore, considering the value of $\boldsymbol{K}$(M–N) and $\boldsymbol{F}_{\text{dia}}$(M–N), it is reasonable to conclude that the strength of the metal-nitrogen bond increases in the order Ni(II)<Cu(II)<Pd(II)<Pt(II). This trend is the same as that in many aliphatic α-amino acids chelates.[1–4] From these facts it might be asserted that the hydroxy group in the β-position of DL-α-serine has no influence on the order of the metal-ligand bond strength, which has been already found in aliphatic α-amino acid chelates having no hydroxy group in the β-position.

Low Frequency Infrared Absorption Bands of Water of Crystallization at Low Temperature

Kunio FUKUSHIMA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka

(Received September 3, 1970)

The low temperature infrared absorption spectra of water of crystallization of $BaCl_2 \cdot 2H_2O$, $CuCl_2 \cdot 2H_2O$ and $K_2C_2O_4 \cdot H_2O$, which have water of crystallization in different bound states, were measured and compared with the room temperature spectra. Corresponding to the change of temperature of the samples, remarkable change in frequencies and intensities was observed for the bands due to the lattice vibrations associated with water of crystallization.

Water of crystallization is classified into several types on the basis of its type of bonding with surrounding ions, electron acceptor or donor groups.[1] The infrared spectra of water of crystallization in the low frequency region vary with the difference of its bound state in the crystals, and they were investigated for aquo complexes by Nakagawa and Shimanouchi[2] and for several inorganic hydrates by van der Elsken and Robinson,[3] respectively. The author carried out calculations of optically active lattice vibrations of $BaCl_2 \cdot 2H_2O$, $BaCl_2 \cdot 2D_2O$,[4] $K_2C_2O_4 \cdot H_2O$, $K_2C_2O_4 \cdot D_2O$,[5] $CuCl_2 \cdot 2H_2O$ and $CuCl_2 \cdot 2D_2O$[6] crystals, which are different from each other in the type of bonding of water of crystallization, and obtained information about the bound state of the water of crystallization. A remarkable change in the far infrared spectra of certain kinds of water of crystallization with change of temperature has been reported.[7] In the present investigation, this change of infrared spectra with change of temperature has been studied for the crystals containing water of crystallization in different bound states.

Experimental

The samples were prepared by recrystallization of $BaCl_2 \cdot 2H_2O$ of Wako Pure Chemical Industries. Ltd., $CuCl_2 \cdot 2H_2O$ of Koso Chemicals Co., Ltd., and $K_2C_2O_4 \cdot H_2O$ of Koso Chemicals Co., Ltd. from their aqueous solutions, respectively. The infrared spectra of the samples in Nujol mull in the 700—60 cm^{-1} region were measured at low temper-

ature. The measurements were made using low temperature cells cooled with liquid nitrogen. The Nujol mull was placed between two CsI plates for the measurements of the infrared spectra of $BaCl_2 \cdot 2H_2O$ and $K_2C_2O_4 \cdot H_2O$ in the 700—400 cm^{-1} region, while it was placed between two polyethylene plates for the measurements of these samples in the 400—60 cm^{-1} region and of $CuCl_2 \cdot 2H_2O$ in the 700—400 cm^{-1} region, respectively. By means of a copper-constantan thermocouple recording system the temperature of the samples was found to be constant within $\pm 2°C$ through the measurements. The infrared spectra were recorded with a Hitachi EPI-L spectrophotometer for the 700—400 cm^{-1} region and with a Hitachi FIS-3 far infrared spectrophotometer for the 400—60 cm^{-1} region. In the measurements of the low temperature spectra with the latter spectrophotometer, the effect of radiation of the samples and the low temperature cell was removed by the double chopping devices in the spectrophotometer. The spectra are shown in Figs. 1—6.

Results and Discussion

(A) $BaCl_2 \cdot 2H_2O$. The infrared spectra at low temperature are shown in Figs. 1 and 2, compared with those at room temperature. Among the bands in the room temperature spectra, which were concluded to be due to water of crystallization on the basis of frequency shift associated with deuteration,[4] those at 684 cm^{-1}, 555 cm^{-1} and 525 cm^{-1} become sharp at low temperature, but do not change their frequencies markedly. On the other hand, at low temperature the bands at 405 cm^{-1} and 330 cm^{-1} increase their frequencies and two other new bands appear at 432 cm^{-1} and 400 cm^{-1}. According to the results of the lattice vibration calculation[4] for the crystal structure (space group, $P2_1/n\text{-}C^5_{2h}$) determined by Padmanabhan,[8] four H_2O rocking vibrations are expected to appear in the infrared absorption spectra in the 400—300 cm^{-1} region (calculated frequencies, 398 cm^{-1}, 328 cm^{-1} (A_u species); 401 cm^{-1}, 334 cm^{-1}. (B_u species). Therefore, the appearance of the four bands is expected, and the fact that the bands in the room temperature spectra have lower frequencies than those of corresponding bands in the low temperature spectra suggests increase of the hindering potential for rocking motion of water of crystallization (the hindering potential about the C axis of H_2O molecule) at low temperature.

(B) $CuCl_2 \cdot 2H_2O$. As are shown in Figs. 3 and 4, three sharp bands appear at 425 cm^{-1}, 400 cm^{-1} and 340 cm^{-1} in the low temperature spectra instead of the one broad band in the room temperature spectra, which has been assigned as due to water of crystallization.[6] According to the calculation of the optically active lattice vibrations[6] for the crystal structure determined by Petersen and Levy,[9] three bands (one B_{1u}, one B_{2u} and one B_{3u} species) due to the rotational lattice vibrations associated with water of crystallization are expected to appear in the infrared absorption spectra. The three sharp bands seem to correspond

9) S. W. Petersen and H. A. Levy, *J. Chem. Phys.*, **26**, 220 (1957).

to the above-mentioned three vibrations. The bands at 250 cm^{-1}, 180 cm^{-1} sharpen and one at 125 cm^{-1} increase its intensity at low temperature. The calculation showed presence of optically active lattice vibrations primarily associated with translational lattice modes of water of crystallization, whose frequencies correspond well to the frequencies of the bands.[6]

(C) $K_2C_2O_4 \cdot H_2O$. The bands at 624 cm^{-1} and 524 cm^{-1} in Figs. 5 and 6 in the room temperature spectra were interpreted as due to water of crystallization on the basis of frequency shift on deuteration and neutron scattering data.[5,10] At low temperature, the former band shifts to higher frequency, while the latter does not change its frequency. According to the calculation of the optically active vibrations,[5] the former band is assigned to a rotational lattice vibration primarily associated with H_2O rocking and wagging modes, and the latter to one primarily associated with an H_2O twisting mode. Therefore, it may be concluded that the degree of hindering around the principal axes, B and C, of the H_2O molecule increase at low temperature, while that around the A axis does not change. At low temperature the bands at 230 cm^{-1} and 244 cm^{-1} increase their intensities. The calculated frequencies, 224 cm^{-1} (A_u species) 208 cm^{-1} (B_u species) of the lattice vibrations associated with the translational lattice modes of water of crystallization[5] suggest an assignment of these bands to the above-mentioned vibrations.

In the crystal of $CuCl_2 \cdot 2H_2O$, the H_2O molecule is bound to Cl^-'s and Cu^{2+} as is shown in Fig. 7B, and the $Cu^{2+} \cdots O$ bond is considered to be strong, as the ion-atom distance is short (1.925 Å). On the other hand, in the crystal of $BaCl_2 \cdot 2H_2O$, the H_2O molecule is bound to Cl^-'s and Ba^{2+}'s as is shown in Fig. 7A. The Ba^{2+}'s are located almost in the direction of the lone-pair orbitals of the O atom (assuming sp^3 hybridization) and thus are in favorable bonding position, although the $Ba^{2+} \cdots$ O distances are rather long (2.7—3.0 Å). In the case of $K_2C_2O_4 \cdot H_2O$, the K^+'s are located off the direction of the lone-pairs of the O atoms and the $K^+ \cdots O$ distance is long (2.933 Å). Therefore, the H_2O molecules are differenlty bound in these crystals. Although it is very difficult to interpret the difference between the room temperature spectra and the low temperature spectra, the following comments will be made here in the present paper. In the case of $CuCl_2 \cdot 2H_2O$, the

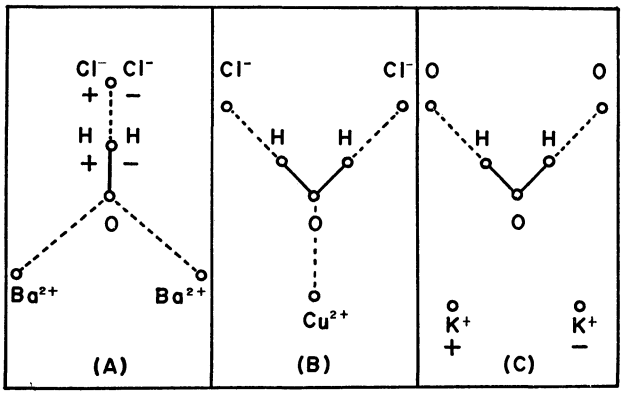

Fig. 7. Schematic representation of water of crystallization in crystals.
(+, above the paper plane; −, below the plane).

water of crystallization is so-called "coordinate water", and two H_2O molecules and two Cl^-'s are bound to Cu^{2+} by covalent type bonds. They altogether form one "molecule", $CuCl_2 \cdot 2H_2O$. Therefore, it is expected that in the room temperature spectra the bands due to H_2O molecules may be better described as ones of $CuCl_2 \cdot 2H_2O$ "molecules" arranged in the crystal. At low temperature, however, the interactions between $CuCl_2 \cdot 2H_2O$ "molecules" increase, and the state of H_2O molecules becomes similar to that of so-called "lattice water". The observed spectral change of sharpening of band width and shift of bands as a whole to lower frequency with temperature depression (see Fig. 3) may be considered as due to change of the bound state of H_2O molecule from "coordinate water" to "lattice type water". On the other hand, in the case of $BaCl_2 \cdot 2H_2O$ and $K_2C_2O_4 \cdot H_2O$, the water of crystallization is so-called "lattice water". The spectral change of the crystals with temperature depression is the increase of frequencies and intensities of some bands along with sharpening of bands. This may be caused by change of the degree of interactions between H_2O molecules and surrounding atoms and ions.

The author wishes to express his gratitude to Professor T. Miyazawa of Osaka University for allowing him to use the Hitachi EPI-L spectrophotometer and the Hitachi FIS-3 far infrared spectrophotometer, and also to Dr. T. Kitagawa and Miss M. Tsuchida of Professor Miyazawa's laboratory for their kind assistance through the measurements.

The Recombination of Iodine Atoms Generated by a C. W. Argon Ion Laser

Naohiko HARADA, Yuji MORI, and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 8, 1970)

The rate constants of iodine-atom recombination in various foreign gases were determined by measuring the relative concentrations of iodine atoms in the photostationary state, through irradiation by a c.w. argon-ion laser at 4880 Å. The relative concentration has been obtained from the absorption intensity for the emission line from an iodine discharge lamp at 1830 Å. The rate constants have been given for the diffusion of iodine atoms and for the second-order recombination of iodine atoms. The values of the diffusion rate constants in various foreign gases have been compared with the calculated values. The logarithmic second-order rate constants in various gases were plotted against their ionization potentials. The plot yielded a straight line, indicating that the formation of the charge-transfer complex between iodine atoms and foreign gas molecules is important in the recombination process, as has been suggested by Porter *et al.*

The gas-phase iodine-atom recombination reaction in the presence of third-body gases has already been studied by several methods. Some of the earliest measurements have been made by Rabinowitch and Wood,[1] using the photostationary state method, by measuring the change in the absorbance of molecular iodine.

The flash-photolysis technique has been applied to iodine-atom recombination by numerous investigators.[2–12] Christie, Harrison, Norrish, and Potter,[3] measuring the decrease of iodine molecules, have pointed out that there is a rapid termolecular reaction, $I+I+I_2 \rightarrow I_2+I_2$.

Porter and Smith[10] have found that the second-order recombination rate constant for iodine atoms shows a negative activation energy which decreases as the chaperon efficiency increases. This was explained by the existence of intermediate complexes, as has been suggested by Rabinowitch and Wood,[1] where the complexes resulted not from normal van der Waals-type interactions but from charge-transfer interactions between the third body (M) and the iodine atom.[9,10,13]

$$I + M \rightleftarrows IM$$

$$IM + I \rightarrow I_2 + M.$$

Strong *et al.*[6] have observed the same rate of recombination at different wavelengths for photolytic initiation; they have concluded that excited atoms ($^2P_{1/2}$) either recombine at the same rate as ground-state atoms or are deactivated to the ground state ($^2P_{3/2}$) before measurements are made.

The present study has been planned in order to investigate the recombination reaction of iodine atoms, a reaction initiated by the intense light from a c.w. argon-ion laser at 4880 Å. This method enables us to detect the iodine atoms directly by absorption.

In this study the recombination rate was measured by monitoring the concentration of the atomic iodine in the ground state, which absorbs the resonance lines of iodine atoms, not by monitoring the concentration of iodine molecules. Under our experimental conditions, the measurements by the former will be more accurate than those by the latter, because only a very small proportion of iodine molecules decreases upon irradiation.

Experimental

1. *C. W. Argon-ion Laser.* An argon-ion laser has been constructed in our laboratory. The maximum output power with a single line at 4880 Å was 810 mW at the discharge current of 28 Å and with a magnetic field of about 600 gauss. The output power from the laser was controlled by changing the discharge current.

2. *Reaction Cell and the Optical System for the Detection of Iodine Atoms.* Figure 1 is a schematic diagram of the optical system used in the present measurements. The monochromatic light beam at 4880 Å from the argon-ion laser entered the quartz reaction cell and induced the photodissociation of iodine molecules into atoms. In order to increase the dissociation rate, a concave mirror with a focal length of 80.2 cm was put behind the cell to reflect the laser beam into the cell. The reaction cell had four windows and a small tube at the bottom. The small tube contained a small amount of iodine crystals and was immersed in a water bath at 22°C (iodine vapor pressure was 0.25 Torr at 22°C).

The 1830 Å light beam from an iodine discharge lamp entered the reaction cell, crossed the laser beam at a right angle, and fell on the incident slit of a monochromator after passing through the cell. The iodine lamp, which was powered by microwave. was made of a quartz tube 20 mm in outer-diameter, and had a side arm immersed in a water-ice bath in order to maintain a constant iodine vapor pressure and to give narrow, unreversed lines. The carrier gas of the lamp was 2 Torr He. The monochromator with a 1440 lines/mm grating was set at 1830 Å with a slit width of 0.5

mm. The intensity of the exit beam from the monochromator was measured and recorded on a chart paper with a conventional photomultiplier-D.C. amplifier-recorder combination. Since the atmospheric oxygen absorbs the light below 1900 Å, nitrogen streamed between the iodine lamp and the cell, in the monochromator and also in the photomultiplier casing.

3. *Materials.* Commercially-available reagent-grade iodine crystals were used after purification by sublimation three times. The foreign gases used in the present study, He, Ne, Ar, Xe, H_2, N_2, NO, CO, CO_2, and C_3H_8, were supplied by the Takachiho Chemical Industry Co. and were used without further purification.

4. *Procedure.* The iodine atoms in the cell were detected by measuring the absorbance for a resonance line of iodine atoms. At first, upon closing the shutter for the laser light, the intensity of the analyzing light at 1830 Å, I_0, was measured. Then, the shutter was opened and the intensity, I, was measured again. The absorbance at 1830 Å, log I_0/I, gives the relative concentration of iodine atoms.

The absorbance by molecular iodine of the laser light was independent of the laser output power and of the pressure of foreign gases, and it remained constant during the reaction, within the limits of experimental error. Thus, it can be said that the production rate of iodine atoms is proportional to the laser output power and that iodine molecules decompose to only a small extent.

The effect of the light absorption at 1830 Å due to molecular iodine on the determination of the iodine-atom concentration can be ignored because of the weak absorption of molecular iodine. Much care was taken in adjusting the optical system so that the analyzing light beam crossed the laser light beam exactly.

Results

Figures 2, 3, and 4 illustrate the results obtained in argon as a foreign gas. Figure 2 shows that the laser output power increases with an increase in the absorbance of iodine atoms at 1830 Å, and the slope

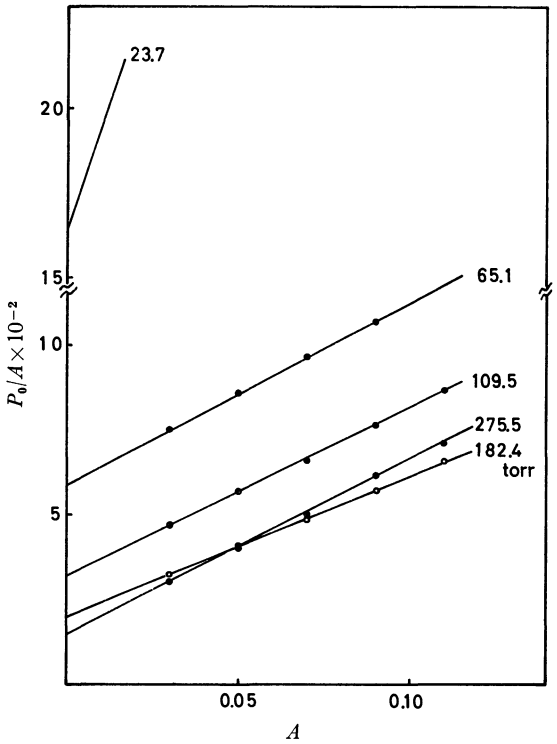

Fig. 3. Plots of P_0/A against A.

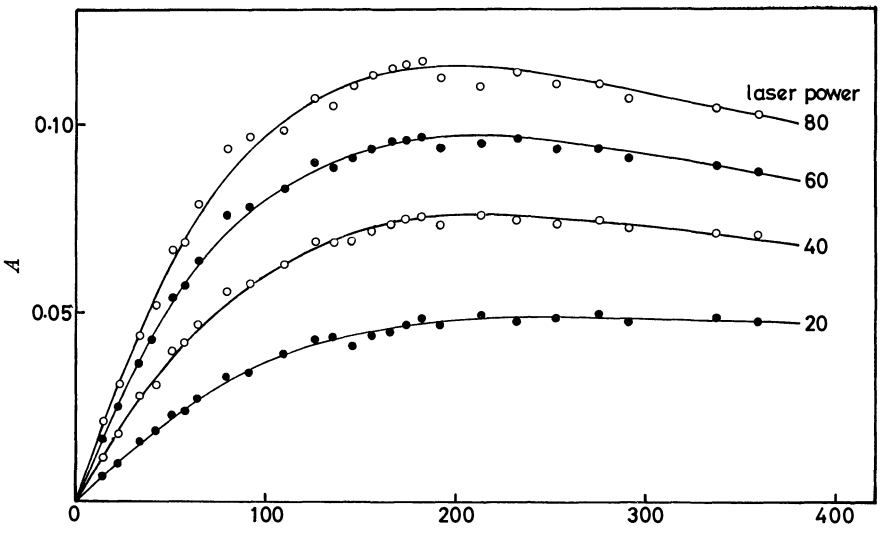

Fig. 4. Variation of absorbance of iodine atoms with the change in argon pressure.

gradually becomes steeper at high absorbances. This is clearly shown in Fig. 3, where the ratio of the laser-output power (P_o) to the absorbance at 1830 Å (A; relative concentration of iodine atoms) increases linearly with the absorbance. This indicates that the participation of the second-order iodine atom recombination becomes important at high concentrations of iodine atoms. The pressure effect of a foreign gas on the iodine-atom recombination is demonstrated in Fig. 4, where the absorbance at 1830 Å may be seen to increase at low foreign-gas pressures, while at high pressures it decreases with an increase in the foreign-gas pressure after it reaches a maximum. This can be interpreted in terms of the decreasing rate of the diffusion of iodine atoms to the wall at low pressures and by the increasing rate of iodine-atom recombination in the gas phase because of the increased second-order rate constant at high pressures of foreign gases.

The absorption of the laser light at 4880 Å by iodine molecules induces the decomposition of iodine molecules into atoms, a half of the atoms in the ground state ($^2P_{3/2}$) and the rest in the excited state ($^2P_{1/2}$):

$$I_2 + h\nu(4880\,\text{Å}) \xrightarrow{I_a} I(^2P_{3/2}) + I^*(^2P_{1/2}) \quad (1)$$

The excited iodine atoms are, however, subjected to fast quenching collisions with molecules before recombination[14,15]:

$$I^*(^2P_{1/2}) + M \longrightarrow I(^2P_{3/2}) + M \quad (2)$$

and have little effect on the recombination reaction.[4]

The mechanisms of the iodine-atom recombination in the gas-phase are believed to involve the following reactions:

1) recombination to form iodine molecules after the diffusion of iodine atoms to the wall of the reaction vessel:

$$I + \text{wall} \xrightarrow[k_3]{\text{(diffusion)}} 1/2\ I_2 + \text{wall} \quad (3)$$

2) recombination of iodine atoms through collisions with foreign-gas molecules:[1]

$$I + I + M \xrightarrow[k_4]{} I_2 + M \quad (4)$$

3) recombination of iodine atoms through collisions with iodine molecules:[3]

$$I + I + I_2 \xrightarrow[k_5]{} 2I_2 \quad (5)$$

Reaction (3) plays an important role in the recombination of iodine atoms at low foreign-gas pressures, while, at higher pressures, reaction (4) predominates over reaction (3). Reaction (5) can not be ignored in spite of the very low concentration of iodine molecules, for the rate constant of reaction (5) has a much larger value than that of reaction (4).[13]

A photostationary-state treatment leads to the next equation for the mechanism of the iodine-atom recombination:

$$\frac{d[I]}{dt} = 2I_a - k_3[I] - (k_4[M] + k_5[I_2])[I]^2 = 0 \quad (6)$$

where [I] is the concentration of iodine atoms, which is proportional to the absorbance of iodine atoms at 1830 Å, [M], the concentration of foreign-gas molecules, and [I_2], that of iodine molecules. Since I_a is proportional to the laser output power (P_o), the next equation can be obtained from Eq. (6):

$$\alpha P_0 = k_3[I] + (k_4[M] + k_5[I_2])[I]^2 \quad (7)$$

and:

$$\frac{\alpha P_0}{[I]} = k_3 + (k_4[M] + k_5[I_2])[I] \quad (8)$$

where α is a constant. This equation can explain the linear relationship between P_o/A and A in Fig. 3, because A gives the relative concentration of iodine atoms. The intercept in the figure gives the relative value of k_3 for a pressure of a foreign gas, and the slope of the linear plot gives the relative value of $k_4[M]+k_5[I_2]$. Since k_3 is inversely proportional to the pressure of a foreign

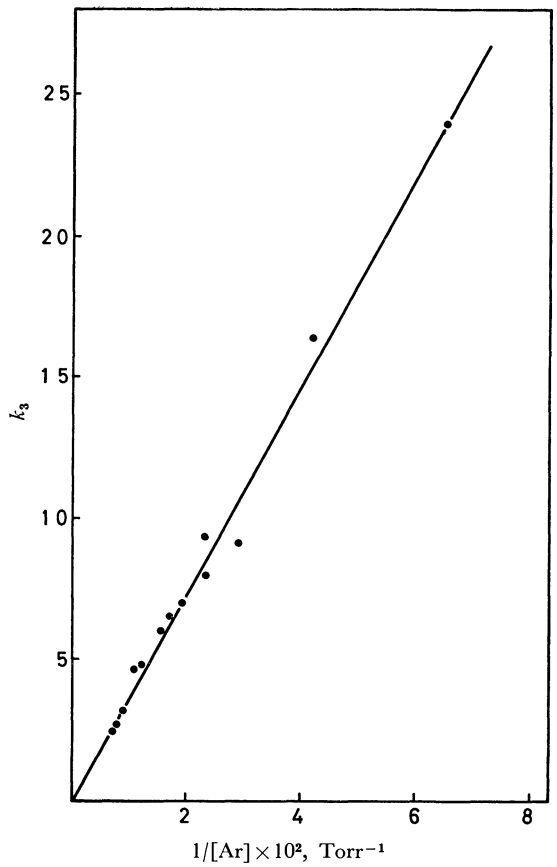

Fig. 5. Plots of k_3 against 1/[Ar].

gas, as is shown in Fig. 5, the relative value of the diffusion-rate constant, β, can be obtained by using the relation:

$$k_3 = \frac{\beta}{[M]} \tag{8'}$$

The plots of the values of $k_4[M]+k_5[I_2]$ for various foreign-gas pressures give the straight line in Fig. 6. From the intercept in the figure, the relative value of the rate constant, k_5, can be obtained, while from the slope of the linear plots, the relative value of k_4 can be obtained. The relative values of β for various foreign gases are listed in Table 1, and those of k_4 and that of k_5 are listed in Table 2.

Discussion

Diffusion-rate Constant. Helium and hydrogen offer the least resistance to the diffusion of iodine atoms, as is shown in Table 1. Xenon shows the slowest diffusion among rare gases. The rates in carbon dioxide and in propane had to be less accurately measured because of the fast rates of the recombination of iodine atoms in these gases. Since there have been no available data of the diffusion coefficient of iodine atoms in various gases, we have calculated the diffusion-rate constant, which can be compared with β.

The diffusion coefficient of iodine atoms in a gas is given by the next equation, based on a simple gas kinetic theory:

$$D = \frac{3}{16}\frac{1}{p\sigma_{12}^2}kT\left(\frac{1}{m_1}+\frac{1}{m_2}\right) \tag{9}$$

where p is the total pressure of the system, σ_{12} is the collision diameter between the iodine atom and the molecule, and m_1 and m_2 are the masses of the iodine atom and the foreign gas molecule respectively. Since this equation involves pressure, we define the diffusion-rate constant by the next expression:

$$D' = \frac{3}{16}\frac{1}{\sigma_{12}^2}kT\left(\frac{1}{m_1}+\frac{1}{m_2}\right) \tag{10}$$

where the total pressure, p, has been approximated by the pressure of a foreign gas. In the calculation, the value of the collision diameter, σ_{12}, has been obtained as a sum of the radius of iodine atoms and the kinetic collision radius of the molecule. The calculated values of D' for various foreign gases are shown in the right column of Table 1.

The relative values of the diffusion-rate constant observed in various foreign gases are plotted against the relative values of D' in Fig. 7. The relation between β and D' is approximately linear; this indicates that the diffusion of iodine atoms can be understood by the usual gas kinetic theory.

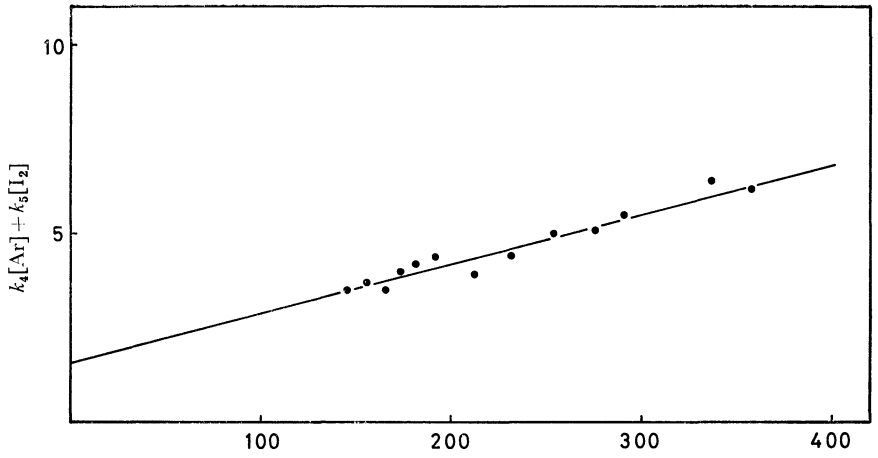

Fig. 6. Plots of $k_4[Ar]+k_5[I_2]$ against [Ar].

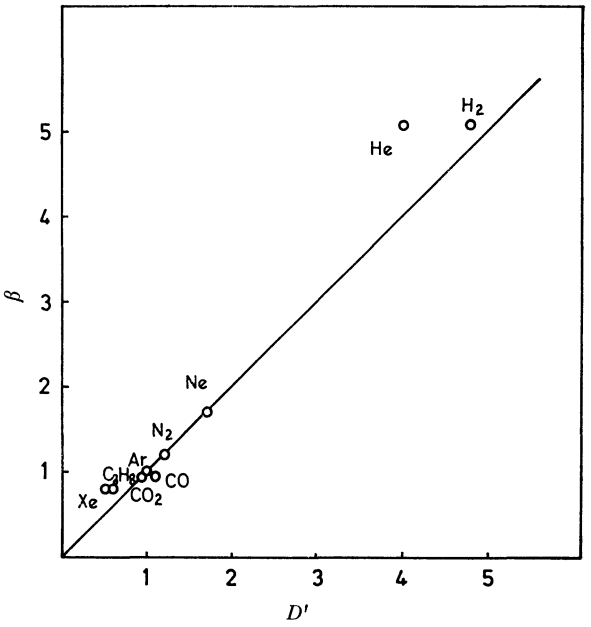

Fig. 7. Relation between β and D'.

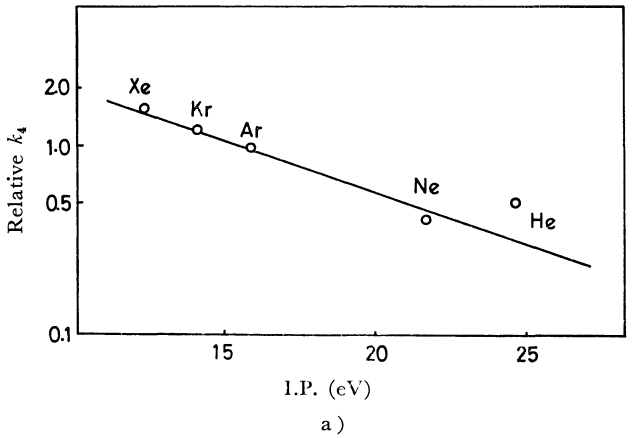
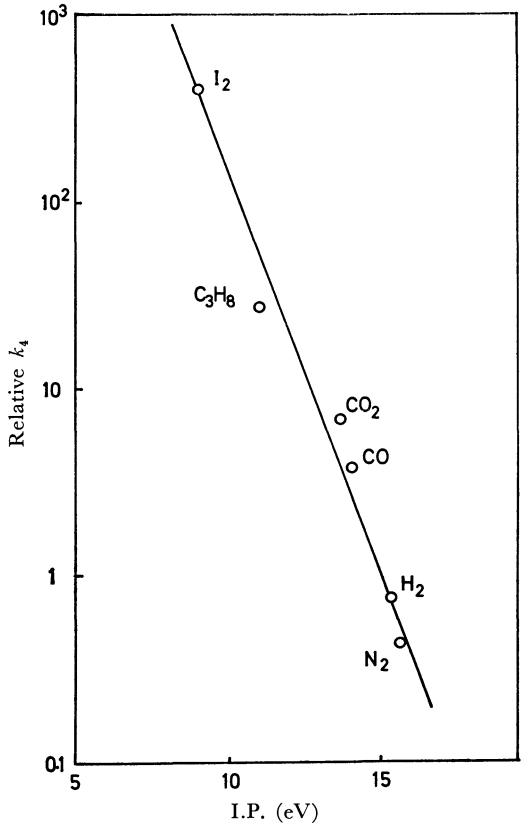
Recombination-rate Constant. The obtained rate constants, though relative, are found to be qualitatively in good agreement with those obtained by other methods[3,13] (Table 2). The efficiency in the recombination process as a third body is smaller in the case of mono-atomic gases (He, Ne, and Ar) and is larger in the case of polyatomic gases, because the additional degrees of the freedom of internal motion make the energy transfer from the atom to the molecule easier.

The exceptionally high rate constant in the case of iodine molecules as the third body, which can not be explained by the van der Waals interaction, may imply the formation, and the considerable stability, of the I_3 molecule.[3] The complex mechanism may also be applied to the iodine atom decay in propane.



a)



b)

Fig. 8a, 8b. Relative values of k_4 for various foreign gases as a function of ionization potential of foreign gases.
a) for mono-atomic gases
b) for molecules.

Callear and Wilson[16,17] have suggested the existence of $I...C_3H_8$ as an intermediate complex in the recombination reaction of iodine atoms.

Porter and Smith[10,13] have suggested that a charge-transfer complex is responsible as an intermediate complex and that the recombination rates increase with decrease in the ionization potential of the third-body gas which acts as a donor. We have plotted the logarithmic relative recombination rate constants against the ionization potentials of added gases in Figs. 8a and 8b, where the values for krypton and xenon are those of Cristie *et al.*[3] The plots yield two straight lines, with different slopes, one for rare gases and another for polyatomic gases. The difference in the slope between mono- and poly-atomic gases is due to the stability of IM in the following elementary reactions.

$$I + M \rightarrow IM \quad (11)$$

$$IM + I \rightarrow I_2 + M \quad (12)$$

The intermediate complex, IM, is more stable for the polyatomic gases than for the monoatomic, because, in the case of polyatomic gases, the excess energy in the complexes will be distributed over the increased internal degrees of freedom.

Detection of $I^*(^2P_{1/2})$. Attempts to detect iodine atoms in the excited state have met with failure, even in a rare gas, because of the low concentration due to the short life of $I^*(^2P_{1/2})$. The rare gases are inefficient quenchers of excited iodine atoms, but iodine molecules are efficient quenchers of excited iodine atoms. The concentration of iodine molecules in the system is sufficient to quench $I^*(^2P_{1/2})$ in a short time. The life time of excited iodine atoms is estimated to be of the order of 10^{-3} sec, using the value of the quenching rate for $I^*(^2P_{1/2})$ by I_2, $k_q=3.0\times10^9$ l $mol^{-1}sec^{-1}$.[14] Since the stationary concentration of excited iodine atoms is estimated to be of the order of 10^{14} atoms/cm^3, the excited iodine atoms can probably be detected with the present apparatus with an improved sensitivity.

We would like to thank Mr. Y. Izumisawa for his assistance with the measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 380—386 (1971)

Charge Transfer Interaction and Chemical Reaction. III. Reactions of *m*-Phenylenediamine and Related Compounds with Chloranil

Takashi NOGAMI, Tsuguo YAMAOKA,* Keitaro YOSHIHARA, and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received September 11, 1970)

The interactions of chloranil with several aromatic amines were studied by measuring visible and ultraviolet absorption spectra at various temperatures between 70°K and 300°K, *m*-aminophenol, *m*-phenylenediamine, *N*,*N*-dimethyl-*m*-phenylenediamine, 1,3,5-triaminobenzene, and 1-methyl-2,4,6-triaminobenzene being taken as electron donors. The *m*-phenylenediamine-chloranil system was studied in detail and outer and inner complexes were found to exist as reaction intermediates. The structure and stability of the inner complex were discussed. Kinetic studies were made for the *m*-phenylenediamine-chloranil and 1,3,5-triaminobenzene-chloranil systems. The enthalpy change, ΔH, for the formation of the outer complex was determined from the temperature dependence of the equilibrium constant. The activation energies, ΔE_1 and ΔE_2, for the processes from the outer complex to the inner complex and from the inner complex to the succeeding intermediate, respectively, were determined by analysing the time dependence of the absorption-peak intensity of the inner complexes measured at several temperatures. The results are as follows: $\Delta H=-3.7$, $\Delta E_1=10$, and $\Delta E_2=22$ (kcal/mol) for the *m*-phenylenediamine-chloranil system; $\Delta H=-2.6$, $\Delta E_1=16$, and $\Delta E_2=14$ (kcal/mol) for the 1,3,5-triaminobenzene-chloranil system.

The aromatic substitution reaction has hitherto been extensively studied.[1] There still remain, however, some important problems unsolved. For instance, the role of the outer (π) and inner (σ) complexes has been discussed by many authors, but is still in dispute.[2]

One of the present authors (S. N.) previously presented the charge-transfer mechanism of the aromatic substitution reaction[3] on the basis of Mulliken's concept[4] on the electron donor-acceptor interaction. In order to clarify further this problem from the experimental point of view, we have carried out several

experimental studies, taking benzoquinone and its halo-derivatives as electron acceptors. In previous papers of this series, the reactions of aniline[5a] and 1,3,5-triaminobenzene[5b] with chloranil were studied, special attention being paid to the roles of the outer (π) and inner (σ) complexes in the reaction. The present paper is concerned with several systems containing meta-substituted derivatives of aniline and chloranil. The *m*-phenylenediamine-chloranil system was studied in particular detail in order to clarify the reaction mechanism and to determine the potential energy curve for the reaction.

Experimental

Materials. 1,3,5-Triaminobenzene, 1-methyl-2,4,6-triaminobenzene, and *N,N*-dimethyl-*m*-phenylenediamine were synthesized by reducing the corresponding nitro compounds catalytically.[6] They were purified by vacuum sublimation. Commercially-available *m*-aminophenol and *m*-phenylenediamine (abbreviated to *m*-PD) were also purified by the same method. Chloranil was purified by repeated recrystallizations from acetone.

Measurements. A Cary recording spectrophotometer model 14 M was used for the measurements of ultraviolet and visible absorption spectra, a quartz cell of 1 cm path length being used. The donor and acceptor solutions, which were separately prepared, were mixed with each other immediately before the absorption measurements. For the measurements at low temperatures, a sample cell was cooled with dry ice-acetone in a quartz dewar vessel designed for the spectroscopic measurements.

The temperature dependence of the equilibrium constant of the outer complex was measured in the range from −84°C to −93°C.[7] For this purpose, a sample cell was immersed in the dewar vessel and was cooled with cold nitrogen gas. The temperature was regulated by the nitrogen-flow velocity. The rate constants for the reaction processes from the outer complex to the inner complex and from the inner complex to the succeeding intermediates, were measured in the temperature range from 9.5 to 25.5°C. The temperature of a sample cell in the dewar vessel was regulated by circulating thermostated water.

Results and Discussion

Temperature or Time Dependence of the Electronic Absorption Spectrum of the m-*PD-chloranil System.* After mixing the acetone solution of *m*-PD with that of chloranil at −80°C (*m*-PD, 2.0×10^{-3} M; chloranil, 1.0×10^{-3} M), the reaction process was studied by measuring the absorption spectra at various stages. The results are shown in Fig. 1. A band at 680 mμ (curve 1) measured immediately after mixing at low temperatures is assigned to the outer complex for the following reasons. The peak position is consistent with the value expected for the *m*-PD-chloranil system from a comparison with the CT band positions observed for the chloranil and trinitrobenzene complexes with several aromatic amines. Furthermore, the band intensity below −80°C changes reversibly with increasing and decreasing temperature, and the equilibrium constant for the 1 : 1 complex formation can be obtained, as will be described later, from the concentration dependence of the absorption intensity of the 680 mμ band. This means that the band is due to the outer 1 : 1 complex.

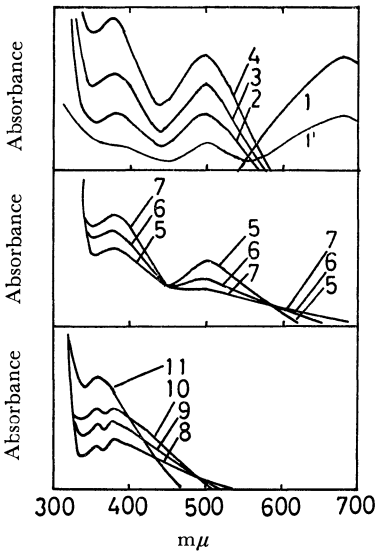

Fig. 1. The absorption spectra of the system containing *m*-PD (2.0×10^{-3} M) and chloranil (1.0×10^{-3} M).
Curve 1: measured at 77°K, immediately after mixing in ethyl ether-isopropyl alcohol (3:1) mixed solvent.
Curve 1': measured at ~200°K, 10 min after mixing in acetone.
Curves 2—11: measured at room temperature for the acetone solution with the following time intervals after mixing:
6, 14, 25, 32, 46, 62, 90, 217, 374 min, and 28 hr, respectively.

The outer complex is stable below −80°C, but at room temperature it is unstable and the 680 mμ band decreases in intensity. Parallel with the intensity decrease of the 680 mμ band, two new absorption bands appear at 500 mμ and 380 mμ. These two bands increase in intensities for 30 min after the mixing, thereafter, the intensity of the 500 mμ band decreases gradually. This band is assigned to the inner (σ) complex between *m*-PD and chloranil for a reason to be described later.

Even when the 500 mμ band starts to decrease in intensity, the 380 mμ band continues to increase. As may clearly be seen from curves 8—11 in Fig. 1, a new band appears at 355 mμ, parallel with the decrease in the intensity of the 380 mμ band. This new band is due to the final product, the 2(*m*-PD) : 1 (chloranil) substitution product, as will be described later. This experimental result shows that the 380 mμ band is due to the reaction intermediate (P_1) between the inner (σ) complex and the final reaction product,

6) T. Yamaoka, H. Hosoya, and S. Nagakura, *Tetrahedron* **24**, 6203 (1968).
7) The temperature range is limited by the instability of the outer complex and also by the solidification of the acetone solution. In order to obtain accurate results within these limitations, we took as many points as possible in the range from −84°C to −93°C.

2,5-dichloro-3,6-di-*m*-aminoanilino-*p*-benzoquinone (P_2). A similar phenomenon was observed for the triaminobenzene-chloranil system.[5b] In this system, the intermediate corresponding to P_1 was isolated as a pure crystal and was identified as the 1 : 1 substitution product, 2,5,6-trichloro-3-triaminobenzo-*p*-benzoquinone from the elemental analysis and also from the NMR spectrum. By an analogy with this P_1 in the present case may be identified as 2,3,5-trichloro-6-*m*-aminoanilino-*p*-benzoquinone (see Fig. 2). The mixture of *m*-PD and chloranil with the concentration ratio of *m*-PD: chloranil = 1 : 5 exhibits the 380-mμ band even after it has been kept for 24 hours at room temperature. This supports the above assignment, because the reaction from the 1 : 1 species (P_1) to the 2 : 1 species (P_2) may be expected to proceed hardly at all in this case where the concentration of chloranil is much larger than that of *m*-PD. The P_1 species has another weak and broad absorption band extending over nearly the whole range of the visible region and with its absorption peak at 630 mμ.

After 28 hours the reaction has almost completely finished, producing the final reaction product with its absorption peak at 355 mμ. It is identified as 2,5-dichloro-3,6-di-*m*-aminoanilino-*p*-benzoquinone ($C_{18}H_{14}Cl_2N_4O_2$) from the elemental analysis[8] and the NMR spectrum.[9]

An absorption spectrum due to the inner (σ) complex similar to the 500 mμ band observed for the *m*-PD-chloranil system was found for several systems containing chloranil and meta-derivatives of aniline, such as *m*-aminophenol, *N*,*N*-dimethyl-*m*-phenylenediamine and 1-methyl-2,4,6-triaminobenzene. Furthermore, the temperature and time dependencies of the absorption spectra observed for these systems are similar to those for the *m*-PD-chloranil system. This seems to mean that the above reaction mechanism holds for the systems containing *m*-derivatives of aniline as electron donor.

The Spectrum and Structure of the Inner (σ) Complex. For all the systems containing chloranil and the *m*-derivatives of aniline studied here, the absorption peak appears at ~500 mμ in the intermediate stage between the outer (π) complex and the 1 : 1 species corresponding to P_1. By an analogy with the corresponding intermediate in other ring-substitution reactions like the nitration, alkylation, and sulfonation of aromatic hydrocarbons, the intermediate with the peak at 500 mμ may be identified as the inner (σ) complex shown in Fig. 2. In this complex, one of the ring-carbon atoms of chloranil taking the sp^3 hybridization forms a new bond with an aromatic amine and is excluded from the conjugated system. Therefore, we can explain the finding that aromatic amines attached to this carbon have hardly any influence on the absorption spectra of the inner complexes.

Benzoquinone also forms inner complexes with several meta-substituted derivatives of aniline in ethanol, and their absorption peaks (λ_{max} = 490 mμ) are almost the same as those for the chloranil complexes. We calculated lower transition energies for the inner (σ) complex between aromatic amine and benzoquinone, assuming the structure shown in Fig. 2. The details of the calculation will be described in the Appendix. The calculated transition energies are 2.14, 4.57, 5.19, 6.55, 6.59, and 7.55 eV. The observed value, 2.53 eV, coincides well with the lowest transition energy calculated. This seems to support the assignment of the 500 mμ band.

Another tentative structure of the inner complex is that an aromatic amine combines with chloranil on one of its ring carbon atoms (see σ' in Fig. 2). This structure, however, may be excluded for the following reason.

The electronic absorption spectrum of the inner complex has no band in the position expected for the benzenium ion-type species of the respective donors. Table 1 shows the peak positions of the ring-protonated and amino-protonated aromatic amines.[10] The ring-protonated aromatic amines exhibit a characteristic band at ~360 mμ. Since the σ' species in Fig. 2 consists of the π-electron system, which is similar to the corresponding ring-protonated aromatic amine, it may be expected to have the characteristic band at ~360 mμ. In actuality, however, the absorption spectrum of the inner complex has no band in the expected position. Therefore, we can exclude the possibility that the inner complex has the structure of σ' in Fig. 2. The fact that P_2 is obtained as the final product also supports the above conclusion as to the structure of the inner (σ) complex.

Contribution of the Outer Complex to the Reaction. Electrophilic aromatic substitution reactions are known to involve both the outer and inner complexes as reaction intermediates.[11] However, it is not well establish-

Table 1. The peak positions of the ring and amino protonated aromatic amines

Amine	Position of protonation	Peak position (mμ)		
1,3,5-Triaminobenzene	ring	365	272	220
	amino	290	220	
N,*N*-Dimethyl-*m*-phenylenediamine	ring	360		
	amino	290	240	
m-Phenylenediamine	ring	360		
	amino	290	240	

8) Found: C, 58.26; H, 4.43; Cl, 18.96; N, 14.41%. Calcd for $C_{18}H_{14}Cl_2N_4O_2$: C, 55.53; H, 3.59; Cl, 18.25; N, 14.39%. The discrepancy between the results of the elemental analysis and the calculated values is due to the existence of small amounts of impurities, for example, the 1 : 1 species and HCl salt of *m*-PD. We tried to purify the sample by chromatography and recrystallization techniques, but we were not successful mainly because of the very small solubility of the sample.

9) The NMR spectrum of the reaction product shows a signal due to the proton of the secondary amine (τ_H = 3.05 ppm). This fact shows that the substitution reaction occurs on the amino group.

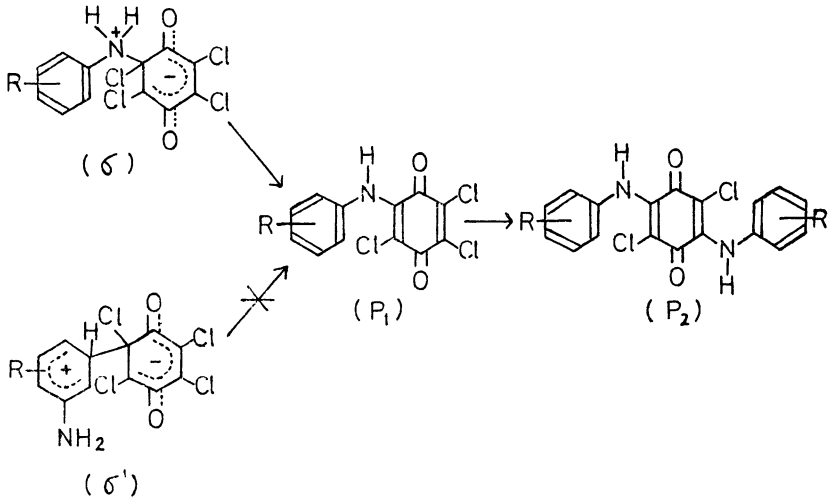

Fig. 2. The structures of the inner complexes ((σ) and (σ')) and the reaction products (P_1 and P_2).

ed whether the outer complex takes part in the main reaction as an intermediate or in a side reaction. The former and latter cases are referred to as "Reaction 1" and "Reaction 2", respectively.

Reaction 1:

$$D + A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \pi \xrightarrow{k_3} \sigma \xrightarrow{k_4} \cdots \rightarrow P$$

Reaction 2:

$$\pi \underset{k_1'}{\overset{k_2'}{\rightleftharpoons}} D + A \xrightarrow[k_3']{} \sigma \xrightarrow[k_4']{} \cdots \rightarrow P$$

Here, D,A,π,σ, and P denote aromatic amine, chloranil, the outer complex, the inner complex, and the final reaction product, respectively. The rate constant for each process is indicated by k_i or k_i'. The ΔH, ΔE_1, and ΔE_2 values are the enthalpy change for the formation of the outer complex, the activation energy from π to σ, and that from σ to the succeeding reaction intermediate, respectively. These notations are used throughout this paper.

Since $k_1[D]_0$ ($[D]_0$ is the initial concentration of the donor) and since k_2 are generally much larger than k_3 and k_4 (or $k_1'[D]_0$, $k_2' \gg k_3'[D]_0$, k_4'), it is difficult to determine which of Reaction 1 or Reaction 2 actually occurs. In connection with this, experimental studies of the Friedel-Crafts reaction are worthy of notice.[12] The reaction was found to occur only when the outer complex is formed; *o*-xylene, which forms the outer complex with t-C_4H_9Cl–BF_3, causes the butylation reaction, but *p*-xylene, which does not form it, is insusceptible to the Friedel-Crafts reagent. These facts show that the outer complex takes part in the Friedel-Crafts reaction.

Another suggestive fact concerning this problem was found by us for the *N*,*N*,*N'*,*N'*-tetramethyl-*p*-phenylenediamine(TMPD)-chloranil system in an ether-isopropyl alcohol (3 : 1) mixed solvent.[13] We can not detect the inner complex when the system of appropriate concentrations of the component molecules, for which the outer complex formation is negligibly small at room temperature, is cooled directly to the temperature of dry ice-acetone. However, the inner complex is formed by raising the temperature of the system to the dry ice-acetone temperature after it has once been cooled to the liquid nitrogen temperature, at which a considerable amount of the outer complex is formed. This seems to indicate that the inner complex can not be formed directly from the component molecules, but only *via* the outer complex. This finding suggests that Reaction 1 is more probable than Reaction 2. Therefore, we carry out kinetic study taking the path of Reaction 1.

Kinetic Study of the Reaction. The rate equations for Reaction 1 are as follows:

$$\frac{d[A]}{dt} = k_2[\pi] - k_1[D][A] \quad (1)$$

$$\frac{d[\pi]}{dt} = k_1[D][A] - (k_2+k_3)[\pi] \quad (2)$$

$$\frac{d[\sigma]}{dt} = k_3[\pi] - k_4[\sigma] \quad (3)$$

These equations are solved under the following two reasonable conditions;

(a) The concentration of D, [D], is much larger than that of A, [A],[14] and is considered to be approximately equal to the initial concentration, $[D]_0$, throughout the reaction.

(b) Since

$$k_1[D]_0,\ k_2 \gg k_3,\ k_4, \quad (4)$$

a preliminary equilibrium exists between the component molecules and the outer complex with the equilibrium constant, K;

$$K = \frac{[\pi]}{[D][A]} \approx \frac{k_1}{k_2} \quad (5)$$

From Eqs. (1), (2) and condition (a), the following differential equation for [π] is derived:

12) G. A. Olah, S. H. Flood, and M. E. Moffat, *J. Amer. Chem. Soc.*, **86**, 1060 (1964); R. Nakane, A. Natsubori, and O. Kurihara, *ibid.*, **87**, 3597 (1965); R. Nakane and A. Natsubori, *ibid.*, **88**, 3011 (1966); R. Nakane, T. Oyama, and A. Natsubori, *J. Org. Chem.*, **33**, 275 (1968).

13) The details will be published in near future.

14) In our experiment, [D]=40[A].

$$\frac{d^2[\pi]}{dt^2} + (k_1[D]_0 + k_2 + k_3)\frac{d[\pi]}{dt} + k_1k_3[D]_0[\pi] = 0 \quad (6)$$

Considering the boundary condition $(d[\pi]/dt)_{t=0} = k_1[D]_0[A]_0 - (k_2+k_3)[\pi]_0$, we can obtain the equation for $[\pi]$:[15]

$$[\pi] = pe^{-\alpha t} + qe^{-\beta t} \quad (7)$$

Here,
$$p = \frac{k_1[D]_0[A]_0 - (k_2+k_3-\beta)[\pi]_0}{\beta-\alpha}$$
$$q = \frac{(k_2+k_3-\alpha)[\pi]_0 - k_1[D]_0[A]_0}{\beta-\alpha}$$
$$\binom{\alpha}{\beta} = \frac{1}{2}\left\{k_1[D]_0 + k_2 + k_3 \mp \sqrt{(k_1[D]_0+k_2+k_3)^2 - 4k_1k_3[D]_0}\right\} \quad (8)$$

By substituting Eq. (7) into Eq. (3) and considering $[\sigma]_0=0$, we can obtain the equation for $[\sigma]$:

$$[\sigma] = \frac{pk_3}{k_4-\alpha}(e^{-\alpha t} - e^{-k_4 t}) + \frac{qk_3}{k_4-\beta}(e^{-\beta t} - e^{-k_4 t}) \quad (9)$$

The approximate forms of Eqs. (7), (8), and (9) can be derived by adopting Eqs. (4) and (5) as follows:[16]

$$\alpha \approx \frac{k_3K[D]_0}{K[D]_0+1} \quad (8)'$$
$$\beta \approx k_1[D]_0 + k_2$$
$$[\pi] \approx pe^{-\alpha t} \quad (7)'$$
$$[\sigma] \approx \frac{pk_3}{k_4-\alpha}(e^{-\alpha t} - e^{-k_4 t}) \quad (9)'$$

Eqs. (8)′ and (9)′ are used to obtain the activation energies, ΔE_1 and ΔE_2. Furthermore, we can derive the following equation from Eq. (9);

$$\int_0^\infty I_\sigma dt = \frac{k_1[D]_0[A]_0 + (\alpha+\beta-k_2-k_3)[\pi]_0}{k_1k_4[D]_0} \times \varepsilon_\sigma L \approx \frac{\varepsilon_\sigma L[A]_0}{k_4} \quad (10)$$

Here, ε_σ and I_σ denote the molar extinction coefficient and absorbance observed with the inner complex, respectively, and L is a light-path length. Equation (10) shows that ε_σ is obtained by measuring the time dependence of I_σ for the inner complex, the I_σ-t curve.

Potential Energy Curve of the Reaction. The *m*-PD-chloranil and TAB-chloranil systems were taken up for the purpose of determining the potential energy curve of the reaction, because the inner complexes in these systems are fairly stable, even at room temperature,[5b] and because the changes in their concentrations with the time can be easily followed by electronicabsorption measurements. We chose the acetone solution for the purpose of determining the potential energy curves, because the main reaction product in this solvent consists of only one species, 2,5-dichloro-3,6-di-*m*-aminoanilino-*p*-benzoquinone, when there is much more *m*-PD than chloranil. On the other hand, at least two main reaction products were found in such solvents as ethyl ether, ethanol, and an ether-isopropyl alcohol mixed solvent, and the reaction mechanism in these solvents seems to be more complicated than that in acetone.

Let us start from the determination of the enthalpy (ΔH) and entropy (ΔS) changes for the outer-complex formation. The absorbance values at the peak position (680 mμ) of the CT band of the outer complex were measured for acetone solutions including various concentrations of *m*-PD and chloranil. The peak molar extinction coefficient, ε_{max}, was determined to be 3120 $M^{-1}cm^{-1}$ from the Benesi-Hildebrand plot[17] measured at −80°C. Assuming ε_{max} to be independent of temperature, the temperature dependence of the equilibrium constant of the outer complex was determined in the range from −84°C to −93°C in the same way as has been described previously.[5a] The ΔH and ΔS for the *m*-PD-chloranil system in acetone were determined to be −3.7 kcal/mol and −13.7 cal/mol·deg, respectively.

The outer complex of the TAB-chloranil system has its absorption peak at 660 mμ in acetone.[5b] The complex is unstable even at temperature of dry ice-acetone, and it is difficult to obtain ε_{max} from the Benesi-Hildebrand plot at a low temperature. Therefore, ε_{max} of the outer complex for this system was estimated to be 2770 $M^{-1}cm^{-1}$ from the reasonable relation: $(I_{max})_{m\text{-PD}}/(I_{max})_{TAB} = (\varepsilon_{max})_{m\text{-PD}}/(\varepsilon_{max})_{TAB}$. Here, $(I_{max})_{m\text{-PD}}$ and $(I_{max})_{TAB}$ are, respectively, the maximum absorbances of the outer complexes measured at −196°C for the *m*-PD-chloranil and TAB-chloranil systems with equal concentrations of chloranil. Since chloranil is almost completely complexed in both solutions, the concentrations of the outer complexes are expected to be almost equal to each other. By the aid of this value, ΔH and ΔS for the TAB-chloranil system in acetone were determined to be −2.6 kcal/mol and −5.4 cal/mol·deg, respectively.

Immediately after mixing acetone solution of each electron donor with that of chloranil ([*m*-PD]=[TAB]=2.0×10^{-2} M, [chloranil]=5.0×10^{-4} M), we started the measurement of I_σ and obtained the I_σ-t curves at several temperatures. Both the systems gave curves which fit in well with Eq. (9)′. Figure 3 shows the result observed at 15.8°C for the *m*-PD-chloranil system. By analysing the experimental results by the aid of Eq. (9)′, the temperature dependences of α and k_4 were obtained. Furthermore, k_3 was obtained from

15) An initial concentration is represented by attaching the suffix 0.

16) The rate equations for Reaction 2 can be solved definitely by the same procedures as have been described above. The final approximate forms are as follows:

$$[\pi] \approx p'e^{-\alpha' t} \quad (11)$$
$$[\sigma] \approx \frac{k_3'[D]_0q'}{k_4'-\alpha'}(e^{-\alpha' t} - e^{-k_4' t}) \quad (12)$$
$$\alpha' \approx \frac{k_3'[D]_0}{1+K[D]_0} \quad (13)$$
$$\beta' \approx (k_1'+k_3')[D]_0 + k_2'$$
Here, $p' = \frac{k_1'[D]_0[A]_0 + (\beta'-k_2')[\pi]_0}{\beta'}$
$$q' = \frac{k_2'[\pi]_0 - (k_1'[D]_0 + k_3[D]_0 - \beta')[A]_0}{\beta'}$$

17) H. A. Benesi and J. H. Hildebrand, *J. Amer. Chem. Soc.*, **71**, 2703 (1949).

α by the aid of Eq. (8)', K being estimated by extrapolating the log K-1/T relation obtained at low temperatures. The values of k_3 and k_4 thus obtained are tabulated in Table 2. From the Arrhenius plot of these results, ΔE_1 and ΔE_2 were determined; the results are given in Table 3.[18]

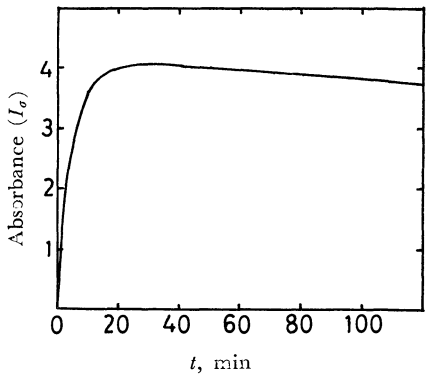

Fig. 3. The time-dependence of the absorption peak intensity observed at 15.8°C for the inner complex between *m*-phenylenediamine and chloranil.

Table 2. Temperature dependence of k_3 and k_4 (in sec^{-1}) for the *m*-phenylenediamine-chloranil and 1,3,5-triaminobenzene-chloranil systems

m-PD-Chloranil	15.8°	20.8°	25.5°
$k_3 \times 10$	2.55	3.33	4.65
$k_4 \times 10^5$	3.52	5.93	12.20
TAB-Chloranil	9.5°	17.7°	22.5°
k_3	1.07	1.69	3.91
$k_4 \times 10^5$	1.92	5.27	6.06

Table 3. The ΔH, ΔE_1 and ΔE_2 values (in kcal/mol) for the *m*-phenylenediamine-chloranil and 1,3,5-triaminobenzene-chloranil systems

	m-PD-Chloranil	TAB-Chloranil
ΔH	−3.7	−2.6
ΔE_1	10	16
ΔE_2	22	14

Figure 4 shows schematically the potential energy curves of the reactions for the *m*-PD-chloranil and TAB-chloranil systems. The structures of P_1 and P_2 are shown in Fig. 2; σ_1 corresponds to σ in the same figure. σ_2, the inner (σ) complex between P_1 and *m*-PD, is tentatively assumed to exist as an intermediate between P_1 and P_2, though it has not yet been observed. The potential energy curves from P_1 to P_2, the parts drawn by broken lines in Fig. 4, are difficult to be investigated for the following two reasons: (1) The σ_2 can not be detected by an electronic absorption measurement, and (2) the absorption bands due to P_1 and P_2 overlap with each other, so the time depenedenc of the absorption peak intensity is difficult to be obtained separately for each band.

18) These values are estimated by assuming a diffusion-controlled reaction.

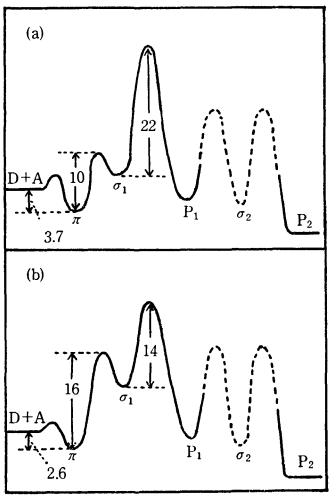

Fig. 4. Experimentally determined potential energy curves for the reactions: (a) between *m*-phenylenediamine and chloranil, (b) between 1,3,5-triaminobenzene and chloranil (unit, kcal/mol).
In both systems, the potential energy curves from P_1 to P_2 could not be determined.

None of the inner complexes formed between aromatic amines under consideration and chloranil can be isolated stably, and their molar extinction coefficients (ε_{max}'s) can not be determined directly. The ε_{max}'s value of the *m*-PD-chloranil system was estimated to be 8600 $M^{-1}cm^{-1}$ by applying Eq. (10) to the I_o-t curve measured at 25°C.

Rate-determining Step of the Reaction. In the *m*-PD-chloranil and TAB-chloranil systems, the rate for the outer-complex formation ($k_1[D]_0$) is probably 10^7 (sec^{-1}) or larger.[18] On the other hand, k_3 and k_4 are 10^0 and 10^{-5} (sec^{-1}), respectively. In actuality, the outer-complex formation is very fast in the reactions under consideration, and it is clear that the inner (σ) complex plays an important role in the rate-determining step. Therefore, it is concluded that Brown's view is the more appropriate to the present systems.

Stability of the Inner Complex. A parallel relationship exists between the electron-donating ability of the meta-substituent group of aniline and the stabilities of the inner complexes; *i.e.*, the following order of the stabilities of the inner complex was found:

m-anisidine(a few seconds)<*m*-aminophenol (a few minutes)<*m*-PD≈*N*,*N*-dimethyl-*m*-PD≈*s*-TAB≈1-methyl-2,4,6-TAB (a few hours)≪*N*,*N*,*N*',*N*'-tetramethyl-*m*-PD (about five days). Here, the time in parentheses indicate the approximate duration of existence for the corresponding inner complex at room temperature.

These facts can be explained as follows. With the increasing electron-donating ability of the meta-substituent, the electron-migration from the amino group to the benzene ring decreases and the nonbonding electron density on the nitrogen atom increases. Thus, chloranil may be expected to form a more stable inner complex with the meta-derivatives of aniline with stronger electron-donating groups.

We should like to express our sincere gratitudes to Dr. Ichiro Hanazaki, The Institute of Physical and

Chemical Research and Dr. Renji Okazaki, The University of Tokyo for their helpful discussions. Thanks are also due to Dr. Fumihiko Hirota of our laboratory for his help in the SCF MO calculation.

Appendix

Calculation of the Electronic Structure of the Inner Complex. We studied theoretically the π-electron structures of the inner complex between benzoquinone and aromatic amine by method combining the CI procedure with the Pariser-Parr-Pople type SCF MO,[19] taking a model of the negative ion in which one of the six ring carbon atoms of benzoquinone is excluded from the conjugated system. In actual calculation, the bond lengths of the ion were taken to be equal to those of benzoquinone.[20] The transition energies were evaluated by the aid of a HITAC 5020E electronic computer at the Computer Centre, The University of Tokyo. The ionization potentials, I_p's, and electron affinities, E_a's of carbon, nitrogen. and oxygen in their valence states were taken from Pilcher-Skinner's table.[21] The core resonance integral, β_{x-y}, was considered only for the nearest neighbours. These quantities are taken to be as follows:

$I_C = 11.2$ eV, $I_N = 28.88$ eV, $I_O = 17.25$ eV,

$E_C = 0.6$ eV, $E_N = 12.25$ eV, $E_O = 2.58$ eV,

$\beta_{C-C} = -2.39$ eV. $\beta_{C-N} = -2.60$ eV, $\beta_{C=O} = -2.60$ eV.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 386—391 (1971)

Molecular Structure of Diacetylene as Studied by Gas Electron Diffraction

Mitsutoshi TANIMOTO,* Kozo KUCHITSU, and Yonezo MORINO*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 28, 1970)

The molecular structure of diacetylene has been studied by gas electron diffraction. Thermal-average bond distances are determined to be: r_g(C–C) = $1.383_7 \pm 0.001_9$ Å, r_g(C≡C) = $1.217_6 \pm 0.001_4$ Å, and r_g (C–H) = $1.093_5 \pm 0.010$ Å. The C–C single bond is about 0.007 Å shorter than that in cyanogen, while the C≡C triple bond is about 0.005 Å longer than that in acetylene. The observed mean amplitudes are slightly larger than the parallel amplitudes based on harmonic calculations. A suggestion has been made to account for the discrepancies by the use of empirical constants representing the interaction between bending and bond-stretching vibrations, which makes the bond distances slightly longer, on the average, in a momentary bent structure than in a linear structure. This interaction also seems to account for a slight difference between the rotational constant B_0 estimated from the above r_g distances and those derived from spectroscopic experiments.

At an early stage of the structure studies by modern methods, Herzberg *et al.*[1] and Pauling *et al.*[2] remarked that a C–C single bond adjacent to a triple bond was shorter than that in saturated hydrocarbons. Subsequently, systematic analyses of experimental data led Stoicheff *et al.*[3] to an empirical rule that a C–C bond distance increases linearly with the number of adjacent atoms. According to Stoicheff,[4] this rule was applicable to most of the C–C distances reported up to 1962 within the uncertainty of 0.005 Å.

There are, however, a number of basic molecules which require further experimental studies. By the use of the recent technique of gas electron diffraction, the structure of some of the molecules studied previously can be determined with somewhat higher accuracy. Thus, from the studies of a number of conjugated aliphatic hydrocarbons with or without heteroatoms, a significant heteroatom effect on the C–C bond distance has been observed.[5–7] As for the molecules with a C–C bond between two triple bonds (the *sp-sp* system), the structure of cyanogen (N≡C–C≡N) was determined by electron diffraction[8] in combination with the rotational constant obtained from high-resolution infrared spectroscopy.[9] The r_g, C–C bond distance, was found to be about 0.01 Å larger than the value expected from the Stoicheff rule.

On the other hand, none of the previous studies of the diacetylene (HC≡C–C≡CH) structure by means of electron diffraction,[2] infrared,[10,11] and rotational

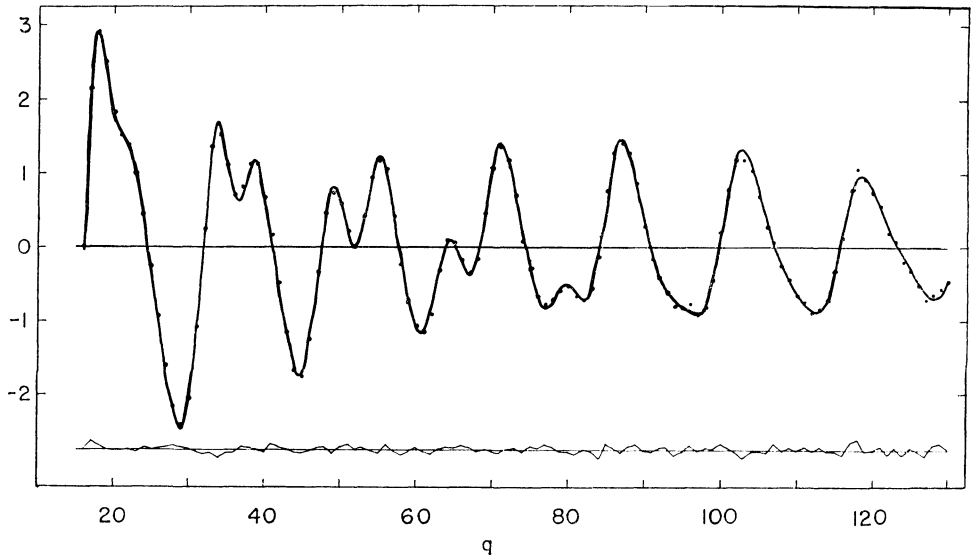

Fig. 1. Molecular intensity curves (dots for observed values and the solid curve calculated from the best-fit model) and the residuals (below).

Raman spectroscopy[12] were of comparable accuracy, nor were they free from the ambiguity due to the assumptions about the structural parameters. The present study aims to determine the structure of this molecule by electron diffraction in order to compare the C–C and C≡C bond distances with those in cyanogen and acetylene, respectively.

Experimental

The sample of diacetylene (95% pure) purchased from Tokyo Kagaku Seiki Co. Ltd. was purified by vacuum distillation. An electron beam of the wavelength of about 0.06 Å, calibrated with reference to the r_a(C=O) distance of carbon dioxide[13] (1.1646 Å), was used to take diffraction photographs at room temperature (23°C) with the camera lengths of 107.79±0.02 mm and 243.23±0.02 mm. Photographic densities measured by a digital microphotometer were converted into electron intensities, from which reduced molecular intensities (Fig. 1) were obtained by a standard technique.[14] Other experimental details have been described elsewhere.[8,13] The radial distribution curve is shown in Fig. 2.

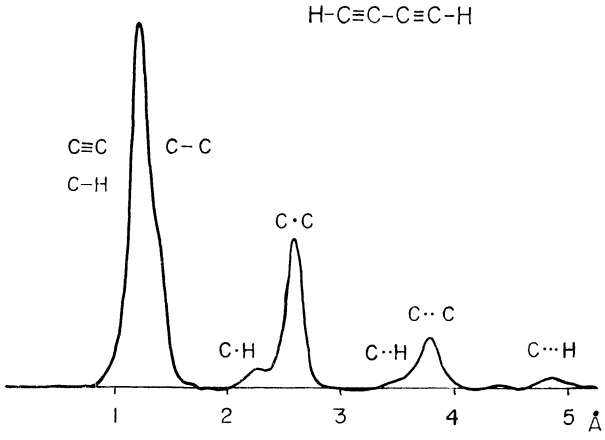

Fig. 2. Observed radial distribution curve.

Analysis

The reduced molecular intensities were fitted to a theoretical expression using a least-squares method[15] with a diagonal weight function estimated from past experience. The κ parameters representing asymmetric probability distributions for bonded pairs (2.0×10^{-5} Å^3 for C–H and 7×10^{-7} Å^3 for C–C and C≡C) were estimated by a diatomic approximation.[16] The κ parameters for nonbonded pairs were ignored. The mean amplitude and the distance for the H–H were fixed to their estimated values, because the contribution of this pair to the molecular intensity is insignificant. Tables 1, 2, and 3 list the r_g distances,

mean amplitudes and linear shrinkages, respectively, derived from the analysis.[14] The uncertainties were estimated as 2.5 times the standard deviations with allowance for systematic errors (particularly, those in the scale factor for the distances and in the extraneous background for the mean amplitudes).[17]

Discussion

Comparison of Bond Distances. C-C Single Bond: The C–C bond distance (r_g) in diacetylene has been determined to be $1.387_7 \pm 0.001_9$ Å, about 0.007 Å shorter than in cyanogen[8] ($1.390_8 \pm 0.002$ Å).[18] This difference is analogous to, but much smaller than, that observed between the C–C distances in butadiene and glyoxal, 1.465±0.003 Å and 1.526±0.003 Å, respectively.[6] As in that case, it seems possible to account for the observed difference at least qualitatively in terms of the difference in π bond orders. According to a semiempirical estimate by the use of the Pariser-Parr-Pople method,[19] the C-C π bond order for diacetylene (0.4—0.5) appears to be slightly (of the order of a few hundredths) larger than that for cyanogen. The absolute magnitude of the estimated bond orders depends so sensitively on the empirical parameters assumed[7] that a more elaborate treatment is necessary for a fully quantitative discussion. The C–C distance in diacetylene conforms to the Stoicheff rule,[4] which predicts a "normal" ≡C–C≡ distance to be 1.379 Å.

C≡C Triple Bond: A significant difference has been observed between the C C bonds (r_g) in diacetylene ($1.217_6 \pm 0.001_4$ Å) and that in acetylene[20] ($1.212_2 \pm 0.001_0$ Å). There seems to be no previous experimental study in which confirmative evidence is given for a change in the triple-bond distance due to conjugation, whereas such a difference of the order of 0.005 Å or less is not unexpected[21] from those in the π bond orders (theoretical) and those in the C C stretching force constants (experimental). For instance, Julg and Pellégatti[22,23] calculated the bond order of the diacetylene C C bond to be 1.906 or 1.888, which, together with their estimates of the gradient $\Delta r/\Delta p$, results in the difference in the C≡C bond distances of $0.122 \times (2-1.906) = 0.011_4$ Å or $0.130 \times (2-1.888) = 0.014_6$ Å, apparently larger than the experimental r_g difference (~0.005 Å) given above.

C–H Bond: The C–H bond distance derived here ($r_g = 1.093_5 \pm 0.010$ Å) has much larger experimental error than those in the C–C distances. While this distance appears to be somewhat larger than those in acetylene[20] ($r_g = 1.083_5 \pm 0.005_0$ Å) and in cyanoacetylene[12,24,25] ($r_s = 1.0574$ Å, $r_0 = 1.057$ Å or 1.069 Å), the differences may be spurious, since they are within the limits of error; moreover, C–H distances are the most sensitive to the difference in the definition of distances.[26]

Effect of Bending Vibrations on Mean Amplitudes. Harmonic Parallel Amplitudes: The observed mean amplitudes are compared in Table 2 with the mean parallel amplitudes, $\langle \Delta z^2 \rangle^{1/2}$, calculated by a conventional method[27,28] (column a) using the quadratic force constants determined by Abe and Shimanouchi.[29] For both bonded and nonbonded pairs the calculated parallel amplitudes are consistently smaller than the observed values. In particular, the observed CC amplitudes seem to have sufficient accuracy to investigate the origin of the "significant" discrepancies.

17) The experimental errors in the distances and mean amplitudes have been estimated with particular caution, since appreciable differences were recognized between the observed and calculated mean amplitudes and rotational constants, as described in the discussion section.

18) The r_g(C–C) distance for cyanogen observed by electron diffraction, $1.392_5 \pm 0.002_2$ Å,[8] has here been revised according to the recalibration of the scaler factor by the use of the infrared rotational constant, as described in Ref. 8.

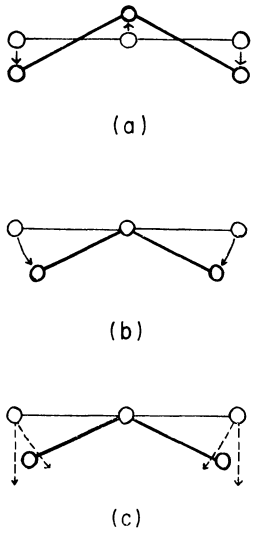

Fig. 3. The loci of the atoms in the bending vibration of a triatomic system: (a) normal coordinates of bending, (b) rod model without bending-stretching interaction, (c) bending-stretching interaction with a positive α parameter is included.

The conventional method ignores the effect of bending vibrations (perpendicular to the equilibrium molecular axis, Fig. 3a) on the displacements of internuclear distances, and the bond-stretching vibrations (parallel to the axis) are assumed to be "harmonic" (here called model a). However, since the present molecule has a low-frequency bending vibration (ν_9=222 cm^{-1}),[30] the stretching displacements should depend appreciably on the bending displacements, and the above approximations may not be valid.

Effect of Bending without Bend-Stretch Interaction: A simple approach to this problem is to assume model b, where the bonds retain their "average" distances in the bending displacements[31-33] (Fig. 3b). The potential function is assumed to have no third-order term proportional to $\Delta r \cdot \phi^2$, which represents the interaction between the stretching and bending displacements. Accordingly, the probability distribution function of a bond distance, $P(r)$, which has a Gaussian form with a slight distortion due to the stretching anharmonicity, is assumed to be independent of the bending displacements.[34]

If one expands an instantaneous distance r (bonded or nonbonded) in terms of the Cartesian displacements parallel and perpendicular to the equilibrium molecular axis, Δz and $\Delta\rho$, respectively, one gets[16,35]

$$r = r_e + \Delta r = r_e + \Delta z + \frac{\Delta\rho^2}{2r_e} - \frac{\Delta z\Delta\rho^2}{2r_e^2} + \frac{\Delta z^2\Delta\rho^2}{2r_e^3} - \frac{\Delta\rho^4}{8r_e^3} + \cdots \quad (1)$$

where $\Delta\rho^2=\Delta x^2+\Delta y^2$. The mean-square amplitude reckoned from the r_g distance is given by

$$l_g^2 = \langle r^2\rangle - \langle r\rangle^2 = \langle \Delta z^2\rangle - \langle \Delta z\rangle^2 + \frac{1}{r_e}(\langle \Delta z\Delta\rho^2\rangle - \langle \Delta z\rangle\langle \Delta\rho^2\rangle) + \frac{1}{r_e^2}\left[\frac{1}{4}(\langle \Delta\rho^4\rangle - \langle \Delta\rho^2\rangle^2) - (\langle \Delta z^2\Delta\rho^2\rangle - \langle \Delta z\rangle\langle \Delta z\Delta\rho^2\rangle) + \cdots \right. \quad (2)$$

where the carets denote thermal averages. Since the molecule is linear in equilibrium, the Cartesian displacements for a nonbonded pair are simply the sums of the corresponding displacements for the component bonded pairs. For instance, a parallel displacement for a nonbonded i-k pair in a linear i-j-k arrangement is given by

$$\Delta z_{ik} = \Delta z_i - \Delta z_k = \Delta z_{ij} + \Delta z_{jk} \quad (3)$$

The parallel displacement for a bonded pair, on the other hand, is related to the bond-stretching displacement, Δr, and the perpendicular displacement,

$$\Delta z(\text{bond}) = \Delta r - \frac{\Delta\rho^2}{2r_e} + \frac{\Delta r\Delta\rho^2}{2r_e^2} - \frac{\Delta\rho^4}{8r_e^3} - \frac{\Delta r^2\Delta\rho^2}{2r_e^3} + \cdots \quad (4)$$

Since the contribution from the second (negative) term is important, the mean projected displacement $\langle \Delta z$ (bond)$\rangle$ is usually much smaller than $\langle \Delta r\rangle$ and is sometimes negative.[16,36]

According to the present assumption, Δr and $\Delta\rho^2$ are independent of each other, and the Δr for a bond is equal to the Δz for a linear structure without bending displacements. The latter can be expressed as a linear combination of the Σ-type normal coordinates (Q_1 through Q_5) with their coefficients a_i determinable from a conventional normal-coordinate analysis,[37]

$$\Delta r = \sum_{i=1}^{5} a_i Q_i \quad (5)$$

The perpendicular displacement, $\Delta\rho^2$, can be calculated in a similar way from the Δx and Δy, which are linear functions of the π-type coordinates, Q_6 through Q_9.

The mean amplitudes for nonbonded pairs calculated by this model, listed in column b of Table 2, are appreciably larger than those based on model a, where all the $\Delta\rho$ displacements in Eqs. (2) and (4) are equal to zero. The observed CC amplitudes lie between a and b, indicating that the latter model overestimates the effect of bending vibrations. Hence, a bending-stretching interaction ought to be introduced in order to attain a better agreement. (See next subsection.)

Shrinkage Effects: The shrinkage[35] calculated by the models a and b are nearly equal, as listed in Table 3. The shrinkage depends essentially on the perpendicular displacements alone and is independent of whether the atoms take rectilinear or curvilinear loci shown in Fig. 3a and 3b, respectively.[35]

Rotational Constants: The r_g distances determined in the present study have been converted into the r_α^0 distances by the equation, which is based on model b,[26,38]

TABLE 4. AVERAGE STRUCTURE AND ROTATIONAL CONSTANTS

		Obsd	Calcd[a] (b)	Calcd[a] (c)
$r_g-r_\alpha^0$ (Å)	C—H	—	0.0038	0.0113
	C≡C	—	0.0062	0.0078
	C—H	—	0.0288	0.0328
B_0 (cm^{-1})		0.14638±0.0001[b]	0.1453±0.0003	0.1464
		0.14641±0.00013[c]		
		0.14689±0.00004[d]		

a) Calculated by models (b) and (c) respectively. See text and footnote a) of Table 2.
b) Infrared, Ref. 10. c) Infrared, Ref. 11. d) Rotational Raman, Ref. 12.

$$r_\alpha^0=r_g-\frac{3}{2}a(\langle\Delta z^2\rangle_T-\langle\Delta z^2\rangle_0)-\langle\Delta\rho^2\rangle_0/2r_e-\delta r \qquad (6)$$

where the centrifugal corrections,[39] δr, are less than 10^{-4} Å for all the bonded pairs. The corrections for the r_g to r_α^0 conversion[40], listed in Table 4 column b, are significant, since they exceed the experimental error of r_g.

The rotational constant for the ground vibrational state, B_0, has been calculated from the r_α^0 parameters on the assumption that the correction from B_z ($\approx B_\alpha^0$)[37] to B_0 conforms to the ordinary second-order formula[41,42] based on infinitesimal vibrational amplitudes. This correction, being proportional to B^2, is trivial for this molecule (-8×10^{-5} cm^{-1}).

The rotational constant estimated in this way, B_0(ED)=0.1453±0.0003 cm^{-1}, is significantly different from any of the spectroscopic values given in Table 4. The infrared values are presumably more accurate than the Raman value, since in the latter experiment the rotational analysis may have been biased by overlapping hot bands, as was pointed out by Maki[9] in the case of cyanogen.

The discrepancy is probably originated, at least in part, in the B_0(ED), which is based on model b for the r_g to r_z conversion. A possible systematic error due to this model has not been counted in the uncertainty given above. A further study in this regard is made in the next subsection.

While the basic scheme of coordinating the average structure derived from electron diffraction and spectroscopy seems to work for a number of nonlinear polyatomic molecules with small vibrational amplitudes,[26,38] a special formalism is required for a calculation of the ground-state rotational constant for a molecule with large-amplitude vibrations (in particular, for a quasi-linear molecule) from a given set of thermal-average distances.[43] None of such a treatment has been made in the present study.

Bend-Stretch Interactions. The discrepancies observed in the mean amplitudes and in the rotational constant discussed above indicate the presence of appreciable contributions from bending-stretching interactions left out in the calculations. Suppose a displacement Δr in Eq. (4) increases with the bending displacement $\Delta\rho^2$ so as to partially compensate for the second term, $-\Delta\rho^2/2r_e$, and the atoms take loci shown in Fig. 3c. Then the mean amplitude should fall in between (a) and (b) of Table 2, and the effective B_0 (ED) should increase. One may thus assume a model c, where the displacement of a bond j is given, in place of Eq. (5), as

$$\Delta r_j=\sum_{i=1}^{5}a_iQ_i+\alpha_j(\phi_j^2+\phi_j'^2) \qquad (7)$$

where α_j is a positive constant. The angles of bending from π on both ends of the bond j, ϕ_j and ϕ_j', can be expanded in terms of the normal coordinates Q_6 through Q_9.

The physical significance of a positive parameter α_j is to introduce into the potential function a negative third-order term, $-\alpha_jf_j\Delta r_j(\phi_j^2+\phi_j'^2)$, where f_j is a second-order force constant for the bond stretching. For a number of linear molecules (CO_2,[32,33] CS_2,[32,33] OCS,[44] HCN(DCN),[45] NNO,[46] C_2H_2(C_2D_2)[47]), where precise values of third-order potential constants are known from spectroscopic experiments, the constants representing the bending-stretching interaction of this sort are all *negative* (of the order of a few tenths of one mdyn). Furthermore, the π bond order of the C–C single bond in diacetylene is expected to decrease with the C≡C–C bending displacements as a result of the decrease in the degree of conjugation, and this effect should make an appreciable positive contribution to α_{C-C}. The corresponding (probably negative) contribution to $\alpha_{C\equiv C}$ seems to be much less important, since the difference in the C≡C bond distances in diacetylene and acetylene is found in the present study to be only about 0.005 Å.

It has been shown, on an empirical basis, that the following set of bending-stretching interactions makes the bonded and nonbonded CC mean amplitudes agree with the observed values as listed in Table 2, column (c):

47) I. Suzuki and J. Overend, *Spectrochim. Acta*, **25A**, 977 (1969); I. Suzuki, private communication, 1970.

$\alpha_{C-C}=0.352$ Årad^{-2}, $\alpha_{C\equiv C}=0.152$ Årad^{-2},

and $\alpha_{C-H}=0.599$ Årad^{-2}.

In addition, the $r_g-r_\alpha^0$ corrections based on this set are shown to result in the B_0 (ED) in excellent accord with the B_0(infrared) as listed in Table 4.

The present model c should be taken with reservation, in spite of the above virtual success, since the bending-stretching interactions given above seem to be larger than those expected for ordinary linear molecules, even if the influence of the conjugation in diacetylene is taken into account. The above α parameters are subject to a further examination with suspicion of systematic errors.

Such a strong bending-stretching interaction, if present, poses a problem in the comparison of bond distances in different molecules. A usual scheme of comparison in terms of the average bond distances, where the difference in the r_g distances is regarded as a good representation of that in the r_e distances,[26] is no longer valid for a group of molecules with very different α parameters. Future systematic studies of the structures of linear conjugated molecules will present a clue to the solution of this problem.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 391—395 (1971)

Inclusion Compounds of Some Charge-Transfer Complexes

Masatake OHMASA*, Minoru KINOSHITA, and Hideo AKAMATU
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received October 3, 1970)

The charge-transfer complex of benzidine and tetracyano-*p*-quinodimethane has been shown to form an inclusion compound with certain molecules such as dichloromethane, dibromomethane and acetone. The molecular volumes of these guest substances are all smaller than 75 cm^3/mol, while the substances which are not included have a molecular volume larger than 80 cm^3/mol. Besides the size, the molecular shape is also considered to be a primary factor for the formation of the inclusion compound. The heat of formation of the inclusion compound with dichloromethane as a guest was determined to be 11.1 ± 1 kcal per mole of the guest substance by the thermochemical measurements. Similar inclusion compounds were also obtained, when 3,3′-diaminobenzidine, 3,3′-dichlorobenzidine and *o*-tolidine were used in place of benzidine.

In a previous paper,[1] we have reported that benzidine (BD) and tetracyanoquinodimethane (TCNQ) form two types of complexes, the type being determined by the solvent used in the preparation. One is the complex which contains solvent molecules in addition to BD and TCNQ, (BD·TCNQ·S)[2], and the other is the complex which does not contain solvent molecules, BD·TCNQ(n). The amount of the solvent contained in the BD·TCNQ·S complex is as much as those of BD and TCNQ, and several solvents which are different in chemical properties form this type of complexes. In the present paper, the BD·TCNQ·S complex will be shown to possess the characteristics of the inclusion compounds.

A variety of inclusion compounds have been studied[3,4] and are known to possess the following common features.[5] They are composed of two components, host and guest, and the host lattice has cavities to include the guest molecules. Although many kinds of molecules are to be included in the cavity of the same host lattice, the formation of an inclusion compound is normally controlled by the size and shape of a guest molecule. The force binding the guest molecules is intermolecular one and the heats of formation of the inclusion compounds fall usually in the range of 5—12 kcal per mole of the guest substance.

The compounds studied here, whose host lattice is comprised by the organic charge-transfer complexes, are found to possess these characteristics.

Experimental

Chemicals. Benzidine, *o*-tolidine (TL), 3,3′-diaminobenzidine (DABD), and 3,3′-dichlorobenzidine (DCBD) were obtained from commercial sources, and used after purification by recrystallization from ethanol or carbon tetrachloride. Synthesis and purification of TCNQ were described previously.[6]

Complex Preparation. BD·TCNQ·S(CH_2Cl_2): To a solution of 35 mg of BD in 80 m*l* of dichloromethane was added a solution of 44 mg of TCNQ in 120 m*l* of dichloromethane at room temperature, and shiny dark green crystals thus formed were collected.

BD·TCNQ(n) (from Chloroform): Dark green polycrystals were obtained by mixing a solution of 16 mg of BD in 10 m*l* of chloroform with a solution of 23 mg of TCNQ in

60 ml of chloroform at room temperature.

Other complexes including TL, DABD, and DCBD complexes were prepared in a similar manner.

Measurement of X-Ray Diffraction Patterns. X-Ray diffraction patterns of powdered samples were measured at room temperature with a diffractometer, Rigaku Denki Geigerflex.

Calorimetric Measurement. A conductive twin microcalorimeter made by Oyodenki Co. was used to determine the heats of reaction, $(-\Delta H_2)$ and $(-\Delta H_3)$, for the reactions defined by Eqs. (2) and (3) in the following section. The heats were measured at constant temperature, 25°C and at 1 atm.

The procedures of the measurement are as follows. (i) About 400 mg of the powdered sample was sealed in a thin-wall glass tube. The saturated solution of BD·TCNQ complex in dichloromethane was placed in the reaction vessel and in the reference vessel. The volume of the solution in each vessel was set at 50 ml.

(ii) The glass tube containing the sample was placed in the reaction vessel and the vessels were laid in the heat resservoir overnight to achieve the thermal equilibrium.

(iii) The glass tube was then broken and the reaction was started. The difference of the temperature between the reaction vessel and the reference vessel was recorded until the reaction was completed and the temperature of the reaction vessel became constant. It took about 3 hr.

(iv) A certain amount of heat was then generated on the side of the reaction vessel by the standard heater and the difference of the temperature was recorded again.

(v) The areas below the recorded curves for the heat of the reaction and the reference heat were measured and the former heat was calculated by using these areas and the latter heat.

(vi) The heat of reaction calculated in this way was then corrected for the heat generated by breaking the glass tube, which was measured in a blank test.

For this experiment, the BD·TCNQ(n) complex was prepared from chloroform. The special grade dichloromethane from Wako-junyaku Co. was used.

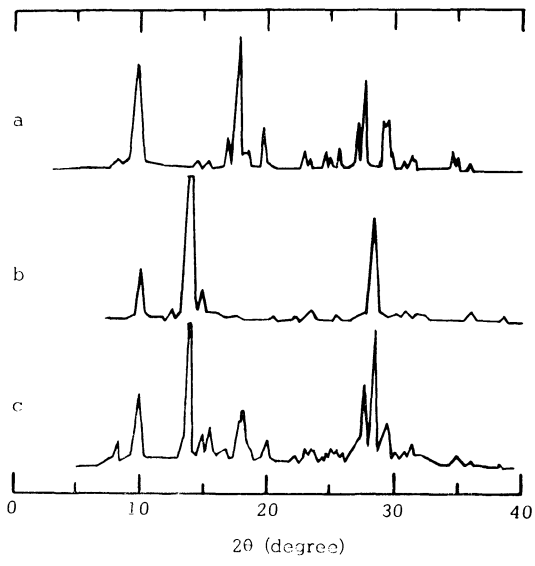

Fig. 1. The X-ray diffraction patterns of powders of BD·TCNQ complexes.
a) BD·TCNQ·S(CH_2Cl_2)
b) BD·TCNQ(n)
c) BD·TCNQ(n) which was exposed to dichloromethane vapor overnight and then placed in a vacuum for several hours (see the text).

Thermogravimetric Analysis (TGA). Thermogravimetric analysis was performed using thermobalance made by Tokyo Koki Seizosho. The heating rate was about 0.75°C/min. Nitrogen gas was slowly streamed about the sample during the measurement.

Differential Thermal Analysis (DTA). The differential thermal analysis for the freshly prepared sample of BD·TCNQ·S(CH_2Cl_2) complex was made with a Rigakudenki DTA apparatus in the air. The heating rate was 2.5°C/min.

Characterization of BD·TCNQ System. To know whether the complex prepared in a solvent contains the solvent molecules or not, the infrared absorption spectrum of the complex was examined. As was described in the previous paper,[1] the spectra of BD·TCNQ·S complexes are similar to one another and are quite different from that of BD·TCNQ(n) complex. In the former spectra are observed the absorption bands which are assigned to the vibrational modes of the solvent molecule contained in the complex, while the bands of the solvent molecule are not observed in the latter. These features are employed as criteria for the characterization of the BD·TCNQ complexes.

Composition of Complexes of TCNQ with TL, DABD, and DCBD. The ratios, (donor) : (acceptor) : (solvent), of the complex of TL, DABD, and DCBD were calculated from the results of elementary analysis of the complex.

Results and Discussion

X-Ray Diffraction Patterns. The X-ray diffraction patterns for powders of BD·TCNQ system are shown in Fig. 1. The pattern for BD·TCNQ·S(CH_2Cl_2) (Fig. 1a) is quite different from that of BD·TCNQ(n) (Fig. 1b). It is therefore concluded that these two complexes have different crystal structures.

The BD·TCNQ(n) and BD·TCNQ·S complexes readily change their structures to each other. When a sample of BD·TCNQ·S(CH_2Cl_2) is heated on a thermobalance, the weight of the sample begins to reduce at about 50°C and becomes constant at about 120°C. When the heated sample is cooled to the room temperature, its X-ray diffraction pattern becomes identical with that for the BD·TCNQ(n) complex. On the other hand, when a sample of BD·TCNQ(n) is exposed to the vapour of dichloromethane at about 200 mmHg and is laid overnight at room temperature, the X-ray diffraction pattern becomes identical with that for BD·TCNQ·S (CH_2Cl_2).

The X-ray diffraction pattern illustrated in Fig. 1c was obtained for the sample of BD·TCNQ(n) which was exposed to the vapour of dichloromethane in the manner described above and then sealed in a vacuum for several hours at room temperature. This pattern is well interpreted as a superposition of the pattern for BD·TCNQ·S(CH_2Cl_2) complex and that for the BD·TCNQ(n) complex.

These facts show that the solvent molecules contained in the complex are very weakly bound in the crystal lattice. Therefore, it is plausible to conclude that the BD·TCNQ·S(CH_2Cl_2) complex is a kind of inclusion compounds. If so, this complex is a new family of the inclusion compounds in the sense that its host lattice is composed of a charge-transfer complex.

Thermodynamic Properties. The heat of formation of the inclusion compound is rather small, because the guest molecule is bound to the host lattice by the intermolecular force. Many inclusion compounds show the value in the range of 5—12 kcal per mole of the guest molecule.[7-10]

The heat of formation ($-\Delta H_f$) of BD·TCNQ·S(CH_2Cl_2) in the following reaction was measured by the calorimetric method.

$$\text{BD·TCNQ(n)(s)} + 1.8\ CH_2Cl_2(g) = \text{BD·TCNQ·S(s)};\ \Delta H_f \quad (1)$$

where (s) and (g) denote that the substance is in the solid state and in the gaseous state, respectively. It was assumed that one mole of BD·TCNQ·S(CH_2Cl_2) contains 1.8 mole of dichloromethane.[11]

Equation (1) is considered to be equivalent to the combination of the following thermochemical equations (2)—(4) according to Hess' law.

$$\text{BD·TCNQ(n)(s)} + 1.8\ CH_2Cl_2(l) = \text{BD·TCNQ·S(sol)};\ \Delta H_2 \quad (2)$$

$$\text{BD·TCNQ·S(sol)} = \text{BD·TCNQ·S(s)};\ \Delta H_3 \quad (3)$$

$$1.8\ CH_2Cl_2(g) = 1.8\ CH_2Cl_2(l);\ \Delta H_4 \quad (4)$$

$$\Delta H_f = \Delta H_2 + \Delta H_3 + \Delta H_4 \quad (5)$$

Here, (l) denotes that the substance is in the liquid state and (sol) shows that the solid substance is placed in the saturated solution of BD·TCNQ complex in dichloromethane.

The heats of reactions, ($-\Delta H_2$) and ($-\Delta H_3$), were measured calorimetrically. The heat of condensation, ($-\Delta H_4$), was calculated from the value given in a literature.[12] In the measurement, the sample of BD·TCNQ(n) or BD·TCNQ·S complex was dropped into the saturated solution of BD·TCNQ complex in dichloromethane in order to avoid the effect of dissolution of the solid. The values of ΔH_f, ΔH_2, ΔH_3, ΔH_4 obtained are given in Table 1.

The heat of formation of BD·TCNQ·S(CH_2Cl_2) per mole of dichloromethane is thus estimated as 11 kcal/mol. This value is reasonable in comparison with that for ordinary inclusion compounds.

Table 1. Heat of formation of BD·TCNQ·S(CH_2Cl_2) complex from BD·TCNQ(n) complex and dichloromethane gas

A)	Heat of formation per one mole of the complex	
	$-\Delta H_2$:	9.1±1 kcal/mol
	$-\Delta H_3$:	−1.2±1 kcal/mol
	$-\Delta H_4$:[a]	12.0 kcal
	$-\Delta H_f$:	19.9±2 kcal/mol
B)	Heat of formation per one mole of dichloromethane	11.1±1 kcal/mol

a) This value was calculated from the value given in Ref. 12.

The TGA curve and the differential thermogram for freshly prepared sample of BD·TCNQ·S(CH_2Cl_2) are presented in Figs. 2 and 3, respectively. The amount of the weight loss of the sample shows that the solvent molecules are completely desorbed from the sample during the heating. This was further confirmed by the fact that, as was mentioned before, the X-ray diffraction pattern of the sample after TGA measurement became identical with that of BD·TCNQ(n).

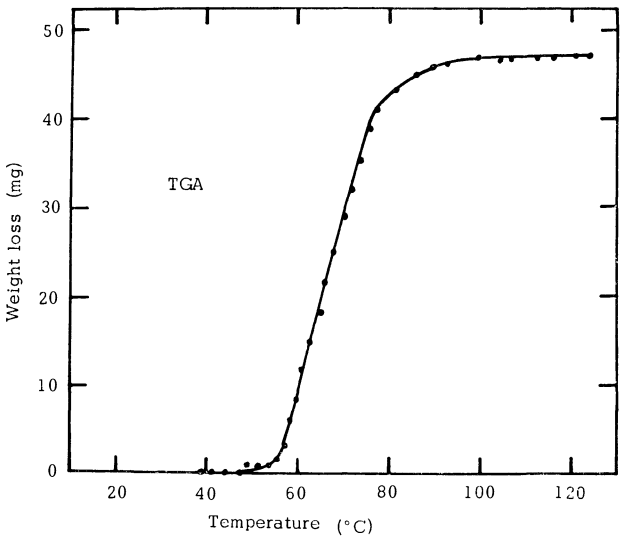

Fig. 2. The thermogravimetric analysis (TGA) curve for BD·TCNQ·S (CH_2Cl_2) complex.
Heating rate was about 0.75°C/min. The weight of the sample was 165 mg before the measurement and 118 mg after the measurement.

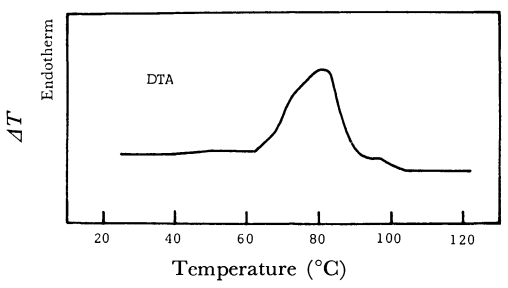

Fig. 3. The differential thermogram of BD·TCNQ·S (CH_2Cl_2) complex.
Heating rate was about 2.5°C/min. The weight of the sample was 136 mg before the measurement and 97 mg after the measurement.

11) The solvent molecules contained in the complex escape slowly from the complex in air at room temperature, so that the composition of the complex changes with time.
As was reported in Ref. 1, the composition of BD·TCNQ·S (CH_2Cl_2) determined spectroscopically was (BD) : (TCNQ) : (CH_2Cl_2) = 1.0 : 1.1 : 1.6. But this composition is not so accurate, because evaporation of dichloromethane from the solid was not strictly considered.
To find the reliable value of the solvent content, TGA measurement of a freshly prepared sample of BD·TCNQ·S(CH_2Cl_2) was carried out. The composition of the complex was then calculated from the result of the measurement and was found as (donor) : (acceptor) : (solvent) = 1 : 1 : 1.8. This result is adopted here.
12) "Landolt-Börnstein, Zahlenwerte und Funktionen," Vol. II, part 4, Springer, Berlin (1961), p. 292.

The curves shown in Figs. 2 and 3 indicate that the included dichloromethane molecules were evaporated in one step, which means that all the solvent molecules are bound equivalently in the crystal of BD·TCNQ·S (CH_2Cl_2).

Inclusion of Solvent Molecules in BD·TCNQ System. It seems that the formation of the BD·TCNQ·S complex is mainly determined by the structural requirement, that is, by the size and the shape of the solvent molecule used in the preparation of the complex. This also indicates that the BD·TCNQ·S complexes are inclusion compounds.

The intermolecular forces between the solvent molecule and the host lattice are not considered to be the determining factor of the formation of the BD·TCNQ·S complex. The molecular volume, the molecular polarizability and the dipole moment of the solvent molecules used in the experiment are compared in Table 2. The type of the complex (solvent contained or not) is also given in the table. The molecular polarizability and the dipole moment are closely related to the dispersion force[13,14] and the electrostatic force which act on the solvent molecule, but these two quantities of the solvents examined so far do not seem to be related to the formation of BD·TCNQ·S complexes. For example, chloroform and 1,1-dichloroethane which give BD·TCNQ(n) complexes have larger molecular polarizability than dichloromethane and ethyl bromide which give BD·TCNQ·S complexes, and the dipole moment of 1,1-dichloroethane is also larger than that of dichloromethane.

Table 2. Molecular volume, molecular polarizability and dipole moment of the solvent used in preparation of BD·TCNQ complexes

Solvent	Type of complex[a]	Molecular volume[b]	Molecular polarizability[c]	Dipole moment[d]
$CHCl_3$	n	80.5	85.2	1.01
CH_3CHCl_2	n	84.1	85.2	2.06

CH_2ClCH_2Cl	(s)[e]	80.1	86.0	1.47

a) The type of BD·TCNQ complex prepared in the solvent. n: BD·TCNQ(n), s: BD·TCNQ·S
b) The value in the unit of cm^3/mole at 20°C.
c) These values are calculated by the equation, $(4/3)\pi N\alpha=[(n^2-1)/(n^2+2)](M/d)$ where n is refractive index, M is molecular weight, d is density, N is Avogadro's number and α is molecular polarizability. The value of α at 20°C in the unit of 10^{-25} cm^3 is listed here.
d) debye unit.
e) The complex prepared in this solvent is considered to include solvent molecules partially, because the infrared absorption spectrum of this complex is a superposition of the spectra of BD·TCNQ(n) and BD·TCNQ·S complexes.

13) F. London, *Z. Phys. Chem.*, **B11**, 222 (1930).
14) D. F. Evans and R. E. Richards, *Proc. Roy. Soc., Ser. A*, **223**, 238 (1954).

The presence of some functional groups in the solvent molecule is not again the determining factor for the formation of BD·TCNQ·S complexes, because 1,1-dichloroethane gives a BD·TCNQ(n) complex, although dichloromethane and ethyl bromide give BD·TCNQ·S complexes.

Unlike the factors mentioned above, there is a close correlation between the molecular volume of the solvent molecule and the formation of BD·TCNQ·S complexes. As is seen in Table 2, the molecular volumes of chloroform and 1,1-dichloroethane which give BD·TCNQ(n) complexes are larger than those of the solvents which are found to be included in BD·TCNQ system. Therefore it is likely that the formation of the BD·TCNQ·S complex is controlled by the size of the solvent molecule on the one hand.

On the other hand, the molecular shape of chloroform and 1,1-dichloroethane is pyramidal, while that of dichloromethane is regarded as a triangle, if the van der Waals' radius of hydrogen atom is neglected. The shape of other solvent molecules which form BD·TCNQ·S complexes can also be regarded as triangular. Acetonitrile molecule is the only exception which is a linear one. Although both chloroform and dichloromethane molecules are composed of carbon, hydrogen and chlorine atoms and are methane type molecules, chloroform molecule is not included in the BD·TCNQ system, while dichloromethane gives a BD·TCNQ·S complex. This shows that the molecular shape of the solvent is another important factor, which determines the formation of the BD·TCNQ·S complex. 1,2-Dichloroethane whose molecular volume is as large as that of chloroform is partially included in the BD·TCNQ system as is shown in Table 2. This fact also indicates the importance of the molecular shape of the solvent.

Complexes of TCNQ with TL, DABD, and DCBD. The charge-transfer complexes of TL, DABD, and DCBD with TCNQ were expected to form inclusion compounds with certain solvents such as dichloromethane, because the molecular structures of these donors are similar to that of BD. Some of these complexes were prepared using dichloromethane or chloroform as a solvent. Their compositions were determined by analyzing the results of elementary analysis. The results are presented in Table 3. As is seen in the table, the system of TL·TCNQ contains a considerable amount of dichloromethane or chloroform and these complexes are considered to be inclusion compounds. The complex of DABD·TCNQ prepared in dichloro-

Table 3. Composition of the complexes of TCNQ with TL, DABD and DCBD

Donor	Solvent used in preparation	Mole ratios[a]
TL	CH_2Cl_2	1 : 1.00 : 1.23
TL	$CHCl_3$	1 : 1.07 : 0.52
DABD	CH_2Cl_2	1 : 1.00 : 0.45
DCBD	CH_2Cl_2	1 : 0.80 : 0.16

a) (Donor) : (Acceptor) : (Solvent)

methane is also regarded as an inclusion compound for the same reason. The complex of DCBD·TCNQ, however, contains a small amount of dichloromethane, and it is questionable that the complex is an inclusion compound. As is shown in Table 3, the amount of TCNQ is less than that of DCBD by a small amount which is nearly the same as the amount of the included solvent. The solvent molecules in this complex, therefore, may be trapped in the vacancies of the TCNQ molecules.

Tolidine·TCNQ system forms an inclusion compound with chloroform in contrast to the BD·TCNQ system. The physical properties of TL·TCNQ·S($CHCl_3$) are similar to those of BD·TCNQ·S(CH_2Cl_2).[15] It seems, therefore, that the structure of the donor molecule is also an important factor for the formation of the inclusion compounds of this type.

The authors wish to thank Professor Nobufusa Saito for the use of his laboratory thermal analysis facilities and Mr. Kenji Nakada for his kind help in the DTA experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 395—400 (1971)

Electronic Properties of Benzidine·TCNQ System

Masatake OHMASA,* Minoru KINOSHITA, and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received October 7, 1970)

The benzidine·tetracyano-*p*-quinodimethane (TCNQ) system forms two types of charge-transfer complexes; one (I) containes some sort of solvent molecules, while the other (II) does not. The electronic properties of I have been found to be unusual in many respects compared to II which shows the properties expected from those of ordinary charge-transfer complexes. I and II did not exhibit ESR absorption, if they were well-grown crystals. However, when they were pulverized to fine powder, I showed a strong absorption while II did not. The visible range absorption spectra of I and II consisted of three main bands, but all the bands of I were found to be shifted to longer wavelengths compared to those of II. In addition to these bands, two shoulders were found in the spectrum of I. The shoulders were considered to be due to the ion radicals produced from benzidine and TCNQ. The electrical resistivities are again quite different from one another. The resistivity of I was found to be 10^3—10^5 ohm cm at room temperature, the value being dependent on the kind of the solvent molecules included, while that of II was 2×10^9 ohm cm. The activation energy for conduction was smaller for I (0.1—0.2 eV) than for II (0.34 eV).

The electronic properties of charge-transfer complexes of tetracyanoquinodimethane (TCNQ) with a series of aromatic diamines were examined in the previous paper.[1] It was found that the complex of benzidine (BD) with TCNQ which was prepared in dichloromethane showed unusual properties compared with the other complexes studied. The electrical resistivity of the BD·TCNQ complex was very low and its infrared absorption spectrum was not explained either by a superposition of the spectra of ionic components or that of neutral components.

Later study revealed that BD and TCNQ form two types of complexes[2]: one is the complex which contains solvent molecules [BD·TCNQ·S][3] and the other is the complex which does not contain solvent molecules [BD·TCNQ(n)]. The former complex was proved to be a kind of inclusion compound.[4] Preliminary examination has revealed that the electronic properties of these two types of complexes are quite different from each other. It was the BD·TCNQ·S complex which was observed previously to show unusual properties.

Several authors[5-9] have studied the effect of the occluded solvent molecules on the electronic properties of charge-transfer complexes and on the difference in the electronic properties of the complexes which are composed of the same donor and acceptor and are prepared from different solvents. Ottenberg *et al.*[7] studied electrical and ESR properties of the *p*-phenylenediamine·*p*-chloranil complex. They observed no significant effect of entrapped solvent molecules on these properties. Cairns and McGeer[8] prepared diaminodurene·TCNE complex in chloroform and tetrahydrofurane and obtained two types of complexes which have different colors. Among these works, the study on polymorphic forms of diaminopyrene·chloranil system by Matsunaga[5,6] is parti-

cularly interesting. He observed that electronic properties of this complex precipitated from benzene were greatly changed by compressing the sample in the presence of benzene. After the compression, electrical resistivity of the sample was greatly reduced and its infrared absorption spectrum was entirely changed. These facts indicate that the occluded solvent has an important effect on the electronic properties of the diaminopyrene·chloranil system. However, the cause of the effect of the occluded solvent is not clear at present.

The benzidine·TCNQ system is similar to the diaminopyrene·chloranil system in some respects, and is considered to be suited for the study of the effect of the occluded solvent, because both BD·TCNQ(n) and BD·TCNQ·S complexes can be prepared individually, and many kinds of solvents are found to form the BD·TCNQ·S complex. In the present study, the electronic properties of BD·TCNQ·S and BD·TCNQ(n) complexes are described in detail and are compared with each other.

Some of the electronic properties of the complexes of TCNQ with *o*-tolidine, 3,3′-diaminobenzidine and 3,3′-dichlorobenzidine were also examined in brief.

Experimental

Complex Preparation. The BD·TCNQ·S and BD·TCNQ(n) complexes were prepared by the method previously.[4]

Infrared Absorption Measurement. To determine the character of the complex, infrared absorption spectra of the complex and related compounds were examined with a Hitachi infrared spectrophotometer in the range of 4000—400 cm^{-1}. The method of Nujol mull was adopted in the measurement.

ESR Absorption Measurement. Electron spin resonance (ESR) absorptions were measured as described in the previous paper.[1]

Visible and Near Infrared Absorption Measurement. Absorption spectra in the visible and infrared regions were measured for the solid samples using the method of Nujol mull.

Electrical Resistivity. Electrical resistivity of a complex was measured in a form of compressed pellet by a DC-method. Measurements on single crystals were also made for BD·TCNQ·S(CH_2Cl_2) at room temperature.

Results and Discussion

Infrared Absorption Spectra. The infrared absorption spectra of BD·TCNQ(n) and BD·TCNQ·S(CH_3COCH_3) are shown in Fig. 1 together with the spectra of BD, BD bromide, TCNQ and lithium salt of TCNQ. The spectra of the complexes containing other solvent molecules are similar to that of BD·TCNQ·S(CH_3COCH_3) complex except for the bands due to the solvent molecules.

The spectra of TCNQ[10,11] and TCNQ anion radical (lithium salt of TCNQ) are clearly different in the following points. Firstly, the C≡N stretching vibration of TCNQ appears at 2223 cm^{-1} and is very sharp, but the corresponding band of TCNQ anion radical appears at 2203 cm^{-1} and is broadened and split.[1] Secondly, a strong absorption band which is located at 1540 cm^{-1} in TCNQ is considered to be a superposition of the ring C=C stretching mode and the ethylenic C=C stretching mode. In the spectrum of TCNQ anion radical, however, no strong band appears at 1540 cm^{-1} and new bands are located at 1580 cm^{-1} and 1507 cm^{-1}. This is considered to be due to the difference in bond lengths of the ring and ethylenic C=C bonds in TCNQ and its anion radical. Thirdly, a strong absorption band is observed at 1183 cm^{-1} for the anion radical, whereas no strong band is observed for TCNQ in this region.

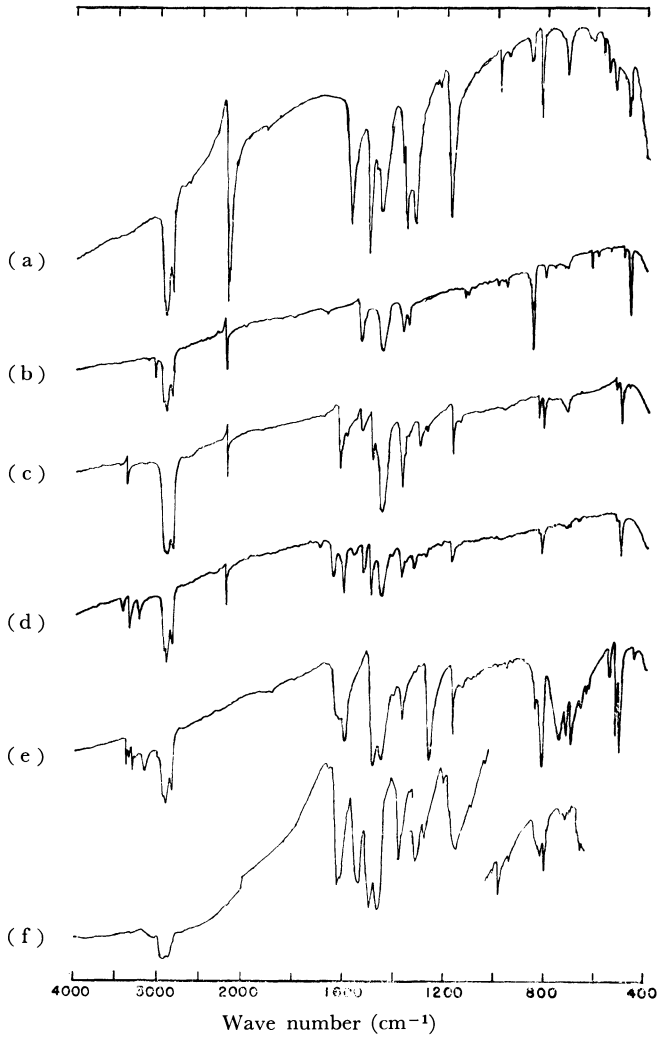

Fig. 1. Infrared absorption spectra of BD·TCNQ complexes and related compounds.
(a) LiTCNQ, (b) TCNQ, (c) BD·TCNQ(*n*), (d) BD·TCNQ·S(CH_3COCH_3), (e) BD, (f) BD·bromide.

The absorption spectra of BD and BD cation radical (BD bromide) are also very different in many respects.[12] In the spectrum of BD cation radical was

10) T. Takenaka, Preprint of Symposium on Molecular Electronic States, October, 1969, Fukuoka, Japan.
11) B. Lunelli and C. Pecile, *J. Chem. Phys.*, **52**, 2375 (1970).
12) The infrared absorption spectrum of BD is very similar to that of aniline and the vibrational modes were assigned according to the assignments of aniline by Evans.[13]
13) J. C. Evans, *Spectrochim. Acta*, **16**, 428 (1960).

observed a fairly intense band at 1545 cm^{-1}, but no intense band was observed around this wave number for BD. The ring stretching mode involving considerable C–N stretching appears at 1268 cm^{-1} for neutral BD, but in the spectrum of BD cation radical, no strong absorption is located in this region and a new band appears at 1318 cm^{-1}. The bands at 1176 cm^{-1} and 1140 cm^{-1} for BD are assigned to the in-plane CH bending modes. For BD cation radical, a fairly broad band is located at 1160 cm^{-1}, but the shape of this band is clearly distinguishable from the shape of the CH bending modes.

(a) BD·TCNQ(n) Complex: In the spectrum of BD·TCNQ(n) complex, the C≡N stretching frequency is slightly shifted to lower values compared with that of neutral TCNQ (from 2223 cm^{-1} to 2205 cm^{-1}), but the band is neither broadened nor split. The C=C ring stretching mode of TCNQ of the complex is observed at the same frequency as that of neutral TCNQ. As for the amine part, the ring stretching mode which is located at 1490 cm^{-1} in neutral BD is observed at 1498 cm^{-1} in the complex, and the bands at 1176 cm^{-1} and 1146 cm^{-1} for the complex are found to be clearly resembling in the frequency and in the shape to the in-plane CH bending modes of neutral BD. Furthermore, no band of the complex is found to correspond to the ring stretching band at 1545 cm^{-1} for BD bromide. From these, it is concluded that BD·TCNQ(n) complex is essentially of non-bonding type.

In the ground state, however, the dative structure seems to contribute to somewhat large extent in this complex, because the ring stretching mode involving considerable C–N stretching is shifted to 1308 cm^{-1} in the complex and the position is close to the band at 1318 cm^{-1} for BD bromide.

(b) BD·TCNQ·S(CH_3COCH_3) Complex: In the BD·TCNQ·S(CH_3COCH_3) complex, the C≡N stretching mode of TCNQ appears at 2210 cm^{-1}, and is neither broadened nor split. The fact suggests that the complex is of non-bonding type.

The following observations, however, show fairly large contribution of the dative structure to the ground state of the complex. The C=C stretching bands which appear at 1540 cm^{-1} in neutral TCNQ are shifted to 1528 cm^{-1} in the complex. The band at 1180 cm^{-1} of the complex shows almost the same frequency and shape as the band at 1183 cm^{-1} of lithium salt of TCNQ. In this complex, the in-plane CH bending mode of neutral BD at 1140 cm^{-1} disappears and a shoulder is located at 1160 cm^{-1} where a band of BD bromide lies. The ring stretching mode involving considerable C–N stretching of BD is observed to be shifted to 1330 cm^{-1} and is found to be rather near the band of BD bromide at 1318 cm^{-1}. Moreover, a new band appears in the complex at 1560 cm^{-1}, where no band is observed in the spectra of BD, BD bromide, TCNQ, and lithium salt of TCNQ. This band may correspond to the band at 1545 cm^{-1} of BD bromide or to the band at 1580 cm^{-1} of lithium salt of TCNQ.

From these observations, it is concluded that BD·TCNQ·S(CH_3COCH_3) complex is neither of non-bonding type nor of ionic type and that its electronic character may be considered to lie in the intermediate between the non-bonding and the ionic characters. The same conclusion is also drawn for BD·TCNQ containing other solvent molecules.

For BD·TCDQ·S complexes, the band characteristic of the solvent included is also observable. For example, the C=O stretching mode of acetone is seen at 1705 cm^{-1} in the spectrum of BD·TCNQ·S(CH_3COCH_3).

Magnetic Properties. The magnetic properties of BD·TCNQ·S complexes are very different from those of BD·TCNQ(n) complex. BD·TCNQ(n) is diamagnetic and exhibit no ESR absorption, whether the sample is in the form of crystal or in the form of finely ground powder. The well-grown crystals of BD·TCNQ·S show no (or sometimes very weak) ESR absorption, but when they are ground to fine powder, they exhibit a strong ESR absorption signal. When the pulverized sample of BD·TCNQ(n) is exposed to the vapor of dichloromethane overnight, it becomes to show a strong ESR absorption. The fact is consistent with the observed change in the X-ray diffraction pattern described in Ref. 4.

The unpaired electrons in BD·TCNQ·S are produced by the following three ways. (i) The spin concentration of a crystalline sample of BD·TCNQ·S complex increases greatly when the sample is ground. For example, when the crystals of BD·TCNQ·S(CH_2Cl_2) were ground in a vacuum at room temperature, the ESR absorption intensity of the sample increased by a factor of 270.

(ii) The spin concentration of freshly prepared samples of BD·TCNQ·S is dependent on conditions of the sample preparation. The sample which was prepared in a concentrated solution of the components and was not composed of well grown crystals showed a larger spin concentration than the complex which was prepared in a dilute solution and was composed of well-grown crystals. The results of the experiments on BD·TCNQ·S (CH_2Cl_2) are shown in Table 1, where relative intensities of the ESR absorption are listed as a measure of spin concentrations.

Table 1. Relation between ESR absorption intensity of BD·TCNQ·S (CH_2Cl_2) complex and the condition of its preparation

Sample	Initial concentration of components[a]		Relative intensity of ESR absorption[b]
1	TCNQ	2.6×10^{-3} mol/l	4.50
	BD	7.6×10^{-3}	
2	TCNQ	2.7×10^{-3}	1.90
	BD	2.5×10^{-3}	
3	TCNQ	9.2×10^{-4}	0.32
	BD	8.3×10^{-4}	

a) These values show the initial concentration of each component in the solution from which the complex is precipitated.
b) ESR absorption intensity is measured within a several hours after filtration of the sample.

(iii) The ESR intensity of BD·TCNQ·S increases gradually when it is exposed to the air.

The facts (i) and (ii) show that the unpaired electrons are produced at the lattice defect and/or on the surface

of the crystals.

The temperature dependence of the ESR intensity of BD·TCNQ·S (CH_2Cl_2) is given in Fig. 2. The ESR intensities of both samples, ground and not ground, increase in proportion to $1/T$ as the temperature is lowered down to 77°K. The fact indicates that the interaction between the unpaired electrons is very weak in the complex. The line shape of the ESR absorption, however, is very much narrowed and asymmetric in a vacuum. For example, the width between the points of half maximum of the absorption curve ($\Delta H_{1/2}$) was 1.1G for BD·TCNQ·S (CH_2Cl_2) in a vacuum. The narrow line width seems to be due to the motional narrowing, because the interaction between unpaired electrons is very weak.

The ESR absorption signal is sensitively changed by an introduction of air. In the air, the absorption line is almost symmetric and Lorentzian, whereas it is symmetric in a vacuum. The line width in the air is greater than that in a vacuum. The width $\Delta H_{1/2}$ of BD·TCNQ·S(CH_2Cl_2) is 3.1G in the air. This behavior suggests that the unpaired electron is produced near the surface. The integrated ESR absorption intensity, however, is not affected so sensitively by the introduction of air, although the intensity increases gradually in the air. The value of g-factor for BD·TCNQ·S(CH_2Cl_2) is 2.0027±0.0004.

The ESR behavior of the unpaired electrons generated by grinding and by the interaction with the air was identical. Therefore, both kinds of the unpaired electrons are considered to belong to the same paramagnetic species.

Visible and Near Infrared Absorption Spectra. The visible and near infrared absorption spectra of solid BD·TCNQ(n), BD·TCNQ·S (CH_2Cl_2) and BD·TCNQ·S(CH_3CN) complexes are shown in Fig. 3. The absorption peaks for the solutions of BD, BD·bromide,[14] TCNQ,[15] lithium salt of TCNQ[16] and BD·TCNQ complex are also shown in this figure. The spectrum of BD·TCNQ·S(CH_2Cl_2) is essentially identical with that reported by T. Amano *et al.*[17]

These spectra are composed of three main bands. The bands for BD·TCNQ·S complexes, however, are shifted to longer wave lengths compared with those of BD·TCNQ(n) complexes.

The bands of BD·TCNQ(n) at 1300 mμ and 520 mμ are assigned to the first and the second charge-transfer band; respectively, because of the following reasons. Firstly, the solution spectra of both BD and TCNQ[15] show individually no absorption peak in the region longer than 450 mμ. Since BD·TCNQ (n) is essentially of non-bonding type as was described before, these two bands of BD·TCNQ(n) are considered to be charge-transfer bands. Secondly, the positions of these two bands are near to the first and the

second charge-transfer bands for the solution of BD·TCNQ, respectively. Thirdly, as is shown in Table 2, the difference in the energies for the peaks at 520 mμ and 1300 mμ of BD·TCNQ(n) is nearly equal to the difference in the energies of the second and the first charge-transfer bands for the solution of BD·TCNQ.

The broad band at about 360 mμ for BD·TCNQ(n) considered to be related to the intramolecular transitions of BD and TCNQ.

As is shown in Fig. 3, the three main bands of BD·TCNQ·S complexes are almost independent of the kind of the solvent contained and their peaks are observed at 1500—1600, 550—560 and ~340 mμ. The lowest energy and the second lowest energy transitions can be assigned to the first and the second charge-transfer bands, respectively, because they are near to the first and the second charge-transfer bands of of BD·TCNQ(n), and because the energy difference in the former bands is equal to that in the latter bands (Table 2).

Table 2. Energies of charge-transfer transitions of BD·TCNQ system

	First C-T band[a)]	Second C-T band[a)]	Difference[b)]
Chloroform solution	1.29 eV	2.56 eV	1.27 eV
BD·TCNQ(n)	0.95	2.38	1.43
BD·TCNQ·S (CH_3CN)	0.78	2.22	1.44

a) The energy at the charge-transfer absorption maximum.
b) The energy difference between the second and the first charge-transfer bands.

Besides the three main bands just discussed, the weak absorption bands were observed in the spectra of BD·TCNQ·S complexes. These bands appear at 430 and 820 mμ as shoulders of the main bands, and their wave lengths are very close to those of the absorption peaks of TCNQ anion radical[16] and BD cation radical.[14] The intensity of these weak bands are dependent on the kind of the solvent included. In fact, as is seen in Fig. 3, these bands are clearly observed in BD·TCNQ·S(CH_2Cl_2), but they are very weak and are scarcely observed in BD·TCNQ·S(CH_3CN). On the other hand, the effect of grinding on the ESR intensity is more remarkable in the former complex than in the latter.[18] By considering these facts, it is concluded that the weak bands at 430 and 820 mμ are due to TCNQ anion radical and BD cation radical which are formed at the lattice defects or on the surface.

It may be pertinent to note here that the complex, which was prepared by grinding carefully an equimolar mixture of BD and TCNQ in an agatemortar, showed similar optical and magnetic properties to those of the BD·TCNQ·S complexes, although the complex thus obtained does not contain solvent molecules. For example, a rather intense ESR absorption was observed with this complex, and its infrared absorption spectrum showed the bands characteristic of BD·TCNQ·S complexes, although the bands characteristic of BD·TCNQ(n) complex were very also weakly observable. In Fig. 4 is shown the optical absorption spectrum in the visible and near infrared region for the complex prepared under the dry condition. The location and the shape of the main bands in the spectrum are very similar to those observed in the spectrum of BD·TCNQ·S complexes shown in Fig. 3.

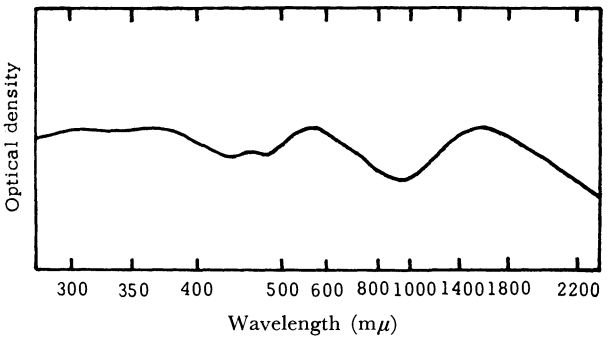

Fig. 4. Optical absorption spectrum of BD·TCNQ complex which was prepared by grinding a mixture of TCNQ and BD powders.

Table 3. Specific resistivities of BD·TCNQ complexes

Solvent included	$\rho_{18°C}$ (Ω·cm)	E (eV)
CH_2Cl_2	7×10^3	0.10
C_2H_5Br	6×10^3	0.12
CH_3CN	7×10^4	0.16
CH_3COCH_3	4×10^5	0.21
no solvent	2×10^9	0.34

Electrical Properties. The electrical resistivities of polycrystalline samples of BD·TCNQ(n) and BD·TCNQ·S complexes were found to follow the equation, $\rho=\rho_0\exp(E/kT)$. The values of E and $\rho_{18°C}$ observed are listed in Table 3. Both E and $\rho_{18°C}$ are lower for BD·TCNQ·S complexes than for BD·TCNQ(n) complex. The resistivities of BD·TCNQ·S complexes are small compared with most of other nonionic molecular complexes.[19,20]

The resistivities of the single crystals of BD·TCNQ·S(CH_2Cl_2) were measured several times. The crystal of the complex was a thin needle and its typical dimension was 2.5 mm × 0.10 mm × 0.06 mm. The resistivity was measured along the long axis at room temperature. The average of the results obtained is $1.4\times10^3\Omega$cm. This value is several times lower than the value for the polycrystalline sample listed in Table 3.

In order to eliminate the possibility that the observed low resistivity be due to ionic conduction, the following experiment was carried out. A pellet of BD·TCNQ·S(CH_2Cl_2) was pressed at 165 kg/cm² and the

18) After grinding in an agatemortar, the spin concentration of BD·TCNQ·S(CH_2Cl_2) increased to 6×10^{22} per mole, while that of BD·TCNQ·S(CH_3CN) to 1×10^{22} per mole.

19) Y. Matsunaga, *Nature*, **205**, 72 (1965).

current was run through it at room temperature until the amount of charge passed had exceeded the amount expected from the Faraday's law by 3 times. No significant decrease was observed in conductivity. The conduction was thus concluded to be electronic in character.

Complexes of TCNQ with o-Tolidine, 3,3'-Diaminobenzidine and 3,3'-Dichlorobenzidine. The electronic properties of these complexes are dependent on the kind of the donor. Thus, 3,3'-dichlorobenzidine (DCBD) which is the weakest of the three donors gives a diamagnetic complex. DCBD·TCNQ complex does not show any ESR absorption whether the sample is ground or not. This behavior is similar to that of BD·TCNQ(n) complexes.

On the other hand, the complex of 3,3'-diaminobenzidine (DABD), which is the strongest of the three donors, shows a strong ESR absorption. No significant effect of grinding on the ESR absorption intensity was observed. These facts indicate that the complex is ionic in character.

The magnetic properties of the complex of *o*-tolidine (TL) and TCNQ which contains dichloromethane or chloroform are similar to those of BD·TCNQ·S complexes. The spin concentration of the sample of TL·TCNQ·S(CH_2Cl_2) was found to be 8×10^{21} per mole before grinding and was found to increase by 16 times after grinding. The line width (ΔH_{msl}) of a sample was observed to be 0.93 G in vacuo, while it became 1.70G in the air. From these observations, it is concluded that TL·TCNQ·S complexes have a similar electronic character to that of BD·TCNQ·S complex. This conclusion was further supported by the fact that the characteristics of the infrared absorption spectra for the former complexes are very similar to those for the latter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 400—403 (1971)

Paper Electrophoresis and Polarography of the Reaction Product between the Chromium(III) Ion and Potassium Hexacyanoferrate(II)[1]

Michiko SHIRAI

Department of Chemistry, Faculty of Hygienic Science, Kitasato University, Minato-ku, Tokyo

(Received September 30, 1969)

In continuation of the previous work (Y. Matsumoto and M. Shirai, Bunseki kagaku, **12**, 608 (1963); Y. Matsumoto and M. Shirai, This Bulletin, **39**, 59 (1966).), results of a study of the colored products resulting from the reaction between the chromium(III) ion and potassium hexacyanoferrate(II) by paper electrophoresis and polarography will be presented in this paper. Paper-electrophoretical experiments illustrated that the negatively-charged complexes containing both Cr and Fe were gradually formed by reaction. In the presence of excess potassium hexacyanoferrate(II), the resulting complexes were constant in color and situation in the electrophoretical patterns, regardless of the molar ratio of reactants. On the other hand, in the case of a reactant molar ratio ($Fe(CN)_6^{4-}$ to Cr^{3+}) below 2.5, the patterns varied with the ratio. The product, sampled either in the form of a reaction mixture or as isolated state (Y. Matsumoto, M. Shirai, and H. Saito, This Bulletin, **41**, 2542 (1968).), was found to present no reduction wave of Cr^{3+} on polarography at the dropping mercury electrode.

The chromium(III) ion slowly reacts with potassium hexacyanoferrate(II) in an aqueous solution to form an orange-yellow to reddish-brown complex which is very soluble in water; this is in contrast with most heavy metal ions, which react rather quickly with the same reagent to form insoluble product.

This contrast, as well as the characteristic coloration, has attracted attention to the nature of the reaction product, especially to its structure in an aqueous solution, so that a number of approaches have been made[2-9] during the last ten years or so.

In the present work, the nature of the product in its aqueous solution, especially of the ion which composes the major moiety of this colored product, was studied using paper electrophoresis and polarography.

Experimental and Results

Electrophoresis was conducted on filter papers (2×40 cm, Toyoroshi Co., No. 51A), each saturated with a 0.1 M KCl solution, for 2 hr under an applied voltage of 200 V in a horizontal-type apparatus. The location of the chromium complex was detected by means of the diphenylcarbazide method.

One milliliter of a chrome alum solution (2 mg/m*l*

for Cr^{3+}) was mixed with 3.2 m*l* of a potassium hexacyanoferrate(II) solution (50 mg/m*l* for $K_4Fe(CN)_6 \cdot 3H_2O$), the molar ratio of hexacyanoferrate(II) to Cr^{3+} being 10 : 1; the chromium concentration in the mixed solution was found to be about 10^{-2} M (reaction mixture 1). This yellow-colored reaction solution gave, on electrophoretical separation, two yellow spots (A and B), both located in the direction toward the positive electrode (Fig. 1). Extracts from both the spots, obtained with distilled water, were decomposed by (1+1) sulfuric acid, and then tested for the presence of Cr and Fe. The spot A proved to contain both Cr and Fe, while the spot B contained Fe alone. Upon the coloration test with diphenylcarbazide, the spot A turned purple, and the spot B, a grayish blue.

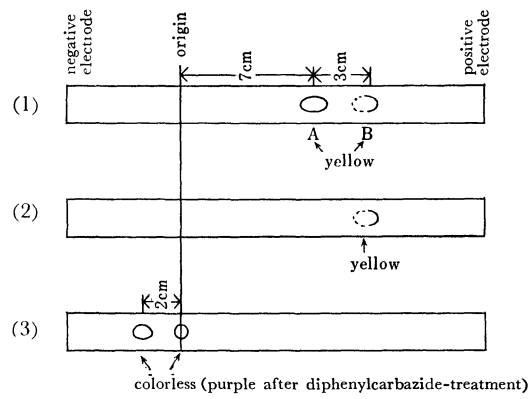

Fig. 1. Paper electrophoresis with (1) yellow-colored reaction mixture, (2) $K_4Fe(CN)_6$ soln, and (3) Cr^{3+} soln.

For reference, a potassium hexacyanoferrate(II) solution and a chrome alum solution of the same final concentrations as the corresponding concentrations in the sample solution were charged individually on other papers and then subjected to electrophoresis. On the reference paper charged with potassium hexacyanoferrate(II), one yellow spot was found in the position as far from the origin as the position B on the paper charged with the sampled solution, while Fe was not found at the position corresponding to A. On the reference paper for the Cr^{3+} solution, were observed two spots which proved to contain Cr by the diphenylcarbazide test; one of them was in the direction toward the negative electrode, and the other was at the point of origin. On the other hand, no chromium-containing spot other than A was observed on the electrophoretical pattern for the sample solution which had stood for an adequate reaction period.

The paper-electrophoretical study thus confirmed that the yellowish-orange-colored and negatively-charged complex ion, which contained both chromium and iron, existed predominantly in the reaction mixture resulting from the reaction between the chromium(III) ion and excess potassium hexacyanoferrate(II).

The process of the gradual formation of the chromium-containing complex from the chromium(III) ion, characterized in terms of the change to a negative species from a positive one, was successfully visualized by paper-electrophoretical patterns varying in the course of the progress of the reaction. A chrome alum solution of 2.5 m*l* (20 mg/m*l* for Cr^{3+}) was mixed with a potassium hexacyanoferrate(II) solution of 10 m*l* (200 mg/m*l* for $K_4Fe(CN)_6 \cdot 3H_2O$), the molar ratio of hexacyanoferrate(II) to Cr^{3+} being 5 to 1 (reaction mixture 2). The concentrations of the reactants in this reaction mixture were made larger than those in the foregoing one (reaction mixture 1) in order that the evidence for any transition state of chromium(III) ion from its free state to any other coordinated state could be observed distinctly; the reactant ratio of 5 : 1 was adopted after it had been confirmed that the reaction solution resulting from this reactant ratio gave qualitatively the same paper-electrophoretical pattern as was given by the solution with a reactant ratio of 10 : 1. The mixed solution of this reactant ratio were allowed to stand for varying periods of time (0, 2, 4 hr and 1 and 2 days) at room temperature after mixing; then they were subjected to paper electrophoresis. The coloration was done by means of the diphenylcarbazide method (Fig. 2).

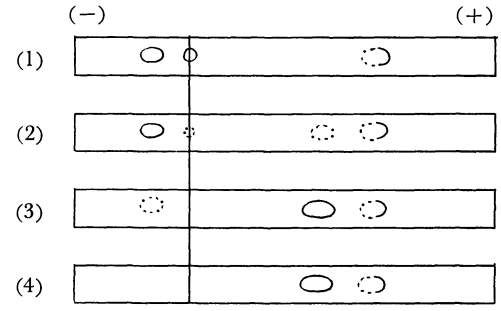

Fig. 2. Paper-electrophoretical patterns of the reaction mixture, altering in the course of the proceeding of the reaction: (1) immediately, (2) 2 hr, (3) 4 hr, and (4) 2 days after mixing reactants.

The results were as follows: (1) with the solution tested immediately after mixing, no colored chromium-containing spot was found, but two chromium-containing spots were detected by means of diphenylcarbazide coloration, one on the original point and another one at a distance from the point of origin in the direction of the negative electrode.

(2) With the solution which had stood for 2 hr after mixing, a yellow chromium-containing spot was found to appear in the direction of the positive electrode in addition to the visually colorless chromium-containing spots still present in the negative electrode direction and on the original point.

(3) With the solution allowed to stand for 4 hr after mixing, there appeared a chromium-containing yellow spot in the positive electrode direction, more intense in color, and a diphenylcarbazide-test-positive spot in the negative electrode direction, weaker in color, than in the foregoing case, *i.e.*, the case of the shorter reaction time. The former kind of spot became the more intense in color, and the latter kind became the weaker, the longer the time which elapsed after mixing. On the point of origin, no chromium-containing spot remained.

(4) Two days later after mixing, all the chromium was contained in the yellow complex which, on electro-

phoresis, is located in the positive electrode direction.

In order to study the properties of the reaction products produced at varying reactant ratios, the solutions were also prepared by mixing 2.5 m*l* of a chromium(III) solution with the Cr^{3+} concentration of 20 mg/m*l* and 10-m*l* portions of potassium hexacyanoferrate(II) solutions with the salt concentrations of 200, 100, 80, 60, 40, and 20 mg/m*l* so that the resulting solutions contained potassium hexacyanoferrate(II) in ratios of 5, 2.5, 2, 1.5, 1, and 0.5 mol respectively to 1 gram ion of the Cr^{3+} ion. After having stood for two days, each colored reaction solution was centrifuged for 15 min at 3000 rpm; the supernatant was then subjected to paper electrophoresis.

The results are shown in Fig. 3. The products of the reaction at the reactant ratios (hexacyanoferrate(II) to Cr^{3+}) below 2.5 were visually similar to, but electrophoretically different from, those of the reactant ratios above 2.5. The lower the ratio of hexacyanoferrate(II) to Cr^{3+} the shorter the distance the corresponding chromium complex was shifted, and the more greenish became the color of the complex.

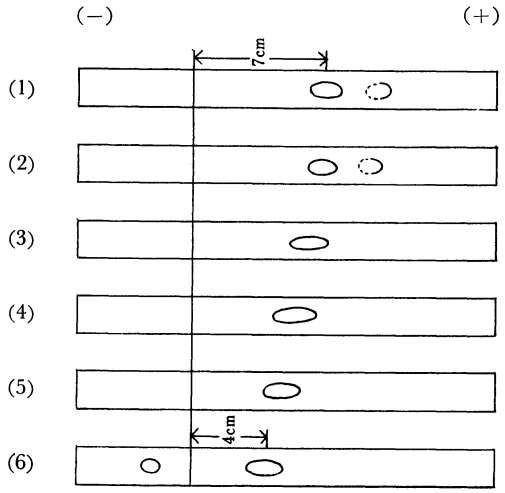

Fig. 3. Paper-electrophoretical patterns along with a variety of reactants ratios: (1) 5, (2) 2.5, (3) 2, (4) 1.5, (5) 1, and (6) 0.5 mol of $K_4Fe(CN)_6$ respectively to 1 gram ion of Cr^{3+}.

The remaining activity of Cr(III) in the reaction solution was further examined by polarography. The reaction mixture at the reactant ratio of 10 : 1 (chromium concentration 10^{-2} M), in which KCl had been added to 1 M, after which N_2 gas had been bubbled through the mixture, was examined by polarography *vs.* a saturated calomel electrode. The characteristic wave for Cr(III) was found to have disappeared, whereas, in the presence of the same concentration KCl, the solution of Cr^{3+} (chrome alum) gave the wave corresponding to $Cr^{3+} \rightarrow Cr^{2+}$, which was proportional in height to the concentration of Cr^{3+} salt in the range from 10^{-2} M (this concentration gave a wave having the reduction current of 18 μA and the $E_{1/2}$ of −0.9 V) to 10^{-3} M, indicating that the diffusion-controlled conditions hold for this concentration range of Cr^{3+}.

Malik reported[6] the disappearance of the reduction wave in these reaction mixtures at the same electrode, without giving interpretation about it.

In order to observe from what reactant ratio chromium(III) wave appears, solutions in molar ratios varying from 0.1 to 1 of potassium hexacyanoferrate(II) per Cr(III) ion were prepared, while the concentration of Cr^{3+} was kept at a constant value (10^{-2} M); the solutions were then allowed to react at 47°C for 2 hr. The reduction wave for Cr^{3+} diminished in height with an increase in the reactant ratio (hexacyanoferrate(II) to the Cr(III) ion) of the reaction solution and almost disappeared when the reactant ratio was raised to 0.5 : 1 (Fig. 4-a).

This depression of the reduction wave took place even immediately after mixing the reactants. The aqueous solutions of chrome alum and of potassium hexacyanoferrate(II) to which KCl had been added were both bubbled through with N_2 gas, and then they were mixed with each other to make a solution containing Cr^{3+}, $Fe(CN)_6^{4-}$, and KCl in concentrations of 10^{-2} M, 10^{-1} M and 1 M respectively; immediately afterwards, this mixed solution was subjected to polarography. The reduction wave could not be observed unless the molar ratio of hexacyanoferrate(II) to Cr(III) decreased to 0.8 : 1 (Fig. 4-b).

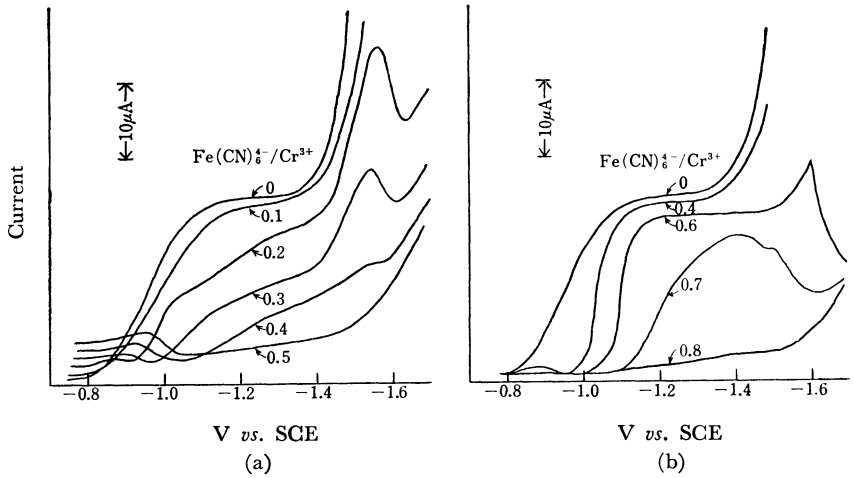

Fig. 4. The gradual disappearance of polarographical reduction wave for Cr^{3+} (10^{-2} M) with the increasing molar ratio of $K_4Fe(CN)_6$ to Cr^{3+} in two cases, (a) after the reaction time of 2 hr at 47°C, and (b) soon after mixing the reactants.

The solution containing the Cr^{3+} ion (10^{-2} M) and potassium hexacyanoferrate(II) (0.5 M), but not potassium chloride, lacked the reduction wave for Cr(III), too.

This disappearance of the reduction wave for Cr(III) was not, however, observed on the polarography of such other chromium(III) complexes, as potassium hexacyanochromate(III), even in the presence of excess potassium hexacyanoferrate(II). An aqueous solution of potassium hexacyanochromate(III) containing 0.5 M potassium hexacyanoferrate(II) as a supporting electrolyte was made using crystals of potassium hexacyanochromate(III) prepared[10] from chromium acetate and potassium cyanide. On polarography, the solution presented a very clear reduction wave corresponding to Cr(III) (Fig. 5).

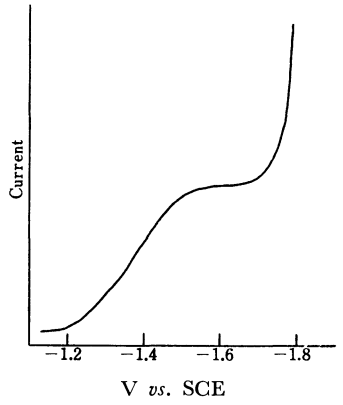

Fig. 5. Polarography of $K_3Cr(CN)_6$ in the presence of 0.5 M $K_4Fe(CN)_6$.

These waves were proportional in height to the Cr concentrations in the range from 10^{-2} to 10^{-3} M.

Recently, it was reported[4] that a reddish-yellow compound could be isolated in a pure form from the reaction mixture by Sephadex G-25 column chromatography. The Cr(III)-hexacyanoferrate(II) complex purified as has been described above was confirmed by paper electrophoresis to be free from the unreacted potassium hexacyanoferrate(II), and it showed no reduction wave on its polarogram.

It was surprising at first glance that even in the reaction mixture which stood only a short time after the mixing of the reactants and which was confirmed on paper electrophoresis still to contain many free Cr^{3+} ions, there was no reduction wave.

The paper-electrophoretical results indicate that this lack of a reduction wave can not be accounted for by presuming a particularly stabilized state of the chromium(III) ion coordinated with hexacyanoferrate(II), but it might well be attributed to the current-insulating effect of the deposition of an insoluble complex, the chromium(II)-hexacyanoferrate(II) complex, produced on the electrode surface by the polarographic reduction of Cr(III).

The insoluble film of the deposition, Cr(II)-hexacyanoferrate(II), would be formed either by the reduction of free Cr(III) ions in the presence of hexacyanoferrate(II) ions or by the reduction of the Cr(III)-hexacyanoferrate(II) complex already formed.

The author is grateful to Professor Yoshio Matsumoto for his help and advice throughout this work.

Distribution of Nickel across the Thickness of Al Anodic Oxide Films Sealed in Nickel Sulphate Solutions

Luigi CAMPANELLA

Italian National Researches Council, Rome, Italy

Institute of Analytical Chemistry, University Rome, Italy

(Received February 23, 1970)

The distribution of nickel across the thickness of Al anodic oxide films, produced in 15.5% w/v H_2SO_4 as electrolyte and sealed in nickel sulphate solutions, is determined and an approximate confirmation of the conical shape of pores is obtained.

As is well known, anodizing of Al in sulphuric acid electrolyte yields porous films of oxide which are usually sealed before being used. On being sealed, anhydrous oxide is hydrated, swells and fills up the hollow of its pores by the transformation into boehmite ($Al_2O_3 \cdot H_2O$), a less dense phase than the preexisting anhydrous alumina. The usual technique of sealing includes immersion in boiling distilled water, hot water vapour, boiling solutions of chromates, dichromates and salts, such as Ni or Co acetate or sulphate, or capillary active organic compound.[1] The use of nickel and cobalt salts is particularly convenient as they prevent the harmful action of silicates and phosphates, always contained in tap water, so that it can be used in place of distilled water as a sealing medium.[2] Nickel and cobalt salts are adsorbed in the film, where they are hydrolized and precipitated as almost colourless hydroxides. This technique of sealing is also very useful for dyed layers. In this case, according to Speiser,[3] three different reactions occur: 1) hydration of films, as in the case of sealing in boiling distilled water, 2) precipitation of the hydroxide in the pores with consequent blocking-in of the dye, 3) chemical reaction between the nickel (or cobalt) compound and the dye to form a new metal complex.

However, the functions of nickel (or cobalt) in the sealing process are not very clear and need further investigation. This paper deals with the distribution of nickel across the full thickness of Al anodic oxides sealed in nickel sulphate solutions.

The study was performed with the aim of improving the knowledge of sealing mechanism, particularly concerning the functions of nickel salts in sealing solutions and the shape of the pores present in the anodic oxide.

Experimental

a) 99.99% Al samples ($5 \times 10 \times 0.1$ cm) were freed from grease with toluene and polished both mechanically and chemically (in 20 g/*l* NaOH solutions), then rinsed successively in distilled water, 1 : 1 HNO_3 solution, and distilled water again. After drying they were anodized in 15.5% w/v H_2SO_4 solution, at 25.0 ± 0.5°C, 1.3 A/dm^2, for 40 min. Stirring and symmetry of the electrolytic bath were warranted by means of rotating anode and the presence of two bored cathodes, larger than the anodized samples (surface area ratio 1 : 3), equidistant from the central anode.

b) Sealing: The anodized samples were washed with running distilled water and immersed for 30 min in boiling $NiSO_4 \cdot 7H_2O$ 15 g/*l* solution.

c) Cationic exchanger Dowex 50-X 8 (100—200 mesh), H^+ form, medium porosity, total capacity approximately 5.0 ± 0.3 meq/g dry, moisture content 50—56% by weight.

Anionic exchanger Dowex 1-X 4 (100—200 mesh), Cl^- form, high porosity, total capacity approximately 3.3 ± 0.3 meq/g dry, moisture 54—60% by weight.

The two ionic exchangers were contained in columns each 30 cm long and 20 mm internal diameter, which were washed before use: the cationic one with 12M HCl and distilled water (flux rate 2 ml/min) and the anionic one with only distilled water (flux rate as above).

d) Spectrophotometer Beckman DU

e) Amel, mod. 461, polarograph.

The anodized sample is kept for a long time in a solution which can dissolve the oxide and nickel is determined in the corroding solution. In order to get consistent information, we assume that chemical attacks proceed uniformly from a layer to the next inner one and that no localized pitting corrosion takes place. The at tacking solutions were Edwards mixture (35 ml/*l* H_3PO_4 85% and 20 g/*l* CrO_3) acting for 0—20 min and 1.5M HCl acting for a prolonged time.

Quantitative determination of nickel was performed by four different methods for nickel solutions in the presence of aluminium.

1) After having acted for the specified time, the Edwards mixture was passed on an anionic exchanger in order to eliminate phosphate and chromate anions. In this operation a reduction of Cr(VI) to Cr(III) by the resin was observed and a green solution resulted at the end of the column, the intensity of this colour not being possible to be accounted for by the presence of Ni(II) ions. Al(III) was separated by passage through the cation exchanger and elution with 1.5M HCl.[4] Nickel was determined gravimetrically by dimethylglyoxime, having masked Cr(III) by adding citrate.[5]

2) After the necessary lapse of time for the dissolution reaction the 1.5M HCl solution was evaporated to dryness and the residue was dissolved in distilled water. Nickel was determined in the resulting solution a) spectrophotometrically by complexing it with α-furildioxime[6–8] and extraction

of the complex with $CHCl_3$, having previously masked Al(III) by citrate or tartrate; b) by back-titration at pH=10 with EDTA and standard Zn(II) solution, using NET as indicator and masking Al by fluoride;[9-11] c) amperometrically in deoxygenated 0.1M NH_4Cl and 0.5M NH_4OH as supporting electrolyte at −1.7 V *vs.* SCE, using dimethylglyoxime as titrating agent: as both nickel and dimethylglyoxime give diffusion currents, a sharp V shaped titration curve was obtained;[12,13] Al was eliminated by the technique described in 1), just above.

Each measurement was carried out for at least three different samples. The results are given by mean values.

Results

In Table 1 the data of the gravimetric determination are given. In Fig. 1 the calibration curve used for the spectrophotometric titration with α-furildioxime is reported: 2, 2.5, 3, 3.5, 4 m*l* of a standard solution of $NiSO_4 \cdot 7H_2O$, *at concentration 14.6 μg Ni/ml, were* taken, put into a volumetric flask and diluted to 25m*l* with distilled water, so obtaining concentration values 29.2, 36.5, 43.8, 51.1, 58.4 μg Ni/25 m*l*, for which the respective optical densities were measured at 435 mμ (Table 2). In Table 3 the results of the spectrophotometric determination are given; they are determined on the basis of the calibration curve previously drawn. In order to calculate the values of the last column, the dilution ratios must also be considered. This ratio was controlled in the different experiments in order to bring optical densities in the range observed during calibration, thus avoiding extrapolating approximations.

Table 1. Data of gravimetric analysis

Time of acting of Edwards mixture (min)	Weight of nickel-dimethylglyoxime (mg/dm²)	weight of nickel (mg/dm²)
3	5.41	1.10
5	6.99	1.42
8	8.81	1.79
10	9.45	1.92
15	9.60	1.95
20	10.00	2.03

Table 2. Data of the calibration curve

m*l* of standard solution diluted to 25 m*l*	Optical density (at 435 mμ)
2.0	0.395
2.5	0.495
3.0	0.600
3.5	0.695
4.0	0.790

24	4.0	1.35	1.60
36	4.0	1.04	1.90
48	4.0	0.95	2.01

In Table 4 and Fig. 2 the results of the amperometric determinations of nickel by dimethylglyoxime (609.05 mg in 250 m*l* 95% ethanol) are reported. In Table 5 the results of the complexometric titration of nickel with 0.0125M EDTA and 0.0170M $ZnSO_4$ are recorded as a function of the time of acting of the corroding solution.

Discussion

By considering the amounts of nickel found in the corroding solution as function of the attacking time, the distribution curve of nickel across the thickness of the oxide layer can be deduced, assuming that

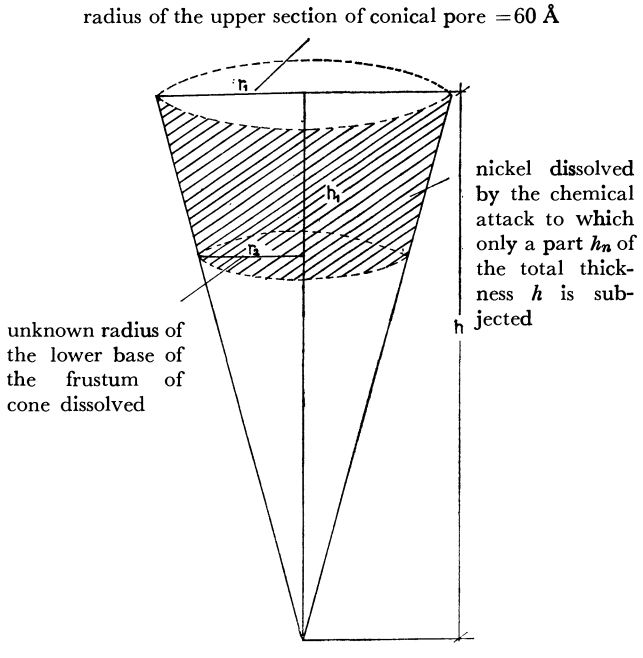

Fig. 3

oxide layers nearer to the basis metal are successively subjected to uniform dissolution. Nickel turns out to be mostly concentrated in the outer portion of the anodic film and the rate of decrease of its concentration through the depth of the oxide supports the conical shape of the pores, as shown in Fig. 3, where nickel content is plotted against percentage of the total thickness (measured by Dermitron, an eddy-currents instrument, manufactured by Unit Process Assemblies Inc., New York).

Considering that the nickel amounts taken off during each attack are those contained in the volumes of the frusta of the cone, which are successively dissolved, and that 2 mg/dm² of nickel are found for the total dissolution of the oxide, a pore can be drawn, taking 120 Å as base diameter[14] and applying the following two equations:

$$r_1^2 h/3 = k m_{tot}$$

$$(r_1^2 + r_n^2 + r_1 r_n) h_n/3 = k m_n$$

where:

- k = a constant term
- r_1 = upper base radius = 60 Å
- r_n = lower base radius
- h = height of the cone, taken approximately as 13 μ, that is, the thickness of the oxide layer, measured by Dermitron, neglecting the thickness of the barrier layer which should be subtracted
- h_n = height of the frusta of the cones successively dissolved
- m_n = nickel content of the corroding solution
- m_{tot} = 2 mg nickel/dm²

The above system must be applied to each conical frustum equivalent to the varying times of chemical attack. All the frusta have the same upper base. Several values for r_n are calculated, by which Fig. 4 can be

drawn, as representing a pore of the oxide film. The approximations introduced can account for the wider angle we found than ISML researchers.[15]

The present work was carried out with the aid of the Italian National Researches Council.

N-Benzenesulphonyl β-Alanine as a Masking Agent for Hg(II)

Nripendra Nath Ghosh and Anjali Bhattacharyya
Department of Inorganic Chemistry, University College of Science, Acharyya Prafulla Chandra Road, Calcutta-9, India

(Received June 16, 1970)

N-Benzenesulphonyl glycine and *N*-benzenesulphonyl α-alanine form water soluble complexes with Hg(II), Cu(II), and Ag(I). But *N*-benzenesulphonyl β-alanine ($R_b^{\beta}H_2$) gives only stable complex ion $Hg(R_b^{\beta})_2^{2-}$, showing that $R_b^{\beta}H_2$ is a highly selective masking agent for Hg(II). Utilising this masking property, methods for detection and determination of Hg(II) have been developed. $R_b^{\beta}H_2$ reacts with Hg(II) at pH≈8, yielding the ion $Hg(R_b^{\beta})_2^{2-}$ and on subsequent treatment with KI, two equivalents of alkali are liberated. On titrating the alkali liberated with a standard acid, the amount of Hg(II) may be calculated. Interferences due to diverse ions have been studied; Br^- and I^- interfere. The spot test of Hg(II) based on the same principle has been developed and it appears to be specific under specified condition. The limit of identification is 0.5 μg with a dilution limit of 1:100000.

A rapid and accurate method for determination of Hg(II) has been described using *N*-benzenesulphonyl glycine (R_bH_2).[1] *N*-Benzenesulphonyl glycine forms water soluble complexes[2] $K_2Hg(R_b)_2$, $Na_2Cu(R_b)_2$, and $KAg(R_b)$ which are stable at pH≈8 or higher. The comparable results are also obtained with the ligand *N*-benzenesulphonyl α-alanine ($R_b^{\alpha}H_2$);[3] the Ag(I) compound could not be isolated in the pure state. But *N*-benzenesulphonyl β-alanine ($R_b^{\beta}H_2$) gives at higher pH only stable complex[3] $K_2Hg(R_b^{\beta})_2$ showing that $R_b^{\beta}H_2$ is highly selective masking agent for Hg(II). Utilising this masking property of $R_b^{\beta}H_2$, detection as well as determination of Hg(II) is possible in presence of various commonly associated cations and anions such as Ag(I), Cu(II), Be(II), Mg(II), Zn(II), Cd(II), Pb(II), Al(III), Fe(III), Cr(III), Bi(III), Zr(IV), Th(IV), U(VI), chloride, sulphate, acetate, phosphate, molybdate, and vanadate.

The compound $R_b^{\beta}H_2$ is a monobasic acid but the dissociation of the hydrogen attached to the nitrogen increases so much on complex formation that it becomes possible to titrate with an alkali in the case of $H_2Hg(R_b^{\beta})_2$, affording complex salts. Thus when Hg(II) solution is titrated with a standard alkali solution in presence of $R_b^{\beta}H^-$ ($R_b^{\beta}H_2$ made neutral to phenolphthalein with KOH), then there occurs the following reaction:

$$Hg^{2+} + 2R_b^{\beta}H^- + 2OH^- = Hg(R_b^{\beta})_2^{2-} + 2H_2O$$

In presence of other metal ions stated above, during this titration Hg(II) gives water soluble $Hg(R_b^{\beta})_2^{2-}$ anion and the other metal cations are precipitated mostly as their hydrous oxides. On adding excess of KI to the neutralised solution, $Hg(R_b^{\beta})_2^{2-}$ reacts according to the following equation:

$$Hg(R_b^{\beta})_2^{2-} + 4I^- + 2H_2O = HgI_4^{2-} + 2R_b^{\beta}H^- + 2OH^-$$

The moles of alkali liberated are equivalent to twice those of Hg(II) present. Therefore

$$1\ ml\ of\ (N)\ H_2SO_4 \equiv 100.3\ mg\ of\ mercury$$

Based on the same principle a virtually specific spot test has been developed for Hg(II).

Experimental

Reagents and Solutions. All solutions were prepared with carbon dioxide free water and the reagents used were of A. R. quality except in a few cases where they were properly purified. The reagent $R_b^{\beta}H_2$ was prepared and purified in the laboratory following the method stated in the literature.[4]
