N-Di-p-methoxytrityldeoxyguanosine Tetramer (V) and (VI). The residual polymer was divided in half. Each polymer was phosphorylated with an appropriate amount of β-cyanoethylphosphate and mesitylenesulfonyl chloride, as has been described above. Then the phosphorylated polymers were activated, and *N*-di-*p*-methoxytrityldeoxylguanosine and thymidine (in appropriate amounts) respectively were added. On the other hand, 0.15 g of the solid that contained (*N*-di-*p*-methoxytrityldeoxyguanosine dimer was phosphorylated and then activated with appropriate amount of the reagents. Then, 0.07 g of *N*-di-*p*-methoxytrityldeoxyguanylyl-*N*-di-*p*-methoxytrityl)deoxyguanosine was added (route (c)). The procedures of the cleaving of the nucleotidic materials and purifications were the same as above.

The material (V) (*via* (b)) appeared in the elution of 95—130 m*l* after a small peak of an ultraviolet-absorbing material when the Sephadex LH-20 column and 95% ethanol were used just as above. Also, the material (V) (*via* (c)) appeared in the elution of 97—143 m*l* in another run. The material (VI) appeared in the elution of 81—121 m*l* (Fig. 2). When these materials were precipitated in the way mentioned above and dried, we obtained 16 mg of the nucleotidic material (V) (*via* (b)), 20 mg of the nucleotidic material (V) (*via* (c)), and 36 mg of the nucleotidic material (VI). Each material was dissolved homogeneously in the solvent A; the R_fs were 0.54—0.56 for the nucleotidic material (V) and 0.48—0.51 for the nucleotidic material(VI), respectively. The ultraviolet characteristics in ethanol solutions of the material(V) were: λ_{max}, 278 mμ (73,800), 264 mμ (74,100), 238 mμ (105,000); λ_{min}, 274 mμ (68,400), 253 mμ (71,200), 226 mμ (93,100): and of the material(VI), λ_{max}, 277 mμ (60,000), 260 mμ (61,200), 232 mμ (83,000); λ_{min}, 270 mμ (59,200), 250 mμ (59,000).

Found: C, 60.00; H, 4.91; N, 11.20%. Calcd for the material(V) (*via* (b)): $C_{124}H_{117}O_{30}N_{20}P_3$: C, 60.54; H, 4.80; N, 11.39%: for $C_{124}H_{121}O_{32}N_{20}P_3$ (dihydrate): C, 59.66; H, 4.89; N, 11.22: for $C_{124}H_{123}O_{33}N_{20}P_3$ (trihydrate): C, 59.23; H, 4.93; N, 11.14%.

Found: C, 57.01; H, 4.91; N, 10.83%. Calcd for the material(VI): $C_{103}H_{102}O_{29}N_{17}P_3$: C, 57.97; H, 4.78; N, 11.16%; for $C_{103}H_{106}O_{31}N_{17}P_3$ (dihydrate): C, 57.01; H, 4.88; N, 10.97%; for $C_{103}H_{108}O_{32}N_{17}P_3$ (trihydrate): C, 56.54; H, 4.93; N, 10.88%.

A comparison of the syntheses of the *N*-di-*p*-methoxytrityldeoxyguanosine tetramer shows that the conversion of each additional reaction was 40—50%, regardless of the length of the additional nucleosidic or nucleotidic materials.

The residual unreacted portions in the addition reaction were found to be nucleotidic materials which lacked the desired sequences, such as [(DMTr)d-Gp]$_2$(DMTr)d-G, [(DMTr)d-Gp]$_3$, and [(DMTr)d-Gp]$_2$T. They were ob-

19) 500 units of the phosphodiesterase in 2.5 m*l* of 0.3M Tris buffer at pH 8.85.

tained in considerable amounts, as is shown in Fig. 2. Those materials were identified and determined after the cleavage of the respective blocking groups, as will be described below.

Deoxyguanylyldeoxyguanylyldeoxyguanylyldeoxyguanosine (d-GpGpGpG). Eight mg of the nucleotidic material(V) (*via* (c)) were treated with 1 m*l* of 80% acetic acid for 5 hr at room temperature. The acetic acid was then evaporated in a vacuum. To the resulting materials, 10 m*l* of dilute ammonium hydroxide was added; the mixture was then centrifuged, and the supernatant was concentrated to 3 m*l*. The supernatant solution was made up to 5 m*l* with 0.2M ammonium bicarbonate. The solution was then placed in a DEAE-cellulose column, just has been described above. The column was washed with 0.02M NH_4HCO_3 until no further ultraviolet-absorbing material was eluted. Then, further elution was carried out using the linear gradient of ammonium bicarbonate described above. The major peak (the 1060—1280 m*l*-portion) was collected and lyophilized. The d-GpGpGpG thus obtained (4.1 mg) was homogeneous in paper electrophoresis at pH 8 (the relative mobility was 0.09 for d-pG=1.0).

The ultraviolet absorption characteristics in water were: λ_{max}, 257 mμ (18,000); λ_{min}, 224 mμ (12,500); $\lambda_{shoulder}$, 268 mμ; in 1M NaCl were: λ_{max}, 256 mμ (26,400); λ_{min}, 224 mμ (12,300) $\lambda_{shoulder}$, 267 mμ.

A portion of the material was incubated at 37° for 12 hr with 0.1 m*l* of the venom phosphodiesterase preparation. Three spots were obtained on chromatography in the solvent C; the R_fs were 0—0.04, 0.35 and 0.69, corresponding to an undegraded material (d-GpGpGpG or d-GpGpG), deoxyguanosine 5′-phosphate, and deoxyguanosine, respectively. The optical density units found on eluting these spots were 0.2, 6.7, and 2.1, respectively. Those results show that the material was d-GpGpGpG and that 98% of the tetranucleotide was degraded; d-pG/d-G=3.2.

Deoxyguanylyldeoxyguanylyldeoxyguanylylthymidine (d-GpGpGpT). Ten mg of the nucleotidic material(VI) was trated with acetic acid by the procedure described in the preceding section. The major peak (1100—1290 m*l* portion) was collected and lyophilized. Thus, d-GpGpGpT was obtained (5.7 mg); it was homogeneous in paper electrophoresis at pH 8 (the relative mobility was 0.11—0.12 for d-pG=1.0). The ultraviolet absorption characteristics in water were: λ_{max}, 263 mμ (30,000); λ_{min}, 230 mμ (18,900); $\lambda_{shoulder}$, 240 mμ: in 1M NaCl were: λ_{max}, 261 mμ (29,200); λ_{min}, 229 mμ (18,700); $\lambda_{shoulder}$, 238 mμ.

The enzymatic hydrolysis by the venom phosphodiesterase yielded 1.0 optical density unit of deoxyguanosine, 2.1 optical density units of thymidine 5′-phosphate, 0.8_5 optical density unit of thimidine 5′-phosphate, and 0.1 optical density unit of deoxyguanylyldeoxyguanosine; *i.e.*, 79% of d-GpGpGpT was hydrolyzed (neglecting the hypochromic effect of degraded nucleotides). Also, the enzymatic degradation by spleen phosphodiesterase was achieved. In this case, 2.0 optical density units of deoxyguanosine 3′-phosphate, 0.6 optical density unit of thymidine, and 0.1_5 optical density unit of undegraded material were yielded. These results confirmed that the resulting tetranucleotide was d-GpGpGpT.

Isolation of By-products, d-GpGpG, d-GpGpGp, and d-GpGpT. The elutions of the peaks (120—155 m*l*, 155—185 m*l*, and 185—300 m*l*) shown in Fig. 2 were concentrated and treated with 80% acetic acid to cleave the blocking group; then they were placed in a DEAE-cellulose column in a way similar to that described above.

From the first portion, two major nucleotidic materials (elutions at 0.120—1.130M NH_4HCO_3 (39 optical density units) and at 0.135—0.165M NH_4HCO_3 (18 optical density units)) were obtained. From the second portion a single major nucleotidic material (elution at 0.130—0.155M NH_4HCO_3 (20 optical density units)), and form the third portion, another single nucleotidic material (elution at 0.125—0.135M NH_4HCO_3 (112 optical density units)) from three ultravioletabsorbing materials, were obtained. These materials were identified as d-GpGpG, d-GpGpGp, d-GpGpGp, and d-GpGpT, respectively by means of enzymatic hydrolyses and electrophoreses.

From the result that d-GpGpGp was found in both the first and the second portions in the Sephadex LH-20 column separation, it might be concluded that a partial cleaving of the blocking group takes place in the course of the synthesis. The greater quantity of d-GpGpT comparing with those of d-GpGpG and d-GpGpGp is believed to be due to one of two routes in the synthesis; one is the route skipping over the first coupling step, and the other is that skipping over the second coupling step.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1677—1682 (1971)

Substituted Benzopyranopyridine and Pyrimidine Ring Syntheses by the Ternary Condensation of Ethyl Cyanoacetate, Salicylaldehyde, and Certain Aldehydes in the Presence of Ammonium Acetate

Akio SAKURAI, Hiroshi MIDORIKAWA, and Yasuo HASHIMOTO*

The Institute of Physical and Chemical Research, Wako-shi, Saitama

**Tokyo Electrical Engineering College, Nishikicho, Chiyoda-ku, Tokyo*

(Received December 5, 1970)

Various 1-substituted benzopyranopyridines were readily prepared by the condensation of ethyl cyanoacetate and salicylaldehyde (or 3-methoxysalicylaldehyde) with aliphatic aldehydes (propion, *n*-butyl, *n*- and isovaleraldehyde) in the presence of ammonium acetate. On the other hand, condensation with aromatic aldehydes such as benzaldehyde and *o*-, *m*-, or *p*-substituted benzaldehydes gave 2-aryl-benzopyranopyrimidines.

In a previous paper,[1] the synthesis of 2- or 1,2-disubstituted benzopyranopyridines by the condensation of ethyl cyanoacetate, salicylaldehyde, and ketones in the presence of ammonium acetate has been reported.

1) A. Sakurai, H. Midorikawa, and Y. Hashimoto, This Bulletin, **43**, 2925 (1970).

The present paper will deal with the syntheses of 1-alkylbenzopyranopyridines (from aliphatic aldehyde) and 2-arylbenzopyranopyrimidines (from aromatic aldehyde) by the reaction of ethyl cyanoacetate and salicylaldehyde or 3-methoxysalicylaldehyde with various aldehydes in the presence of ammonium acetate.

The reaction of ethyl cyanoacetate and salicylaldehyde or 3-methoxysalicylaldehyde with aliphatic aldehydes was carried out by refluxing a mixture of the ester, salicylaldehyde, aliphatic aldehyde, and ammonium acetate (molar ratio 1:1:1:1-1.5) in ethanol. In this case, the condensation of the amino group of 3-amidinocoumarin[1] (I) with the carbonyl group of the aldehyde, cyclization between the methylene group adjacent to the aldehyde carbonyl and the 4-position of the coumarin ring, and subsequent dehydrogenation took place to form 1-alkyl-4-amino-5-oxo-[1]-benzopyrano[3,4-*c*]pyridines (II).

However, when isobutyraldehyde was employed as the aldehyde reactant, the corresponding product of the type II was not obtained. The NMR spectrum (in CF_3CO_2H) of IIa (from propionaldehyde) showed only a methyl singlet at 2.9 ppm, while IIb (from *n*-butyraldehyde) showed a methyl triplet at 1.55 ppm and a methylene quartet at 3.35 ppm in a higher field than the aromatic-ring region. These facts indicated that the methylene group adjacent to the aldehyde carbonyl was involved in this cyclization. On the other hand, the condensation with aromatic aldehydes (benzaldehyde or its derivatives) gave 2-aryl-4-amino-5-oxo-[1]benzopyrano[4,3-*d*]pyrimidines (IV). In this case, 1 mol each of ethyl cyanoacetate, salicylaldehyde, and benzaldehyde (or its derivatives) reacted with 2 mol of ammonia to give IV, with the elimination of 1 mol of ethanol and 2 mol each of water and hydrogen. The compound IVa was also obtained by the condensation of 3-amidinocoumarin or 3-cyanocoumarin with benzaldehyde in the presence of ammonium acetate

a) All spectra were taken in potassium bromide disks; cm^{-1}

(Scheme 2).

The infrared spectra of IV revealed slightly lower shifted absorption bands for a primary amino group at about 3400 and 3300 cm^{-1} and at about 1700 cm^{-1} for a coumarin-type carbonyl group. This shows the presence of intramolecular C=O···H_2N bonding, as is shown in the compounds obtained by condensation with ketones.[1] When heated with acetic anhydride in pyridine, type IV compounds were converted to their corresponding monoacetylated derivatives (V). On

a) Parts per million downfield from tetramethylsilane in CF_3CO_2H; s=singlet, d=doublet, t=triplet, q=quartet, sx=sextet, m=multiplet

the other hand, type II compounds gave diacetylated derivatives (III) under the same reaction conditions. In the infrared spectra of III, carbonyl stretching bands shifted to frequencies higher by from 20 to 30 cm^{-1} than those of the compounds II. However, the carbonyl bands of V appeared in the region nearly the same as or slightly lower than those of the compounds IV, and the imino stretching band always appeared at 3250 cm^{-1}. These data, therefore, can reasonably be explained by the presence of intramolecular hydrogen bonding in the compounds II and IV.

a) Parts per million downfield from tetramethylsilane in CF_3CO_2H; s=singlet, d=doublet, t=triplet, q=quartet, m=multiplet, br=broad

Experimental

All the melting points are uncorrected. The infrared spectra were determined by means of potassium bromide disks. The NMR spectra were determined in trifluoroacetic acid at 60 Mc, using tetramethylsilane as the internal standard. The chemical shifts are reported as parts per million downfield from TMS.

Reaction of Ethyl Cyanoacetate and Salicylaldehyde or 3-Methoxysalicylaldehyde with Aldehydes. A mixture of ethyl cyanoacetate (0.03 mol), salicylaldehyde or 3-methoxysalicylaldehyde (0.03 mol), aldehyde (0.03 mol), and ammonium acetate (0.04 mol) in ethanol (10 m*l*) was refluxed for 0.5—1.5 hr. A pale yellow crystalline matter precipitated out during the reaction. The experimental results and spectral data are summarized in Tables 1,3,5,6,8, and 10.

Reaction of 3-Amidinocoumarin (1) and Benzaldehyde. A mixture of 1 (2.82 g), benzaldehyde (1.59 g), and ammonium acetate (1.54 g) in ethanol (5 m*l*) was refluxed for 0.5 hr. A crystalline precipitate was formed during the reaction; this was collected, and washed with ethanol and then with water. Recrystallization from pyridine afforded 0.9 g of pale yellow crystals; mp 265—267°C. By their infrared spectra and the results of elemental analyses, this compound was identified with IVa.

Reaction of 3-Cyanocoumarin and Benzaldehyde. A mixture of 3-cyanocoumarin (2.55 g), benzaldehyde (1.59 g), and ammonium acetate (1.54 g) in pyridine (5 m*l*) was heated for 1 hr. The pale yellow crystals which precipitated were then recrystallized from pyridine to give 0.8 g of almost white crystals; mp 262—264°C. This compound was proved to be identical with IVa by a study of their infrared spectra.

Reaction of the II and IV Compounds and Acetic Anhydride. To a solution of II or IV (0.001 mol) dissolved in pyridine (3—5 m*l*), acetic anhydride (5—8 m*l*) was added, the mixture was then refluxed for 2—4 hr. After standing overnight at room temperature, the crystalline precipitate thus formed was washed with dilute methanol. The experimental results and spectral data are summarized in Tables 2,4,7,9, and 10.

The authors wish to express their thanks to Dr. Taro Hayashi and Dr. Tatsuo Takeshima for their kind advice. Thanks are also due to Dr. Haruo Homma and his staff for their microanalyses, to Mr. Jun Uzawa for his measurements of the NMR spectra, and to Mr. Hironori Ogawa for his measurements of the IR spectra.

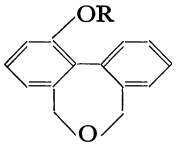
Nuclear Magnetic Resonance Study of the Effect of the Hydrogen Bond on the Internal Rotation of Biphenyls

Michinori Ōki, Kageyasu Akashi, Gaku Yamamoto, and Hiizu Iwamura
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo
(Received December 8, 1970)

Internal rotation about the pivot bond of several biphenyl derivatives has been studied by means of the nuclear magnetic resonance technique using non-identical chemical shifts of the two methyls in the isopropyl group which is located close to the center of dissymmetry. The results with the 2-methoxy and 2-hydroxy derivatives are compared. The solvent effect is marked in 2-hydroxy derivatives. These results, together with the substituent effect, indicate that the fact that the energy of activation for rotation about the pivot bond of the 2-hydroxy derivatives is a little higher than the corresponding methyl ether may be attributed to the stabilization of the ground state resulting from the presence of intramolecular O–H···π interaction. The infrared data agree with the above conclusion.

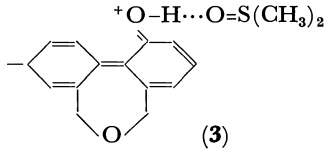
In recent years it has become very common to use the nuclear magnetic resonance technique in investigating the internal rotation. Originally, a biphenyl derivative had to be resolved into optical isomers in order to investigate the rotation about the pivot bond, because polarimetry was a sole method for the investigation. Nowadays, however, it is also possible to study the internal rotation of biphenyls by means of NMR,[1-5] and it has been confirmed that the process which is observed by polarimetry and that studied by NMR are the same.[5,6] These investigations have revealed that the solvent effect on the internal rotation in biphenyl is very small, if present at all.[4,5,7]

However, a paper[8] from this laboratory has shown that a distinct solvent effect was observed in the internal rotation of 1-hydroxy-5,7-dihydro[*c*,*e*]oxepin (**1**). This compound shows an energy of activation for the internal rotation in dimethyl sulfoxide smaller by *ca.* 1 kcal/mol than that in deuteriochloroform. This phenomenon is not observed with the corresponding methyl ether (**2**). Thus, the hydrogen bond must be playing an important role in decreasing the energy of activation for **1**.



(**1**): R=H
(**2**): R=CH_3

Two possibilities may be pointed out with regard to the decrease in energy of activation by the formation of the hydrogen bond. The first is the possibility that the transition state of the inversion of biphenyls is stabilized in dimethyl sulfoxide because of the decrease in the electronegativity of oxygen on formation of the hydrogen bond, with a concomittant increase in the electron density at the position 1 or with an increase in the contribution of the resonance structure (**3**). The second is the stabilization of the ground state due to the presence of the intramolecular O–H···π interaction, which may be very little in dimethyl sulfoxide because of the strong proton-accepting ability of the sulfoxide. The first possiblity will lower the transition state in dimethyl sulfoxide relative to that in deuteriochloroform, whereas the second possibility will lower the ground state in deuteriochloroform relative to that in dimethyl sulfoxide. In either case, the energy of activation will be lowered.



(**3**)

In the above discussion, the effect of the intermolecular hydrogen bond in **1** is disregarded, though it could be important at the concentration used for the NMR study. However, as will be seen later, the IR study indicates that the effect may be disregarded.

We wish here to report on the effect of the substituents on the internal rotation of biphenyls as studied by NMR, and to present a basis on which it can be concluded that the internal O–H···π interaction is an important factor in lowering the energy of activation for rotation about the pivot bond.

Syntheses

After several attempts at synthesizing some substituted derivatives of **1**, it was found that introducing a desired substituent at a desired position of **1** was very difficult. Therefore, we decided to use some isopropyl derivatives which have been shown[9] to give rise to magnetically non-equivalent methyl groups when the rotation about the pivot bond is slow on the NMR time scale.

The syntheses of many of the necessary methoxy

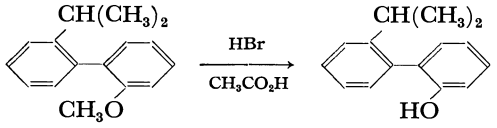
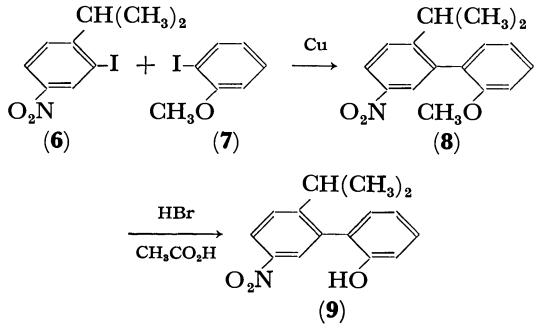
compounds have previously been reported.[9] In such cases, the methoxy compounds (**4**) were demethylated by refluxing in acetic acid with hydrogen bromide to give the corresponding hydroxybiphenyl derivatives (**5**):



(**4**) (**5**)

Treating 2-isopropyl-5-nitroiodobenzene (**6**) and 2-methoxyiodobenzene (**7**) under the Ullmann conditions yielded 2-isopropyl-5-nitro-2′-methoxybiphenyl (**8**), which was then demethylated as above to give **9**:



(**6**) (**7**) (**8**) (**9**)

Experimental

Measurements. The NMR spectra were measured on a spectrometer, either a Japan Electron Optics JNM C-60H and JNM C-60HL, a Hitachi R 20A, or a Varian Associates A-60 spectrometer. The solvents were dimethyl-d_6 sulfoxide or tetrachloroethane, and the concentration was *ca.* 0.3 mol/*l* or *ca.* 8% (w/w). Cyclooctane was used as the internal standard. The calibration of the coalescence temperature was determined by studying the chemical-shift difference between methylene and hydroxyl protons of ethylene glycol. This calibration was applied to the other range of temperature, and the error was estimated to be ±2°C.

In cases where the coupling constant is smaller than the chemical shift at the lower temperature, the quartets due to the magnetically non-equivalent methyls in isopropyl group coalesce when the temperature is raised, the chemical shift gradually decreases, and a broad single-peaked curve is obtained at the coalescence temperature (T_c). When the temperature is raised by 1°C from the T_c, two broad peaks are observable, indicating that the T_c is fairly dependable. On the other hand, in the cases where the coupling constant is larger than the chemical shift, the two peaks in the higher field and the two peaks in the lower field coalesce when the temperature is raised.

Various approximating methods have been presented to derive the kinetic data from the temperature-dependent NMR information. In this study, the following two equations were used to obtain the data:

$$\frac{1}{\tau} = \frac{\pi(\delta\nu_0)}{2(w-w_0)} \quad (1)$$

where τ is the average half-life time; $\delta\nu_0$, the difference in chemical shifts when the exchange is negligible; w, the half-band width at a given temperature, and w_0, the half-band width when the exchange is fast.

$$\frac{1}{\tau} = \frac{\pi(\delta\nu_0)}{\sqrt{2}} \quad (2)$$

Equation (2) is applicable at the coalescence temperature.

The effect of the population of the conformers with respect to the isopropyl group on the difference in chemical shift was calibrated by extrapolating the linear part of the $\delta\nu_0$ *vs.* temperature correlation at low temperatures.

The half-band width of cyclooctane, which was added as an internal standard, was used as w_0 by carefully adding a definite amount of cyclooctane to the solution.

The infrared spectra were obtained on a Perkin-Elmer 112 G single-beam grating spectrophotometer. Data obtained with *ca.* 1 mmol/*l* solution in carbon tetrachloride are given in Table 5. The spectra were also obtained with a tetrachloroethane solution, the concentration being *ca.* 0.3 mol/*l*, in order to obtain data which should be useful in discussing the NMR results.

Syntheses of the Materials. The Ullmann Reaction: When a mixture of 20 g (0.1 mol) of 2-methoxyiodobenzene, 15 g (0.05 mol) of 2-isopropyl-5-nitroiodobenzene, and 15 g of copper bronze was heated at 180°C, the reaction set in; the temperature was then raised to 260°C. After it had then been cooled, 20 more grams of copper bronze was added, and the mixture heated at *ca.* 200°C for 1 hr. The mixture was cooled and extracted with acetone in a Soxhlet apparatus. The extract was concentrated and chromatographed on alumina to give 1.5 g of 2-methoxy-2′-isopropyl-5′-nitrobiphenyl, mp 84—85°C. NMR (δ from TMS in CCl_4): 1.05 (3H, d J=7); 1.15 (3H, d J=7); 2.60 (1H, septet); 3.82 (3H, s); 6.9—8.4 (7H, m).

Found: C, 70.83; H, 6.32; N, 5.13%. Calcd for $C_{16}H_{17}NO_3$: C, 70.83; H, 6.32; N, 5.16%.

2-Methoxy-5-nitro-2′-isopropylbiphenyl, mp 107°C, was similarly prepared from 2-methoxy-5-nitroiodobenzene and 2-isopropyliodobenzene, the yield being 14%. NMR (δ from TMS in CCl_4): 1.05 (3H, d J=7); 1.10 (3H, d J=7); 2.83 (1H, septet); 3.72 (3H, s); 6.8—8.3 (7H, m).

Found: C, 70.87; H, 6.55; N, 4.99%. Calcd for $C_{16}H_{17}ON_3$: C, 70.83; H, 6.32; N, 5.16%.

Demethylation of the Methyl Ethers. To a solution of 1 g of the biphenyl derivative in 10—20 m*l* of acetic acid, 15—20 m*l* of 47% aqueous hydrogen bromide and *ca.* 5 m*l* of acetic anhydride were added, after which the mixture was heated for *ca.* 5 hr. The mixture was then poured onto ice water and extracted. The recrystallization of the acidic part gave the desired 2-hydroxy-2′-isopropylbiphenyl derivative. The data are given in Table 1.

Table 1. 2-Hydroxy-2′-isopropylbiphenyls

b) DMSO and TCE stand for dimethyl sulfoxide and tetrachloroethane, respectively.

avoided. This error may come from the facts that the signal of cyclooctane was chosen as the standard of the half-band width and that the chemical shifts of the methyl groups change according to the change in population with the temperature, in addition to the methods of approximation used in this study. However, it is possible to minimize the error if we limit the data of the half-band width to a fairly large value and limit the temperature to a small range. Thus, we decided to use a single temperature, the highest coalescence temperature among those of the compounds studied. Table 2 shows the coalescence temperatures and the pertinent data of the phenols; in Table 4 only the rates of the internal rotation of the methyl ethers in tetrachloroethane are given, because those in dimethyl sulfoxide are quite similar. The solvent effects on the rates of internal rotation and the free energies of activation for the hydroxy compounds are given in Table 3. The errors other than the systematic are estimated to be ±0.2 kcal/mol.

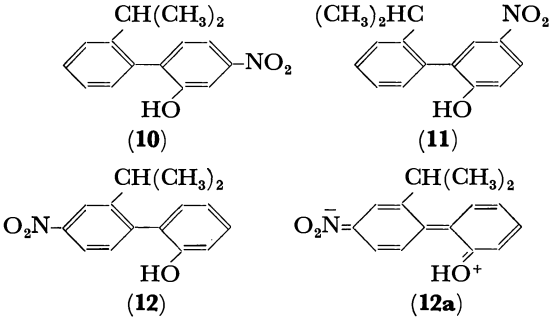
Discussion

Since we have obtained only the free energy of activation, it will be safer to compare some corresponding compounds rather than to discuss the absolute values. A comparison of the data obtained with the hydroxy compounds with those of the methoxy derivatives will be made. Since it was pointed out in a previous paper[9)] that two factors—electron density and through conjugation—must be considered in discussing the internal rotation of biphenyls about the pivot bond, it is not safe to compare the data of compounds which have different substituents or which have the same substituents at different positions.

The data in Tables 2 and 3 suggest that the energies of activation for rotation of the hydroxylic compounds are not much different in dimethyl sulfoxide. Indeed, the differences are within the range of error. If the intermolecular hydrogen bonding between the phenols and dimethyl sulfoxide played an important role in lowering the energy of activation, compound **12** should show a smaller value of the energy of activation than the other compounds because the resonance structure (**12a**) is favored on forming the hydrogen bond. The experimental data, however, show an increasing tendency, although small. Therefore, the lowering of the electronegativity of the oxygen in the hydroxyl group due to the formation of the hydrogen bond is negligibly small.



From the results shown in Tables 2—4, together with the fact that the $\Delta G^{\ddagger}$'s for rotation about the pivot bond of 2-methoxybiphenyl derivatives in dimethyl sulfoxide are not very different from those in chlorinated hydrocarbons (see reference 8 and the Results of this paper), it is clear that there are some compounds which give similar $\Delta G^{\ddagger}$ values irrespective of the nature of the substituent (hydroxy or methoxy), whereas some compounds show a fairly large difference in $\Delta G^{\ddagger}$'s and k's. The methoxy compounds belong to the first category, and, among the hydroxy compounds, those which possess a nitro group in the ring not having a hydroxyl group are classified in the first category, and the others in the second. These phenomena may best be understood when the effect of the O–H···π interaction is considered.

Since those compounds which have a nitro group at the ring having a hydroxyl group may be expected to be more acidic, the intramolecular interaction is fairly strong. On the other hand, the nitro group attached to the benzene ring which is to be the proton acceptor will decrease the basicity of the π-electron system. Thus, the O–H···π interaction will be stronger and the

ground state will be more stabilized with compounds **10** and **11** than with compounds **9** and **12**. The difference in the energy of activation between these two groups is *ca.* 1 kcal/mol; this is in good agreement with the data obtained by the infrared method with 4-nitro-2-hydroxybiphenyl and 2-hydroxy-4'-nitrobiphenyl.[10]

It is an interesting phenomenon that compound **5** shows a tendency similar to that of compounds **10** and **11**. We have no good explanation for this, but wish tentatively to attribute it to the steric effect of the isopropyl group. That is, because of the steric requirement of the isopropyl group, the biphenyl derivatives studied here will have two benzene rings almost perpendicular to each other, the conformation favoring the intramolecular O–H···π interaction. Thus it may be considered that, unless the π-system is unfavorable for accepting the proton, almost all the molecules will be of the intramolecularly interacting species, leveling the effect of the O–H···π interaction to the same order of magnitude as compounds **5**, **10**, and **11**.

Table 5. Infrared spectral data of 2-hydroxy-2'-isopropylbiphenyls

Substituent		ν_{OH}(cm^{-1})	A(mol$^{-1}\cdot l\cdot$cm^{-2})
none	i[a]	3553.7	1.0×10^4
	f[a]	—	—
4-NO_2	i	3541.8	1.35
	f	—	—
5-NO_2	i	3530.0	1.4
	f	—	—
4'-NO_2	i	3570.0	0.2
	f	3602.8	1.3
5'-NO_2	i	3571.1	0.3
	f	3602.8	1.3

a) i and f denote O–H···π interacting and free species, respectively.

Support for this postulate may be obtained from the data given in Table 5. As may be seen, even the compound **5** does not show any O–H stretching absorption due to the free hydroxyl group. This indicates that introducing the isopropyl group at the 2'-position favors the intramolecular O–H···π interaction compared with 2-hydroxybiphenyl, which has shown absorption due to the free hydroxyl group.[11] Indeed, even 4-nitro-2-hydroxybiphenyl showed some free hydroxyl groups, the presence of which made the calculation of the interaction energy possible.[10] The shift (*ca.* 10 cm^{-1}) of the absorption band to a lower frequency than in the corresponding compounds lacking the isopropyl group also suggests that the O–H···π interaction is favored in the isopropyl compounds.

It may be argued that, at the concentration suitable for the NMR study, the inter- rather than the intramolecular hydrogen bond is important. Therefore, in order to justify the above discussion, infrared spectral study at that concentration is needed. The infrared absorptions in the 3μ region of compounds **5**, **9**, **11**, and **12** were thus measured at a 0.3 mol/l concentration in tetrachloroethane. Although there remains some ambiguity because of the solvent absorption, the results indicate that these compounds have no absorption below 3500 cm^{-1}; this suggests that they exist as, at least mainly, monomers. The compounds **5** and **11** have only one absorption, at *ca.* 3530 and *ca.* 3540 cm^{-1} respectively, which may be attributed to the intramolecularly interacting (O–H···π) molecular species.[12]

On the other hand, compounds **9** and **12** have two absorptions at the same wave numbers (3580 and 3560 cm^{-1}), the intensity being larger with the latter band. The band at the higher frequency may be attributed to the free form because it is at too high a frequency to be assigned to the dimer.[13] The band at the lower frequency may be assigned to the O–H···π interacting species, because the 20 cm^{-1} shift to a lower frequency is quite normal for the interaction. Thus the infrared spectral data support the above conclusion drawn from the NMR results.

There are many points to be clarified with regard to the substituent effect on the energy of activation for the internal rotation about the pivot bond of biphenyls. For example, it is not at all clear why the nitro group at the 5- or 5'-position lowers the energy of activation. We have intentionally omitted some discussions familiar to stereochemists, such as those of the buttressing effect and the difference in the sizes of hydroxyl and methoxyl groups, since the data presented here can not be discussed in detail. However, we believe that, as a first approximation, the intramolecular O–H···π interaction is an important factor in governing the energy of activation for the internal rotation of 2-hydroxybiohenyl derivatives.

11) M. Ōki and H. Iwamura, *ibid.*, **34**, 1395 (1961).

12) The O–H stretching absorption of the O–H···π interacting species at a 3×10^{-3} mol/l concentration in carbon tetrachloride is located close to 3550 cm^{-1}. See Table 5.

13) The absorption due to the dimer of hydroxy compounds is considered to be at *ca.* 3490 cm^{-1}.

Reactions of *p*-Benzoquinone Derivatives with Ethylenediamine

Teruzo ASAHARA, Manabu SENŌ, and Takuma TESHIROGI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 12, 1970)

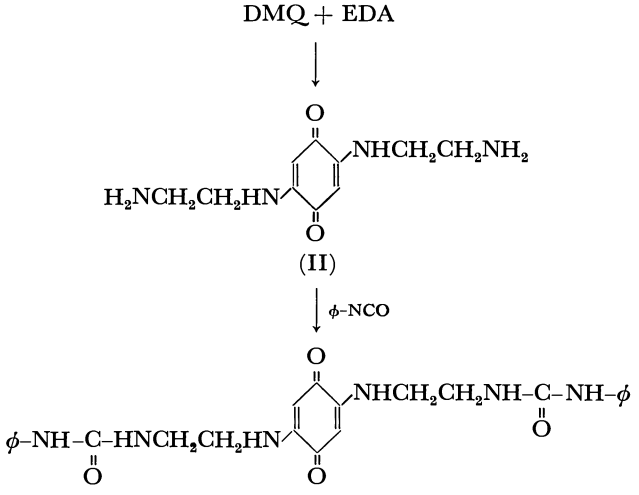
From the reaction results of *p*-benzoquinone derivatives with various amino compounds, it becomes clear that chloranil reacts with ethylenediamine to afford an unexpected product. The spectroscopic analyses of the product show that this is an addition compound with some contribution of charge-transfer structures. Bromanil gives a similar product upon reaction with ethylenediamine.

It is well known that *p*-benzoquinones react with amine derivatives. For example, *p*-benzoquinone (BQ) and 2,5-dimethoxy-*p*-benzoquinone (DMQ) react with ethanolamine (EtA) to afford 2,5-bis(2-hydroxyethylamino)-*p*-benzoquinone, and chloranil (CA) reacts with EtA to give 2,5-bis(2-hydroxyethylamino)-3,6-dichloro-*p*-benzoquinone.

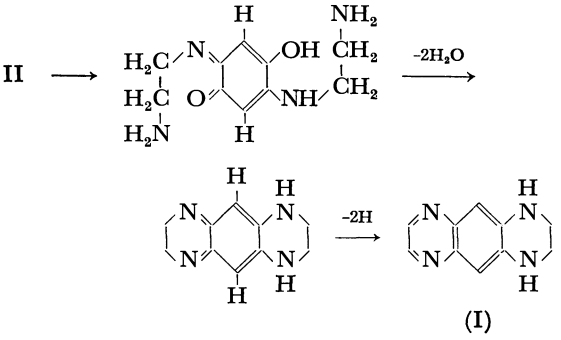
Harley-Mason and Laird[1] reported the successful formation of 1,2,3,4-tetrahydro-1,4,5,8-tetraazaanthracene (I) through the reaction of 2,5-dihydroxy-*p*-benzoquinone (DHQ) with ethylenediamine (EDA) by passing air into the aqueous reaction mixture. During the investigation to extend these synthetic processes to other amine derivatives, we have found that chloranil and bromanil do not afford products with the expected structures by the reaction with EDA. The present report will deal with these reactions.

Results and Discussion

It was found that 2,5-bis(2-aminoethylamino)-*p*-benzoquinone (II) was obtained when a dispersion of DMQ and EDA in ethanol was kept overnight at room temperature. This indicates that EDA reacts with DMQ in the same way as EtA does. As II is unstable at elevated temperature, it was identified as the adduct with phenyl isocyanate.



A yellow product was obtained by heating II in water for several hours. This compound was identified as the tetraazaanthracene derivative, I, which was also prepared by Harley-Mason through another route,[1] by IR and elementary analysis and by a study of its electronic spectrum. The following reaction scheme may be supposed:



That is, II is tautomerized to an *ortho*-quinone derivative, followed by dehydration to a ring-closed product. This is unstable and is oxidized by oxygen in air to I.

Next, the reaction of CA with amines was investigated. CA reacts easily with monoacetylethylenediamine (AcEDA) to afford 2,5-bis(2-acetoaminoethylamino)-3,6-dichloro-*p*-benzoquinone. This product is hydrolyzed easily to chloranic acid in concentrated hydrochloric acid; therefore, the structure could be determined.

CA was dissolved homogeneously in hot benzene, and into this solution one or two equivalents of EDA in benzene were added, drop by drop. A green product(IIIa) was obtained by adding one molar equivalent of EDA, and a yellow product(IIIb) was obtained by adding two molar equivalents of EDA. These reactions were traced by means of the electronic spectra of the reaction mixtures. The CA solutions in acetone with a definite concentration were mixed with the EDA solutions in acetone in various concentrations; after the mixtures had stood for half an hour, their electronic spectra were recorded at around 380 mμ. The details of the experimental conditions and the results are listed in Fig. 1. CA has a peak at 323 mμ, and only the tail is shown in Fig. 1(No. 1). When EDA is added, a peak appears at 373 mμ; its intensity becomes greater with an increase in the concentration of EDA and attains a maximum with a slightly bathochromic effect, (5 mμ) at a molar ratio EDA/CA of unity (No. 4). By a further increase in the EDA concentration, this peak decreases in intensity and shifts to a lower wavelength, but the peak increases again in intensity at a molar ratio EDA/CA of two (No. 5).

The spectroscopic properties of the two products, IIIa and IIIb, were examined. The infrared spectra of IIIa and IIIb are similar to one another. The

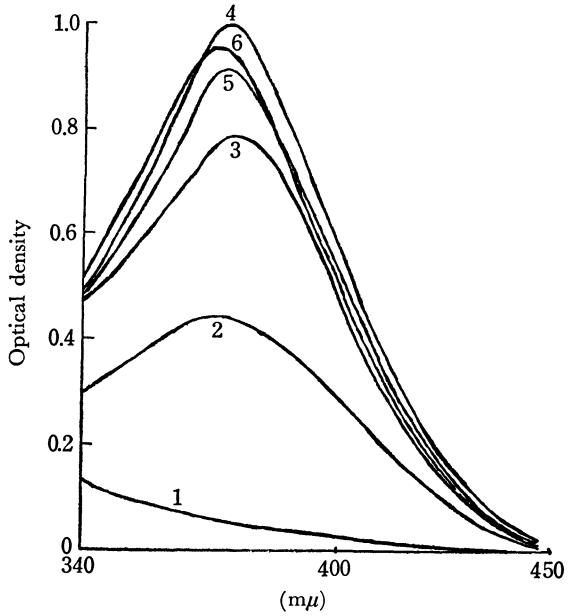

Fig. 1. Electronic spectra of the reaction of CA with EDA.

Run No.	CA(mol/l) $\times 10^4$	EDA(mol/l) $\times 10^4$
1	1.8	0
2	1.8	0.6
3	1.8	1.2
4	1.8	1.8
5	1.8	3.6
6	1.8	4.2

peaks assigned to the stretching vibrations of the $-NH_2$ and $-CH_2-$ groups and the deformation vibration of the $-CH_2-$ groups are found at 3300, 2900, and 1420 cm^{-1} respectively, but no peak assigned to >C=O is clearly found.

The proton NMR spectra of EDA, IIIa, and IIIb were obtained at 60 MHz in dimethyl sulfoxide-d_6, with reference to tetramethylsilane as the internal standard. The peaks of protons of the $-CH_2-$ and $-NH_2$ groups of EDA are found at 2.50 and 1.30 ppm; those of IIIa, at 3.27 and 7.68 ppm, and of IIIb at 2.82 and 6.13 ppm, respectively. The peaks of $-NH_2$ were determined by adding deuterium oxide. The intensity ratio of the $-NH_2$ to the $-CH_2-$ group, however, is not equal in the spectra of IIIa and IIIb, probably because of the presence of a small amount of water in the solvent.

In the mass spectrum of IIIa, the *m/e* value of the parent ion is 246; this is equal to the value referred to CA, and the spectrum pattern is similar to that of CA. In the mass spectrum of IIIb, the parent ion is *m/e* 248 and the spectrum pattern is very similar to that of tetrachlorohydroquinone (TCHQ).

Moreover, the following result was obtained. IIIb reacts with acetic anhydride in the presence of pyridine as a catalyst to afford tetrachlorohydroquinone diacetate. It is clear from IR and elementary analysis that this product is the same as the compound obtained by the acetylation of TCHQ with acetyl chloride in pyridine.

Similar behavior was observed for bromanil (BA). That is, while BA reacts with AcEDA to give 2,5-bis(2-acetoaminoethylamino)-3,6-dibromo-*p*-benzoquinone, it does not react with EDA to afford the expected product; instead, IVb is obtained from the mixture. This product reacts with acetic anhydride to afford tetrabromohydroquinone diacetate, as in the case of CA.

These investigations lead to the following interesting conclusion. While CA and BA react easily with aliphatic and aromatic amines, they react with EDA to afford unexpected addition products. The structures of these addition compounds, IIIb and IVb, could not be definitely determined from these results, but they might be similar to those of the reaction intermediates in reactions of CA and aromatic amines examined by Nagakura *et al.*[2] The reaction properties of CA described above are in accord with the result that the reaction of CA and *o*-phenylenediamine does not give a well-defined product, unlike the reactions with *m*- and *p*-phenylenediamine.

Experimental

2,5-Bis(2-aminoethylamino)-p-*benzoquinone (II).* Four grams of DMQ and 16 g of EDA were dispersed in 200 m*l* of ethanol, and the mixture was then left standing overnight. By filtration, a red-violet solid was obtained as the product (II); yield, 6 g. The product (0.3 g) was dissolved in 50 m*l* of DMF, then after which 1 m*l* of phenyl isocyanate was added. The reaction mixture was heated at 100°C for one hour, and then cooled and poured into water. The dispersed solid was collected, dried, and recrystallized from acetic acid; mp 254°C.

Found: C, 62.05; H, 5.77; N, 18.07%. Calcd for $C_{24}H_{26}N_4O_6$: C, 62.33; H, 5.67; N, 18.17%.

1,2,3,4-Tetrahydro-1,4,5,8-tetraazaanthracene (I). One gram of II was dispersed in 300 m*l* of water, and the mixture was refluxed for ten hours. Water was removed under reduced pressure, and the yellow residue was recrystallized from nitrobenzene to afford yellow needles.

Found: C, 64.46; H, 5.29; N, 30.04%. Calcd for $C_{10}H_{10}N_4$: C, 64.50; H, 5.41; N, 30.09%.

2,5-Bis(2-acetoaminoethylamino)-3,6-dichloro-p-*benzoquinone.* A mixture of 10 g of CA and 20 g of AcEDA in 200 m*l* of ethanol was refluxed for five hours. After cooling, the dispersed solid was collected by filtration and dried; crude yield, 15 g (98%). It was recrystallized from a mixture of pyridine and water. mp 246°C.

Found: C, 44.77; H, 4.70; N, 14.88%. Calcd for $C_{14}H_{18}N_4Cl_2O_4$: C, 44.56; H, 4.77; N, 14.85%.

The Reaction Product from CA and One Mole Eqivalent of EDA (IIIa). Five grams of CA were dissolved in 100 m*l* of hot benzene, and into the resulting solution 2.44 g of EDA in 50 m*l* of benzene were added, drop by drop. Green solids separated out immediately. The hot mixture was filtered to collect a solid product, which was then dried under reduced pressure; yield, 6.5 g.

Found: C, 20.99; H, 2.19; N, 8.00; Cl, 40.48%.

The Reaction Product from CA and Two Mole Equivalents of EDA (IIIb). Five grams of CA and 4.88 g of EDA were mixed in a way similar to that used in the case of IIIa; yield, 9.2 g.

Found: C, 33.39; H, 3.43; N, 15.00; Cl, 36.00%. Calcd for $C_{10}H_{16}N_4Cl_4O_2$: C, 32.81; H, 4.41; N, 15.31; Cl, 38.74%.

2) T. Nogami, K. Yoshihara, H. Hosoya, and S. Nagakura, *J. Phys. Chem.*, **73**, 2670 (1969).

The Reaction Product from BA and Two Mole Equivalents of EDA (IVb). Into 8.6 g of BA in 120 m*l* of hot benzene, 4.88 g of EDA in 50 m*l* of benzene were added; yield, 6.5 g.

Found: C, 22.55; H, 2.37; N, 8.11; Br, 56.84%. Calcd for $C_{10}H_{16}N_4Br_4O_2$: C, 22.02; H, 2.97; N, 10.30; Br, 58.77%.

Tetrachlorohydroquinone Diacetate. One gram of IIIb and a few drops of pyridine were added to 10 m*l* of acetic anhydride, and the mixture was heated at 40°C for three hours. The reaction mixture was poured into water, and the precipitates were collected by filtration and recrystallized from a mixture of dioxane and water; mp, 247°C (lit. 252°C).

Found: C, 36.30; H, 1.53; Cl, 42.52%. Calcd for $C_{10}H_6Cl_4O_4$: C, 36.14; H, 1.81; Cl, 42.77%.

Tetrabromohydroquinone Diacetate. This was prepared from IVb and acetic anhydride and was recrystallized from acetic acid; mp 284°C (lit. 283°C).

Found: C, 23.88; H, 0.89; Br, 61.88%. Calcd for $C_{10}H_6Br_4O_4$: C, 23.56; H, 1.19; Br, 62.69%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1689—1691 (1971)

A Synthesis of Thyrotropin-Releasing Factor

Ken INOUYE, Keiko NAMBA, and Hideo OTSUKA

Biochemistry Division, Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received December 25, 1970)

A procedure is given for the synthesis of thyrotropin-releasing factor (TRF), a tripeptide L-pyrogultamyl-L-histidyl-L-proline amide. Benzyloxycarbonyl(Z)-glutaminyl-histidyl-proline amide (III) is obtained as an intermediate by the coupling of Z-glutamine *p*-nitrophenyl ester with histidyl-proline amide which is derived from the crystalline Z-dipeptide amide. Deprotection of III and the subsequent cyclization produce TRF in a moderate yield. Compound III and the corresponding N^{α}-acetyl derivative have little or no TRF activity.

Recently the structure of thyrotropin-releasing factor (TRF, or thyrotropin-releasing hormone, TRH), isolated from porcine[1] and ovine hypothalami,[2] has been elucidated to be a tripeptide L-pyroglutamyl-L-histidyl-L-proline amide. Both a synthetic preparation of the tripeptide amide and natural TRF (porcine) have been shown to be active in man.[3] This important finding as well as the fact that porcine and ovine hormones are chemically identical suggests that TRF is not species-specific among a wide variety of mammals. Because of its very minute occurrence in nature, it seems difficult to isolate TRF from natural sources in quantities sufficient for biochemical investigations and for clinical use. A chemical synthesis of this tripeptide amide will, therefore, become of extreme importance to meet such requirements. Some syntheses have appeared already.[4] We also wish to report a simple procedure for synthesizing the hormone. The present synthesis consists of a step-by-step elongation from C-terminal of the peptide chain, using a benzyloxycarbonyl group for N^{α}-protection, to obtain glutaminyl-histidyl-proline amide which undergoes facile transformation into the corresponding pyroglutamyl peptide (TRF). The procedure is outlined in Fig. 1.[5]

Benzyloxycarbonyl-proline amide, derived from the corresponding acid by a mixed anhydride method, was converted into the crystalline free base of proline amide (I) by catalytic hydrogenolysis. Coupling of I with benzyloxycarbonyl-histidine azide[6] yielded a crystalline dipeptide, benzyloxycarbonyl-histidyl-proline amide (II), in 85 per cent yield. Compound II was treated with hydrogen bromide in acetic acid, followed by coupling with benzyloxycarbonyl-glutamine *p*-nitrophenyl ester[7] to give benzyloxycarbonyl-glutaminyl-histidyl-proline amide (III). A crude preparation of compound III was partially purified by chromatography on a silica gel column with methanol-chloroform (1:3) as solvent. Further purification was performed on a column of carboxymethyl(CM) cellulose using an ammonium acetate buffer with a linear concentration gradient. The effluent solution was monitored at 245 mμ in order to detect the peptide emerging from the column. The pure preparation of III thus obtained was submitted to deprotection with hydrogen bromide in acetic acid. The resulting hydrobromide of glutaminyl tripeptide (IV) was converted into the acetate by passing through a column of an anion-exchange resin (acetate form). The final step leading to the formation of the desired

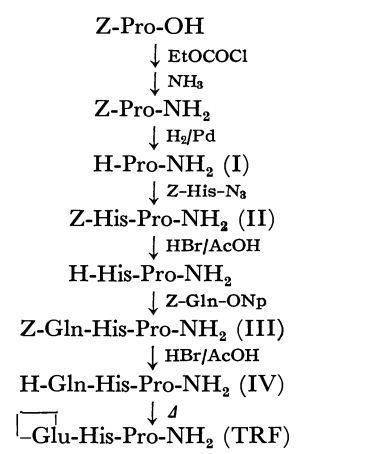

Fig. 1. Synthesis of pyroglutamyl-histidyl-proline amide (TRF).[5]

pyroglutamyl peptide (TRF) is a brief heat treatment of IV (acetate) in acetic acid. The reaction was followed by thin-layer chromatography (silica gel); IV and TRF have R_f values of 0.05 and 0.24, respectively, in methanol-chloroform (1:1) as solvent. Purification of crude TRF was easily achieved by chromatography on a CM cellulose column using an ammonium acetate buffer. The TRF preparation thus obtained was found to be homogeneous to Pauly reagent in thin-layer chromatography (E. Merck Cellulose F, in *n*-butanol:acetic acid:pyridine:water=30:6:20:24, BAPW) and its $[\alpha]_D$ was identical with a literature value[4a] within the error of measurement. The elemental and the amino acid analyses were also in good accordance with the theoretical values.

TABLE 1. THYROTROPIN-RELEASING ACTIVITY OF SYNTHETIC TRF AND RELATED COMPOUNDS[10]

Method	Compound[a] and dose	Number of animals	TRF activity (%increase in blood radioactivity)
A[8]	Saline	4	111.3±24.0
	TSH standard 0.2 mU	6	131.7±14.7
	TSH standard 0.4 mU	6	144.8±17.4
	Synthetic TRF 2 ng	5	153.0± 9.8
	III 2 ng	7	95.0± 5.3
	V 2 ng	7	89.6± 5.4

	Synthetic TRF 20 ng[b]	7	328.4±27.7

a) TSH=Thyrotropin, III=Z-Gln-His-Pro-NH_2, V=Ac-Gln-His-Pro-NH_2
b) Dose per 100 g body weight

The synthetic TRF was then subjected to biological assays. An in vivo thyrotropin-releasing activity in mice was assayed by the method of Schally *et al.*,[8] and the effect of elevating the blood levels of TSH in rats was estimated by the McKenzie method.[9] Some results are presented in Table 1, in which the data on compound III and acetyl-glutaminyl-histidyl-proline amide (V), derived from IV by acetylation in aqueous pyridine, are also shown.[10] A level as low as 2 ng of the present TRF preparation can release thyrotropin (TSH) in mice, whereas both III and V are devoid of activity at least at the same level. These data as well as those of the chemical characterization are likely to provide evidence for the identity of our synthetic TRF with the natural hormone.

Experimental

All melting points were uncorrected.

Benzyloxycarbonyl-proline Amide. A solution of benzyloxycarbonyl-proline (24.9 g, 0.1 mol) and triethylamine (15.3 m*l*, 0.11 mol) in anhydrous tetrahydrofuran (250 m*l*) was chilled in an ice-salt bath (below −10°C) and to this was added dropwise ethyl chloroformate (10.5 m*l*, 0.11 mol). The mixture was stirred for 10 min, and then concentrated aqueous ammonia (28%, 19.2 m*l*) was introduced. After the mixture had been stirred at room temperature for 30 min, the solvent was removed by evaporation *in vacuo*. To the residue were added ethyl acetate (30 m*l*) and water (30 m*l*), and the mixture was shaken vigorously. The organic phase was further washed with N hydrochloric acid, 5% sodium bicarbonate and water, dried over sodium sulfate and evaporated *in vacuo* to give an oily residue which crystallized from ethyl acetate-petroleum ether; yield 20.1 g (81%), mp 90—91° C, $[\alpha]_D^{27}$ −35.0±0.4° (*c* 2.06, ethanol). Lit,[11] mp 94°C, $[\alpha]_D^{23}$ −33.8° (*c* 2, ethanol).

Found: C, 63.17; H, 6.55; N, 11.53%. Calcd for $C_{13}H_{16}N_2O_5$: C, 62.89; H, 6.50; N, 11.28%.

Benzyloxycarbonyl-histidyl-proline Amide (II). Benzyloxycarbonyl-proline amide (2.2 g, 9 mmol) was hydrogenolyzed over palladium in methanol for 1.5 hr. Removal of the solvent yielded *proline amide (I)* as a sirupy residue which crystallized upon addition of ether; wt. 1.24 g, mp 101—102°C, $[\alpha]_D^{23}$ −86.5±1.2° (*c* 1.08, methanol).

An ethyl acetate solution of benzyloxycarbonyl-histidine azide (derived from 4.1 g (13.5 mmol) of the hydrazide in the usual manner)[6] was added to compound I (1.2 g) obtained above and the mixture was kept at 4°C overnight. Removal of the solvent by evaporation *in vacuo* yielded a sirupy residue which was crystallized from methanol-water. After recrystallization from water the product amounted to 2.95 g (85%); mp 102—104 °C, $[\alpha]_D^{24}$ −40.7±0.7° (*c* 1.13, methanol).

Found: C, 58.56; H, 6.10; N, 17.48%. Calcd for $C_{19}H_{23}N_5O_4 \cdot 1/4H_2O$: C, 58.52; H, 6.07; N, 17.96%.

Benzyloxycarbonyl-glutaminyl-histidyl-proline Amide (III). Compound II (1.54 g, 4 mmol) was dissolved in saturated hydrogen bromide in acetic acid (15 m*l*) and the mixture was allowed to stand at room temperature for 40 min, followed by the addition of ether to yield fine precipitates. The precipitates (1.98 g) were dissolved in dimethylformamide (25 m*l*) and to this was added triethylamine (1.68 m*l*, 12 mmol). The hydrobromide of triethylamine which separated was filtered off and benzyloxycarbonyl-glutamine *p*-nitrophenyl ester (1.61 g, 4 mmol)[7] was added to the filtrate. The

mixture was kept at 4°C for 65 hr and evaporated *in vacuo*. The sirupy residue was triturated with ethyl acetate and the mixture was filtered off to collect precipetates which were washed with ethyl acetate and ether and dried *in vacuo* (2.65 g) The precipitates were dissolved in methanol-chloroform (1:3 by vol.) and the solution was submitted to a column of silica gel (E. Merck, 0.05—0.2 mm, 90g) which had been prepared with methanol-chloroform (1:3). The same solvent system was used for elution. Fractions which gave a single component (R_f=0.35, sulfuric acid charring) on thin-layer chromatography (Silica gel G, methanol-chloroform (1:2) as solvent) were pooled and evaporated *in vacuo* to afford a residue which solidified upon treatment with ethyl acetate (1.98 g). The partially purified material (0.80 g) was chromatographed for further purification on a column (1.7×53 cm) of carboxymethyl cellulose (Serva, 0.56 meq/g) using an ammonium acetate buffer (pH 5.0, 2000 m*l*) with a linear concentration gradient of 0.005—0.1 M. Ten-m*l* fractions were collected and their absorptivity at 245 mμ was recorded. Fractions (tubes 41—52) corresponding to a major peak were pooled, evaporated and lyophilized; wt. 0.49 g (53%), $[\alpha]_D^{25}$ −60.4 ±1.1° (*c* 0.88, water), −46.1±0.9° (*c* 0.98, methanol).

Found: C, 52.70; H, 6.00; N, 17.00%. Calcd for $C_{24}H_{31}N_7O_6 \cdot 1/2CH_3COOH \cdot 3/2H_2O$: C, 52.62; H, 6.36; N, 17.18%.

Pyroglutamyl-histidyl-proline Amide (Thyrotropin-releasing Factor, TRF). To compound III (0.20 g) was added saturated hydrogen bromide in acetic acid (*ca.* 5 m*l*) and the mixture was kept at room temperature for 60 min, followed by precipitation by the addition of ether. The resulting precipitates were filtered off, washed with ether and dried *in vacuo* to give *glulaminyl-hislidyl-proline amide hydrobromide (IV)*; wt. 0.26 g, $[\alpha]_D^{25}$ −13.8±0.5° (*c* 0.98, methanol).

Found: C, 30.91; H, 5.03; N, 15.64%. Calcd for $C_{16}H_{25}N_7O_4 \cdot 3/2HBr \cdot 2H_2O$: C, 31.11; H, 5.14; N, 15.87%.

The hydrobromide (IV) obtained above (0.25 g) was dissolved in water and the solution was passed through a column (1.2×10 cm) of Amberlite CG—400 (acetate form); the column was washed with portions of water. The aqueous solutions were combined and evaporated *in vacuo* at a bath temperature of 50°C. The residue was dissolved in glacial acetic acid (20 m*l*) and the solution was heated at 95°C for 15 min. After removal of the solvent by evaporation *in vacuo* the residue was subjected for purification to chromatography on a column (1.7×30 cm) of carboxymethyl cellulose (Serva, 0.56 meq/g) using an ammonium acetate buffer (pH 5.0, 1440 m*l*) with a linear concentration gradient of 0.005—0.1 M. Fractions (7.5 m*l*/tube) were collected and their absorptions at 245 mμ were recorded. There were two peaks, I (tubes 8—10) and II (31—42), on the chromatogram and the tubes corresponding to peak II were pooled and evaporated *in vacuo*. The resulting glassy residue was dried *in vacuo* and then precipitated from acetic acid-ether to yield pure TRF as hygroscopic colorless powder; wt. 0.11 g, $[\alpha]_D^{25}$ −43.4±0.8° (*c* 1.01, 95% acetic acid). Lit,[4a] $[\alpha]_D^{25}$ −44.8° (*c* 1, 95% acetic acid). Homogeneous on thin-layer chromatography (Cellulose F, E. Merck) to Plauy reagent; R_f=0.47 (BAPW). Amino acid ratios in acid hydrolysate:[12] His 1.00, Glu 0.90, Pro 1.14, NH_3 1.01.

Found: C, 50.63; H, 6.56; N, 20.78%. Calcd for $C_{16}H_{22}N_6O_4 \cdot 1/2CH_3COOH \cdot 1/2H_2O$: C, 50.86; H, 6.28; N, 20.94%.

Acetyl-glutaminyl-histidyl-proline Amide. Cmopund IV (0.156 g) was dissolved in 90% pyridine (4 m*l*) at 0°C, and to this solution was added acetic anhydride (0.1 m*l*) and the mixture was kept at 0°C for 90 min. After addition of water (2 *ml*) the mixture was evaporated *in vacuo*. The residue was dissolved in water and the solution was passed through a column (1.2×9 cm) of Amberlite CG-400 (acetate); the column was washed with portions of water. The aqueous solutions were combined and evaporated *in vacuo* to give a residue which was reprecipitated from acetic acid-ether; yield 0.098 g (80%), $[\alpha]_D^{25}$ −50.5±0.8° (*c* 1.11, methanol). Thin-layer chromatography (Cellulose F, F. Merck); R_f=0.45 (BAPW).

Found: C, 46.55; H, 6.40; N, 19.65%. Calcd for $C_{18}H_{27}N_7O_5 \cdot 1/2CH_3COOH \cdot 2H_2O$: C, 46.81; H, 6.82; N, 20.11%.

Grateful acknowledgement is made to Dr. Masahiro Sakoda, Kobe University School of Medicine, for performing biological assays. We also thank Dr. Mitsuo Ebata and his staff for amino acid analysis, Dr. Kaoru Kuriyama and his staff for optical rotation measurements, and members of our microanalysis laboratory for elemental microanalysis.

Aroyloxy-Radikal. Die Aktivierungsenergien bei der Kohlendioxyd-Abspaltung und bei der Anlagerung an Benzol-Doppelbindung

Tadashi SUEHIRO und Mototoshi ISHIDA
Chemisches Institut der Gakushuin Universität, Mejiro, Tokio

(Eingegangen am 11. Januar, 1971)

Bei der Einwirkung von Trityl-Radikal auf Benzoylperoxyd-carbonyl-^{14}C, *p*-Chlorbenzoylperoxyd-carbonyl-^{14}C bzw. auf *p*-Methoxybenzoylperoxyd-carbonyl-^{14}C in Benzol bei 25°C und 45°C wurde die Ausbeute an Kohlendioxyd, Tetraphenylmethan und an Benzoesäure-trityl-ester nach der Isotopen-Verdünnungsmethode bestimmt. Aus der Abhängigkeit der Ausbeute von Temperatur wurden die relativen Aktivierungsenergien der Aroyloxy-Radikale bei der Kohlendioxyd-Abspaltung ($E_{1,r}$) und bei der Anlagerung an die Benzol-Doppelbindung ($E_{4,r}$) im Vergleich zu der bei der Kombination mit Trityl-Radikal (E_5) errechnet. Die relativen Aktivierungsenergien waren wie folgt: Bei Benzoyloxy-Radikal $E_{1,r}=12.9$ Kcal/Mol und $E_{4,r}=6.3$ Kcal/Mol; bei *p*-Chlorbenzoyloxy-Radikal $E_{1,r}=13.5$ Kcal/Mol und $E_{4,r}=6.2$ Kcal/Mol; bei *p*-Methoxybenzoyloxy-Radikal $E_{1,r}=14.7$ Kcal/Mol und $E_{4,r}=6.1$ Kcal/Mol.

Die Reaktivität des freien Radikals mit der Aktivierungsenergie der betreffenden Reaktionen zu bewerten ist von Bedeutung. Viele Forscher[1-4] nahmen Interesse an der Zersetzlichkeit des Aroyloxy-Radikals, darunter haben Bevington und seine Mitarbeiter[1] mit Hilfe der Vinyl-Polymerisationstechnik die Aktivierungsenergie vom Benzoyloxy-Radikal bei der Kohlendioxyd-Abspaltung (Reaktion (1)) auf 14 Kcal/Mol[1c] geschätzt. Die Unsicherheit ihrer Bestimmung besteht darin, dass sie statt der Aktivierungsenergie des Benzoyloxy-Radikals bei der Anlagerung an die Äthylen-Doppelbindung des Styrols (Reaktion (2)) die der Kettenwachstumsreaktion[5] von 7 Kcal/Mol, d. h. die der Anlagerung des Polymer Radikals an Olefin-Doppelbindung angenommen haben. Die Ergebnisse der anderen Forscher enthalten eine Aktivierungsenergie der entsprechenden Referrenz-Reaktion. Wir haben auf anderem Wege die Messungen der Aktivierungsenergie von Aroyloxy-Radikal bei der Kohlendioxyd-Abspaltung (Reaktion (1)) und bei der Anlagerung an Benzol (Reaktion (4)) vorgenommen, darüber wir hier berichten wollen.

$$ArCOO\cdot \longrightarrow Ar\cdot + CO_2 \quad (1)$$

$$ArCOO\cdot + PhCH{=}CH_2 \longrightarrow PhCHCH_2OCOAr \quad (2)$$

Experimentelle Methode und Ergebnisse

Wir haben uns mit der Einwirkung von Trityl-Radikal auf Benzoylperoxyd in aromatischen Lösungsmitteln beschäftigt,[6] dabei haben wir festgestellt, dass das Aroyloxy-Radikal, das aus Peroxyd durch Einwirkung von Trityl-Radikal erzeugt wird (Reaktion (3)), konkurrierend sich an den aromatischen Ring anlagert (Reaktion (4)) und sich mit Trityl-Radikal vereinigt (Reaktion (5)). Nebenbei läuft Reaktion (1) in geringerem Masse ab. Die Reaktion (4) führt weiter zur Bildung von Tetraphenylmethan (Reaktion (6)). Man kann daraus ersehen, dass die Reaktionen (1), (4), (5) und (6) zusammen die Reaktion von Benzoyloxy-Radikal in Aromaten in Gegenwart des Radikal-Abfängers Trityl-Radikals darstellen. Dass die Reaktion (4) die geschwindigkeits-bestimmende Stufe der Tetraphenylmethan-Bildung ist, ist ebenfalls bewiesen worden.[6c] Wenn man infolgedessen die Mengenverhältnisse von Kohlendioxyd und Tetraphenylmethan bezüglich auf Benzoesäure-trityl-ester aus der Reaktion (5) in ihrer Temperatur-Abhängigkeit bestimmt, so erhält man die Aktivierungsenergien der Reaktionen (1) und (4) relativ zu (5).

$$(ArCOO)_2 + Ph_3C\cdot \longrightarrow ArCOOCPh_3 + ArCOO\cdot \quad (3)$$

$$ArCOO\cdot + PhH \longrightarrow ArCOOPhH\cdot \quad (4)$$

$$ArCOO\cdot + Ph_3C\cdot \longrightarrow ArCOOCPh_3 \quad (5)$$

$$ArCOOPhH\cdot + Ph_3C\cdot \longrightarrow (ArCOOPhHCPh_3) \longrightarrow ArCOOH + PhCPh_3 \quad (6)$$

Obwohl die Aktivierungsenergie der Reaktion (5) noch nicht ermittelt wurde, lässt sie sich sicherlich als 0—3 Kcal/Mol verwerten, darüber wird nachher berichtet.

Wir haben bei 25°C und 45°C die Ausbeute an Kohlendioxyd und an Tetraphenylmethan bei der Einwirkung von Trityl-Radikal auf Benzoylperoxyd-carbonyl-^{14}C, *p*-Chlorbenzoylperoxyd-carbonyl-^{14}C und auf *p*-Methoxybenzoylperoxyd-carbonyl-^{14}C in Benzol ermittelt und daraus die Temperatur-Abhängigkeit der Geschwindigkeit der Reaktionen (1) und (4) bezüglich auf die Reaktion (5) errechnet. Die Ergebnisse sind in den Tabellen (1), (2) und (3) wiedergegeben.

Die Ausbeute an Benzoesäure-trityl-ester aus der Reaktion (5) wurde durch Abziehen der Ausbeute der Reaktionen (1) und (4) aus 100% erhalten. Die gute Ausbeute wurde mit der Isotopen-Verdünnungsmethode der gesamten Trityl-Gruppe von den Produkten Tetraphenylmethan und Benzoesäure-trityl-ester beim Um-

b) Die Ausbeute an Trityl-ester ist von der Reaktion 5.

setzen von Benzoylperoxyd, 96—97% bezogen auf 2 mal Mol Hexaphenyläthan festgestellt.

Die Bestimmung der Ausbeute an Kohlendioxyd und an Tetraphenylmethan wurde nach der Isotopen-Verdünnungsmethode durchgeführt. Das entwickelte Kohlendioxyd-^{14}C wurde zunächst durch die Grignard-Reaktion in Benzoesäure-carbonyl-^{14}C übergeführt und als Benzoesäure-phenacyl-ester ermittelt. Der Isotopie-Effekt bei der Grignard-Reaktion kann rechnerisch vernachlässigt werden, weil die Reaktion in guter Ausbeute (75—78% nach der Reinigung durch Sublimation) verläuft und der Fehler höchstens nur wenige Prozent beträgt.

Die Geschwindigkeit der Kohlendioxyd-Abspaltung (Reaktion (1)) bei 25°C relativ zu der Ester-Bildung (Reaktion (5)) kann man wie folgt ausdrücken:

$$[d(CO_2)/dt/d(\text{Trityl-ester})/dt]_{25} = k_{1,25}(ArCOO\cdot)_{25}/k_{5,25}(ArCOO\cdot)_{25}(Ph_3C\cdot)_{25} \quad (7)$$

Auf gleiche Weise erhält man für 45°C die Gleichung (8):

$$[d(CO_2)/dt/d(\text{Trityl-ester})/dt]_{45} = k_{1,45}(ArCOO\cdot)_{45}/k_{5,45}(ArCOO\cdot)_{45}(Ph_3C\cdot)_{45} \quad (8)$$

Die Temperatur-Abhängigkeit der relativen Geschwindigkeit, Reaktion (1) gegenüber Reaktion (5), kann man folgenderweise formulieren:

$$\frac{k_{1,45}/k_{5,45}(Ph_3C\cdot)_{45}}{k_{1,25}/k_{5,25}(Ph_3C\cdot)_{25}} = \frac{[d(CO_2)/dt/d(\text{Trityl-ester})/dt]_{45}}{[d(CO_2)/dt/d(\text{Trityl-ester})/dt]_{25}} \quad (9)$$

Wenn Hexaphenyläthan in derselben Konzentration verwendet wird, kann man die Konzentration bei 45°C, $(Ph_3C\cdot)_{45}$, im Vergleich zu der Konzentration bei 25°C aus den Dissoziationskonstanten, $K_{25}=5.72\times10^{-4}$ und $K_{45}=20.9\times10^{-4}$ Mol/l[7)], als $1.92=(20.9/5.72)^{1/2}$ er-

TABELLE 4. AKTIVIERUNGSENERGIEN DER AROYLOXY-RADIKALE (Kcal/Mol)

Substituent vom Benzoylperoxyd	Kohlendioxyd-Abspaltung	Anlagerung an Benzol-Doppelbinding	Kombination mit Trityl-Radikal
(H)	$12.9+E_5$ (± 0.9)	$6.3+E_5$ (± 0.1)	(E_5 $=2.0$)
p-Cl	$13.5+E_5'$ (± 1.5)	$6.2+E_5'$ (± 0.1)	(E_5' $=1.5$)
p-CH_3O	$14.7+E_5''$(± 0.8)	$6.1+E_5''$(± 0.1)	($E_5''$$=1.5$)

rechnen. Weiter bei Ersetzen
$[d(CO_2)/dt/d(\text{Trityl-ester})/dt]$ durch $[(CO_2\%)/(\text{Trityl-ester}_{\text{Reakt.5}}\%)]$
erhält man folgende Gleichung:

$$\frac{(k_1/k_5)_{45}}{(k_1/k_5)_{25}} = \frac{1.92\times[(CO_2\%)/(\text{Trityl-ester}\%)]_{45}}{[(CO_2\%)/(\text{Trityl-ester}\%)]_{25}} \quad (10)$$

Beim Auftragen von log (k_1/k_5) gegen $1/T$ erhält man $E_1-E_5=12.9$ Kcal/Mol für Benzoyloxy-Radikal, 13.6 Kcal/Mol für *p*-Chlorbenzoyloxy-Radikal und 14.7 Kcal/Mol für *p*-Methoxybenzoyloxy-Radikal.

Auf gleiche Weise errechnet man für $E_4-E_5=$ 6.3 Kcal/Mol für Benzoyloxy-Radikal, 6.2 Kcal/Mol für *p*-Chlorbenzoyloxy-Radikal und 6.1 Kcal/Mol für *p*-Methoxybenzoyloxy-Radikal. Sie sind in Tabelle 4 zusammengestellt.

Diskussion

Die genaue zahlenmässige Verwertung von E_5, E_5' und E_5'' ist schwierig. Man hat dazu als Vergleichswert 0—2 Kcal/Mol bei Kombination zweier kleiner Alkyl-Radikale[8] und 1—5 Kcal/Mol bei den grösseren und polymeren Alkyl-Radikalen[9]. Ungefähr 7 Kcal/Mol findet man für die Kombination zweier Trityl-Radikale.[7b] Wir nehmen vorläufig einfach $E_5=$ 2.0 Kcal/Mol an, weil man bei der Annahme des geometrischen Mittelwerts der Reaktionsgeschwindigkeit der Kreuz-Kombination eine Aktivierungsenergie von 3.5 Kcal/Mol[10] erhält und weil die Kombination wegen der polaren Eigenschaften der Reaktionspartner beschleunigt werden kann.[11] E_5' ist wahrscheinlich kleiner als E_5, weil *p*-Chlorbenzoyloxy-Radikal elektronegativer als Benzoyloxy-Radikal ist. Den Unterschied, $E_5-E_5'=0.5$ Kcal/Mol ziehen wir aufgrund der Differenz der Aktivierungsenergie von 1.2 Kcal/Mol zwischen den durch Trityl-Radikal induzierten Zersetzungen von Benzoyl- und *p*-Chlorbenzoylperoxyden[7a] vor. Ähnlicherweise nehmen wir an $E_5-E_5''=$ 0.5 Kcal/Mol.[7a]

Unter dieser Annahme erhält man $E_1=15$ Kcal/Mol für Benzoyloxy- und *p*-Chlorbenzoyloxy-Radikale und 16.2 Kcal/Mol für *p*-Methoxybenzoyloxy-Radikal. Weiter errechnet man $E_4=8.3$ Kcal/Mol für Benzoyloxy-Radikal, $E_4'=7.7$ Kcal/Mol für *p*-Chlorbenzoyloxy-Radikal und $E_4''=7.6$ Kcal/Mol für *p*-Methoxybenzoyloxy-Radikal.

Der Wert 15 Kcal/Mol für E_1 steht in guter Übereinstimmung mit dem von 14 Kcal/Mol von Bevington und anderen.[1c] Simamura und andere[4] berichteten den Unterschied von 10 Kcal/Mol zwischen den Aktivierungsenergien bei der Kohlendioxyd-Abspaltung von Benzoyloxy- und Acetyloxy-Radikalen. Nimmt man den Wert 6.6 Kcal/Mol[12] für Acetyloxy-Radikal an, so rechnet man für E_1 16.6 Kcal/Mol, der auch dem anderen Wert nahekommt. Unser Ergebnis $E_1''=$ 16.2 Kcal/Mol steht auch im Einklang mit dem 17 Kcal/Mol von Bevington und anderen.[1d] Der *p*-Chlor-Substituent übt keine merkliche Wirkung auf die Aktivierungsenergie bei der Zersetzung von Aroyloxy-Radikal in Aryl-Radikal und Kohlendioxyd aus, dagegen erhöht der *p*-Methoxy-Substituent die Aktivierungsenergie.

Die erhaltenen Ergebnisse von der Aktivierungsenergie der Reaktion (4) sind plausibel klein, wenn man auf die schnelle umkehrbare Anlagerung des Aroyloxy-Radikals an die aromatische Doppelbindung[13] Rücksicht nimmt. Für die rapide Anlagerungsreaktion des Aroyloxy-Radikals an die Benzol-Doppelbindung konnten wir keinen Einfluss der Substituenten *p*-Methoxy-, H und *p*-Chlor- auf die Aktivierungsenergie differenzieren. Man kann sich hier nur qualitativ vorstellen, dass Aroyloxy-Radikal mit negativen Substituenten sich schneller an die Doppelbindung anlagert als das Radikal mit positiven Substituenten.

Beschreibung der Versuche

Die typische Durchführung der Versuche ist folgende: Man löst im Dunkeln in der Stickstoff-Atmosphäre 399.07 mg (0.821 mMol) Hexaphenyläthan und 223.67 mg (0.924 mMol) Benzoylperoxyd-carbonyl-^{14}C (24046±43 c/m/mg) in je 20 m*l*

Sauerstoff freiem reinem Benzol und stellt sie gesondert in eine umgekehrt U-förmige Reaktionsapparatur. Nach dem Kühlen der beiden Lösungen mit flüssigem Stickstoff evakuiert man die Apparatur und schliesst sie im Vakuum ab. Man erwärmt im Dunkeln die Apparatur in einem Thermostat von 25°C solange, bis die Lösungen die Temperatur erreichen und sich vermischen und lässt sie im Thermostat 4 Stunden stehen. Man kühlt die Mischung mit flüssigem Stickstoff ab und verbindet die Apparatur mit einem Vakuum-System, das von einer Ampulle mit 2.53 mMol Phenylmagnesiumbromid in 5 m*l* Äther und von einem Reservoir mit nicht radioaktivem Kohlendioxyd eingerichtet ist. Man destilliert das Kohlendioxyd, das bei der Umsetzung von Trityl-Radikal mit Peroxyd entwickelt wurde, in die Grignard-Lösung ein, während man die Mischung der Umsetzung bei Raumtemperatur und das Grignard-Reagens bei der Temperatur des flüssigen Stickstoffs hält. Aus dem Kohlendioxyd-Reservoir destilliert man 2.336 mMol von nicht markiertem Kohlendioxyd in zwei Portionen zunächst in die Umsetzungsmischung von Trityl-Radikal und Peroxyd ein und anschliessend von dort aus in das Grignard-Reagens über. Man schmilzt dann die Grignard-Mischung im Ampulle ein und lässt die Mischung über Nacht bei Raumtemperatur einwirken. Man zersetzt die Mischung der Grignard-Reaktion mit 6N Salzsäure, reinigt die rohe Benzoesäure durch Vakuum-Sublimation und führt sie in den Phenacyl-ester. Man reinigt den Ester zunächst durch Chromatographie an Aluminiumoxyd mit Essigester als Laufmittel und dann durch Kristallisation aus Isopropanol, bis der konstante Schmelzpunkt von 119—119.5°C erreicht wird (Probe für die Analyse des Phenacyl-esters). Zu der Reaktionsmischung vom Trityl und Peroxyd fügt man 49.63 mg des markierten Tetraphenylmethan (4245±15 c/m/mg), zersetzt den Überschuss vom Peroxyd durch Natriumjodid in Aceton, trennt Benzoesäure ab, und chromatographiert die neutralen Produkte an Aluminiumoxyd mit Benzol-*n*-Hexan als Laufmittel. Das eluierte rohe Tetraphenylmethan-^{14}C reinigt man durch Vakuum-Sublimation bei 200°C und durch mehrmalige Umkristallisation aus Benzol, bis der Schmelzpunkt 286—286.5°C (im Einschlussrohr) erreicht wird (Probe für die Analyse des Tetraphenylmethans).

Die Bestimmung der Radioaktivität erfolgte mit einem Gerät von Beckman LS-200 Szintirationszähler mit PO-POP-PPO in Toluol. Für diese Bestimmung danken wir Herrn Dr. N. Morikawa von der Universität Tokio vielmals.

Nucleoside Analogs. II. A Synthesis of 9-Adenyl-deoxyinositols

Tetsuo SUAMI, Yasushi FUKAI, Yukio SAKOTA, Makoto KARIMOTO, Nobuo TAKOI, and Yoko TSUKAMOTO

Department of Applied Chemistry, Faculty of Engineering Keio University, Koganei-shi, Tokyo

(Received January 30, 1971)

Four 9-adenyl-deoxyinositols were prepared by a reaction between 4-amino-6-chloro-5-nitropyrimidine (**1**) and inosamines (**2a**, **2b**, **2c**, and **2d**), followed by a reduction and a cyclization. In the present article, 1-(6′-amino-9′-purinyl)-1-deoxy-*scyllo*-inositol (**5a**), 1-(6′-amino-9′-purinyl)-1-deoxy-*muco*-inositol (**5b**), 2-(6′-amino-9′-purinyl)-2-deoxy-*epi*-inositol (**5c**), and 2-(6′-amino-9′-purinyl)-2-deoxy-*myo*-inositol (**5d**) were described. These compunds exhibited an inhibitory effect against *piricularia oryzae*.

An alternation of a ribose moiety in naturally occurring adenosine may yield a biologically active nucleoside analog. Along this consideration, dihydroxycyclohexane analogs of the nucleoside have been described in a previous paper.[1)]

In connection with the previous paper of this series,[1)] four biologically active 9-adenyl-deoxyinositols (**5a**, **5b**, **5c**, and **5d**) have been prepared by a reaction between 4-amino-6-chloro-5-nitropyrimidine (**1**)[2)] and inosamines (**2a**, **2b**, **2c**, and **2d**), followed by reduction of a nitro group and cyclization of an imidazole ring, which will be described in the present article.

When a mixture of **1** and *scyllo*-inosamine (**2a**),[3,4)] was heated in 2-methoxyethanol under reflux for 20 hr, 1-(4′-amino-5′-nitro-6′-pyrimidinylamino)-1-deoxy-*scyllo*-inositol (**3a**) was obtained in 78% yield. Reduction of **3a** with zinc powder in boiling water afforded 1-(4′,5′-diamino-6′-pyrimidinylamino)-1-deoxy-*scyllo*-inositol (**4a**) in 87% yield, which was used for a successive synthesis without any further purification. Cyclization of **4a** was carried out by heating in formamide to give 1-(6′-amino-9′-purinyl)-1-deoxy-*scyllo*-inositol (**5a**) in a yield of 52%. The compound **5a** showed an ultraviolet absorption characteristic of an adenine at 263 mμ.[5)]

An analogous reaction beginning with *muco*-inosamine-1 (**2b**)[4)] and **1** afforded 1-(6′-amino-9′-purinyl)-1-deoxy-*muco*-inositol (**5b**) in 25% yield.

Reactions between *epi*-inosamine-2 (**2c**)[3,6,7)] and **1**

and between *myo*-inosamine-2 (**2d**)[3,8,9] and **1** yielded 2-(6′-amino-9′-purinyl)-2-deoxy-*epi*-inositol (**5c**) and 2-(6′-amino-9′-purinyl)- 2-deoxy-*myo*-inositol (**5d**) respectively by an analogous after-treatment. In these reactions, besides the compounds **5c** and **5d**, 2-(6′-purinylamino)-2-deoxy-*epi*-inositol (**6c**) and 2-(6′-purinylamino)-2-deoxy-*myo*-inositol (**6d**) were obtained. These structural assignments were agreeable with their ultraviolet absorption maxima.[10–12]

The biological activities of 9-adenyl-deoxyinositols against *piricularia oryzae* will be reported elsewhere.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and uncorrected. The infrared spectra were determined in a potassium bromide disc with a Hitachi EPI-2 spectrometer. The ultraviolet absorption spectra were determined in water with a Hitachi EPS-2 spectrometer.

4-Amino-6-chloro-5-nitropyrimidine (1). The compound was prepared by the method of Boon and coworkers.[2]

Scyllo-*Inosamine (2a).* The compound was prepared by the method of Suami and coworkers.[4]

1-(4′-Amino-5′-nitro-6′-pyrimidinylamino)-1-deoxy-scyllo-*inositol (3a).* A mixture of 1.75 g of **1** and 1.79 g of **2a** in 200 m*l* of 2-methoxyethanol was heated under reflux in a presence of a small amount of triethylamine for 20 hr. After the mixture was settled overnight at room temperature, crystals were collected by filtration and washed with water to give 2.48 g (78% yield) of the product, mp above 300°C.

Found: C, 37.87; H, 4.90; N, 21.71%. Calcd for $C_{10}H_{15}N_5O_7$: C, 37.86; H, 4.77; N, 22.08%.

1-(4′,5′-Diamino-6′-pyrimidinylamino)-1-deoxy-scyllo-*inositol (4a).* To a suspension of 60 g of zinc powder in 600 m*l* of boiling water, 1.0 g of **3a** was added with a mechanical agitation. The mixture was heated under reflux for 6 hr, and then it was filtered. The filtrate was evaporated under reduced pressure to a 100 m*l* volume. The residual solution was settled at room temperature to give pale yellow crystals. Crystals were collected by filtration to give 0.79 g (87% yield) of the product, mp 281—283°C (dec.).

1-(6′-Amino-9′-purinyl)-1-deoxy-scyllo-*inositol (5a).* A 0.5 g-portion of **4a** was heated with 10 m*l* of formamide under reflux for 40 min. After the mixture was settled overnight at room temperature, crystals were collected by filtration to give 0.39 g of a crude product. The product (200 mg) was dissolved in boiling water (200 m*l*) and the solution was decolorized with active charcoal. After cooling, the solution gave 0.14 g (53% yield) of crystals which were collected by filtration, mp above 300°C. UV λ_{max} (pH 1) 258; (pH 7) 263; (pH 13) 263 mμ.

Found: C, 44.42; H, 5.44; N, 23.81%. Calcd for $C_{11}H_{15}N_5O_5$: C, 44.44; H, 5.09; N, 23.56%.

muco-*Inosamine-1 (2b).* Hexaacetyl *muco*-inosamine-1 was prepared by the method of Suami and coworkers.[4] A 6.0 g-portion of the hexaacetyl derivative was hydrolyzed in 6N hydrochloric acid and then treated with Amberlite IRA-400 to give 2.03 g (81% yield) of **2b**, mp 184—200°C (dec.).

1-(4′A-mino-5′-nitro-6′-pyrimidinylamino)-1-deoxy-muco-*inositol (3b).* A mixture of 0.49 g of **1** and 0.54 g of **2b** was heated in 2-methoxyethanol (40 m*l*) for 3 hr under reflux with a small amount of triethylamine. The mixture was evaporated *in vacuo* and the residue was crystallized in water. The crystals were collected by filtration and washed with chloroform to give 0.68 g (77% yield) of **3b**, mp 260—261°C.

Found: C, 37.77; H, 4.88; N, 21.88%. Calcd for $C_{10}H_{15}N_5O_7$: C, 37.86; H, 4.77; N, 22.07%.

1-(4′,5′-Diamino-6′-pyrimidinylamino)-1-deoxy-muco-*inositol (4b).* A 1.0 g-portion of **3b** was reduced by analogous procedures as described in **4a** to give 0.73 g (81% yield) of **4b**, mp 166—171°C.

1-(6′-Amino-9′-purinyl)-1-deoxy-muco-*inositol (5b).* A

8) G. E. McCasland and E. C. Horswill, *J. Amer. Chem. Soc.*, **75**, 4020 (1953).

9) T. Suami, S. Ogawa, and M. Uchida, This Bulletin, **43**, 3577 (1970).

10) T. Okano, S. Goya, A. Takadate, and Y. Ito, *J. Pharm. Soc. Jap.* **86**, 649 (1966).

11) G. B. Elion, E. Burgi, and G. H. Hitchings, *J. Amer. Chem. Soc.*, **74**, 411 (1952).

12) J. A. Montgomery and L. B. Holum, *ibid.*, **80**, 404 (1958).

0.5 g-portion of **4b** was heated in formamide (10 ml) for 30 min. The mixture was treated analogously by the method as described in **5a** to give 0.27 g of a crude product. Recrystallization from water afforded 0.21 g (41% yield) of **5b**, mp 287—288.5°C. UV λ_{max} (pH 1) 259; (pH 7) 260; (pH 13) 261 mμ.

Found: C, 44.34; H, 5.35; N, 23.31%. Calcd for $C_{11}H_{15}N_5O_5$: C, 44.44; H, 5.09; N, 23.56%.

epi-*Inosamine-2 (**2c**)*. *epi*-Inosamine-2 hydrochloride was prepared by the method of Suami and coworkers.[7] The hydrochloride was treated with Amberlite IRA-400 to give **2c** in 90% yield. Mp 195—200°C (dec.).

2-(4'-Amino-5'-nitro-6'-pyrimidinylamino)-2-deoxy-epi-*inositol (**3c**)*. A mixture of **1** (1.40 g) and **2c** (2.16 g) was heated in 2-methoxyethanol for 3 hr as described in **3a** to give 2.57 g of a crude product. Recrystallization from water afforded 2.36 g (93% yield) of **3c**, mp 264—265°C.

Found: C, 37.77; H, 4.90; N, 21.80%. Calcd for $C_{10}H_{15}N_5O_7$: C, 37.86; H, 4.77; N, 22.08%.

2-(4',5'-Diamino-6'-pyrimidinylamino)-2-deoxy-epi-*inositol (**4c**)*. (A) **3c** (1.54 g) was reduced with zinc powder (10 g) in boiling water (100 ml) analogously as described in **4a** to give 1.07 g of a crude product. Recrystallization from water afforded 0.87 g (62% yield) of **4c**, mp 165—170°C. (B) To a mixture of ferrous sulfate (8.9 g) and barium hydroxide (10.6 g) in 100 ml of water, **3c** (1.0 g) was added with agitation and the mixture was heated at 90°C for 30 min. The warm mixture was filtered and the filtrate was evaporated under reduced pressure to 20 ml. The residual solution was settled in a refrigerator to give 0.73 g (81% yield) of **4c** as pale yellow crystals, mp 166—171°C.

2-(6'-Amino-9'-purinyl)-2-deoxy-epi-*inositol (**5c**) and 2-(6'-purinylamino)-2-deoxy*-epi-*inositol (**6c**)*. **4c** (0.70 g) was heated in formamide (10 ml) for 30 min under reflux. The mixture was evaporated *in vacuo* and the residue was warmed in 0.4 N hydrochloric acid (14 ml) for 30 min at 50°C. The solution was passed through a column (1.5 cmφ) of Amberlite CG-120 (H^+ form) and subsequently the column was washed with water. The product was eluted from the column with 2.5N ammonia (100 ml) and the eluate was decolorized with active charcoal. The solution was evaporated under reduced pressure to a small volume, and the residue was settled in a refrigerator to give 0.38 g of a crude product. The product was recrystallized from water to give 0.11 g (15% yield) of **5c** as needle crystals, mp 282—283°C. UV λ_{max} (pH 1) 261; (pH 7) 262; (pH 13) 263 mμ.

Found: C, 44.50; H, 5.37; N, 23.70%. Calcd for $C_{11}H_{15}N_5O_5$: C, 44.44; H, 5.09; N, 23.56%.

From the mother liquor of **5c**, another crop of crystal was obtained. Recrystallization from water afforded 0.19 g (26% yield) of crystals, mp above 310°C. The product was identified to be **6c**. UV λ_{max} (pH 1) 275; (pH 7) 268; (pH 13) 275 mμ.

Found: C, 44.64; H, 5.53; N, 23.38%. Calcd for $C_{11}H_{15}N_5O_5$: C, 44.44; H, 5.09; N, 23.56%.

myo-*Inosamine-2 (**2d**)*. Hexaacetyl *myo*-inosamine-2[3] was prepared by the method of Suami and coworkers[9] beginning with pentaacetyl 1-bromo-1-deoxy-*scyllo*-inositol.[8] **2d** was obtained from the hexaacetyl compound by an analogous method used for **2b**. Mp 263—265°C (dec.).

2-(4'-Amino-5'-nitro-6'-pyrimidinylamino)-2-deoxy-myo-*inositol (**3d**)*. A mixture of **1** (0.35 g) and **2d** (0.40 g) was heated in 2-methoxyethanol for 3 hr as described in **3a** to give 0.57 g (90% yield) of crystals, mp 302—304°C (dec.).

Found: C, 37.76; H, 4.91; N, 21.98%. Calcd for $C_{10}H_{15}N_5O_7$: C, 37.86; H, 4.77; N, 22.07%.

2-(4',5'-Diamino-6'-pyrimidinylamino)-2-deoxy-myo-*inositol (**4d**)*. A 1.0 g-portion of **3d** was reduced with zinc powder as described in **4a** to give 0.67 g (74% yield) of the product as pale yellow needles, mp 294—304°C (dec.).

2-(6'-Amino-9'-purinyl)-2-deoxy-myo-*inositol (**5d**) and 2-(6'-purinylamino)-2-deoxy*-myo-*inositol (**6d**)*. A 2.5 g-portion of **4d** was heated in formamide (70 ml) for 1 hr in a nitrogen atomosphere. The reaction mixture was treated analogously as described in **5c** to give 0.82 g of a crude product. Recrystallization from water afforded 0.41 g (16% yield) of needles of mp 257—258.5°C (dec.), which was identified to be **6d**. UV λ_{mxa} (pH 1) 266; (pH 7) 270; (pH 13) 276 mμ.

Found: C, 44.44; H, 4.77; N, 23.81%. Calcd for $C_{11}H_{15}N_5O_5$: C, 44.44; H, 5.09; N, 23.56%.

From the mother liquor, 0.15 g (6% yield) of crystals were obtained, which was identified to be **5d**. Mp 325—327°C (dec.). UV λ_{max} (pH 1) 260; (pH 7) 261; (pH 13) 262 mμ.

Found: C, 44.46; H, 5.20; N, 23.73%. Calcd for $C_{11}H_{15}N_5O_5$: C, 44.44; H, 5.09; N, 23.56%.

The authors are grateful to professor Sumio Umezawa for his helpful advice and Mr. Saburo Nakada for his elementary analyses. This research has been supported financially in part by a grant of the Japanese Ministry of Education, to which the authors' thanks are due.

Synthetic Studies of the Flavone Derivatives. XXII.[1] The Synthesis of Eupatoretin and Eupatin

Kenji FUKUI, Takashi MATSUMOTO, and Sachihiko IMAI

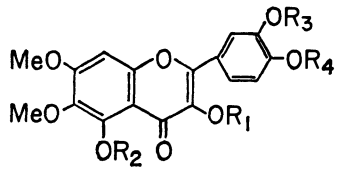
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received December 7, 1970)

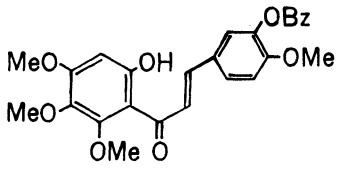
Recently, Kupchan *et al.*[2] reported the isolation of two new cytotoxic flavonols, eupatoretin and eupatin, from *Eupatorium semiserratum*. On the bases of chemical and spectral studies, they proposed that the structures of these flavonols were 3,3′-dihydroxy-4′,5,6,7-tetramethoxyflavone (I) for eupatoretin and 3,3′,5-trihydroxy-4′,6,7-trimethoxyflavone (II) for eupatin. In a previous paper,[3] we reported the synthesis of 3,4′,5-trihydroxy-3′,6,7-trimethoxyflavone (III), an isomer of eupatin, the structure of which had earlier been assigned to chrysosplenetin.[4]

For the structural confirmation of these natural pigments, we have now studied the syntheses of flavonols, I and II. By the method of Hörhammer *et al.*,[5] 3-benzyloxy-2′-hydroxy-4,4′,5′,6′-tetramethoxychalcone (IV) was converted into 3′-benzyloxy-3-hydroxy-4′,5,6,7-tetramethoxyflavone (V) in an 18% yield under improved reaction conditions without chromatographic purification (lit.[5]:10% yield after chromatography). The catalytic debenzylation of V in ethanol in the presence of Pd-C (10%) gave I, mp 150—151°C, which was shown to be identical with natural eupatoretin by a mixed-melting-point determination and by a spectral comparison. The synthetic I was further characterized by the preparation of its diacetate (VI), mp 151—152°C. Subsequently, the selective demethylation[3] of the C_5-methoxyl group in I with anhydrous aluminum chloride in dry nitrobenzene was carried out; the demethylated flavonol II was thus obtained as golden yellow needles, mp 244.5—245.5°C, which then gave triacetate (VII), mp 218—220°C. The synthetic II was also found to be identical with natural eupatin by a direct comparison.

The structures of eupatoretin and eupatin are thus confirmed to be I and II respectively.



I $R_1=R_3=H$, $R_2=R_4=Me$
II $R_1=R_2=R_3=H$, $R_4=Me$
III $R_1=R_2=R_4=H$, $R_3=Me$
V $R_1=H$, $R_2=R_4=Me$, $R_3=Bz$
VI $R_1=R_3=Ac$, $R_2=R_4=Me$
VII $R_1=R_2=R_3=Ac$, $R_4=Me$



IV

Experimental[6]

3′-Benzyloxy-3-hydroxy-4′,5,6,7-tetramethoxyflavone (V). To a hot solution of IV (830 mg) in methanol (83 ml), we added hydrogen peroxide (30%: 3.5 ml) and an aqueous potassium hydroxide solution (20%: 13 ml). The mixture was refluxed for 1 min, poured into a mixture of ice and water (300 ml), and then immediately acidified with dilute hydrochloric acid. The yellow precipitates were collected, washed with water, and then recrystallized from ethanol to give V as yellow needles, mp 146—148°C, which gave a brown ferric chloride reaction in ethanol; yield, 150 mg (18%) (lit.[5] mp 142—143°C, yield 10%). UV λ_{max}^{EtOH} mμ (log ε); 235[7] (4.35), 254.5 (4.37), 360 (4.36).

3,3′-Dihydroxy-4′,5,6,7-tetramethoxyflavone (I). A solution of V (145 mg) in ethanol (50 ml) was submitted to catalytic hydrogenolysis at *ca.* 30°C in the presence of Pd-C (10%: 75 mg). After the catalyst had been filtered off, the filtrate was evaporated and the residue was recrystallized from benzene to give I as bright yellow plates, mp 150—151°C, which gave a brown ferric chloride reaction in ethanol; yield, 75 mg (62%). The mixed melting point with natural eupatoretin (mp 150—152°C[8]) was 150—152°C. UV: λ_{max}^{EtOH} mμ (log ε); 256 (4.34), 361 (4.29).

Found: C, 60.96; H, 4.72%. Calcd for $C_{19}H_{18}O_8$: C, 60.96; H, 4.85%.

3,3′-Diacetoxy-4′,5,6,7-tetramethoxyflavone (VI). A mixture of I (30 mg), acetic anhydride (0.4 ml), and dry pyridine (0.6 ml) was refluxed for 1 hr. The crude product was

recrystallized from benzene containing *n*-hexane to give the diacetate (VI) as colorless needles, mp 151—152°C, which gave a negative ferric chloride reaction in ethanol; yield, 27 mg (73%). UV: λ_{max}^{EtOH} mμ (log ε); 232[7](4.33), 264.5 (4.25), 319(4.42). Lit.[2] mp 145—147°C, UV: λ_{max}^{EtOH} mμ (ε); 235(28300), 263(25000), 316(31000).

3,3′,5-Trihydroxy-4′,6,7-trimethoxyflavone (II). The flavonol I (50 mg) was added to a mixture of anhydrous aluminum chloride (0.5 g) and dry nitrobenzene (5.0 m*l*). The mixture was allowed to stand at room temperature for 5 hr and then poured into a mixture of ice (10 g) and concentrated hydrochloric acid (3.0 m*l*) with stirring and cooling. After the removal of the nitrobenzene by steam distillation, the residual precipitates were collected, washed with water, and then recrystallized from methanol to give II as yellow needles, mp 244.5—245.5°C, which gave a dark green ferric chloride reaction in ethanol; yield, 18 mg (37%). The mixed melting point with natural eupatin (mp 244.5—245.5°C[8]) was 244.5—245.5°C. UV: λ_{max}^{EtOH} mμ (log ε); 259(4.34), 272[7](4.19), 294[7](3.83), 368(4.33).

Found: C, 60.04; H, 4.41%. Calcd for $C_{18}H_{16}O_8$: C, 60.00; H, 4.48%.

3,3′,5-Triacetoxy-4′,6,7-trimethoxyflavone (VII). A mixture of II (12.5 mg), acetic anhydride (0.2 m*l*), and dry pyridine (0.3 m*l*) was refluxed for 2 hr. The crude product was then recrystallized from benzene containing *n*-hexane to give the triacetate (VII) as colorless needles, mp 218—220°C, which gave a negative ferric chloride reaction; yield, 10 mg (60%). UV: λ_{max}^{EtOH} mμ (log ε); 260(4.19), 319(4.44).

Found: C, 59.22; H, 4.47%. Calcd for $C_{21}H_{22}O_{11}$: C, 59.26; H, 4.56%.

The authors are grateful to Professor S. Morris Kupchan, Universty of Virginia, for his gifts of natural eupatoretin and eupatin.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1699—1701 (1971)

The Reactions of Hexafluoropropylene with Arylamines and the Preparation of *N*-(2,3,3,3-Tetrafluoropropyl)arylamines

Nobuo ISHIKAWA and Takayoshi MURAMATSU

Department of Synthetic Chemistry, Faculty of Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received December 12, 1970)

Nucleophilic additions of alkylamines to fluoroolefins are well known.[1] For instance, alkylamines react exothermally with tetrafluoroethylene or chlorotrifluoroethylene to give acetamidines (**2**) *via* imidylfluorides (**1**):[2]

$$RNH_2 + CF_2{=}CFX \longrightarrow \underset{\mathbf{1}}{R\text{-}N{=}CFCHFX} + HF$$

$$RNH_2 + \mathbf{1} \longrightarrow \underset{\mathbf{2}}{R\text{-}N{=}C(NH\text{-}R)\text{-}CHFX} + HF$$

As arylamines are less basic than alkylamines, they are less reactive to fluoroolefins, and little is known about the reactions of arylamines with perfluoroolefins. The early work of Knunyants and his co-workers[3] revealed that aniline and perfluoroisobutene in ether gave the condensed product **3**, which could then be hydrolyzed by sulfuric acid into an amide **4**.

$$PhNH_2 + CF_2{=}C(CF_3)(CF_3) \longrightarrow \underset{\mathbf{3}}{PhNHCF{=}C(CF_3)(CF_3)} + HF$$

$$\mathbf{3} + H_2O \longrightarrow \underset{\mathbf{4}}{PhNH\text{-}C(=O)\text{-}CH(CF_3)(CF_3)} + HF$$

On the other hand, England and his co-workers[2] reported that aniline reacted with 0.25 mol of tetrafluoroethylene at 135°C to give difluoroacetamidine (**5**) in an 85% yield:

$$PhNH_2 + CF_2{=}CF_2 \longrightarrow \underset{\mathbf{5}}{PhN{=}C(NHPh)\text{-}CHF_2}$$

We carried out the reactions of aromatic amines with hexafluoropropylene, using dimethylformamide as the solvent. They reacted even at room temperature, and two kinds of products were obtained, depending upon the relative concentration.

As an example, when a dilute solution (about 10%) of *p*-toluidine in dimethylformamide was allowed to react with 2 mol of hexafluoropropylene, a compound with a mp of 93.5—94°C was obtained. From the IR, NMR, and mass spectra, the structure of this compound was found to be *N*-*p*-tolyl-α,β,β,β-tetrafluoropropionamide (**6**). In the IR spectrum, the presence of the –CONH group was shown by strong bands at 1675 (C=O) and 3340 (N-H) cm^{-1}, and in the mass spectrum the parent peak of *m/e* 235 and other reasonable fragment peaks appeared. In the NMR spectra, two kinds of fluorine atoms (CF_3 and CHF) and four kinds of hy-

drogen atoms (NH, aromatic 4H, CHF and CH_3) appropriately appeared.

When a rather concentrated solution (about 22%) of *p*-toluidine was allowed to react with 1.5 mol of hexafluoropropylene in the same manner, we obtained another compound with a mp of 87—88.5°C. The absorption spectra of this compound were quite different from those of **6**, and we confirmed that this compound is the condensed product of 2 mol of *p*-toluidine and 1 mol of hexafluoropropylene, *i.e.*, *N,N'*-di-*p*-tolyltetrafluoropropionamidine (**7**). The IR spectrum had no C=O band, and the mass spectrum showed an appropriate parent peak (*m/e* 324) and fragment peaks. Two kinds of fluorine atoms (CF_3, CHF) and four kinds of hydrogen atoms (Me_2, (aromatic 4H)$_2$, NH, and CHF) were present in the NMR spectra.

The scheme of the above reactions seems to be as follows. The reaction of arylamine and hexafluoropropylene gives the imidylfluoride (**8**) first. When the reaction mixture is then treated with water, this **8** is hydrolyzed into the propionamide (**9**), but if an excess arylamine is present in the reaction system, **8** reacts with it further to give the propionamidine (**10**):

$$ArNH_2 + CF_2{=}CFCF_3 \longrightarrow ArNHCF_2CHFCF_3$$

$$\downarrow -HF$$

$$ArN{=}CFCHFCF_3 \quad \mathbf{8}$$

$$\xrightarrow{H_2O,\ (-HF)} ArNHCCHFCF_3 \quad \mathbf{9}$$

$$\xrightarrow{ArNH_2} ArN{=}CCHFCF_3 \quad \mathbf{10}$$

In addition to *p*-toluidine, we reacted aniline, *o*- and *m*-toluidines, and 2,4-xylidine with hexafluoropropylene at a low arylamine concentration; in each case, we could obtain the corresponding tetrafluoropropionarylide in a good yield (Table 1).

Because of the strong electronegativity of the fluorine atom, these tetrafluoropropionarylides were not stable to alkali, and when heated in a dilute aqueous sodium hydroxide solution they were readily hydrolyzed to arylamine and tetrafluoropropionic acid. Therefore, we carried out the reduction of the carbonyl groups of these amides with lithium aluminum hydride and thus obtained stable *N*-(tetrafluoropropyl)arylamines. The physical properties of these amines are listed in Table 1.

Experimental

N-p-*Tolyl-α,β,β,β-tetrafluoropropionamide (6).* A solution of 2.14 g (0.02 mol) of *p*-toluidine in 20 m*l* of dimethylformamide was put into an autoclave (100 m*l*) and cooled to about −40°C. 0.04 Mol of liquefied perfluoropropylene was then added to the autoclave, and the temperature of the reaction vessel was allowed to rise to room temperature (20°C), whereupon the mixture was agitated magnetically at this temperature for six hours. Then the reaction mixture was thrown into water; after it had been stirred for a while, an oily matter solidified and a pale yellow crystalline mass separated out. This was filtered off, washed, and dried to give 4.04 g of (85.2%) the crude product. After recrystallization from dilute methanol, colorless crystals with a mp of 93.5—94°C were obtained. IR: 3340 (N–H), 1675 (C=O), 1145, 1188 (C–F) cm^{-1}. NMR (in $CDCl_3$): ^1H τ 7.72 (CH_3, s), 4.88 (CHF, dq), 2.47—3.07 (arom–H, dd), 1.72 (NH, br); ^{19}F δ −3.0 (CF_3, dd), +122.8 (CHF, m) from external CF_3CO_2H. MS: *m/e* 91 ($C_6H_5CH_2$), 106 ($CH_3C_6H_4NH$), 134 ($CH_3C_6H_4NHCO$), 235 ($C_{10}H_9ONF_4$).

The reactions with other arylamines were run similarly, and the products (Table 1) gave similar IR and NMR spectra.

N,N'-*Di*-p-*tolyl-α,β,β,β-tetrafluoropropionamidine (7).* A solution of 4.28 g (0.04 mol) of *p*-toluidine in 15 m*l* of dimethylformamide was allowed to react with 0.06 mol of hexafluoropropylene in the same manner as in the above reaction. After five hours, the reaction mixture was treated with water; 4.72 g (72.8%) of yellow crystals were thus obtained. This crude product was dissolved in benzene, and the solution was chromatographed on an activated alumina column. The yellow band was eluted with benzene, the solvent was evaporated, and the residue was recrystallized from dilute methanol, thus giving colorless crystals with a mp of 87—88.5°C

Found: F 23.1%, Calcd for $C_{17}H_{16}F_4N_2$: F 23.4%. IR: 3240 (N–H), 1133, 1183 (C–F) cm^{-1}. NMR (in $CDCl_3$): ^1H τ 7.78 (CH_3, s), 4.42 (CHF, m), 2.85—3.70 (arom–H, dd), 2.62 (NH, br); ^{19}F δ −3.3 (CF_3, dd), +124.4 (CHF, m) from external CF_3CO_2H. MS: *m/e* 65 (C_5H_5), 91 ($C_6H_5CH_2$), 107 (C_7H_7NH+H), 218 ($C_7H_7N{=}C{-}CHFCF_3$), 324 ($C_{17}H_{16}N_2F_4$).

N-*(2,3,3,3-Tetrafluoropropyl)*-p-*tolylamine.* A solution of 1.52 g (0.04 mol) of lithium aluminum hydride in 50 m*l* of diethyl ether was cooled in an ice-salt bath and then a solution of 4.70 g (0.02 mol) of **6** in 15 m*l* of diethyl ether was

stirred mechanically in at 0—5°C. After the addition, stirring was continued for three hours at room temperature; the solution was then allowed to stand for one day. Into the reaction mixture a small amount of ethyl acetate and water was then added cautiously in order to decompose the excess lithium aluminum hydride; the ether layer was evaporated, and then the residue was distilled out in a vacuum. A colorless liquid with a bp of 108—109°C/17 mmHg which weighed 3.30 g (74.7%) was thus obtained. IR: 3440 (N–H), 1150, 1186 (C–F)cm^{-1}. NMR: ^{1}H τ 7.89 (CH_3, s), 6.98 (NH, br), 6.59 (CH_2, m), 5.55 (CHF, m), 3.02—3.90 (arom–H, m); ^{19}F δ +0.01 (CF_3, dd), +125.8 (CHF, m) from external CF_3CO_2H.

The other tetrafluoropropionarylamides were also reduced in the same manner (Table 1): their products gave similar IR and NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1701—1702 (1971)

A Cleavage of a Furan Derivative Observed during the Curtius Reaction

Takao YOSHIDA, Hakuji KATSURA, and Takeo KANEKO

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received December 14, 1970)

It is well known that furfuryl alcohol derivatives are easily attacked by acidic reagents to afford γ-diketones, γ-ketoacids, or γ-lactones. In this paper a conversion of a furfuryl alcohol derivative to a γ-valerolactone derivative in the absence of acidic reagent during the Curtius reaction is reported.

Furfuryl alcohol (I) was converted to 2-hydroxymethylfuran-3,4-dicarboxylic acid dimethylester (II) by the Alder-Rickert reaction.[1] 2-Acetoxymethylfuran-3,4-dicarboxylic acid (IV), which was obtained by alkaline hydrolysis of dimethylester (II) followed by acetylation with acetic anhydride-pyridine, was treated with thionyl chloride to give 2-acetoxymethylfuran-3,4-dicarbonylchloride (V). Diacyl azide (VI), which was prepared from the reaction of acyl chloride (V) with sodium azide, was subjected to the Curtius reaction in ethanol or benzyl alcohol-benzene solution.

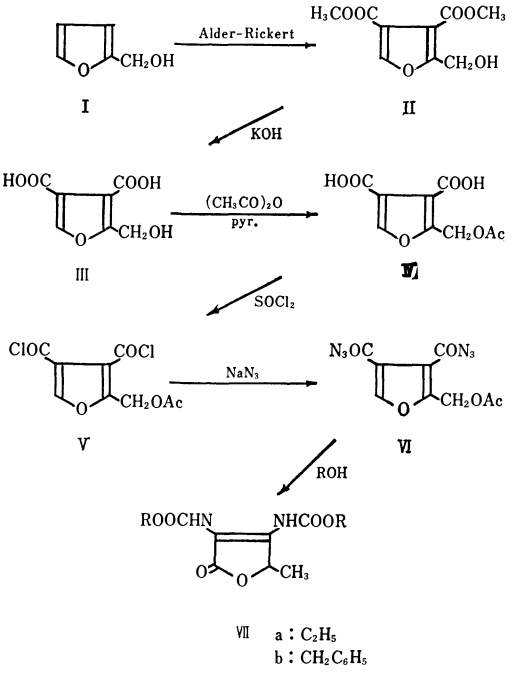

Fig. 1.

The structures of the products separated by means of silica gel column chromatography were elucidated from IR, NMR, and UV spectroscopic studies. When diacyl azide (VI) was heated in ethanol, the product showed the absorption at 1780, 1690, 1190 cm^{-1} in IR spectrum which indicated the presence of α,β-unsaturated γ-lactone. In NMR spectrum signals of a three proton doublet at δ1.55 (J=6.5 Hz) and one proton quartet at δ 5.70 (J=6.5 Hz) appeared. This showed the presence of structure of $>CH-CH_3$ in the molecule. UV spectrum also showed λ_{max} at 267.5 mμ (ε, 15.500). From these results as well as from elemental analysis and molecular weight measurement, the structure of the product was confirmed to be α,β-dehydro-α,β-dicarbethoxyamino-γ-valerolactone (VII, a). When benzyl alcohol was used on the Curtius reaction, the product which showed similar spectra to those of VIIa in IR and NMR was confirmed to have the structure of α,β-dehydro-α,β-dicarbobenzyloxyamino-γ-valerolactone (VII, b).

Experimental

All melting points are uncorrected. IR, NMR, and UV were measured by use of Jasco IR-S, Varian A-60, and Hitachi EPS-3 spectrometers, respectively.

2-Hydroxymethylfuran-3,4-dicarboxylic Acid Dimethylester (II). A mixture of furfuryl alcohol (1) (4.9g, 0.05 mol), acetylenedicarboxylic acid dimethylester (7.2 g, 0.05 mol) and anhydrous dioxane (20m*l*) was heated under reflux for 5 hr. After dioxane was removed, the residue was dissolved in ethyl acetate (50m*l*). The solution was subjected to hydrogenation with 10% palladium on charcoal under atmospheric pressure at room temperature. When one equivalent (0.05mol) of hydrogen was absorbed, the catalyst was filtered off and the filtrate was evaporated to remove ethyl acetate. The residue was heated to 200°C under reduced pressure of about 100 mmHg until the generation of ethylene stopped. Subsequent distillation at 2 mmHg afforded 2-hydroxymethylfuran-3,4-dicarboxylic acid dimethylester (II) (9.0 g, 84%), bp 140—141°C/2 mmHg. IR (neat): 3450, 1730, 1600, 1200, 1080, 770 cm^{-1}. NMR ($CDCl_3$): δ 3.83, 3.87 (7H, s-s), 4.73 (2H, s), 7.87 (1H, s).

Found: C, 49.80; H, 4.74%. Calcd for $C_9H_{10}O_6$: C, 50.47; H, 4.71%.

1) K. Alder and H. F. Rickert, *Ber.*, **70**, 1354 (1937); K. Hofmann, *J. Amer. Chem. Soc.*, **67**, 421, 738 (1945).

2-Hydroxymethylfuran-3,4-dicarboxylic Acid (III). 2-Hydroxymethylfuran-3,4-dicarboxylic acid dimethylester (II) (12.9 g, 0.06 mol) was dissolved in methanol (60 ml). To this solution sodium hydroxide aqueous solution (8.4 g in 20 ml) was added dropwise with cooling, and the reaction mixture was allowed to stand for 18 hr at room temperature. After evaporating methanol under reduced pressure, the residual solution was acidified with concentrated hydrochloric acid (14.5 ml). Precipitated crystals were collected on a funnel and washed with a small amount of cold water. Recrystallization from water gave 2-hydroxymethylfuran-3,4-dicarboxylic acid (III) (7.7 g, 16%), mp 173°C (dec). IR (Nujol): 3300, 1720, 1620, 1015, 765 cm^{-1}.

Found: C, 44.98; H, 3.19%. Calcd for $C_7H_6O_6$: C, 45.17; H, 3.25%.

2-Acetoxymethylfuran-3,4-dicarboxylic Acid (IV). A mixture of 2-hydroxymethylfuran-3,4-dicarboxylic acid (20 g, 0.11 mol), acetic anhydride (40 ml) and pyridine (80 ml) was stirred for 10 min until disolution was complete. After the increase in temperature of the solution stopped, the solution was gradually heated and kept at about 100°C for 4 hr. The crystalline product obtained after the reaction mixture had been cooled was collected and dissolved in water (100 ml). The solution was acidified with concentrated hydrochloric acid to precipitate crude product. Recrystallization from ethyl acetate gave 2-acetoxymethylfuran-3,4-dicarboxylic acid (IV) (12.5 g, 51%), mp 156.5—157°C. IR (Nujol): 1725, 1200, 1050, 770 cm^{-1}.

Found: C, 47.22; H, 3.53%. Calcd for $C_9H_8O_7$: C, 47.38; H, 3.53%.

2-Acetoxymethylfuran-3,4-dicarbonyl Chloride (V). A mixture of 2-acetoxymethylfuran-3,4-dicarboxylic acid (IV) (4 g, 0.018 mol) and thionyl chloride (10 ml) was heated under reflux for 1 hr. After evaporating excess of thionyl chloride, distillation of the residual oil afforded 2-acetoxymethylfuran-3,4-dicarbonyl chloride (V) (4.4 g, 95%) bp 128°C/1 mmHg. IR (neat): 1750—1790, 1600, 1220, 750 cm^{-1}.

Found: Cl, 25.77%. Calcd for $C_9H_6O_5Cl_2$: Cl, 26.75%.

α,β-Dehydro-α,β-dicarbethoxyamino-γ-valerolactone (VII,a). To a solution of sodium azide (2.2 g, 0.034 mol) in water (10 ml), which was cooled with ice-salt bath, was added a solution of 2-acetoxymethylfuran-3,4-dicarbonyl chloride (V) (4.4 g, 0.017 mol) in anhydrous ether (20 ml) during 30 min with vigorous stirring. The reaction mixture was then stirred for an additional 3 hr at below 0°C. The ethereal layer was washed well with cooled saturated sodium bicarbonate solution and cooled water, and dried over anhydrous magnesium sulfate. Ether was removed under reduced pressure at room temperature. Crude acyl azide (VI) (5.3 g) thus obtained was dissolved in ethanol (20 ml), and the ethanol solution was heated gradually under nitrogen atmosphere. After the first vigorous evolution of gas ceased, the reaction mixture was refluxed for an additional 2 hr. Ethanol was removed under reduced pressure and residual oil was subjected to column chromatography on silica gel (Kieselgel, 0.02—0.5 mm, 50 g). The fraction eluted with carbon tetrachloride-chloroform (1:1, 600 ml) afforded 1.3 g of crude product. Recrystallization from methanol gave α,β-dehydro-α,β-dicarbethoxyamino-γ-valerolactone (VII,a) (710 mg, 16%) mp 120—121°C. IR (Nujol): 3350, 3100, 1780, 1740, 1690, 1570, 1270, 1190, 1050 cm^{-1}. NMR ($CDCl_3$): δ 1.30 (6H, t), 1.55 (3H, d, J=6.5 Hz), 4.21, 4.23 (4H,q,q), 5.70 (1H,q, J=6.5 Hz) UV: λ_{max}^{EtOH} 267.5 mμ (ε=15.500).

Found: C, 48.45; H, 5.85; N, 10.26%; mol wt (Rast), 268. Calcd for $C_{11}H_{16}O_6N_2$: C, 48.52; H, 5.92; N, 10.29%; mol wt, 272.

α,β-Dehydro-α,β-dicarbobenzyloxyamino-γ-valerolactone (VII,b). The crude acyl azide (VI), prepared from 2-acetoxye methylfuran-3,4-dicarboxylic acid (4.5 g, 0.017 mol) by the same procedure as described above, was heated under reflux with benzyl alcohol (3.9 g, 0.036 mol) in benzene (20 ml) for 2.5 hr. After evaporating benzene, the residual oil was subjected to column chromatography on silica gel (Kieselgel, 0.02—0.5 mm, 50 g). The fraction eluted with chloroform-carbon tetrachloride (1:1, 300 ml) afforded α,β-dehydro-α,β-dicarbobenzyloxyamino-γ-valerolactone (VII, b) (770 mg, 11%) mp 115—116°C (recrystallized from methanol). IR (Nujol): 3350, 1750, 1735, 1700, 1570, 1270, 1190, 1030 cm^{-1}. NMR ($CDCl_3$): δ 1.50 (3H,d, J=6 Hz), 5.17 (4H, s), 5.70 (1H,d, J=6 Hz), 7.35 (10H, s).

Found: C, 63.71; H, 5.14; N, 7.08%. Calcd for $C_{21}H_{20}O_6N_2$: C, 63.63; H, 5.09; N, 7.07%.

Deuteron Quadrupole Interactions in Two Modifications of Oxalic Acid Dihydrate Crystal

Takehiko CHIBA and Gen SODA*

Department of Chemistry, Nihon University, Sakurajosui, Setagaya-ku, Tokyo

**Department of Physical Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka*

(Received December 21, 1970)

A brief account has been previously published of the deuteron quadrupole interactions in the α and β modifications of the deuterated oxalic acid dihydrate crystal, $C_2O_4D_2 \cdot 2D_2O$, in relation to their structures.[1] In this note, the details of the results of deuteron magnetic resonance and a discussion with reference to the structures, as determined by recent extensive diffraction studies,[2] will be given.

As is to be expected from the similarities in their structures, the deuteron resonance spectra of the α-form have features similar to those of the β-form, which have been measured previously.[3] The water deuterons showed spectra characteristic of a 180°-flip motion of D_2O: lines of stationary deuterons at low temperatures, fast-motion-averaged lines at high temperatures, and broadened-out lines in the intermediate temperature range. The values of the deuteron quadrupole coupling (eqQ/h), the asymmetry parameter (η), and the direction cosines of the principal axes of the field gradient tensors are listed in Table 1[4] ($|q_{zz}| \geq |q_{yy}| \geq |q_{xx}|$ assumed). The values listed for the β-form are those revised by the computor processing[5] of the previous experimental results[3] by including some additional new data.

The two empirical relations[1,5] that 1) the z principal axis is in the bond direction, and that 2) the y principal axis is perpendicular to the plane formed by the D–X–Y, are examined. In view of the structure determined by the neutron diffraction studies,[2] as is shown in Table 2, the deviation angles from these relations, θ_z and θ_y, are within the range usually found, namely, $\theta_z \lesssim 3°$ and $\theta_y \lesssim 10°$, providing other evidence of the usefulness of determining bond directions from the deuteron resonance.

The eqQ *vs.* r(O···O) (the hydrogen bond length)-plot generally fits well to the smooth curve relation

previously presented (Fig. 1).[3,5,6] Small systematic deviations for the water deuterons need to be mentioned, however. The D_3^α and D_2^β points above the curve of the eqQ *vs.* r(O···O)-plot are from bent hydrogen bonds (156° and 157°), while the D_2^α and D_3^β points are from nearly straight hydrogen bonds (168° and 170°). The fitting to a smooth curve is perfect if eqQ is plotted against r(O···O), as in Fig. 1. This seems reasonable because, in a weak hydrogen bond, the strength of the bond must primarily be determined by the electrostatic interaction between the H and the hydrogen-bond-acceptor atom. This is also consistent with the good correlation of eqQ-r(O···D) as given in the form of an empirical equation.[5] The O–D distance, which reflects the hydrogen bond strength, should have primary importance in determining the eqQ. The correlation between eqQ and r(O–D) is, however, not very satisfactory (Fig. 1), (see also Fig. 5 of Ref. 7).

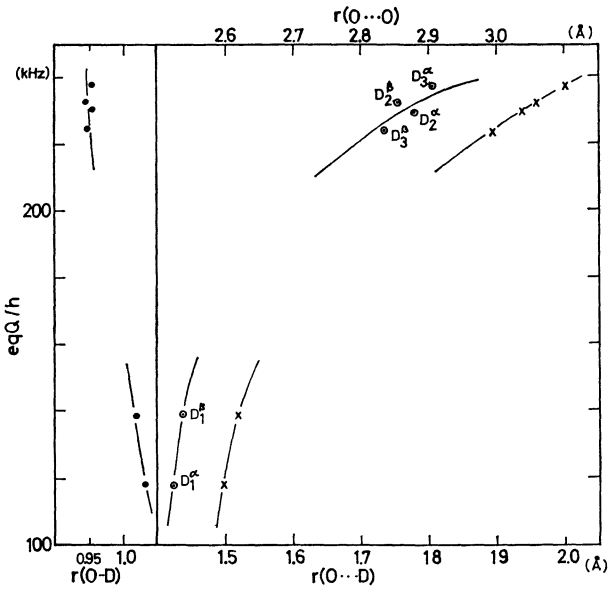

Fig. 1. Deuteron quadrupole coupling values in α- and β-$C_2O_4D_2 \cdot 2D_2O$ plotted against r(O...O) (⊙), r(O...D) (×), and r(O–D) (●).

The dependence of the eqQ on the r(O···O) or on r(O···D) is so apparent that it seems reasonable to ascribe the origin of the marked positive temperature dependence of the eqQ of the D_1^α to the temperature variation of the r(O···O) or r(O···D). If the r(O···O) dependence of eqQ is estimated from a comparison of the D_1^α and D_1^β data at room temperature, an increase in the eqQ of D_1^α from 107.1 kHz at 191°K to 118.0 kHz at 298°K must be caused by the 0.008 Å increase in the r(O···O). The maximum thermal expansion in the *ac* plane of the α-form crystal is reported to be in the direction nearly parallel to the O–D_1···O and O–D_3···O, with a coefficient of 0.0114 for a 90—290°K change.[8] This amounts to a lengthening of 0.079 Å for each pair of O–D_1···O and O–D_3···O bonds if we assume this expansion to be shared by these two hydrogen-bond systems. Actually, the expansion is accompanied by the deformation of various parts, and the fraction shared by the O–D_1···O bond is not known, but the increase in the O–D_1···O length by 0.008 Å from 191° to 298°K is small enough to be well explained by the thermal expansion.

The large amplitudes of a torsional oscillation approximately perpendicular to the plane of the oxalic acid molecule and a translational oscillation about the axis approximately parallel to the C–C bond were concluded to exist in these crystals from the large thermal parameters observed in the structure analyses.[2] This may be another possible cause of the positive temperature dependence of eqQ. These oscillations force the OD_1 group to oscillate in the direction perpendicular to the O–D_1···O bond, thus tending to increase the average D_1···O separation. The total mean-square amplitude at room temperature of these two oscillations for the OD_1 group is 0.060 Å^2 ((0.24 Å)^2). As a rough estimate, if these oscillation frequencies are assumed to be less than 50 cm^{-1}, a decrease in the average D···O distance by more than 0.0067 Å can be expected for a 298° to 191° K change. The assumed frequency range may not be unreasonable for the type of oscillations considered here, and this mechanism can explain most of the required change in the D···O distance. Other effects, such as the bending vibration of the OD bond, which lead to a (normal) negative temperature variation of the eqQ may also be present, and the observed temperature dependence of eqQ is actually a sum of various contributions.

A similar but smaller positive temperature dependence of eqQ for acid deuteron is observed for the β-form crystal (5.7 kHz for −70°—67°C) and in potassium binoxalate, KDC_2O_4 (6.1 kHz for −37.3°—137.7°C).[7] These phenomena may also be due to the mechanisms of the types considered above. For deuterons in weaker hydrogen bonds, the lengthening of the hydrogen-bond distance by thermal expansion or by oscillation makes a smaller contribution to the temperature dependence of eqQ. This is probably the reason why temperature dependence of the eqQ of water deuterons can often be well explained by the simple Bayer theory.[9,10]

A change in the strength of the O–D···O bond indicated by the positive temperature dependence of eqQ would imply a decrease in the OH vibration frequency with the temperature. In this respect, the

6) The correlation of the eqQ values of water deuterons for reduction by a torsional motion, as in Fig. 5 of Ref. 3, is not made.

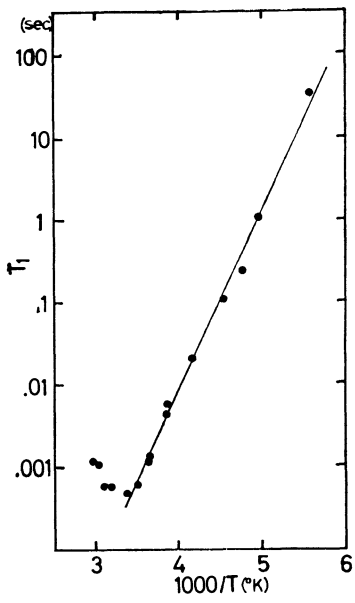

Fig. 2. Temperature dependence of T_1 of water deuterons in α-form $C_2O_4D_2 \cdot 2D_2O$.

temperature dependence of the vibration spectra in these crystals is of interest.

Because data on the line-width change with the temperature in the α-form crystal were rather poor, we estimated the barrier height of the flip motion of the D_2O to be 9.7 kcal/mol from the temperature dependence of the spin-lattice relaxation time, T_1 (Fig. 2.) This value is less than 10.7 kcal/mol (a revised value of the previous measurement[3,11]) for the β-form; this is consistent with the fact[5] that the hydrogen bonds linking the water molecule are slightly longer in the α-form than in the β-form.

Experimental

The α-form $C_2O_4D_2 \cdot 2D_2O$ crystals were grown from a saturated solution, whose deuterium content was controlled to about 90%, by gradual cooling. The angular dependence of the quadrupole splittings when the magnetic field was rotated about the *a*, *b*, and *c** axes was measured at various temperatures; the quadrupole coupling tensors were then determined by the method described previously.[5] The T_1 of D was measured by the pulse method using the 180°—90° pulse sequences at 10 MHz.[11] The magnetic field was applied in a direction (nearly parallel to the *c* axis) on the *ac* plane where quadrupole splittings of the water deuterons are sufficiently small to give a single-valued T_1. In this setting, D_1 lines are about 40 kHz apart and need not be considered.

The measurement of the deuteron resonance and the computor analysis of the data were done at the Institute for Solid State Physics, The University of Tokyo. We wish to thank Professor Y. Kakiuchi of the Institute for his interest in this work and for providing the facilities. We also wish to thank Messrs. A. Suetaka and T. Kataoka for their assistance in the experiment.

Enthalpy of Vaporization of Some Organic Substances at 25.0°C and Test of Calorimeter

Kazuhito KUSANO and Ingemar WADSÖ*

Faculty of Engineering, Miyazaki University, Miyazaki

**Thermochemistry Laboratory, University of Lund, Chemical Center, Lund, Sweden*

(Received December 21, 1970)

In the course of the calibration of ebulliometers at around 200°C, some recommended standard substances,[1] such as aniline, methyl benzoate, and nitrobenzene, were carefully purified. For these compounds, no calorimetric data of the enthalpy of vaporization (ΔH_v) at 25.0°C have been found in the literature. On the other hand, there is some doubt whether or not it is possible to measure the ΔH_v for compounds having such a high boiling temperature by means of a calorimeter which is constructed so as to pass an inert carrier gas through its cavities in order to evaporate the substance.

An attempt was made to examine the possibilities of determining the ΔH_v-values for these low-vapor-pressure compounds and, if possible, to compare the ΔH_v-values with those calculated from their vapor pressure–temperature relations.

Experimental

Materials. Aniline, methyl benzoate, nitrobenzene, and diethylene glycol diethyl ether were employed in this investigation. All of these compounds were obtained from commercial sources and were of a puris grade (B.D.H.). Prior to the purifications, diethylene glycol diethyl ether was dried over metallic sodium,[2] whereas the standard substances were treated by shaking them over molecular sieves (4A). The compounds were purified by repeated fractional distillations under a regulated reduced pressure so as to distil the compounds at around 100°C. The best fractions collected

were dried again over the respective desiccant and then distilled into dried 5-m*l* glass ampoules placed in a small Brühl apparatus containing Drierite on its bottom. The ampoules filled with the substances were flushed with dry nitrogen and then sealed. The purity of the samples, judged by glc, was, in all cases, shown to be 99.9 mol% or better; besides, the water content, also analysed by glc,[3] was estimated to be less than 0.015 wt%. Some physical properties of these compounds are listed in Table 1.

Calorimeter and Calorimetric Procedures. Main part of the calorimeter is made up of a hollow cylindrical silver vessel. Details of the construction of the calorimeter and of the calorimetric procedures have been described elsewhere.[16-18]

In the course of the experimental determinations of methyl benzoate and aniline, the electrical energy supplied to the calorimeter and/or the evaporation time has been altered in order to determine whether or not the ΔH_v-values observed are affected by such experimental conditions. However, the influence of neither the electrical energy nor the evaporation time was observed in any cases, as may be seen in Table 2.

Results and Discussion

The results of the calorimetric determinations are summarised in Table 2. Since the uncertainties accompanying the average values of ΔH_v, given by the standard deviations, are found to be less than 40 J/mol, the reproducibility of each experimental run is considered to be quite satisfactory. However, in the present cases, since the correction terms,[16-18] most of which consist of an zero-effect correction which is estimated to contain a error of more than 10% in itself, amount to several hundred joules at the highest, the uncertainty caused by the correction terms serves to decrease the accuracy of each observed ΔH_v-value. In addition to this, since some systematic errors decrease the accuracy, it is advisable to round the last significant figures in each average ΔH_v-value.

The observed ΔH_v-values for methyl benzoate and for nitrobenzene gave an excellent agreement with the respective literature values compiled by Dreisbach;[15] on the contrary, for aniline, a result higher than the literature value[15] by 1.55 kJ/mol was observed. The ΔH_v-values evaluated from the vapor pressure-temperature relation,[20] using data compiled by Stull,[21] gave poor agreement in all cases. No ΔH_v datum for diethylene glycol diethyl ether could be found in the literature, but that determined in this investigation is acceptable since the plot of the ΔH_v-value *versus* the normal boiling temperature falls on a point to be expected from the same relations of 1,2-dialkoxyethanes and 2-alkoxyethyl acetates[17] and of a homologous series of $C_2H_5(OCH_2)_nCH_3$.[22]

From the experimental results, it can be concluded that a calorimeter of this type can be used for the determination of the enthalpy of vaporization at 25.0°C for compounds with normal boiling temperature up to 210°C.

One of the author (K.K.) wishes to thank Mrs. Kyôko Nakahara for her kind suggestions and the Ministry of Education (Japan) for an award of a grant for an Oveseas Research Visitor (42-甲-91).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1708—1709 (1971)

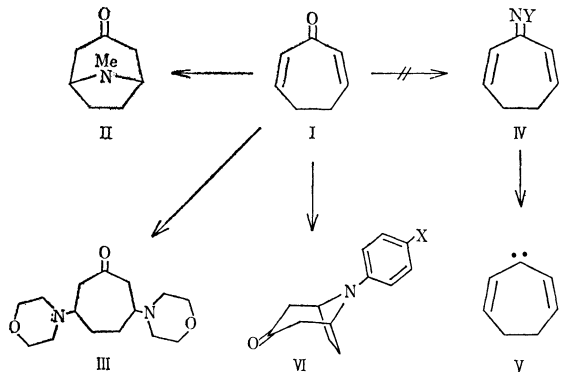
The Reaction of Cyclohepta-2,6-dienone with Amines

Toshiya SATO, Kenji SATO, and Toshio MUKAI
Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received December 22, 1970)

Cyclohepta-2,6-dienone (I) was found to react with primary amines or secondary amines to afford tropinone-type adducts (II) or a 1:2 adduct such as III in good yields. We wish to describe the results here, including those of the reactions of I with some carbonyl reagents.

First of all, we attempted to synthesize oxime (IV: Y=OH), tosylhydrazone (IV: Y=NHTs), and hydrazone (IV: Y=NH_2) in order to form cyclohepta-2,6-dienylidene (V) or its precursor, the diazo compound.[1] However, the reaction of I with the corresponding carbonyl reagents resulted in the formation of resinous products, and we failed to isolate the expected product. An inspection of the IR and NMR spectra of the products indicates the absence of the C=C bond and an olefinic proton. This means an amino group of the reagents is added to the dienone system of I. For comparison with this behavior, the reactions of other amines with I were also investigated.



Y=OH, $NHTs$, NH_2

When cyclohepta-2,6-dienone (I) was treated with aqueous methylamine in an alcoholic solution, tropinone (II) could be obtained; this had been reported by Horák who, however, identified the formation of II by paper chromatography.[2] Although this method was suggested by Robinson in 1917,[3] it is a method of preparing tropinone in addition to variant methods discovered by Robinson,[3] Willstätter,[4] Schöpf,[5] and Turro.[6] The similar reaction of I with arylamines afforded *N*-arylnortropionone derivatives (VI) in fairly good yields, which are shown in Table 1. The structure of the products could be elucidated on the basis of elemental analysis and a study of the IR, UV, and NMR spectra (see Table 1 and Experimental section). Derivatives which possess an ethyl, isopropyl, benzyl or β-hydroxyethyl group at the *N*-position were synthesized by Robinson's method,[7] whereas so far *N*-aryl derivatives have not been synthesized. Thus, the reaction of I with arylamines is a unique method for the synthesis of the *N*-arylnortropinones.

TABLE 1. *N*-ARYL DERIVATIVES OF NORTROPINONE

X in VI	Mp (°C)	Yield (%)	IR(C=O) in KBr cm^{-1}	UV in EtOH nm (log ε)	
OMe	134	93	1709	250(4.14)	308(3.20)
Me	96	68	1701	252(4.14)	293(3.17)
H	103	91	1704	250(4.14)	287(3.22)
Cl	155	73	1709	258(4.16)	300(3.18)
NO_2	202	45	1712	231(3.58)	392(4.13)

When even 1 equivalent of morpholine was reacted with I at room temperature, a 2:1 adduct (III) was formed. As expected, the yield of III was increased by the use of 2 equivalents of the amine. The structure of III was proved by elemental analysis and by a study of the spectral data (see Experimental section).

The addition reaction of cross-conjugated α,β-unsaturated ketones with amines has been known for a long time.[8] Recently, it was found that, under irradiation, alcohols and acids added to I.[9] In addition, the photochemical addition of diethylamine to cycloheptenone or cyclooctenone has also been reported.[10] However, our experiment clarified that amines added readily to the enone system of I in the dark reaction, as had been reported before.[8]

Experimental

Tropinone (II). A 40% aqueous solution of methylamine (7 g, 90 mmol) was gradually added, under ice-cooling, to a solution of I (9.73 g, 90 mmol) dissolved in ethanol (15 m*l*). After the reaction mixture had been allowed to stand at a room temperature for 2 hr, it was extracted with ether. The evaporation of the ethereal extract, followed by the distillation of the residual oil, afforded an oil (bp 79—89°C/7 mmHg, 6.9 g, 55%) which partially crystallized on standing. The recrystallization of the crystalline part from cyclohexane provided needles, mp 41—42°C, which were identical with tropinone (lit, mp 42°C).[3] It also afforded quaternary ammonium iodide, mp 266°C (lit, mp 265°C)[11] in a quantitative yield when treated with methyl iodide in acetone.

N-Arylnortropinone (VI). To a solution of I (432 mg,

4 mmol) dissolved in ether (20 m*l*), we added aniline (372 mg, 4 mmol); the resulting mixture was allowed to stand at room temperature for 3 hr, during which period some crystals deposited. Filtration, followed by recrystallization from cyclohexane, provided needles (VI: X=H), mp 103°C (444 mg). The chromatography of a benzene-solution of a non-crystallized part on an alumina column afforded needles, mp 103°C (285 mg). The combined yield was 91%. The NMR spectrum in $CDCl_3$ (60 MHz) showed τ 2.33—3.26 (5H, multiplet), 5.30 (2H, broad singlet), and 7.1—8.2 (8H, multiplet).

Other derivatives (VI: X=OMe, Me and Cl) could be obtained in a similar way, that is, by treating I with the corresponding base in an ethanolic solution. For the synthesis of the *p*-nitrophenyl derivative (VI: X=NO_2), however, it was necessary to reflux the ethanolic solution containing I and *p*-nitroaniline (each 4 mmol in 10 m*l*) for 15 hr. The results of elemental analyses of the products are shown in Table 2.

Table 2. Elemental analyses of *N*-arylnortropinones (VI)

	X=	OMe	Me	H	Cl	NO_2

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1709—1710 (1971)

Partial Molar Heats of Solution of Hydrated Electrolytes in Saturated Solutions

Haruo NAKAYAMA

Department of Chemistry, Faculty of Engineering, Yokohama National University, Ooka-machi, Minami-ku, Yokohama

(Received December 23, 1970)

Partial molar heats of solution of several hydrated electrolytes in saturated solutions ($\Delta H_s(sat) \equiv \bar{H}_2(sat) - H_2^s$) have been determined calorimetrically. From the results obtained, the following two subjects have been discussed: (1) the correlation between the values of $\Delta H_s(sat)$ and the dissolution process of hydrated electrolytes, and (2) the legitimacy of calculating a derivative $(\partial \ln \gamma_\pm / \partial \ln m)_{T,P}$ in a saturated solution from the value of $\Delta H_s(sat)$ and the temperature dependence of the solubility.

A solid sample of a hydrated electrolyte, sealed in an ampoule, was dissolved into 45 m*l* of a solvent, which consisted of an aqueous solution of the same electrolyte, the concentration of which was greater than 60% of its solubility. For each salt, $\Delta H_s(sat)$ has been obtained by extrapolating the observed heats of solution to saturation solubility. These values are listed in the second column of Table 1. They may be in error by as much as 3—4%.

Generally, for a hydrated electrolyte with the formula of $A_{\nu_+}X_{\nu_-} \cdot nH_2O$, the solubility in water, m'_{sat},[1] is expressed by the following equation:[2]

$$-\nu \boldsymbol{R} \ln\left(\frac{m'_{sat}}{m'_{sat}+M/(n+\nu)}\right) - n\boldsymbol{R} \ln\left(\frac{m'_{sat}+M/n}{m'_{sat}+M/(n+\nu)}\right) = \frac{\Delta H_s(sat)}{T} - \Delta S_m{}^F + \Delta C_p \ln\left(\frac{T_m}{T}\right) - S^E \qquad (1)$$

where $\nu = \nu_+ + \nu_-$, $\boldsymbol{R}$ is the gas constant, ΔS_m^F is the molar entropy of fusion at the melting point (T_m), ΔC_p is the difference in molar-heat capacities at a constant pressure between a liquid (fused) state and a solid state, and S^E is the entropy of mixing of a liquid (fused) electrolyte other than the cratic term (the left-hand side of Eq. (1)).

For $CaCl_2 \cdot 6H_2O$, for which all the experimental data are available,[3,4] the terms of the above equation become, at 25°C:

$$-\nu \boldsymbol{R} \ln\left(\frac{m'_{sat}}{m'_{sat}+M/(n+\nu)}\right) - n\boldsymbol{R} \ln\left(\frac{m'_{sat}+M/n}{m'_{sat}+M/(n+\nu)}\right) = 0.048\boldsymbol{R},$$

1) m' is molality suitable for a hydrated electrolyte; *i.e.*, an m′ solution of the hydrated electrolyte with a general formula $A\nu_+X\nu_- \cdot nH_2O$ contains $m'\nu_+$ moles of cation A, $m'\nu_-$ moles of anion X, and $m'n$ moles of water in 1000 g of solvent (water). Hence $m' = m/(1 - nm/M)$, where m is usual molality and $M = 55.51$.

2) H. Nakayama, *Bull. of the Faculty of Engineering, Yokoyama National University*, **19**, 29 (1970). The derivation of Eqs. (1) and (2) is briefly given in appendix.

3) "Solubilities of Inorganic and Organic Compounds," Vol. 1, ed. by H. Stephen and T. Stephen, Pergamon Press, London (1963).

4) "International Critical Tables of Numerical Data, Physics, Chemistry and Technology," McGraw-Hill Book Comp., New York (1928).

$\Delta H_s(sat)/T=15.16\boldsymbol{R}$ (this work, Table 1), $\Delta S_m^E=14.81\,\boldsymbol{R}$, $\Delta C_p\ln(T_m/T)=0.41\boldsymbol{R}$; consequently, from Eq. (1), $S^E=0.71\,\boldsymbol{R}$. A notable feature of this example is that the terms having significant values are $\Delta H_s(sat)/T$ (entropy of solution in a saturated solution) and ΔS_m^E, and that these two terms are of approximately the same magnitude. This situation is typical of aqueous solutions of hydrated electrolytes for the following reasons.

Thermodynamically, the dissolution of a solid solute may be divided into two processes: (1) the melting of a solid solute, and (2) the mixing of the melt with a solvent. In the case of an aqueous solution of a hydrated electrolyte, the change in entropy (and also in enthalpy) due to the latter mixing process will be small since the melt of a hydrated electrolyte already contains considerable amounts of water.[5] The $\Delta C_p\ln(T_m/T)$ term in Eq. (1) will also be small because of the low melting point of the hydrated electrolyte. Consequently, it may be concluded that the dissolution process of a hydrated electrolyte is essentially specified by the melting process of a solid state.

On the other hand, $\Delta H_s(sat)$ is connected with the temperature dependence of the solubility $(\partial\ln m'_{sat}/\partial(1/T))_P$ by the following equation:[2]

$$\Delta H_s(sat) = -\nu\boldsymbol{R}\left(1-\frac{nm_{sat}}{M}\right)^2 \times\left(1+\left(\frac{\partial\ln\gamma_\pm}{\partial\ln m}\right)_{sat,T,P}\right)\cdot\left(\frac{\partial\ln m'_{sat}}{\partial(1/T)}\right)_P, \quad (2)$$

where $\gamma_\pm$ is the mean activity coefficient based on the m unit. From this relation, we may expect that the derivative $(\partial\ln\gamma_\pm/\partial\ln m)_{T,P}$ in a saturated solution can be calculated from the thermal data $(\Delta H_s(sat)$ and $(\partial\ln m'_{sat}/\partial(1/T))_P)$ only. In Table 1, the values of $(\partial\ln\gamma_\pm/\partial\ln m)_{sat,T,P}$ obtained in this procedure are compared with those obtained by the graphical differentiation of the existing $\gamma_\pm - m$ data. They are in good agreement within the limits of experimental accuracy. This proposed method may also be applied to other electrolytes.

Experimental

The calorimeter used was a twin-type micro-calorimeter manufactured by Ōyōdenki Kenkyujo (CM-502). The hydrated electrolytes, which were separated from their saturated solutions at 25°C, were left in an atmosphere of a constant vapor pressure of water (the dissociation pressure of each salt) until no more change in weight was observed.

Appendix

If we choose the pure liquid (fused) state as the standard state, the activity of a solid solute, a_2^s, may be given by the following equation:[6]

$$\boldsymbol{RT}\cdot\ln a_2^s = -\Delta H_m^F(1-T/T_m) + \Delta C_p(T_m-T-T\cdot\ln(T_m/T)). \quad (A\text{-}1)$$

On the other hand, when a solid solute is in equilibrium with its saturated solution, $\boldsymbol{RT}\cdot\ln a_2^s$ can be expressed as:

$$\boldsymbol{RT}\cdot\ln a_2^s = (\bar{H}_2(sat)-H_2^l) - T(\bar{S}_2(sat)-S_2^l), \quad (A\text{-}2)$$

Table 1. The partial molar heats of solution of hydrated electrolytes in saturated solutions at 25°C. And the comparison of the values of $(\partial\ln\gamma_\pm/\partial\ln m)_{sat,T,P}$ calculated from thermal data and those observed directly

Electrolytes	ΔH_s (sat) (kcal/mol)	$(\partial\ln\gamma_\pm/\partial\ln m)_{sat,T,P}$ Calcd from Eq. (2)[a]	Observed[b]
$BaCl_2\cdot2H_2O$	4.35	+0.30	+0.39[7]
$NaBr\cdot2H_2O$	3.15	+0.78	+0.62[8]
$MgCl_2\cdot6H_2O$	2.85	+5.50	+5.02[9]
$CaCl_2\cdot6H_2O$	8.98	+2.42	+2.55[10]
$Na_2SO_4\cdot10H_2O$	14.90	−0.40	−0.40[11]

a) The slope $(\partial\ln m'_{sat}/\partial(1/T))_P$ is obtained by graphical differentiation of the solubility data.[3]
b) The values obtained by graphical differentiation using $\gamma_\pm$ data cited.

where the superscript l stands for a liquid state. We may rewrite the enthalpy term of Eq. (A-2) as:[6]

$$\bar{H}_2(sat)-H_2^l = (\bar{H}_2(sat)-H_2^s)-\Delta H_m^F+\Delta C_P(T_m-T) = \Delta H_s(sat)-\Delta H_m^F+\Delta C_P(T_m-T). \quad (A\text{-}3)$$

The entropy term of Eq. (A-2) can be expressed as:

$$\bar{S}_2(sat)-S_2^l = -\boldsymbol{R}\left\{\nu_+\ln\left(\frac{X_+^{sat}}{X_+^l}\right)+\nu_-\ln\left(\frac{X_-^{sat}}{X_-^l}\right)+n\ln\left(\frac{X_{H_2O}^{sat}}{X_{H_2O}^l}\right)\right\}+S^E, \quad (A\text{-}4)$$

with

$$X_+^{sat}=\frac{\nu_+m'_{sat}}{M+m'_{sat}(n+\nu)},\quad X_+^l=\frac{\nu_+}{n+\nu},$$

$$X_-^{sat}=\frac{\nu_-'m_{sat}}{M+m'_{sat}(n+\nu)},\quad X_-^l=\frac{\nu_-}{n+\nu},$$

$$X_{H_2O}^{sat}=\frac{M+nm'_{sat}}{M+m'_{sat}(n+\nu)},\quad X_{H_2O}^l=\frac{n}{n+\nu},$$

where X^{sat} and X^l represent the mole fraction in a saturated solution and in a liquid (fused) state respectively. By combining these four equations, we finally get Eq. (1).

The entropy of solution of a solid solute is connected with the temperature dependence of the solubility by the following equation:[6]

$$\bar{S}_2(m')-S_2^s=\left(\frac{\partial(\mu_2(m')-\mu_2^s)}{\partial\ln m'}\right)_{T,P}\cdot\left(\frac{\partial\ln m'_{sat}}{\partial T}\right)_P. \quad (A\text{-}5)$$

The chemical potential of a hydrated electrolyte ($A\nu_+X\nu_-\cdot n H_2O$) becomes:

$$\mu_2(m')=\mu^{0'}(T,P)+\boldsymbol{RT}\ln(m\gamma_\pm)+n\boldsymbol{RT}\ln a_1, \quad (A\text{-}6)$$

in which a_1 is the activity of water. By inserting Eq. (A-6) into Eq. (A-5) and using the Gibbs-Duhem relation, $M\mathrm{d}\ln a_1+m\mathrm{d}\ln a_2=0$, we obtain for a saturated solution:

$$\bar{S}_2(sat)-S_2^s=\nu\boldsymbol{RT}\left(1-\frac{nm_{sat}}{M}\right)^2\cdot\left\{1+\left(\frac{\partial\ln\gamma_\pm}{\partial\ln m}\right)_{sat,T,P}\right\}\times\left(\frac{\partial\ln m'_{sat}}{\partial T}\right)_P. \quad (A\text{-}7)$$

This equation is identical with Eq. (2), since $\Delta H_s\,(sat)=T(\bar{S}_2(sat)-S_2^s)$.

5) For instance, for $CaCl_2\cdot6H_2O$ the water content is 49.3% in the melt and 54.7% in the saturated solution (at 25°C).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1711—1712 (1971)

The Chemical Behavior of the ^{72}As Formed by the EC Decay of ^{72}Se in an Organic Solvent

Takeshi SOTOBAYASHI, Toshio SUZUKI, and Tomohiko NODA
Department of Chemistry, Faculty of Science, University of Niigata, Niigata

(Received December 24, 1970)

Many papers have been published on the chemistry of a hot atom formed as a result of isomeric transition with internal conversion or negative beta decay.[1-6] Since, however, little information is available on the chemical behavior of an EC-decay product, we attempted to study the chemical behavior of 26-h ^{72}As, an EC-decay product of 8.4-d ^{72}Se, in an organic solvent. In the present work, some organic-solvent solutions of two selenium compounds of different chemical natures (selenocyanate complex and selenium tetrabromide) were prepared by a liquid-liquid extraction method, and the separation of ^{72}As from the solvent solution and the oxidation state of the separated ^{72}As were studied.

TABLE 1. THE NUCLEAR PROPERTIES OF ^{72}As AND PROTON-INDUCED SELENIUM ISOTOPES

Type of production	Nuclide	Half-life	Mode of decay	Major γ-radiations (keV)
—	^{72}As	26 h	EC, β^+	510, 835
p,4n	^{72}Se	8.4d	EC	46
p,3n	^{73}Se	42m, 7.1m	EC	359, 685
p,2n	^{74}Se	stable	—	—
p, n	^{75}Se	120 d	EC	120, 136, 265, 280, 401

An arsenic trioxide target was irradiated with 30-MeV protons in the frequency-modulated cyclotron of the Institute for Nuclear Study of the University of Tokyo. Table 1 shows the nuclear properties of ^{72}As and proton-induced selenium isotopes. The ^{72}Se and ^{75}Se were γ-spectrometrically identified in the target two weeks after the irradiation. The target was dissolved in 6M hydrochloric acid, together with a selenium carrier (SeO_2). Elemental selenium was precipitated by passing sulfur dioxide through the target solution. The precipitate was separately dissolved in 0.1M potassium cyanide and 4M hydrobromic acid, and then converted into potassium selenocyanate and selenium tetrabromide respectively. From these two radioselenium solutions (0.1 mg Se/m*l*), two kinds of organic solutions of purified radioselenium were prepared by the following two procedures. All the radioactivities were γ-spectrometrically measured by using a 3 in $\times$3 in NaI(Tl) scintillation detector coupled with an 800-channel pulse-height analyzer.

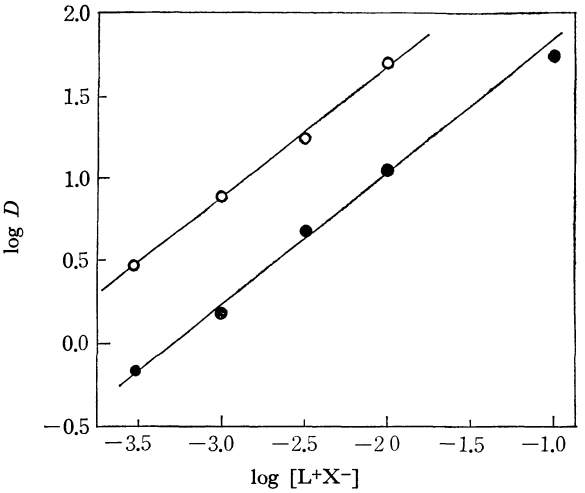

Fig. 1. log D *vs.* log (L^+X^-) plot.
L^+X^-: TPA or TAMA,
—●—: Extraction of $Se^{72,75}$ with TPA in chloroform,
—○—: Extraction of $Se^{72,75}$ with TAMA in chloroform.

First, radioselenium was extracted from the 0.1M potassim cyanide solution into a chloroform solution of 0.01—0.001M tetraphenylarsonium chloride (TPA) or 0.1—0.01M trialkylmethylammonium chloride (TAMA),[7] which had been pre-equilibrated with a 0.1M potassium cyanide solution. Figure 1 shows the extraction behavior of radioselenium with TPA or TAMA in chloroform; the logarithm of the distribution ratio, (D), is plotted against that of the concentration of the extracting reagent (TPA or TAMA). These log-log plots, with an equal slope of about 0.82, suggest that the extracted species with TPA and TAMA were, as expected, $Ph_4As^+SeCN^-$ and $R_3MeN^+SeCN^-$ [7] respectively. Secondly, radioselenium was quantitatively extracted into benzene containing 1 *w*/*v* % phenol from a 4M hydrobromic acid solution. The chemical form of the extracted selenium species is believed to be $SeBr_4$.[8] These two sample solutions (chloroform and benzene) were allowed to stand in a glass vessel for more than one day to obtain a sufficient amount of ^{72}As growing from ^{72}Se. Thereafter, each organic solution was transferred to a second vessel. The inner walls of the emptied vessel were carefully washed with a small portion of the respective solvent

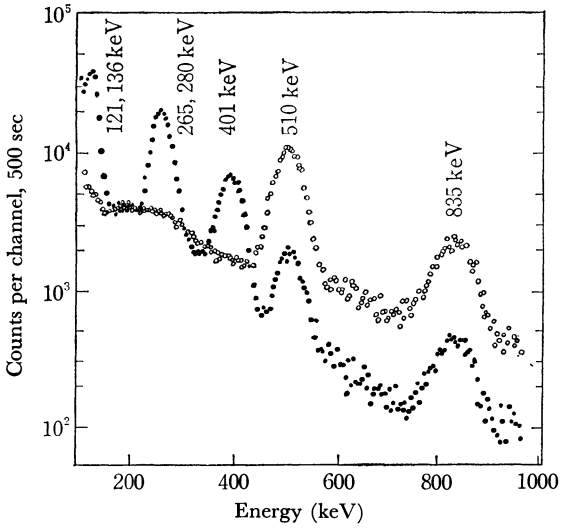

Fig. 2. A set of γ-spectra for an organic phase (TPA, —●—) and its corresponding hydrochloric acid solution containing the deposited fraction of ^{72}As (—○—).

solution, and subsequently with a few milliliters of concentrated hydrochloric acid.

Figure 2 shows the set of γ-spectra for organic and aqueous solutions in the 110– to 1000-keV range. As is shown in Fig. 2, most of the radioselenium proved to remain in the organic solution. Most ^{72}As freshly growing from its parent during equilibration was found in the hydrochloric acid — on the vessel walls. The respective activity fractions of ^{72}As on the walls and in the organic solution were determined by measuring the photopeak areas at 835 keV. The results are summarized in the third column of Table 2.

It should be noted that ^{72}As showed a similar depositing behavior on the vessel walls for the two extracted selenium compounds of different chemical natures. The deposited fraction of ^{72}As seems to decrease with the increase in the concentration of the complexing reagent (TPA). Further, it was found that the fraction of ^{72}As on the walls varied with the ratio of the area in contact with the organic solution to the total volume of the organic solution; the ^{72}As fraction on the walls increased by a factor of 1.5 when the ratio changed from 3.8 to 7.4 cm^2/m*l*. A further examination was carried out in order to determine the percentage abundances in the oxidation state of the deposited ^{72}As obtained in the same way as in the above experiments. As^{3+} and As^{5+} were separated by a conventional hydrochloric acid-benzene extraction method.[9] The results are presented in the last column of Table 2. It may clearly be seen from Table 2 that about 75% of the ^{72}As recovered on the walls existed in the 3+ oxidation state, regardless of the difference in chemical nature of the extracted selenium compound.

Table 2. Deposited fraction of ^{72}As on vessel walls and oxidation state of deposited ^{72}As

Extracting reagent	Aqueous phase	Fraction on vessel walls of ^{72}As (%)	Relative abundance As^{3+} (%)	Relative abundance As^{5+} (%)
TPA, 10^{-3}M	0.1M KCN	81—90	73	27
TPA, 10^{-2}M	0.1M KCN	41—56	75	25
TAMA, $2\cdot10^{-2}$M	0.1M KCN	53	73	27
Benzene[a)]	4M HBr	64—77	78	22

a) The benzene phase contained 1 *w/v* % phenol.

From the present observations, it can be said that the effects of an EC decay process, followed by the bond rupture of the ^{72}Se-tagged compounds, probably play a major role in determining the deposition behavior of ^{72}As.

The authors wish to express their appreciation to Prof. Kazumasa Miyano of the Nuclear Physics Laboratory for his helpful discussions.

Effect of Pressure on Graphitization of Carbon. VIII. Effect of Water on the Graphitization of Carbon under High Pressure

Kanichi KAMIYA* and Michio INAGAKI

Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received December 24, 1970)

It has been reported[1-3] that the graphitization of carbon is promoted remarkably by pressurizing and that the heterogeneous graphitization, in which one domain in coke or char particle is completely graphitized and the other part remains ungraphitized, is observed under high pressure. The pyrophyllite, $Al_2O_3 \cdot 4SiO_2 \cdot H_2O$, which has been used as a pressure transmitting material, begins to be dehydrated around 400°C.[4] The water derived from pyrophyllite was found to accelerate the graphitization of carbon under pressure in the presence of calcite or

calcium carbonate.[5]

In the present work, the effect of water on graphitization of carbon under pressure was investigated by comparing results obtained in experiments of dry system in which calcined pyrophyllite was used as a pressure transmitting material and those in a wet system in which a small amount of water was added to carbon specimen.

Pressurizing of the specimen was carried out by using a piston-cylinder type vessel. The details on experimental apparatus and procedure were reported previously.[2,3] The high pressure cell arrangement used is shown in Fig. 1. In the experiments of dry system, calcined pyrophyllite disks were inserted into the artificial graphite heater (e, in Fig. 1) in place of raw pyrophyllite disks which had been used in previous works. Calcination of pyrophyllite was performed at 970°C in air. The completion of dehydration was confirmed by measuring ignition loss (about 6.2%). The mechanical strength of pyrophyllite was found to increase rapidly when calcined above 1000°C.[4] Pyrophyllite calcined at 970°C maintained the original texture, but was a little harder than the raw material. The other parts of cell arrangement were exactly the same as in the previous one. The sample used was a typical soft carbon, the polyvinyl chloride coke, PV-7, carbonized to 680°C. Heat treatment temperature of specimen (HTT) was determined from the consumed electric input-power by using the relation between temperature and consumed power established beforehand. Heat treatments were carried out at several temperatures between 1200°C and 1800°C for various residence times under 5 kbar. The carbons heat-treated under pressure showed a composite profile of (00 l) diffraction lines. The content of the graphitic component G_S was evaluated for the heat-treated carbon by the same procedure as reported in details previously.[1-3]

The variation of content of G_S with HTT for a constant residence time of 60 min is shown in Fig. 2a). In comparison with results of experiments where raw pyrophyllite disks were used in the graphite heater, the development of the component G_S with respect

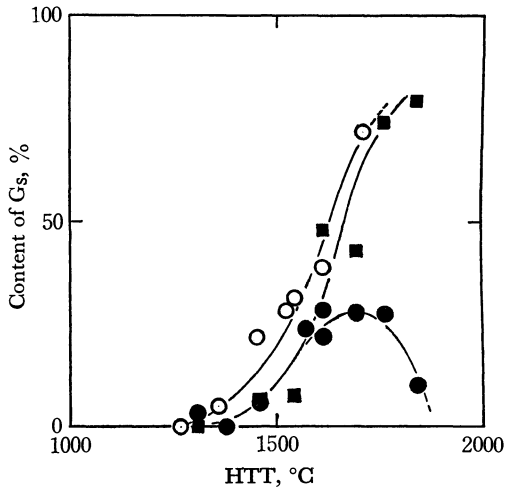

Fig. 2a. Variation of content of the component G_s with HTT for 60 min under 5 kbar.
○ with raw pyrophyllite
● with calcined pyrophyllite
■ with calcined pyrophyllite and water of 20 mg.

to HTT was found to be depressed in the present experiments where calcined pyrophyllite disks were used. Above 1700°C, content of G_S decreased with the increase in HTT. The decrease in the content of G_S was assumed to be due to the fact that, above this HTT, homogeneous graphitization occurred more easily than the heterogeneous one.[6] The variation of content of G_S with residence time at 1800°C under

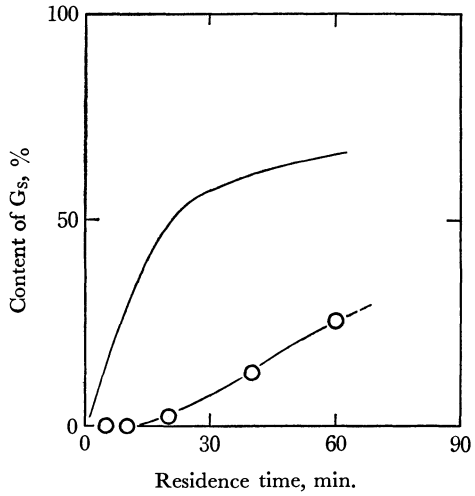

Fig. 2b. Variation of content of the component G_s with residence time at 1590°C under 5 kbar.
— with raw pyrophyllite
○ with calcined pyrophyllite

5 kbar is shown in Fig. 2b). The variation of content of G_S in the case where raw pyrophyllite has been used is also shown. It is clear that heterogeneous graphitization was depressed without any water which originated from the dehydration of pyrophyllite. Even though the pyrophyllite disks in the heater were calcined, there remains the possibility that water might

5) S. Hirano, Théses (March, 1970) Nagoya University.

6) K. Kamiya, M. Inagaki, H. Saito, and T. Noda, This Bulletin, **43**, 926 (1970).

come into the specimen through a boron nitride sleeve from the pyrophyllite cylinder surrounding the graphite heater. In order to eliminate the possibility, the whole pyrophyllite cylinder was calcined at 970°C. Since it became harder with calcination, a part of applied load may have been supported by the cylinder and the pressure in the specimen might be much lower than expected. No exact value of pressure was figured out in this case. The heterogeneous graphitization, however, seemd to occur because a small amount of the graphitic component could be detected on (004) diffraction profile.

In the experiments of wet system, distilled water of about 20 mg was added to the sample and the heat treatments were carried out by using the same pressure cell arrangement as that shown in Fig. 1. The amount of water corresponded roughly to that derived from the complete dehydration of two disks of raw pyrophyllite in the graphite heater and was about 20 weight percent of carbon specimen. Almost the same results as those with raw pyrophyllite were obtained with this arrangement as shown in Fig. 2a).

From the results, it can be said that water accelerates heterogeneous graphitization under pressure, but has nothing to do with the occurrence of heterogeneous graphitization. Heterogeneous graphitization or two-phase graphitization, was found to be possibly caused by the stress-concentration at the contacts between the coke particles.[7)]

The authors wish to thank Dr. T. Noda, president of Mie University, for his valuable discussion and perusal of the paper, and Prof. S. Naka of the Faculty of Engineering, Nagoya University, for his encouragement and valuable discussions.

The Dehydration of Alcohols to Ethers or Olefins with Triphenyl[(phenylcarbamoyl)methyl]phosphonium Inner Salt[1]

Suketaka Ito and Shigetsugu Sugiura

Department of Industial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano

(Received December 31, 1970)

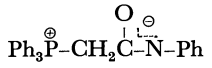
An equilibrium has been set up between benzylidenetriphenylphosphorane with alcohol and the corresponding phosphonium alkoxide, and the equilibrium mixture has been shown to undergo the Wittig reaction successfully.[2,3]

It has been reported, however, by Grayson and Keough[4] that phosphonium salts containing a benzyl group react with ethanolic sodium ethoxide (or butanolic sodium butoxide) to give toluene, ether, and tertiary phosphine oxide, and that the same products are obtained from the corresponding phosphorane and alcohol. In another report, by Speziale and Ratts,[5] dichloromethylenetriphenylphosphorane has been shown to react with *t*-butanol to afford isobutene, along with dichloromethane and phosphine oxide. In these investigations, the reactivities of other types of alcohols have not been studied.

In this paper we wish to describe the reaction of several alcohols, including a diol, and phenol with the title phosphonium inner salt.

Results and Discussion

Triphenyl[(phenylcarbamoyl)methyl]phosphonium Inner Salt (Ia). Ia could be obtained in a 80—90% yield by the treatment of triphenyl[(phenylcarbamoyl)methyl]-phosphonium chloride(VIII) with sodium hydride in benzene containing a small amount of dimethyl sulfoxide. Although Trippett and Walker[6] postulated the ylide form of Ia as the intermediate in the reaction of methylenetriphenylphosphorane with two molecules of phenyl isocyanate, the IR and the NMR spectrum of Ia exhibit no N–H peak; therefore, Ia exists in the inner salt form, that is, the betaine form, in which the negative charge can be more delocalized by resonance than in the ylide form:



Ia

Reaction of Ia with Alcohols. When Ia was allowed to react with alcohol in benzene or excess alcohol under refluxing in a slow stream of nitrogen, an ether and/or an olefin were observed as the volatile products. All the olefins except cyclohexene were allowed to be absorbed in a bromine-dichloromethane solution, and were determined as dibromides. The diethyl ether and cyclohexene were condensed in a cold trap, and the

a) The amount of sodium alkoxide was 10 percent excess to VIII.

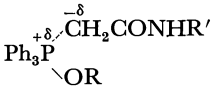
other ethers were detected directly from the reaction mixtures by means of GLC.

Acetanilide (VIa) and triphenylphosphine oxide (VII) were also obtained; for example, the yields of VIa and VII in the reaction of ethanol for 3 hr were 77 and 74% respectively.

The treatment of Ia with phenol in refluxing benzene gave acetanilide; no volatile products were observed in this case. When methanol was added to the above reaction mixture (Ia+phenol), anisole was obtained. The alcohols, the ethers, and the olefins obtained are summarized in Table 1. The reaction of alcohols with Ia can be illustrated as follows:

The final step of this reaction may be analogous to the second step of the Michaelis-Arbusov reaction. On account of the steric hindrance, the secondary and tertiary alcohols are less reactive and gave olefins exclusively in poor yields. The primary alcohols afforded ethers in fairly good yields, and those containing an eliminatable hydrogen atom in the β-position generated olefins as a by-product, whereas no ethylenic product was obtained in the reaction of ethanol or butanol with benzylidenetriphenylphosphorane.[4] The high reactivity of allyl and benzyl alcohol is reasonable and parallel with the observation in the reaction of monobromocyanoacetamide and triethyl phosphite with these alcohols.[7]

Reaction of Phosphonium Chlorides with Alcoholic Sodium Alkoxides. Table 2 shows the yields of ethers and olefins in the reactions of the corresponding phosphonium chloride (VIII) with sodium alkoxide in alcohol. The yields of ethers are higher in the reactions of VIII than in those of Ia, probably because of the relative stability of Ia in alcohol. Table 3 shows the results of the reactions of the related phosphonium salts with butanolic sodium butoxide. In Scheme 1, the driving force for the collapse of III to IV is attributed to a weakening of the P–C bond, because the negative



charge of the leaving group can be delocalized. Therefore, if the R′ of the leaving group is electron-attractive, III can probably alter to IV with ease.[8] On the other hand, the electron-attractive ability of R′ may facili-

7) T. Mukaiyama, O. Mitsunobu, and T. Obata, *J. Org. Chem.*, **30**, 101 (1965).

8) Grayson and Keough[4] observed the decreased reactivity of the unsubstituted benzyltriphenylphosphonium chloride compared to the *p*-nitro homolog and the inertness of the butyltriphenylphosphonium salt in the ether-formation reaction.

tate the abstraction of the amido proton by a base and may also cause the stabilization of I. In view of these opposite effects, it may be difficult to obtain an unequivocal relationship between the nature of the *N*-substituents of the phosphonium chlorides and their reactivity in this reaction.

Experimental[9)]

Triphenyl[(phenylcarbamoyl)methyl]phosphonium Inner Salt (Ia). A mixture of 12.9 g (0.03 mol) of triphenyl (phenylcarbamoyl)-methyl phosphonium chloride(VIII) and 80 m*l* of dry benzene was refluxed under a nitrogen atmosphere for 2 hr with 1.1 g (0.033 mol) of dispersed sodium hydride in mineral oil (72%) and 2 g of dimethyl sulfoxide. The reaction mixture was then cooled, and a small amount of precipitates was removed by decantation. Crystallization was then induced by scratching the flask containing the solution. After standing for 2 hr, the resulting crystalline precipitate was filtered, washed with two 10-m*l* portions of benzene, and dried *in vacuo*. The yield of Ia was 10.4 g (87%). The recrystallization of Ia from benzene gave pale yellow needles; mp 122—125°C.

Found: C, 79.11; H, 5.67; N, 3.13%; mol wt (MS), 395
Calcd for $C_{26}H_{22}NOP$: C, 78.97; H, 5.61; N, 3.54%; mol wt 395.5.

The treatment of Ia with gaseous hydrogen chloride in benzene afforded the starting quaternary phosphonium salt quantitatively.

Reaction of Ia with Ethanol.[10)] A mixture of 7.91 g (0.02 mol) of Ia and 50 m*l* of absolute ethanol was refluxed for 3 hr in a slow stream of nitrogen. In a cold trap (−70°C) connected to the reaction flask through a condenser, was condensed diethyl ether (54%), which was determined by means of GLC using a 2.25-meter polyethylene glycol-6000 column at 50°C. The reaction mixture was cooled, concentrated, and then chromatographed on 40 g of 100-mesh silica gel (2.2×30 cm; benzene-ether, and benzene-ethanol) to give 2.08 g (77%) of acetanilide(VIa, mp 114—115°C) 4.11 g (74%) of triphenylphosphine oxide(VII, mp 156—157°C). VIa (82%) could be detected also directly from the reaction mixture by means of GLC using a 2.25-meter silicone grease DC-550 column at 200°C.

Reaction of Triphenyl[(phenylcarbamoyl)methyl]phosphonium Chloride (VIII) and Related Compounds with Alcoholic Sodium Alkoxide. Phosphonium Chlorides. These compounds were prepared from triphenylphosphine (0.2 mol) and the corresponding halides (0.2 mol) by a modification of the procedure of Fuerst and his associates[11)] by treatment in refluxing ethanol (50—70 m*l*) for 3—4 hr. Yields: 80—90% (except one example). Triphenyl[(benzylcarbamoyl)methyl]phosphonium chloride: colorless prisms; mp 230—233°C; yield, 80%.

Found: C, 72.38; H, 5.78; N, 3.08%. Calcd for $C_{27}H_{25}$-NOP: C, 72.74; H, 5.65; N, 3.14%. Triphenyl[(*p*-nitrophenylcarbamoyl)methyl]phosphonium chloride: pale yellow prisms; mp 212—213°C;[12)] yield, 24%. (Found: C, 65.38; H, 4.77; N, 5.79%).

Reaction of VIII with Sodium Butoxide in Butanol.[13)] A mixture of 2.16 g (0.005 mol) of VIII and 20 m*l* of *n*-butanol containing 0.0055 mol of sodium butoxide was refluxed for 1 hr in a stream of nitrogen. The 1-butene thus generated was allowed to be absorbed in a bromine—dichloromethane solution in a trap connected to the reaction flask through a condenser. The reaction mixture was cooled, and then dibutyl ether (74%) in butanol was detected by means of GLC using a 2.25-meter silicone grease DC-550 column at 80°C.

9) Melting points are uncorrected. The yields of the products are shown in mole percentage. For the micro-analysis, a Perkin-Elmer Elemental Analyzer Model 240, and a Shimadzu Gas Chromatograph Model GC-2C for the GLC determination were employed.

10) The reactions of Ia with alcohols were represented by this example.

11) H. Fuerst, G. Wetzke, W. Berger, and W. Schubert, *J. Prakt. Chem.*, **17**, 299 (1962).

12) Fuerst *et al.*[11)] reported the melting point of this compound to be 79°C.

13) The reactions of the phosphonium chlorides with alcoholic sodium alkoxides were represented by this example.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1717 (1971)

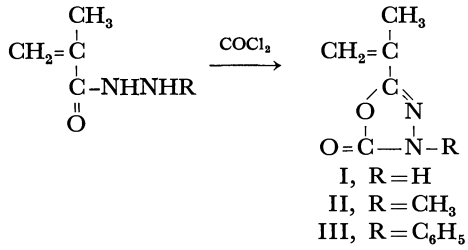
Syntheses and Reactions of Functional Polymers. LVII. Synthesis and Polymerization of Isopropenyl-1,3,4-oxadiazolin-5-ones

Takeshi ENDO, Takeshi INOUE, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

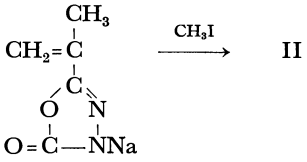
(Received January 7, 1971)

It has been reported[1] that 2-alkyl-1,3,4-oxadiazolin-5-ones are obtained by the reaction of hydrazides with phosgene, but the synthesis of 2-isopropenyl-1,3,4-oxadiazolin-5-ones is not known. We found that 2-isopropenyl-1,3,4-oxadiazolin-5-ones I-III were obtained easily by the reaction of corresponding hydrazides with phosgene.



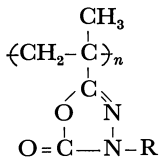
I, R=H
II, R=CH_3
III, R=C_6H_5

II was also obtained by the reaction of sodium salt of I with methyl iodide.



The structures of I-III were confirmed by IR spectrum and elementary analysis. The results are given in Table 1. IR spectra indicate three characteristic absorption bands.

Radical polymerization of I-III was carried out in bulk to give new type polymers containing oxadiazolone group in the side chain.



P-I, R=H
P-II, R=CH_3
P-III, R=C_6H_5

The results are shown in Table 2. The absorption attributable to double bond (C=C) in the polymers disappeared, and the absorption of C=N shifted to a higher wave number as compared with monomer due to the absence of conjugation with double bond (C=C). The polymers obtained were soluble in dipolar aprotic solvents such as dimethylformamide (DMF), dimethyl sulfoxide and methylpyrrolidone, but insoluble in common solvents such as water, alcohol and benzene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1718—1719 (1971)

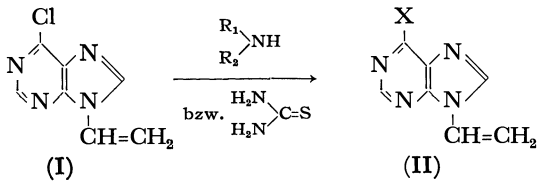
Synthese Einiger 6-Substituierten 9-Vinylpurine

Kiichi TAKEMOTO, Fumio KAWAKUBO, und Koichi KONDO

Abteilung für Petrochemie, Technische Fakultät der Universität Osaka, Suita, Osaka

(Eingegangen am 5. Februar, 1971)

Im Zusammenhang mit einer Reihe von Untersuchungen über Vinylverbindungen der Nucleinbasen[1] haben wir einige 6-substituierten 9-Vinylpurine (II) neu hergestellt. Als Homologe sind bisher 9-Vinyladenin[2,3], 9-Vinylhypoxanthin[4] und 6-Chlor-9-vinylpurin (I)[5] bekannt, und die Polymerisation sowie



(I) (II)

($R_1=R_2=CH_3$ od. C_2H_5)

die Eigenschaften der erhaltenen Polymeren wurden näher untersucht.[6] Nach einem einfacheren Prinzip stellten wir einige noch unbekannten 9-Vinylpurine ausgehend von 6-Chlor-9-vinylpurin (I) dar: 6-Dimethylamino-9-vinylpurin (II, $X=N(CH_3)_2$) wurde aus I in wäßriger Dimethylaminlösung nach 4-stündigem Rühren bei Raumtemperatur, 6-Diäthylamino-9-vinylpurin (II, $X=N(C_2H_5)_2$) wurde aus I in wäßriger Diäthylaminlösung nach 2-stündigem Rückflüß, 6-Hydrazino-9-vinylpurin (II, $X=NHNH_2$) wurde aus I in Hydrazinhydrat nach 30-minutenlangem Rühren bei Raumtemperatur, und 6-Mercapto-9-vinylpurin (II, X=SH) wurde aus I unter Einwirkung von äquimolarem Thioharnstoff in Äthanollösung nach zweistündigem Rückfluß gewonnen. IR und NMR-Spektren bestätigen die Konstitutionen der Produkte. Die Verbindungen mit Dimethylamino- sowir Diäthylaminogruppen sind in Wasser, Benzol und Alkohol löslich, und die 6-Hydrazino-9-vinylpurin ist in Wasser löslich, in Benzol und Äthanol aber sehr schwer löslich. Im Gegensatz zu diesen Vertretern ist 6-Mercapto-9-vinylpurin sowohl in Wasser als in allen gewöhnlichen Lösungsmitteln unlöslich, nur in wäßriger NaOH-Lösung aber löslich.

Unter den hergestellten Vinylpurinen lassen sich nur 6-Dimethylamino- und 6-Hydrazinoderivate unter der radikalischen Bedingung polymersieren: der Polymerisationsumsatz beträgt bei jenem Vertreter 32%, und bei diesem Vertreter wenig, wenn die Polymerisation in Dimethylsulfoxid bei 80°C in 8 Stunden in Gegenwart von 10^{-3} Mol/*l* Azobisisobuttersäuredinitril durchgeführt wird. In der gleichen Versuchsbedingung beträgt der Umsatz bei 6-Chlor-9-vinylpurin 88%. Die Polymere sind farbloses Pulver, enthalten nicht mehr Vinylgruppe, sind in allgemeinen in Wasser und Methanol löslich, in Äther aber unlöslich. Die Synthese der anderen neuen 9-Vinylpurine, sowie die Versuche über die Eigenschaften der hergestellten monomeren und polymeren 9-Vinylpurine in bezug auf ihre 6-ständigen Substituenten sind im Gange.

Beschreibung der Versuche

6-Chlor-9-vinylpurin (I). 6-Chlor-9-vinylpurin wird aus 6-Chlorpurin bei der Umsetzung mit Vinylacetat in Anwesenheit von Quecksilber(II)-salz hergestellt.[5]

6-Dimethylamino-9-vinylpurin (II, $X=N(CH_3)_2$). 0.50 g (2.8 mMol) I wird in 20 m*l* wäßr. 50%iger Dimethylaminlösung 4 Stde. bei Raumtemperatur gerührt. Die Lösung wird dann eingeengt und der Rückstand aus Petroläther umkristallisiert. Ausbeute 0.45 g (86% d. Th.), farblose Nadeln.

6-Diäthylamino-9-vinylpurin(II, $X=N(C_2H_5)_2$). 0.50 g (2.8 mMol) I wird in 20 m*l* wäßr. 50%iger Diäthylaminlösung 2 Stde. unter Rückfluß gekocht. Die Lösung wird dann eingeengt, der gebliebene Rückstand dreimal mit je

30 m*l* Äther extrahiert, und das so extrahierte Produckt nach Einengen in Wasser umgefallen. Ausbeute 1.35 g (58% d. Th.), farblose Nadeln.

6-Hydrazino-9-vinylpurin(II, X=NHNH$_2$). 0.50 g (2.8 mMol) I wird in 20 m*l* Hydrazinhydrat 30 Minuten bei Raumtemperatur gerührt. Der gebildete Niederschlag wird dann abfiltriert, und aus Wasser-Äthanol-Gemisch (1:1) umkristallisiert. Ausbeute 0.50 g (85% d.Th.), farblose Nadeln.

6-Mercapto-9-vinylpurin(II, X=SH). 0.50 g (2.8 mMol) I wird mit äquimolarer Menge Thioharnstoff in 20 m*l* Äthanol 2 Stde. gerührt. Das niedergeschlagene Produkt wird dann abfiltriert, in 1 N-NaOH-Lösung gelöst, und mit Essigsäure umgefällt. Ausbeute 0.37 g (75% d.Th.), hellgelbes amorphes Pulver.

SHORT COMMUNICATIONS

Chronopotentiometric Oxidation of Biferrocenyl in Anhydrous Acetonitrile and in Methylene Chloride[1)]

Tamotsu MATSUMOTO, Masanori SATO, and Akio ICHIMURA[2)]

Laboratory of Analytical and Inorganic Chemistry, Faculty of Textile Science, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received January 21, 1971)

It is well known from voltammetric studies that ferrocene as well as its substituted derivatives generally shows a reversible one electron oxidation wave in non-aqueous solvents.[3)] By using chronopotentiometry at the bright platinum anode, we found that biferrocenyl which consists of two equivalent ferrocenyls shows two step waves, each corresponding to one electron oxidation.

The current reversal chronopotentiograms of biferrocenyl in both solvents are shown in Figs. 1 and 2. Results of the current reversal at the first oxidation step show the oxidation proceeds reversibly in both solvents, because the ratio of transition time τ (A)/τ (A') equals 3/1, and $E_{0.25\,\tau(A)}$ equals approximately $E_{0.22\tau(A)}$. On the contrary, the second oxidation step seems completely irreversible in acetonitrile, since no reduction wave is shown by the current reversal at the second oxidation step (ABA' in Fig. 1). Nevertheless the reduction wave corresponding presumably to the reduction of the oxidized product in the case of the current reversal at the first oxidation step remains unchanged. The product at the second oxidation step is more stable in methylene chloride than in acetonitrile. As is shown in Fig. 2, the reduction wave (B') of the oxidized product at the second oxidation step appears in spite of its irreversible character. In curve ABB'A', Fig. 2, the ratio of transition times, τ(A):τ(B):τ(B'):τ(A'), is equal to 1.0:2.5:0.3:0.9, which is approximately equal to the theoretical value[4)]; 1.0:3.0:0.29:1.05.

$$\mathrm{Fc\text{-}Fc} \underset{+e}{\overset{-e}{\rightleftarrows}} \mathrm{Fc^+\text{-}Fc}, \quad (A/A') \qquad \mathrm{Fc^+\text{-}Fc} \underset{+e}{\overset{-e}{\rightleftarrows}} \mathrm{Fc^+\text{-}Fc^+}. \quad (B/B')$$

Biferrocenyl: 0.406 mmol/*l* (Fig. 1); 0.144 mmol/*l* (Fig. 2). Supporting electrolyte: 0.1M-Et_4NClO_4 (Fig. 1); 0.05M-Bu_4NClO_4 (Fig. 2).

Concerning the mechanism of the electrochemical oxidation of the biferrocenyl, it seems that in analogy to the oxidation of ferrocene derivatives each ferrocenyl group in a biferrocenyl molecule is oxidized at different potentials (Table 1). Denoting $(C_5H_5)Fe(C_5H_4)$- by Fc–, the following oxidation scheme can hold in both solvents.

$$\mathrm{Fc\text{-}Fc} - \mathrm{e} = \mathrm{Fc^+\text{-}Fc} \quad \text{(1st wave)}$$

$$\mathrm{Fc^+\text{-}Fc} - \mathrm{e} = \mathrm{Fc^+\text{-}Fc^+} \quad \text{(2nd wave)}$$

The reason for the splitting of the oxidation step can be understood by considering that for the first oxidation of one ferrocenyl group the other ferrocenyl group in a same molecule acts as an electron donating substituent group. Consequently the quarter wave potential is shifted to a more negative direction compared with that of ferrocene. Contrary to this, at the second oxidation step, the oxidized form of one ferrocenyl group acts as an electron withdrawing substituent group to the other ferrocenyl group. Thus, the characteristic potential of the second wave is shifted to the more positive potential compared with that of ferrocene. As for the second oxidation step in acetonitrile solvent, it seems that the product reacts chemically with an unoxidized biferrocenyl causing disproportionation to give Fc$^+$–Fc, which is identical with the product at the first oxidation step.

On the Composition of the Pentacyanocobaltate(I) Complex

Nobufumi MAKI and Yukio ISHIUCHI
Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu
(Received February 16, 1971)

The question of the composition and structure of the pentacyanocobaltate(I) ion formed by the reduction of pentacyano-cobaltate(II) and -cobaltate(III) complexes still remains in a controversial state in spite of a number of works done on this problem.[1] Nowadays, however, the $[Co^{I}(CN)_5H]^{3-}$ formula has been widely accepted and used as the most possible structure since Griffith and Wilkinson[2] proposed it on the basis of the proton NMR spectrum. In addition, it has already been established that the reaction between $[Co^{I}(CN)_5]^{4-}$ and H^+ can proceed in water.[3]

In the present study, the stoichiometric relation between $[Co^{I}(CN)_5]^{4-}$ and H^+ was determined to be always 2:1, suggesting a dimeric configuration of the pentacyanocobaltate(I) complex in solution. That is, the findings that both the polarographic reductions of Co(III)→Co(I) and of $2H^+ \rightarrow H_2$ can take place simultaneously at −1.75 V (*vs.* SCE) at the dropping mercury electrode (DME)[4] suggested to us the idea of employing the diffusion currents of both waves to follow the reaction between $[Co^{I}(CN)_5]^{4-}$ and H^+ by means of amperometric titrations.

The titrations of the parent complexes, $K_m[Co(X)(CN)_5]$, were carried out with 0.2 N HCl under a stream of nitrogen at the constant potential (−1.75 V) at which the current had reached a limiting plateau, indicating the formation of the $[Co^{I}(CN)_5]^{4-}$ ion at the DME, where the ligand, X, denotes the ion, $S_2O_3^{2-}$, SO_3^{2-}, N_3^-, NO_2^-, SCN^-, I^-, Br^-, or Cl^-, or the molecule, OH_2. The neutral solution to be titrated was prepared by dissolving the crystals of the complex at 10^{-2} M in a 0.5 M Na_2SO_4 solution which had been deaerated by nitrogen. As one example, Figure 1 illustrates the titration of the $[Co^{I}(CN)_5]^{4-}$ ion formed by the reduction of the $K_4[Co(S_2O_3)(CN)_5]$ complex with 0.2 N HCl. At the beginning of titration, the current remains constant while the H^+ ions are being consumed by the $[Co^{I}(CN)_5]^{4-}$ to be titrated. The end-point is indicated by the beginning of an increase in the reduction wave of H^+ ions; the new current corresponds to the reduction of excess hydrogen ions. The following reaction schemes are considered to be the most plausible:

$$2[Co^{III}(S_2O_3)(CN)_5]^{4-} \xrightarrow{2e} 2[Co^{I}(S_2O_3)(CN)_5]^{6-}$$
$$\downarrow$$
$$2[Co^{I}(CN)_5]^{4-} + 2S_2O_3^{2-}$$
$$\downarrow$$
$$[Co^{I}(CN)_5\text{-}H\text{-}Co^{I}(CN)_5]^{7-}.$$

A blank test was carried out, in advance, individually for 0.5 M Na_2SO_4, 0.01 M $Na_2S_2O_3$[5], 0.01 M NaBr[5], and so on, but a straight line without a break was obtained for each solution; the $(2H^+ \rightarrow H_2)$ current increased linearly at −1.75 V when 0.2 N HCl (0—1.5 m*l*) was added, indicating that no reaction of capturing H^+ ions takes place between them.

The sixth ligand, such as $S_2O_3^{2-}$, was confirmed by using a Kalousek commutator[6] to be released from the $[Co^{I}(X)(CN)_5]^{n-}$ ion at the DME.

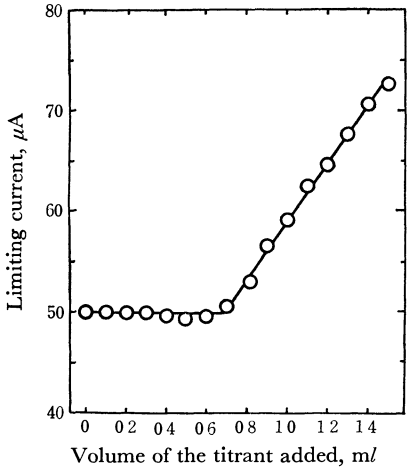

Fig. 1. Amperometric titration curve of the $[Co(S_2O_3)(CN)_5]^{4-}$ ion (35 m*l*) with 0.2N HCl (f=1.173) at −1.75 V (*vs.* SCE). The concn. of the complex: 10^{-2}M in 0.5M Na_2SO_4 (25°C).

TABLE 1. RESULTS OF AMPEROMETRIC TITRATIONS

Compound	Volume of HCl added at equiv. point m*l*	Mole of HCl consumed at equiv. point	Ratio of $[Co^{I}(CN_5)]^{4-}$/H^+ at equiv. point
$K_4[Co(S_2O_3)(CN)_5]$	0.69	1.62×10^{-4}	2.16
$K_4[Co(SO_3)(CN)_5]\cdot3H_2O$	0.70	1.64×10^{-4}	2.13
$K_3[Co(N_3)(CN)_5]\cdot2H_2O$	0.71	1.67×10^{-4}	2.11
$K_3[CoBr(CN)_5]$	0.67	1.57×10^{-4}	2.22

Table 1 summarizes some of the results. Thus, the molar ratio of the $[Co^{I}(CN)_5]^{4-}$ ion to H^+ was approximately 2:1, irrespective of the kind of the ligand, X. This result, combined with the evidence [2] of the existence of a direct linkage between the metal and H^+, suggests that the pentacyanocobaltate(I) complex takes a dimeric structure through a cobalt-hydrogen linkage, such as has been mentioned above.

Infrared Study on Interaction between Porphyrin and Divalent Metal Ion

Hisanobu Ogoshi and Zen-ichi Yoshida
Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto
(Received March 3, 1971)

In contrast to the NMR, ESR, and electronic spectra of metalloporphyrins, their infrared spectra have not been understood because of complication. Although only empirical assignment has been done for some observed infrared bands of the naturally occurring porphyrin complexes,[1,2] no systematic band assignment has been made for metalloporphyrins. However, the highly symmetrical metalloporphyrin enables us to assign some characteristic absorptions. Here we reprot the interaction between aromatic ligand and metal ion in the ground state in terms of the aromatic C–H bending vibrations.

The aromatic meso protons of porphyrins are easily exchanged with deuterium in D_2O–D_2SO_4. The band at 835 cm^{-1} of metal-free octaethylporphyrin has been assigned to the meso C–H out-of-plane bending vibration since it disappears on deuteration.[3] It was found that three absorptions for Zn(II)-octaethylporphyrin at 3110, 1220, and 836 cm^{-1} were found to disappear upon deuteration. They are assigned to the C–H stretching (ν(C–H)), in-plane bending (δ(C–H)), and out-of-plane bending (π(C–H)) vibrations, respectively. Zn(II)-octaethylporphyrin-d_4 shows three new bands at 2260, 942, and 638 cm^{-1}. Similarly the bands at 3040, 1227, and 836 cm^{-1} of Zn(II)-octamethylporphyrin are shifted to 2245, 916, and 638 cm^{-1} upon deuteration.

The δ (C–H) and π (C–H) frequencies of various divalent metal complexes of cotaethylporphyrin are listed in Table 1. The stronger coordination between aromatic ligand and metal ion results in the higher frequency shift in the order Pd>Ni>Co>Cu>Zn>Mg. The δ (C–H) frequency is more dependent on the nature of the metal ion than the π (C–H) frequency. The order of the frequency shift is similar to that of the metal sensitive vibration around 1000 cm^{-1} [1,4] and vibrations appearing in the far-infrared region.[1,5] Thus, the frequency shifts of the δ (CH) and π (CH) show clearly the effect of metal ion on aromatic ligand. The order found for the frequency shift is the same as that for the stability replacement reaction,[6] for the one electron-oxidation potential[7] and for the hypsochromic shift in electronic spectrum.[5,7] The shifts of the δ (C–H) and π (C–H) might be related to the changes of the electronic structure of the porphyrin ring. The higher electronegativity of the metal ion or the less ionic character of the metal-porphyrin bond causes the larger shift towards higher frequencies.

Table 1. Frequencies of the in-plane and out-of-plane bending vibrations of the aromatic C–H bond[a]

Complex	In-plane (cm^{-1})	Out-of-plane (cm^{-1})
Mg(II)-OEP	1217	834
Zn(II)-OEP	1220	836
Cu(II)-OEP	1223	837
Co(II)-OEP	1228	837
Ni(II)-OEP	1229	837
Pd(II)-OEP	1229	839

Pyrolysis of Allethrin

Yasuo NAKADA, Yasuo YURA, and Keisuke MURAYAMA
Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo
(Received March 11, 1971)

Pyrolyses of pyrethroidal compounds have been described by Murayama *et al.*,[1,2] but no work has been done in isolation and structure. We have obtained five compounds by pyrolysis of allethrin, the structures of which are reported in this communication.

Pyrolysis of allethrin was carried out in a pyrex glass tube at 400°C under nitrogen. A typical gas chromatograph of the reaction products is shown in Fig. 1. The reaction products were separated into two fractions and a residue by distillation.

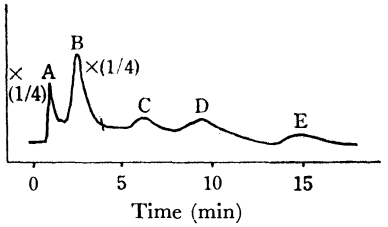

Fig. 1. Gas chromatograph of reaction products. Column: 15%-Silicone XE-60, 191°C.

The first fraction, bp 50—60/38 mmHg, corresponding to peak A, mainly consisted of one compound purified by preparative gas chromatography. Identification of this compound (I) as 2,6-dimethylhepta-2,4-diene was based on the following; *m/e* 124 (M^+) and 109 (M-15); IR, ν_{max} cm^{-1}: 2910; UV, λ_{max}^{EtOH} mμ (log ε): 238 (3.56); NMR[3]: four methyls at 9.07 (d, 3H), 8.95 (d, 3H), 8.28 (s, 3H), and 8.22 (s, 3H), a proton at 7.70 (m, 1H) and olefinic protons at 4.0—4.9 (m, 3H).

The second fraction, bp 90—120/6 mmHg, peak B, consisting of two compounds, II and III, was identified as pyrocin[4] and crysanthemic acid respectively by comparison with authentic samples.

The distillation residue, with peaks C, D, and E in Fig. 1, was separated into three compounds IV, V, and VI by column chromatography on silica gel. Identification of compound IV, corresponding to peak C, as 2,7-diallyl-3,6-dimethyl-1-indanone was based on the following; *m/e* 240 (M^+), 225 (M-15), and 199 (M-41); IR, ν_{max} cm^{-1}: 1710 and 821 (1,2,3,4-tetra-substituted phenyl); UV, λ_{max}^{EtOH} mμ (log ε): 252 (4.11) and 315 (3.44); NMR[5]: a doublet methyl at 8.64 (3H, J=3.5 Hz), a singlet methyl at 7.70 (3H), an allylic methylene as a doublet at 6.56 (2H, J=3.2 Hz), two multiplet vinyl singals at 4.8—5.2 (4H) and 4.0—4.4 (2H), and two doublet protons centered at 2.88 (1H, J=4.0 Hz) and 2.76 (1H, J=4.0 Hz) corresponding to the aromatic protons.

The mass, IR, UV, and NMR spectral data of compound V were very similar to those of compound IV; *m/e* 240 (M^+), 225, and 199; IR, ν_{max} cm^{-1}: 1718 and 830; UV, λ_{max}^{EtOH} mμ (log ε): 262 (4.15) and 293 (3.49); NMR[5]: 8.71 (d, 3H; J=3.7 Hz), 7.67 (s, 2H), 6.55 (dd, 2H; J=2.3 and 1.0 Hz), 4.8—5.3 (m, 4H), 2.88 (d, 1H; J=4.0 Hz) and 2.59 (d, 1H; J=4.0 Hz). An aromatic proton of compound V was found at a lower field than that of compound IV. Thus we concluded that compound V was 2,4-diallyl-3,5-dimethyl-1-indanone, an isomer of compound IV. Compound VI was identified as allethrin by comparison with the retention time (*glc*) and IR spectrum of an authentic sample.

We postulate the reaction mechanism for the pyrolysis of allethrin as shown in Scheme 1.

Partial Ion-Association Constant for Contact Ion-Pairs in Aqueous $[Co(NH_3)_6]^{3+}$-I^- Systems

Haruhiko YOKOYAMA and Hideo YAMATERA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received March 31, 1971)

It has been known for many years that ion-pairs can be classified into several classes with different structures and properties; partial ion-association constants for each class of ion-pairs have been reported only in rare cases.[1] Classifying the ion-pair $[Co(NH_3)_6]^{3+}I^-$ into two classes, *contact ion-pairs* and *separated ion-pairs* (those separated by *one or more* solvent molecules), we give partial ion-association constants for each class of ion-pairs.

The spectrophotometric study was made at 25.0± 0.1°C on aqueous systems of a constant ionic strength of 0.062 containing $[Co(NH_3)_6](ClO_4)_3$, KI, and $NaClO_4$. An absorption band which appears near 37 kK on the addition of iodide to an aqueous solution of hexamminecobalt(III) perchlorate is known to be due to the $[Co(NH_3)_6]^{3+}I^-$ ion-pair.[2] Except for the iodide ion (hydrated) and the metal complex ion, no other species absorb light in the wave number range of interest (30—45 kK). The absorbance, D, of the solution can thus be expressed as:

$$D = \varepsilon_M[M]+\varepsilon_A[A]+\varepsilon_{M\cdot\cdot A}[M\cdot\cdot A]+\varepsilon_{M\cdot A}[M\cdot A] \quad (1)$$

where ε symbolizes the molar extinction coefficient and where M, A, M··A, and M·A represent the metal complex ion, the anion (iodide ion), the separated ion-pair, and the contact ion-pair respectively. Equation (1) can be modified to give:

$$\Delta D = (\varepsilon_{M\cdot A(CT)}-\varepsilon_A)[M\cdot A] \quad (2)$$

with $\Delta D = D-\varepsilon_M c_M-\varepsilon_A c_A$, if the following assumptions are made: (i) $\varepsilon_{M\cdot\cdot A}=\varepsilon_M+\varepsilon_A$, and (ii) $\varepsilon_{M\cdot A}=\varepsilon_{M\cdot A(CT)}+\varepsilon_M$. The symbol c denotes the analytical concentration of each species, and $\varepsilon_{M\cdot A(CT)}$ is the molar extinction coefficient of the iodide-to-complex charge transfer absorption in the contact ion-pair. Assumption (i) is equivalent to defining the separated ion-pair as the class of ion-pairs that were not spectrophotometrically distinguished from the bulk of ions in the experiment. According to assumption (ii), iodide-to-complex charge transfer absorption occurs in the contact ion-pair in place of iodide-to-solvent charge transfer absorption, whereas the absorption due to transitions in the metal complex remains unaffected.

The values for ΔD were obtained by comparing the absorbance at each wave number of a solution containing the complex and iodide ions with those of two solutions containing each ion separately. Figure 1 shows three series of results obtained with different concentrations of the complex ion, but with the same iodide concentration. An isosbestic point exists at ν=40.7± 0.1 kK and ΔD=0. Here, $\varepsilon_{M\cdot A(CT)}$ is equal to ε_A, which was measured to be 1600± 150. This observation implies that the above-mentioned assumptions are a good approximation.

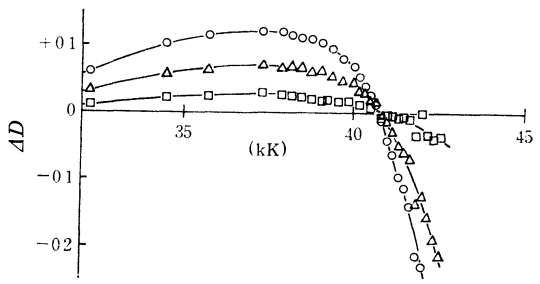

Fig. 1. ΔD for $[Co(NH_3)_6]$ $(ClO_4)_3$-KI-$NaClO_4$ solutions of ionic strength of 0.062. c_A=0.002M; c_M=0.002M(□), 0.006M(△) and 0.010M(○)

Assuming different values of [M·A] and using the observed ε_A values, we calculated $\varepsilon_{M\cdot A(CT)}$ for each wave number and drew hypothetical absorption curves. Only certain values of [M·A] within a narrow range gave absorption curves of a reasonable shape. Thus, we obtained 2300±300 for the $\varepsilon_{M\cdot A(CT)}$ value at 37.3 kK, where the charge transfer band has its maximum, and 1150± 150 at 32.3 kK, where measurements were made for the determination of the ion-association constants, as will be described below.

We define the *partial ion-association constants* for the separated and contact ion-pairs as well as the *total ion-association constant* as follows:

$$K_{sep} = \frac{[M\cdot\cdot A]}{[M][A]}, \quad K_{cont} = \frac{[M\cdot A]}{[M][A]}$$

$$K = K_{sep} + K_{cont} = \frac{[M\cdot\cdot A]+[M\cdot A]}{[M][A]} = \frac{x}{(c_M-x)(c_A-x)}$$

where x is the total molar concentration of ion-pairs. Combining these equations with Eq. (1), one has:

$$\frac{c_M c_A}{\Delta D} = \frac{K(c_M+c_A-x)}{K_{cont}(\varepsilon_{M\cdot A(CT)}-\varepsilon_A)} + \frac{1}{K_{cont}(\varepsilon_{M\cdot A(CT)}-\varepsilon_A)}$$

Plots of the observable quantity on the left-hand side *vs.* c_M+c_A-x (where x is a small correction to be considered in successive approximations) will give the total ion-association constant, K, as (slope)/(intercept). Actually, from spectrophotometric measurements at 32.3 kK on aqueous $[Co(NH_3)_6]$ I_3-KI systems of a constant ionic strength of 0.06, we obtained 9.0±0.6 for K and 2.41×10^{-4} for the intercept, $1/\{K_{cont}(\varepsilon_{M\cdot A(CT)}-\varepsilon_A)\}$. The latter, in combination with the $\varepsilon_{M\cdot A(CT)}$ value given above, leads to the values of the partial ion-association constants: 3.6±0.5 for K_{cont} and, accordingly, 5.4±0.8 for K_{sep}.

The α-Chlorination of Sulfoxides with *N*-Chlorosuccinimide

Gen-ichi TSUCHIHASHI and Katsuyuki OGURA
Sagami Chemical Research Center, Ohnuma, Sagamihara, Kanagawa
(Received April 10, 1971)

Dimethyl sulfoxide, the only sulfoxide that is industrially produced, has been frequently used as a solvent and a reagent.[1] It is very significant that this sulfoxide is further utilized by its transformation into other useful sulfoxides; chloromethyl methyl sulfoxide seems to be an important intermediate for this purpose.[2] Although many efforts have been exerted on the α-chlorination of sulfoxides,[3] it has been difficult to isolate the monochloro derivative in a high yield by the chlorination of dimethyl sulfoxide because of the formation of such by-products as bis(chloromethyl) sulfoxide, and dichloromethyl methyl sulfoxide.[4] In this communication, we wish to report on the chlorination of sulfoxides with *N*-chlorosuccinimide (NCS), with which dimethyl sulfoxide reacts to give only chloromethyl methyl sulfoxide in an excellent yield.

$$CH_3SOCH_3 \xrightarrow[\text{base}]{\text{NCS}} CH_3SOCH_2Cl \quad 87\text{—}90\%$$

To a stirred solution of dimethyl sulfoxide (3.91 g) in dichloromethane (30 m*l*), we added NCS (7.00 g) and potassium carbonate (2.0 g) at room temperature. Stirring was then continued for 15 min. After the subsequent addition of dichloromethane (50 m*l*), the solution was filtered and the filtrate was fractionally distilled. A colorless oil (5.01 g, 90% yield) was thus obtained; it was confirmed to be pure chloromethyl methyl sulfoxide by spectroscopic and tlc analyses: bp 90°C/4 mmHg; $n^{24°}$ 1.5051; the NMR spectrum (in $CDCl_3$): δ 2.69 s (3H) and 4.38 s (2H); the IR spectrum (film): ν_{SO} 1058 cm^{-1}. Found: C, 21.51; H, 4.66; S, 28.47%. Calcd for C_2H_5ClOS: C, 21.34; H, 4.48; S, 28.48%.

A similar treatment of dimethyl sulfoxide with NCS in the presence of pyridine afforded chloromethyl methyl sulfoxide in a 87% yield, but this reaction required a longer period of time than that in the presence of potassium carbonate.

Similarly the reactions of methyl phenyl sulfoxide, dibenzyl sulfoxide, and thiolane 1-oxide with NCS in the presence of pyridine gave the corresponding α-chlorosulfoxides in 89, 91, and 60% yields respectively. Benzyl methyl sulfoxide (I) also reacted with NCS in the presence of pyridine to afford α-chlorobenzyl methyl sulfoxide (II) and benzyl chloromethyl sulfoxide (III) in 51 and 34% yields respectively. When potassium acetate was used as the base, II was obtained in a 77% yield, while III was not detected in the reaction mixture. This result may suggest that two mechanisms are operative in the α-chlorination of sulfoxides with NCS; *i.e.*, the reaction is

$$\underset{\text{I}}{PhCH_2SOCH_3} \xrightarrow[\text{base}]{\text{NCS}} \underset{\text{Cl}\quad\text{II}}{PhCHSOCH_3} + \underset{\text{III}}{PhCH_2SOCH_2Cl}$$

(a) mainly ionic in the presence of pyridine and (b) radicalic in the presence of such insoluble bases as potassium carbonate and potassium acetate. This consideration is supported by the following observations: (1) an induction period clearly exists in the reaction of dimethyl sulfoxide with potassium carbonate; (2) the addition of hydroquinone changes the amount of II produced by the chlorination of I with NCS in the presence of pyridine, but the yield of III remains unchanged (Table 1).

Table 1. Chlorination of I with NCS[a]

HO-⟨⟩-OH	Distribution[b]			II/III
	I	II	III	
0	9.1	52.4	38.9	1.36
0.3 eq.	37.7	29.3	33.0	0.88
1.0 eq.	36.5	28.3	35.3	0.80
0[c]	27.1	20.2	52.6	0.38
0[d]	7.9	72.1	20.1	3.59

a) I, 150 mg; pyridine, 0.5 m*l*; CCl_4, 10 m*l*.
b) Determined by a NMR analysis.
c) A mixture of $PhCD_2SOCH_3$, $PhCDHSOCH_3$, and $PhCH_2SOCH_3$ (90.6:8.9:0.5).
d) A mixture of $PhCH_2SOCD_3$, $PhCDHSOCD_3$, and $PhCH_2SOCD_2H$ (84.0:5.6:10.5).

Kinetic isotope effects were examined by using two deuterio derivatives of I, *i.e.*, $PhCD_2SOCH_3$ and $PhCH_2SOCD_3$. The results are shown in Table 1. The deuterium isotope effects (k_H/k_D) for both benzyl and methyl positions were calculated to be within the range of 3.0—3.5. This magnitude of isotope effects implies that proton transfer is the rate-determining step for the ionic path of the reaction.

Studies of the detailed mechanism of this reaction are now being undertaken.

The Differential Thermal Analysis of Potassium Oxalate[1)]

Tatsuo HIGASHIYAMA and Shigeo HASEGAWA*

College of Liberal Arts, Okayama University, Tsushima, Okayama

* *Research Laboratory for Surface Science, Okayama University, Tsushima, Okayama*

(Received September 17, 1970)

From the differential thermal and thermogravimetric analyses of potassium oxalate together with the X-ray diffraction studies, three crystallographic modifications of the anhydrous salt were found. When potassium oxalate monohydrate crystals were dehydrated at, *e.g.*, 140°C, phase II, which is stable below 381°C, appears. The crystal in phase II has an orthorhombic unit cell ($a=10.9$, $b=6.11$, and $c=3.44$ Å at 17°C) and transforms at 381°C into phase I, which is stable above 381°C up to the temperature where the decomposition begins. The crystals in phase I belong to the tetragonal system ($a=7.01$ and $c=7.53$ Å at 404°C). The transition between phases II and I is not reversible in an exact sense, and when cooled phase I endures down to 215°C, where it transforms (reversibly) into phase III. Phase III can exist at room temperature. When heated, phase III transforms into phase I at 215°C (often accompanied by a partial transformation to phase II). The resulting phase then transforms into phase II. At all temperatures below 381°C phases I and III are metastable with respect to phase II, and they transform into phase II. The decomposition of potassium oxalate in an oxygen-free atmosphere seems to proceed in two stages.

The thermal decomposition of potassium oxalate complexes of di- and tri-valent metal in the solid state has been studied by several investigators,[2-6)] and it has been reported that in many cases potassium oxalate or potassium hydrogen oxalate results as an intermediate decomposition product; this may affect the further decomposition processes of those materials. Many of the reports, however, do not seem to have referred in detail to the thermal behavior of potassium oxalate itself. Studies of the decomposition of potassium oxalate have been made by thermogravimetric analysis (TGA),[6,7)] but no differential thermal analysis (DTA) of the material seems to have been reported yet.

In the course of DTA studies of potassium tetroxalate,[8)] we found that potassium oxalate has two crystallographically-different phases, I[9)] and II[9)]. To obtain further information about potassium oxalate, the thermal behavior of the material was studied in more detail by means of DTA, TGA, and X-ray diffraction methods, and another new phase of the anhydrous salt was found. Some features of the decomposition and transitions of potassium oxalate will be reported in this paper.

Experimental

Materials. The potassium oxalate monohydrate was prepared from commercial guaranteed-grade oxalic acid and potassium carbonate and was recrystallized five times from water. The potassium oxalate anhydrate ($K_2C_2O_4$) was obtained by dehydrating the hydrous salt at about 125°C for more than 4 hours.

Procedures. The DTA and TGA curves were obtained using a "High-temperature-type Differential Thermal and Thermogravimetric Analyser" (Rigaku Denki Co.). Pt-Pt·Rh (13%) thermocouples were used as the temperature detectors, and α-alumina was used as the reference material. The sample material was powdered in an agate motar (powder size smaller than 200 meshes), and about 400 mg of the material was charged in a platinum cell in the manner shown in Fig. 3(f) by tapping the botton of the cell. These procedures were conducted in an dry-air atmosphere when the specimen was the anhydrous salt. When necessary, the specimen was dried again in the DTA-TGA apparatus by evacuation. In most thermal measurements, the heating and cooling rate was about 2.5°C/min unless otherwise specified.

The X-ray diffraction studies at high temperatures were made on a diffractometer equipped with a modified specimen heating apparatus (Rigaku Denki Co.). In X-ray measurements, the heating rate was about 2.5°C/min and the cooling rate was 5—10°C/min. After attaining a given temperature, the specimen was kept at that temperature for about 10 min and diffraction patterns were taken at the scanning speed of 1°/min.

Results and Discussion

Figures 1(a) and (a′) show the simultaneously-recorded DTA and TGA curves of potassium oxalate monohydrate. The endothermic peak, P_1, which is associated with the dehydration of the water of crystallization appears at 135°C (peak temperature, PT). No other peak appears up to 381°C, where the second endothermic peak P_2 (PT 391°C) begins to appear. The TGA curve shows a gradual weight loss from around 426°C, indicating the decomposition of $K_2C_2O_4$. The pattern of the DTA curve accompanying this decomposition is strongly affected by the atmospheric conditions. When measurements were made in an atmosphere of flowing dry air (Fig. 1(a)), where a sufficient supply of oxygen gas to the specimen would be expected, the specimen shows two exothermic

peaks, P_3 and P_5, probably due to the combustion of the carbon monoxide gas produced by the decomposition. When the heating rate was 1°C/min, the separation of these two peaks was less clear. After thermal measurements up to about 612°C the resulting solid substance was potassium carbonate. Figure 1(b) is the DTA thermogram when the measurement was made in dry air at 1 atm with no flow. The exothermicity of the decomposition is decreased compared with the case of a flowing atmosphere, and the temperature of completion of the decomposition becomes higher. Figure 1(d) shows the DTA curve when the measurement was made in dry nitrogen gas with a flow at 1 atm. In this case, two endothermic peaks, P_3 and P_5 (PT 547 and 570°C respectively), appear corresponding to the decomposition of $K_2C_2O_4$. When the measurement was made in N_2 gas at 1 atm with no flow, the thermogram (c) in Fig. 1, which is rather similar to Fig. 1(b), was obtained. The (b) and (c) curves have features intermediate between the former two cases (Figs. 1(a) and 1(d)).

Figure 2(a) shows the DTA thermogram for the measurement in the vacuum of the order of 10^{-2} mmHg. This curve, showing endothermic peaks of P_3 and P_5, is quite similar to the (d) curve in Fig. 1 except that the shape of the P_2 peak is deformed more broadly and its peak temperature is shifted to the higher side because of the smaller thermal conductivity of the specimen in a vacuum. The apparent exothermic peak, P_4, at 555°C, appears clearly in a flowing N_2 gas atmosphere and *in vacuo*, but we could find, by the X-ray diffraction method, no evidence for it as a real peak. The TGA curve in Fig. 2 indicates that the apparent peak, P_4, is accompanied by a clear change in the decomposition rate; this is supported by X-ray diffractometry and pressure measurement of the evolved gases. Figure 2(b) shows the thermogram obtained *in vacuo* when the heating rate was 5°C/min. The curve is displaced to the higher-temperature side as a whole as a result of the increase in the heating rate. The TGA curve (b') shows an apparent weight increase accompanying the endothermic peak, P'_3, instead of showing a weight loss. This phenomenon may be due to the proper jetting of the resulting gases, which might be effective in a vacuum.

In the case of the measurements in N_2 gas and *in vacuo*, the temperature of the completion of the decomposition becomes higher and an exothermic peak, P_6, in Figs. 1 and 2 sometimes appears just before the completion of the decomposition. (Otherwise, P_7 in Fig. 1 often appears). The weight change accompanying P_6 is small; this might suggest that P_6 in Figs. 1 and 2 corresponds to the improvement of the crystallinity of the K_2CO_3 resulting from the decomposition process. The decomposition products in these cases were gray or dark gray, indicating the presence of carbon.

From these findings, it might be said that the supply of O_2 gas or the ease of carrying off the resultant gases plays an important role in the decomposition mechanism, and that the decomposition of $K_2C_2O_4$ in an O_2-free atmosphere proceeds through two stages. The first stage might be associated mainly with the $K_2C_2O_4 \rightarrow K_2CO_3 + CO$ reaction, and the second one, with $2\,K_2C_2O_4 \rightarrow 2\,K_2CO_3 + C + CO_2$.

The TGA curve (a') in Fig. 1 shows that there is no weight change accompanying the P_2 endothermic peak (PT 391°C), which begins to appear from 381°C. When the specimen was once heated up to 408°C (over the P_2 peak) and then submitted at once to the cooling DTA, the thermogram shown in Fig. 3(a) was obtained. A broad exothermic peak, P_1 (PT 341°C), appears from around 360°C, but no other peak appears below the peak temperature. As the period of heat-treatment increases, the peak which corresponds to P_1 in Fig. 3(a) shifts to the lower-temperature side and its peak area decreases (Fig. 3(a')). When the original specimen was heated to a temperature above *ca.* 410°C, treated for a longer time (*e.g.*, 1 hr), and then subjected to the cooling DTA, the thermogram shown in Fig. 3(b) was obtained. A very broad exothermic peak, P''_1 (PT 267°C), in Fig. 3(b) appears from around 304°C, and two other exothermic peaks, P_2 and P_3, appear at 226 and 212°C (PT) respectively. The P_3 peak is less displaced than P_2 when the cooling rate is changed. If the specimen is heat-treated at 420°C for 1 hr (TGA shows that about 0.6% of the specimen is decomposed by this heat-treatment), the broad peak, P''_1, in Fig. 3(b) almost disappears. When the specimen which had undergone the thermal-treatment heating above 390°C and cooling below 210°C was further heat-treated above *ca.* 410°C for a long enough time (*e.g.*, 1 hr), the peak which cor-

responds to P_2 in Fig. 3(b) did not appear (Fig. 3(c)).

After the original specimen had been heat-treated at, *e.g.*, 420°C for a longer time (1 hr), it was cooled to around 145°C and then heated again for the heating DTA (Fig. 3(d)). There thereupon appeared an endothermic peak, P'_3 (PT 219°C), which corresponds to the exothermic peak, P_3, in Fig. 3(b), and a broad exothermic peak at around 265°C. The endothermic peak at around 390°C, which may correspond to P_2 in Fig. 1, appears as a clear double peak. When this specimen was submitted again to the cooling DTA just after attaining 420°C, the thermogram (e) in Fig. 3 was obtained. It should be noted that the peaks which correspond to P_1 in Fig. 3(a) and P_3 in Fig. 3(b) appear, but not the peak which corresponds to P_2 in Fig. 3(b). On the other hand, when the specimen which has shown the thermogram in Fig. 3(d) was submitted from the K point to the cooling DTA, it did not show any peak.

The specimen once heated to 408°C and quickly cooled to, *e.g.*, 360°C does not show in the heating DTA the endothermic peak which corresponds to P_2 in Fig. 1, indicating that the change associated with the peak is not reversible. This peak does appear, however, if the specimen once heated to 408°C and then quickly cooled to 360°C is kept there for a longer time. This is true even for the specimen heat-treated at higher temperatures (*e.g.*, 370°C). The lower the temperature, and the longer the heat-treatment, the larger the peak area of the endothermic peak which corresponds to P_2 in Fig. 1.

When the specimen once heated around or above 408°C is cooled quickly below 351°C, it often shows, in the heating DTA, an endothermic shoulder peak, P'_5 (PT 388°C) in Fig. 3(d), in addition to the peak which corresponds to P_2 in Fig. 1. It seems interesting that the temperature of 351°C coincides with that where the broad exothermic peak P_1 in Fig. 3(a) begins to appear. When the specimen once heated to 400°C was quenched to 0°C, kept there for about 2 min, and quickly heated (to 310°C in 14 min, then to 400°C at 2.5°C/min), it showed the shoulder peak. When this specimen was further heat-treated at 400°C for 1 hr, quickly cooled to 273°C, and then heated as before, it shows a clear double peak. By the repetition of the heating, cooling, and heat-treatment descrived above, the shoulder peak P_5 (or P'_5) in Fig. 3(d) becomes the main peak, while the original main peak, P_6, becomes the shoulder. Similar phenomena were observed for the specimen heat-treated at other temperatures. The shoulder peak, P_5 (or P'_5), in Fig. 3(d) disappears if the specimen so treated as to show the peak is further heat-treated at 360°C for 12 hr, though it does not disappear upon heat-treatment at 306°C for 1 hr.

The X-ray diffraction method was employed to elucidate what phenomena or changes these peaks correspond to.

Figure 4(a) shows the X-ray powder diffraction pattern of $K_2C_2O_4$ at room temperature for the Cu-$K\alpha$ radiation. The crystallographic data of the $K_2C_2O_4$ crystal have not yet been reported. One may index the diffraction lines assuming that $K_2C_2O_4$ crystal has an orthorhombic unit cell with cell constants of $a=10.90$, $b=6.11$, and $c=3.44$ Å at 17°C. From the observed density data (2.381 g/cc at 25°C) of the material, a unit cell can be said to contain 2 chemical units.

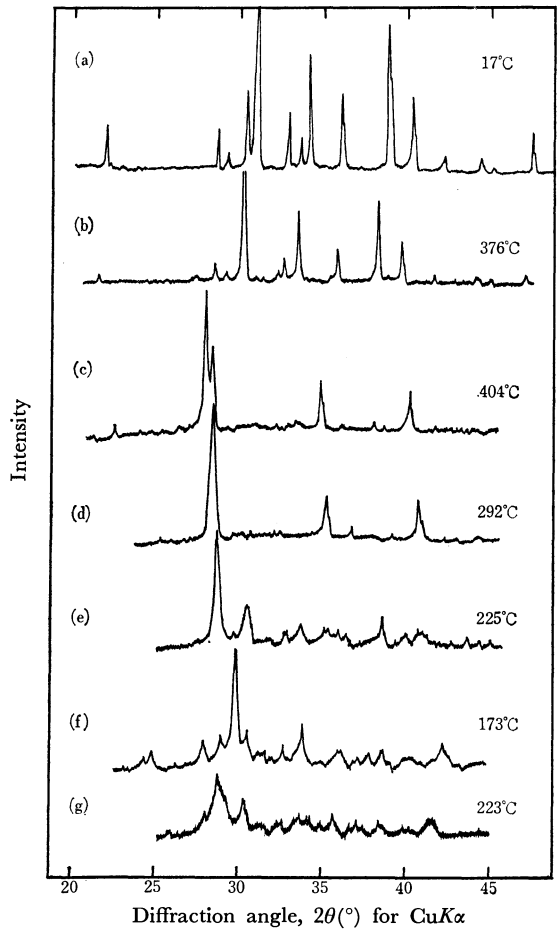

Fig. 4. X-Ray diffraction patterns of $K_2C_2O_4$. (d)—(f): in cooling process.

When $K_2C_2O_4$ crystals were heated in the X-ray high-temperature apparatus up to 376°C (B in Fig.1), the specimen shows the diffraction pattern shown in Fig. 4(b). We may index the diffraction lines in this pattern assuming that $K_2C_2O_4$ crystals have lattice parameters of $a=11.01$, $b=6.16$, and $c=3.56$ Å. When the specimen was heated to 404°C and treated there (C in Fig. 1), it showed the diffraction pattern shown in Fig. 4(c). This pattern has no similarity with the pattern (b) in Fig. 4. One may index the diffraction lines assuming that the crystals have a tetragonal unit cell with cell constants of $a=7.01$ and $c=7.53$ Å. From these facts, it may be concluded that the endothermic peak, P_2, in Fig. 1 corresponds to the polymorphic transition of potassium oxalate anhydrate crystals. As has been stated above, this transition does not occur reversibly in an exact sense. We shall refer to the phase stable below 381°C as phase II, and to that phase stable above 381°C, as phase I.

When the $K_2C_2O_4$ specimen is once heated to 410°C, kept for a rather short time—until the diffraction lines which belong to phase II disappear, and cooled to 310°C (D in Fig. 3(a)), extra lines which seem to belong

to phase II are observed in the diffraction pattern. Figure 4(d) shows the diffraction pattern when the specimen which has been heat-treated at 410°C for a long enough time, is cooled to 292°C (E in Fig. 3(b)). No extra line is seen in this pattern. When a similarly heat-treated specimen is cooled to 225°C (G in Fig. 3(b)), some extra diffraction lines appear (Fig. 4(e)) in addition to the lines in Fig. 4(d). If the specimen which had experienced a transformation history such as II →I→III (see below)→II→I is heat-treated at 410°C for a long enough time and then cooled to 310°C, it gives the diffraction lines of phase I only. When this specimen is cooled to 263°C (F in Fig. 3(b)), some extra diffraction lines appear (prominently at $2\theta=30.4°$). These new peaks disappear when this specimen is cooled to 231°C. When this specimen is further cooled to and kept for a long time at 226°C, it gives a pattern similar to Fig. 4(e). At 225°C, we may index the original diffraction lines assuming that the specimen has lattice constants of $a=$ 6.94 and $c=7.45$ Å.

Thus, the broad exothermic peak, P'_1, in Fig. 3(b) as well as the P_1 peak in Fig. 3(a) may be regarded as the peaks accompanying the transformation from phase I to phase II. The cause for the appearance of the P_2 peak in Fig. 3(b) is not clear. This peak might also correspond to the I→II transformation. However, the findings with respect to the peak seem to be more favorably explained if we say that the peak is due to rearrangement of the molecules in the lattices with less regularity, which might exist in phase I or which might have resulted from the I→II transformation at a lower temperature (*e.g.*, 250°C), to a structure more stable at the temperatures which the peak covers.

When the specimen heat-treated well at above 410°C is cooled down to H in Fig. 3(b) (173°C), it gives the diffraction pattern shown in Fig. 4(f), which is not at all similar to the (d) or (e) patterns in Fig. 4 or to that of the original specimen at the same temperature. Thus, the sharp exothermic peak, P_3, in Fig. 3 (b)is due to the second phase transition. We call this new phase as phase III. In a dry-air atmosphere, phase III is fairly stable at room temperature, especially when it has been properly prepared. It seems interesting that when the specimen completely transformed into phase I is quenched to 0°C, phase I still remains (though it is only a small portion)and the main portion is not phase III but phase II.

When the specimen which gives the diffraction pattern of phase III is heated again to 223°C (J in Fig. 3(d)) it gives the pattern shown in Fig. 4(g). The presence of the diffraction lines of phase I indicates that the transition between phases III and I occurs (at least partly) reversibly; this is supported by the DTA findings. We can also find in Fig. 4(g) many diffraction lines which belong to phase II; this means that the transition from phase III to phase II occurs to a considerable extent. As may be seen from Fig. 4(g), the crystallinity of the resultant phases is poor. If we heat this specimen up to K (*e.g.*, 300°C) over the peak, P_4 (PT 265°C), in Fig. 3(d), it gives a diffraction pattern of phase II with an improved crystallinity. Thus, the exothermic peak, P_4, in Fig. 3(d) may correspond both to the transformation of $K_2C_2O_4$ from phase I to phase II and to the improvement of the crystallinity of the resulting phase II.

As has already been stated, the heating DTA of the specimen which is in phase III gives an endothermic double peak at around 390°C. If, however, we heat-treat the specimen in phase III at, *e.g.*, 360°C for 12 hr, it shows a single peak. The double peak may then be explained as follows. The first endothermic peak (P_5 in Fig. 3(e)) may correspond to the transformation into phase I of the poor-crystalline or amorphous part of the specimen resulting from a transformation history such as II→I→III→II, rather than be due to the presence of another new phase, II′. The poor-crystalline part may be more easily and completely transformed into phase I than the crystalline part of phase II. The second endothermic peak corresponds to the transformation from phase II to phase I.

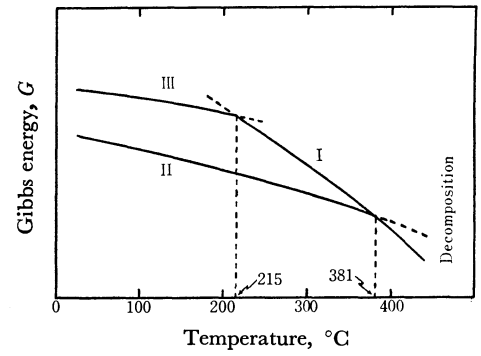

Fig. 5. Schematic representation of phase diagram of $K_2C_2O_4$.

The results discussed above may be summarized schematically as is shown in Fig. 5. Phase II is stable below 381°C, and phase I is stable above that temperature. When crystals in phase I are cooled, phase I endures down to 215°C, where phase III appears and exists below that temperature. At all temperatures below 381°C, phase I and III are meta-stable with respect to phaseII.

The Crystal Structure of Bis(pyridine-2-acetamide)copper(II) Perchlorate

Masao SEKIZAKI, Fumiyuki MARUMO,* Kazuo YAMASAKI, and Yoshihiko SAITO*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

**The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo*

(Received October 22, 1970)

The crystal structure of bis(pyridine-2-acetamide)copper(II) perchlorate, $Cu(paaH)_2(ClO_4)_2$, was determined from three-dimensional X-ray photographic data and refined by block-diagonal least-squares methods, using 1698 independent reflections to give $R=0.12$. The crystals are monoclinic with a space group of C2/c. There are four formula units in a unit cell with dimensions of: $a=10.957$, $b=12.178$, $c=15.566$ Å, and $\beta=108.7°$. The complex is centrosymmetric and square-planar, with two ligand molecules coordinating to the copper atom in *trans* positions through the amide-oxygen and the ring-nitrogen atoms. Two perchlorate ions coordinate weakly to the central copper atom through one of the four oxygen atoms from the top and bottom of the plane containing copper, amide-oxygen, and ring-nitrogen atoms.

In the course of studies of the bivalent metal complexes of acid amides,[1-7] X-ray crystal analyses of $[Ni(H_2O)_2(piaH)_2]Cl_2$[3] and $[Ni(pia)_2]2H_2O$[4] have revealed that the former has a structure with octahedral coordination through the amide-oxygen and ring-nitrogen atoms of the ligand, while that the latter has a structure with square-planar coordination through the amide-nitrogen and ring-nitrogen atoms, where piaH denotes pyridine-2-carboxamide. On the basis of these results and also on the basis of spectral and magnetic studies, the structures of several complexes with other acid amides have been assigned.[5-7] The copper complex of pyridine-2-acetamide (abbreviated as paaH), $Cu(paaH)_2(ClO_4)_2$, has been assigned a structure similar to $[Ni(H_2O)_2(piaH)_2]Cl_2$, *e.g.*, an octahedral structure with coordination through amide-oxygen and ring-nitrogen atoms.[7] The fifth and sixth positions of the octahedron are presumably occupied by two perchlorate ions. To confirm the assigned structure, this complex was subjected to X-ray crystal analysis.

Experimental

The crystals of the complex, $Cu(paaH)_2(ClO_4)_2$, were obtained by letting a mixture of aqueous solutions of one mole of copper perchlorate and two moles of pyridine-2-acetamide stand overnight, as has been reported previously.[7] The blue prismatic crystals were elongated along the *c*-axis. The unit-cell dimensions were determined from the higher-order reflections of Weissenberg photographs ($CuK\alpha_1$, $\lambda=1.5405$ Å). The systematic absences were *hkl* for $h+k$ odd and *h0l* for *h* and *l* odd. Hence, the space group was $C2/c$ or Cc. The former was tentatively assumed, but it was indeed verified at a later stage of the structure analysis by the calculation of the structure factors. The crystal data are given in Table 1. Equi-inclination Weissenberg photographs were taken about [010] and [1$\bar{1}$0] up to the tenth and second layers respectively. The multiple-film technique was employed, and $CuK\alpha$ radiation was used. The cross section of the specimen used for intensity measurements was about 0.3×0.2 mm. A total of 1698 independent reflections were collected. The intensities were estimated visually and were converted to $|F|$ by applying the Lorentz, polarization,and spot-shape corrections. Absorption and extinction corrections were not made.

$D_x=1.80$ g·cm^{-3}	
$D_m=1.79$ g·cm^{-3}	

Solution and Refinement of the Structure

The general positions are eightfold for the space group $C2/c$. The copper atoms must lie on a set of fourfold special positions, since there are only four formula units in the unit cell. The complex is thus required to have a center of symmetry or a twofold axis of rotation. The coordinates of the copper and chlorine atoms were determined from the prominent peaks in the Patterson function. The copper atoms were found to lie on the centers of symmetry. A three-dimensional electron density map was then calculated with all the terms, the signs of which were calculated on the basis of the copper and the chlorine atoms. The resulting maps showed the positions of all the lighter atoms except three oxygen atoms of a perchlorate ion. One more Fourier synthesis of the electron density gave the positions of the three remaining atoms.

At this stage it appeared that the ligand coordinates to the central atom through the ring-nitrogen and one atom of the amide group. However, it was not pos-

sible to distinguish between the oxygen and nitrogen atoms of the amide group. Therefore, the atomic scattering factor of oxygen was applied to these atoms in the initial block-diagonal least-squares refinement. The R-value obtained was 0.32; the coordinating atom of the amide group showed a reasonable isotropic temperature factor compared with those of the other atoms of the ligand, whereas the atom of the amide group not bonded to the copper atom showed about four times as large a temperature factor as the other atoms in the ligand. Therefore, it is not appropriate to assign oxygen to the non-coordinating atom of the amide group, and subsequent refinements have been continued on the assumption of the amide-oxygen coordination.

After six cycles of block-diagonal least-squares refinements with isotropic thermal parameters, the R-value decreased to 0.22; further refinements with anisotropic thermal parameters finally reduced the R-value to 0.12. The final results show that the distance between the carbon atom, C(7), and the coordinating atom is 1.23 Å, and that the distance between C(7) and the other atom attached to C(7) is 1.31 Å (Fig. 1 and Table 3). These values correspond, respectively, to the C=O and C–N bond distances found in the related molecules.[3,4,8,9] This fact proves that the assumption of the amide-oxygen coordination is correct and that the ligand coordinates to the copper atom through the ring-nitrogen and amide-oxygen atoms. This result is in agreement with that presumed from the infrared spectral data.[7]

The final three-dimensional electron density map showed more ill-defined and lower peaks at the atomic positions of the perchlorate ion than at those of the complex cation. Moreover, the temperature factors of the atoms of the perchlorate ion are several times larger than those of the others (Table 2). These facts indicate a larger thermal motion and/or positional disorder for the former. Clearly the uncertainty in atomic positions of the perchlorate ion is responsible for the comparatively high R-value. The atomic scattering factors used for the calculations were taken from the "International Tables for X-ray Crystallography." The calculations were carried out on the FACOM 270-30 computer at the Institute for Solid State Physics, the University of Tokyo, and on the HITAC 5020E computer at the Computing Center of the University of Tokyo, using the programs of the UNICS System. The final atomic parameters are listed in Table 2. The table of the observed and calculated structure factors is kept by the Chemical Society of Japan.[10]

Description of the Structure and Discussion

The interatomic distances and angles are listed in Tables 3 and 4. The structures of the complex ion and the perchlorate ion are illustrated in Figs. 1 and 2, together with the interatomic diatances and angles. The atomic arrangement in the crystal is shown in Fig. 3 in projection along the b-axis. The complex is centrosymmetric, having two ligand molecules in *trans* positions. The copper atom is surrounded by a distorted octahedron of six coordinating atoms, four of which are the amide-oxygen atoms and the ring-nitrogen atoms of the pyridine-2-acetamide molecules. These four coordinating atoms lie on the same plane with the central copper atom. The other two weakly

coordinating atoms are the oxygen atoms of the perchlorate ions, which lie on the normal through the copper atom. This general feature of the structure is completely coincident with that presumed from the spectral and magnetic data in the previous paper.[7] The equations of the coordination plane and the best-plane through the pyridine ring and the deviations of various atoms therefrom are given in Table 5. The six-membered chelate ring is not planar, but is in a boat form, a methylene carbon atom (C(6)) being off the coordination plane at 1.33 Å. On the contrary, the five-membered chelate ring and the pyridine ring in $[Ni(H_2O)_2(piaH)_2]Cl_2$, which has no methylene group, are almost perfectly coplanar.[3] The pyridine ring in the present complex does not lie on the coordination plane, but is tilted at an angle of about 33° with respect to the coordination plane in the Cu–N(1)–C(3) direction. This distortion of the ligand molecule is

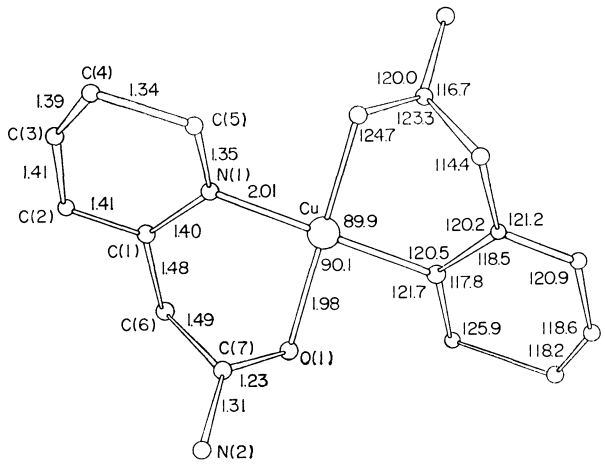

Fig. 1. Atomic arrangement, bond distances and angles of the complex ion.

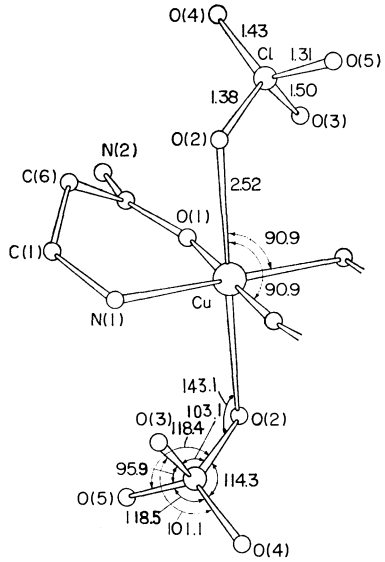

Fig. 2. Atomic arrangement, bond distances and angles of the perchlorate ion.

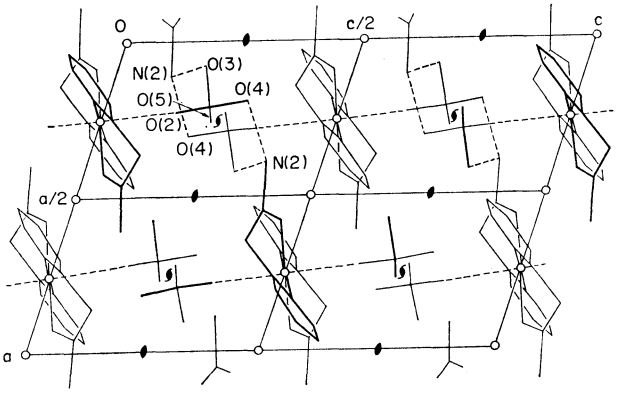

Fig. 3. Projection of the structure along the *b*-axis.

certainly due to an additional methylene group. The coordinate bond distances of this complex (Cu–O, 1.98; Cu–N, 2.01 Å) are not very different from those observed in $[Ni(H_2O)_2(piaH)_2]Cl_2$ (Ni–O, 2.045; Ni–N, 2.022 Å).[3]

The perchlorate ion forms a distorted tetrahedron with Cl–O distances of 1.31—1.50 Å and O–Cl–O

where $X=ax+cz\cos\beta$, $Y=by$ and $Z=cz\sin\beta$; x, y, and z are the fractional coordinates referred to the crystal axes.

	Deviations from (A)	Deviations from (B)
Cu	0.00 Å	—
O(1)	0.00	—
N(1)	−0.00	0.02
C(1)	0.63	−0.02
C(2)	0.62	0.01
C(3)	−0.06	−0.00
C(4)	−0.69	0.00
C(5)	−0.65	−0.01

angles of 95.9—118.5° (Fig. 2 and Table 3). One of the oxygen atoms, O(2), lies on a line through the copper atom and almost perpendicular to the coordination plane. The Cu–O(2) distance is 2.52 Å, which is comparable with the distances found for the other complexes in which a tetrahedral anion coordinates weakly as a unidentate ligand, *e.g.*, Cu–O, 2.60 Å for $Cu(en)_2(ClO_4)_2$,[11] Cu–F, 2.56 Å for $Cu(en)_2(BF_4)_2$,[12] and Cu–O, 2.62 Å for $Cu(histamine)_2(ClO_4)_2$[13]. These values support the weak coordination of the perchlorate ion in this case. Consequently, it may be appropriate to express this complex as $[Cu(ClO_4)_2(paaH)_2]$ rather than as $[Cu(paaH)_2](ClO_4)_2$. Such a weak coordination is sometimes called "semi-coordination," which means an intermediate between bonding and non-bonding states. This result supports the presence of interaction between the perchlorate ion and the copper atom presumed in the infrared spectral studies previously reported.[7]

All the complex entities are oriented in a O(2)···Cu ···O(2) direction nearly parallel to the plane (010). The short contacts between N(2) and O(3) and between N(2) and O(4) are 2.97 and 3.04 Å respectively (Fig. 3 and Table 4). These contacts appear to be intermolecular hydrogen bonds of the N–H···O type. No other strong interaction seems to be present between the perchlorate and the complex ions. All the complex entities are linked with each other by these hydrogen bonds, forming layers parallel to the plane (102). These layers are connected with the semi-coordination bond of Cu–O(2).

Part of the expenses of the present study was met by a Scientific Research Grant of the Ministry of Education, to which the authors' thanks are due.

Configuration Interaction Studies on Contact Shift and Contact Nuclear Spin-Spin Coupling in Paramagnetic Transition Metal Complexes

Hajime KATÔ and Hiroshi KATO*

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe

** Department of General Education, Nagoya University, Chikusa-ku, Nagoya*

(Received October 23, 1970)

The magnitude of the contact shift for hydrogen nuclei is directly related to the unpaired electron density, ρ_H, on the proton. The mechanism by which the unpaired electrons transfer from the transition metal *d*-orbitals to the ligand orbitals is studied on the basis of the method of intergroup (ligand and metal) configuration interaction. The ρ_H is given as a sum of two terms, ρ_H^P and ρ_H^D, due to the spin-polarization mechanism and the spin-delocalization mechanism respectively. When the interaction between metal and ligand is restricted to a localized bond N–M, such as nickel(II)-benzylamine, $\rho_H^P \simeq -(C_M^m)^2|\chi_H^{(0)}|^2\pi_{HN}\langle NM|NM\rangle/3 \simeq 0.001-0.0001$ (Here π_{HN} is the mutual atom(H)-atom(N) polarizability.). When the interaction between metal and ligand is not restricted to a special localized bond, as in metalocene, $\rho_H^P \simeq -(C_M^m)^2|\chi_H^{(0)}|^2\ \pi_{HH}\langle HM|HM\rangle/3 \simeq 0.01-0.001$. The spin delocalization term has the order of magnitude of: $\rho_H^P \simeq -(C_M^m)^2(\beta_{MN})^2|\chi_H^{(0)}|^2(P_{HN})^2/2(\delta E)^2$ (Here P_{HN} is the bond order between the H and N atomic orbitals.). If the proton H is not directly bonded to the atom N, $\rho_H^D \simeq 0.0001$. If the proton H is directly bonded to the atom N, $\rho_H^D \simeq 0.001$. By disregarding the contributions smaller than the order of magnitude $O(S^2)$, the formulation of the contact nuclear spin-spin coupling constant is derived. The most dominant term is identical with the formula which was derived by Pople and Santry for singlet free-ligand molecules.

The purpose of this paper is to report a study of the contact shift and the contact nuclear spin-spin coupling in paramagnetic transition metal complexes. The unpaired electrons which are formally in *d* orbitals of the transition metal are partly delocalized to the ligands. The mechanism by which the spin reaches

the nuclei on the ligand is closely related to the geometry of the complex and the details of the metal-ligand bonding. Hence, a study of the mechanism of the contact shift and the contact nuclear spin-spin coupling will give us information about the metal-ligand bonding. The present study is based on the method of intergroup (ligand and metal) configuration interaction. This method has the advantage of fixing the attention on the dominant mechanism of the transfer of the unpaired electrons.

The effects of paramagnetism on nuclear resonance shifts have been recognized since the discovery of the nuclear magnetic resonance(NMR).[1] Resonance shifts in paramagnetic molecules can arise from certain electron-nucleus interactions.[2-4] The shifts in the NMR arising from electron spin-nuclear spin coupling are called contact shifts. The pseudocontact shift can arise when the complex is not magnetically isotropic.[2,3] We shall ignore the pseudocontact contribution for the sake of simplicity. The isotropic contact shift arises principally from the Fermi contact term,[5] which is proportional to the odd electron density at the nucleus.[6-8] The magnitude of the contact shift for hydrogen nuclei is thus directly related to the unpaired electron density in the hydrogen 1*s* orbital. For a paramagnetic system of spin, *S*, contact interactions between the spin of the unpaired electron and the nuclear spin of the proton lead to the shift of the NMR frequency given by[9,10]

$$\frac{\delta \mathbf{H}_{\mathrm{H}(i)}}{\mathbf{H}} = -A_{\mathrm{H}(i)} \frac{\gamma_e}{\gamma_{\mathrm{H}}} \frac{g\beta S(S+1)}{3kT}, \qquad (1)$$

where $A_{\mathrm{H}(i)}$ is the electron spin-nuclear spin coupling constant for the *i*th hydrogen atom. A_{H} is related to the unpaired spin density, ρ_{H}, by[11]:

$$A_{\mathrm{H}} = a \times \rho_{\mathrm{H}} \qquad (\text{here } a = 1596[\text{gauss}])$$

In Eq. (1), **H** is the resonance field, $\delta \mathbf{H}_{\mathrm{H}(i)}$ is the resonance field shift for the *i*th proton, γ_e and γ_{H} are, respectively, magnetogyric ratios of the electron and the resonating proton, *g* is the electronic *g* factor, and β is the Bohr magneton.

Intergroup Configuration Interaction

In paramagnetic-transition-metal complexes, the unpaired electrons which are formally located in the transition metal are partly delocalized to the ligands. The discussion below is based on the method of intergroup (ligand and metal) configuration interaction. We will consider the self-consistent-field molecular orbitals (SCF MO's) for an individual group.

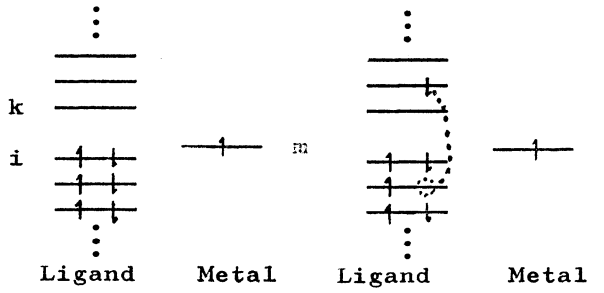

Fig. 1 Fig. 2

Fig. 1. Configuration diagram for the lowest energy configuration.
Fig. 2. Configuration diagram for spin polalization mechanism.

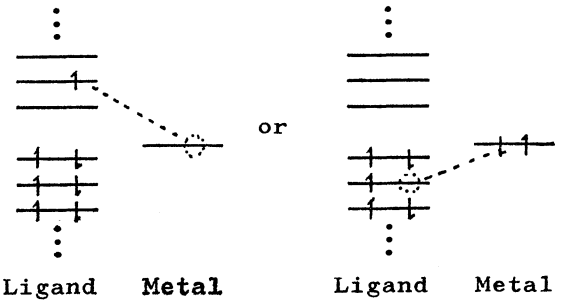

Fig. 3. Configuration diagrams for spin delocalization mechanism.

As an approximation to the configuration interaction problem for the paramagnetic transition metal complexes, we take the lowest energy state to be as shown in the configuration diagram (Fig. 1). The normalized wavefunction for this state is represented by:

$$\Phi_0 = |i\,\bar{i}\,m|, \qquad (2)$$

where *i* denotes the occupied ligand orbitals and where *m* denotes the metal orbitals, hereafter, *k* denotes the vacant ligand orbitals. In these approximations, the charge-transferred states,

$$\Phi_{im} = |i\,\bar{m}\,m|, \qquad (3)$$

$$\Phi_{mk} = |i\,\bar{i}\,k|, \qquad (4)$$

and the singly-excited doublet states:

$$\Phi_{ik}(1) = (2|i\,k\,\bar{m}| - |i\,\bar{k}\,m| - |\bar{i}\,k\,m|)/\sqrt{6}, \qquad (5)$$

$$\Phi_{ik}(2) = (|i\,\bar{k}\,m| - |\bar{i}\,k\,m|)/\sqrt{2}, \qquad (6)$$

arise the delocalization of the unpaired electrons and spin polarization in the ligand. The doublet-state functions, Φ_o, Φ_{im}, Φ_{mk}, $\Phi_{ik}(1)$, and $\Phi_{ik}(2)$, are taken here as the basis of a variational calculation of the wavefunctions.

By the first-order perturbation approximation, the ground state wavefunction, ${}^2\Phi_g$ is found to be:

$${}^2\Phi_g = \Phi_0 + \sum_i^{occ} \lambda_{im}\Phi_{im} + \sum_k^{vac} \lambda_{mk}\Phi_{mk} + \sum_i^{occ}\sum_k^{vac} \lambda_{ik}^{(1)}\Phi_{ik}(1) + \sum_i^{occ}\sum_k^{vac} \lambda_{ik}^{(2)}\Phi_{ik}(2), \qquad (7)$$

: $(i'\neq i,\ k'\neq k)$ $=0$	$:O(0)$

$$\lambda_{im}=\frac{\langle\Phi_{im}|H|\Phi_0\rangle}{\delta E_{im}},\quad \lambda_{mk}=\frac{\langle\Phi_{mk}|H|\Phi_0\rangle}{\delta E_{mk}},$$

$$\lambda_{ik}^{(1)}=\frac{\langle\Phi_{ik}^{(1)}|H|\Phi_0\rangle}{\delta E_{ik}},\quad \lambda_{ik}^{(2)}=\frac{\langle\Phi_{ik}^{(2)}|H|\Phi_0\rangle}{\delta E_{ik}}.$$

Here,

$$\delta E_{im}=\langle\Phi_{im}|H|\Phi_{im}\rangle-\langle\Phi_0|H|\Phi_0\rangle, \tag{8}$$

$$H=H_L+H_M+H_{LM}. \tag{9}$$

H_L and H_M are Hamiltonians in an average effective field, which are due to the electrons in the ligand and the metal respectively. Since the wavefunctions, (φ_i, φ_k) and (φ_m, $\varphi_{m'}$), are taken to be SCF MO for H_L and H_M respectively, the molecular integrals, $\langle i|H_L|k\rangle_{i\neq k}$ and $\langle m|H_M|m'\rangle_{m\neq m'}$, are equal to zero. H_{LM} represents the term corresponding to the electron-electron and electron-core interaction over the ligand and the metal.

Contact Shifts and Unpaired Electron Distribution.

The present formulation is primarily intended for the estimation of the contact shift of the transition-metal complexes. Since the contact shifts are proportional to the unpaired electron density at the proton, it is necessary to evaluate the molecular integral $\langle {}^2\Phi_g|\rho_H|{}^2\Phi_g\rangle$. ρ_H is the spin density operator at the ligand proton, H. The orders of the magnitude of λ_{im}, λ_{mk}, λ_{ik}, and λ_{ik}, are $O(S_{mi})$, $O(S_{km})$, $O(S_{km}S_{mi})$ and $O(S_{km}S_{mi})$ respectively.[12] The other matrix elements in $\langle {}^2\Phi_g|\rho_H|{}^2\Phi_g\rangle$ have also been evaluated; they are shown in Table 1. By disregarding the contributions smaller than the $O(S^3)$ order, we obtain

$$\rho_H=\langle {}^2\Phi_g|\rho_H|{}^2\Phi_g\rangle=\rho_H{}^P+\rho_H{}^D, \tag{10}$$

where:

$$\rho_H{}^P=\frac{4}{\sqrt{6}}\sum_i^{occ}\sum_k^{vac}\lambda_{ik}^{(1)}\langle i|\rho_H|k\rangle, \tag{11}$$

and

$$\rho_H{}^D=(-2\sum_i^{occ}\lambda_{im}\langle i|\rho_H|m\rangle+2\sum_k^{vac}\lambda_{mk}\langle m|\rho_H|k\rangle+\sum_i^{occ}\sum_{i'}^{occ}\lambda_{im}\lambda_{i'm}\langle i|\rho_H|i'\rangle+\sum_k^{vac}\sum_{k'}^{vac}\lambda_{mk}\lambda_{mk'}\langle k|\rho_H|k'\rangle). \tag{12}$$

ρ_H^P is the contribution due to the spin-polarization mechanism (see Fig. 2), while ρ_H^D is the contribution due to the spin-delocalization mechanism (see Fig. 3).

Spin-polarization Mechanism. In this section, we will discuss the spin-polarization mechanism. The (ik)-element of the spin polarization term in Eq. (10) is:

$$(\rho_H{}^P)_{ik}=\frac{4}{\sqrt{6}}\lambda_{ik}^{(1)}\langle i|\rho_H|k\rangle. \tag{13}$$

The molecular orbital, $|i\rangle$, is expressed as a linear combination of atomic orbitals:

$$|i\rangle=\sum_\mu C_\mu{}^i\chi_\mu. \tag{14}$$

Since the one-center term is the most dominant in $\langle i|\rho_H|k\rangle$, $(\rho_H^P)_{ik}$ is, approximately:

$$(\rho_H{}^P)_{ik}=\frac{4}{\sqrt{6}}\lambda_{ik}^{(1)}C_H{}^iC_H{}^k|\chi_H^{(0)}|^2, \tag{15}$$

where:

12) K. Fukui and H. Fujimoto, This Bulletin, **41**, 1989 (1968).

$$\lambda_{ik}^{(1)} = -\frac{2}{\sqrt{6}}\sum_{\mu,\nu} C_\mu{}^k C_\nu{}^i \frac{\langle \mu m | \nu m\rangle}{\delta E_{ik}}. \quad (16)$$

Hence,

$$(\rho_H{}^P)_{ik} = -\frac{4}{3}\frac{1}{\delta E_{ik}}\sum_{\mu,\nu} C_\mu{}^k C_\nu{}^i C_H{}^k C_H{}^i |\chi_H^{(0)}|^2 \langle \mu m | \nu m\rangle. \quad (17)$$

Let us denote the atomic orbitals of the transition metal, of the adjacent atom in the ligand, of the ligand proton, H, and of the proton-attached nucleus as M, N, H, and C respectively. Then, the spin density at the proton H due to the spin polarization mechanism, ρ_H^P, may be writtern as:

$$\begin{aligned}\rho_H{}^P &= \sum_i^{occ}\sum_k^{vac} (\rho_H{}^P)_{ik} \\ &= -\{(C_M{}^m)^2/3\}(\pi_{HN}\langle NM|NM\rangle + \pi_{HH}\langle HM|HM\rangle \\ &\quad + \sum_{t\neq N,H}\pi_{Ht}\langle tM|tM\rangle + \sum_{t,u(t\neq u)}\pi_{H,tu}\langle tM|uM\rangle), \end{aligned} \quad (18)$$

where $\pi_{NN}{}'$ is completely analogous to the mutual atom-atom polarizability associated with the atoms N and N'[13]:

$$\pi_{NN'} = 4\sum_i^{occ}\sum_j^{vac}\frac{C_N{}^i C_N{}^i C_{N'}{}^j C_{N'}{}^j}{\delta E_{ij}}, \quad (19)$$

χ_N is an atomic orbital at the nucleus, N, and $\pi_{H,tu}$ is the atom-bond-polarizability defined by:

$$\pi_{H,tu} = 2\sum_i^{occ}\sum_j^{vac}\frac{C_H{}^i C_H{}^j (C_u{}^i C_t{}^j + C_t{}^i C_u{}^j)}{\delta E_{ij}}. \quad (20)$$

When the interaction between metal and ligand is restricted to the localized bond N–M:

$$\pi_{HN}\langle NM|NM\rangle > \pi_{HH}\langle HM|HM\rangle \gtrsim \pi_{Ht}\langle tM|tM\rangle.$$

Thus ρ_H^P may be written as:

$$\rho_H{}^P \simeq -\frac{1}{3}(C_M{}^m)^2 |\chi_H^{(0)}|^2 \pi_{HN}\langle NM|NM\rangle. \quad (21)$$

That is, the order of magnitude of $\langle AM|AM\rangle$ (A= N, H, t) is $(S_{AM})^2$, $(S_{NM})^2 \gg (S_{HM})^2 \simeq (S_{tM})^2$ in the above N–M localized bond. The order of magnitude is $C_M^m \simeq 1$, $\chi_H(0) \simeq 1$, $\pi_{HN} \simeq -(0.1)^2/10[(eV)^{-1}]$, and $\langle NM|NM\rangle \simeq 3$ [eV]. Accordingly, ρ_H^P is of the order of magnitude of 0.001—0.0001. The contact shifts for the amino proton of the nickel(II)-benzylamine complex[14] can be explained by this mechanism (Table 2*a*). The alternative character of spin density (the change in the sign of the spin density) can be explained by the alternative character of $\pi_{NN'}$. Further, Eq. (21) shows that the sign of ρ_H^P is the same as the sign of J_{NH} (the I–I coupling constant between N and H AO.) of a free molecule, because $J_{NH} \propto \pi_{NH}$ and $\langle NH|NH\rangle > 0$.

When the interaction between metal and ligand is not restricted to a special localized bond, $\pi_{HH}\langle HM|HM\rangle \geq \pi_H\langle tM|tM\rangle$. Accordingly, ρ_H^P may be written as:

$$\rho_H{}^P \simeq -\frac{1}{3}(C_M{}^m)^2 |\chi_H^{(0)}|^2 \pi_{HH}\langle HM|HM\rangle. \quad (22)$$

The order of magnitude is $C_M^m \simeq 1$, $\chi_H^{(0)} \simeq 1$, $\pi_{HH} \simeq 1/10$ [$(eV)^{-1}$], and $\langle HM|HM\rangle \simeq 0.1$ [eV]. Accordingly, ρ_H^P is of the order of magnitude of 0.01—0.001. The large contact shifts and the hyperfine coupling constants for paramagnetic metallocene[15,16] can be explained by this mechanism (Table 2*b*).

Spin-delocalization Mechanism. In this section, we will discuss the spin-delocalization mechanism. In the LCAO form, the spin delocalization term in Eq. (10) is:

$$\begin{aligned}\rho_H{}^D \simeq &\Big(\sum_i^{occ}\sum_{i'}^{occ}\lambda_{im}\lambda_{i'm}C_H{}^i C_H{}^{i'} + \sum_k^{vac}\sum_{k'}^{vac}\lambda_{mk}\lambda_{mk'}C_H{}^k C_H{}^{k'}\Big)|\chi_H^{(0)}|^2 \\ &- \Big(2\sum_i^{occ}\lambda_{im}C_H{}^i C_M{}^m - 2\sum_k^{vac}\lambda_{mk}C_M{}^m C_H{}^k\Big)\chi_H^{(0)}\chi_M^{(0)}, \end{aligned} \quad (23)$$

where $\chi_M^{(0)}$ is the value of the metal orbital at the proton H. The value of the metal orbital at the proton H is insignificant (the order of the magnitude of $\chi_H^{(0)}\chi_M^{(0)}$ is calculated to be 0.001[17]), so it will be omitted. λ_{im} and λ_{mk} may be approximated in the order of magnitude as follows:

$$\lambda_{im} \simeq \frac{C_M{}^m C_N{}^i \beta_{MN}}{\delta E_{im}}, \quad \lambda_{mk} \simeq \frac{C_M{}^m C_N{}^k \beta_{MN}}{\delta E_{mk}},$$

where β_{MN} is the core-resonance integral between the atomic orbitals M and N. Then,

Table 2. Spin density on the ligand proton calculated from the observed contact shift referenced against diamagnetic ligand by Eq. (1)—(3)

a) $[Ni\ (bz)_6]^{2+}$ ($bz = C_6H_5CH_2NH_2$):
$\rho^{NH_2} = -0.0003$, $\rho^{CH_2} = +0.0001$, $\rho^{H_{ortho}} = -0.000004$, $\rho^{H_{meta}} = +0.000004$, $\rho^{H_{para}} = -0.000004$.

b) Ni $(C_5H_4\text{-}CH_3)_2$:

13) C. A. Coulson and H. C. Longuet-Higgins, *Proc. Roy. Soc.*, **A191**, 39 (1947); *ibid.*, **A193**, 447 (1948).
14) R. J. Fitzgerald and R. S. Drago, *J. Amer. Chem. Soc.*, **89**, 2879 (1967); *ibid.*, **90**, 2523 (1968).
15) M. F. Retting and R. S. Drago, *ibid.*, **91**, 1361, 3432 (1969).
16) R. Prins, *J. Chem. Phys.*, **50**, 4808 (1969).
17) S. E. Anderson and R. S. Drago, *J. Amer. Chem. Soc.*, **91**, 3656 (1969).

$$\rho_H^D \simeq (C_M^m)^2\beta_{MN}^2|\chi_H^{(0)}|^2\left\{\left(\sum_i^{occ}\frac{C_H^iC_N^i}{\delta E_{im}}\right)^2+\left(\sum_k^{vac}\frac{C_H^kC_N^k}{\delta E_{mk}}\right)^2\right\}. \quad (24)$$

Taking the mean excitation energy (δE) approximation, one obtains:

$$\rho_H^D \simeq (C_M^m)^2\beta_{MN}^2|\chi_H^{(0)}|^2(P_{HN})^2/2(\delta E)^2, \quad (25)$$

where:

$$P_{HN} = 2\sum_i^{occ} C_H^iC_N^i.$$

The order of magnitude is $C_M^m \simeq 1$, $\beta \simeq 5$ [eV], $P_{HN} \simeq 0.1$, and $\delta E \simeq 10$[eV], so ρ_H^D is of the order of magnitude of 0.0001. Thus, if the proton H is not directly bonded to the atom N, the spin-delocalization mechanism is not important. However, if the proton H is directly bonded to the atom N, $P_{HN} \simeq 0.5$ and ρ_H^D is of the order of magnitude of 0.001—0.0001. Therefore, the spin-delocalization mechanism is not negligible in this case. The bipyridine proton contact shift in α,α'-bipyridine chelates of Fe(III)[18] can be explained by this mechanism (Table 2*c*). Further, if only the integral $\langle i|H|m\rangle$ is not equal to zero, $\rho_H^D \simeq (\beta_{NH}/E_{im})^2 \times (P_{HN}^i)^2$; that is the partial bond order $(P_{HN}^i)^2$ is proportional to the spin densities of the related atoms. The total amount of odd electrons transferred to the ligand is estimated by means of the values of $(\beta_{NM}/\delta E_{im}) \simeq 0.1$.

Contact Nuclear Spin-Spin Coupling

Ramsey[19] has shown by the perturbation therory that the contact nuclear spin-spin coupling constant, $J_{NN'}$ between the nuclei N and N' can be written as:

$$J_{NN'} = -\frac{2}{3h}\left(\frac{16\pi\beta h}{3}\right)^2\gamma_N\gamma_{N'} \times\sum_n\frac{\langle\Phi_0|\sum_k\delta(\mathbf{r}_{kN})\mathbf{S}_k|\Phi_n\rangle\langle\Phi_n|\sum_j\delta(\mathbf{r}_{jN'})\mathbf{S}_j|\Phi_0\rangle}{\delta E_{n0}}, \quad (26)$$

where Φ_0 denotes the ground state MO and where Φ_n represents the nth excited state MO. A theory of spin-spin coupling for a singlet molecule has been given by Pople and Santry[20] and the contact nuclear spin-spin coupling constant has been represented by:

$$J_{NN'} = -\frac{1}{4h}\left(\frac{16\pi\beta h}{3}\right)^2\gamma_N\gamma_{N'}|\chi_N^{(0)}|^2|\chi_{N'}^{(0)}|^2\pi_{NN'}. \quad (27)$$

Let us assume Eq. (7) as the ground-doublet-state wavefunction. In the evaluation of the proton-proton coupling constant of the ligand molecule, the molecular integrals $\langle i|\rho_N|m\rangle$ are insignificant and will be omitted. Neglecting any contributions smaller than the $O(S^2)$ order, we obtain:

$$J_{NN'} = -\frac{2}{3h}\left(\frac{16\pi\beta h}{3}\right)^2\gamma_N\gamma_{N'}(A+B+C+D), \quad (28)$$

where:

$$A = \sum_{i'}^{occ}\frac{1}{\delta E_{i'm}}(\sum_i^{occ}\lambda_{im}\langle i|\rho_N|i'\rangle)(\sum_i^{occ}\lambda_{im}\langle i'|\rho_{N'}|i\rangle), \quad (29)$$

$$B = \sum_{k'}^{vac}\frac{1}{\delta E_{mk'}}(\sum_k^{vac}\lambda_{mk}\langle k|\rho_N|k'\rangle)(\sum_k^{vac}\lambda_{mk}\langle k'|\rho_{N'}|k\rangle). \quad (30)$$

$$C = \sum_{i'}^{occ}\sum_{k'}^{vac}\frac{1}{\delta E_{i'k'}}\frac{2}{3}\langle i'|\rho_N|k'\rangle\langle k'|\rho_{N'}|i'\rangle, \quad (31)$$

$$D = \sum_{i'}^{occ}\sum_{k'}^{vac}\frac{1}{\delta E_{i'k'}}\frac{4}{3\sqrt{6}} \times\{\langle i'|\rho_N|k'\rangle[\sum_{k\neq k'}^{vac}\langle k'|\rho_{N'}|k\rangle\lambda_{i'k}^{(1)}+\sum_{i\neq i'}^{occ}\langle i'|\rho_{N'}|i'\rangle\lambda_{ik'}^{(1)} +\frac{2}{3}(\langle i'|\rho_{N'}|i'\rangle+\langle k'|\rho_{N'}|k'\rangle\lambda_{i'k'}^{(1)}] +\langle k'|\rho_{N'}|i'\rangle[\sum_{k\neq k'}^{vac}\langle k|\rho_N|k'\rangle\lambda_{i'k}^{(1)}+\sum_{i\neq i'}^{occ}\langle i|\rho_N|i'\rangle\lambda_{ik'}^{(1)} +\frac{2}{3}(\langle i'|\rho_N|i'\rangle+\langle k'|\rho_N|k'\rangle)\lambda_{i'k'}^{(1)}]\}. \quad (32)$$

Only the third term, C, in Eq.(28) is of the order of magnitude of $O(1)$; the other terms, A, B, and D, are of the order of magnitude of $O(S^2)$. Accordingly, Eq. (28) may be written approximately by only the C-term. Then;

$$J_{NN'} = -\frac{1}{h}\left(\frac{16\pi\beta h}{3}\right)^2\gamma_N\gamma_{N'} \times\sum_{i'}^{occ}\sum_{k'}^{vac}C_N^iC_N^kC_{N'}^iC_{N'}^k|\chi_N^{(0)}|^2|\chi_{N'}^{(0)}|/\delta E_{i'k'} = -\frac{1}{4h}\left(\frac{16\pi\beta h}{3}\right)^2\gamma_N\gamma_{N'}\pi_{NN'}|\chi_N^{(0)}|^2|\chi_{N'}^{(0)}|^2, \quad (33)$$

where we have considered the contribution from only the atomic orbital of the nucleus N in the evaluation of the molecular integral, $\langle k'|\rho_N|k\rangle$. Eq. (33) is identical with Eq. (27), which was derived by Pople and Santry for a singlet free molecule.[20] From this result, we can conclude that: the proton-proton coupling constant of the ligand molecule in paramagnetic transition metal complexes is approximately identical with that of a singlet free ligand molecule and that the effect of a paramagnetic metal on $J_{NN'}$ is of the order of magnitude of $(S_{LM})^2$. The spin-spin couplings observed for the ligand quinoline of the nickel(II) aminotropone-imineate[21] is $J_{23}=4.0\pm0.2$ Hz, $J_{34}=7.9\pm0.2$ Hz, and $J_{78}=7.9\pm0.2$ Hz, and for a free quinoline[22] $J_{23}=4.1\pm0.2$ Hz, $J_{34}=8.5\pm0.3$ Hz, and $J_{78}=8.2\pm0.3$ Hz. These observed results are in good agreement with the above conclusion.

Summary

When the interaction between metal and ligand is restricted to the localized bond N–M, as in nickel(II)-benzylamine,

$$\rho_H^P \simeq -(C_M^m)^2|\chi_H^{(0)}|^2\pi_{HN}\langle NM|NM\rangle/3 \simeq 0.001—0.0001.$$

When the interaction between metal and ligand is not restricted to a special localized bond, as in metallocene,

$$\rho_H^P \simeq -(C_M^m)^2|\chi_H^{(0)}|^2\pi_{HH}\langle HM|HM\rangle/3 \simeq 0.01—0.001.$$

The spin-delocalization term has the order of magnitude of $\rho_H^D \simeq -(C_M^m)^2(\beta_{MN})^2|\chi_H^{(0)}|^2(P_{HN})^2/2(\delta E)^2$. If the proton H is directly bonded to the atom N, $\rho_H^D \simeq 0.001$. If

the H proton is not directly bonded to the atom N, $\rho_H^D \simeq$ 0.0001. The mechanism by which the spin reaches the nuclei on the ligand is closely related to the geometry of the complex and the details of the metal-ligand bonding. The magnitude of the contact shift gives us information about the mechanism and the metal-ligand bonding.

The most dominant term in $J_{NN'}$ derived for a transition metal complex, is identical with the formula which was derived for a singlet free-ligand molecule by Pople and Santry.[20] This implies that the proton-proton coupling constant of the ligand molecule in paramagnetic-transition metal complexes is nearly equal to that of the singlet free-ligand molecule and that the effect of the paramagnetic metal on $J_{NN'}$ is of the order of magnitude of $(S_{LM})^2$.

The authors wish to thank Professor Teijiro Yonezawa for his generous support of this work. They also wish to thank Dr. Isao Morishima for his helpful discussions.

Dehydration and Dehydrogenation of Alcohols over Acid-Base Bifunctional Catalysts

Hiroo NIIYAMA and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 12, 1970)

Alkaline earth silicates having both acidic and basic sites can be considered as acid-base bifunctional catalysts. Dehydration and dehydrogenation of alcohols over these catalysts were carried out. Correlation between the selectivity and acid-base properties of alcohols and the catalysts was studied. It was found that acid-base properties of both the catalysts and the alcohols were cooperative in determining the selectivity of reaction.

The dehydration and dehydrogenation of alcohols over oxide catalysts have been studied by many investigators. Some oxides particularly tend to promote dehydration, whereas others have mainly dehydrogenating effects. Several hypotheses[1] were proposed concerning the cause of selectivity; *i.e.*, (1) a geometric factor of the surface structure,[2] (2) type of semiconductor,[3] (3) acidic and basic characters,[4] and (4) some other special parameters, *e.g.*, $\eta \equiv$(cation radius)^3/(mol volume per cation) (charge of cation) proposed by Eucken[5] and Wicke.[6] These attempts were partially successful. However, the relation between the surface properties and reaction mechanism or the nature of the active sites is still obscure. It was the object of this study to clarify the cause of selectivity using acid-base bifunctional catalysts.

Experimental

Preparation of Catalysts. Colloidal silica (Nissan Chem. Co., Snowtex O) was kneaded with equal moles of an alkaline earth hydroxide ($Mg(OH)_2$, $Ca(OH)_2$, $Sr(OH)_2$, $Ba(OH)_2$) for 3 hr and calcined at 100°C for 24 hr. It was then heated at 290°C for 24 hr in an autoclave with aqueous ammonia under 80—90 kg/cm^2 pressure. Products were washed several times with ion-exchanged water and then calcined at 600°C for 3 hr.

Measurements of Acidity and Basicity. A titration method in an aprotic medium was employed. Before the measurement, samples were heated at 550°C for 1 hr under air and then degassed at 300°C under 10^{-5}mmHg pressure. *n*-Butylamine (0.02N) and benzoic acid (0.02N) in benzene were used for titration in acidity and basicity measurements, respectively. The following indicators were used; neutral red ($pK_a+6.8$), methyl red ($pK_a+4.8$), dimethyl yellow ($pK_a+3.3$), benzeneazodiphenylamine ($pK_a+1.5$), benzalacetophenon ($pK_a-5.6$), and phenolphtalein ($pK_a+9.3$).

Preparation of Deutrated n-*Propanol* (C_3H_7OD).[7] 200 ml of *n*-propanol was subjected to reaction with 5 g of metallic sodium. Unreacted *n*-propanol was removed by vacuum distillation and then 3 g of D_2O were introduced. Produced *n*-C_3H_7OD was trapped with liquid nitrogen. Deutrium concentration was estimated by IR spectroscopy from OD and OH absorption bands and the amount of *n*-C_3H_7OH was confirmed to be negligible.

Reaction Apparatus. The usual fixed bed flow type reactor was employed. A reactant was kept in an evaporator maintained at a constant temperature and introduced into the catalyst bed with hydrogen as the carrier gas. In front of the reactor, a sample inlet made of rubber was attached in order to inject poisonous materials.

All the system was heated to prevent the condensation of reactant or products. Vaporous products were taken out by a sampling cock and analyzed by gas chromatography.

Results and Discussion

Acid-base properties of the catalysts. The properties of the catalysts are given in Table 1. All the catalysts

Table 1. Structure and surface properties of the catalyst

Catalyst	Structure	Surface area (m^2/g)	Maximum acid strength(H_0)	Acidity [a] (10^{-7} eq/m^2)	Basicity [b] (10^{-7}eq/m^2)
$MgO \cdot SiO_2$	Speolite	194	−5.6	22.4	[c]
$CaO \cdot SiO_2$	Xonotlite	46	+3.3	7.5	13.7
$SrO \cdot SiO_2$	Strontium metasilicate	9.0	+3.3	3.3	18.9
$BaO \cdot SiO_2$	Barium metasilicate	2.0	+4.8	0	30.3

a) Measured at $H_0=3.3$ b) Measured at $H_0=9.3$ c) Abnormal color was observed.

except for $MgO \cdot SiO_2$ showed fine patterns in X-ray diffraction. The order of acidic nature (acidity and acid strength) was as follows. $MgO \cdot SiO_2 > CaO \cdot SiO_2 > SrO \cdot SiO_2 > BaO \cdot SiO_2$.

The acidic nature of $MgO \cdot SiO_2$ was attributed to the unsaturation of the bond which was produced by the replacement of four coordinated silicon with magnesium.[8] The degree of unsaturation decreases with the increase of ionic radius of the replaced cation and also with the decrease of electronegativity of metal. Thus the sequence of acidic nature can be explained.

On the other hand, the order of basicity was as follows. $BaO \cdot SiO_2 > SrO \cdot SiO_2 > CaO \cdot SiO_2 > MgO \cdot SiO_2$. This was the complete reverse of the order of acidic nature but the same as that of basic nature of the corresponding alkaline earth oxides (BaO>SrO>CaO>MgO).[9] Thus the basicity could be attributed to the small electronegativity of the alkaline earth metals. The amount of uncombined alkaline earth oxides unavoidably present before the progress of chemical reaction in the solid phase, was very small and confirmed to be negligible.[10] It is concluded that these silicates have basic sites as well as acidic sites.

Dehydration and dehydrogenation of alcohols. $CaO \cdot SiO_2$, which showed both acidic and basic natures in comparable degree was chosen as the catalyst in the selectivity studies of this reaction. It showed both dehydration and dehydrogenation activities.

Addition of acidic and basic materials. Figures 1 and 2 show the effects of pyridine and phenol addition on

the decomposition of *n*-butanol. These poisons gave no reaction products. 10 μl of the substances were introduced into the system as a pulse. Addition of pyridine brought a decrease in the dehydration activity with considerable increase in dehydrogenation activity. On the other hand, phenol inhibited the dehydrogenation reaction and gave no effect on dehydration. The effects were reversible. Thus it was concluded that dehydration took place on acidic sites and dehydrogenation on basic sites.

The promoter action of pyridine can be attributed to the inductive effect of adsorbed pyridine. Because of high electron donating ability of pyridine, adjacent sites become rich in electron density and these sites act as basic sites. This hypothesis was confirmed.

Isotope effects on both reaction rates. Either *n*-C_3H_7OH or *n*-C_3H_7OD was introduced into the reactor alternatively. Reaction rates were estimated in the steady state. Experiments were repeated several times and the mean values are given in Table 2. No isotope

TABLE 3. DEHYDRATION AND DEHYDROGENATION OF FIVE ALCOHOLS OVER $CaO \cdot SiO_2$

Reactant	Reaction temperature	Reaction product	Rate of reaction (mol/g hr)		Activation energy (kcal/mol)	
			Dehydration	Dehydrogenation	Dehydration	Dehydrogenation
Ethanol	320—360°C	Ethylene, Ether Acetaldehyde	7.0×10^{-5} [b]	1.8×10^{-4}	35[b]	14
n-Propanol	290—320°C	Propylene Propionaldehyde	8.6×10^{-5}	6.2×10^{-5}	29	19
n-Butanol	310—350°C	*n*-Butene Butylaldehyde	1.7×10^{-4}	1.5×10^{-5}	26	23
Isopropanol	290—240°C	Propylene Acetone	1.5×10^{-3}	3.5×10^{-6}	23	17
t-Butanol	150—190°C	Isobutene	1.3		33	

a) Sum of the ethylene and ether formation.
b) Activation energy of ethylene formation. Activation energy of (ethylene+ether) formation was 30 kcal/mol.

effect was found in the dehydration reaction while the value 0.53 was obtained for k_D/k_H in the dehydrogenation. This value was close to 0.34 which was obtained by calculation[11] on the assumption that an isotope effect comes from the difference of the zero point energy of reactants. It was concluded that OH rupture was the rate determining step in the dehydrogenation reaction.

Decomposition of five Alcohols. Dehydration and dehydrogenation of five alcohols were carried out. Experimental conditions and the results are given in Table 3. In the dehydration of ethanol, ethylene, and ether were found in the products. Ethylene formation and ether formation took place competitively in the low conversion region. The activation energy shown in Table 3 and Fig. 4 was calculated from the rate of ethylene formation because the reaction paths differed from each other. The reaction rate at 310°C under 55 mmHg of alcoholic pressure was taken as an index of the reactivity of alcohol.

Correlation between the reactivity and Taft's σ^*[12] which represents the electron donating ability of the aliphatic group attached to OH group is shown in Fig. 3. Negative correlation for dehydration and a positive one for dehydrogenation were obtained.

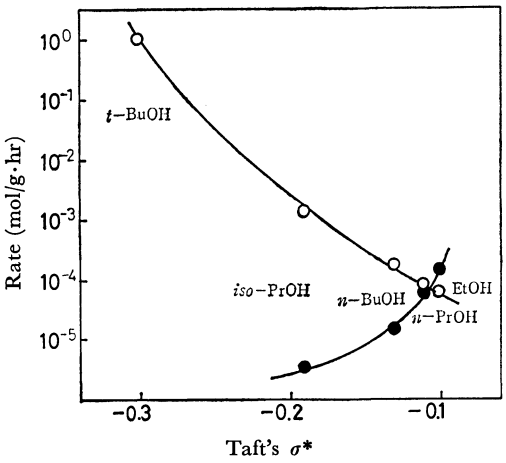

Fig. 3. Correlation between Taft's σ^* and reactivity of alcohols.
—○— dehydration rate
—●— dehydragenation rate

The heat of carbonium ion formation (ΔHc_+) could also be an index of electron donating ability.[13] The larger the ΔHc_+, the more unstable the carbonium ion and thus, the smaller the electron donating ability. Figure 4 shows the correlation between ΔHc_+ and reactivity. Almost the same correlation were obtained.

The activation energies for primary alcohols are also plotted in Fig. 4. Good correlation between ΔHc_+ and the activation energy of primary series indicates that this reactivity sequence can be referred to an energetic factor.

Both horizontal axes in the figures can also be considered to express electron density of OH group, or acid-base properties of alcohol. Therefore, it is concluded that dehydration tend to take place as the basicity of alcohol increases and dehydrogenation becomes predominant as the acidity of the alcohol increases.

The reactivity sequence of alcohols over this catalyst is quite different from that observed over metal catalysts. Over the copper catalyst which is commonly used in the dehydrogenation of alcohols, ethyl, *n*-propyl, and *n*-butyl alcohol have almost the same reactivity,

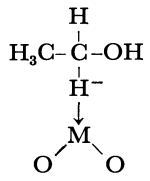
Table 4. Catalytic activity of various alkaline earth silicates

Silicates	Dehydration rate		Dehydrogenation rate		Selectivity[c]
	mol/g·hr	mol/meq·hr [a]	mol/g·hr	mol/meq·hr[b]	
$MgO \cdot SiO_2$	65×10^{-3}	147×10^{-3}	——	——	0
$CaO \cdot SiO_2$	2.8×10^{-3}	82×10^{-3}	0.18×10^{-3}	2.9×10^{-3}	0.06
$SrO \cdot SiO_2$	0.018×10^{-3}	12×10^{-3} [d]	0.015×10^{-3}	0.88×10^{-3}	0.45
$BaO \cdot SiO_2$	0.0097×10^{-3}	——	0.0065×10^{-3}	1.1×10^{-3}	0.40

a) Rate per unit acidity (H_0 +3.3)
b) Rate per unit basicity
c) Selectivity is defined as dehydrogenation rate/total rate.
d) Acidity measured was below 0.003, and the value 0.0015 was assumed for the acidity.

and isopropanol reactivity five times higher than that of primary alcohols.[14] This suggests that the hydrogen release from carbinol carbon is the rate determining step over metal catalysts.

Eucken showed that the dehydrogenation selectivity increased over various oxides in the decomposition of ethanol could be correlated well with η[5]. Selectivity increased as η became greater. They considered that the matal atom was exposed on the surface of the oxide as the ionic radius, as well as η, increased. They proposed the following mechanism. If the dehydrogenation activity of this catalyst is attributed to the hydride ion affinity of metal, the reactivity sequence would differ from the one obtained.



Tanaka *et al.*[4] pointed out that the physical meaning of η is acid-base properties of the surface. This coincides with our results.

Reaction mechanisms. Reaction mechanisms for both reactions (for example, ethanol decomposition) can be expressed as follows.

Dehydration

$$CH_3CH_2OH + H^+A \xrightarrow{I} CH_3CH_2\text{-}OH \xrightarrow{II} \underset{H^+\cdots A}{}$$

$$\underset{A}{CH_3\text{-}CH_2^+} + H_2O \xrightarrow{III} CH_2{=}CH_2 + H_2O + H^+A$$

The reactivity sequence suggests that either process I or II is rate determining.

Dehydrogenation

$$CH_3CH_2OH + B \xrightarrow{I} CH_3CH_2O^- \cdots H^+B \xrightarrow{II}$$

$$CH_3CH\text{-}O \xrightarrow{III} CH_3CHO + H_2 + B$$
$$H^- \cdots H^+B$$

H^+A; acidic site B; basic site

The reactivity sequence and existence of an isotope effect suggest that process I is the rate determinig step.

Activity and Selectivity of the Various Alkaline Earth Silicates. Decomposition of *n*-butanol over alkaline earth silicates with various acidity and basicity was studied. No dehydrogenation reaction was found over $MgO\cdot SiO_2$, while both reactions were observed over $CaO\cdot SiO_2$, $SrO\cdot SiO_2$, $BaO\cdot SiO_2$. Reaction rates at 350°C are given in Table 4. Selectivity was defined as dehydrogenation rate/total consumption rate.

Selectivity increased with the increase of the basic nature of the catalyst. Dehydration rate per unit acidity showed no specific value. It increased with the increase of acid strength. Besides acidity, acid strength also plays a role in the dehydration of alcohols. On the other hand, dehydrogenation rate per unit basicity remained constant.

***Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo*

(Received November 17, 1970)

The ultraviolet absorption spectrum of diprotonated-2,7-diaminofluorene has been divided into two components polarized along the long and the short axes of the molecule by using the results of the dichroic spectra in the stretched PVA sheet. By a comparison of the experimental results with those calculated by means of a semi-empirical LCAO-ASMO-SCF-CI approximation including a variable β method the assignment of the absorption bands has been made. It has been found that the compound has five absorption bands above 210 mμ. The existence of the additional 300 mμ band of fluorene has been explained theoretically by increasing the ionization potentials of the 9- and 10-carbon atoms by 3 eV from the usual value (11.42 eV).

Biphenyl shows a structureless intense absorption band at 247 mμ in a non-polar solvent. On the other hand, fluorene, which is formed by bridging a methylene group at the 9- and 10-carbon atoms of biphenyl, has a band with a well-defined fine structure at about 300 mμ in addition to the 261 mμ band, which corresponds to the 247 mμ band of biphenyl.

Many theoretical and experimental investigations of the electronic spectrum of biphenyl have been published. For instance, Gondo[1] has calculated the electronic transition energies of biphenyl, in which the effects of twisting the 1–1′ bond in biphenyl are taken into account. Berlman and Steingraber[2] have determined the fluorescence lifetime of biphenyl and found a hidden band on the longer-wavelength side of the intense 247 mμ band.

On the other hand, only a few papers have reported on the spectrum of fluorene. Momicchioli and Rastelli[3] have calculated the transition energies and oscillator strengths for fluorene by the method of PPP with variable electronegativity, taking into account the small shortening of the 1–1′ distance and slight parameter changes.

In this paper, the absorption spectrum of diprotonated-2,7-diaminofluorene above 220 mμ has been divided into two kinds of absorption curves which are polarized along the short axis (C_2-axis) and the long axis of the molecule, by using the results of the dichroic spectra in the stretched PVA sheet.[4] We call these divided absorption curves "divided spectra." Using the divided spectra, we have determined a number of the absorption bands and the polarization directions. Furthermore, semi-empirical LCAO-ASMO-SCF-CI calculations including a variable β approximation for the above compound have been made. By a comparison of the experimental and the calculated results, the assignment of each band has been clarified.

Experimental

Materials. Diprotonated-2,7-diaminofluorene was used in place of fluorene, because the saturated concentration of fluorene in a PVA sheet was too small for the dichroic spectra to be measured. Since the absorption spectrum of diprotonated-2,7-diaminofluorene is almost identical with that of fluorene, the results obtained from the former can be regarded as representing the results from the latter.

The 2,7-diaminofluorene used here was obtained commercially and was purified by repeated recrystallizations from alcohol. The PVA powder used for the preparation of the sheets was a commercial product (mean degree of polymerization=1500, Nippon Gosei Co., Ltd., NM-14); it was used without further purification.

Measurements. The dichroic spectra using stretched PVA sheets were determined by a method described elsewhere.[5]

Divided Spectra. The method of obtaining the divided spectra has already been described[5]; that is, the relation between R_d and R_s is represented by:

$$2r^2 = \frac{2(T-1)+(T+1)R_d}{2T+(T-1)R_d} \tag{1}$$

where

$$T = \frac{R_s^2}{(R_s^2-1)}[1-\{\pi/2-\tan^{-1}(R_s^2-1)^{-1/2}\}(R_s^2-1)^{-1/2}]$$

R_d is the dichroic ratio ($R_d=D_{//}/D_{\perp}$), R_s is the stretching ratio of the PVA sheet, and r is a parameter whose inverse cotangent, $\cot^{-1}r$, indicates the angle between a transition moment and the orientation axis of a molecule.

In the case of a planar molecule having at least one C_2 symmetry axis, the absorption spectrum is divided into two kinds of absorption curves whose transition moments are parallel (x) and perpendicular (y) to the symmetry axis by the use of the dichroic spectra.

From Eq. (1), $R_{d\infty}$ is represented as:

$$R_{d\infty} = 2r^2 \tag{2}$$

where $R_{d\infty}$ is the dichroic ratio for stretching the PVA sheet to infinity. The observed optical density, D, in the unstretched PVA sheet and the ratio of D_x and D_y are given by:

$$D = D_x + D_y \tag{3}$$

$$\frac{D_x}{D_y} = \frac{2-R_{d\infty}\cot^2\varphi}{R_{d\infty}-2\cot^2\varphi} \tag{4}$$

where D_x and D_y are the optical densities whose transition moments are along the x- and y-axes respectively, and where φ is the angle between the x-axis and an orientation axis of a

molecule. Hence, by using Eqs. (2), (3), and (4), D can be divided into D_x and D_y.

Method of Calculation

The Pariser-Parr-Pople approximation[6] including a variable β method[7] was employed. The one-center repulsion integrals were obtained from the valence-state ionization potentials $I(r)$ and the electron affinities $A(r)$, $(rr|rr)=I(r)-A(r)$. The two-center repulsion integrals were evaluated by using the Nishimoto and Mataga equation, $(rr|ss)=14.397/(a_{rs}+R_{rs})$, where a_{rs} is a parameter determined from the equation:

$$14.397/a_{rs}=\{(rr|rr)+(ss|ss)\}/2.$$

The resonance integrals, β_{rs}'s, were adjusted at every iteration of the SCF calculations by means of the $\beta_{rs}=-1.84\ -0.51P_{rs}$ relation, where P_{rs} is the bond order of the r–s bond.

The valence-state ionization potential and the electron affinity for each carbon atom were taken as 11.42 eV and 0.58 eV respectively. The geometry and the numbering of the atoms used here are shown in Fig. 1.

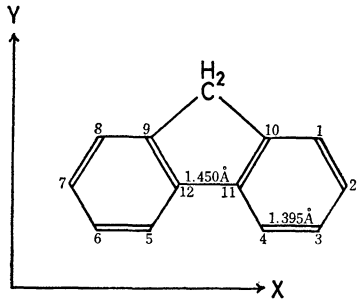

Fig. 1. Geometry of fluorene.

Results and Discussion

In Fig. 2 the absorption spectra of biphenyl, fluorene, and diprotonated-2,7-diaminofluorene are shown. As may be seen from this figure, the absorption curve of diprotonated-2,7-diaminofluorene is almost the same with that of fluorene; therefore, it seems reasonable to regard the results obtained from diprotonated-2,7-diaminofluorene as representing those of fluorene.

Biphenyl shows only one absorption maximum, at 257 mμ, above 210 mμ, whereas fluorene has an additional band at 300 mμ besides the 262 mμ band, which corresponds to the 247 mμ band of biphenyl. Figure 3 shows the "divided spectra" of diprotonated-2,7-diaminofluorene. From this figure, it is clear that the additional band at 300 mμ is polarized to the x-axis. The polarization of the intense 263 mμ band is along the x-axis, but a weak band polarized along the y-axis is hidden under this intense band. The absorption tail at around 220 mμ consists of two kinds of bands (x- and y-polarization). Thus, it may be concluded that fluorene has five absorption bands above 210 mμ.

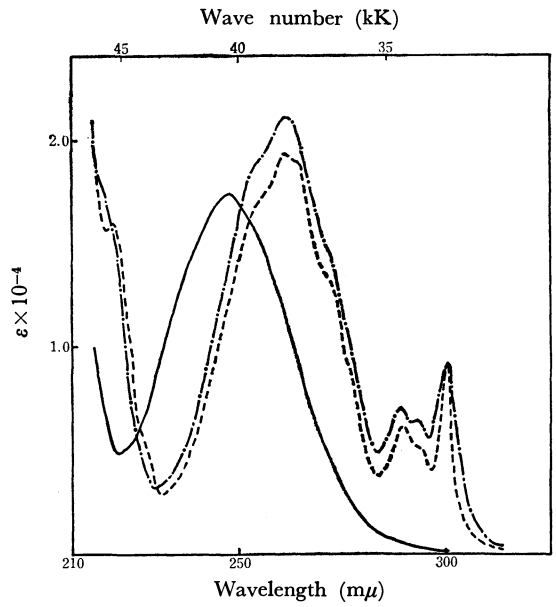

Fig. 2. Absorption spectra of biphenyl (——, in ethanol), fluorene (----, in ethanol), and diprotonated-2,7-diaminofluorene (—·—, in 80% ethanol).

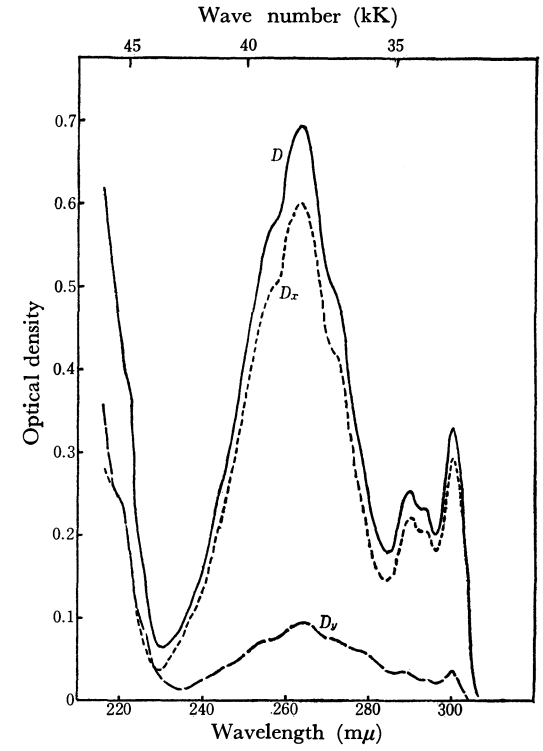

Fig. 3. Divided spectra of diprotonated-2,7-diaminofluorene.
D: The absorption spectrum in the non-stretched PVA sheet.
D_x: The x-component of D. D_y: The y-component of D.

According to Platt,[8] the additional 300 mμ band of fluorene may be interpreted as corresponding to the hidden band of biphenyl (^1L_b). This is not consistent with the present experimental results, because the ^1L_b band should be polarized to the short axis (y-axis) of the molecule. According to the calculated results obtained by Momicchioli *et al.*,[3] fluorene has five transitions below 6 eV; the lowest transition is of

TABLE 1. A COMPARISON OF THE EXPERIMENTAL AND CALCULATED RESULTS FOR FLUORENE ($I(9)=I(10)=14.42$ eV)

	Transition energy Calcd eV (mμ)	Obsd eV (mμ)	Ocsillator sterngth Calcd	Polarization Calcd	Obsd	Symmetry
I	4.17 (297)	4.13 (300)	0.2982	x	x	B_1
II	4.25 (292)	4.71 (263)	0.0051	y	y	A_1
III	4.67 (266)	4.71 (263)	0.5389	x	x	B_1
IV	5.72 (217)	5.64 (220)	0.0781	y	y	A_1
V	5.83 (213)		0.1359	x	x	B_1

$^1A_1 \rightarrow {}^1A_1$ while the other four transitions are of $^1A_1 \rightarrow {}^1B_1$ type. These calculated results are also not sufficient to explain the results of the "divided spectra, since the polarizations of the four calculated transitions are along the x-axis (in the "divided spectra", two y-polarized bands are found); besides, the oscillator strength of the transition which may correspond to the 300 mμ band is too small. Therefore, in order to explain the results of the "divided spectra," we carried out MO calculations.

Commonly, there are two concepts for interpreting the effects of a methylene group on the π-electron system; one is that of hyperconjugation, and the other, an inductive concept. In the present paper, the effects of the methylene group in fluorene were treated as inductive; we calculated the state energies and the excited-state wave functions, increasing the ionization potentials of the carbon atoms at the 9 and 10 positions of biphenyl.[9] The results of the calculations are shown in Fig. 4. The results when the ionization potentials of the two carbon atoms are 14.42 eV agree well with those of the "divided spectra." The results calculated for biphenyl are also shown in Fig. 4a. In this case, four forbidden transitions are found at 34.1 kK (293 mμ), 34.5 kK (290 mμ), 45.8 kK (218 mμ), and 46.4 kK (216 mμ). A weak absorption band corresponding to the forbidden transition at 34.1 or 34.5 kK has been observed at 33.6 kK (298 mμ) in crystal and in solution at low temperatures.[10–13]

The four forbidden transitions of biphenyl become allowed transtions when the ionization potentials of the carbon atoms at the 9 and 10 positions are increased, and the four forbidden transitions at 34.1, 34.5, 45.8, and 46.4 kK are changed to the y-, x-, x-, and y-polarized transitions respectively. This may be due to the fact that, when the ionization potentials are increased, the symmetry of the π-electron system of biphenyl skeleton is reduced from D_{2h} to C_{2v}, in which the biphenyl skeleton is assumed to be a plane. By assuming that the two benzene rings of biphenyl are not coplanar, the symmetry of the π-electron system is also reduced from D_{2h} to D_2; however, Gondo[1] has indicated that the forbidden transitions of biphenyl are not changed into allowed transitions by this treatment.

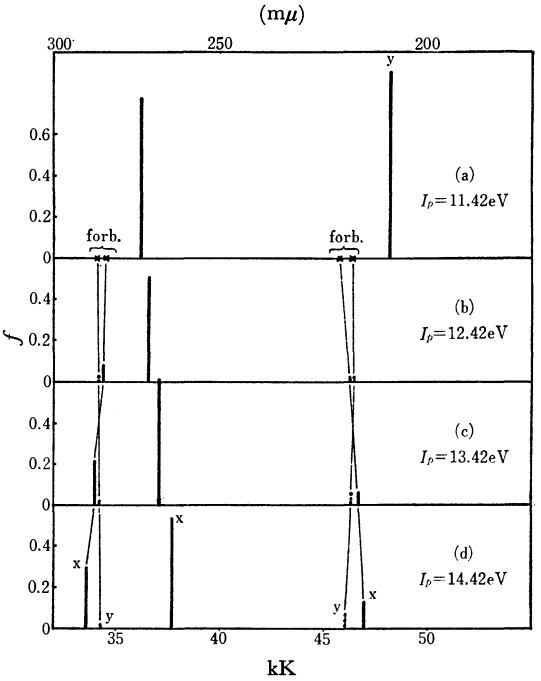

Fig. 4. Changes in the transition energies of biphenyl for the variation of the ionization potentials of the 9- and 10-carbon atoms.

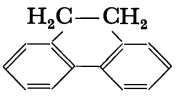
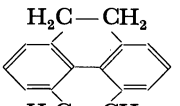


9,10-dihydrophenanthrene



4,5-dimethyl-9,10-dihydrophenanthrene

Mislow *et al.*[14] have observed an additional band at 300 mμ in the case of 9,10-dihydrophenanthrene, as in the case of fluorene. This may be explained just as in the case of fluorene. However, the additional 300 mμ band disappears upon the introduction of two methyl groups at the 4- and 5-carbon atoms of 9,10-dihydrophenanthrene.[14] This may be attributed to the fact that the approximate symmetry of the π-electron system again becomes D_{2h} (4,5-dimethyl-9,10-dihydrophenanthrene) from C_{2v} (9,10-dihydrophenanthrene) upon the introduction of the two methyl groups.

In Table 1 the calculated results of fluorene ($I(9)=I(10)=14.42$ eV) are summarized and compared with the results of the "divided spectra."

The Effect of Benzene on the Reaction of the Recoil Bromine Atom with Ethyl Bromide[1)]

Takanobu SHIOKAWA, Toshiro SATO,* and Kenjiro KONDO**

Department of Chemistry, Faculty of Science, Tohoku University, Kotohiracho, Sendai

(Received December 17, 1970)

An attempt was made to estimate the effect of benzene on the recombination reactions of the recoil bromine atoms activated by the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ and $^{81}Br(n,2n)^{80m}Br$ reactions in ethyl bromide and benzene mixtures. It seems to be reasonable to conclude, from the consideration of the parent yield, that the reactions leading to the formation of parent molecules in the thermal and high-energy regions can be classified into two reaction types. Judging from the results of the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction, approximately 53% of the parent yield from the high energy reactions in the pure ethyl bromide system is formed through the de-excitation process of the excited ethyl bromide labelled by the direct substitution reaction of the energetic recoil atom, while 47% is formed by the reaction of the recoil atom with ethyl radicals in the cage. The reaction of ethylene with hydrogen bromide, which is produced by the decomposition of the labelled excited ethyl bromide, contributes about 51% of the parent yield from the thermal energy reaction; the rest is formed by the other thermal reactions. Furthermore, no essential difference was observed between the recombination reactions of the recoil ^{82}Br and ^{80m}Br atoms produced by the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ and $^{81}Br(n,2n)^{80m}Br$ reactions respectively.

Many investigations have been carried out into the chemical effects associated with the nuclear transformations of bromine atoms in organic bromide systems, with emphasis laid especially on the recombination processes of recoil bromine atoms in the pure organic bromide systems.

Recently, binary and ternary mixtures of the organic bromides and hydrocarbons, such as benzene or cyclohexane, have been employed in order to evaluate precisely the recombination processes of the recoil bromine atoms in the high- and thermal-energy regions.[2-8a)] However, most of these studies have been made in terms of overall organic yields.

It has now been attempted to estimate the individual yields of labelled products and to make more detailed interpretations of the recombination processes of recoil bromine atoms.

The individual yields resulting from the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ and $^{81}Br(n,2n)^{80m}Br$ reactions in the mixtures of benzene and ethyl bromide were examined. Important information was obtained from the correlation between the parent yields from the high- and the thermal-energy reactions upon the addition of benzene, and from the isotope effects between ^{80m}Br and ^{82}Br recoil atoms.

Experimental

Materials. E.P.-grade ethyl bromide and G.R.-grade benzene, supplied by the Junsei Chemical Co., Ltd., were purified with the ordinary method described in Ref. 8, and their purities were checked by means of a gas chromatograph. The contents of the impurities in the ethyl bromide and benzene used for the experiments were less than 0.025% and 0.001% respectively. The bromine used was the highest grade available.

Irradiation. About 0.3—0.5 m*l* portions of the mixtures of ethyl bromide and benzene or bromine was sealed into a quartz ampoule. Thermal neutron irradiations were made 3—5 min in a pneumatic tube of JRR-1 of the Japan Atomic Energy Research Institute at room temperature at a neutron flux of 3×10^{11}n/cm^2/sec, with a concomitant gamma ray dose rate of 10^4R/hr. In the case of the $^{81}Br(n,2n)^{80m}Br$ reaction, all the irradiations were made for 2 hr with 14 MeV neutrons at a flux of 10^6n/cm^2/sec resulting from the $^3H(^2H,n)^4He$ reaction, where the effect of thermal neutrons and γ-dose on the organic yield was neglected.

Determination of Organic Yields. The irradiated samples were separated into organic and inorganic fractions by using the ordinary extraction method,[8)] and the overall organic yield was determined as a ratio of the activity in the organic fraction to the total activity. All the extraction procedures were performed after the irradiated samples had been allowed to stand long enough for the $^{78}Br(t_{1/2}$: 6.5m) produced by the $^{79}Br(n,2n)^{78}Br$ reaction in the fast neutron experiment and the $^{80m}Br(t_{1/2}$:4.38hr) produced by the $^{79}Br(n,\gamma)^{80m}Br$ reaction in the thermal neutron experiment to decay out. The organic fraction was then divided into two aliquots: one (Aliquot I) was used as the standard, and the other (Aliquot II) was submitted to gas chromatographic separation after the addition of various organic bromides as carriers. Each fraction of the organic bromides was collected in a coiled glass tube cooled in a dry-ice ethanol bath at the outlet of the column. The various products were separated by means of a gas chromatograph in a temperature-programmed all-stainless-steel column (0.6 cm in diameter and 3 m long), using tricresyl phosphate or silicone DC 703 as

staionary phase and helium as the eluent gas. Furthermore, the collected ethyl bromide and the Aliquot I mentioned above were each allowed to completely react with the sodium metal by using ethanol as the solvent; then the concentration of bromine present in these fractions was determined by the Volhard method. The parent (P) and other product yields (Q) are given by the following formulas:

$$P = \frac{A_p}{A_o} \times \frac{S_o}{S_p} \times R\,(\%)$$

$$Q = \frac{A_q}{A_p} \times P\,(\%)$$

R: overall organic yield
A_p: activity of the collected ethyl bromide fraction
A_o: activity of the Aliquot I
A_q: activity of the product
S_o: concentration of bromine of the Aliquot I
S_p: concentration of bromine in the collected ethyl bromide fraction

The higher-boiling-point products, which were inseparable by means of the gas chromatograph, were observed in this system, so these procedures were necessary to obtain the absolute yields of the organic products. Only the products having boiling points lower than that of dibromobenzene were investigated; no attempt to obtain the yields of the various products other than ethyl bromide was made in the (n, 2n) experiment.

Activity Measurements. The activities of the ^{82}Br from the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction and of the ^{80m}Br from the $^{81}Br(n,2n)^{80m}Br$ reaction were meaured by using a sodium iodide crystal scintillation counter. The experimental error arising from the activity measurements were of the following magnitudes: (1) for overall organic yields: ±2—3%, and (2) for the product yield: ±3—15%. No correction was made for the ^{82}Br formed by (n,γ) on ^{81}Br, which accounts for 7% of the total ^{82}Br activity.[9]

Results

In order to estimate the contribution of the thermal reaction (scavenger sensitive reaction) and the high-energy reaction (scavenger insensitive reaction) to the product yields in ethyl bromide and benzene mixtures, it is necessary to establish the scavenger curves for a number of mixtures of ethyl bromide and benzene. As a typical example, Fig. 1 indicates the scavenger curve of each product obtained in the mixture of ethyl bromide (0.87 mf: mole fraction)-benzene (0.13 mf) in the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction and of ethyl bromide (0.89 mf)-benzene (0.11 mf) in the $^{81}Br(n,2n)^{80m}Br$ reaction. Although, in this experiment, the organic yields were not corrected for the ^{82}Br directly formed by the $^{81}Br(n,\gamma)^{82}Br$ reaction, which accounts for about 7% of the total ^{82}Br,[9] it can be expected that its contribution to the organic yields is very small, since the overall organic yields for the ^{82}Br formed by the $^{81}Br(n,\gamma)^{82}Br$ and $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ processes were almost the same as those for the ^{80m}Br and ^{80}Br produced by (n,γ) on ^{79}Br in the pure ethyl bromide.[8a,10]

The fraction of the high-energy-reaction yield for each labelled product is given as an intercept on the coordinate axis by extrapolating each scavenger curve to zero scavenger concentration. The scavenger curve for dibromobenzene shows a minimum at a bromine concentration of 0.05 mf, and the yield gradually increases at higher bromine concentrations. The value of 0.23% at 0.05 mf of bromine was employed as the approximate yield due to the high-energy reaction.

The scavenger curves of 1,1- and 1,2- dibromoethane were very similar to the results previously reported by Shaw *et al.*[11] for their recoil study of the ^{80m}Br produced by (n,γ) on ^{79}Br in the pure ethyl bromine system; it showed almost a $(1-C)$ dependency at bromine concentrations higher than 0.15 mf (C: mole fraction of bromine). On the other hand, the parent scavenger curve showed a $(1-C)/(1+C)$ dependency at bromine concentrations higher than 0.15 mf. and the parent yield due to the high-energy reactions was obtained by the normalization by $(1-C)/(1+C)$. The experimental data for each product due to the thermal and the high-energy reactions obtained in this way are summarized in Figs. 2 and 3, together with the total yields from both the thermal and high-energy reactions in the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction. The total organic

yields obtained in the (n,2n) experiment were shown in Ref. 8a.

For the systems in which the overall organic yield were not obtained experimentally, the overall organic yields, as estimated graphically, were used for the calculation.

The most interesting aspect of the results shown in Figs. 2 and 3 is that the parent yields from the thermal and the high-energy reactions are affected similarly by the addition of benzene. This suggests that there is a close correlation between the formations of the labelled parent molecules in both the reaction regions. The sum of the product yields in the two reaction regions in the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction is given by a dotted line in Figs. 2 and 3. Here, the yields of other products, such as tetra-bromomethane, tri- and tetra-bromoethane, were less than 0.2 percent at most and are not included in Figs. 1, 2, and 3.

As is shown in Fig. 2, the total organic yield from the thermal energy reaction was very close to the sum of the yields of the individual products obtained experimentally. On the other hand, Fig. 3 shows that the sum of each product yield from the high-energy reactions was very low, compared with the total organic yield; especially, it was only about 40—60% of the total organic yield at benzene concentrations higher than 0.2 mf. This difference corresponds to the yields of the higher-boiling-point products which were not analyzed in this experiment. Furthermore, the sharp increase in the yields of higher-boiling-point products from the high-energy reactions at 0—0.2 mf of benzene can be practically accounted for as compensation for the decrease in both parent yields due to the thermal and the high-energy reactions as is shown in Fig. 4. This definitely suggests that, in the presence of benzene, there are some reaction

paths interrupting the formation of the labelled parent molecules from the thermal and the high-energy reactions. On the other hand, the yields of CH_3Br, CH_2Br_2, $CHBr_3$, 1,1- and 1,2-$C_2H_4Br_2$ decreased gradually as the benzene concentration became higher; however there were no remarkable effects on the formation of these labelled molecules by the addition of benzene. The parent yields from the thermal and the high-energy reactions are approximately 0.5—3.9 percent higher in the $^{81}Br(n,2n)^{82m}Br$ reaction than those in the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction, as is shown in Fig. 4. However, the parent-yield curves very similar tendency for the addition of benzene in both nuclear transformations.

Discussion

Recombination Reactions of Recoil ^{82}Br and ^{80m}Br Atoms. It appears from Fig. 4 that, in the presence of 0—0.2 mf of benzene, the parent yields from the thermal and the high-energy reactions in the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction decreased abruptly in a similar fashion, and that, furthermore, this decrement in both the parent yields was almost equal to the increase in the yields of the higher-boiling-point products due to the high-energy reactions. This suggests that a part of the recoil bromine atoms react with ethyl bromide during the slowing-down process, thus contributing to the formation of some excited species labelled with ^{82}Br, and that, in the presence of benzene, higher-boiling-point products are produced by the reactions of those exicted species with benzene.

These trends can be explained by assuming that a part of the recoil atoms can undergo the substitution reaction with the bromine atom of ethyl bromide by means of billiard ball-type elastic collisions, or inelastic collisions with ethyl bromide molecules, thus forming a labelled excited ethyl bromide. As is illustrated in Fig. 5, the labelled excited ethyl bromide should be partially de-excited by the interaction with neighbouring molecules, and it gives the parent yield from the high-energy reaction through the path 2. The residual is decomposed to give ethylene and hydrogen bromide through the path 1 by the analogy with the pyrolysis of ethyl bromide.[12] Then, the radioactive hydrogen bromide formed through the path 1 reacts thermally with the ethylene which is produced either through path 1 or by the pyrolitic decomposition of ethyl bromide molecules at the near site of recoil events, thus contributing to the formation of the labelled ethyl bromide due to the thermal reactions, as is shown in Eq. (1). Ethylene produced by a reaction other than path 1 also reacts with the radioactive bromine molecule and contributes to the formation of labelled 1,2-dibromoethane by means of the thermal reactions shown in Eq. (2);

$$CH_2{=}CH_2 + H^*Br \longrightarrow CH_3CH_2{}^*Br \quad (1)$$

$$CH_2{=}CH_2 + {}^*Br_2 \longrightarrow CH_2BrCH_2{}^*Br \quad (2)$$

It may be reasonable to assume that the reaction (1) of ethylene with hydrogen bromide will be predominant over the reaction (2) from the viewpoint of radiolysis and pyrolysis. However, in the presence of a bromine scavenger, ethylene will be immediately scavenged, and both the reactions, (1) and (2), are suppressed. Meanwhile, it is conceivable that, in the presence of benzene, these labelled excited ethyl bromide molecules may react instantaneously with benzene molecules through the path 3 in Fig. 5, thus contributing to the formation of higher-boiling-point products due to the high-energy reactions. The reaction mechanisms for the path 3 are not clear because these higher-boiling-point products have not been identified experimentally. However, it may be presumed that these excited ethyl bromide molecules have sufficient energies in excess of the activation energy required for the path 3.[13]

$$C_2H_5{}^*Br \longrightarrow CH_2CH_2 + H^*Br \quad \cdots\cdots(1)$$

$$\text{Higher boiling point products} \quad \cdots\cdots(3)$$

Fig. 5. Reaction paths of the excited ethyl bromide

Similarly, Rowland *et al.*[14–16] indicated that the decomposition and the de-excitation of the tritiated parent molecules in the excited state play an important role in determining the distribution of the yields of the various labelled products in the gas-phase reactions of recoil tritium with alkyl chlorides and hydrocarbons. Since little attention has been paid to the analysis of higher-boiling-point products, only the yields of thep roducts separated by gas chromatography were discussed. The authors have found that a considerable portion of the overall organic yields in the systems containing benzene, such as $C_6H_6+Br_2$ and $C_6H_6+C_6H_5Br$ systems, consists of higher-boiling-point products.

On the other hand, several radicals should be produced during the slowing-down processes of the energetic recoil bromine atoms, and a part of the recoil atoms which have escaped from the direct substitution reaction will recombine with such radicals in both the energy regions. In the cage, the recombination reactions of the recoil atoms with these radicals take place before the radicals start diffusing away, and consequently, contribute to the yields due to the high-energy reaction (immediate recombination reaction).

The recoil bromine atom which has escaped from the cage reacts with radicals or other reactants (C_2H_5Br, *etc.*) and thus contributes to the formation of labelled products in the thermal-energy region. The parent yield from the recombination reaction in the cage depends on the concentration of ethyl radicals, which will gradually be diminished by the addition of benzene because of the decrease in the collision probability of the recoil atom with the ethyl bromide molecule. Thus, the fact that the parent yield from the high-energy reactions shows a gradual decrease at benzene concentrations of more than 0.2 mf may be ascribed to the gradual

12) N. N. Semenov, "Some Problems of Chemical Kinetics and Reactivity," Pergamon Press, London (1958), p. 228.

13) Path 3 will probably involve the reaction of the excited ethyl bromide with C_6H_5 or C_6H_7 radicals formed in the recoil site.

decrease in the recombination reaction of the recoil bromine atom with the ethyl radical in the case. If it is assumed that the parent yield from the recombination reaction in the cage at 0—0.2 mf of benzene shows a dependence on the benzene concentration in the same manner as that obtained at about 0.2—0.8 mf of benzene, it is possible to divide the parent yield from the high-energy reaction in the pure ethyl bromide system into two parts by extrapolating the yield curve to zero mole fraction of benzene in Fig. 4.

The parent yield from the recombination reaction in the cage is estimated to be about 47% from the intercept of the yield curve in Fig. 4; the remaining 53% results from the de-excitation of the excited ethyl bromide molecules formed by the substitution reactions (path 2 in Fig. 5). Similarly, the parent yield from the thermal energy reactions can be classified into two parts by extrapolating the plateau of the yield curve at 0.2—0.8 mf of benzene in Fig. 4. It may be presumed that approximately 49% of the parent yield from the thermal energy reaction is formed by the reactions indicated by Eqs. (3), (4), and (5), while about 51% arises from the reactions of ethylene with the labeled hydrogen bromide produced through the path 1 in Fig. 5. The reaction shown in Eq. (5) may be disregarded because its activation energy is 25 kcal/mol,[17] too high for the thermal atoms to be involved.

$$C_2H_5 + {}^*Br \longrightarrow C_2H_5{}^*Br \quad (3)$$

$$C_2H_5 + {}^*Br_2 \longrightarrow C_2H_5{}^*Br + Br \quad (4)$$

$$C_2H_5Br + {}^*Br \longrightarrow C_2H_5{}^*Br + Br \quad (5)$$

The active bromine atoms escaped from the site of recoil events normally form inorganic compounds such as H*Br, as has already been shown.[18,19] The scavenger curve of 1, 2-dibromoethane in Fig. 1 shows a slight increase in the yield at low bromine concentrations. This fact indicates that there are $CH_2CH_2{}^{82}Br$ radicals formed by the reaction of ^{82}Br with CH_3CH_2Br in the high-energy region, as was postulated by Shaw *et al.*[11] in their study of the recombination reaction of the ^{80m}Br produced by the (n,2n) reaction of ^{81}Br in the pure ethyl bromide system. Another explanation would be possible for the sharp fall of the parent yield at 0—0.2 mf of benzene in Fig. 3 if the $CH_2CH_2{}^{82}Br$ radical could be considered a labeled excited species instead the labelled excited ethyl bromide. However, this explanation is not acceptable since there is no correlation between the parent and 1,2-dibromoethane yields upon the addition of bromine, as is illustrated in Fig. 1.

As is shown in Fig. 2, the parent and the total organic yields from the thermal-energy reactions show quite different features at 0.2—0.8 and at 0.8—1.0 mf of benzene. This can be understood by considering that, at high benzene concentrations, the reaction of recoil bromine atoms with hydrogen radicals resulting from Eq. (6) becomes predominant and contributes to the sharp decrease in the parent and the total organic yields from the thermal reactions. Similar reactions have been postulated by Shaw[4] to account for the overall organic yield obtained in the solution of ethyl iodide and iodine in benzene. As to the yields of the other products, such as dibromomethane, 1,1- and 1,2-dibromoethane, no remarkable effect was observed in either energy region on the addition of benzene, indicating that benzene acts almost as a diluent.

$$C_6H_6 + C_6H_5 \longrightarrow C_6H_5C_6H_5 + H \quad (6)$$

Isotope Effect between the $^{81}Br(n,2n)^{80m}Br$ and $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ Reaction. In the case of the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction, various products labelled with ^{82m}Br, such as $H^{82m}Br$, $CH_3{}^{82m}Br$, $Br^{82m}Br$, and $C_2H_5{}^{82m}Br$, undergo further isomeric transition to the ground state of ^{82}Br. As a consequence of the isomeric transition, followed by the Auger electron emission, ^{82}Br should have a high positive charge. It is postulated that this highly positive charge is partially neutralized by electron transfer from the remainder of the molecule or the neighbouring molecule, and that the recoil ^{82}Br obtains a considerable recoil energy ($\sim$10eV) resulting from Coulombic repulsion.[20] The individual product yields resulting from the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction in the pure ethyl bromide were almost equal to those previously reported by other investigators for the $^{79}Br(n,\gamma)^{80}Br$ and $^{79}Br(n,\gamma)^{80m}Br$ reaction.[10,11] The absence of any isotope effect between these nuclear transformations seems reasonable, since the chemical fate of the recoil atom must be determined after it has lost most of its energy and can thus be expected not to be influenced by the slight difference in the initial energy.

However, in the case of the $^{81}Br(n,2n)^{80m}Br$ reaction with a recoil energy about 1000 times greater than that of the $^{81}Br(n,\gamma)^{82}Br$ reaction, an energy dependency of the organic yield might be expected. The parent yields due to the thermal and the high-energy reactions from the $^{81}Br(n,2n)^{80m}Br$ reaction were a little higher than those in the $^{81}Br(n,\gamma)^{82m}Br \xrightarrow{I.T} {}^{82}Br$ reaction, as is illustrated in Fig. 4.

However, the yield curve in Fig. 4 indicates a very similar dependence on the benzene concentration in both nuclear transformations. These results suggest that there is no essential difference in the mechanisms between these nuclear transformations. The differences between the parent yields for ^{82}Br and ^{80m}Br at 0—0.2 mf of benzene can be explained mainly in terms of the different probability of the formation of labeled excited ethyl bromide because of the low collision probability of ^{82}Br with a lower recoil energy in comparison with ^{80m}Br. Furthermore, it can be understood that a much higher recoil energy, causing disturbance over a wide range in the system, serves to enhance the parent yields resulting from the reactions in the cage and thermal recombination reactions after the recoil atoms have diffused away.

The Emission Spectra of Hydrogen Atoms Produced from Methanol by Electron Impact

Iwao FUJITA, Motoyoshi HATADA,* Teiichiro OGAWA,[1] and Kozo HIROTA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

* *Osaka Laboratory for Radiation Chemistry, Japan Atomic Energy Research Institute, Mii, Neyagawa, Osaka*

(Received December 25, 1970)

The emission spectra of several fragmental species, especially of hydrogen atoms, produced by the electron impact (energy: 240 eV) of gaseous methanol and deuteromethanols have been investigated. The intensity ratios of the Balmer-β lines of the H and D atoms are *ca.* 2.9:1 for CH_3OD and *ca.* 1:1.8 for CD_3OH, indicating that the excited hydrogen atoms result from the O–H bond scission, as well as from the C–H bond scission, of the parent methanol molecules. The ratio of the scission probability of a C–H bond to that of the O–H bond is calculated to be 0.8, taking into account the correction of the isotope effect. It was concluded that the excited hydrogen atoms are produced by the primary process of fragmentation *via* a superexcited species.

The emission spectra of simple molecules under electron impact have been studied extensively by several investigators,[2–5] and information has been obtained on the lifetime of the excited species thus produced by the use of the spectrophotometric method.[6–8] However, few studies have dealt with the emission spectra of organic molecules.[9]

In the radiation-chemical reaction of methanol, the primary process is generally considered[10] to be the split-off of a hydrogen atom from the methyl group of a methanol molecule, Eq. (1a). This conception is based on various pieces of

$$CH_3OH \begin{cases} \nearrow \dot{C}H_2OH + H & (1a) \\ \searrow CH_3\dot{O} + H & (1b) \end{cases}$$

evidence; *e.g.*, the $\dot{C}H_2OH$ radical was found in irradiated solid methanol by the ESR method,[11] and the peak of the CD_2OH^+ ion appeared abundantly in the mass spectrum of CD_3OH.[12] Contradicting the above conclucion, however, one critical experiment[13] reported that, in the γ-ray radiolysis of CH_3OD, the amount of HD in the produced hydrogen reached 60%, and also a little D_2 appeared. This finding can be easily explained if the scission of the C–H and the O–H bonds is assumed to occur with the same probability in the primary process of fragmentation, but the result was later understood in terms of an ion-molecule reaction.[12] Most methods hitherto used identify only the products which have already been stabilized. Unlike these indirect methods, however, emission spectra under electron impact may give direct information as to the excited hydrogen atoms produced by electron impact.

In the present investigation, the emission spectra of the fragmental species produced from methonal and deuteromethanols by electron impact were observed, and the origin of excited hydrogen atoms was discussed on the basis of the isotopic ratio of the hydrogen produced.

Experimental

The electron-impact apparatus was described in a previous paper.[14] The acceleration voltage of the electrons was 240 V and the electron current was between 20 and 300 μA. The gas pressure was estimated at about 10^{-2}mmHg by the use of a Pirani gauge attached near the collision chamber.

The photoemission was observed in the direction perpendicular to the electron beam, and the gas flow, through a quartz window by means of a Shimadzu GE 100 grating monochromator equipped with an EMI-6256B photomultiplier.

The CH_3OH was obtained from Nakarai Chemicals, and the CD_3OD and CH_3OD, from Merck. The CD_3OH was prepared from CD_3OD *via* $(CD_3O)_2Mg$, and was distilled in a vacuum four times. In order to eliminate the mixing of hydrogen occluded in the wall of the apparatus, the sample gas was introduced into the reservoir and collision chamber and then removed by evacuation. This procedure was repeated until a constant spectrum was obtained.

Results

Figure 1 shows the emission spectrum obtained by the electron impact of CH_3OH in the region from 350 to 500 nm. Similar spectrum can be observed from CD_3OD. No bands of the excited methanol molecule, the CH_3 radical, the CH_2 radical, or their ions are found in the same wavelength region. The intense peaks in the spectrum belong to the Balmer series of the H atom and the comet-tail band system of the CO^+ ion. The Balmer-α (656.3 nm) was not observed because of the low sensitivity of the photomultiplier in the longer-

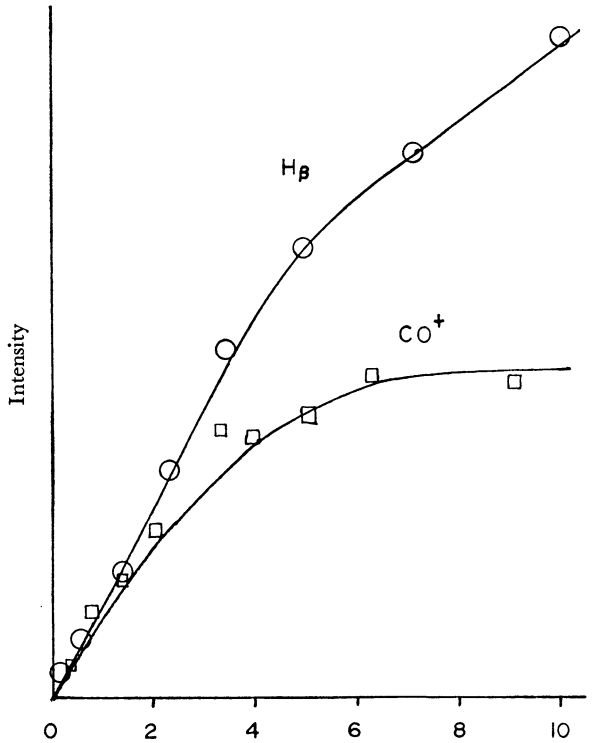

Fig. 3. Dependency of intensities of the H_β and the comet-tail (2,0) band on the gas pressure; the target current: 50 μA.

wavelength region, whereas Balmer-β (486.1 nm), Balmer-γ (434.0 nm), Balmer-δ (410.2 nm), and Balmer-ε (397.0 nm) were clearly observed. The "ct" sign in Fig. 1 represents the comet-tail band (CO^+ A $^2\Pi \longrightarrow$ X $^2\Sigma^+$), while the two numbers in parentheses following represent the vibrational quantum numbers of the upper and lower electronic states respectively. Furthermore, the Baldet-Johnson band (CO^+ $B^2\Sigma^+ \longrightarrow$ A $^2\Pi$) and the 430 nm band of the CH radical (A $^2\Delta \longrightarrow$ X $^2\Pi$) are found.

The linear dependency of the intensities of the Balmer-β line and the comet-tail (2,0) band on the target current, as shown in Fig. 2, indicates that the excited species are produced primarily by a collison of a parent molecule with an electron. The dependency of the intensities of these peaks on the pressure in the gas reservoir is shown in Fig. 3. The pressure in the collision chamber was estimated to be higher than one seven-hundredth of the pressure in the gas reservoir. The intensities of the Balmer-β line and the comet-tail (2,0) band increase linearly with an increase in the gas pressure up to a certain pressure, but they increase more slowly above this pressure. The levelling-off of the intensities at higher gas pressures may be due to the collisional deactivation of the excited species, and not to the self-absorption of the emission. Similar behavior has also been reported for the emission spectrum of carbon monoxide by Rothe and McCaa,[15] who

15) D. E. Rothe and D. J. McCaa, Technical Report CAL No. 165 (1968).

observed that the intensities of the emission bands of CO^+ increase rapidly up to *ca.* 5×10^{-2} mmHg in pressure and thereafter increase gradually, while the neutral CO bands (Herzberg and Angstrom) increase rapidly with an increase in the carbon monoxide pressure.

In order to find the absolute cross-section of the Balmer-β line from methanol, a mixture of a known composition of CD_3OD and CH_4 was bombarded by electrons, and the intensities of the Balmer-β emissions of the H and D atoms, which are separated by 1.3 Å, were measured. The cross-section of the Balmer-β emission from CD_3OD is determined to be *ca.* 4×10^{-19} cm^2 by normalization to the absolute cross-section of the Balmer-β line from CH_4 reported by Vroom and De Heer,[9] although the present cross-section may involve some error because of the relatively high pressure.

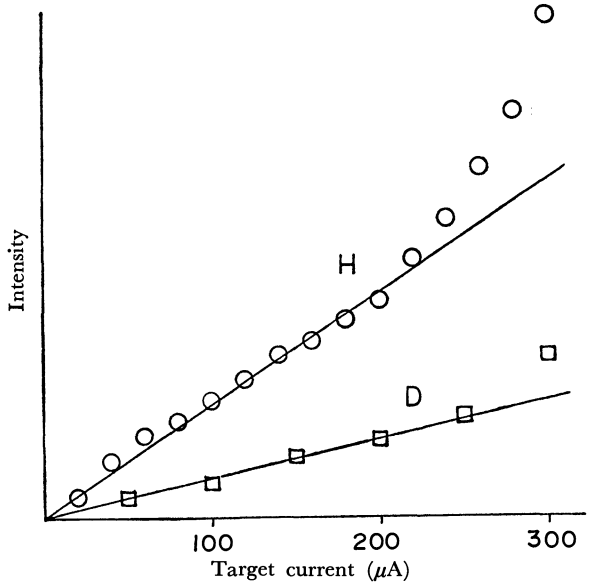

Fig. 4. Intensity of Balmer-β emission of H and D from CH_3OD; the pressure in the gas reservoir: 10 mmHg.

In order to determine the emission probabilities of the Balmer-β radiation of hydrogen atoms from the methyl group and the hydroxyl group separately, the intensity ratios of the Balmer-β emissions of the H and D atoms from CH_3OD and CD_3OH were determined. Figure 4 shows the intensities of the Balmer-β emissions of H and D from CH_3OD against the target current. The curves deviate upwards from the linear lines above a certain target current, indicating the contribution of some excited hydrogen atoms produced by collisions with two or more electrons. The intensity ratio of the Balmer-β line of H to that of D resulting from the bombardment of CH_3OD is about 2.9 in the linear part of Fig. 4, whereas that of D to that of H from CD_3OH is about 1.8. The disagreement of the above ratios for CH_3OD and CD_3OH indicates the existence of an isotope effect.

Assuming that the bond scissions of the methyl and hydroxyl groups are independent of each other, and that their isotope effect is equal in size in both groups, the following two conclusions can be drawn from the above results. First, the emission probability of D is less than that of H by *ca.* 20%, a value which is comparable to the isotope effect observed for CH_4 and CD_4.[9] Second, the probability of the production of the excited hydrogen atom from the methyl group is less by *ca.* 20% than that from the hydroxyl group per each hydrogen atom, taking into account the correction of the isotope effect.

Discussion

In the radiolysis of methanol, it was previously concluded, as has been mentioned above, that the primary process of fragmentation is a C–H bond scission.[10] This conclusion, supported by several experimental results, seems reasonable on the basis of the difference in the bond energies of the C–H and O–H bonds, the former having the smaller bond energy by 7.5 kcal/mol.[16] Nevertheless, the present measurement of the production of excited hydrogen atoms shows that a bond scission of the O–H bond is as probable as that of a C–H bond. However, this study is concerned only with the production of the excited hydrogen atom, and not with that of the hydrogen in the ground state. Therefore, the contribution of the excited hydrogen atoms to the overall production of hydrogen atoms is not established by the present experiment.

The emission probabilities of hydrogen atoms from the methyl and hydroxyl groups are of nearly the same magnitude; those from methanol and methane are also found to be comparable. These findings are interesting with regard to the result on some hydrocarbons that the number of excited hydrogen atoms produced in a particular energy level is practically independent of the hydrocarbons.[9]

Table 1. Energies for reactions

Reaction	Energy (eV)	Ref.
$CH_3OH \longrightarrow CH_3\dot{O}+H$	4.3	16
$CH_3OH \longrightarrow \dot{C}H_2OH+H$	4.0	16
$CH_3OH \longrightarrow CH_3OH^+ + e$	10.83	19
$H\,(n=1) \longrightarrow H\,(n=4)$	12.75	

The excited hydrogen atom must be produced *via* a superexcited methanol molecule, as was pointed out by Platzman *et al.*,[17,18] because the sum of the bond energy of the C–H or O–H bond and the excitation energy of a hydrogen atom is greater than the ionization energy of methanol, as is shown in Table 1. The autoionization and dissociation of the superexcited molecule compete, and the isotope effect exists only in the dissociation process, which is affected by the nuclear mass difference. Hence, the superexcited molecule containing a heavier isotope has, in general, a smaller probability of dissociation. The isotope effect of the Balmer emission from methanol mentioned above is, therefore, reasonable.

Since the intensity ratio of the Balmer line of H to

19) M. I. Al-Joboury and P. W. Turner, *J. Chem. Soc.*, **1964**, 4434.

that of D had to be measured at pressures as high as 10^{-2} mmHg because of the weak intensity of the lines, the secondary effects which affect the intensity ratio, such as collisional deactivation or self-absorption, might occur in the present system. However, further discussion along these lines could not be made because of the present lack of quantitative data on these effects.

Conclusion

By the electron impact of methanol, various excited fragments, such as the H atom, the CO^+ ion, and the CH radical, were produced, but no larger excited fragments, no excited parent molecule, and none of the corresponding ions could be found in the spectral range from 350 to 500 nm.

It was concluded that the excited hydrogen atom resulted from the scission of the O–H bond as well as from that of the C–H bond, and that the probabilities per bond of the above two processes were of nearly the same magnitude, if the isotope effect is considered. It is not certain, however, if this process is as important as the one which produced the hydrogen atom in the ground state, so that the present finding may not contribute much to clarifying the total split-off processes of the hydrogen atom from methanol.

By a comparison of the Blamer-β emission for CH_3OD and CD_3OH, an isotope effect of about 20% was preliminarily estimated for the dissociative excitation for the H and D in the molecules, the former having the larger cross-section. This effect can be explained by a process including superexcitation.

We should like to express our gratitude to Professors S. Ikeda and Y. Yokoyama for allowing us to use a Shimadzu GE 100 monochromator and various accessories in their laboratory.

Studies of the Surface of Titanium Dioxide. I. The Effect of Reduction by Hydrogen on the Heat of Immersion in Water

Toru IWAKI and MASAJI MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 28, 1970)

The reduced state of the surface of titanium dioxide was studied by the measurement of the heat of immersion in water. When the titanium dioxide was reduced by hydrogen at 500°C, the heat value decreased appreciably with an increase in the pressure of hydrogen, in contrast to the increase in the heat value due to the reduction by an organic contaminant. The heat value was not restored to the original state even after oxygen had been introduced at 500°C to the reduced sample, while the color of the sample returned to white from bluish gray. These phenomena were interpreted by examining the adsorption of water, the reduced amount, and the reflectance spectrum.

It is well known that titanium dioxide is subject to a change in color from its initial white state to gray or bluish gray when heated *in vacuo* from 300 to 500°C. This color change has been considered to be caused by a removal of oxygen atoms from the surface. Such a reduction of titanium dioxide has been regarded as attributable to organic compounds which come from stopcock grease, diffusion pump oil, *etc.* in a vacuum system, and which are also occluded in titanium dioxide during its preparation.[1,2] When heated at a high temperature, these organic compounds are oxidized, resulting in the removal of oxygen atoms on the surface.

Titanium dioxide is also reduced easily by contact with a reducing gas, such as hydrogen or carbon monoxide, at a high temperature.[3] The removal of one oxygen atom from titanium dioxide produces two electrons which reside in the oxygen vacancy or the titanium ion. Reduced titanium dioxide is also well known to be an *n*-type semiconductor and to play an important role as a catalyst for such chemical reactions as the Fisher-Tropsch synthesis. Therefore, the investigation of the reduction of titanium dioxide is of interest in connection with the nature of the defect structures of solid surfaces. A number of studies of the bulk properties of reduced titanium dioxide have been performed for rutile modification by various methods,[4] but scarcely none have been done for anatase.

In the present study, the effect of an organic contaminant on the surface properties of anatase treated under several conditions was examined by measuring the heat of immersion in water. Further, in order to investigate the properties of the defect structure of the surface, the heat of immersion in water, the adsorption of water vapor, the weight change caused by the reduction, and the reflectance spectra were measured on anatase samples which were reduced by hydrogen

and reoxidized by oxygen.

Experimental

Material. Titanium dioxide supplied by Teikoku Kako Co., Ltd., was purified by the method described in a previous paper.[5] X-ray analysis showed well-crystallized anatase for the sample outgassed at 500°C.

The titanium dioxide was treated under the following several sets of conditions in order to investigate the effect of the organic contaminant on the heat of immersion:

(1) Outgassing at 500°C for 5 hr at 10^{-5} mmHg.

(2) Outgassing at 500°C for 5 hr with a liquid nitrogen trap just before the sample in order to prevent the effect of the vapor of the stopcock grease.

(3) After the (1) treatment, introducing oxygen gas through a liquid nitrogen trap for 2 hr at a pressure of 0.5 atm and 500°C and then outgassing at room temperature for 0.5 hr.

(4) After the (2) treatment, introducing oxygen in the manner described above.

(5) After the condensation of diffusion pump oil on the surface of titanium dioxide, outgassing as in the (1) treatment.

(6) After the (2) treatment, introducing hydrogen gas through a liquid nitrogen trap at 0.5 atm and 500°C for 2 hr and then outgassing at 500°C for 0.5 hr.

Further, in order to examine the reduced state of the surface brought about by the reduction with hydrogen, titanium dioxide was treated under the following conditions:

(7) After the (2) treatment, introducing hydrogen gas at various pressures, ranging from about 0.01 to 1 atm, in the same way as in (6).

(8) After the (6) treatment, introducing oxygen gas through a liquid nitrogen trap for 0.5 hr at 0.5 atm and room temperature or 500°C, and then outgassing for 0.5 hr at room temperature.

Heat of Immersion. The heat of immersion was measured at 25°C by using a calorimeter, as was described previously.[6] The detection limit of the temperature difference was $\pm 1.7 \times 10^{-5}$°C, and the heat evolved in the calorimeter could be measured within ±1%. The heat of breaking of a vacant ampoule was found to be 0.3±0.05 J; this was calibrated for the heat-of-immersion data.

Surface Area. The surface area of the sample was determined by nitrogen adsorption at 77°K using the BET method; the area of a nitrogen molecule was assumed to be 16.2 Å^2 at that temperature. The surface area of each sample was 144 m^2/g, independent of the treatment, except for a sample treated with oxygen at 500°C after reduction with hydrogen (treatment (8)); the surface area of that sample was 139 m^2/g.

Adsorption of Water Vapor. The adsorption isotherms of water vapor on several samples were measured volumetrically at 25°C.

Reduced Amount. The amounts of titanium dioxide reduced by hydrogen at 500°C for 2 hr were obtained with a Cahn RG electrobalance.

Reflectance Spectrum. The reflectance spectrum was measured at 25°C with a Hitachi Perkin-Elmer 139 spectrophotometer over the wavelength range from 300 to 900mμ.

Table 1. Heat of immersion of titanium dioxide in water

	Treatment	ΔH, erg/cm^2	Color
(1)	500°C, no trap	726	white or brown
(2)	trap	715	white
(3)	O_2	695	white
(4)	trap, O_2	695	white
(5)	oil	731	brown
(6)	H_2 (0.5 atom)	558	bluish gray

Results and Discussion

Effect of Organic Contamination on the Heat of Immersion. The values of the heat of immersion of titanium dioxide treated under the several sets of conditions are represented in Table 1. As is obvious by comparison of the (1) treatment with (2), the heat value is lowered slightly by using the liquid nitrogen trap. The sample became slightly brownish in the case of (1), but did not color in the case of (2). By the (3) or (4) treatment, the heat value was further decreased slightly as a result of the elimination of the organic contaminant by oxidation. Since the heat value was not so remarkably affected by the organic contaminant in the above cases, minute quantities of diffusion-pump oil were condensed on the sample. The results obtained by the treatment are shown in (5) of Table 1; the results indicate that the heat value increased by about 5% as compared with that of the (4) treatment. These results show that the heat of immersion is not influenced by the organic contaminant so remarkably as in the case of rutile reported by Hollabaugh and Chessick; in the latter case, the heat value increased by 120 erg/cm^2. The high value of the immersional heat is considered to arise from the reduced state of the rutile surface.[2] Therefore, the hydrogen gas was admitted to the sample at 500°C as in the (6) treatment in order to produce the reduced state to a considerable degree. In contrast to our expectations, the heat value for the surface decreased appreciably. Moreover, the sample was tinged bluish gray, different from the color caused by an organic contaminant. It seems that the surface state produced by the reduction with hydrogen is different from that produced with an organic contaminant. No further details of the effect of an organic contaminant on the surface properties were examined. Instead, the effect of reduction by hydrogen on the surface state will hereinafter be described.

Reduced State of Titanium Dioxide. In general, the surface of titanium dioxide is covered with hydroxyl groups. When the titanium dioxide is heated *in vacuo* at a high temperature, the surface hydroxyl groups may be removed as follows:

$$2OH^- \longrightarrow H_2O + O^{2-} \quad (1)$$

The resulting oxygen anion may be displaced from its original position to form a bridge, Ti–O–Ti. On the contrary, when dehydrated titanium dioxide is rehydrated, hydroxyl groups are again formed on the surface.

When a hydrogen molecule is introduced to the titanium dioxide at a high temperature, it removes the

oxygen anion as a water molecule, producing a defect structure according to the reaction:

$$O^{2-} + H_2 \longrightarrow H_2O + \square + 2e^- \quad (2)$$

where $\square$ is an oxygen vacancy.

In many studies of reduced rutile by examinations of the electric conductivity, the paramagnetic resonance, the dielectric relaxation, *etc.*, some results favor the oxygen vacancy as a dominant defect, some favor the interstitial titanium ion, and some favor a combination of the two.[7] At a high temperature, there are interstitial titanium ions, which may form the Magnéli interfaces as a result of the diffusion of oxygen vacancies.[8] Barbanel *et al.* have recently reported, from the measurement of the density of rutile, that the interstitial Ti^{3+} ion appeared when a rutile was heated above 750°C *in vacuo*.[9] In the present study, the reduction of the sample by hydrogen did not occur at 400°C, but it proceeded gradually at 500°C. Therefore, the oxygen vacancies produced may be present for the most part on the surface rather than in the bulk. The surface area of the sample may be expected to be changed by the reduction, but the nitrogen adsorption experiments showed no appreciable change in the surface area, even under the treatment with hydrogen at 1 atm.

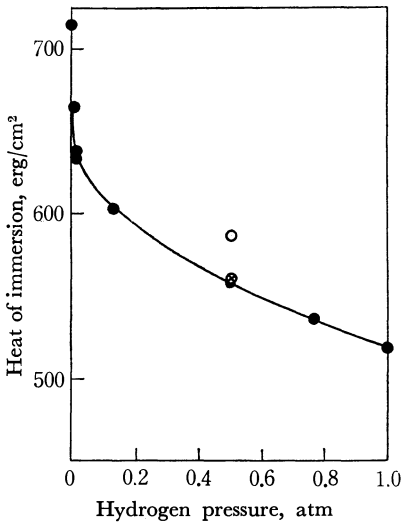

Fig. 1. Heat of immersion of titanium dioxide as a function of the pressure of hydrogen.
●, reduced at 500°C; ⊗, reoxidized at room temperature; ○, reoxidized at 500°C

Effect of Reduction on the Heat of Immersion and Adsorbed Amount of Water Vapor. The values of heat of immersion are shown in Fig. 1 as a function of the pressure of hydrogen, the pressures ranging from 0.01 to 1 atm. The heat value decreased with an increase in the pressure of hydrogen, rapidly in the lower pressure region and gradually in the higher one. The possibility of the removal of hydroxyl groups on the surface by the reduction is present in this case. Morimoto *et al.* have ascertained the water content of anatase treated at 500°C to be *ca.* 0.3 hydroxyl groups per 100Å.[2,10] If the decrease in the heat value by the reduction were responsible only for the removal of hydroxyl groups on the surface, the heat value might decrease by *ca.* 30 erg/cm². The heat of the immersion of the sample in dry benzene was measured to be 155 erg/cm²; this was not altered by the reduction. Therefore, the decrease in the heat may be caused mainly by the reduced state of the surface structure rather than by the hydroxyl groups.

Then, titanium dioxide reduced with hydrogen at 0.5 atm and 500°C was reoxidized by oxygen at 0.5 atm and room temperature or 500°C (treatment (8)). The values of the heat of immersion for the two samples in water are indicated in Fig. 1. In the former case the heat value was not varied at all, while in the latter case it was slightly increased.

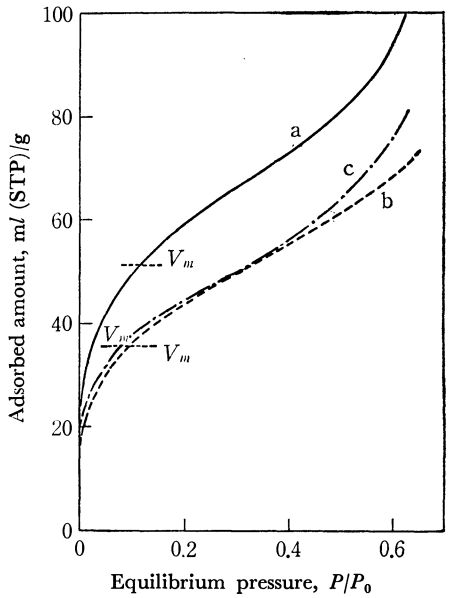

Fig. 2. Adsorption isotherms of water vapor on the surface of titanium dioxide; (a) outgassed at 500°C, (b) reduced with hydrogen at 0.5 atm, and (c) reoxidized at 500°C.

Table 2. Monolayer volume and surface area of water adsorbed on the surface of titanium dioxide

Treatment	V_m, ml (STP)/g	S_{H_2O}, m²/g	S_{H_2O}/S_{N_2}
(a) 500°C	50.7	147	1.02
(b) H_2 (0.5 atom)	36.3	105	0.73
(c) H_2–O_2 (500°C)	36.2	105	0.76

Figure 2 shows the adsorption isotherms of water vapor on the following three kinds of surfaces of titanium dioxide: outgassed at 500°C (a), reduced by 0.5 atm of hydrogen (b), and reoxidized by oxygen at 500°C (c). Table 2 lists the amount of water adsorbed on the surface corresponding to the monolayer obtained by the BET method, the surface area, S_{H_2O} being determined

by assuming the cross-sectional area of water molecule to be 10.8 Å², and the ratio of the area to the area being obtained from nitrogen adsorption, S_{H_2O}/S_{N_2}. In the case of (a), the monolayer of water covers the entire surface obtained from nitrogen adsorption because S_{H_2O}/S_{N_2} is nearly one, whereas in the cases of (b) and (c), the surface shows a somewhat hydrophobic character. The number of sites for water to be adsorbed on the surface may be altered by the reduction.

Reduced Amount. The change in the weight of titanium dioxide by the reduction with hydrogen at 500°C is given in Fig. 3 as a function of the pressure of hydrogen. The value at 0.006 atm of hydrogen was obtained by the volumetric method, because it is difficult to get the exact value at pressures lower than 0.05 atm by the gravimetric method because of a thermomolecular effect.

If the composition of titanium dioxide evacuated at 500°C is stoichiometric, the amount of oxygen atoms removed by the reduction with hydrogen at 0.5 atm is calculated from Fig. 3 to be 0.3% of all the oxygen atoms of titanium dioxide; the composition of $TiO_{1.994}$ can thus be obtained. Among all the oxygen ions, those on the surface layer are calculated to be 13.3% for the (001) plane, 10.6% for the (100) plane, and 9.9% for the (101) plane. These planes are the cleavage faces of anatase.[11] If the elimination of oxygen atoms from titanium dioxide is limited to the surface oxygen atoms, which account for 11.3% of the total, the oxygen atoms removed should become 2.7%, resulting in the composition of $TiO_{1.946}$ for the surface layer. Thus, the oxygen vacancies per surface area should become 0.32/100 Å². The real surface of reduced titanium dioxide, however, may have fewer oxygen vacancies than the values calculated above since the reduction may occur also in the bulk.

The relationship between the reduced amount and the hydrogen pressure in Fig. 3 resembles fairly well that between the heat of immersion and the hydrogen pressure in Fig. 1. The decrease in the heat of immersion per reduced weight takes a constant value, 210 erg/cm² per mg of oxygen vacancy, in the pressure range higher than 0.05 atm. This means that hydrogen atoms eliminate the oxygen atoms on the surface which are active to the water molecule. The weight of the reduced titanium dioxide could not be restored completely to the original weight by oxidation even at 500°C; about three quarters of the weight loss was recovered.

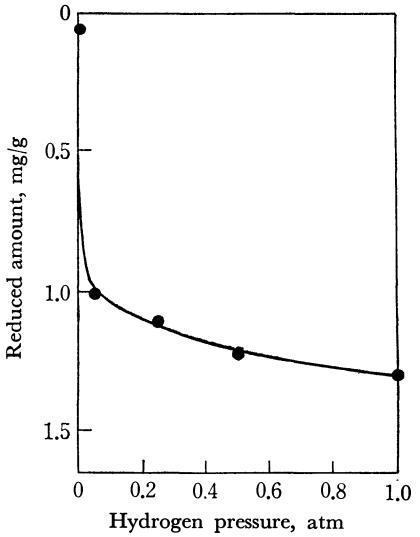

Fig. 3. Reduced amount of titanium dioxide as a function of the pressure of hydrogen.

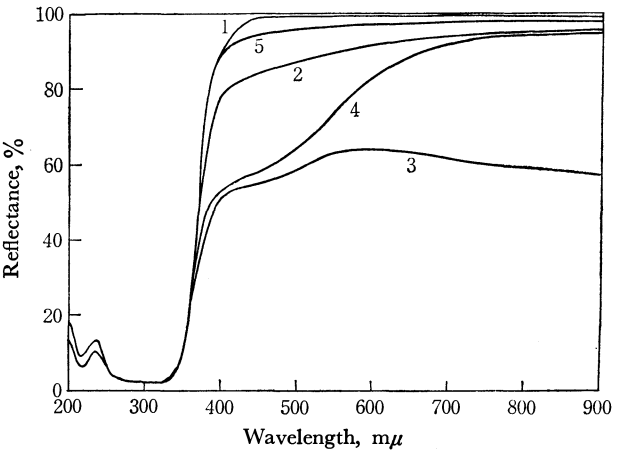

Fig. 4. Reflectance spectra of titanium dioxide; (1) unreduced, (2) outgassed at 500°C, (3) reduced with hydrogen at 0.5 atm, (4) reoxidized at room temperature, and (5) reoxidized at 500°C.

Color Changes by Reduction and Reoxidation. Titanium dioxide reduced by hydrogen was tinged with a bluish-gray color. It showed a brown color after being oxidized by oxygen at room temperature, but it became white when oxidized at 500°C. The reflectance spectra for these samples are shown in Fig. 4. An absorption in the ultraviolet region with an absorption edge of 360 mμ is caused by a transition from the valence band, the $2p$ state of O^{2-}, to the upper conduction band, the $3d$ state of Ti^{3+}, which is the fundamental absorption.[12] For the reduced sample, other absorption bands emerged in the longer-wavelength range: a shoulder at 440 mμ and a broad absorption band with a maximum above 900 mμ. The latter band disappeared when oxygen was introduced to the reduced surface at room temperature, while both bands disappeared after coming into contact with oxygen at 500°C, whereupon the spectrum was similar to the original one. The differences between the reflectances of the reduced samples and that of the unreduced sample are shown in Fig. 5. The increase in intensity of the absorption bands at both 440 mμ and above 900 mμ with an increase in the degree of reduction indicates that these bands are caused by irregularities in the lattice.

The former band is similar to a band resulting from indirect transition which is observed in germanium and silicon.[13] This forbidden transition from valence band to conduction band may be made possible by

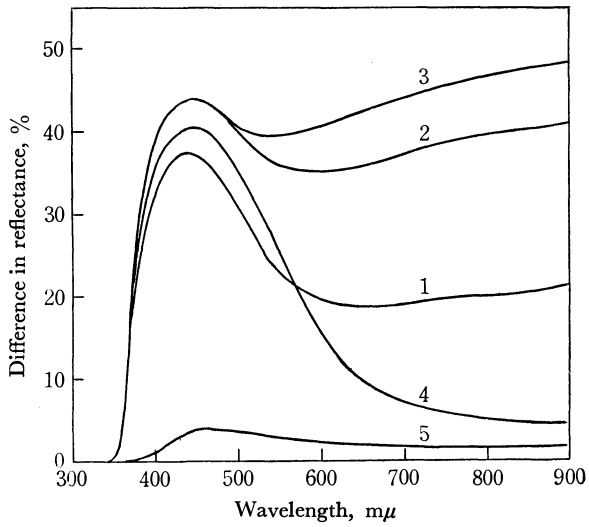

Fig. 5. Differences between reflectance of unreduced sample and those of the samples treated as follows: (1) reduced with hydrogen at 0.1 atm, (2) reduced with hydrogen at 0.5 atm, (3) reduced with hydrogen at 1 atm, (4) reoxidized at room temperature, and (5) reoxidized at 500°C.

crystal imperfections. The latter band may be responsible for the bluish-gray coloration. In a reduced sample of rutile, this coloration is considered to be caused by an excitation of electrons from the donor state as well as from the conduction band to the additional conduction band (absorption band mixiumum at $h\nu$= 1 eV).[14] However, the excitation of electrons may be made impossible by the adsorption of oxygen on the reduced surface at room temperature. The adsorbed oxygen molecules become O_2^- [15] by drawing electrons from the donor state and the conduction band, resulting in the formation of a depletion layer near the surface. Oxygen admitted to the reduced sample at 500°C may be incorporated into the crystal lattice as O^{2-} to reproduced a considerably less irregular lattice near the surface.

Conclusion. From the results of the heat of immersion in water, the weight change, and the color change, it may be considered that titanium ions are present, in a considerable part, around oxygen vacancies on the surface when titanium dioxide is reduced. Such a surface may weakly interact with water, since a certain number of active oxygen ions, which strongly attract water molecules to form surface hydroxyl groups, are removed from the surface. When the surface is reoxidized at 500°C, the electronic state of the surface can return to the original unreduced state, but the interaction of the surface with water can not be restored. Even though oxygen is incorporated on the reduced surface as O^{2-}, it may no longer be such an active oxygen ion as that on the unreduced surface.

The Crystal Spectra of Molecular Compounds of 1,6-Diaminopyrene

Takako AMANO,[1] Haruo KURODA, and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received January 13, 1971)

Polarized absorption spectra were observed on the single crystals of molecular compounds which involve 1,6-diaminopyrene as electron donor and *p*-chloranil, *p*-bromanil, *p*-iodanil, and tetracyano-*p*-quinodimethane as electron acceptor. It is shown that, in spite of the low ionization potential of diaminopyrene 6.56 eV, its solid molecular compounds with chloranil, bromanil, and iodanil are of non-ionic type, and their crystal spectra exhibit the general features characteristic of a typical charge-transfer molecular compound composed of neutral molecules. The diaminopyrene-TCNQ compound was found to be of ionic type. Although the bromanil and iodanil compounds of diaminopyrene exhibit two charge-transfer bands, in the region below 10 kK and at about 20 kK respectively, the chloranil compound does not show the near-infrared charge-transfer band corresponding to the charge transfer from the highest occupied orbital of the donor to the lowest vacant orbital of the acceptor. A discussion is given for this phenomenon from the overlap between the donor and acceptor orbitals.

The solid molecular compounds of 1,6-diaminopyrene with chloranil and bromanil have been reported to be organic semiconductors of relatively good electrical conductivity.[2-6] The visible absorption spectra of the crystalline powders of these molecular compounds were first examined by Kronick *et al.* and Scott *et al.* by using the KBr-pellet method.[7,8] They concluded from the observed spectra that a considerable fraction of the constituent molecules are in ionic states at room temperature, and estimated the ionic fraction as 90

percent in the chloranil compound and 30 percent in the bromanil compound.

The spectra of these molecular compounds were re-examined later by Matsunaga.[9] He applied the method of diffuse reflectance spectroscopy on the crystalline powder of these molecular compounds, and obtained results considerably different from those reported by the previous workers. He suggested that both molecular compounds are of an essentially nonionic type.

In view of the considerable discrepancies found between the spectra reported by the two groups, it seems worthwhile to examine the single crystal spectra of these molecular compounds. In the present paper, we will report on the polarized absorption spectra of the single crystals of the 1,6-diaminopyrene compounds which involve *p*-chloranil, *p*-bromanil, *p*-iodanil, and tetracyano-*p*-quinodimethane (TCNQ) as electron acceptor.

Experimental

TCNQ and 1,6-diaminopyrene were synthesized by the methods described in literatures.[10,11] Chloranil was obtained commercially, and purified by recrystallization and sublimation *in vacuo*. Bromanil and iodanil were kindly supplied by Prof. T. Handa of Science University of Tokyo. The crystals of all molecular compounds except that of diaminopyrene-TCNQ were prepared from benzene or toluene solutions containing appropriate amounts of the donor and acceptor. The crystal of the diaminopyrene-TCNQ was prepared from an acetonitrile solution.

The composition of each molecular compound was determined by elemental analysis of crystals. Polarized absorption spectra of the 10—35 kK region were measured on single crystals of microscopic size with a microspectrophotometer.[12] The edges of a prominent face of the crystal were tentatively chosen as the directions of the polarization of light in the measurement of the polarized absorption spectra.

Results

Diaminopyrene-Chloranil. This compound crystallizes from a benzene solution as brown needles or parallelepiped crystals.[13] The mole ratio of the donor to the acceptor was found to be 1:1. The crystal exhibits a marked dichroism when observed under a polarizing microscope.

The polarized absorption spectra observed on a thin parallelepiped crystal are shown in Fig. 1. We will denote the two edges of the crystal by *X*- and *Y*-directions. The spectra were observed for light polarization parallel and perpendicular to the *X*-direction, which we will call the $//X$ and $\perp X$ spectra, respectively. The results are shown in Fig. 1(a). A broad absorption band with a maximum of 18—19 kK and a sharper peak at 24.5 kK appear in the $//X$ spectrum. The intensity is larger in the former and smaller in the latter in the $//X$ spectrum as compared with the $\perp X$ spectrum. The difference of polarization direction in the above two absorption bands can be seen much more clearly in the $//Y$ and $\perp Y$ spectra, shown in Fig. 1(b). The first band appears only in the $//Y$ spectrum with a maximum at 18.5 kK, while the 24.5 kK peak appears only in the $//Y$ spectrum.

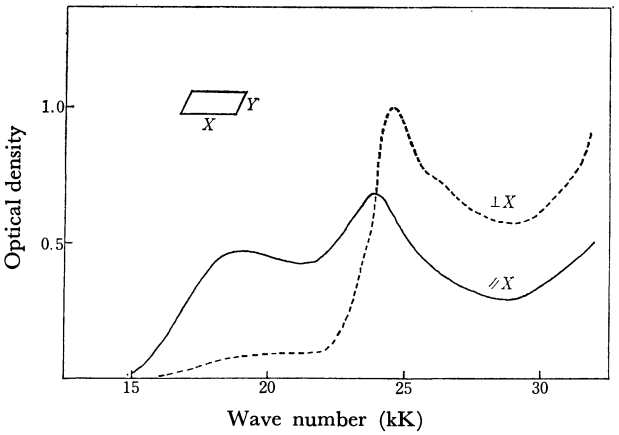

Fig. 1(a). Polarized absorption spectra of diaminopyrene-chloranil crystal: $//X$ and $\perp X$ spectra

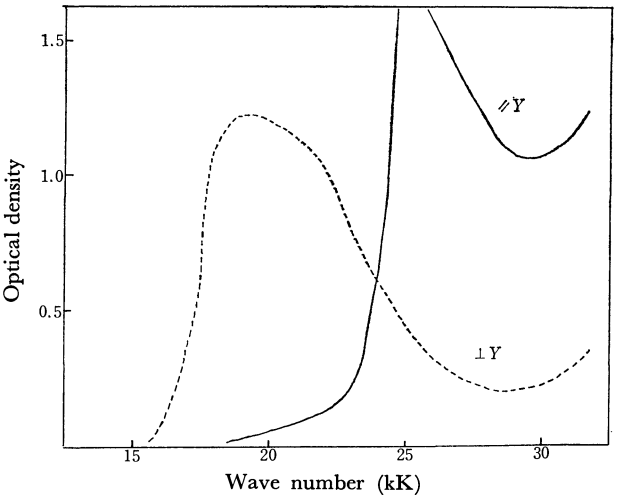

Fig. 1(b). Polarized absorption spectra of diaminopyrene-chloranil crystal: $//Y$ and $\perp Y$ spectra

In order to confirm the polarization direction of these absorption bands, we observed the variations of the optical densities at 18.5, 23.5, and 25 kK as a function of the direction of light polarization. The results are shown in Fig. 2, which shows clearly, first, that the principal axis of absorption at 18.5 kK is perpendicular to that at 25 kK, and, second, that the former makes an angle of about 30° with respect to *X*-direction.

13) It has been reported by Matsunaga[9] that there are two crystalline forms, brown and green. From the benzene solution, we could obtain only the brown crystal which seems to correspond to Matsunaga's brown form. However, when chloroform or diethyl ether was used as solvent, we noticed that a small amount of green crystals were formed besides the brown crystals. The former exhibited an absorption spectrum quite different from the latter. The nature of the green crystal is not clear, but seemingly it is associated with some oxidation products of diaminopyrene.

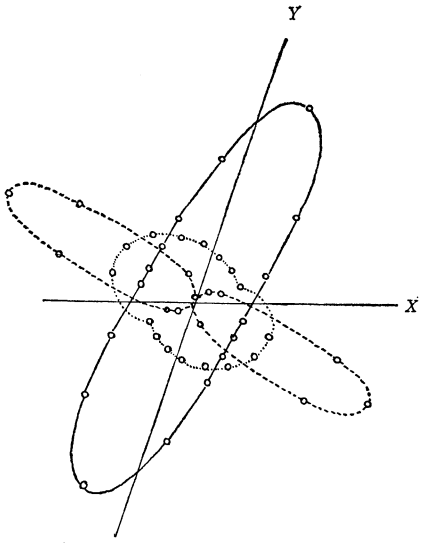

Fig. 2. Dependence of optical density on the direction of light polarization observed on a prominent face of diaminopyrene-chloranil crystal.
------: 18.5 kK ·····: 23.5 kK ——: 25.0 kK

It was not possible to obtain an accurate absorption spectrum of a needle crystal, but the main features of the spectra obtained for the light polarizations parallel and perpendicular to the elongated axis, were found to be similar to the $\perp Y$ and $/\!/ Y$ spectra of a parallelepiped crystal, shown in Fig. 1.

Our results for the brown crystal agree with the results reported by the previous workers as regards the locations of the above two bands, but we find no peak corresponding to the sharp peak at 17.5 kK reported by Kronick *et al.*,[7] who attributed it to the monopositive ion of diaminopyrene, neither we find any band corresponding to the 8 and 15 kK ones reported by Matsunaga.[9,14]

The infrared spectrum of the crystalline powder of this compound can be explained by assuming that the crystal is essentially composed of neutral molecules of the donor and acceptor as suggested by Matsunaga.[9,15] The powder was found to be diamagnetic around room temperature. Although a very weak paramagnetic resonance absorption was detectable, it was most likely to be associated with the presence of a trace of impurities or some oxidation products. All these data suggest that the brown form of diaminopyrene-chloranil crystal has an essentially non-ionic ground state.

The absorption spectra of the diaminopyrene and that of the diaminopyrene cation are reproduced in Fig. 3. If we assume a non-ionic structure for the diaminopyrene-chloranil compound, we can assign the strong absorption band in the 23—30 kK region of the crystal spectrum to the one associated with the lowest π–π^* transition of diaminopyrene. In the 10—22 kK region, we can not expect any local excitation band associated with an intramolecular transition of the donor or acceptor. Thus the 18.5 kK band should be considered as a charge-transfer band. Apparently the above interpretations are consistent with observed polarizations of the absorption bands in the crystal spectrum.

It should be noted, however, that the 1:1 complex formed between diaminopyrene and chloranil in a chloroform solution exhibits two charge-transfer bands in the visible region, the maxima of which are located respectively at 9.9 and 19.0 kK. It is hard to expect that the first charge-transfer band appearing at 9.9 kK in the solution is shifted to a higher energy as much as 10 kK in the crystal. In fact, the corresponding charge-transfer band does appear at about 7 kK in the crystal spectra of the bromanil or iodanil compounds of diaminopyrene. Therefore, we should assign the 18.5 kK band of the diaminopyrene-chloranil to one corresponding to second or third charge-transfer excitation, and not

to one associated with the lowest charge-transfer excitation.

Diaminopyrene-Bromanil and Diaminopyrene-Iodanil. Both these compounds crystallized as dark-brown needle crystals, and the mole ratio of donor to acceptor was found to be 1:1.

We observed the polarized absorption spectra of the crystals for light polarizations parallel and perpendicular to the elongated axis of a needle crystal, which we will call the L-axis of the crystal.

The observed spectra are shown in Fig. 4 and Fig. 5. As can be seen, the crystal spectra of the two molecular compounds are quite similar to each other. Both show a strong near-infrared absorption band[16] polarized exclusively in the L-axis direction, and another strong band of different polarization in the 24—32 kK region, which exhibits an appreciably higher intensity in the $\perp L$ spectrum than in the $/\!/L$ spectrum. Besides these two absorption bands, there is one weak band of $/\!/L$ polarization around 20 kK, which appears as a shoulder at the tail of the strong ultraviolet band.

Table 1. Charge-transfer bands of 1,6-diaminopyrene-haloanil molecular compounds
(kK units)

Acceptor	1st CT band		2nd CT band	
	$CHCl_3$ soln.	cryst.	$CHCl_3$ soln.	cryst.
Chloranil	9.9_0	—	*ca* 19	19.2
Bromanil	9.2_6	<10	*ca* 19	~20
Iodanil	9.5_2	<10	*ca* 19	~20

The 1:1 molecular complex formed in a chloroform solution between diaminopyrene and bromanil exhibits two charge-transfer bands, the first located at 9.26 kK and the second at 19 kK. In the case of the diaminopyrene-iodanil complex in a chloroform solution, the first charge-transfer band is at 9.52 kK and the second at 19 kK. Since there is no absorption band of diaminopyrene in the region below 22 kK, it is most likely that the first two absorption bands of $/\!/L$ polarization found in the crystal spectra of the bromanil and iodanil compounds of diaminopyrene are associated with the charge transfer from a donor molecule to a neighboring acceptor molecule, and the ultraviolet band is a local-excitation band associated with the intramolecular transitions of diaminopyrene. The general features of the crystal spectra mentioned above are in accord with the behaviors usually found for the crystal spectrum of a typical charge-transfer molecular compound composed of neutral molecules. On the other hand, it is impossible to understand the observed crystal spectra of the bromanil and iodanil compounds of diaminopyrene if we assume an ionic structure for their ground state. Their infrared spectra are also quite similar to each other, which can be understood by assuming that they are composed of neutral molecules of the components.

Diaminopyrene-TCNQ. This compound crystallizes as a dark-brown parallelepiped crystal. The mole ratio in the crystal is again 1:1. The polarized absorption spectra are shown in Fig. 6. The general features of the crystal spectra are quite different from those of the preceeding three molecular compounds. Although this compound also exhibits an intense near-infrared absorption band polarized parallel to the longer edge of the crystal (the X-direction), its maximum is located at considerably low energy as compared with the corresponding bands of other molecular compounds. The absorption in the visible and ultraviolet region is strongly polarized in the $\perp X$ direction, where we find three absorption maxima located at about 13, 19, and 23 kK, respectively.

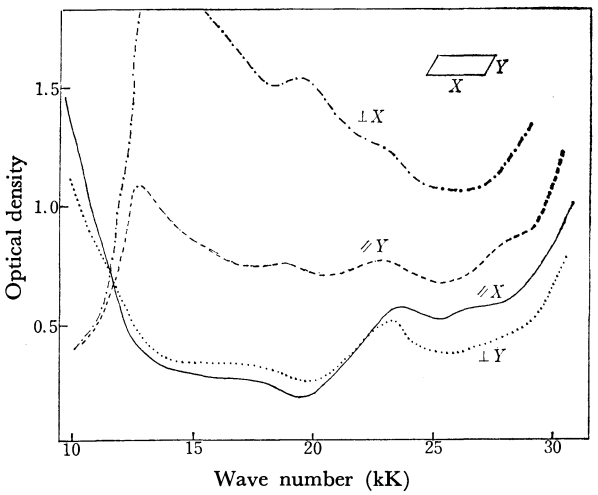

Fig. 6. Polarized absorption spectra of diaminopyrene-TCNQ crystal.

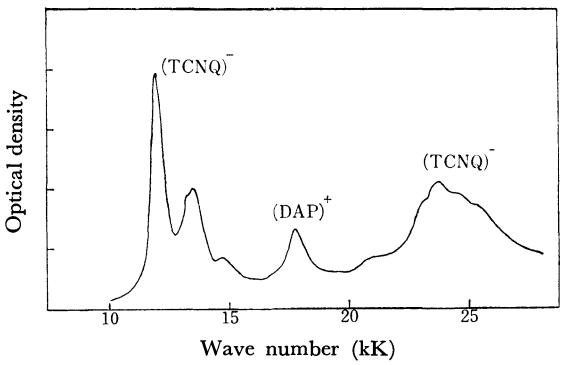

Fig. 7. Absorption spectrum of the acetonitrile solution of diaminopyrene-TCNQ.

The absorption spectrum of an acetonitril solution of the diaminopyrene-TCNQ is shown in Fig. 7, which corresponds to the superposition of the spectrum of the monopositive ion of diaminopyrene and that of the mononegative ion of TCNQ. Although both ions have their first absorption bands in the 10—15 kK region, the peaks in this region of the solution spectrum are almost entirely due to the TCNQ ion. The 17.8 kK sharp peak is due to the second band of the diaminopyrene ion, and the broad band in the 22—27 kK region

16) We were unable to determine the wavenumber of the absorption maximum from the observation of the single crystal spectrum, due to the inapplicability of our microspectrophotometer to this region. From observation of the powder spectra of these molecular compounds, the maximum was found to be at about 7kK in both cases.

is due to the TCNQ ion.

If we compare the crystal spectrum of the diaminopyrene-TCNQ with its solution spectrum, we note that all absorption bands in the crystal spectrum except the near-infrared one which is polarized in the $//X$ direction, can be understood as the local-excitation bands associated with the transitions of the diaminopyrene ion or those of the TCNQ ion. Presumably, the 12.5 kK strong band is mainly associated with the lowest π–π^* transition of the TCNQ ion, and the 19.5 kK weak band is due to the 17.8 kK transition of the diaminopyrene ion. They are considerably broadened and shifted as compared with the corresponding bands in the solution spectrum. The absorption band of the TCNQ ion in the 22—27 kK region is known to be composed of two transitions,[17] one strong transition with the transition moment parallel to the long axis of the TCNQ ion, and one weak one with the transition moment parallel to the short axis. We could attribute the weak band found at 24.6 kK in the $//X$ spectrum of the crystal to the one associated with the short-axis polarized transition of the TCNQ ion. Seemingly, the absorption band associated with the long-axis polarized transition of the TCNQ ion is markedly shifted to higher energy in the crystal. We could attribute the steep rise of absorption above 28 kK to the tail of this absorption band.

The infrared spectrum of the crystalline powder of the diaminopyrene-TCNQ suggests also that TCNQ is, in fact, in the ionic state in this molecular compound. Interestingly, however, the intensity of the paramagnetic resonance absorption is so small that the spin concentration estimated from the observed intensity corresponds to only 6.6 percent of the value expected when each ion provides one independent spin center. This suggests the presence of a strong interaction between neighboring radical ions. The appearance of a very strong charge-transfer band in the crystal spectrum is in accord with this interpretation.

Discussion

From the energy of the first charge-transfer band of the diaminopyrene-chloranil complex in solution, the ionization potential of diaminopyrene can be estimated as 6.54 eV.[18] The value estimated from the energy of the corresponding band of the diaminopyrene-bromanil complex is 6.57 eV.[19] Thus the average value is 6.56 eV.

We carried out the calculation of π-orbitals of diaminopyrene by the *variable-β* modification of the Pariser-Parr-Pople method.[20] The occupied molecular orbitals thus obtained are given in the appendix.

From the result of such a calculation, we can predict the ionization potential of diaminopyrene as 6.51 eV, which is in good agreement with the experimentally estimated values mentioned above.

Thus we believe that the ionization potential of diaminopyrene is 6.5—6.6 eV, which is smaller than the ionization potential of tetramethyl-*p*-phenylenediamine (TMPD). It should be noted that, in spite of this low ionization potential of diaminopyrene, the solid molecular compounds of diaminopyrene with chloranil, bromanil and iodanil, are of the non-ionic type, whereas TMPD forms an ionic compound with chloranil.[22]

The electron affinity has been estimated by Briegleb as 1.37, 1.40, 1.36, and 1.7 eV respectively for chloranil, bromanil, iodanil, and TCNQ.[23] Thus, the difference between the ionization potential of the donor, I_D, and the electron affinity of the acceptor, A_A, is about 5 eV for the chloranil, bromanil, and iodanil compounds of diaminopyrene, and below 5 eV for the diaminopyrene-TCNQ. This means that the lower limit of $I_D - A_A$ that gives a non-ionic crystal is located below 5 eV when the electron donor is diaminopyrene. This seems to be markedly low as compared with the molecular compounds of various other amines. A similar situation can be found, however, in the molecular compounds of tetramethylbenzidine. Presumably this is associated with the effect of molecular size of the donor on the Coulomb energy term which is to have significant contribution to the stability of the ionic structure.

Another problem to be considered is the absence of the first charge-transfer band in the crystal spectrum of the diaminopyrene-chloranil. As shown in the appendix, the diaminopyrene molecule has two closely spaced occupied levels of the symmetries, b_g and a_u at about 1.6 eV below the highest occupied orbital of the symmetry of b_g. In the bromanil and iodanil compounds of diaminopyrene, the first charge-transfer band must be associated with the charge transfer from the highest occupied orbital of a diaminopyrene molecule to the lowest vacant orbital of the neighboring acceptor molecule, and the second charge-transfer band at 19 kK must be associated with the charge transfer from either one of the second or third occupied orbitals, or with those from both of them. The energy difference between the first and second charge-transfer bands is nearly equal to the difference of the orbital energies.

In the case of diaminopyrene-chloranil, we were unable to find any absorption band corresponding to the first charge transfer bands of the bromanil and iodanil compounds. We must attribute the charge-transfer band found at 18.5 kK in the crystal spectrum of the diaminopyrene-chloranil to the one corresponding to the 19 kK charge-transfer band found for the diamino-

17) S. Hiroma, H. Kuroda, and H. Akamatu, This Bulletin, **44**, 9 (1971).

18) We have newly established the empirical relation
$$h\nu_{CT} = 0.87 I_D - 4.46 \text{ (eV)}$$
between the frequency of the charge-transfer band of a chloranil complex and the ionization potential of the donor. The equation was used to the estimate the ionization potential of diaminopyrene.

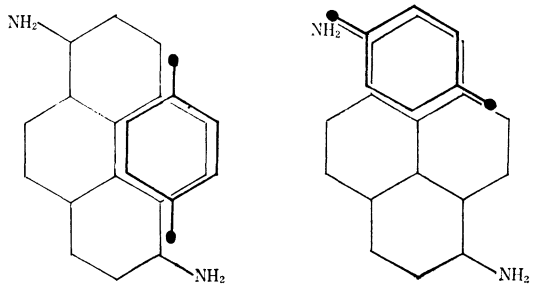
19) Here we assumed the relation
$$h\nu_{CT} = 0.928 I_D - 4.95 \text{ (eV)}$$
cf. M. Kinoshita, This Bulletin, **35**, 1609 (1962).

20) Refer to Ref. 21, for the details of calculation and the procedure of estimating the ionization potential.

21) T. L. Kunii and H. Kuroda, *Theoret. Chim. Acta*, **11**, 97 (1968).

22) T. Amano, H. Kuroda, and H. Akamatu, This Bulletin, **41**, 83 (1968).

23) These values seem to be too small to be taken as the absolute values of the electron affinities. In fact, Lyons has recently given the following values: chloranil 2.05 eV, TCNQ 2.46 eV (L. E. Lyons, private communication). The essential point of the discussion given here is unaffected by taking these values, but we have to reduce the value of $I_D - A_A$ by about 0.7 eV for all molecular compounds discussed here.



Model A Model B

Fig. 8. Models for the stacking of molecules of diaminopyrene-quinone.

pyrene-bromanil and the diaminopyrene-iodanil.

At present, we have no information on the relative arrangement of the donor and acceptor in these molecular compounds. We therefore took two models of the molecular arrangement illustrated in Fig. 8, and estimated the overlap between the donor and acceptor orbitals. The results indicate that model A is favorable for the charge transfer from the a_u orbital of diaminopyrene, but not for that from the b_g orbitals, while model B is favorable for the charge transfer from the latter orbitals and not for that from the former orbital. This suggests that the charge-transfer bands associated with charge transfer from the highest and second highest occupied orbitals of the symmetry b_g could appear when the relative arrangement of the donor and acceptor molecules in the crystal is the one illustrated by model B. On the other hand, these bands, would be almost absent and the charge-transfer band observable with a moderate intensity would be the one associated with the charge-transfer from the third highest occupied orbital of the symmetry a_u, if the molecular arrangement is of the type of model A. Presumably, diaminopyrene-chloranil corresponds to the latter case and diaminopyrene-bromanil and diaminopyrene-iodanil to the former.

Positron-lifetime Measurements in Polymerizing Organic Solids

Yasuo Ito, Kouji Okuda, and Yoneho Tabata

Department of Nuclear Engineering, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received January 23, 1971)

The measurement of the e^+ lifetime in solid monomers during polymerization has been carried out. The mechanism of solid-state polymerization can be analyzed by the measurement of the lifetime of positrons and the amounts of positronium formed. This method was applied to the solid-state polylmerization of acrylamide. It was found from the experiments that the lifetime spectrum changes remarkably in the induction period of polymerization. The decrease in the annihilation rate λ_2 was interpreted in terms of the formation of a larger free volume during polymerization. The intensity of the slow component was also observed to decrease in the induction period of polymerization. The accumulation of active species which capture positrons and the decrease in the number of free volumes were suggested as explanations of the phenomena.

During the last 20 years, the positron annihilation in matter has been studied extensively, and most of the experimental results have been collected.[1-3] Although the experimental data have as yet a qualitative character, it is expected that positron annihilation can be used as a probe in the study of solid materials. A positron can capture an electron in a medium in which it is slowing down, and form a bound state which is called positronium (Ps). There are two ground states of Ps: the triplet state Ps, with total spin $S=1$, and the singlet state Ps, with total spin $S=0$. The lifetime of the singlet Ps (s-Ps) is so short ($\tau=0.125$ nsec) that its component is not separable from the component of the free annihilation of positrons in condensed media. The intrinsic lifetime of the triplet Ps (t-Ps) is 140 nsec, but the lifetime is considerably reduced in condensed media, since t-Ps can possibly be annihilated with electrons of the surrounding molecules *via* the following several processes:

(1) The e^+ in t-Ps can sample electrons of the surrounding molecules and be annihilated rapidly. This process is called "pick-off" annihilation. The lifetime is related to the size of the free volumes in which t-Ps can reside. The smaller the free volume in a medium, the shorter the lifetime of t-Ps.[4,5]

(2) If t-Ps can react with impurities in the medium and form a bound-state "positronium compound", the lifetime of t-Ps is reduced, because the positron is situated in a dense electron cloud and may be annihilated rapidly.[6]

(3) If the impurity molecule has an unpaired electron, t-Ps is converted into s-Ps upon collision with it and is annihilated rapidly. This process is called "triplet-to-singlet conversion" or "exchange collision." Most of the annihilation by these processes is followed by the emission of two photons of 0.51 MeV in opposite directions.

In most organic solids, the lifetime spectrum of positrons is composed of two or three components. The slow component of the lifetime spectrum may, in general, be attributed to the decay of t-Ps through the processes mentioned above.

The intensity of the slow component (I_2) is thought to be equal to the ratio of the quantity of positrons which form t-Ps and then annihilated with a slow pick-off rate compared to that of the total of positrons. If there is a certain quantity of impurities in the system which can trap positrons, I_2 is decreased.

All these features of positron annihilation in condensed media may make it possible to obtain some useful information about the structure of the solids and active species trapped in them. Some experimental results on positron annihilation in irradiated organic solids have been already reported.[7-9]

For several years, we have been studying the positron annihilation phenomena in various monomer solids which can be polymerized by irradiation.[10] The polymerizing solids are one of the most interesting systems in which to apply the annihilation method to study the reaction mechanism, because a remarkable structural change occurs during polymerization. The present paper will report the results of the lifetime measurements of solid acrylamide and related compounds as a function of the irradiation dose.

Experimental

Acrylamide (AA) and propionamide (PA) were used for the experiment. AA was purified by sublimation, and the PA was recrystallized from methanol. A position source, about 15μ Ci of ^{22}NaCl enveloped in a thin nickel foil (5μ thick), was placed in the center of glass ampoule. The powdered monomer was introduced into the ampoule, which was then sealed off under a vacuum (1×10^{-4} mmHg). The internal radius of the ampoule was 12 mm, and the packing density of AA powder was about 0.6 g/cm^3. Under such conditions, only a negligible portion of positrons annihilated in the wall of the glass ampoule.

The lifetime of the positron in the solid monomers was measured before and after γ-ray irradiation with a ^{60}Co

source at 30°C. The dose rate was 2×10^5 R/hr. Since it took about 2 days to obtain a time spectrum with good statistics of the coincidence-counting rate, the samples were preserved at −78°C during the lifetime measurements. Therefore the post-polymerization of the irradiated solid monomers does not proceed during the lifetime measurement.

The lifetime was measured using a Weisberg-type time-to-amplitude converter[11] which had been constructed in our laboratory. Two $1\phi\times1$ in. Naton 136 scintillators coupled to Phillips 56 AVP photomultipliers were used as the detectors of γ-rays. The output pulse from the time-to-amlitude converter was analyzed by a 200-channel pulse-height analyzer. The resolution of the lifetime measurement, $W_{1/2}$, the full width at half maximum of the time spectrum of prompt γ-rays from a ^{60}Co source, was 0.7 nsec.

A FORTRAN IV program which can decompose a time spectrum into several components was made, and each time spectrum was analyzed with it by means of an electronic computor HITAC 5020, being thus decomposed into two components. The value of I_2 was calculated by the method of Green and Bell.[12] All attempts to decompose the spectra into three components were unsuccessful.

On the other hand, the polymerization of AA was followed by measuring the conversion of monomers to polymers. The polymers were isolated by dissolving the monomers in methanol. The irradiation of monomers was carried out under conditions similar to those in the case of the lifetime measurement, except that a positron source was not introduced with monomers in the ampoule. Furthermoer, the volume change of monomers during γ-ray irradiation was measured by dilatometry. For the experiment, the powdered monomer was pressed to make a tablet. The packing density was 0.85 g/cm^3, and the tablet was put into a dilatometer capsule.

Results and Disscussion

The powdered monomers were irradiated with a dose rate of 2×10^5 R/hr at 30°C. The annihilation rate λ_2, and the intensity, I_2, of the slow component as a function of the irradiation does are shown in Fig. 1. The kinetic curve of polymerization is shown in Fig. 2, together with the results of dilatometry. The kinetic curve is a typical S-shaped one composed of induction (0—1 Mrad), proparation (1—2 Mrad), and saturation (3 Mrad) periods.

The volume of the monomer decreases during polymerization, since the density is higher in the amorphous-polymer phase than in the crystalline monomer. The value of I_2 in the monomer crystal ($I_2=20.8\pm3.2\%$) is largest among several monomers examined by us.[10] A crystallographic study of the AA crystal[13] had shown that molecules form a layer through hydrogen bonding, and that the distance between adjacent layers is large. Therefore, we can expect there to be large free volumes between these layers. It would be expected that t-Ps can diffuse or jump into the large free volume in the AA crystals and be annihilated with a slow pick-off rate. On the other hand, there are several cases where t-Ps cannot encounter large free volumes in densely-packed crystals. In such cases, slow components can not be

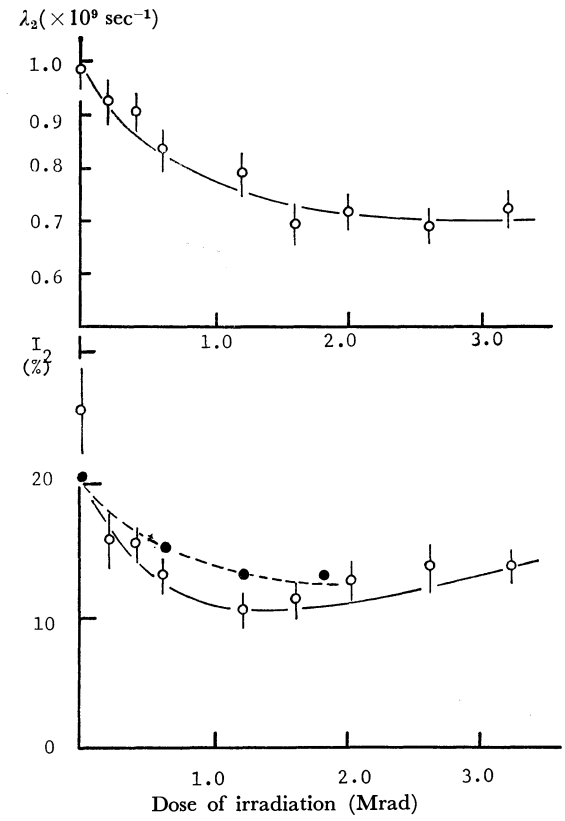

Fig. 1. λ_2 and I_2 in irradiated solid acrylamide as a function of irradiation dose. Irradiation was carried out at 30°C (-○-) and −78°C (--●--) with a dose rate of 2×10^5 R/hr. The bars at each point indicate the statistical average deviation of the counting rate.

observed due to the rapid pick-off annihilation. Examples of the latter case are the monomer crystals of dimethylitaconate,[10] crystalline polyethylene,[14] and crystalline polytetrafluoroethylene.[15] In these solids, the

value of I_2 decreases with an increase in the crystallinity.

It must be noted that decreases in λ_2 and I_2 are observed in the induction period of polymerization. In the induction period, the conversion is still low, and the decrease in the overall volume of the solid is small, as is shown in Fig. 2. The decrease in λ_2 must be related mainly to the formation of a larger free volume, because any other annihilation processes of t-Ps, such as Ps compound formation or exchange collision, may only lead to an increase in λ_2.

It is known, as a result of the crystallographic study of the monomer, that the monomer molecules are closely aggregated in layers parallel to *bc* plane, and that there are 10 other double bonds within a distance of 5 Å from a double bond.[13] Therefore, the polymerization can be expected to proceed within a layer at the initial stage of polymerization, and the polymer phase produced can be expected to be separated from the monomer phase. Vacancies should then be produced around the polymer chains, and they make the free volumes larger by combining with original free volumes in the crystals. T-Ps can stay stable in such large free volumes and be annihilated at a lower pick-off rate. This may be the reason for the decrease in λ_2 during the induction period.

Figure 3 shows the results of the lifetime measurements of AA and PA irradiated at −78°C. Since PA is a saturated analogue of AA, it does not polymerize upon irradiation. Therefore, it is quite reasonable that λ_2 does not decrease on irradiation in the case of PA. On the other hand, λ_2 also decreases in AA irradiated at

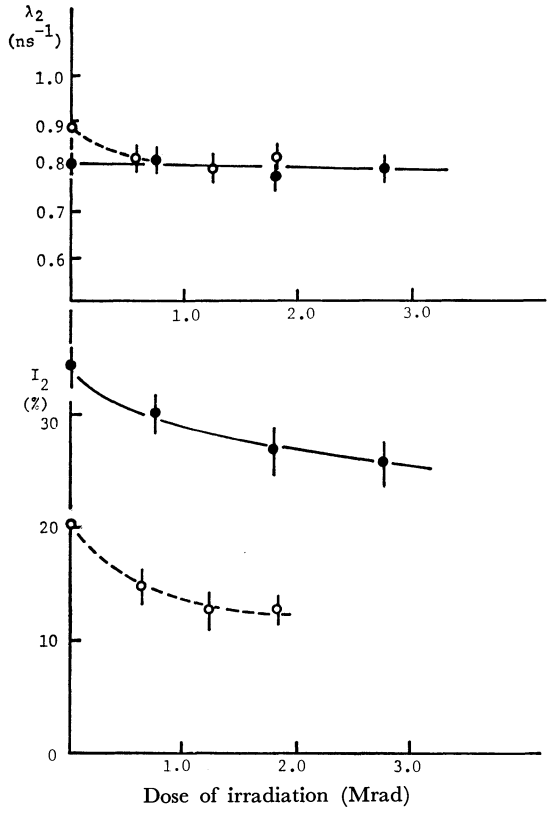

Fig. 3. λ_2 and I_2 in irradiated AA (--●--) and PA (-○-) as a function of irradiation dose. Irradiation was carried out at −78°C with a dose rate 2×10^5 R/hr.

−78°C. No polymer was detectable gravimetrically after irradiation at that temperature. However, there is an evidence that the oligomer is produced at low temperatures. For example, the ESR spectrum of AA irradiated at −196°C indicates the presence of the initiating radical species, but it changes to the spectrum of the propagating one when the temperature is raised above −94°C.[16] Therefore, the oligomer must be formed in AA irradiated at −78°C; in this case, larger free volumes are formed near the oligomer chains by a mechanism similar to that already explained.

It is interesting that λ_2 decreases to a small extent in the propagation period, in which the most remarkable change in the structure of the solid monomers must be taking place. This suggests that no free volume larger than that formed in the induction period is produced in the propagation period. As is shown in Fig. 1, the value of I_2 decreases in the induction period of the polymerization of AA. Since the decrease in I_2 was also observed in the irradiated PA (Fig. 3), the decrease in I_2 may not be directly correlated to the polymerization process. One possible explanation is that active species or impurities produced by γ-ray irradiation can capture positrons to form positron compound. Anothar explanation is that the quantity of free volumes which are responsible for the long-lifetime component in the AA solid monomer decreases gradually due to the polymerization in the crystal. Since I_2 decreases faster in a polymerizing AA solid at 30°C than in AA or PA irradiated at −78°C (Figs. 1 and 3), the decrease in the quantity of free volumes, together with the positron-compound formation, should occur in the polymerizing AA solid.

The value of I_2 is slightly increased in the later stage of polymerization (Fig. 1). This might be due to the effect of irradiation on the polymer produced. In order to determine whether or not this assumption is good, the lifetime of positrons in irradiated poly-AA was measured. Poly-AA was obtained by the radiation polymerization of the solid monomer. The procedure of sample preparation was the same as has already been described. Since the lifetime spectrum in poly-AA was complicated, we have not succeeded in decomposing it into several components. However, the lifetime spectrum did not practically change up to the irradiation dose of 2 Mrad, and at 3 Mrad the slow component apparently decreased. This result contradicts with the assumption made above, and the small increase in I_2 in the later stage of polymerization can not be attributed to the secondary effect of irradiation on the polymer produced.

Another possible explanation is that some active species which can capture positrons have disappeared due to annealing or recombination in the later stage of polymerization. This assumption seems to be supported by the following experimental results. The AA solid monomer, pre-irradiated to 2 Mrad at −78°C, was thermally treated, and the lifetime measurements were made. The variations in λ_2 and I_2 are indicated in Table 1, together with the conversion of post-polymerization. I_2 decreases with the irradiation dose at −78°C,

16) I. Nitta, S. Onishi, and T. Tanei, Paper presented at the 11th Annual Meeting of the Polymer Sci. (1962).

Table 1. Post-polymerization of acrylamide and lifetime measurement during the polymerization

	$\lambda_2 \times 10^9$ sec^{-1}	I_2 (%)	Conversion (%)
Before irradiation	0.883±.0033	20.8±3.2	—
After irradiation at −78°C(2Mrad)	0.861±0.039	13.1±1.9	trace
Kept for 2.5 hr at room temperature	0.796±0.047	14.9±2.3	4.2
Kept for 2.0 hr at 50°C	0.766±0.032	14.9±1.4	8.5
Further irradiation at−78°C(0.5 Mrad)	0.764±0.034	13.7±1.3	—

in agreement with the results presented in Fig. 3. However, it is slightly increased as post-polymerization proceeds. Therefore, a certain amount of active species which can capture positrons may have disappeared during the thermal treatment of the solid.

Conclusion

The lifetime spectrum has shown a remarkable change in the induction period of polymerization, and the decrease in λ_2 has been interpreted in terms of the formation of a larger free volume during polymerization. Such a free volume is also formed when oligomers are produced by the irradiation at low temperatures; the lifetime spectra have shown evidence of this.

I_2 also decreases in the induction period of polymerization, but this decrease may not be directly related to the polymerization process. Two possible explanations, that is, the accumulation of active species which capture positrons and the decrease in the number of free volumes, have been suggested. The former process may occur at least in the case of solid PA.

From these experiments, it has been clearly demonstrated that important information about the induction period can be obtained by the lifetime measurement of the positrons in solid monomers.[10] We expect that a detailed study of this kind may offer useful information concerning the mechanism of solid-state polymerization.

We should like to acknowledge the continuing encouragement of Prof. K. Oshima. We are also indebted to Dr. K. Hasegawa and Mr. K. Okawa for the instruction in constructing the time-analyzing equipment.

Radiotracer Studies on Adsorption of Surface Active Substance at Aqueous Surface. III. The Effects of Salt on the Adsorption of Sodium Dodecylsulfate

Kazuo Tajima

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received January 25, 1971)

The adsorbed amounts were measured on the surface of aqueous solutions containing tritiated sodium dodecylsulfate (TSDS) and varying amounts of NaCl by the direct radiotracer method. The surface tensions were also measured for the same solutions by the drop-volume method. The Gibbs adsorption isotherm, derived without assuming the adsorption of the chloride ion, was applied, and the amounts of adsorption were calculated for both dodecylsulfate and chloride ions. The observed amounts of dodecylsulfate adsorption were confirmed to be in good agreement with those calculated, and the calculated amounts of chloride adsorption turned out to be nearly zero or slightly negative, which is usually theoretically assumed because of the ionic repulsion due to the adsorbed dodecylsulfate. Further, the adsorption of the dodecylsulfate ion attained a constant and saturate value beyond a certain concentration (SAC) below the critical micelle concentration (CMC). The logarithms of SAC were found to vary linearly with the logarithms of CMC for the range of salt concentration studied. The value of SAC being in a close relation with the surface phenomena is considered to be another measure of the surface activity of surfactants.

There have been many studies to check the validity of the Gibbs adsorption isotherm.[1-5] By a radiotracer method, we have also experimentally confirmed that the adsorption of the ionic surfactants on an aqueous surface from their solution takes place in accordance with the Gibbs equation both in the absence of and in the presence of in an excess amount of an inorganic salt having a cation in common.[6,7] However, there has no paper dealing with the direct measurement of adsorption at the air-solution interface of the ionic surfactant as a function of the concentration of the coexisting salt. Matijevic and Pethica,[8] though, derived a Gibbs ad-

sorption isotherm which can be applied to the solution of sodium dodecylsulfate (SDS) in the presence of sodium chloride, and calculated the adsorbed amount of the dodecylsulfate ion from the surface-tension concentration relation of the solution. In their derivation of the adsorption equation, they assumed that the excess of the chloride ion at the surface is negligible in amount. This assumption, although acceptable from the theoretical viewpoint,[9] has not been confirmed experimentally.

In the present paper, the Gibbs adsorption isotherm is applied from a more general viewpoint, with no preliminary assumption of the adsorbed amount of solute ions in the solution and with activity in place of concentration. The validity of the adsorption equation thus derived is confirmed by the direct measurement of the amount of adsorption by a radio-tracer method.

Theoretical

The Gibbs adsorption isotherm[10] is written, in a general form, as:

$$-\mathrm{d}\gamma = RT\sum\Gamma_i \,\mathrm{d}\ln a_i \tag{1}$$

where γ represents the surface tension, and Γ_i and a_i, the surface excess and the activity of the ith ionic species in solution respectively. Assuming that the bulk solution is electrically neutral as a whole and that surface hydrolysis is absent (bulk hydrolysis was confirmed to be absent, as judged from the pH being unaffected by the dissolution of SDS), Eq. (1) is rewritten for the SDS solution containing sodium chloride as:

$$-\mathrm{d}\gamma = RT\Gamma_{\mathrm{Na}^+}\mathrm{d}\ln a_{\mathrm{Na}^+} + RT\Gamma_{\mathrm{D}^-}\mathrm{d}\ln a_{\mathrm{D}^-} + RT\Gamma_{\mathrm{Cl}^-}\mathrm{d}\ln a_{\mathrm{Cl}^-} \tag{2}$$

where the three subscripts Na^+, D^-, and Cl^- denote sodium, dodecylsulfate, and chloride ions respectively. Using the activity coefficient and the concentration instead of the activity, and differentiating Eq. (2) with respect to C_{D^-}, while keeping the concentration of NaCl constant (therefore, $\mathrm{d}\,C_{\mathrm{Na}^+}=\mathrm{d}\,C_{\mathrm{D}^-}$), we obtain the following equation:

$$-\left(\frac{\mathrm{d}\gamma}{RT\,\mathrm{d}\ln C_{\mathrm{D}^-}}\right)_{\mathrm{NaCl}} = \Gamma_{\mathrm{Na}^+}\frac{C_{\mathrm{D}^-}}{C_{\mathrm{Na}^+}} + \Gamma_{\mathrm{D}^-} + 2\Gamma_{\mathrm{Cl}^-}\frac{\mathrm{d}\ln f_{\pm}^{\mathrm{NaCl}}}{\mathrm{d}\ln C_{\mathrm{D}^-}} + 2\Gamma_{\mathrm{D}^-}\frac{\mathrm{d}\ln f_{\pm}^{\mathrm{NaD}}}{\mathrm{d}\ln C_{\mathrm{D}^-}} \tag{3}$$

where C's denote the concentration of the ions specified and $f_{\pm}^{\mathrm{NaCl}}$ and $f_{\pm}^{\mathrm{NaD}}$, the mean activity coefficients of NaCl and SDS respectively. Similarly, differentiating Eq. (2) with respect to C_{Cl^-} while keeping the concentration of NaD constant, we obtain:

$$-\left(\frac{\mathrm{d}\gamma}{RT\,\mathrm{d}\ln C_{\mathrm{Cl}^-}}\right)_{\mathrm{NaD}} = \Gamma_{\mathrm{Na}^+}\frac{C_{\mathrm{Cl}^+}}{C_{\mathrm{Na}^+}} + 2\Gamma_{\mathrm{D}^+}\frac{\mathrm{d}\ln f_{\pm}^{\mathrm{NaCl}}}{\mathrm{d}\ln C_{\mathrm{Cl}^-}} + 2\Gamma_{\mathrm{Cl}^-}\frac{\mathrm{d}\ln f_{\pm}^{\mathrm{NaD}}}{\mathrm{d}\ln C_{\mathrm{Cl}^-}} \tag{4}$$

Putting

$$\frac{\mathrm{d}\ln f_{\pm}^{\mathrm{NaCl}}}{\mathrm{d}\ln C_{\mathrm{D}^-}} = \frac{\mathrm{d}\ln f_{\pm}^{\mathrm{NaD}}}{\mathrm{d}\ln C_{\mathrm{D}^-}} \equiv \alpha$$

$$\frac{\mathrm{d}\ln f_{\pm}^{\mathrm{NaCl}}}{\mathrm{d}\ln C_{\mathrm{Cl}^-}} = \frac{\mathrm{d}\ln f_{\pm}^{\mathrm{NaD}}}{\mathrm{d}\ln C_{\mathrm{Cl}^-}} \equiv \beta$$

and using the notations:

$$\frac{C_{\mathrm{D}^-}}{C_{\mathrm{Na}^+}} = a, \qquad \frac{C_{\mathrm{Cl}^-}}{C_{\mathrm{Na}^+}} = b \tag{5}$$

$$\left.\begin{aligned} -\left(\frac{\mathrm{d}\gamma}{RT\,\mathrm{d}\ln C_{\mathrm{D}^-}}\right)_{\mathrm{NaCl}} &= I_{\mathrm{Cl}^-} \\ -\left(\frac{\mathrm{d}\gamma}{RT\,\mathrm{d}\ln C_{\mathrm{Cl}^-}}\right)_{\mathrm{NaD}} &= I_{\mathrm{D}^-} \end{aligned}\right\} \tag{6}$$

Eqs. (3) and (4) are then rewritten as:

$$I_{\mathrm{Cl}^-} = \Gamma_{\mathrm{Cl}^-}(a+2\alpha) + \Gamma_{\mathrm{D}^-}(1+a+2\alpha) \tag{7}$$

$$I_{\mathrm{D}^-} = \Gamma_{\mathrm{D}^-}(b+2\beta) + \Gamma_{\mathrm{Cl}^-}(1+b+2\beta) \tag{8}$$

From the condition of electric neutrality at the surface of the solution, we further obtain:

$$\Gamma_{\mathrm{Na}^+} = \Gamma_{\mathrm{D}^-} + \Gamma_{\mathrm{Cl}^-} \tag{9}$$

by combining Eqs. (7), (8), and (9), we have:

$$\Gamma_{\mathrm{Na}^+} = \frac{1}{2(1+\alpha+\beta)}(I_{\mathrm{D}^-}+I_{\mathrm{Cl}^-}) \tag{10}$$

$$\Gamma_{\mathrm{D}^-} = \frac{1}{2(1+\alpha+\beta)}[I_{\mathrm{Cl}^-}(1+b+2\beta) - I_{\mathrm{D}^-}(a+2\alpha)] \tag{11}$$

$$\Gamma_{\mathrm{Cl}^-} = \frac{1}{2(1+\alpha+\beta)}[I_{\mathrm{D}^-}(1+a+2\alpha) - I_{\mathrm{Cl}^-}(b+2\beta)] \tag{12}$$

Estimating the activity coefficient of NaCl and SDS by using the limiting law of the Debye-Hückel theory, as in the previous paper,[7] the values of α and β are given as:

$$2\alpha = -aA\sqrt{C_{\mathrm{Na}^+}} \tag{13}$$

$$2\beta = -bA\sqrt{C_{\mathrm{Na}^+}} \tag{14}$$

where A is the constant in the Debye-Hückel limiting equation, which takes the value of 1.18 at 25°C. By substituting Eqs. (13) and (14) into Eqs. (10), (11), and (12), we obtain:

$$\Gamma_{\mathrm{Na}^+} = \frac{1}{1+i}(I_{\mathrm{Cl}^-}+I_{\mathrm{D}^-}) \tag{15}$$

$$\Gamma_{\mathrm{D}^-} = \frac{1}{1+i}[I_{\mathrm{Cl}^-}(1+bi) - I_{\mathrm{D}^-}ai] \tag{16}$$

$$\Gamma_{\mathrm{Cl}^-} = \frac{1}{1+i}[I_{\mathrm{D}^-}(1+ai) - I_{\mathrm{Cl}^-}bi] \tag{17}$$

where:

$$i = 1 - A\sqrt{C_{\mathrm{Na}^+}} \tag{18}$$

expresses the activity coefficient of the uni-univalent ion at a sufficiently dilute solution and is equal to unity when the mean activity coefficient is unity. It is worth noting that Γ_{D^-} and Γ_{Cl^-} can be separately calculated by Eqs. (16) and (17), if i is calculated according to Eq. (18), and that I_{Cl^-}, I_{D^-}, a and b are calculated from the γ *vs.* C_{NaCl} or γ *vs.* C_{NaD} curves (Eq. (5)) and from Eq. (6). The validity of Eq. (16) can be checked by comparing the value of Γ_{D^-} thus calculated with that measured directly by a radiotracer method for the solutions containing both SDS and NaCl. Further, by putting $\Gamma_{\mathrm{Cl}^-}=0$ and $i=1$, Eqs. (16) and (17) give the same

equation as Matijevic and Pethica's. Here, we are in a position to check experimentally whether or not the theoretical assumption of $\Gamma_{Cl^-}=0$ in their derivation of the equation is valid.

Experimental

The tritiated sodium dodecylsulfate (TSDS) and sodium chloride were the same substances as those used in a previous paper.[7] The surface tension of solutions containing NaCl and SDS was measured by the drop-volume method, and Harkins and Brown's correction[11] was applied. The value of Γ_{D^-} was also measured directly by a radiotracer method using a sheet scintilation counter. The details of the measurements were the same as those described in preceding paper.[6,7] The pH of the bulk solutions was controled at 6±0.2 (25.0°C).

Results and Discussion

Adsorption Isotherm. Figure 1 shows the adsorption isotherms of SDS measured by the radiotracer method at the surface of an aqueous solution containing various concentrations of sodium chloride. Figures 2 and 3 show the curves of γ *vs.* log C_{D^-}, with C_{Cl^-} kept constant for the former and of γ *vs.* log C_{Cl^-}, with C_{D^-} kept constant for the latter. In Figs. 4a, b, and c, the observed values of Γ_{D^-} and those calculated by applying Eqs. (16) and (17) to the data of Figs. 2 and 3 are shown as circles and solid lines respectively. The broken lines in these figures show the values of Γ_{D^-}, which are calculated by assuming $i=1$ in Eq. (16). It may be seen in these figures that the values of Γ calculated from Eqs. (16) and (17) (solid lines) are, as a whole in good agreement, with the observed values except for the adsorption at low concentrations of SDS and NaCl. The broken lines ($i=1$) gradually deviate from both solid lines and observed Γ_{D^-} values in the region of a large concentration of SDS. As for the deviation of solid lines from the observed values of adsorption in a dilute solution of SDS, a similar tendency was also observed in the case of the salt-free SDS solution, where the surface tension used for the calculation was also measured by a drop-volume method. It should be noted that different surface tension values are obtained for the salt-free SDS solution when it is measured by the drop-volume and Wilhelmy plate methods. Therefore, in the case of a low NaCl concentration, such as in Fig. 4a, we should use the surface tension data, as measured by the Wilhelmy plate method to be described below. Unfortunately, the γ *vs.* C_{D^-} relation measured by the Wilhelmy plate method is lacking for the SDS solution with a 1×10^{-3} mol/l NaCl concentration. It can, however, be obtained graphi-

cally by an interpolation, of the γ *vs.* C_{D^-} data for the SDS solution measured by the Wilhelmy plate method, reported in a previous paper.[6] From the γ *vs.* log-C_{D^-} relation thus obtained and from the γ *vs.* logC_{Cl^-} relation similarly obtained, Γ_{D^-} and Γ_{Cl^-} can be calculated by applying Eqs. (16) and (17). The results are shown by a chain line in Fig. 4a. It is evident that the chain line is in better agreement with observed values than a solid line would be. Thus, it is confirmed that the Wilhelmy plate method always offers correct values of the surface tension for the calculation of the amount of adsorption, while the drop-volume method gives incorrect values, the error becoming smaller at ionic strengths larger than about 10×10^{-3} mol/*l*. This may be due to the rapid surface aging at a higher ionic concentration, which makes it possible to obtain an almost equilibrium value of the surface tension at a relatively short time of measurement.

Now, it should be noted that, although the non-adsorption of the chloride ion at an aqueous surface can be theoretically anticipated for aqueous solution containing SDS and NaCl, the experimental evidence has been lacking. The results of the present studies empirically confirm the almost zero value or a slightly negative value of Γ_{Cl^-} as is shown in Figs. 4a, b, and c, although the values of Γ_{Cl^-} in the solution with a lower SDS concentration involve some uncertainties similar to those of Γ_{Cl^-} in dilute solutions. It may be seen that the values of Γ_{D^-} (broken lines) calculated from Eq. (16), assuming $i=1$, agree closely within the limits of experimental error with those obtained by the Matijevic and Pethica equation, which assumes $\Gamma_{Cl^-}=0$ ($i=1$). This agreement confirms the $\Gamma_{Cl^-}=0$ assumption to be valid as far as the calculation of Γ_{D^-} according to Matijevic and Pethica equation is concerned. However, as for the calculation of Γ_{Cl^-}, small but distinct negative values are indicated, and Eqs. (16) and (17) are better applied to the calculation of the adsorption from the solution of two mixed surfactants containing a common cation, although the additional measurements shown in Fig. 3 are required for the calculation of Γ_{Cl^-} and Γ_{D^-}. In this connection, it may be inferred that Dixon *et al.*[12] made a mistake in calculating the amounts of the adsorption of Aerosol OT and Aerosol OTN at the surface of their mixed solution. They treated the two solutes as independent of each other and used simply:

$$\Gamma_{OT} = I_{OTN}, \quad \Gamma_{OTN} = I_{OT} \tag{19}$$

where Γ_{OTN}, I_{OTN}, *etc.* denote the corresponding quantities shown in Eq. (6), with D and Cl replaced by OT and OTN respectively. However, since the system

b) Ref. 7

contains the Na^+ ion in common, we must use equations with the form of Eqs. (16) and (17) instead of Eq. (19).

Saturated Adsorption. The values of the saturated adsorption, Γ_S, of the dodecylsulfate ion in various concentrations of coexisting sodium chloride, together with the corresponding value of the molecular area, are shown in Table 1. A decrease in the molecular area, A, due to the increase in the concentration of sodium chloride is seen; it can be qualitatively interpreted as the effect of added salt on diffuse double layers of the adsorbed ion. The value of SAC, which is the bulk concentration beyond which Γ_S shows a constant and saturate value, is listed in the third column of Table 1. This SAC, which is smaller than the CMC (critical micelle concentration), was determined more accurately by the isotherm (Fig. 1) obtained by the radiotracer method. The correlation between SAC and CMC gives a good linearity, as is shown in Fig. 5. This linearity is expressed as;

$$\log \text{SAC} = 1.16 \log \text{CMC} - 0.04 \qquad (20)$$

The value of SAC is confirmed to be about 30—40% of the CMC for all the concentrations of NaCl studied in the present experiments. Van Voorst Vader[13] has reported that the adsorption amount of the ionized surfactant in the aqueous solution is approximately constant within the concentration range of 20—30% of the CMC when the inorganic salt is present. Further, even in another report[14] which insists on a continuous increase in the surfactant adsorption up to the CMC in the presence of salt, the surface tension *vs.* log concentration relation for the surfactant solution does not deviate appreciably from the linear relationship in the range of 30% of the CMC. Accordingly, a constant adsorption is more likely than a gradual increase in the amount of adsorption up to the CMC.

It is considered that, if the adsorbed phase can be assumed as a two-dimensional solution, the state of

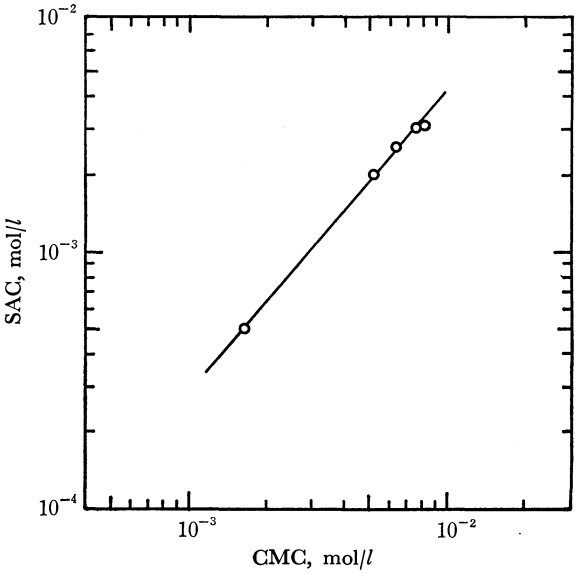

Fig. 5. Relation between SAC and CMC.

saturated adsorption at the surface may be considered as the formation of a two-dimensional micelle or a surface micelle; therefore, SAC corresponds to the concentration of the surface micellization, as in a usual micellization in the bulk solution. This similarity leads to the consideration that the surface phenomena of the surfactant solution at the air-solution interface, *e.g.*, foaming, surface viscosity, surface tension lowering and so on, may be expected to show some characteristic behavior in the vicinity of the SAC. For instance, Miles and Ross[15] and Dreger *et al.*,[16] applying the "pour test" to many sodium alkylsulfates in a foam experiment, found that the foam height first increased with the concentration and then reached a constant value at a concentration which was about 40—50% lower than the CMC. Also, Burcik[17] found the same tendency for the original foam volume of a sodium laurate solution, produced by the pouring method. Thus, the values of SAC might be used as another measure of the surface activity of the surfactant solution, which in some cases directly parallels the surface phenomena at the air-solution interface.

The author wishes to express his hearty thanks to Professor T. Sasaki for this encouragement and guidance throughout the experiments. He is grateful also to Professor M. Muramatsu for his helpful discussions and advice.

Effects of Pressure on the Chemical Properties of Solid Surfaces. V. The Surface Acidity of the Compressed Aluminum Sulfate

Takeshi KAWAKAMI, Akihiro KONNO, and Yoshisada OGINO

Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aramaki Aoba, Sendai

(Received January 29, 1971)

In order to clarify the mechanism of the acidity change due to compression, aluminum sulfate was compressed under various pressures ranging from 0 to 4200 kg/cm² and at a temperature of 20, 65, or 80°C, and the surface acidity and the structure of these samples were measured. It was found that the acidity change due to compression was proportionate to the protonic acid. Lewis acid was made to appear only by heating the sample at temperatures higher than 90°C. Further, for the purpose of increasing the surface acidity, the compression of the sample at lower temperatures was found to be more effective than the compression at higher temperatures. In addition to the spectroscopic data, the results of DTA and TGA experiments supported the idea that the observed acidity change resulted from the distortion of the structural unit of aluminum sulfate.

In the previous works[1-3] which treated the effects of pressure on the chemical properties of solid surfaces, the present authors have found that the surface acidities of various metal sulfates vary on compression. In these works the acidity change was discussed in terms of the change in the crystal structure as well as in terms of the change in the water content in the sample. However, the discussion was only qualitative, and the details of the mechanism of the acidity change due to compression could not be clarified. Therfore, the present authors have undertaken a new series of experimental works designed to clarify the mechanism of the acidity change.

In the present work, aluminum sulfate octadecahydrate was used as a sample. The surface acidity was measured by a conventinal titration method. The structural changes due to compression were investigated by means of infrared spectroscopy, far-infrared spectroscopy, Raman spectroscopy, differential thermal analysis, and so on. In this paper, the details of the experimental results will be presented and the relation between the acidity change and the structural change will be discussed.

Experimental

Material. Commercial aluminum sulfate octadecahydrate was used as the raw material of sample.

Preparation of the Sample. The raw sulfate was compressed by the procedures described in the previous papers.[1-3] The compression was carried out under various pressures, ranging from 0 to 4200 kg/cm², and at a desired temperature of either 20, 65, 80°C. In every case, pressure was applied over a 10-min period. The resulting cyclindrical pellet, 6 mm in diameter and 2 mm in height, was pulverized in a mortar. The pulverized material was subjected to drying in vacuum for 45 min at a temperature of 18°C. The resulting dry material served as a sample for the desired measurements. In order to minimize the effects from the change in ambient conditions, compressions, pulverizings, dryings and weighings were carried out in an air-conditioned room.

For the sake of convenience, the samples which were subjected to the compression at 20, 65, and 80°C were defined as P_{20}, P_{65}, and P_{80} respectively. Then, for instance, $P_{65,4200}$ means the sample which was compressed under a pressure of 4200 kg/cm² and at a temperature of 65°C.

Surface Acidity. The surface acidity was determined by Benesi's method[4] with the following four indicators: dicinnamalacetone ($pK_a = -3.0$), benzeneazodiphenylamine ($pK_a = 1.5$), *p*-diphenylaminoazobenzene ($pK_a = 3.3$), and phenylazonaphthylamine ($pK_a = 4.0$). The acidity measurements were also carried out in the air-conditioned room.

Qualitative Tests for Lewis Acid. In order to identify Lewis acid on the sample powder, the color of the sample surface was observed by adding phenolphthalein or trithylchloride as an indicator. That is, a given amount of the sample powder was transferred to a 50-m*l* conical flask containing 10 m*l* of purified benzene. Then, several drops of a 0.1 % benzene solution of an indicator were added and color of the sample surface was observed.

Surface Areas. The specific surface area of the sample was evaluated by applying the BET theory to the adsorption data of nitrogen at −195°C.

Water Content. The content of aluminum in a given amount of the sample powder was determined by a conventional gravimetric analysis, and on the basis of these results the water content in the sample was calculated.

Differential Thermal Analysis (DTA) and Thermogravimetric Analysis (TGA). DTA and TGA runs were carried out on a Rigaku Denki Thermoflex R-8000 unit. The DTA curves and the TGA curves were obtained at a temperature programming rate of 5°C/min.

X-Ray Diffraction. Powder X-ray diffraction patterns of the sample were obtained with a Shimadzu GX-1 X-ray Diffractometer. The Cu$K\alpha$ radiation (Ni filter) at 30 kV and 15 mA was used. The sample powder was coated with a collodion film to prevent interference from air moisture.

Infrared and Far-infrared Spectroscopy. The infrared spectra for the 400—4000-cm^{-1} wave number range were obtained with Perkin-Elmer Model 125 and Perkin-Elmer Model 337 Infrared Spectrophotometers. A Hitachi FIS-3 Infrared Spectrophotometer was used to obtain spectra for the 30—400-cm^{-1} wave number range.

A nujol technique was employed in every case except when the spectra for the O–H stretching vibration was obtained. In the latter case, a chlorobutadiene technique was employed.

Raman Spectroscopy. The Raman spectra of the sample powder were obtained with a Ūkigōsei RL-II Spectroscope.

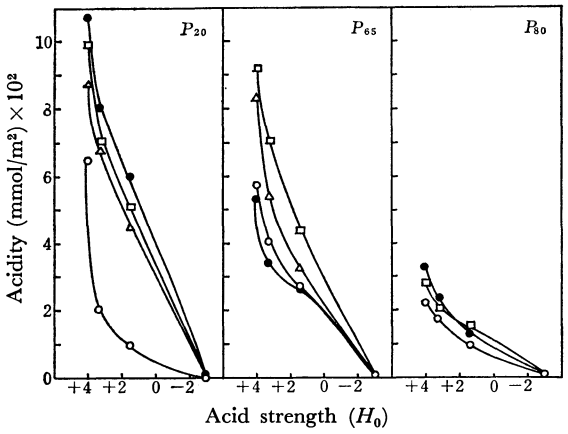

Fig. 1. Acid strength distribution curves for aluminum sulfate samples compressed under various conditions.
(○) $P_{T,0}$; (□) $P_{T,1400}$; (△) $P_{T,2800}$; (●) $P_{T,4200}$

Results

Surface Acidity. Acid-strength distribution curves for aluminum sulfate samples compressed under various conditions are given in Fig. 1, where the acidity values per unit of surface area are indicated as a function of the H_0 value. As can be seen in this figure, the surface acidity for every sample of P_{20}, P_{65}, and P_{80} increased on compression. Further, it can be said that a lower compacting temperature is preferable in order to increase the acidity value within the range of $H_0 = -3.0$—$+1.5$.

Identification of Lewis Acid. As can be seen in Table 1, none of the samples compressed at temperatures lower than 80°C showed any sign positive to the existence of Lewis Acid. Therefore, it might be concluded that only protonic acid appeared on compression. On the other hand, the color test (Table 1) against the samples which had been dehydrated at 89—104°C showed that Lewis acid appeared on the surface of the sample.[5]

Water Content. The water contents in the samples treated under various conditions are given in Fig. 2.

Table 1. Identifications for lewis acid

Compacting condition	Indicator	
	Phenolphthalein	Trithylchloride
$P_{20,0-4200}$	No color	No color
$P_{65,0-4200}$	No color	No color
$P_{80,0-4200}$	No color	No color
$T=80$	No color	
$T=90$	Pink (faint)	
$T=108$	Pink	
$T=128$	Pink (deep)	
$T=155$	Pink (deep)	

[ ] : Samples heated at various temperatures without compression. For example, $T=80$ means the sample heated at 80°C and at zero compacting pressure.

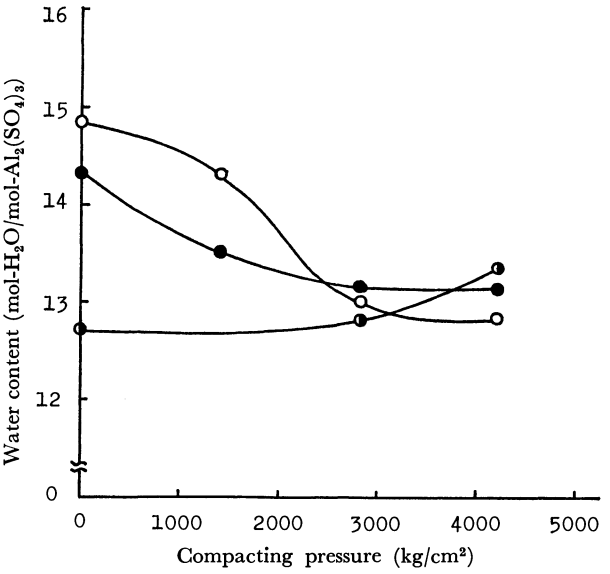

Fig. 2. Relations between the compacting pressure and the water contents in the samples compressed at various temperatures: (○), P_{20}; (●), P_{65}; (◑), P_{80}

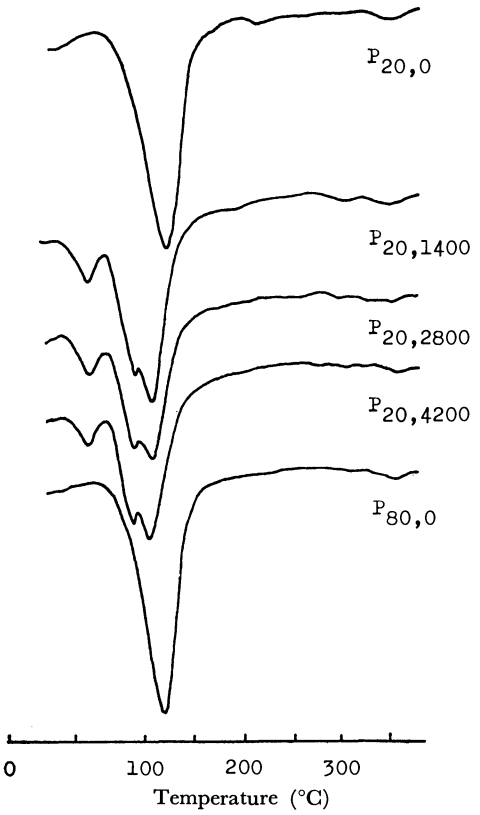

Fig. 3. DTA curves for aluminum sulfate samples compressed under various conditions.

DTA and TGA. DTA curves for several samples are given in Fig. 3. On the basis of a comparison of this figure with the results of the chemical analysis of water and the TGA data, the DTA endothermic peaks were attributed to the dehydration processes from the sample. For example, an endothermic peak appearing at 59°C for the $P_{20,0}$ sample was attributed to the desorption of the physically-adsorbed water.

Further, from the results of TGA it was found that

the amount of dehydratin at 89—104°C from each sample was as follows:

$P_{20,0}$ 12.3 mol-H_2O/mol-$Al_2(SO_4)_3$
$P_{20,1400}$ 12.3 mol-H_2O/mol-$Al_2(SO_4)_3$
$P_{20,2800}$ 12.3 mol-H_2O/mol-$Al_2(SO_4)_3$
$P_{20,4200}$ 12.3 mol-H_2O/mol-$Al_2(SO_4)_3$

It must be noted that these values were approximately equal to 12.

In addition to the above-mentioned fact, the DTA data revealed another interesting fact. A marked difference between the DTA curve for the uncompressed sample and that for the compressed sample was observed. That is, an original endothermic peak which had appeared at 89—104°C in the uncompressed sample split into two endothermic peaks in the compressed sample.

X-Ray Diffractions. The Powder X-ray diffraction patterns for the various samples are given in Fig. 4. These patterns prove that the aluminum sulfate used in this study consisted of crystals of octadecahydrate, hexadecahydrate, and tetradecahydrate. From the low intensity of the diffraction peaks for the tetrahydrate, the content of this hydrate in the sample seemed to be small.

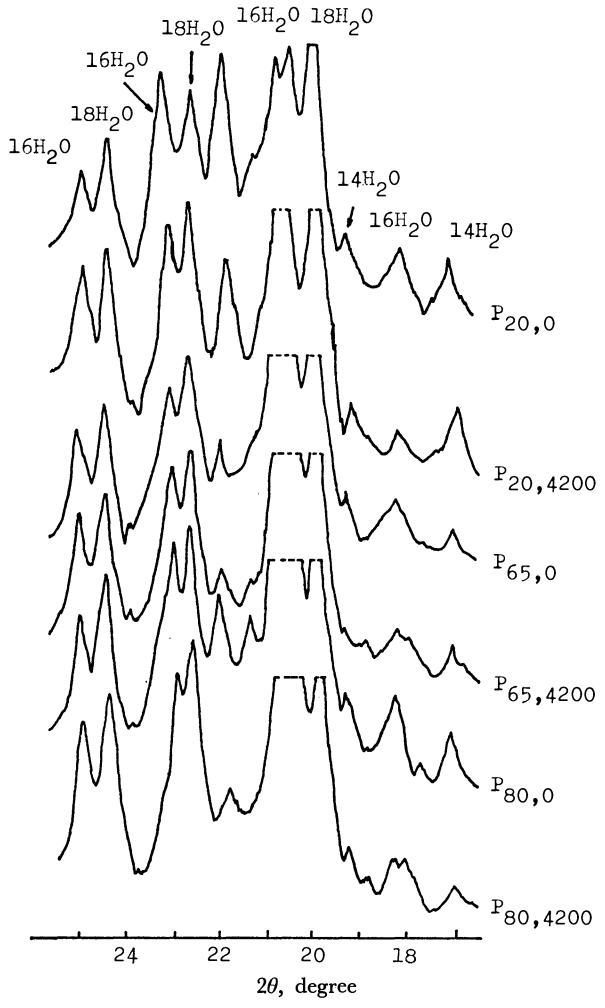

Fig. 4. X-Ray diffraction patterns for aluminum sulfate samples compressed under various conditions.

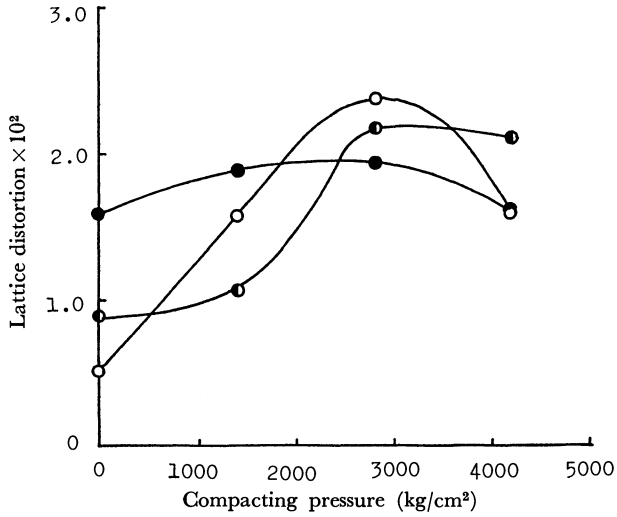

Fig. 5. Relations between the lattice distortion and the compacting pressure: (○) P_{20}; (◐) P_{65}; (●) P_{80}

The degree of lattice distortion calculated by applying Hall's method[6] to the X-ray diffraction data is given in Fig. 5. As can be seen in this figure, the degree of lattice distortion for octadecahydrate was proved to increase with the increase in the compacting pressure, except for the P_{80} sample.

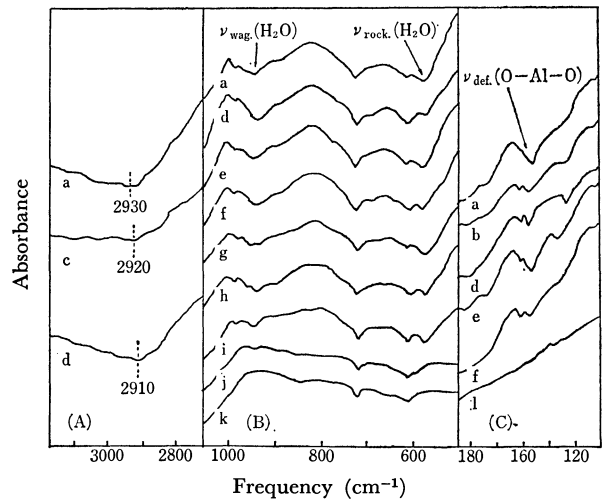

Fig. 6. Infrared and far infrared spectra for alumimun sulfate samples compressed under various conditions: ((a) $P_{20,0}$; (b) $P_{20,1400}$ (c); $P_{20,2800}$; (d) $P_{20,4200}$; (e) $P_{65,0}$; (f) $P_{65,4200}$; (g) $P_{80,0}$; (h) $P_{80,4200}$) and for the samples heated at various temperatures without compression: ((i) 90°C; (j) 130°C; (k) 155°C; (l) 105°C)

Infrared Spectra and Far-infrared Spectra. The infrared spectra of samples prepared under various conditions are given in Fig. 6. Among the absorption bands in this figure, the bands assigned to both ν_{OH} and ν_{O-Al-O} were found to vary on compression. The details of the change in the absorption spectra are given below.

i) On the compression of the sample, the peak position of a broad band ranging from 2500 cm^{-1} to 3500

6) W. H. Hall, *Proc. Phys. Soc.*, **A62**, 741 (1949).

cm^{-1}, which was assigned to the OH stretching vibration[7], shifted to lower frequencies—*i.e.* $P_{20,0}$: 2930 cm^{-1}, $P_{20,2800}$: 2920 cm^{-1}, $P_{20,4200}$: 2910 cm^{-1}.

ii) The band appearing at 155 cm^{-1} for the uncompressed sample was assigned to the O–Al–O deformation.[8] When the sample was compressed, the original 155 cm^{-1} band split into two peaks (Fig. 6); this splitting was more marked in the $P_{20,4200}$ sample than in the $P_{65,4200}$ sample.

iii) As can be seen in the Fig. 6 (i), the heating of the uncompressed sample at 90°C resulted in a decrease in the intensities of the absorption for both $\nu(H_2O)_{rock.}$ and $\nu(H_2O)_{wag.}$.

A further increase in the heating temperature resulted in the almost complete disappearance of these absorption bands (Fig. 6, j,k).

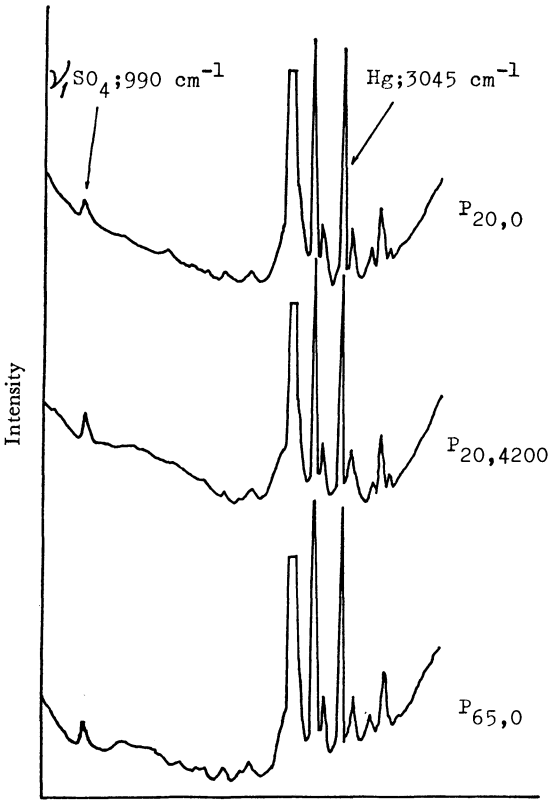

Fig. 7. Raman spectra for aluminum sulfate samples compressed under various conditions.

Raman Spectra. The Raman spectra for several samples are given in Fig. 7. The line which appeared at 990 cm^{-1} was assigned to the ν_1 vibration of sulfate ions in the sample. The relative intensity of this line against the intensity of the line for mercury (3045 cm^{-1}) is given in Table 2.

TABLE 2. RELATIVE INTENSITY OF THE RAMAN ν_1 LINE FOR SO_4^{-2}

Compacting condition	Relative intensity
$P_{20,0}$	7.0×10^{-2}
$P_{20,4200}$	12.8×10^{-2}
$P_{65,0}$	9.3×10^{-2}
$P_{65,4200}$	9.3×10^{-2}

Discussion

Acidity Change on Compression. Similar to a previous work,[1] the present reseach revealed that the surface acidity of aluminum sulfate hydrate varies on the compression of the sample. Furthermore, in the present study it was found that the degree of the acidity change due to compression was a function of the compacting temperature. This fact suggests that the surface acidity might be controlled by changing the compacting temperature as well as the compacting pressure. With respect to this point, it seems to be important that the degree of the acidity change was larger when a lower compacting temperature was employed.

The acidity which appeared on the compressed sample could not be referred to Lewis acid of a high strength, the acidity was referred to protonic acids with a strength of $H_0 \geq -3.0$. The experimental results shown in Table 1 indicate that Lewis acid was made to appear only by heating the sample to a temperature higher than 90°C. Since the compression was carried out below 80°C, it is natural to consider that the observed acidity on the compressed sample surface would have a protonic character.

Surface Areas, Water Contents, and Acidity Changes. The acidity change observed in the present study must be related to the change in the structure of the aluminum sulfate sample. However, the acidity change could not be explained by a simple structural change. For instance, the surface area of the sample varied also on compression, but this change was not proportional to the observed acidity change. That is, the surface acidity per unit of surface area varied also on compression. Moreover, the observed acidity change due to compression was not proportional to the degree of dehydration from the sample.

Crystal Structure and Acidity Changes. On the basis of the experimental results on the X-ray diffraction as well as on the water content of the sample, it was thought that the hydrates in the sample have nonstoichiometric compositions with respect to water. That is, the results of the X-ray diffraction study showed that the sample contains aluminum sulfate octadecahydrate, aluminum sulfate hexadecahydrate, and a small amount of aluminum sulfate tetradecahydrate. Therefore, the water content in the sample should be larger than 14 mol-$H_2O/Al_2(SO_4)_3$. However, as was shown in the previous section, the results of the chemical analysis showed that the water content in the sample was less than 14 mol-$H_2O/Al_2(SO_4)_3$. This discrepancy seems to show that the water content in each of the observed hydrates has a smaller value than the corresponding formular value.

The nonstoichiometric water content may produce distortions of the crystal structure of the aluminum sulfate hydrate. Indeed, the distortion of the crystal lattice of the sample was found to be considerable, as is shown in Fig. 5. Thus, the lattice distortion was suspected of causing the acidity change.

Unfortunately however, examinations based on this suspicion showed that the correlation between the observed acidity change and the degree of lattice distortion was incomplete. That is, the acidity change was found to be proportional to the degree of lattice distortion only for a series of samples made at a given compacting temperature; a change in the compacting temperature resulted in a change in the proportionality constant. Thus, the correlation was incomplete. Therefore, the observed lattice distortion can not be considered as the primary factor which determines the surface acidity.

Structural Unit for Aluminum Sulfate Hydrate. Considering the observed nonstoichiometric water content as well as the works of Gamo,[7] Prask,[8] and Taylor,[9] the model given in Fig. 8 (A) was adopted as a structural unit of aluminum sulfate hydrate. According to this model, there are 12 mol of coordinated-water (I) per unit of $Al_2(SO_4)_3$. In the present study, it was assumed that the water (I) could not be removed by compression, though the anion-water (II) could be removed by compression. Therefore, the number of moles of the anion-water (II) was thought to be variable and capable of having a value corresponding to the water content in the sample (only one water molecule is shown in Fig. 8).

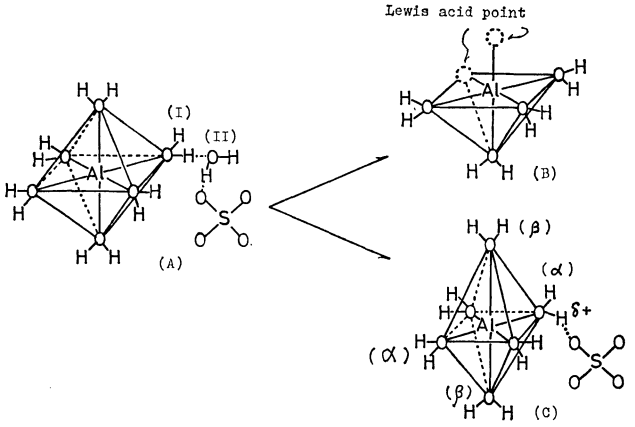

Fig. 8. A structural model for aluminum sulfate hydrate (A), the dehydrated aluminum sulfate hydrate (B) and the compressed aluminum sulfate hydrate (C).

Appearance of Lewis Acid at Higher Temperature. The proposed structural model explains the fact that Lewis acid appeared when the sample was heated to a temperature higher than 90°C. According to the results of the DTA and TGA experiments, the heating of the sample to a temperature higher than 90°C resulted in a considerable dehydration. Further, the total amount of the dehydration occurring at 90—104°C was found to be ~12 mol-H_2O/mol-$Al_2(SO_4)_3$. This means that the coordinated water (I) was removed by the heating. If any of the coordinated water is removed, vacant sites may appear around an aluminum ion (Fig. 8(B)). These vacant sites may exhibit the nature of Lewis acid.

Acidity Change on Compression. A distorted structural unit shown in Fig. 8 (C) was considered to explain the appearance of a protonic acid center in the compressed sample. As can be seen in this figure, the octahedron around an aluminum ion is deformed. That is, the distance between the central Al^{3+} ion and each of the coordinated-water is no longer equivalent, and there appear two sorts of coordinated water, *i.e.*, H_2O (α) and $H_2O(\beta)$. Now, since the distance between Al^{3+} and $H_2O(\alpha)$ is smaller than the original value, stronger interaction between Al^{3+} and $H_2O(\alpha)$ may result and the covalent character in the Al^{3+}–$H_2O(\alpha)$ may increase. Thus, some positive charges may appear on the H atom in the $H_2O(\alpha)$ molecule. This is a protonic acid center. In this manner, the increased acidity of the compressed sample can be explained by considering the increased content of the distorted structural unit.

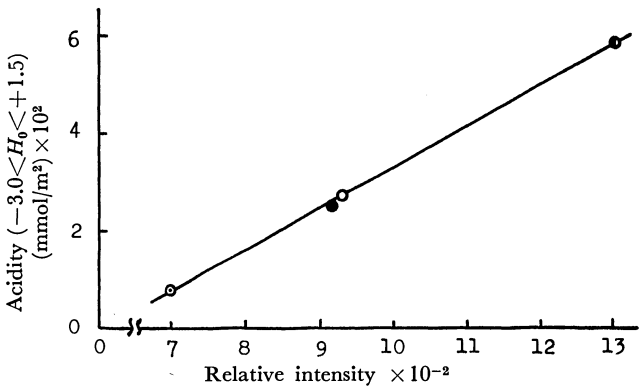

Fig. 9. Relations between the surface acidity (H_0=−3.0—+1.5) and the relative intensity of the Raman ν_1 line for SO_4^{-2}: (⊙) $P_{20,0}$; (◑) $P_{20,4200}$; (○) $P_{65,0}$; (●) $P_{65,4200}$.

In deforming the octahedral structural unit, chemical forces exerted by sulfate ions around the octahedron seem to play an important role. Since the compression results in the dehydration of anion-water (II), the sulfate ion may be displaced toward the octahedron. Therefore, the interaction between the sulfate ion and the coordinated water (α) may increase. This may promote the ionization of a H atom into $H^{\delta+}$ in the $H_2O(\alpha)$ molecule and result in the deformation of the octahedron. The experimental results shown in Fig. 9 indicate that, irrespective of the compacting pressure as well as the compacting temperature, the surface acidity of the sample can be regarded as a unique function of the relative intensity of the Raman ν_1 line of the sulfate ion. This fact indicates the intimate relation between the surface acidity and the behavior of sulfate ions in the sample.

Experimental Evidence for the Proposed Mechanism. The following experimental results also support the above described mechanism for the acidity change due to compression:

i) The existence of two kinds of coordinated water (α,β) in the compressed sample is supported by the following facts: (a) The DTA endothermic peak which corresponds to the dehydration of the coordinated water (II) was found to be a single peak for the uncompressed sample, whereas the peak for the compressed sample split into two peaks. (b) The far-in-

9) D. Taylor and H. Basset, *J. Chem. Soc.*, **1952**, 4431.

frared spectra assigned to the O–Al–O deformation in the uncompressed sample appeared at 155 cm^{-1} as a single band, whereas the O–Al–O deformation absorption for the compressed sample split into two bands.

ii) One experimental fact (i-b) mentioned above supports the supposition that the degree of the interaction between the O atom and the Al^{3+} ion in a $H_2O(\alpha)$-Al^{3+}-$H_2O(\alpha)$ group may be different from that in a $H_2O(\beta)$-Al^{3+}-$H_2O(\beta)$ group.

iii) The supposition that the interaction between the sulfate ion and the H atom in a $H_2O(\alpha)$ molecule would be increased by compression may be supported by the fact that the infrared absorption which was assigned to the O–H stretching vibration shifted toward a somewhat lower wave number as the compacting pressure of the sample was increased.

iv) The displacement of sulfate ions toward an octahedron may result in an increase in the concentration of the sulfate ion in the sample. This expectation was supported by the fact that the relative intensity of the Raman ν_1 peak of the sulfate ion increased on the compression of the sample.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1777—1780 (1971)

The Electronic Spectra of the Anion Radical Salts Derived from 2,3-Dicyano-1,4-benzoquinone and 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone[1)]

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received January 30, 1971)

The anion radical salts derived from 2,3-dicyano-1,4-benzoquinone and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone were prepared. The absorption spectra in an acetonitrile solution and the solid-state spectra were examined for these anion radical salts. Unlike the absorption spectra in solution, in the solid-state spectra strong charge-transfer bands appeared and there were blue-shifts of the high-energy bands. These spectroscopic features were discussed on the basis of the charge-transfer interaction between the anion radicals. The solid-state properties of these salts were compared with those previously investigated for the anion radical salts of the halogen-substituted *p*-benzoquinones.

In general, solid ion radical salts have been a matter of great interest,[2-9)] because the ion radical molecules form, in themselves, a plane-to-plane stacking into columns so as to make a large overlap between their half-filled molecular orbitals.[10)] In this case, any individual ion radical molecule interacts through charge-transfer most strongly with one or two other radicals. In a previous paper,[7)] the solid-state properties were examined for the anion radical salts of *p*-chloranil, 2,5-dibromo-3,6-dichloro-1,4-benzoquinone, and *p*-bromanil. The electronic spectrum of the solid salt was found to be different from the monomer spectrum of the anion radical in solution and to show the intermolecular charge-transfer band. The charge-transfer interaction between the anion radicals was much affected not only by the kinds of halogen substituents in the anion radical molecules, but also by the species of the counter cations.

The present paper will describe some stable anion radical salts of cyano-substituted *p*-benzoquinones. The measurements of the solid-state spectra as well as the absorption spectra in an acetonitrile solution were attempted for the anion radical salts derived from 2,3-dicyano-1,4-benzoquinone (*p*-H_2QCy_2) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (*p*-Cl_2QCy_2). We shall examine how the charge-transfer interaction between the anion radicals contributes to the solid-state spectra of these anion radical salts. The solid-state spectra of these salts are interesting in comparison with those of the anion radical salts of the halogen-substituted *p*-benzoquinones.[7]

Experimental

Materials. *p*-H_2QCy_2 was synthesized from *p*-benzoquinone according to the method of Thiele *et al.*,[11] while *p*-Cl_2QCy_2 was commercially available. These compounds were purified by recrystallization from ethylene dichloride.

The following four anion radical salts were prepared according to the method of Matsunaga[12]: Na^+ *p*-$Cl_2QCy_2^-$, K^+-*p*-$Cl_2QCy_2^-$, Na^+ *p*-$H_2QCy_2^-$ and K^+ *p*-$H_2QCy_2^-$. In this method, the anion radical salts were made by the one-electron reduction of the corresponding quinones with alkali metal iodides in an acetonitrile solution.

Measurements. The absorption spectra in an acetonitrile solution were measured at room temperature, using a Beckman DK-2A spectrophotometer at concentrations of the order of 10^{-4}—10^{-5} mol/*l*.

The diffuse reflection spectra of the solid salts were recorded on a Beckman DK-2A spectroreflectometer at room temperature in the range from 4.0 kK to 30.8 kK. In order to avoid cation exchange between the salt and the diluent, the sodium salts were ground and diluted with sodium chloride, while the potassium salts were similarly treated with potassium bromide. The solid-state spectra were then obtained by plotting the diffuse reflection spectra using the Kubelka-Munk equation, $f(R)=(1-R)^2/2R$, in which R is the reflectance. The experimental details were the same as those described in previous papers.[4-8]

The Absorption Spectra in Solution

Some of the absorption spectra of these anion radical salts in an acetonitrile solution are reproduced in Fig. 2. The spectra are not changed when the counter cation of the salt is replaced. Since the concentrations are so dilute, the salts seem to be completely dissociated. The obtained spectra are those of the anion radical monomer, because the counter cations of the salts are simple alkali metal cations.

The p-Cl_2QCy_2 *Anion Radical (Fig. 2, Curve a).* This anion radical in an acetonitrile solution appears reddish violet, and is quite stable at room temperature. The absorption spectrum of the anion-radical monomer has absorption peaks at 17.1 kK and 18.3 kK, a band at 21.9 kK with a shoulder around 22.9 kK, and a strong absorption at 28.7 kK. These spectroscopic features are found to be in good accordance with those

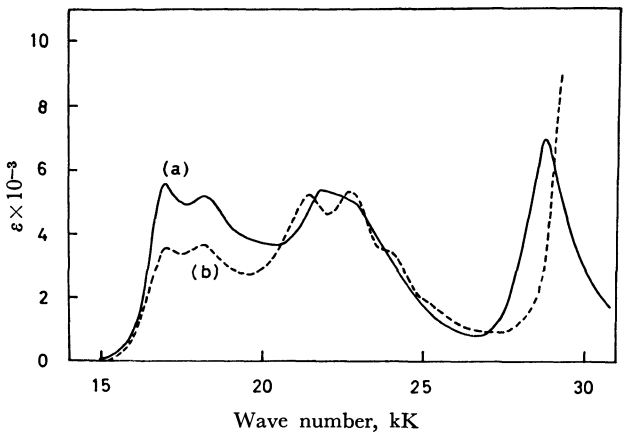

Fig. 2. The absorption spectra of (a) Na^- *p*-$Cl_2QCy_2^-$ and (b) Na^+ *p*-$H_2QCy_2^-$, in acetonitrile solution.

of the *p*-Cl_2QCy_2 anion radical previously reported by Iida and Akamatu,[13] who produced the *p*-Cl_2QCy_2 anion radical by a one-electron transfer reaction from the 7,7,8,8-tetracyanoquinodimethane anion radical to *p*-Cl_2QCy_2 in an acetonitrile solution.

The p-H_2QCy_2 *Anion Radical (Fig. 2, Curve b).* This anion radical in an acetonitrile solution appears red, and is also quite stable at room temperature. The absorption spectrum of the anion radical monomer is composed of absorption peaks at 17.1 kK and 18.2 kK and at 21.5 kK and 22.7 kK, a shoulder around 23.9 kK, and a strong absorption in the energy region higher than 29 kK. Although this absorption spectrum seems to be similar to that of the *p*-Cl_2QCy_2 anion radical, the introduction of the chlorine substituents into the *p*-H_2QCy_2 anion radical causes some shifts in their corresponding bands. Unlike as in the *p*-Cl_2QCy_2 anion radical, the splitting of the band peaks at 21.5 kK and 22.7 kK and the shoulder around 23.9 kK are noted in the case of the *p*-H_2QCy_2 anion radical.

The Solid-State Spectra

Na^+ p-$Cl_2QCy_2^-$ *(Fig. 3, Curve a).* The solid-state spectrum of this salt shows a strong absorption at 12.6 kK and high-energy bands at 21.2 kK and 25.5 kK. This spectrum was found to be different from the monomer spectrum of the *p*-Cl_2QCy_2 anion radical in solution. The band at 12.6 kK appears in the low-energy region where the anion radical monomer does not absorb. This spectroscopic feature is very similar to that for the anion radical salts of halogen-substituted *p*-benzoquinones.[7] The solid-state spectrum of Na^+ *p*-$Cl_2QCy_2^-$ can be compared with that of Na^+ *p*-Chloranil$^-$, since the *p*-Cl_2QCy_2 anion radical molecule is analogous to the *p*-chloranil anion radical. The value for the low-energy band at 12.6 kK of Na^+ *p*-$Cl_2QCy_2^-$ was found to be almost coincident with that for the band at 11.6 kK of Na^+ *p*-Chloranil$^-$, which is known, according to a previous investigation,[7] to arise from the charge-transfer transition between the *p*-chloranil anion radicals in the solid state. The intensity of the

11) J. Thiele and J. Meisenheimer, *Ber. Deut. Chem. Gesell.*, **33**, 675 (1900); J. Thiele and F. Günther, *Liebig's Ann. Chem.*, **349**, 59 (1906).

12) Y. Matsunaga, *J. Chem. Phys.*, **41**, 1609 (1964).

13) Y. Iida and H. Akamatu, This Bulletin, **40**, 231 (1967).

low-energy band for Na+ p-$Cl_2QCy_2^-$ is as strong as that for Na+ p-Chloranil$^-$. Judging from these results, the low-energy band at 12.6 kK for Na+ p-$Cl_2QCy_2^-$ seems to be attributable to the charge-transfer transition between the p-Cl_2QCy_2 anion radicals. In this case, the p-Cl_2QCy_2 anion radicals will be stacked close enough together for the π orbitals to overlap, and the π–π transitions of the monomer will be perturbed in the field of the other anion radicals. This is shown as appreciable blue-shifts of the high-energy bands at 21.2 kK and 25.5 kK for the solid-state spectrum of Na+-p-$Cl_2QCy_2^-$, compared to the monomer absorptions of the p-Cl_2QCy_2 anion radical at 17.1 kK and 21.9 kK respectively.

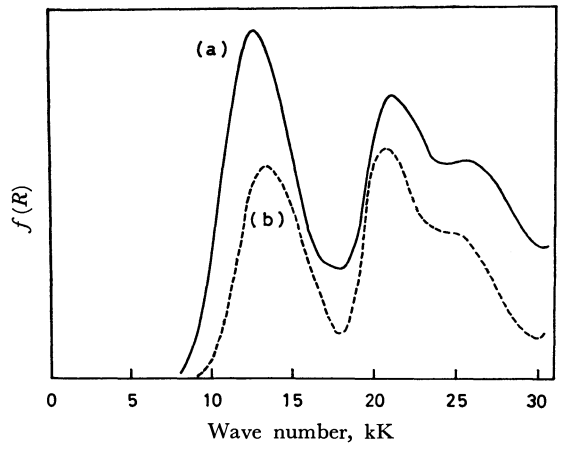

Fig. 3. The solid-state spectra of (a) Na+ p-$Cl_2QCy_2^-$ and (b) K+ p-$Cl_2QCy_2^-$.

K+ p-$Cl_2QCy_2^-$ (Fig. 3, Curve b). The solid-state spectrum of this salt shows a low-energy band at 13.3 kK and high-energy bands at 20.7 kK and 25.0 kK. The locations of the band peaks for this salt were found almost to coincide with those for Na+ p-$Cl_2QCy_2^-$. Although the intensity of the low-energy band for K+ p-$Cl_2QCy_2^-$ is somewhat weaker than that for Na+ p-$Cl_2QCy_2^-$, the electronic structures of the solid salts do not appreciably depend on the counter cations now under consideration.

Na+ p-$H_2QCy_2^-$ (Fig. 4, Curve a). This salt gives the solid-state spectrum composed of a low-energy band at 10.7 kK with a shoulder around 14.3 kK, high-energy bands at 21.2 kK and 24.5 kK, and a shoulder in the energy region higher than 30.0 kK. Unlike as in Na+ p-$Cl_2QCy_2^-$, not only the band peak at 10.7 kK but also the shoulder around 14.3 kK are noted for the charge-transfer bands of Na+ p-$H_2QCy_2^-$. The intensities of these bands are quite strong. Although these bands are not completely resolved, they consist of two prominent peaks, and the splitting is approximately 3.6 kK. The energy of the first-band peak at 10.7 kK for Na+ p-$H_2QCy_2^-$ is lower than that at 12.6 kK for Na+ p-$Cl_2QCy_2^-$. Two charge-transfer absorptions are often observed for salts in which the charge-transfer interaction between the ion radicals is remarkably strong.[14] The charge-transfer interaction for Na+ p-$H_2QCy_2^-$ appears to be stronger than that for Na+ p-$Cl_2QCy_2^-$. The high-energy bands at 21.2 kK and 24.5 kK for the solid-state spectrum of Na+ p-$H_2QCy_2^-$ can be assigned to the shifted bands of the p-H_2QCy_2 anion radical monomer at 17.1 kK and 21.5 kK respectively.

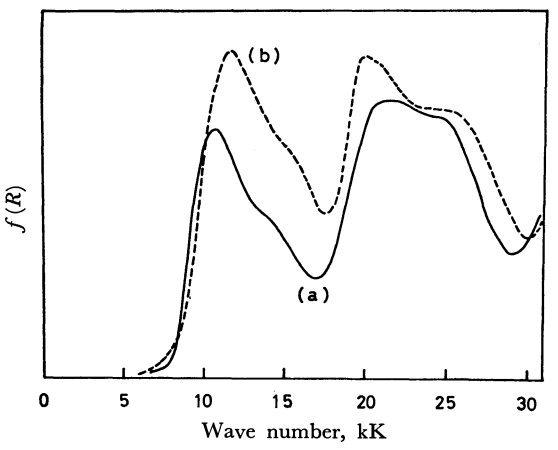

Fig. 4. The solid-state spectra of (a) Na+ p-$H_2QCy_2^-$ and (b) K+ p-$H_2QCy_2^-$.

K+ p-$H_2QCy_2^-$ (Fig. 4, Curve b). This salt shows the solid-state spectrum composed of a low-energy absorption at 11.7 kK, a shoulder around 15.4 kK, high-energy bands at 20.0 kK and 25.0 kK, and a shoulder in the energy region higher than 30.0 kK. It is interesting to see that the spectroscopic features for this salt are similar to those for Na+ p-$H_2QCy_2^-$. Therefore, the situations of the charge-transfer interaction for these substances seem to be much alike.

Discussion

The above-mentioned results of the solid-state spectra of these anion radical salts clearly show that a strong charge-transfer interaction takes place between the anion radical molecules. Therefore, the anion radical molecules can be expected to be stacked in a face-to-face manner and to form, in themselves, linear chain columns; this feature of the crystal structure has been found in a number of other ion radical salts.[10] The charge-transfer absorption characteristic of the solid salts should be ascribed to the transition of the type $\langle\cdots Q^- Q^- Q^- Q^-\cdots\rangle \longrightarrow \langle\cdots Q^- Q^0 Q^{2-} Q^-\cdots\rangle$, where Q denotes a quinone molecule. However, a question still remains as to why the broad and doublet structure of the charge-transfer absorption appears in the p-H_2QCy_2 anion radical salts. A possible explanation has been proposed by Tanaka and Mizuno.[9] According to their discussion, if there are two sites in the one-dimensional radical column in a unit cell, there are two kinds of charge-transfer states; one is from the left site to the right site, and the other is from right to left. The splitting of the charge-transfer absorption occurs when one takes into consideration the interaction term between these two states. Although

14) Two charge-transfer absorptions have also been observed for the solid-state spectra of the cation radical salts of p-phenylenediamine bromide and Würster's red bromide. In these solid salts, the charge-transfer bands are extraordinarily large, and the overlap integral between the half-filled molecular orbitals of the cation radicals is the largest in the series of Würster cation radical salts. See Refs. 4 and 9.

this off-diagonal element does not have terms proportional to the first order in the nearest neighbour electron overlap, it includes an electron-electron interaction of a dipolar type. With respect to the intermolecular separation between the anion radical molecules, the p-H_2QCy_2 anion radicals should be stacked more closely than the p-Cl_2QCy_2 anion radicals, since the latter include the bulky chlorine substituents. Therefore, the splitting of the charge-transfer absorption seems to be more important for the p-H_2QCy_2 anion radical salts than for the p-Cl_2QCy_2 anion radical salts. This is in agreement with the experimental results of the charge-transfer absorptions.

On the other hand, the charge-transfer interaction between the anion radical molecules in these anion radical salts was found to be almost independent of the species of the counter cations under consideration. This fact is in contrast to that for the anion radical salts of halogen-substituted p-benzoquinones, where the charge-transfer interaction is much reduced in the potassium salts in comparison with that in the sodium salts.[7]

In conclusion, the charge-transfer interaction between anion radical molecules was found to take place not only in the anion radical salts of halogen-substituted p-benzoquinones but also in the anion radical salts of cyano-substituted p-benzoquinones. This kind of interaction is regarded as characteristic of ion radical salts in general.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1780—1783 (1971)

Ionization of Some Quinones by the Interaction with Aliphatic Amines

Tsuguo YAMAOKA* and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received February 8, 1971)

The interactions of alkylamines with *p*-benzoquinone and its chloro-derivatives in ethanol and ethyl ether were studied by the rapid scan spectrophotometric method. The formation of anion radicals was found spectroscopically for the *n*-butylamine-*p*-benzoquinone, *n*-butylamine-chloranil, dimethylamine-*p*-benzoquinone, and tri-*n*-butylamine-chloranil systems. The rates of ionization reactions were determined to be 0.30 sec^{-1} mol^{-1} (at 253.7°K), 0.89 $sec^{-1}mol^{-1}$ (at 222.7°K), and 1.39 $sec^{-1}mol^{-1}$ (223.2°K) for the tri-*n*-butylamine-chloranil, *n*-butylamine-chloranil, and *n*-butylamine-*p*-benzoquinone systems, respectively. The activation energy for ionization of the tri-*n*-butylamine–chloranil system in ethanol was estimated to be 0.57 kcal/mol.

The reactions of aromatic amines with *p*-benzoquinone and its derivatives are typical examples of interactions between electron donors and acceptors. Recent studies[1,2] showed that the inner (σ) and outer (π) complexes exist as reaction intermediates in this type of reactions. The reaction mechanism was clarified for the system including chloranil as electron acceptor and *m*-phenylenediamine or *s*-triaminobenzene[3] as electron donor, by detecting the intermediates spectrophotometrically at various temperatures. Another type of reaction between electron donor and acceptor may include ionization as an intermediate process. Nagakura and Tanaka[4] presented the electron-transfer theory for some aromatic substitution reactions and pointed out that ionized species may exist as intermediates for the reactions. Kosower[5] emphasized that ionization processes play an important role in various electron donor-acceptor reactions. Furthermore, in the reaction producing diethylaminovinyltrichloro-*p*-benzoquinone from triethylamine and chloranil, electron transfer was considered to be the first step of the reaction although the process was not directly observed.[6]

The existence of ionic species has been demonstrated for many systems including electron donors and acceptors.[7–12] Detailed experimental studies have been made in particular for systems including aromatic amines such as *N,N*-dimethyl- and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine as electron donors.[13,14]

In spite of many works on the formation of ionic species in systems including electron donors and acceptors, kinetic studies of the ionization process are scanty. In this paper, the existence of ionic species as reaction intermediates will be demonstrated by the rapid scan spectrophotometric technique for some quinone-

aliphatic amine systems. Furthermore, the rate of ionization process will be determined by the electric conductivity measurement.

Experimental

Materials. Chloranil was recrystallized three times from acetone. *p*-Benzoquinone and 2,5-dichloro-*p*-benzoquinone were purified by vacuum sublimation. Ethanol was distilled after refluxing with magnesium ethylate. Ethyl ether was dried with sodium metal and distilled. Commercially available *n*-butylamine and tri-*n*-butylamine of GR grade were used without further purification after their purities had been checked by gas chromatography. The alcoholic or ethereal solutions of the other amines were obtained by dissolving gaseous amines which were generated by heating their hydrochlorides with sodium hydroxide.

Measurement. A Hitachi rapid scan spectrophotometer RSP-2 located at the Institute of Industrial Science, The University of Tokyo, was used to measure visible and ultraviolet spectra. The apparatus is equipped with an automatically controlled mixing cell. Spectra could be measured every 1/3 second in the wavelength range from 200 mμ to 700 mμ. The electric conductivity and its time dependence were measured with a vibrating reed electrometer and an oscilloscope.

Results and Discussion

Change in Absorption Spectra Caused by the Ionization of Quinones. Reactions of primary, secondary, and tertiary amines with *p*-benzoquinone and its chloroderivatives were investigated spectroscopically in ethanol and ethyl ether. Most reactions were so rapid that the change in visible and ultraviolet absorption spectra was pursued only by the rapid scan spectroscopic method. Concentrations of quinones were adjusted to about 10^{-4} mol/*l*, and an excess amount of amines was used in order to keep their concentrations approximately constant throughout the reaction.

First, let us describe interactions of primary amines with quinones. When *n*-butylamine is mixed with chloranil in ethanol, the spectrum rapidly changes as is shown in Fig. 1. At 1/3 second after mixing, the spectrum with a couple of peaks due to a vibrational structure appears in the region of 420—450 mμ. It is undoubtedly ascribed to the chloranil anion radical from the peak positions and shapes.[8] With the gradual disappearance of these peaks the intensity of an absorption band at 360 mμ increases. This band coincides with that of 2,5-di-*n*-butylamino-3,6-dichloro-*p*-benzoquinone observed by Buckley *et al.*[15] The result shows that an electron transfer occurs from *n*-butylamine to chloranil prior to the substitution reaction.

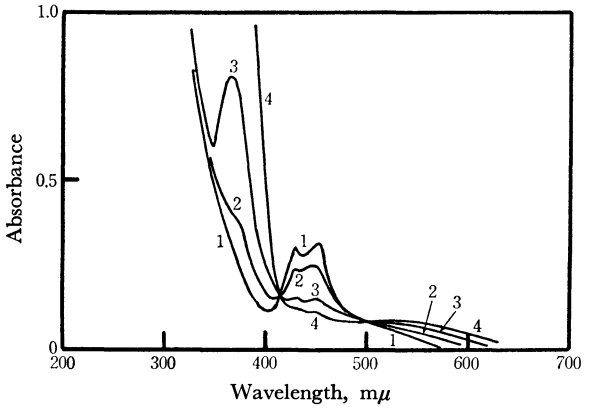

Fig. 1. The electronic absorption spectra of the *n*-butylamine - chloranil system in ethanol. Curves 1, 2, 3, and 4 are the spectra measured at 1/3 sec, 1 sec, 5 sec, and 30 sec, respectively, after the mixing.

A similar spectral change was observed for the methylamine - chloranil - ethanol system. The situation is the same for the systems including *p*-benzoquinone or 2,5-dichloro-*p*-benzoquinone instead of chloranil.

The ionization seems to be sensitive to the polarity of solvents and also the structure of electron acceptor. When *n*-butylamine and *p*-benzoquinone were mixed in ethyl ether, no absorption due to the *p*-benzoquinone anion radical was observed, only absorption bands due to the mono- and di-*n*-butylamino derivatives of *p*-benzoquinone appeared. This seems to mean that the ionic species is unstable in a weakly polar solvent like ethyl ether. When the electron affinity of the quinone is greater, the absorption of the anion radical appears even in ethyl ether. For instance,

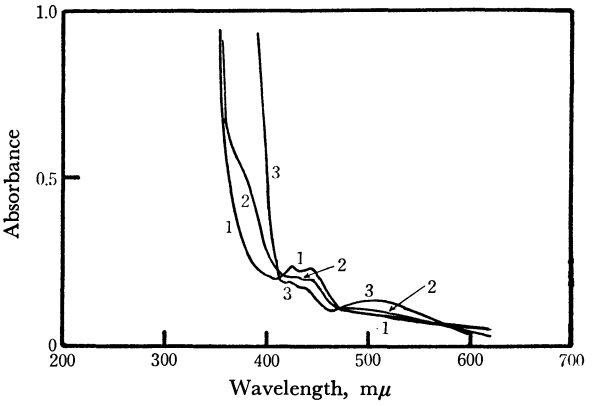

Fig. 2. The electronic absorption spectra of the *n*-butylamine - chloranil system in ethyl ether. Curves 1, 2, and 3 are the spectra measured at 1/3 sec, 1 sec, and 10 sec, respectively, after the mixing.

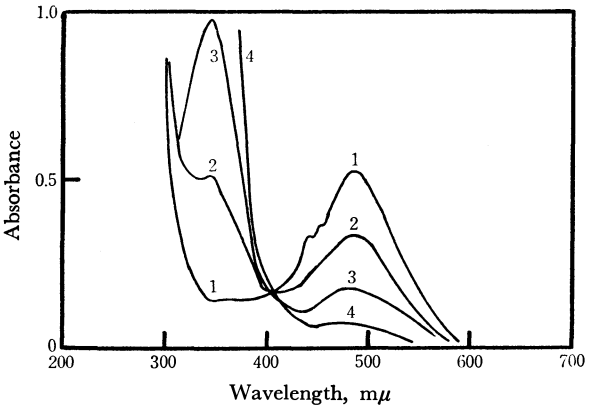

Fig. 3. The electronic absorption spectra of the dimethylamine - *p*-benzoquinone system in ethanol. Curves 1, 2, 3, and 4 are the spectra measured at 1/3 sec, 2 sec, 5 sec, and a few minutes, respectively, after the mixing.

15) D. Buckley, H. B. Henbest, and D. Slade, *J. Chem. Soc.*, **1957**, 4891.

the chloranil-*n*-butylamine system apparently shows an absorption due to the chloranil anion radical as is shown in Fig. 2, while the 2,5-dichloro-*p*-benzoquinone-*n*-butylamine system shows no such absorption.

In the interactions of secondary amines with quinones, the change in the absorption spectrum of the dimethylamine-*p*-benzoquinone-ethanol system takes place as shown in Fig. 3. At 1/3 second after mixing, an absorption band due to 2-dimethylamino-*p*-benzoquinone appears at 480 mμ for this system. Besides this band, there appears a shoulder due to the *p*-benzoquinone anion radical. This suggests that the anion exists as a precursor to 2-dimethylamino-*p*-benzoquinone. The dimethylamine-chloranil-ethanol system gives at 1/3 second after mixing, absorption peaks due to 2-dimethylamino-3,5,6-trichloro-*p*-benzoquinone but no peak due to the chloranil anion radical. It might be noted that the spectrum of the anion radical was not observed for the system containing dimethylamine as electron donor, while it was found for the system containing methylamine with the higher ionization potential. This seems to mean that the reaction rate of ionization is much lower than that of the successive process for the dimethylamine-chloranil-ethanol system.

The tri-*n*-butylamine-chloranil-ethanol system shows the absorption of the chloranil anion radical as seen in Fig. 4. In this system, the anion radical is stable and no further reaction occurs. The ionization of the system including tri-*n*-butylamine as electron donor largely depends on the electron affinity of quinone and also on the polarity of solvent. For example, in ethanol 2,5-dichloro-*p*-benzoquinone is ionized, though slowly, by the interaction with tri-*n*-butylamine but in the case of *p*-benzoquinone no ionization occurs. In ethyl ether neither quinones are ionized by the interaction with tri-*n*-butylamine.

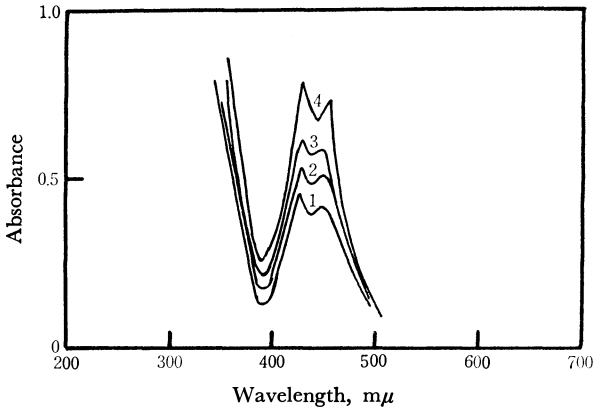

Fig. 4. The electronic absorption spectra of the tri-*n*-butylamine-chloranil system in ethanol. Curves 1, 2, 3, and 4 are the spectra measured at 1/3 sec, 1 sec, 5 sec, and a few minutes, respectively, after the mixing.

Rate of Ionization. Since the rapid scan spectrophotometric measurement could not be made at low temperatures, we undertook to use electric conductivity for the purpose of determining the rate of electron transfer from amine to quinone at various temperatures. In order to check the reliability of the measurement, the rate measured spectroscopically for the tri-*n*-butylamine-chloranil system at room temperature was compared with that obtained by aid of the conductivity measurement. The rate constants measured simultaneously by both methods coincide well with each other. Conductivity measurements were carried out at low temperatures at which the reactions succeeding the ionization actually stopped.

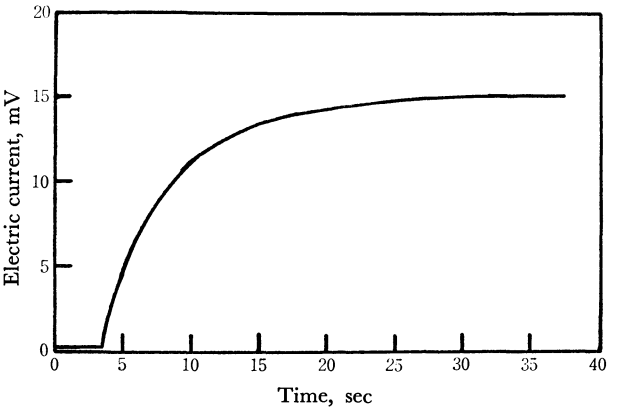

Fig. 5. Change in the electric conductivity of the ethanolic solution including tri-*n*-butylamine and chloranil.

Figure 5 shows the time dependence of conductivity of the ethanolic solution including tri-*n*-butylamine and chloranil. If the initial concentration of the amine, $[A_0]$, is excessively large compared with that of chloranil, $[Q_0]$, the electric current of the solution may change with time t as shown by the equation

$$I = \rho Q_0(1-e^{-[A_0]kt}) \qquad (1)$$

where k is the rate constant for the reaction, Amine+Quinone$\rightarrow$Amine$^+$+Quinone$^-$, and ρ is a constant determined by the electric charge and mobility of the ion, by the electrode voltage, and by the sizes of

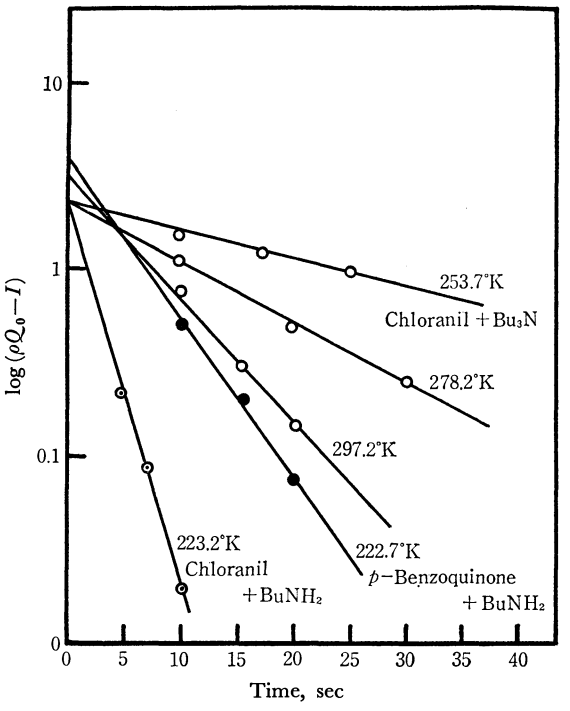

Fig. 6. Plots of log ($\rho Q_0 - I$) against the reaction time, t.

Table 1. Ionization rate constants for some aliphatic amine quinone systmes

Quinone	Amine	Rate constant ($sec^{-1}mol^{-1}$)
Chloranil	NBu_3	0.30 (253.7°K)
		0.71 (278.2°K)
		1.63 (297.2°K)
Chloranil	$BuNH_2$	0.89 (222.7°K)
p-Benzoquinone	$BuNH_2$	1.39 (223.2°K)

the electrodes. As is shown in Fig. 6, the plots of $\log(\rho Q_0 - I)$ against t give a straight line for each system. This means that the observed rate of ionization fits well into Eq. (1). The rate constant of ionization was estimated from the slope of the straight line. The results are summarized in Table 1. This table shows that the rate of ionization is the smallest for the chloranil-tri-*n*-butylamine system. This is rather unexpected because tri-*n*-butylamine has the smallest ionization potential among the amines used in the present study, and suggests that the rate of ionization is sensitive to the steric factor of the amines.

The temperature dependence of the rate constant was measured for the system containing chloranil and tri-*n*-butylamine in ethanol; the result is shown in Fig. 6. The activation energy of ionization was estimated to be 0.57 kcal/mol. The activation energies for the other primary and secondary amine systems could not be measured because the succeeding chemical reactions are rapid at higher temperatures.

We are greatly indebted to Prof. S. Hayano and Dr. M. Fujihira, The Institute of Industrial Science, The University of Tokyo, for their kindness in permitting us to use the rapid scan spectrophotometer and also for their kind advice. One of the authors (T. Y.) would like to thank Prof. T. Tsunoda, Chiba University, for continued encouragement throughout the study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1783—1788 (1971)

Structures of Bicyclo[2.2.2]octene and Bicyclo[2.2.2]octadiene as Studied by Gas Electron Diffraction

Akimichi YOKOZEKI and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received February 10, 1971)

Bicyclo[2.2.2]oct-2-ene and bicyclo[2.2.2]octa-2,5-diene have been investigated by gas electron diffraction. They are found to have C_{2v} symmetry in respect of the thermal-average nuclear positions. The structural parameters with estimated limits of error (the r_g bond lengths and the angles difined in the r_α structure) determined by a least-squares analysis on the molecular intensities are as follows for octene and octadiene, respectively: C(sp^3)–C(sp^3) (weighted average of the C_1–C_7 and C_7–C_8 bonds) = 1.549±0.008 and 1.553±0.017 Å, C(sp^2)–C(sp^3) = 1.509±0.015 and 1.521±0.008 Å, C(sp^2)–C(sp^2) = 1.341±0.008 and 1.339±0.005 Å, C(sp^3)–H (average) = 1.112±0.008 and 1.105±0.012 Å, ∠C–C=C = 114.2±0.6° and 113.5±0.5°, the dihedral angle θ between the C_1–C_2–C_3–C_4 and C_1–C_6–C_5–C_4 planes = 121.2±2.1° and 123.4±2.2°, ∠C=C–H = 122.4±6.0° and 125.5±4.0°, ∠H–C–H = 109.2±4.0° and 111.3±7.0°. A conformational analysis based on an empirical prescription of strain energies, similar to that of Jacob *et al.*, and a molecular-orbital analysis (CNDO/2) have accounted for the observed bond angles given above to within 1.5°.

A previous paper has reported on the structure and intramolecular motions of bicyclo[2.2.2]octane (BO) in the gas phase.[1] The weighted average of the C_1–C_2 and C_2–C_3 bond distances (r_g(average) = 1.542±0.004 Å) is similar to the C–C bond distance in cyclohexane,[2] and the C–C–C bond angles (∠C_1–C_2–C_3 = 109.7°±0.7° and ∠C_2–C_1–C_6 = 108.9°±0.6° in terms of the r_α structure[3]) are close to the tetrahedral angle. The potential function for the twisting motion around the D_{3h} symmetry axis has a broad minimum and probably has a hump of the order of 0.1 kcal/mol at the D_{3h} conformation.[4]

In connection with the above investigation, bicyclo[2.2.2]octene (BE) and bicyclo[2.2.2]octadiene (BD), in which the ethylene bridges in BO are partly replaced by vinylene bridges, are of interest in view of the influence of the double bonds on structural parameters. The observed heats of hydrogenation for these compounds,[5] which are larger than those expected from that for cyclohexene, indicate that the rings are appreciably strained. To our knowledge, however, no study of the structures of BE and BD has been reported, and even the symmetry of the molecules is uncertain.[5] Therefore, their structures have been investigated by means of gas electron diffraction.

Since these molecules have unequivalent pairs of closely-spaced C–C bond distances (C_1–C_2, C_1–C_7, and

C_7–C_8), a separation of those pairs[6,7] was a serious problem in the present analysis. In order to elude the trouble, all the C(sp^3)–C(sp^3) bond distances were assumed to be equal, and the weighted average value ($\frac{1}{3}[2r_g(C_1-C_7)+r_g(C_7-C_8)]$), instead of the individual bond distances, was determined.

Experimental

Purified samples of BE and BD were supplied by courtesy of Dr. Hiroshi Tanida of Shionogi Research Laboratory. Diffraction photographs were taken at 20°C on Fuji Process Hard plates with an apparatus equipped with an r^3-sector[8]; the accelerating voltage (stabilized within 0.01%) and the bean current were about 40 kV and 0.35 μA, respectively. The pressures of the samples maintained in thermal equilibrium with their solid states were about 4 Torr for BE and 7 Torr for BD. Typical experimental conditions are listed in Table 1. Other experimental and interpretational procedures have been described in a previous paper.[1] Reduced molecular intensity and radial distribution curves are shown in Figs. 2 and 3.[9] The calculations were carried out by using the HITAC-5020E at the Computer Centre of the University of Tokyo.

initial stage of the present analysis. Even though a flexible quasi-C_{2v} structure (like that observed in BO) or a rigid C_2 structure seemed to be improbable because of the presence of vinylene bridges, the C_{2v} symmetry had to be proved experimentally. If they have C_{2v} symmetry, the numbers of independent parameters sufficient to describe the geometrical arrangements are 16 and 14 for BE and BD, respectively. In this symmetry, the ethylene bridges ($-CH_2-CH_2-$) is borne to have a *cis* conformation around the C–C axis. For a C_2 symmetry with twisted conformations, the numbers of independent parameters are 28 and 25 for BE and BD, respectively. In order to facilitate the analysis and to limit the variable parameters to a reasonable number, the following assumptions about the parameters (in regard to the r_a structure[1,3]) were made.

1) All the C(sp^3)–H bond distances are equal.

2) The C(sp^3)–H bond distances are equal to that of ethylene[10] (r_a=1.0896 Å).

3) The vinylene group (C–CH=CH–C) is planar.

4) The H–C_j–H plane of the methylene group is perpendicular to the C_i–C_j–C_k plane and bisects the C_i–C_j–C_k angle, and *vice versa*.

5) The C–C–H angles at the bridgehead are equal; *i.e.*, $\angle C_2$–C_1–H=$\angle C_6$–C_1–H=$\angle C_7$–C_1–H.

Besides the above assumptions, the following constraint was introduced.

6) All the C(sp^3)–C(sp^3) bond distances are equal.

As mentioned in the introduction, this assumption was almost imperative for the present analysis. The influence of this constraint on the results is discussed in later sections. The above assumptions reduce the independent parameters for C_{2v} symmetry to eight for either molecule, while for C_2 symmetry one additional parameter is required. For either molecule the parameters to be determined are: four bond distances (weighted-average C(sp^3)–C(sp^3) and C(sp^3)–H, C(sp^2)–C(sp^3), and C=C), three bond angles ($\angle$C–C=C, $\angle$C=C–H, $\angle$H–C–H), the angle θ defined by the two straight lines connecting the center of the $C_1\cdots C_4$ with those of the C_2–C_3 and C_5–C_6 distances, and the torsional angle ϕ (the dihedral angle between the C_1–C_7–C_8 and C_4–C_8–C_7 planes). The parameter ϕ is a measure of whether the molecule has C_{2v} or C_2 symmetry in regard to the thermal-average nuclear positions.

Y(C–C)	0.11	Y(C=C)	0.48

a) The estimated force constants taken from cyclohexane[12] and several olefins (butene, pentene, *etc.*).[13] The torsional (Y) and wagging (W) force constants are in md·Å units, while the others are in md/Å units.

10) K. Kuchitsu, *J. Chem. Phys.*, **44**, 906 (1966).

Calculation of Mean Amplitudes and Shrinkage Corrections. The root-mean-square vibrational amplitudes and shrinkage corrections[11] for all the atom pairs in BE and BD were calculated from a normal-coordinate analysis by using the Urey-Bradley force constants (listed in Table 2) transferred from those for cyclohexane[12] and normal olefins (butene, pentene, *etc.*).[13] The procedures have been described elsewhere.[11]

Since the force constant Y characterizing the torsional motion[1] is not known for a *cis* conformation about a C–C single bond, Y was assumed to be equal to that for the *gauche* conformation (0.11 md·Å for cyclohexane,[12] as discussed in a previous paper.[1]) The lowest twisting frequencies calculated from the above Y value for BE and BD are higher than for BO, and they depend less sensitively on Y. A change in Y from 0.11 to 0.025 md·Å leads to that in the lowest twisting frequency from 163 to 120 cm^{-1} for BE and from 203 to 170 cm^{-1} for BD, while for BO the change is from 134 to 66 cm^{-1}. Therefore, the uncertainty in the calculated mean amplitudes due to that in Y is much less than that for BO, and the ϕ parameters determined in the following analysis is essentially free from the assumption about the Y value. The uncertainties in the assumed force constants were estimated to be 10—20%, *i.e.*, three times the random standard errors quoted in the force constants determined by the Urey-Bradley analysis.[12-14] In that event, the errors in the calculated mean amplitudes caused by the above-mentioned uncertainties in the force constants were at most $\pm$5% for bonded atom pairs and less than $\pm$10% for nonbonded pairs. These

uncertainties were of the order of the experimental errors, which were estimated for analogous molecules (*e.g.*, triethylenediamine[15]). Therefore, the calculated values listed in Table 3 were used as constant parameters for the subsequent analysis, and the systematic errors in the structural parameters due to this procedure were estimated to be less than their random standard errors.

Least-Squares Analysis. Initial values of the structural parameters were taken from a preliminary analysis of the radial distribution curves: C=C=1.34 Å, C(sp^2)–C(sp^3)=1.51 Å, C(sp^3)–C(sp^3) (average)=1.55 Å, ∠C–C=C=114°, ∠θ=120°. C_{2v} structures ($\phi \sim 0°$) were suggested at this stage. The nine parameters mentioned above were determined for either molecule by a least-squares analysis on the molecular intensities with a preset weight function[16] and with the estimated mean amplitudes and shrinkage corrections. The most probable values and their error matrices[17] are listed in Tables 4 and 5, respectively. As a result of the above analyses, the ϕ parameters, started from 10°, converged to zero. If the molecules had double-minimum potentials in terms of ϕ, similar to that in BO, the ϕ parameters should have converged to significantly nonzero values when the above-mentioned Y values were used. (In fact, this has been observed in the case of BO, where the ϕ parameter depended on Y.) In order to further examine this problem, the dependence of the ϕ parameters on Y was investigated by the use of different sets of the mean amplitudes. Essentially zero ϕ parameters were obtained from any set used in the analysis.

In order to estimate the systematic error due to the assumption 6, the constraint 6 was released in the least-squares analysis. Strong correlation between the C_1–C_7 and C_7–C_8 distances was observed in the error matrices, and as a result, they were determined only with standard errors of about 0.014 Å, and their weighted averages deviated from those given in Table 4 by about 0.003 Å for BE and 0.005 Å for BD. At the same time, the C_1–C_2 (C(sp^2)–C(sp^3)) distances changed from those listed in Table 4 by about 0.01 Å for BE and 0.004 Å for BD, respectively. Other parameters changed only within their random standard errors. Therefore, the systematic errors from this source were taken into account in the C(sp^3)–C(sp^3) (average) and C(sp^2)–C(sp^3) parameters.

a) Molecular structures of bicyclo [2.2.2] octane (BO), octene (BE), and octadiene (BD) by gas electron diffraction. The distances are represented by r_g in Å units and the angles by an r_α representation.
b) Ref. 1.
c) Ref. 21 (calculated values).
d) The present work.
e) Calculated values based on a strain-relief mechanism (see text).
f) Weighted average of the C(sp^3)–C(sp^3)bond distances and that of the C(sp^3)–H bond distances.

The limits of error in the most probable values of the structural parameters, quoted in Table 4, were estimated to be 2.5 times the random standard errors listed in Table 5 as diagonal elements plus systematic errors [those mentioned above and the experimental systematic errors (0.12% for the distance parameters due to sector imperfection, uncertainty in the electron wavelength, *etc.*[3])].

Discussion

Molecular Symmetry. The ϕ parameters determined from the analysis are essentially zero, regardless of the torsional force constant (Y) assumed in the analysis. This implies that these molecules have C_{2v} conformations in respect of the thermal-average nuclear positions and that the potentials of torsion in BE and BD have relatively sharp minima around the C_{2v} positions ($\phi=0°$). In these molecules, unlike BO, the torsional motion couples with a twist around the double bond (C_2–C_3), which demands a high cost of energy.

Bond Distances. The structural parameters determined above are compared with BO in Table 6. The weighted-average values of the C(sp^3)–C(sp^3) bond lengths are 1.542±0.004 (which is similar to that in cyclohexane[2]), 1.549±0.008 and 1.553±0.017 Å for BO, BE, and BD, respectively. The corresponding values for norbornane and norbornadiene[5] are 1.549± 0.003 and 1.573±0.014 Å. The C(sp^2)–C(sp^3) bond distances are 1.509±0.015 Å for BE (analogous to that in propylene, r_s=1.501±0.004 Å[18]), 1.521±0.008 Å for BD and 1.535±0.007 Å for norbornadiene. The above systematic differences in the C–C single bond distances, notwithstanding their relatively large limits of error, may be regarded as the influence of intramolecular strain. The double bond distances in such bicyclic compounds, on the contrary, are nearly equal to those in normal olefins (*e.g.*, 1.337 Å for ethylene[10]). This can be explained by considering that the stretching force constant for double bonds is, in general, several fold larger than that for single bonds, so that the former distance is hardly influenced by the intramolecular strain.

Bond Angles. The effect of angle strain in these bicyclic compounds is also exhibited. The deviation in the C–C–C bond angles from the tetrahedral angle increases in the sequence of BO, BE, and BD. The C=C–C bond angles are about 6° smaller than the trigonal angle, while the corresponding deformation in norbornadiene is about 12°. The C_1–C_4 distances in the three molecules are nearly equal, 2.59, 2.57, and 2.56 Å for BO, BE, and BD, respectively. On the other hand, the dihedral angle θ appears to increase as the molecules have more vinylene groups. A similar trend has been observed in norbornane and norbornadiene.

The above observation can be predicted semiquantitatively, as listed in Table 6, by a strain-relief mechanism similar to that of Jacob *et al.*[19] In the present calculation the strain energy in the molecule was constructed only in terms of angle deformations and nonbonded interactions. The force constants for the deformations of the C–C–C and C–C=C bond angles were assumed to be equal to each other, 0.687 md·Å, as estimated from the Urey-Bradley force fields for saturated hydrocarbons reported by Schachtschneider and Snyder.[14] Standard values for the C–C–C and C–C=C angle were chosen to be the tetrahedral and trigonal angles, respectively. All the nonbonded interactions among the C–C, C–H, and H–H pairs were

calculated by use of the functions reported by Hendrickson[20] and by Jacob *et al.*[18] The latter functions are much harder than the former, so that the latter appears to overestimate the steric interactions. In fact, a minimization of the total energy showed that the energy for BD was about 30 kcal/mol *smaller* than that for BE according to the latter function, whereas the energy for BD was about 10 kcal/mol *larger* than that for BE according to the former. In spite of the above discrepancies, the conformational analyses for bond angles were in good agreement with each other (within 0.5°). In addition, the model used in the present study gave bond angles in BO similar to those based on a more elaborate scheme by Gleicher and Schleyer[21] (within 1°).

For the purpose of comparison, another conformational analysis was made by means of a quantum-mechanical scheme known as SCF CNDO/2.[22] A program written by Segal[23] was used in the calculations. The energy was minimized by varying two independent parameters ($\angle$C–C=C and θ) systematically in step of 0.5°, while other parameters were assumed to be constant and equal to the observed values listed in Table 4. The $\angle$C–C=C and θ parameters were predicted to be 114.5° and 121.0° for BE and 115.0° and 122.5° for BD, respectively, in essential agreement with the corresponding values (Table 6) derived from the above-mentioned classical method.

The authors wish to thank Professor Yonezo Morino for his continual encouragement and Drs. Hiroshi Tanida and Kazuo Tori of the Shionogi Research Laboratory for their supply of the samples and for their stimulating discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1788—1791 (1971)

The Electron-acceptor Strengths of Some Substituted Naphthoquinones

Gunzi SAITO and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received February 19, 1971)

The electron-acceptor strengths of the substituted naphthoquinones were compared with that of *p*-chloranil in terms of their complexing properties. The following electron affinities were estimated: 2.05 eV for 2,3-dichloro-1,4-naphthoquinone, 2.24 eV for 2,3-dichloro-5-nitro-1,4-naphthoquinone, 2.74 eV for 2,3-dicyano-1,4-naphthoquinone, and 2.78 eV for 2,3-dicyano-5-nitro-1,4-naphthoquinone.

Cyano and nitro groups are strongly electronegative, as is indicated by their large Hammett constants. Consequently, the electron-acceptor strength of aromatic molecules is much enhanced by the introduction of such substituents.[1] For example, *p*-benzoquinone is a rather weak acceptor; it is comparable in strength with *s*-trinitrobenzene. On the other hand, the 2,3-dicyano and 2,6-dinitro derivatives are among the strongest.[2] Their strengths can well be compared with those of tetracyanoethylene (TCNE) and tetracyanoquinodimethane (TCNQ). The other cyano and nitro compounds so far examined for their acceptor strengths include 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), *p*-cyananil, tetracyano-1,4-naphthaquinodimethane, trinitrophenanthrenequinone, and the nitro derivatives of fluorenemalononitrile.[2-6] However, 1,4-naphthoquinone and its derivatives have scarcely been studied. Continuing the search for a strong electron acceptor,[7] we have examined the acceptor strengths of 2,3-dicyano-1,4-naphthoquinone (DCNQ) and its 5-nitro derivative (DCNNQ) in terms of their complexing properties. In comparison with them, their precursors, 2,3-dichloro-1,4-naphthoquinone (Cl_2NQ) and its 5-nitro derivative (Cl_2NNQ), were also studied.

Experimental

Cl_2NQ and *p*-chloranil were commercially obtained. Cl_2NNQ, DCNQ, and DCNNQ were prepared starting from Cl_2NQ following the procedures of Inoue *et al.* and Wallenfels *et al.*[3,8] They were purified by recrystallization from suitable solvents. DCNQ was finally sublimed in a vacuum. The fourteen aromatic hydrocarbons, twenty-one aromatic monoamines, seven diamines, and eight other compounds listed in Table 1 were employed as electron donors. All the spectra

were recorded at room temperature by means of a Beckman DK 2A spectrophotometer, using quartz cells with 1-cm and 5-cm path lengths. The solvent used throughout the measurements was Wako reagent-grade chloroform.

Results and Discussion

Several criteria for the electron-accepting properties of π-acceptors have been proposed by various authors.[9] The comparison of the energies at the charge-transfer (CT) absorption maxima in the molecular complexes of two acceptors with the same series of donors is one of them. The electron affinity estimated by this method may be affected, to some extent, by the kind of solvent and also by the kind of donor. Of course, we must compare the complexes of the same bond type, π–π or n–π. In the present work, we used about fifty π-donors with the hope of averaging the specific effect of the donor molecule on the energy of the CT absorption. McConnell *et al.* have proposed that the energy, $h\nu_{CT}$, observed in solution can be approximately expressed by:

$$h\nu_{CT} = I_D - E_A - C, \quad (1)$$

where I_D is the ionization potential of the donor, D, where E_A is the electron affinity of the acceptor, A, and where C represents the electrostatic energy in the dative-bond structure of the complex and also some other minor terms.[10] The difference in $h\nu_{CT}$ of the complexes of a given donor with two acceptors, 1 and 2, is, then:

$$(h\nu_{CT})_1 - (h\nu_{CT})_2 = (E_A)_2 - (E_A)_1 + (C_2 - C_1). \quad (2)$$

The last term is not necessarily zero. Batley and Lyons estimated the change to be no greater than 0.4 eV.[11] Moreover, one of the present authors has demonstrated that this term is a few kK even if the sizes and shapes of the component molecules are very different.[12] We chose *p*-chloranil for the reference, as was done in our previous work. The positions of the maxima of the CT absorption bands exhibited by the acceptors and also by the reference mixed with various donors are presented in Table 1. The linear relationships obtained by the least-squares method are as follows:

$$\begin{aligned} &Cl_2NQ && (h\nu_{CT})_1 = 1.003(h\nu_{CT})_2 + 3.285 \\ &Cl_2NNQ && (h\nu_{CT})_1 = 0.969(h\nu_{CT})_2 + 1.785 \\ &DCNQ && (h\nu_{CT})_1 = 1.034(h\nu_{CT})_2 - 2.292 \\ &DCNNQ && (h\nu_{CT})_1 = 0.977(h\nu_{CT})_2 - 2.603 \end{aligned} \quad (3)$$

The slopes found here are in good agreement with that required by Eq. (2). The intercepts may be considered as measures of the difference in the electron affinity between the naphthoquinones and the reference. The greater the electron affinity of the acceptor, the smaller the energy of the CT absorption maximum; therefore, the negative intercepts for DCNQ and DCNNQ indicate that these two are stronger electron acceptors than *p*-chloranil is. If we take the electron affinity of *p*-chloranil as 2.46 eV, following Farragher and Page,[13] those of the present acceptors are 2.05 eV in Cl_2NQ, 2.24 eV in Cl_2NNQ, 2.74 eV in DCNQ, and 2.78 eV in DCNNQ. These naphthoquinones appear to have acceptor strengths comparable with those of dichloro-*p*-xyloquinone, *p*-fluoranil, *o*-bromanil, and TCNQ respectively. It must be noted that the above-mentioned values cannot be compared directly with the affinities in the literature. Briegleb assumed the affinity of *p*-chloranil as 1.37 eV, and Batley and Lyons took the iodine molecule as their reference and estimated the affinity of *p*-chloranil as 2.59 eV. Thus, our values may be about 1 eV higher than the former estimations, but a little less than the latter.

The effect of substituents on the acceptor strength of the naphthoquinones and related compounds will now be examined in more detail. The energies of the CT absorptions in the pyrene complexes fit well the linear relationship given by Eq. (3); that is, the calculated values, 19.5 kK, 17.6 kK, 14.5 kK, and 13.2 kK for the complexes of Cl_2NQ, Cl_2NNQ, DCNQ, and DCNNQ respectively, are in excellent agreement with the observed values presented in Table 1. Therefore, the energies in the pyrene complexes will be used for the purpose of comparing the acceptor strengths in the following discussion.

The difference in energy between the Cl_2NQ complex and the DCNQ complex is 4.9 kK, while that between the Cl_2NNQ complex and the DCNNQ complex is 4.3 kK. These values are close to that of 4.5 kK evaluated for the increase in acceptor strength by the replacement of chlorine atoms with cyano groups at the 2 and 3 positions of *p*-benzoquinone. The latter was obtained on the basis of the following energies: 18.2 kK with the 2,3-dichloro derivative, 13.7 kK with the 2,3-dicyano derivative, 16.2 kK with *p*-chloranil, and 11.7 kK with DDQ given in an earlier work.[14] When a substituent is introduced to a molecule, its effect on the energy level can be correlated with the π-electron density on the carbon atom to which the substituent is to be introduced.[15] The π-electron distribution in the accepting molecular orbital, in other words, the lowest vacant molecular orbital, of a quinone molecule is, as a first approximation, given by twice the unpaired electron distribution in the semiquinone ion. By the analysis of the hyperfine structure of the electron-spin-resonance spectrum, the latter can be estimated, for the ring-proton splitting constant is approximately proportional to the unpaired electron density on the carbon atom to which the proton is attached.[16] The four equivalent protons in the *p*-benzosemiquinone ion have been reported by Adams *et al.* to show a spacing of 2.37 oersteds.[17] In the case of the 2,3-dichloro-*p*-benzosemiquinone ion examined by Venkataraman *et al.*, the splitting due to the two equivalent protons was

** The CT absorption band could not be detected.

found to be 2.319 oersteds.[18] On the other hand, the proton splitting constants in the 1,4-naphthosemiquinone ion are 3.22 oersteds at the 2 and 3 positions and 0.57 oersteds at the 5, 6, 7, and 8 positions.[17] An expected quintet with a spacing of 0.6 oersteds has been observed for the 2,3-dichloro-1,4-naphthosemiquinone ion.[19] As the present study indicated that the introduction of an electronegative substituent to the 2 position of 1,4-naphthoquinone affects the acceptor strength as much as the introduction of the same to *p*-benzoquinone does, the substituent situated on the 5 or 6 position of naphthoquinone must be less effective than that introduced to benzoquinone. The increase in the acceptor strength by a nitro group substituted at the 5 position of Cl_2NQ and that of DCNQ is in accordance with this prediction. Hammond has shown that the difference in the energy of the CT absorption maximum between the *p*-benzoquinone complex and the mononitro-*p*-benzoquinone complex is 4.0—4.4 kK, and that between the latter and the 2,6-dinitro-*p*-benzoquinone complex is 2.4 kK.[2] On the other hand, the substitution of a nitro group at the 5 position of Cl_2NQ brings about a change of 2.0 kK in the energy of the CT absorption maximum, and that at the 5 position of DCNQ, a change of 1.4 kK.

The above data clearly show that the effect of substituents on the acceptor strength is mutually dependent. The stronger the acceptor to which an electronegative substituent is introduced, the less the effect. This tendency may be considered as a kind of cumulative influence. Peover has estimated the electron affinity of unsubstituted 1,4-naphthoquinone to be 0.20 e V(1.5 kK) lower than that of *p*-benzoquinone.[20] We have found here that the Cl_2NQ complex shows a CT absorption maximum located 1.3 kK higher than that of the 2,3-dichloro-*p*-benzoquinone complex, while the CT absorption of the DCNQ complex is located only 0.9 kK higher than that of the 2,3-dicyano-*p*-benzoquinone complex. Thus, the difference in the electron affinity between a benzoquinone and the corresponding naphthoquinone becomes progressively smaller when the substituents are more electronegative. This trend sug-

gests that the cumulative influence is more pronounced in the benzoquinone series than in the naphthoquinone series.

Finally, we must add that almost all the complexes between DCNNQ and monoamines were found to be transitory. However, Cl_2NNQ and DCNQ gave time-independent colored solutions when mixed with most of the donors examined.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1791—1796 (1971)

Some New Oxygenated Cobalt Complexes

Megumu MUNAKATA*

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received December 22, 1969)

Cobalt(II) complexes with ornithine, 2,4-diaminobutyric acid and 2,3-diaminopropionic acid were studied as new oxygen complexes. The former complex was reversibly, while the latter two complexes were irreversibly oxygenated at room temperature. These oxygenated complexes were diamagnetic and showed electronic absorption spectra similar to that of oxygenated cobalt histidine complex, and they were assumed to be O_2-bridged binuclear complexes, $L_2Co\text{-}O_2\text{-}CoL_2$ (L: ligand). Cobalt and O_2 of the binuclear complexes existed in the state of Co(III) and O_2^{2-}, respectively. Thermodynamic measurements showed that oxygenation was an exothermal process, and deoxygenation an endothermal one. The reversibility correlated with the reduction potential of the central cobalt(III) ion and the enthalpy change of the oxygenation. Easier deoxygenation corresponded to more positive reduction potential and to smaller enthalpy change.

Since it was found that bis(salicylaldehyde)ethylenediamine cobalt (II) reversibly combined with molecular oxygen,[1] oxygen complexes of metal chelates were noted as an interesting model for the oxygen carrying compounds such as hemoglobin and hemocyanin.[2-6] Burk *et al.*[6] reported that among histidine complexes of transition metals, only the cobalt complex possessed the ability to combine reversibly with molecular oxygen. Hearon[7] explained the results as follows. Cobalt forms octahedral complexes, while the available structure of nickel and copper complexes are tetrahedral or square planar. An unpaired electron of cobalt (II) ion accounts for the stabilization of the oxygenated complex. By the combination of cobalt histidine complex with molecular oxygen, the pairing occurs between unpaired electrons from cobalt (II) ion and molecular oxygen. The binuclear structure of peroxide form was proposed from the diamagnetic nature of the oxygenated complex,[8,9] and the reactions are expected to be

$$Co^{2+} + 2HHid \rightleftarrows Co(Hid)_2 + 2H^+ \quad (1)$$

$$2Co(Hid)_2 + O_2 \rightleftarrows [Co(Hid)_2]_2O_2 \quad (2)$$

where HHid is histidine.

In the present research, new oxygenated cobalt complexes with 2,3-diaminopropionic acid, 2,4-diaminobutyric acid and ornithine were prepared. They were identified by elemental analyses of the isolated complex salts, the uptake oxygen gas and electronic absorption spectra of the solutions. The valency states of the central cobalt ion and coordinated molecular oxygen were estimated and thermodynamic properties were obtained. From the results, the effect of ligand-field, the redox potential of the cobalt ion and the enthalpy change on the oxygenation-deoxygenation reversibility were discussed.

Experimental

Materials. 2,3-Diaminopropionic acid and 2,4-diaminobutyric acid were obtained from Sigma Chemical Company, and histidine methyl ester and *N*-acetylhistidine were obtained from Cyclo Chemical Coorporation. The other chemicals used were of reagent grade.

Preparation of Cobalt Complex. Bis(histidinate) Cobalt(II): This chelate was synthesized according to the method of Sano and Tanabe.[10]

Found: C, 37.34; H, 4.75; N, 21.90%. Calcd for $Co(C_6H_8N_3O_2)_2\cdot H_2O$: C, 37.41; H, 4.71; N, 21.82%.

Bis(2,3-diaminopropionate) Cobalt(II) and Bis(2,4-diaminobutyrato) Cobalt(II): These chelates were synthesized in the same way as in cobalt histidine chelate.

Found: C, 23.15; H, 5.76; N, 18.38%. Calcd for $Co(C_3H_7N_2O_2)_2\cdot 2H_2O$: C, 23.92; H, 5.98; N, 18.60%. Pale pink powder.

Found: C, 29.46; H, 6.57; N, 16.85%. Calcd for $Co(C_4H_9N_2O_2)_2\cdot 2H_2O$: C, 29.18; H, 6.67; N, 17.02%. Pale pink powder.

μ-Oxy-bis(Cobalt dihistidinate), $[Co(Hid)_2]_2O_2\cdot 7H_2O$: This

chelate was synthesized according to the above method.[10]

Found: C, 31.96; H, 5.16; N, 18.51%. Calcd for $[Co(C_6H_8N_3O_2)_2]_2O_2 \cdot 7H_2O$: C, 31.65; H, 5.27; N, 18.46%. Brown powder.

μ-Oxy-bis[Cobalt di(2,3-diaminopropionate)], $[Co(DAP)_2]_2O_2 \cdot 5H_2O$: A solution containing 2,3-diaminopropionic acid monohydrochloride (10 mmol) and cobalt(II) chloride 6-hydrate (5 mmol) in 10 m*l* of water was adjusted to pH 8.5 with a 1 N sodium hydroxide. After oxygen gas was passed for about 10 min at 10°C and 40 m*l* of acetone added, the solution was cooled. The resulting brown precipitate was collected on a funnel, washed successively with 60 per cent acetone, acetone and ether, and dried over calcium chloride under reduced pressure to give brown powder.

Found: C, 21.96; H, 5.71; N, 16.95%. Calcd for $[Co(C_3H_7N_2O_2)_2]_2O_2 \cdot 5H_2O$: C, 22.09; H, 5.83; N, 17.18%.

μ-Oxy-bis[Cobalt di(2,4-diaminobutyrate)], $[Co(DAB)_2]_2O_2 \cdot 6H_2O$: The same procedure as in the synthesis of $[Co(DAB)_2]_2O_2 \cdot 5H_2O$ was employed, using cobalt(II) chloride 6-hydrate and 2,4-diaminobutyric acid 2-hydrochloride. Brown powder.

Found: C, 26.54; H, 6.52; N, 15.40%. Calcd for $[Co(C_4H_9N_2O_2)_2]_2O_2 \cdot 5H_2O$: C, 26.45; H, 6.61; N, 15.43%.

The numbers of water were confirmed also by the weight loss at 40° and 100°C from the thermogravimetric curves of the complexes.

Apparatus and Procedures. Polarograms were obtained with a Yanagimoto recording polarograph, P. B.-104. Sample solutions contained 10^{-3} M cobalt(II) ion, 2×10^{-3} M chelating agent, 0.1 M potassium chloride, 0.05% gelatin, and 10^{-2} M potassium dihydrogen phosphate-disodium hydrogen phosphate buffer or 10^{-2} M ammonium chloride-ammonia buffer.

The stability constant of oxygenated complexes was determined with a Warburg manometer.[8] A solution of chelating ligand and a buffer solution were pipetted into the main room of reaction vessel and cobalt(II) chloride solution, into the sub-chamber of the vessel. The reaction volume was 2.00 m*l*, the final concentration of cobalt(II) ion was 10^{-2} M and the amount of chelating ligand was so arranged that the cobalt ion was completely converted to the chelate when two solutions were mixed. After the solutions were kept at the desired temperature (5—70°C) for a few minute in a water bath, cobalt solution was transferred into the main room and the mixture was shaken until equilibrium was attained. Oxygen consumption was then measured with a manometer, and the stability constant was calculated by the equation

$$K = \frac{[(CoL_2)_2O_2]}{[CoL_2]^2[O_2]}$$

where $[CoL_2]$ is the conentration of cobalt(II) chelate and $[O_2]$ is the solubility of oxygen gas under the conditions applied.

Results and Discussion

New Oxygenated Cobalt Complexes. The reaction

a) A: Spectra of these cobalt complexes are the same as that of oxygenated cobalt histidine complex reported by Hearon.[7]
B: Same as cobalt(II) chelate
C: Same as cobalt(III) chelate
C′: Same as cobalt(III) complex named as irreversible complex by Hearon[7]

b) Conditions of oxygen-uptake measurements;
Concentration of cobalt chelate: 10^{-2}M
Volume of the solution : 2.0 m*l*
Temperature : 30°C

c) Recovery of oxygen gas was attained by acidifying the solution after standing for the assigned time.

behaviors of various cobalt(II) chelates with oxygen gas are summarized in Table 1, which includes the three new oxygenated complexes found. Oxygen release was made by acidifying the solution, which had been contacted with air or oxygen gas for an appropriate time. As the contact time was prolonged, oxygen recovery became lower, accompanying color change. This phenomenon indicates that the oxygenated complexes are slowly oxidized to the cobalt(III) chelate. It can be deduced that if a reasonable amount of oxygen is released by acidification, the main reaction of cobalt(II) chelate by contact with oxygen gas is oxygenation, but not oxidation. Table 1 is classified according to this concept. Oxygenation, oxidation, and no-reaction could be also spectrophotometrically distinguished, because the absorption spectra of cobalt(II) chelates, cobalt(III) chelates and the oxygenated complexes differ from each other.

Cobalt(II) chelates with 2,3-diaminopropionic acid (HDAP), $NH_2 \cdot CH_2 \cdot CH < \begin{matrix} COOH \\ NH_2 \end{matrix}$, 2,4-diaminobutyric acid (HDAB), $NH_2 \cdot CH_2 \cdot CH_2 \cdot CH < \begin{matrix} COOH \\ NH_2 \end{matrix}$, and ornithine (HOrn), $NH_2 \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot CH < \begin{matrix} COOH \\ NH_2 \end{matrix}$, are readily oxygenated. The oxygen uptake behaviors are shown in Fig. 1.

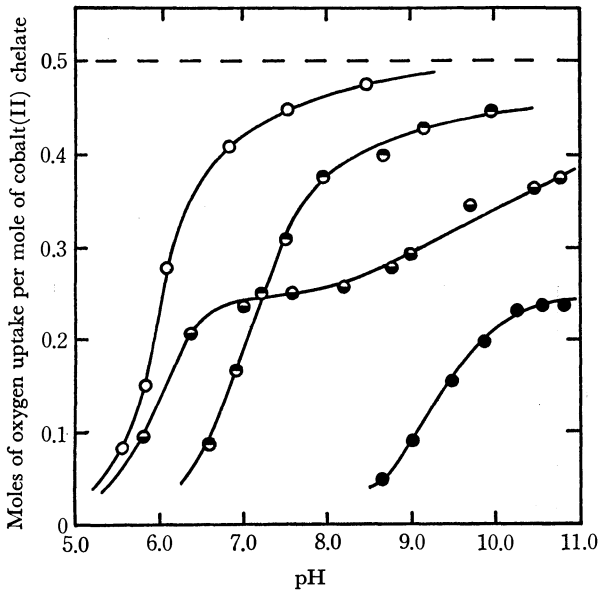

Fig. 1. Oxygen uptake of Cobalt(II) chelates.

volume: 2 ml
temperature: 30°C

The reversibility of oxygenation-deoxygenation was studied by measuring the color change of solution, which occurred by aeration and thereafter by bubbling nitrogen gas. The anaerobic solutions are slightly pink, but they become deep amber in the oxygenation process. The oxygenated ornithine complex can be easily deoxygenated, but the DAP and the DAB complexes are hardly deoxygenated at room temperature. The reversibility increases in the order

$$[Co(DAP)_2]_2O_2 < [Co(DAB)_2]_2O_2$$
(partially deoxygenated)
$$\ll [Co(Orn)_2]_2O_2 < [Co(Hid)_2]_2O_2$$
(reversibly deoxygenated)

It has been considered that the imidazole ring is essential for the specific oxygenation of cobalt histidine chelate. Any oxygenated cobalt(II) chelates with amino acids, which did not have imidazole ring, were not found up to date, and further more the chelate with 1-methylhistidine, imidazole of which is blocked, is not oxygenated. However, the chelate with *N*-acetylhistidine, the amino group of which is blocked but not imidazole, does not absorb oxygen gas, and this shows that amino group is also dispensable. On the other hand, the new oxygenated complexes indicate that the imidazole ring is not always necessary. But it can be stated that the ligands having two nitrogen doners and a carboxyl or a carbonyl group are suitable. Carboxyl or carbonyl group seems to play an important role in the oxygenation reversibility, because the histidine chelate and the histidine methyl ester chelate are reversibly oxygenated, but not the histamine chelate.

Magnetic Properties and Electronic Absorption Spectra. Magnetic moments of the oxygenated cobalt complexes were obtained at 25°C with the Gouy balance. Oxygenated complexes of $Co(DAP)_2$, $Co(DAB)_2$, and $Co(Orn)_2$ showed 0.17, 0.14, and 0.15 Bohr magnetons, respectively. As reported on diamagnetic $[Co(Hid)_2]_2O_2$,[8] such small moments can be attributed to cobalt(II) chelate impurity resulting from incomplete oxygenation, and the new oxygenated complexes should be diamagnetic. Figure 2 show the electronic absorption spectra of the new oxygenated cobalt complexes. The shape

of the spectra resembles that of the oxygenated histidine complex, but are quite different from those of the cobalt(II) chelates (Fig. 3) and the cobalt(III) chelates[11] (Fig. 4). From these results, the new oxygenated complexes may be regarded as diamagnetic O_2-bridged binuclear cobalt complexes like the histidine complex, in which one unpaired electron from each of the cobalt(II) ions is paired with each of two unpaired electrons from molecular oxygen.

Valency States of Cobalt and Coordinated Molecular Oxygen in Oxygenated Cobalt Complexes. Figure 5 shows the polarograms obtained with cobalt(II) DAP chelate ($Co(DAP)_2$), the oxygenated complex ($[Co(DAP)_2]_2O_2$), and the cobalt(III) chelate ($[Co(DAP)_2]^+$).[12] The oxygenated complex, $[Co(DAP)_2]_2O_2$,

pH: 8.70 (pH: 10 for Orn)
Temperature: 30°C
a) $K=\dfrac{[(CoL_2)_2O_2]}{[CoL_2]^2\,[O_2]}$

but not with the cobalt(II) chelate. The second wave (b) is observed only with oxygenated complexes. Although the exact value can not be measured, because of little overlap with wave (c), the half-wave potential (−0.96 V *vs.* SCE) is nearly equal to the reduction potential of hydrogen peroxide (−0.95 V). The potential is independent of the kind of oxygenated complexes, and wave (b) might result from hydrogen peroxide produced in the reduction process of cobalt(III) to cobalt(II):

$$[L_2Co^{III}\text{–}O_2^{2-}\text{–}Co^{III}L_2] \xrightarrow[2H^+]{2e^-} 2Co^{II}L_2 + H_2O_2$$

The last wave (c) is attributed to the reduction of cobalt(II) to metallic cobalt.

The polarograms of cobalt histidine complexes are shown in Fig. 6. The *i-E* curve is deformed by passing air or oxygen gas through the solution, but it slowly returns to the original shape by bubbling nitrogen gas. The first wave of polarograms obtained with the anaerobic solution is the oxidation wave, which might be attributed to the oxidation of cobalt(II) to cobalt(III) (A and D in Fig. 6). As oxygenation proceeds by aeration, the negative current decreases and simultaneously positive current increases (B and C in Fig. 6), but the half-wave potential remains almost constant (−0.03 V). These solutions give the second wave at the same potential (−0.97 V) as that of $[Co(DAP)_2]_2O_2$, *i.e.* the reduction potential of hydrogen peroxide. The current increases with the increase in positive current of the first wave, but the ratio of the former current to the latter is somewhat smaller than unity. This may be caused by the difference in both diffusion currents. Caglioti *et al.*[13] also reported that the polarograms of $[Co(Hid)_2]_2O_2$ showed the redox wave of cobalt(III)/cobalt(II) and the reduction wave of hydrogen peroxide. The third and fourth waves may be due to the reduction of cobalt(II) to cobalt(I) and cobalt(I) to cobalt(0), respectively. The other oxygenated complexes, $[Co(DAB)_2]_2O_2$ and $[Co(Orn)_2]_2O_2$ show a similar polarographic behavior. The reduction potentials of the central cobalt(III) ions and O_2-type oxygen are given in Table 2.

These results lead to the conclusion that the coordinated molecular oxygen accepts two electrons from two cobalt(II) ions to attain the state of O_2^{2-}, and at the same time, two cobalt(II) ions are oxidized to cobalt(III) ions.

13) V. Caglioti, P. Silvestroni, and C. Futlani, *J. Inorg. Nucl. Chem.*, **13**, 90 (1960)

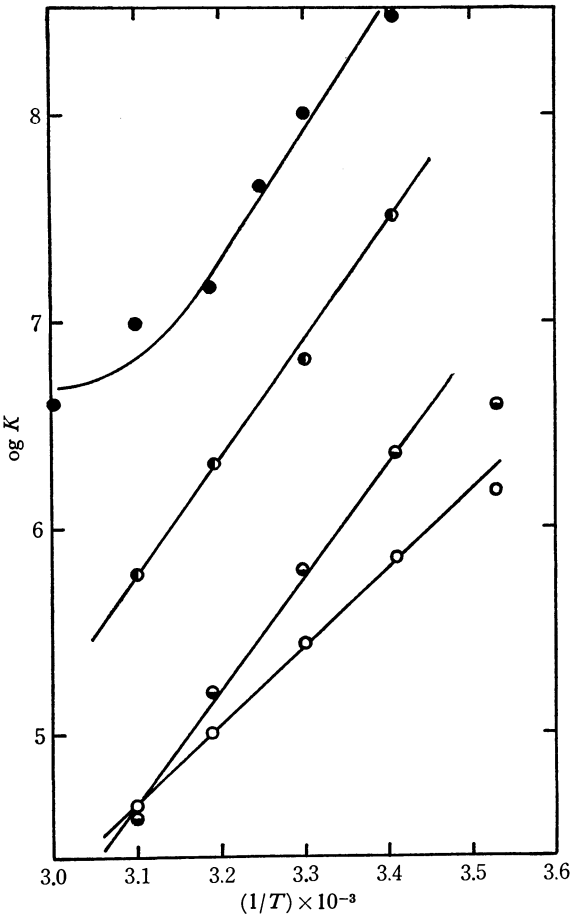

Fig. 7. Stabilities of oxygenated cobalt complexes.
○: $[Co(Orn)_2]_2O_2$; ◒: $[Co(Hid)_2]_2O_2$;
◐: $[Co(DAB)_2]_2O_2$; ●: $[Co(DAP)_2]_2O_2$;
pH=8.70 (pH=10.0 for $[Co(Orn)_2]_2O_2$)
$K=[(CoL_2)_2O_2]/[CoL_2]^2\cdot[O_2]$

Accordingly, two electrons of O_2^{2-} must be returned to the cobalt(III) ions by deoxygenations. This is confirmed by the fact that the oxygenated complexes, of which the central cobalt(III) ion gives more positive reduction potential, can be more easily deoxygenated.

Thermodynamics of Oxygenation of Cobalt Chelates. In Table 2, are presented the stability constants of the oxygenated complexes and the enthalpy changes of the oxygenation calculated from Fig. 7. Oxygenation is an exothermal process and the enthalpy change is larger in irreversible oxygenation than in the reversible one. In other words, deoxygenation, an endothermal pro-

cess, occurs when the enthalpy change of the oxygenation is small. The histidine complex is unique, because $[Co(Hid)_2]_2O_2$ is more easily deoxygenated than $[Co(Orn)_2]_2O_2$ in spite of the higher enthalpy change. This may be due to the presence of the imidazole ring, although no definite explanation can be given.

Effect of Ligand-Field on Oxygenation. Cobalt chelates with glycine, alanine, proline, and glutamic acid are neither oxygenated nor oxidized, whereas the chelates with *o*-phenanthroline (phen), ethylenediamine (en), and diethylenetriamine (dien) are oxidized immediately after oxygenation (Table 1).

From the spectrochemical series or the strength order of ligand-field,

$$\text{oxalate} < \text{glycine} < \text{en} \sim \text{dien} < \text{phen} \quad \text{(ligand)}$$

$$F^- < O < N < C \quad \text{(donor atom)},$$

it might be reasonable to consider that ligand-field of (N-O) type ligands, glycine, 1-methylhistidine, and *N*-acetylhistidine is weaker than of that (N–N) type ligands, en, dien, phen, and histamine. As observed above, ligands available to the oxygenation are (N–N) type compounds with a carboxyl or carbonyl group at the α position to an amino group. In such a situation, carboxyl or carbonyl group probably weakens the coordination power of the nitrogen atom. This anticipation is ascertained by the fact that ligand-field absorption band (20.3 kK) of cobalt(II) histidine methyl ester chelate appears at the frequency region between those of (N–N) type histamine chelate (20.5 kK) and (N–O) type glycine chelate (20.0 kK).

These results and polarographic data suggest that an important factor of oxygenation is the strength of ligand-field and at least medium strenght is favorable for reversible oxygenation.

Effect of Solvent on Deoxygenation. In aqueous solution, $[Co(DAP)_2]_2O_2$ and $[Co(DAB)_2]_2O_2$ are hardly deoxygenated, and irreversibly oxidized slowly even at room temperature and rapidly at higher temperatures (Fig. 8). However, in the solution containing more than 60 per cent ethanol, those complexes can be deoxygenated at higher temperatures. Although the experiments in other organic solvents could not be carried out, because of the low solubility of oxygenated

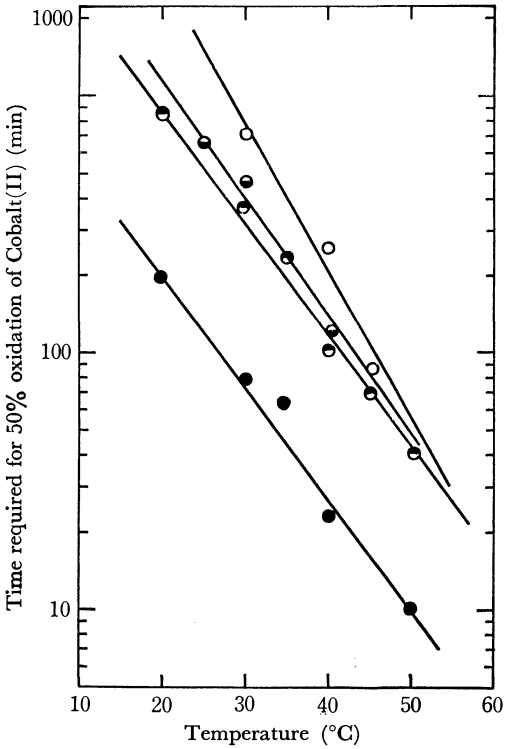

Fig. 8. Oxidation of oxygenated cobalt complexes.
○: $[Co(Hid)_2]_2O_2$ ◓: $[Co(Orn)_2]_2O_2$
◒: $[Co(DAB)_2]_2O_2$ ●: $[Co(DAP)_2]_2O_2$
pH: 8.70 (except for pH 10.00 in $[Co(Orn)_2]_2O_2$)

complexes, it can be expected that oxygenated complexes are more easily deoxygenated in nonpolar solvents than in aqueous solution.

In this paper, discussion was made mainly from the viewpoint of the ligand-field strength of the chelating agents. Changes of entropy and enthalpy might be important, because reduction potential of the central cobalt(II) ion is related to the free energy. In order to understand more closely the reversible mechanism the entropy effect must be considered.

The author wishes to express his deep gratitude to Prof. Tsunenobu Shigematsu, Dr. Masayuki Tabushi, and Dr. Masakazu Matsui for their unfailing guidance throughout the course of this work.

Electron-Transfer Reactions of Multidentate Ligand Cobalt(III) Complexes. II. The Effect of Nonbridging Ligands

Yoshimi KURIMURA and Kousaburo OHASHI*

College of General Education, Ibaraki University, Mito

**Department of Chemistry, Ibaraki University, Mito*

(Received September 24, 1970)

The specific rates for the Fe^{2+} reductions of *cis*-$Co(en)_2ACl^{2+}$ (A=methyl-, ethyl-, propyl-, butyl-, ethanol-, and propanolamine), $Co(dien)(en)Cl^{2+}$ and $Co(tetren)Cl^{2+}$ have been determined. The observed rates are relatively insensitive to the *cis*-ligand of the A. The rate constant for the *cis*-$Co(en)_2ACl^{2+}$ decreases with an increase in the size of the A ligand. In such cases as that of the aminoalcohol ligand, the rate is greater than that of the corresponding alkylamine ligand complex. The effect of chelation by nonbridging ligands has been discussed by comparing the relative effectiveness for Fe^{2+} reductions of CoN_5Cl^{2+} ($N_5=(NH_3)_5$, $(en)_2NH_3$, (dien)(en), and tetren) with that for Cr^{2+} reductions of some Co(III) complexes.

One of the most interesting points encountered in the inner-sphere electron-transfer reactions of Co(III) complexes may be the effect of nonbridging ligands on the specific rates of the reactions. It has been demonstrated that the reactivity patterens of Co(III) complexes in the electron-transfer reactions which proceed through bridged activated complexes may be much affected by the effects of the ligand-field strength of the *trans*-ligand (the a effect)[1,2] and by the energy required to stretch the *trans*-ligand away from the Co(III) center (the b effect).[3] Another explanation has been proposed by Fraser;[4] he explained the effect of chelate formation by nonbridging ligands on the reactivity of the Co(III) complexes with a CoN_5X^{n+} configuration, where X is OAc^-, Cl^-, and SO_4^{2-}, in terms of the solvation energy (the c effect).

It has been shown in the previous paper[5] that the effects of both (a) and (b) may be important in the Fe^{2+} reductions of *cis*-CoN_4XCl^{n+} ($N_4=(NH_3)_4$, $(en)_2$, and trien, $X=H_2O$ and Cl^-), since the free energy for bond stretching for the Co–N bond, in which N is the nitrogen atom located in the *trans*-position to the chloride ion, has a relatively large portion of free energy of activation.

The effect of *cis*-ligand on the rate has also been studied, and it has been demonstrated that the size of the nonbridging *cis*-ligand of B is not the most important factor in determining the reactivity of *cis*-$Co(en)_2BCl^{2+}$.[6,7]

The purposes of this study are to investigate the effect of the nonbridging ligand in the Co(III) complexes and to obtain some detailed information about the effect of the *cis*-ligand in the Fe^{2+} reductions of *cis*-$Co(en)_2ACl^{2+}$ complexes.

Experimental

Materials. *cis*-$[Co(en)_2ACl]Cl_2$,[8,9] $[Co(tetren)Cl]Cl_2$[10] (tetren=tetraethylenepentamine), and $[Co(dien)(en)Cl]Cl_2$[10] (dien=diethlenetrianime and en=ethylenediamine) were prepared by the procedures described in the references cited. The identities of these complexes were confirmed analytically and spectrophotometrically. The preparation of the iron(II) perchlorate solution and the determinations of concentrations of iron(II), the perchlorate anion, and the hydrogen ion were carried out using procedures previously reported.[5] All the other chemicals were of a reagent grade and were used without further purification. The concentrations of perchlorate and hydrogen ions in the iron(II) solution were adjusted by the addition of sodium perchlorate and perchloric acid.

Kinetic Measurements. The general procedure was to make up the reaction mixture in a Erlenmayer flask, and then to transfer the mixture to a spectrophotometer cell, which had been placed in a thermostated cell compartment of a Hitachi Model 124 spectrophotometer, using a injection syringe. The reactions were followed by observing the decrease in the absorbance of the Co(III) complexes at the wavelength in the vicinity of the first absorption maximum. The wavelengths used were 535 nm, 525 nm, and 480 nm in the cases of *cis*-$Co(en)_2ACl^{2+}$, $Co(dien)(en)Cl^{2+}$, and $Co(tetren)Cl^{2+}$ respectively. All the measurements were carried out under pseudo-first-order conditions, in which there was much more iron(II) than Co(III) complexes. The second-order rate constant for the iron(II) reduction of the Co(III) complex defined by $-d[Co(III)]/dt=k[Co(III)][Fe(II)]$ was calculated from the concentration of iron(II) and the slope of the $\log(A_t-A_\infty)$ *vs.* time plot, which is equal to $-k[Fe^{2+}]/2.303$, where A_t is the absorbance at time t; A_∞, the absorbance after all the Co(III) complex has been reduced to Co(II), and k, the rate constant. The value of A_∞ was calculated by the $A_\infty=\varepsilon[Co(II)]$ equation, where [Co(II)] is equal to the initial concentration of the Co(III) complex and where ε is the molar extinction coefficient of the aquo-cobalt(II) ion.

Results

Reductions of cis-*Co(en)$_2$ACl^{2+}.* In all cases, the $\log(A_t-A_\infty)$ *vs.* t plots were substantially linear for at

least 2 half-lives. Summeries of the kinetic measurements and activation parameters are presented in Tables 1 and 2 respectively.

Reductions of Co(dien)(en)Cl^{2+} and Co(tetren)Cl^{2+}. The second-order rate constant for the Fe^{2+} reduction of Co(dien)(en)Cl^{2+} was obtained from the slope of the $\log(A_t-A_\infty)$ plot (see Fig. 1) and the concentration of the Fe^{2+}. The $\log(A_t-A_\infty)$ plots were linear up to 1000 min in all cases, so the effect of aquations of the Co(III) complexes could be neglected. The reported rate constant for the aquation of Co(dien)(en)Cl^{2+} is 5.2×10^{-7} sec^{-1} at 35°C and pH=1.[8] Though the rate of the disappearence of the Co(dien)(en)Cl^{2+} was followed up to 1000 min, the value of A_t-A_∞ was relatively small since the reduction rate was very slow; therefore, the rate constants obtained were of poor quality. The second-order rate constants for the Fe^{2+} reduction of the Co(dien)(en)Cl^{2+} are presented in Table 3. Our attempt to determine the rate constant for the Fe^{2+} reduction of Co(tetren)Cl^{2+} by the above method failed because of the extremely slow reaction rate. The absorbance of a reaction mixture containing 0.46 M of iron(II) and 5.0×10^{-3} M of the complex at 580 nm under the conditions of $\sum[ClO_4^-]$

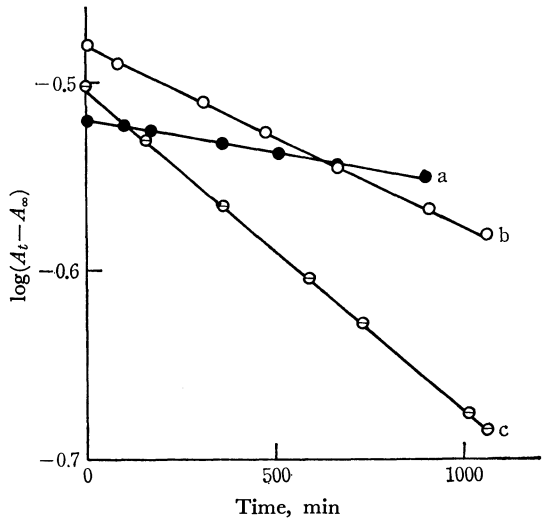

Fig. 1. Plots of $\log(A_t-A_\infty)$ *vs.* time for Fe^{2+} reduction of $Co(dien)(en)Cl^{2+}$.
a: $[Co(III)]=4.51\times10^{-3}$M, 25.0°C
b: $[Co(III)]=4.61\times10^{-3}$M, 33.0°C
c: $[Co(III)]=4.76\times10^{-3}$M, 40.0°C
$[Fe^{2+}]=0.37$M, $\sum[ClO_4^-]=1.0$M, $[H^+]=0.10$M

$=1.0$ M and $[H^+]=0.10$ M hardly decreased for 40 hr after the initiation of the reaction at 25°C. Therefore, the rate constant for the Fe^{2+} reduction of the Co(tetren)-Cl^{2+} was estimated not to exceed $10^{-8}M^{-1}sec^{-1}$ at 45°C.

Discussion

Effect of the Nonbridging cis*-Ligand.* It may be reasonable to assume that all the reactions now beeing studied proceed *via* a chloride-bridged activated complex[3,5]. In such reactions of Co(III) complexes, it has been suggested that the effect of the nonbridging *cis*-ligand on the rate is of minor importance.[6] This trend also seems to be valid for the reactions of *cis*-$Co(en)_2ACl^{2+}$ with Fe^{2+} (Table 1). However, detailed information about the effect of the *cis*-ligand of the A is given by the results summarized in Table 1. The specific rate of the *cis*-$Co(en)_2NH_3Cl^{2+}$ is smaller than that of the alkylamine complexes under investigation. In such cases as the alkylamine ligands, the value of the ligand field may be slightly lowered in comparison to the ligand field for NH_3.[11,12] This may account for smaller effectiveness of the *cis*-$Co(en)_2NH_3Cl^{2+}$ than that of the *cis*-$Co(en)_2NH_2CH_3Cl^{2+}$. In the case of the alkylamine ligand, the reactivity successively decreases with an increase in the size of the amine ligand from methylamine to butylamine. Similar behavior was also observed in the case of the amino-alcohol ligand. A distinctive correlation between pK_a and the specific rate could not be found in the reactions of *cis*-$Co(en)_2ACl^{2+}$ with Fe^{2+}. A decrease in the rate with an increase in the size of the A may be due to a decrease in the stabilization of the activated state as the size of the A increases. The aminoalcohol complex is much more effective than the corresponding alkylamine complex. For example, the rate constant for the ethanolamine complex is 1.7 times that for the ethylamine complex. This suggests that the introduction of a hydroxyl group into the nonbridging *cis*-ligand facilitates the reaction rate. The presence of a hydroxyl group in the nonbridging ligand may stabilize the activated complex due to an increase in the solvation energy relative to that of the activated complex formed by the corresponding alkylamine ligand complex and Fe^{2+}.

$Co(tetren)Cl^{2+}$	$<10^{-8}$ [b]	this work

a) 25.5°C. b) 25°C.

Effect of Chelation by Nonbridging Ligands. The relative effectiveness for Fe^{2+} reductions of the CoN_5-Cl^{2+} is appreciably decreased with an increase in the number of chelate rings in the Co(III) complex, as is shown in Table 4. The decreasing order of the effectiveness is $Co(NH_3)_5Cl^{2+}>Co(en)_2NH_3Cl^{2+}>Co$-$(dien)(en)Cl^{2+}>Co(tetren)Cl^{2+}$. Similar behavior was also observed in the Fe^{2+} reductions of *cis*-CoN_4OH_2-Cl^{2+}.[5] The effect of the *trans*-ligand on the rate of the electron-transfer reactions which proceed *via* the bridged activated complexes may be classified into: a) the ligand-field strength of the *trans*-ligand[1,2] and b) the energy required to stretch the *trans*-ligand away from the Co(III) center.[3] The relative reduction rate would be smaller if the *trans*-ligand has a stronger ligand field and/or if more energy is required to stretch the metal-ligand bond along the z axis. The relative effectiveness for Cr^{2+} reductions of CoN_5X^{n+} is decreased with an increase in the number of the chelate ring when $X=SO_4^{2-}$; however, the effectiveness is almost the same when $X=OAc^-$ and perhaps also when $X=Cl^-$.[4] The solvation effect was introduced by Fraser[4] to explain such results.

If we consider that the effects of (a) and (b) mentioned above are major factors in determining the rate of the electron-transfer reactions of the Co(III) complexes, the relative effectiveness for Cr^{2+} reductions of the CoN_5X^{n+}, whenever $X=OAc^-$, Cl^-, or SO_4^{2-}, would

11) M. Paris and N. F. Feiner, *Inorg. Nucl. Chem. Lett.*, **3**, 337 (1967).
12) S. C. Chan and K. Y. Hui, *Aust. J. Chem.*, **20**, 2529 (1967).

be changed by replacing the nonbridging ligand by an other ligand, for example, by replacing NH_3 by en or en by tetren, since the ligand-field strength may be increased in the order of NH_3<en<tetren and the energy needed for the removal of these ligand from the Co(III) center may be in the same order. On the other hand, when the solvation effect is considered to be only the predominant factor in determining the rate, the relative effectiveness for the Fe^{2+} reductions of the $Co(NH_3)_5Cl^{2+}$, $Co(en)_2NH_3Cl^{2+}$, Co(dien)(en)Cl^{2+}, and Co(tetren)Cl^{2+} would be almost the same as in the cases of Cr^{2+} reductions of the CoN_5OAc^{2+}, because the over-all charge on the Co(III) and Co(II) complexes and on the Fe(II) and Fe(III) complexes are identical, since the $FeCl^{2+}$ is the only Fe(III) species produced in the reaction:

$$CoN_5Cl^{2+} + Fe^{2+} \longrightarrow Co^{2+} + 5N + FeCl^{2+}$$

though it would dissociate into Fe^{3+} and Cl^- under the experimental conditions.[13]

Therefore, we assume that the free energies for the bond stretching of the Co–N bonds (ΔF_s) are very little in the case of CoN_5X^{n+}–Cr^{2+} reactions and large for CoN_5X^{n+}–Fe^{2+} reactions. It seems reasonably to say that the specific rates of the former reactions are hardly affected by chelate formation by nonbridging ligands if the over-all charge described above is not changed. However, the specific rates of the latter reactions are appreciably affected by the chelate formation of the nonbridging ligands, since ΔF_s may be mainly affected by the nature of the *trans*-ligand in this case. Such an assumption was reasonably accepted in the Fe^{2+} reductions of *cis*-CoN_4XCl^{n+} (N=NH_3, 0.5 en, and 0.25 trien and X=H_2O and Cl^-) in the previous work.[5] The results obtained here account for the fact that one of the most important factors in determining the rates of the electron-transfer reactions of the Co(III) complexes is the free energy for bond stretching of the Co–N bond in the Fe^{2+} reductions of *cis*-CoN_4XCl^{n+} and CoN_5Cl^{2+}. The major factors which affect the effectiveness may be: the effect of the solvation in the Cr^{2+} reductions of $CoN_5SO_4^+$, the ligand-field strength of the *trans*-ligand, and the energy required to stretch the Co–N bond in the Fe^{2+} reductions of the CoN_5Cl^{2+}, and the effect of the solvation, the ligand-field strength of the *trans*-ligand, and the stretching energy in the Fe^{2+} reductions of the *cis*-$CoN_4Cl_2^+$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1800—1807 (1971)

The Photonuclear Reactions Leading to ^{24}Na and ^{28}Mg

Tatsuya SAITO*

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received November 24, 1970)

The photonuclear reaction yields of ^{24}Na and ^{28}Mg in magnesium, aluminum, silicon, phosphorus, and sulfur were obtained at energies between 20 MeV and 250 MeV by the induced radioactivity method. The ^{12}C(γ,n)^{11}C yield was used as a standard for the beam monitor. The excitation curves of the ^{27}Al→^{24}Na, ^{28}Si→^{24}Na, ^{30}Si→^{28}Mg, ^{31}P→^{24}Na, ^{31}P→^{28}Mg, ^{32}S→^{24}Na, and ^{32}S→^{28}Mg reactions were obtained from the yields by the photon-difference method. Each of these excitation functions indicates a peak in the 50—70 MeV energy range, except in the case of the sulfur target, in which the peak is due to the contribution from the compound-nucleus process. The interaction of photons with nuclei at photon energies exceeding the peak energy region probably does not lead to the formation of the compound nucleus. In the energy range from 70 MeV up to 150 MeV, the cross sections are due to the contribution from the quasi-deuteron process. At energies above 150 MeV and up to 250 MeV, the quasi-deuteron and pion production processes compete. In the high-energy photonuclear reaction mechanisms, the quasi-deuteron and pion production processes must be considered at the initial cascade process, but the evaporation process may be considered after the cascade process.

Photonuclear reactions have been studied, and detailed information has been obtained in the low-energy giant-resonance region.[1-3] Above the giant-resonance region, however, our information about the photonuclear cross sections and the reaction mechanisms is very scarce.

Many workers have investigated high-energy reactions induced by high-energy-charged particles, and the details of these mechanisms are by now well known.[4] The mechanism of high-energy nuclear reactions, the cascade evaporation process, is currently regarded as providing the proper description for reactions initiated by particles with incident energies large in comparison with the binding energies of the nucleons within the target nucleus.[5,6] A similar reaction induced by high

energy bremsstrahlung with a maximum energy greater than 100 MeV was expected. It is an interesting problem to study the mechanisms by which the complex nucleus absorbs high-energy photons. In this fields, the following processes have been proposed to explain the photonuclear cross section data: the quasi-deuteron and the pion production processes. In order to explain the high-energy photonuclear reactions, several experiments have previously been reported on the yields and cross sections as determined by the activation method.[7-9] Debs *et al.*[7,8] irradiated several elements of medium weight by 320 MeV bremsstrahlung, thus obtaining the relative yields. By their data, the mechanism of the high-energy photonuclear reaction was explained by a model in which, after a direct process, a few particles were emitted from a struck nucleus by evaporation. Di Napoli *et al.*[10,11] irradiated carbon and iodine at energies between 300 MeV and 1000 MeV, and showed the (γ, n) excitation curves. In this energy region, these reactions result from the photopion process. Van Hise *et al.*[12] irradiated ^{32}S, ^{40}Ca, and ^{66}Zn at energies up to 300 MeV. The reactions in these experiments generally receive important contributions from both the quasi-deuteron and pion emission processes above the pion threshold. The reactions leading to ^{24}Na have already been reported. The excitation curves for the ^{27}Al→^{24}Na and ^{31}P→^{24}Na reactions up to 260 MeV have been reported by Gorbunov *et al.*[13] In addition, the yields of ^{24}Na from the ^{27}Al→^{24}Na, ^{28}Si→^{24}Na, ^{31}P→^{24}Na, ^{32}S→^{24}Na, ^{39}K→^{24}Na, and ^{40}Ca→^{24}Na reactions have been reported at energies from 100 MeV to 1200 MeV by Noga *et al.*[14]

The purpose of the present experiments is to obtain information about the character of the interaction of photons with nuclei in the energy range from 20 MeV to 250 MeV. Especially, the work reported here will improve our understanding of the high-energy photonuclear processes that occur at energies above the low-energy giant-resonance region.

Experimental

Targets and Irradiations. The target elements used in this experiment were magnesium, aluminum, silicon, phosphorus, sulfur, carbon, and gold. All of them were in their elemental form and well sufficiently pure. The impurities in these target substances were found to be negligible in amount. The irradiation sample had a weight of 100—1000 mg and was contained either in a quartz tube or in a Pyrex tube. The experimental methods were described in detail in previous papers.[15-17] The sources of electrons were obtained with the linear electron accelerator of Tohoku University from 30 MeV to 250 MeV and with that of the Japan Atomic Energy Research Institute at 20 MeV. The electron beam in the energy region from 30 MeV to 75 MeV, accelerated by the "High Current" accelerating section of the machine, produced bremsstrahlung in a 3-mm-thick platinum converter.

The sample tubes were held in alignment with the bremsstrahlung beam and were placed in a water-cooled stainless holder.

In the energy region from 100 MeV to 250 MeV, the electron beam accelerated by the "High Energy" accelerating section produced bremsstrahlung in a 0.2-mm-thick tantalum converter. All of these electrons were not converted to bremsstrahlung in a converter. The rest of the electrons were swept away with a sweeping magnet. The sample tubes were held in alignment with the bremsstrahlung beam behind the sweeping magnet and were placed in an aluminum holder.

The electron beam at 20 MeV was converted with a 2-mm-thick platinum converter. The irradiation time was 20 min—2 hr.

Radioactivity Measurement. After irradiation, the target samples were each transferred into "cold" aluminum foils. The gamma-ray spectra were measured at a suitable counting geometry by using a 36-cm^3 Ge(Li) detector coupled to a TMC 1024-channel pulse-height analyzer and a 3″ϕ×3″ NaI(Tl) crystal coupled to a Toshiba 800-channel pulse-height analyzer.

Nuclide identification for ^{24}Na, ^{28}Mg, ^{11}C, and ^{196}Au was made from the knowledge of the target nuclides,[18] the gamma-ray spectra, and the decay data. In these experiments, chemical separation was used if necessary, and gamma-ray spectrometric measurements were performed after having

been cooled for a time.

Typical gamma ray spectra are shown in Figs. 1 and 2.

Yield Calculation. The disintegration rate was determined by absolute calculations, *i.e.*, the chemical yield, the counting efficiencies, the branching ratio, and the internal conversion ratio. Each of these target samples was wrapped with a thin sheet of gold which was used for the determination of the relative intensity of the bremsstrahlung dose. The intensity integrated over the time of irradiation was standardized by means of the $^{12}C(\gamma,n)^{11}C$ reaction, whose absolute yield had been measured as a function of the peak bremsstrahlung energy up to 260 MeV by Barber *et al.*[19]

The yield was expressed by the following equation:[15]

$$Y(E) = \frac{D_0}{IM(1-e^{-\lambda t})}$$

where D_0 is the disintegration rate at the end of irradiation, I is the radiation dose rate, M is the amount of target nucleus expressed in atoms, and λ is the decay constant. The target elements used were not enriched ones, and it was assumed for the sake of simplicity that each of these elements consisted entirely of its most abundant isotope.

Results

The yield curves for the $^{25}Mg(\gamma, p)^{24}Na$, $^{27}Al\rightarrow{}^{24}Na$, $^{28}Si\rightarrow{}^{24}Na$, $^{31}P\rightarrow{}^{24}Na$, and $^{32}S\rightarrow{}^{24}Na$ reactions and the $^{12}C(\gamma, n)^{11}C$ curve for the monitor reaction are shown in Figs. 3 and 4, while those for the $^{30}Si(\gamma, 2p)^{28}Mg$, $^{31}P(\gamma, 3p)^{28}Mg$, and $^{32}S(\gamma, 4p)^{28}Mg$ reactions are shown in Fig. 5. The solid points in these figures represent the results obtained. The cross section curves for the $^{27}Al\rightarrow{}^{24}Na$, $^{28}Si\rightarrow{}^{24}Na$, $^{31}P\rightarrow{}^{24}Na$, $^{32}S\rightarrow{}^{24}Na$, $^{30}Si(\gamma, 2p)^{28}Mg$, $^{31}P(\gamma, 3p)^{28}Mg$, and $^{32}S(\gamma, 4p)^{28}Mg$ reactions as calculated from the photon-difference method[20] are shown in Figs. 6—12 respectively.

Discussion

General Considerations. The wavelength of the bombarding particle energies decreases with an increase in the energy, and at energies around approximately 100 MeV it becomes smaller than the mean distance between nucleons in the nucleus, while the time of interaction of the particles with the nucleus is shorter than the characteristic nuclear time.

The characteristics of high-energy particles enable us to obtain information on nuclear characteristics not accessible to other methods. The individual production rates of a photonuclear reaction can be obtained by the measurement of the cross sections.

Investigations of the evidence of the emission of particles with $Z\geqq 2$, carried out by radiochemical methods, are of extreme importance. The particles emitted have specific characteristics. Most of the

previous experiments studied high energy photonuclear reactions and involved observations of the emitted nucleons rather than observations of the residual nuclei.

However, the interpretation of a whole series of experimental data obtained in high-energy photonuclear reactions demands an understanding of the structure of the nucleus, especially with regard to the association

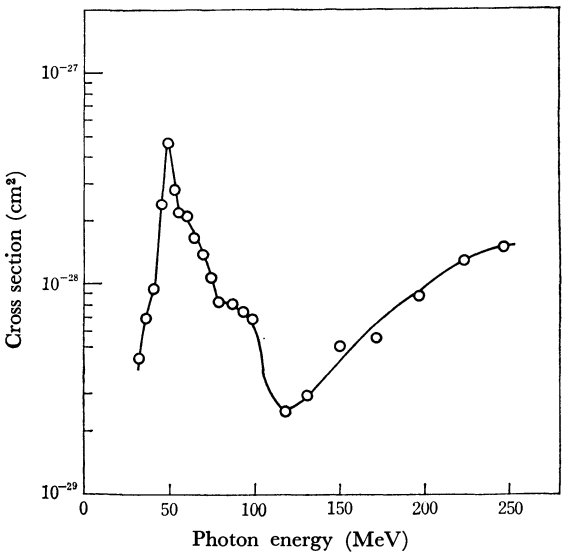

Fig. 10. The excitation function for the reaction $^{30}Si(\gamma,2p)^{28}Mg$.

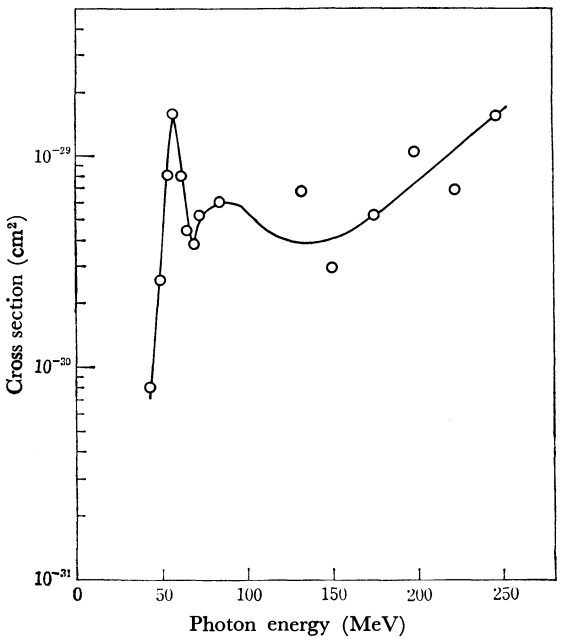

Fig. 11. The excitation function for the reaction $^{31}P(\gamma,3p)^{28}Mg$.

of nucleons within it. The study by the activation method gives important information on the activation yields for the complex nucleus by high-energy photons.

Reaction Path. For convenience in the consideration of the reaction path leading to ^{24}Na and ^{28}Mg, Tables 1 and 2 list the reaction types and the mass threshold values calculated on the basis of the mass differences.[21]

Aluminum and phosphorus are both single isotopic elements, while magnesium, silicon, and sulfur are not.

In the case of the magnesium target, the $Mg \rightarrow {}^{24}Na$ reaction was attributed to the $^{25}Mg(\gamma, p)^{24}Na$ reaction.

21) Nuclidic mass values used were those listed in G. Friedlander, J. W. Kennedy, and J. M. Miller, "Nuclear and Radiochemistry," 2nd ed., J. Wiley and Sons, New York, London (1964), p. 533.

The ^{27}Al→^{24}Na reaction can result from three different processes, (γ,^{3}He), (γ, dp) and (γ, 2pn), whose thresholds are 23.71, 29.20, and 31.41 MeV respectively. Since the registration of the corresponding activity from the aluminum target began at energies around the thresholds of the (γ, dp) and (γ, 2pn) reactions, it is obvious that, of the three, the latter two processes play the most substantial parts. The ^{27}Al→^{24}Na reaction was attributed to the ^{27}Al(γ, 2pn)^{24}Na reaction by Meyer *et al.*[22]

		(γ, 4p4n)	77.04

Sometimes neutron backgrounds are serious enough to cause the production of ^{24}Na by the ^{27}Al(n, α)^{24}Na reaction. Since ^{24}Na activities due to the ^{27}Al(n, α)-^{24}Na reaction irradiated by 20 MeV bremsstrahlung could scarcely be measured, the (n, α) reaction is negligibly small.

The yield of the Si→^{24}Na reaction is the sum of the yields of the ^{28}Si→^{24}Na, ^{29}Si→^{24}Na, and ^{30}Si→^{24}Na reactions. With the excitation energies below 45 MeV, the ^{29}Si(γ, αp)^{24}Na and ^{30}Si(γ, αpn)^{24}Na reactions may play the most substantial part, but above 45 MeV, the yields of the ^{29}Si→^{24}Na and ^{30}Si→^{24}Na reactions are negligibly small, because the isotopic abundances of ^{29}Si and ^{30}Si are as low as 4.70% and 3.09% respectively. Therefore, the reaction product, ^{24}Na, from the ^{28}Si→^{24}Na reaction is obtained *via* the (γ, 3pn) and (γ, d2p) processes. The ^{24}Na yield from ^{31}P is the result of a large number of reactions, of which the energetically most convenient reaction (γ, ^{7}Be) has a threshold of 31.78 MeV, while the energetically least convenient reaction (γ, 4p7n) has a threshold of 69.36 MeV. The experimental threshold of the ^{24}Na yield from ^{31}P is in the neighborhood of 45 MeV. This indicates that, in those reaction processes involving the emission of complex particles, *i.e.*, α-particles, the reaction type (γ, α2pn) plays a substantial part.

The yield of the S→^{24}Na reaction is the sum of the yields of the ^{32}S→^{24}Na, ^{33}S→^{24}Na, ^{34}S→^{24}Na, and ^{36}S→^{24}Na reactions. Below 60 MeV, the ^{34}S(γ, 2αpn)^{24}Na and ^{32}S(γ, α3pn)^{24}Na reactions play the most substantial parts, but above 60 MeV, the ^{32}S(γ, 5p3n)^{24}Na and ^{32}S(γ, α3pn)^{24}Na reactions play the most substantial parts. In order to understand the results of these experiments, the existence of α-particle grouping within the nuclei must be considered.

The reaction paths leading to ^{28}Mg are the ^{30}Si(γ, 2p)^{28}Mg, ^{31}P(γ, 3p)^{28}Mg, and ^{32}S(γ, 4p)^{28}Mg reactions, if the ^{33}S→^{28}Mg, ^{34}S→^{28}Mg, and ^{36}S→^{28}Mg reactions are neglected.

22) R. A. Meyer, W. B. Walters, and J. P. Hummel, *Nucl. Phy.*, **A122**, 606 (1960).

The production yields for ^{24}Na and ^{28}Mg are actually sums of the beta decay chains for their respective masses. The contributions from the products of $Z \neq 11$ to the sodium activites and those of $Z \neq 12$ to the magnesium activities may be disregarded because the ratio of the cross sections for the production of ^{24}Ne and ^{24}Na is negligibly small for proton-induced reactions.[23]

Photonuclear Reaction Yields. In Figs. 3—5 the observed yields data for the reactions studied are plotted as 5 MeV bin width in the energy range between 30 MeV and 65 MeV. In the energy range from 100 MeV to 250 MeV, they were plotted as 50 MeV bin width. In the yield curve, the yield data at 75 MeV bremsstrahlung are added, and they are modified to an adequate smooth curve. The errors in these data are less than 20%. The systematic errors arise from absolute counting factors, beam attenuation in targets, the beam monitor, and the target position monitor. The latter two factors are the main sources of error.

The yield ratios of $Y(^{28}\mathrm{Mg})$ to $Y(^{24}\mathrm{Na})$ were computed for silicon, phosphorus, and sulfur targets, they are shown in Fig. 13.

It should be noted that the yield-ratio curve of silicon does not represent the ratio in a true sense, because not all target nuclides leading to ^{24}Na and ^{28}Mg are the same. In the case of silicon, the rapid

23) R. G. Korteling and A. A. Caretto, Jr., *J. Inorg. Nucl. Chem.*, **29**, 2863 (1967).

decrease up to 45 MeV of the yield ratio curve is due to the differences in the threshold energies, *i.e.* 42.99 MeV and 40.77 MeV leading to ^{24}Na and 23.99 MeV leading to ^{28}Mg. In the energy region between 45 MeV and 250 MeV, the gradual decrease in the yield ratio is independent of the difference in the threshold energy. In the peak energy region, it may be considered that the contribution of the compound nucleus process decreases, while that of the quasi-deuteron process increases.

Photonuclear Reaction Cross Sections. In Figs. 6—8, 10, and 11, the low energy peak is shown for each figure. In order to explain this, the compound nucleus model, which is in good agreement with relative low energy experimental data, is considered. In forming a compound nucleus, an incident particle is absorbed by the nucleus, and its energy is distributed among the nucleons in a nucleus. The principal and initial assumption of the theory of the compound nucleus is satisfied only if the range of the particle in the nuclear material is considerably smaller than the dimensions of the nucleus and if the excitation energy of the compound nucleus associated with one particle is considerably smaller than the energy required to separate this particle from the nucleus. For incident particle energies greater than about 50 MeV, neither of these conditions is satisfied. Nevertheless, in the energy region up to 100 MeV, the compound nucleus model is still reasonable. It is, then, not unreasonable to consider the experimental data at high energies from the point of view of this model.

At photon energies exceeding about 60—80 MeV, the energy and momentum of the photon are also absorbed by a group of nucleons which leaves the nucleus, transferring to it only a part of the energy. One such mechanism, proposed by Levinger,[24] is the quasi-deuteron mechanism. In such an interaction, it may turn out that the probability of transferring a given portion of energy to the nucleus varies little with the energy of the incident particle and that, consequently, the cross section for the production of a given isotope will also vary little.

The reaction types leading to ^{28}Mg investigated here, *i.e.*, $(\gamma, 2\mathrm{p})$, $(\gamma, 3\mathrm{p})$, and $(\gamma, 4\mathrm{p})$, do not include the emission of neutrons. On the contrary, the reaction types leading to ^{24}Na, *i.e.*, $(\gamma, 3\mathrm{pn})$, $(\gamma, 4\mathrm{p3n})$, $(\gamma, \mathrm{d2pn})$, and others, do involve the emission of neutron. After quasi-deuteron absorption, a neutron and a proton share the energy of the incoming photon and either escape from the nucleus or collide with other nucleons. In the light nuclei region, it may be very rare that a neutron or a proton collides with other nucleus. For this reason, the reaction cross sections leading to ^{28}Mg may have small values if the cross sections depend on the quasi-deuteron process. In the energy region between 70 MeV and 150 MeV, each of the cross-section data leading to ^{28}Mg is shown to have a relatively lower value compared with the peak cross section data, but that leading to ^{24}Na has almost the same value as the peak cross section data. In the energy region between 100 MeV and 150 MeV, it is difficult to explain the

24) J. S. Levinger, *Phys. Rev.*, **84**, 43 (1951).

cross section data by the compound nucleus model, but the quasi-deutron model is suitable to explain the data.

At energies above 150 MeV, which is the pion threshold energy, the quasi-deuteron and pion production processes compete. In the case of contributions to the reaction cross section from processes associated with pion production, two types of mechanisms must be considered. One involves those events in which pions are produced and emitted from the nucleus. The other involves events in which pions are produced and then re-absorption process within the nucleus. For the light nuclei, the pion re-absorption process is generally less than 10% of that for pion emission.[22] In the energy region between 150 MeV and 250 MeV, the photo-pion reaction is the sum of the productions of both charged and neutral pions. For example, to the ^{27}Al→^{24}Na reaction is now added the following photonuclear reactions. ^{27}Al(γ, $\pi^0$2pn)^{24}Na, ^{27}Al(γ, π^+p2n)-^{24}Na, ^{27}Al(γ, π^-3p)^{24}Na, *etc.* Therefore, many reaction paths must be considered for the photon absorption processes in complex nuclei, if the pion productions take part in the reaction observed. Among the high-energy photonuclear reaction mechanisms, the quasi-deuteron and pion production processes must be considered at an initial cascade process, but the evaporation process may be considered after the cascade process. According to the cascade theory, the incident photon does not transfer all its energy to the nucleus, as is assumed in the theory of the compound nucleus, but interacts with individual nuclear particles, giving them a part of its energy. Some of the nucleons which have taken part in the cascade process fly out of the nucleus, forming the experimentally observed component of high-energy nucleons, while the rest are absorbed by the nucleus, transferring their energy to the latter. The excited nucleus thus formed after the cascade process passes back to the ground state by the evaporation process. The analytical calculation of the cascade process is, even in principle, very laborious, moreover, at the present time, it is quite impossible, since a number of the cascade characteristics have no analytical expression. Hence, in order to calculate the cascade process, the Monte Carlo statistical method may be carried out with the use of a high-speed electronic computer; such calculations will be reported elsewhere.

Recoil Study. It is very difficult to obtain information about photonuclear reaction mechanisms by velocity measurements of the protons and neutrons ejected in these complex reactions. In order to gain more information, measurements of the angular distributions of emitted particles are needed. Radiochemical techniques were suitable for observations of the recoil properties of the heavy residual nuclei. The target foils used in this experiments were 3.12 mg/cm^2 magnesium and 4.57 mg/cm^2 aluminum. These were, in all cases, considerably thicker than the fragment ranges and were surrounded by recoil catchers consisting of 3.14 mg/cm^2 Mylar foils. The fraction of the ^{24}Na atoms that recoiled from the target into the Mylar catchers was measured by using a 3″ϕ×3″ NaI (Tl) crystal coupled with a 800-channel pulse-height analyzer. A number of thick-target recoil experiments were performed in the energy range from 30 MeV to 250 MeV. The results of the recoil studies are shown in Figs. 14 and 15. The listed quantities, FW and BW, are the fragments of the ^{24}Na atoms recoiling into the forward and backward fractions respectively. All of these data are shown in the laboratory system. It is assumed that the *FW/(FW+BW)* value shows the angular distribution of the ^{24}Na fragment. The ^{25}Mg (γ, p)^{24}Na reaction is due to the contribution from the compound nucleus process in the low-energy region.[25] Gorbunov *et al.*[13] assumed that, at energies above 60—80 MeV, the interaction of photons with nuclei proceeds mainly *via* photon absorption by a group to intranuclear nucleons. However, as may be seen in Figs. 14 and 15, in the energy range from 30 MeV to 60 MeV, the *FW/(FW+BW)* value of the ^{25}Mg(γ, p)-^{24}Na reaction is the same as that of the ^{27}Al→^{24}Na reaction. Therefore, it may be concluded that the low energy peak of the ^{27}Al→^{24}Na, ^{28}Si→^{24}Na, ^{30}Si→^{28}Mg, ^{31}P→^{24}Na, and ^{31}P→^{28}Mg reactions are due to the contribution from the compound nucleus process.

Isotopic Fractionation in a Thermal Ion Source

Hitoshi KANNO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received November 27, 1970)

Isotopic fractionation behavior in a thermal ion source was theroretically studied. An equation relating to the observed isotope ratio with the evaporated fraction of the sample was derived under conditions where two kinds of chemical species, atomic (atomic ions and neutral atoms) and molecular (molecular ions and molecules) species, simultaneously evaporate from the filament. It was demonstrated that integrations of all ion currents for two isotopes do not necessarily give a true ratio of the two isotopes in the sample when two evaporating chemical species are ionized at different rates. Isotopic fractionation curves for halides and elements of lithium, potassium, and rubidium are presented.

Fractionation effects in a thermal ion source are a serious problem in mass spectrometry, especially in isotope ratio measurements. In order to obtain the precise isotope ratios of samples, attempts have been made by many investigators[1,2] to estimate the degree of fractionation and to find appropriate correction methods.

The quantitative analyses of Eberhardt *et al.*[3] showed that evaporation of sample in a single filament ion source follows the Rayleigh distillation formula[4] and that atomic species (atomic ions and neutral atoms) are the only species evaporating from the filament. Their treatment, however, is insufficient in that the results can not be applied to a multiple filament ion source in which not only atomic but also molecular species (molecular ions, neutral molecules and their fragments) evaporate from the filament.

The isotopic fractionation factor in the evaporation of molecular species differs greatly from that of atomic species so that the net fractionation depends to a great extent on the molar ratio of atomic species to molecular species in the vapor leaving the filament. By taking this into account quantitative analysis seems to be helpful for clearing the extent of fractionation and improving mass spectrometric techniques and correction methods for precise isotope ratio measurements.

In this paper, variation of observed isotope ratio with percentage of the evaporated sample was theoretically calculated under conditions where both atomic and molecular species simultaneously evaporate from the filament, and it was shown that integrations of all ion currents for two isotopes do not necessarily give the true ratio of the two isotopes in the sample when two evaporating chemical species, atomic species and molecular species, are ionized at different rates.

Theoretical

When the vapor pressure of an isotopic substance is of the order of magnitude such that the chance of an evaporated atom or molecule returning to the filament is very small, the total mass of vapor escaping from the unit area of surface in unit time is given by Langmuir's equation[5]

$$\mu = p \cdot c \left(\frac{M}{2\pi RT}\right)^{1/2} \tag{1}$$

where p is vapor pressure of an evaporating isotopic substance in pure state, c, its molar concentration in a sample on the filament, M, its molecular (or atomic) weight, R, gas constant, and T, absolute temperature. Thus the number of moles N evaporating per unit area in unit time is

$$N = \mu/M = p \cdot c(2\pi MRT)^{-1/2} \tag{2}$$

For a mixture of two isotopic chemical species of masses M_1, M_2, concentrations of c_1, c_2, evaporating from a surface of filament, the numbers of moles of the two isotopes evaporating will be

$$\begin{aligned} N_1 &= p_1 \cdot c_1(2\pi M_1 RT)^{-1/2} \\ N_2 &= p_2 \cdot c_2(2\pi M_2 RT)^{-1/2} \end{aligned} \tag{3}$$

At such high temperatures as in thermal ion sources, the difference of vapor pressures between two isotopic substances will be negligibly small, so that

$$p_1 = p_2 \tag{4}$$

Hence the ratio of the molar concentrations of two isotopic species in the vaporized vapor (isotope ratio in the vapor) is given by

$$r = \frac{N_1}{N_2} = \frac{c_1}{c_2}\left(\frac{M_2}{M_1}\right)^{1/2} = \gamma \cdot R \tag{5}$$

where γ $(=(M_2/M_1)^{1/2})$ is a fractionation factor, and R $(=c_1/c_2)$ is the isotope ratio of the sample remaining on the filament. Accordingly, when some fractions of the sample on the filament are thermally decomposed into atomic species (or molecular fragments) and vaporization takes place in both atomic species A and molecules B, isotope ratios of the vapors A and B just evaporating from the filament are

$$\begin{aligned} r_a &= \alpha R \\ r_b &= \beta R \end{aligned} \tag{6}$$

where

$$\begin{aligned} \alpha &= \sqrt{\frac{MA_h}{MA_l}} \\ \beta &= \sqrt{\frac{MB_h}{MB_l}} \end{aligned} \tag{7}$$

4) Lord Rayleigh, *Phil. Mag.*, **42**, 493 (1896).
5) I. Langmuir, *Phys. Z.*, **14**, 1273 (1913).

Here MA and MB are the molecular (or atomic) weights of vapors A and B, and the subscripts h and l denote heavy and light isotopes, respectively. In the case of lithium iodide, A and B may be either $Li^{(0,+)}$ or LiI. It is also assumed that the residual sample on the filament undergoes continuous and complete mixing and that there is no isotopic fractionation between chemical species A and B.

Now we consider the course of evaporation. If the chemical species A and B simultaneously evaporate from the filament, the material balance requires

$$dA + dB = dQ \tag{8}$$

where dA and dB are the amounts (in moles) of A and B evaporating from the filament in a time interval from t to $t + dt$, and dQ is the corresponding change (in moles) of the sample on the filament.

Let us denote the mole fractions of lighter isotopic species of the vapors A and B by n_a and n_b, and of the residual sample by n_c, respectively. Then the molar quantities of the lighter isotopic species of A and B just escaping from the filament will be given by $n_a dA$ and $n_b dB$. Thus we get

$$n_a dA + n_b dB = d(n_c Q) \tag{9}$$

and

$$r_a = \frac{n_a}{1-n_a}, \quad r_b = \frac{n_b}{1-n_b}, \quad R = \frac{n_c}{1-n_c} \tag{10}$$

For the sake of simplicity we assume that molar quantity of vapor B is always k times as much as that of vapor A throughout the course of evaporation, *viz.*,

$$dB = k dA \tag{11}$$

Combining this relation with Eqs. (6), (8), (9), and (10), we obtain the following differential equation

$$\frac{1}{k+1}\left(\frac{\alpha R}{1+\alpha R}+\frac{\beta k R}{1+\beta R}\right)dQ = \frac{R dQ}{1+R}+\frac{Q dR}{(1+R)^2} \tag{12}$$

The solution is

$$\log\left(\frac{Q}{Q_0}\right) = a\log\left(\frac{R}{R_0}\right) + \log\left(\frac{R+1}{R_0+1}\right) + b\log\left(\frac{c+dR}{c+dR_0}\right) \tag{13}$$

where

$$a = (k+1)/\{(\alpha-1) + (\beta-1)k\}$$
$$b = (\alpha-\beta)^2 k/(cd)$$
$$c = (\alpha-1) + (\beta-1)k$$
$$d = (\alpha-1)\beta + \alpha(\beta-1)k$$

and Q_0 is the initial quantity and R_0 the isotope ratio (true isotope ratio) of the sample. When $\alpha=\beta$, this equation becomes

$$(\alpha-1)\log\left(\frac{Q}{Q_0}\right) = \log\left(\frac{R}{R_0}\right) + (\alpha-1)\log\left(\frac{R+1}{R_0+1}\right) \tag{14}$$

which is the well-known Rayleigh distillation formula.

If the residence time of vapor A and B in the ion source is short enough to prevent the cross mixing of the vapors at different instances, the mean isotope ratio of the vaporized species in the ion source can be expressed in terms of α, β, k, and R as follows.

$$r_m = \frac{n_a dA + n_b dB}{(1-n_a)dA + (1-n_b)dB}$$
$$= \frac{(\alpha+\beta k)R + \alpha\beta(k+1)R^2}{(k+1)+(\beta+\alpha R k)} \tag{15}$$

Furthermore, if the ionization efficiencies[6] of the chemical species A and B have the same value, the observed isotope ratio (r_{ob}) is equal to r_m, and if the ionization efficiency of vapor A is much greater than that of B, r_{ob} is approximately equal to r_a. This is summarized as follows

$$r_{ob} = r_m \quad (\text{when } I_a = I_b)$$
$$r_{ob} = r_a \quad (\text{when } I_a \gg I_b)$$
$$r_{ob} = r_b \quad (\text{when } I_a \ll I_b)$$

where I_a and I_b are the ionization efficiencies of vapors A and B, respectively.

Calculation and Discussion

Calculations have been made for lithium, potassium and rubidium when halides of these elements are adopted as the working material. The calculated observable isotope ratios (r_{ob}) for iodides of these elements are shown in Figs. 1, 2, and 3 as a function of the fraction of the sample remaining on the filament. In these calculations it is implicitly assumed that chemical forms of vapor species are either $M^{(0,+)}$ or MI, and that ionization efficiencies of both vapor species are identical (M=Li, K, and Rb, I is iodine). As shown in Figs. 1, 2, and 3, the isotope ratio to be observed significantly deviates from the true isotope ratio when the fractions of atomic species $M^{(0,+)}$ in vaporizing substances are large and the fraction evaporated is large or small.

It is of importance to know how much is evaporated when the observed isotope ratio gives the true isotope ratio of the sample.

(e) $k=\infty$
A: $K^{(0,+)}$ $\alpha=1.02532$ B: KI $\beta=1.00605$

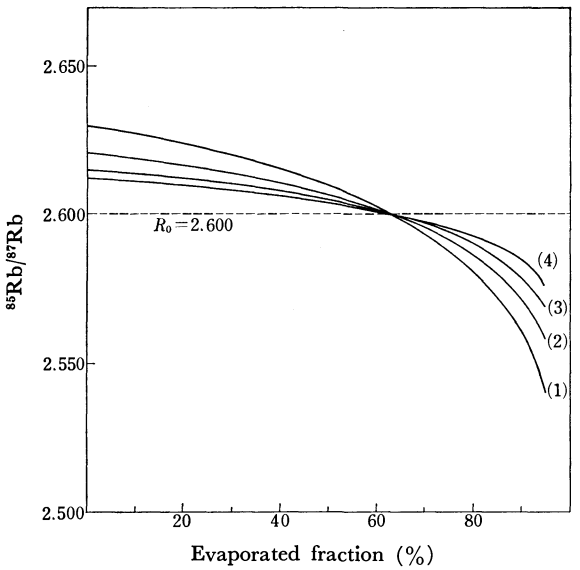

Fig. 3. Variation of $^{85}Rb/^{87}Rb$ with composition of vaporizing species.
(a) $k=0.00$ (b) $k=0.40$ (c) $k=1.00$ (d) $k=4.00$
(e) $k=\infty$
A: $Rb^{(0,+)}$ $\alpha=1.01169$ B: RbI $\beta=1.00470$

When $\alpha=\beta$, we get from Eq. (15)

$$r_{ob} = \alpha R = R_0$$

Substituting this relation into Eq. (14), we have

$$(\alpha-1)\log\left(\frac{Q}{Q_0}\right) = -\log\alpha + (\alpha-1)\log\frac{R_0+\alpha}{\alpha(R_0+1)}$$

Generally α is nearly equal to unity, *i.e.*, $\alpha=1+\varepsilon$ and $\varepsilon\ll 1$, thus

$$\frac{R_0+\alpha}{R_0+1} \approx 1, \qquad \log\alpha \approx \varepsilon$$

which leads to

$$Q = Q_0/e \approx 0.37Q_0$$

When $\alpha\neq\beta$ but $I_a=I_b$, the same result is also deduced if only α and β are nearly unity. We see that when the fraction evaporated being near 63% ($Q\approx 0.37\ Q_0$), observed isotope ratio (r_{ob}) can be regarded as the true isotope ratio (R_0) of the sample material, and that when $Q<0.37Q_0$, r_{ob} is larger than R_0 and when $Q<0.37\ Q_0$, r_{ob} is smaller than R_0. However, it should be pointed out that when $\alpha\neq\beta$ and $I_a\neq I_b$ (probably this is the usual case in a multiple filament ion source) the above relation is not realized as will be shown later.

Fractionation curves of the halides and elements of lithium, potassium and rubidium are presented in

Figs. 4, 5, and 6. It is apparent from these figures that fractionation of lithium iodide is the smallest. If most of the vaporizing species are molecules and molecular ions, isotopic fractionation of lithium can be reduced to minimum by adopting lithium iodide as the working material. On the other hand, in the cases of potassium and rubidium the deviations from the true isotope ratios are larger than those of lithium when the bromides or iodides of these elements are used for the isotope ratio measurements. This stems from the fact that the mass difference of potassium (or rubidium) isotopes is twice as much as that of lithium isotopes. Thus fractionation factor of lithium is more effectively decreased with the use of a heavy compound as a working material than potassium and rubidium. In other words, in the case of lithium the error from fractionation can be reduced to a considerable extent by only adopting a heavy compound as a sample and making lithium emit from the filament as a high mass molecule or molecular ion. The latter condition is practically effected by using a multiple filament ion source. This shows that elements having isotopes of large mass differences are difficult for overcoming the fractionation problem. For example, in measurements of lead where hydroxide, nitrate and sulfide are usually adopted as chemical forms of the sample, and of rare earth elements such as gadolinium and neodymium where nitrate and perchlorate are used, fractionation factors do not decrease so effectively as expected because the vaporizing species from the filament are considered to be either atomic species or decomposed molecular fragments such as $MO^{(0,+)}$ and M_2O_3. Thus in measurements of these elements we must make some other corrections for fractionation to obtain precise isotope ratios.[7,8]

As a matter of fact, the partial mixing of the successively vaporizing substances occurs in an ion source, and the actually observed deviations from the true isotope ratio may not be so large as expected from Eq. (14).

Eberhardt *et al.*[3] observed that different chemical forms and different filament materials yield differences in the observed isotope ratios, and stated that measured isotope ratios of rubidium increased in the order: sulphate on tungsten - sulfate on tantalum - chloride on tungsten - chloride on tantalum. Ozard and Russel[9] have observed in their lead isotope ratio measurement that the fractionation pattern of a rhenium filament is different from that of a tantalum filament. These observations may be partly explained by the fact that both the composition of vaporizing species and their ionization efficiencies are greatly influenced by the chemical form of the sample, condition of filament surface (temperature of filament, filament material), type of ion source (single or multiple filament ion source) and impurities in the sample and filament. It is well known that ionization of lead is significantly reduced by large alkali ions arising from contaminations.

In the calculations presented in Figs. 1, 2, and 3, ionization efficiencies of vapors A and B were assumed to be the same. However, in actual cases in a multiple filament ion source this is rare so that observed fractionation also varies with the change of ionization efficiencies of the vapors.

Table 1 shows fractionation data of lithium iodide with the conditions (a) $k=1.0$ and $I(\mathrm{LiI})=I(\mathrm{Li})$, (b) $k=1.0$ and $I(\mathrm{LiI})\gg I(\mathrm{Li})$, and (c) $k=1.0$ and

7) G. W. Wetherill, *J. Geophys. Res.*, **69**, 4403 (1964).
8) J. A. Cooper, P. H. Reynolds, and J. R. Richards, *Earth Planet. Sci. Lett.*, **6**, 467 (1969).
9) J. M. Ozard and R. D. Russel, *ibid.*, **8**, 331 (1970).

$I(\mathrm{LiI}) \ll I(\mathrm{Li})$. It should be noted that when $I(\mathrm{Li}) \gg I(\mathrm{LiI})$, r'_{ob} $(=1/r_{ob})$[10] is lower than R_0' $(=1/R_0)$ in the evaporated fraction ranging from 0 to 84% and that when $I(\mathrm{Li}) \ll I(\mathrm{LiI})$, r'_{ob} is larger than R_0' from 9 to 100%. Accordingly, this suggests that integrations of all ion currents for both isotopes do not necessarily give the true isotope ratio because of the fact that non-ionized vaporization also affects observed fractionation.

In conclusion, the theory presented here, though too much idealized to give a real picture of fractionation, is adequate to give the qualitative or even semi-quantitative behavior of fractionation in a thermal ion source, and therefore, the derived results are applicable to actual cases.

The author's thanks are due to Professor Hiroshi Hamaguchi, Nobufusa Saito and Hisao Mabuchi of the University of Tokyo for their kind interest and encouragement. Numerical calculations were carried out using a HITAC 5020 computer at the computer center of the University of Tokyo.

10) Lithium isotope ratio is usually presented as $^7\mathrm{Li}/^6\mathrm{Li}$.

Conductometric Determination of Ion-pair Formation Constants of Tris(ethylenediamine)cobalt(III) Ion with Maleate and Fumarate Ions in Aqueous Solutions

Shunzo KATAYAMA and Reita TAMAMUSHI

The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received December 14, 1970)

The conductance behavior of mixtures was investigated for the systems tris(ethylenediamine)cobalt(III)-chloride-sodium maleate and tris(ethylenediamine)cobalt(III)chloride-sodium fumarate in aqueous solutions of various ionic strengths at 25°C. Appreciable deviation of the measured conductivity from additivity was attributed to the ion-pair formation of tris(ethylenediamine)cobalt(III) ion with maleate Ma^{2-} and fumarate Fu^{2-} ions. The concentration formation constants K_c at various ionic strengths were determined by means of computer analysis of the deviation. The thermodynamic ion-pair formation constants K at 25°C were as follows: log K= 3.60 for $[Co(en)_3]^{3+}\cdot Ma^{2-}$ and log K=2.95 for $[Co(en)_3]^{3+}\cdot Fu^{2-}$.

In a previous paper,[1] the continuous variation method was applied to the determination of the ion-pair formation constants of $[Co(NH_3)_6]^{3+}\cdot SO_4^{2-}$ and $[Co(en)_3]^{3+}\cdot SO_4^{2-}$ from the conductance measurement of $[Co(NH_3)_6]Cl_3$—Na_2SO_4 and $[Co(en)_3]Cl_3$—Na_2SO_4 mixtures. The good agreement of the results obtained with those of Jenkins and Monk[2] suggests that the conductance measurement of mixtures is a useful method for determining formation constants, particularly when applied to the systems of relatively high ionic strengths where the theoretical equations of conductance behavior lose their validity. The method is also applicable to the study of ion-pair formation in systems where a pure sample is difficult to obtain.

This paper deals with the application of the continuous variation method to the conductometric determination of ion-pair formation constants of tris(ethylenediamine)cobalt(III) ion with maleate and fumarate ions at 25°C in aqueous solutions of varying ionic strengths. The results will provide some information on the *cis-trans* isomeric effect in the ion-pair formation.

Experimental

Materials. Tris(ethylenediamine)cobalt(III)chloride was prepared according to the procedure in literature[3]; the sample was purified by two recrystallizations from its aqueous solution containing a few drops of acetic acid. Sodium maleate, Na_2Ma, of analytical reagent grade was washed by ethanol and ethyl ether, then dried at 80°C until it became constant in weight. Sodium fumarate, Na_2Fu, of analytical reagent grade was purified by recrystallization from its aqueous solution. The purity of the samples was examined by conventional chemical analysis of the components and by conductivity measurements in aqueous solutions. Chemical analysis and conductivity measurements gave the results shown in Tables 1 and 2, respectively. The limiting ionic equivalent conductivity λ^0 of $[Co(en)_3]^{3+}$ was in agreement with that reported by Jenkins and Monk,[2] and the λ^0-values

(Limiting ionic equivalent conductivities, $\lambda°$, of $[Co(en)_3]^{3+}$, Ma^{2-} and Fu^{2-} are shown in parenthesis)

of Ma^{2-} and Fu^{2-} were in fairly good agreement with the results of Topp and Davies.[4]

Preparation of Solutions. Each solution of different ionic strengths was carefully prepared by using the conductivity water of low specific conductivity ($<2\times10^{-7}$ ohm^{-1} cm^{-1}) in an atmosphere of purified nitrogen gas, and the pH-values of these solutions were adjusted to 9 with sodium hydroxide. In aqueous solutions of pH 9 the concentrations of HMa^- and HFu^- ions can be ignored.

Conductivity Measurement. The electric conductivities of mixtures were measured by mixing the solutions of same ionic strength at various volume fractions. The apparatus and the reproducibility of measurements were the same as those described previously.[1] All measurements were carried out in a water-thermostat of 25.000±0.005°C which was electrically grounded.

Results and Discussion

In tris(ethylenediamine)cobalt(III)chloride—sodium maleate and tris(ethylenediamine)cobalt(III)chloride–sodium fumarate mixtures (systems I and II, respectively), a large deviation of the measured conductivity from additivity was observed at each ionic strength. The deviation, $\Delta\kappa$, of the mixture, consisting of a C_1 molar solution of tris(ethylenediamine)cobalt(III)chloride (abbreviated as MCl_3) and a C_2 molar solution of

Ionic strength: (a) 0.001, (b) 0.003, (c) 0.01, (d) 0.03, (e) 0.1.

Na_2B (B^{2-}=Ma^{2-} or Fu^{2-}) at the volume fractions x and $(1-x)$, respectively, is given by the equation

$$10^3\Delta\kappa = 10^3\kappa - C_1 x\Lambda_m(MCl_3) - C_2(1-x)\Lambda_m(Na_2B) \quad (1)$$

where κ is the specific conductivity of the mixture, and Λ_m the molar conductivity of the species specified in parenthesis at the ionic strength of the mixture. Figures 1(a—e) show the deviation as a function of volume fraction x of the complex. The $\Delta\kappa$-values of system I were always larger than those of system II, and the deviation reached a maximum at x=0.5—0.6 in each case.

The following ion-pair formations are expected to occur in systems I and II.

$$M^{3+} + B^{2-} \rightleftarrows M^{3+}\cdot B^{2-}$$
$$M^{3+} + Cl^- \rightleftarrows M^{3+}\cdot Cl^-$$
$$Na^+ + B^{2-} \rightleftarrows Na^+\cdot B^{2-}$$

where M^{3+} represents tris(ethylenediamine)cobalt(III) cation. In the present discussion, however, the contribution of ion-pair formation of $M^{3+}\cdot Cl^-$ and $Na^+\cdot B^{2-}$ is neglected, and the deviation of the observed conductivities from additivity is assumed to be entirely due to the formation of $M^{3+}\cdot B^{2-}$. This assumption seems to be reasonable, because the formation constants of $M^{3+}\cdot Cl^-$ and $Na^+\cdot B^{2-}$ should be much smaller than those of $M^{3+}\cdot B^{2-}$.

The deviation $\Delta\kappa$ is then related to the molar concentration of ion-pair $M^{3+}\cdot B^{2-}$ by the equation

$$[M^{3+}\cdot B^{2-}] = \frac{10^3\Delta\kappa}{\alpha} \quad (2)$$

$$\alpha = |z(M^{3+}\cdot B^{2-})|\lambda(M^{3+}\cdot B^{2-}) - |z(M^{3+})|\lambda(M^{3+}) - |z(B^{2-})|\lambda(B^{2-})$$
$$= \lambda(M^{3+}\cdot B^{2-}) - 3\lambda(M^{3+}) - 2\lambda(B^{2-}) \quad (3)$$

where z is the charge number of ionic species, and λ the ionic equivalent conductivity at the ionic strength of the mixture.

The concentration formation constants K_c of $M^{3+}\cdot B^{2-}$ were determined by analysing the $\Delta\kappa$-values according to the same methods given previously.[1] In method (i) the K_c-values were obtained by estimating the values of parameter α at each ionic strength, while in method (ii) a set of K_c and α for the best fit between the observed and calculated $\Delta\kappa$-values was obtained by computer calculation. Table 3 summarizes the concentration formation constants thus determined for $[Co(en)_3]^{3+}\cdot Ma^{2-}$ and $[Co(en)_3]^{3+}\cdot Fu^{2-}$ at various ionic strengths, I.

The thermodynamic formation constants K were then determined by the extrapolation of the log K_c *vs.* $\sqrt{I}$ plots as shown in Fig. 2, and are given in the first line of Table 3. The values of log K obtained by the two methods of calculation are in relatively good agreement. The computer calculation, however, is expected to give more reliable K_c-values particularly at higher ionic strengths, because the analysis can be made without introducing arbitrariness into the estimation of parameter α.

Our study shows that the ion-pair formation constant of $[Co(en)_3]^{3+}\cdot Ma^{2-}$ is about 3 times larger than that of $[Co(en)_3]^{3+}\cdot Fu^{2-}$. A similar tendency of maleate and fumarate ions towards ion-pair formation has been reported by Topp and Davies[4] for $Ba^{2+}\cdot Ma^{2-}$, $Ba^{2+}\cdot Fu^{2-}$, $Ca^{2+}\cdot Ma^{2-}$, and $Ca^{2+}\cdot Fu^{2-}$ in aqueous solutions at 25°C, where the K-value of $Ba^{2+}\cdot Ma^{2-}$ was found to be about 5 times as large as that of $Ba^{2+}\cdot Fu^{2-}$, and the K-value of $Ca^{2+}\cdot Ma^{2-}$ to be about 3 times as large as that of $Ca^{2+}\cdot Fu^{2-}$.

TABLE 3. LOGARITHM OF CONCENTRATION FORMATION CONSTANTS, log K_c, OF ION-PAIRS $[Co(en)_3]^{3+}\cdot Ma^{2-}$ AND $[Co(en)_3]^{3+}\cdot Fu^{2-}$ AT 25°C AND AT VARIOUS IONIC STRENGTHS, I

(The values of log K, K being thermodynamic formation constant, are also included)

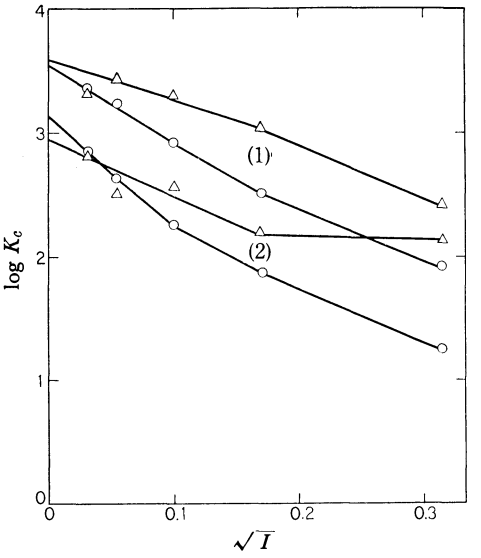

Fig. 2. Concentration formation constants of (1) ion-pair $[Co(en)_3]^{3+}\cdot Ma^{2-}$ and (2) ion-pair $[Co(en)_3]^{3+}\cdot Fu^{2-}$ as a function of ionic strength (25°C).
-○-: determined by estimating α (method (i))
-△-: determined by computer calculation (method (ii))

According to Bjerrum's theory of electrostatic interactions,[5] the ion-pair formation constant between ions i and j of opposite charge in aqueous solutions at 25°C is given by the equation

$$\log K = 0.4386 + 3\log|z_i z_j| + \log Q(b) \quad (4)$$
$$\log b = \log|z_i z_j| - 7.1468 - \log a$$

where $Q(b)$ is a function of b, and a the distance of closest approach of the ions. Introducing the values of log K given in Table 3 into Eq. (4), we obtain a=4 Å for $[Co(en)_3]^{3+}\cdot Ma^{2-}$ and a=6 Å for $[Co(en)_3]^{3+}\cdot Fu^{2-}$

5) C. B. Monk, "Electrolytic Dissociation," Academic Press, London (1961), pp. 272—275.

respectively. On the other hand, the Stokes radii of $[Co(en)_3]^{3+}$, Ma^{2-}, and Fu^{2-}, calculated from their limiting ionic equivalent conductivities, are: $r_s([Co(en)_3]^{3+})=3.7$ Å and $r_s(Ma^{2-}, Fu^{2-})=3.0$ Å. It is interesting to note that the a-value for $[Co(en)_3]^{3+}\cdot Ma^{2-}$ is significantly smaller than the sum of the Stokes radii of the ions. The result suggests that the charge distribution in ions and/or some interactions other than electrostatic attraction should be considered in the ion-pair formation between $[Co(en)_3]^{3+}$ and Ma^{2-} or Fu^{2-}.

The present work provides further evidence for the *cis-trans* isomeric effect in the ion-pair formation. However, much more information will be needed for a discussion on the isomeric effect.

We wish to thank Mrs. K. Takahashi for her kind collaboration in computer calculation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1815—1822 (1971)

Multidentate Ligand Substitution Reactions. XII. Substitution Reactions of the Nickel(II)-nitrilotriacetate Complex with Diethylenetriaminepentaacetic Acid in the Presence of Ethylenediamine and of the Nickel(II)-*N*-(2-hydroxyethyl)-iminodiacetate Complex with Ethylenediaminetetraacetic Acid and Cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic Acid

Mutsuo KODAMA, Sadatsugu KARASAWA, and Toshiyuki WATANABE

Department of Chemistry, Ibaraki University, Bunkyo, Mito, Ibaraki

(Received December 22, 1970)

The substitution reactions of the nickel(II)-nitrilotriacetate complex with diethylenetriaminepentaacetic acid in the presence of ethylenediamine and of the nickel(II)-*N*-(2-hydroxyethyl)-iminodiacetate complex with ethylenediaminetetraacetic acid and cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic acid were studied by employing the polarographic method. In the presence of ethylenediamine, the reaction of the nickel(II)-nitrilotriacetate complex with diethylenetriaminepentaacetic acid was found to proceed through the following four pathways:

$$NiX_2^{4-} \underset{\text{rapid}}{\rightleftharpoons} \begin{cases} NiX^- + \begin{cases} Z^{5-} \overset{k_1^+}{\rightleftharpoons} NiZ^{3-} + X^{3-} \\ HZ^{4-} \overset{k_2^+}{\rightleftharpoons} NiZ^{3-} + HX^{2-} \end{cases} \\ NiA^{2+} + \begin{cases} Z^{5-} \overset{k_3^+}{\rightleftharpoons} NiZ^{3-} + A^0 \\ HZ^{4-} \overset{k_4^+}{\rightleftharpoons} NiZ^{3-} + HA^+ \end{cases} \end{cases} \quad (\text{rapid: } NiXA^-)$$

where X^{3-} and Z^{5-} denote completely-deprotonated nitrilotriacetate and diethylenetriaminepentaacetate anions respectively, and A°, ethylenediamine. By comparing the rate constants of the substitution reactions of the nickel(II)-nitrilotriacetate and ethylenediamine complexes with their dissociation rate constants, the structure of the reaction intermediate was determined. From the concentration dependence of the reaction rate, the reactions of the nickel(II)-*N*-(2-hydroxyethyl)-iminodiacetate complex with ethylenediaminetetraacetic acid and with cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic acid were concluded to proceed through the following two reaction pathways:

$$\text{i)}\quad NiX_2^{2-} \underset{\text{rapid}}{\rightleftharpoons} NiX^0 + Y^{4-} \overset{k_1^+}{\rightleftharpoons} NiY^{2-} + X^{2-}$$

$$\text{ii)}\quad NiX_2^{2-} \underset{\text{rapid}}{\rightleftharpoons} NiX^0 + HY^{3-} \overset{k_2^+}{\rightleftharpoons} NiY^{2-} + HX^-$$

where X^{2-} and Y^{4-} mean completely-deprotonated *N*-(2-hydroxyethyl)-iminodiacetate and ethylenediaminetetraacetate or cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetate anions. From a comparison of the rate constants for the reaction of the *N*-(2-hydroxyethyl)-iminodiacetate complex with those for the corresponding reaction of the iminodiacetate complex, it was found that the hydroxyethyl group in the *N*-(2-hydroxyethyl)-iminodiacetate anion rather accelerates the dissociation of the *N*-(2-hydroxyethyl)-iminodiacetate anion from the nickel(II) ion.

In previous papers,[1,2] we studied the substitution reaction of the nickel(II)-ethylenediaminetetraacetate (EDTA) complex with Eriochrome Black T (BT). In those papers, we mentioned that in the presence of the ammonia or thiocyanate anion the nickel(II)-EDTA

1) M. Kodama, C. Sasaki, and M. Murata, This Bulletin, **41**, 1333 (1968).

2) M. Kodama and K. Miyamoto, *ibid.*, **42**, 833 (1969).

complex shows the same kinetic behavior as in its absence, but the rate of the reaction was reducd, appreciably by increasing the concentration of the ammonia or thiocyanate anion. This was ascribed to the fact that, although the reaction proceeds only through the normal nickel(II)-EDTA complex, even in the presence of the ammonia or thiocyanate ion, its concentration is reduced by the formation of a mixed ligand complex with an ammonia or thiocyanate ion. Diethylenetriaminepentaacetic acid (DTPA) also reacts with the nickel(II)-nitrilotriacetate (NTA) complex at a measurable rate and displaces the NTA anion from its nickel(II) complex.[3] This reaction was found to proceed only through the 1:1-ratio nickel(II)-NTA complex. In the presence of ethylenediamine (EN), contrary to the observation of the effect of ammonia on the substitution reaction of nickel(II)-EDTA with BT, the substitution reaction of DTPA with the nickel(II)-NTA complex proceeds not only through the nickel(II)-NTA complex with a 1:1 ratio, but also through the nickel(II)-EN complex with a 1:1 ratio. We also studied the steric effect of the leaving group on the rate of the substitution reactions of nickel(II)-aminopolycarboxylate complexes with BT and demonstrated that the cyclohexane ring of cyclohexane-1, 2-diamine-*N*,*N*,*N*′,*N*′,-tetraacetate(CyDTA) anion slows the reaction considerably.[4] As in the case of the nickel(II)-iminodiacetate (IDA) complex,[5] the nickel(II)-*N*-(2-hydroxyethyl)-iminodiacetate (HIDA) complex also reacts with EDTA and CyDTA. Although the HIDA has the hydroxyethyl group, the reactions of the nickel(II)-HIDA complex with EDTA and CyDTA proceed much faster than would be expected for a simple glycinate mechanism. In this paper, first, we will study the substitution reaction of the nickel(II)-NTA complex with DTPA in the presence of EN and will determine the detailed reaction mechanism and rate constants. Secondly, we will deal with the substitution reactions of the nickel(II)-HIDA complex with EDTA and CyDTA, and will discuss the effect of the hydroxyethyl group of the HIDA ion on the rate of the substitution reaction.

Experimental

Reagents. The standard nickel(II) nitrate solution was prepared by dissolving a known amount of metallic nickel (99.99 %) in dilute nitric acid (1+1) and by then removing the excess nitric acid by distillation under reduced pressure. NTA, EDTA, CyDTA, and DTPA were recrystallized from their aqueous solutions by adding pure ethanol and hydrochloric acid. Their standard solutions were prepared by dissolving them in doubly-distilled water. In this study, EN purified by distillation under reduced pressure was used. The other chemicals were of analytical reagent grades and were used without further purification.

Apparatus and Experimental Procedures. All the d.c. polarograms and current-time curves were recorded by means of a Yanagimoto pen-recording polarograph, PA-102. The characteristic features of the dropping mercury electrode (DME) used in this study have been described previously.[3] For all the spectrophotometric measurements, a Hitachi EPS-3 recording spectrophotometer with a pair of 1-cm quartz cells was used. The pH was measured with a glass electrode pH-meter (a Hitachi-Horiba F-5). The rate of the substitution reaction was determined by measuring the change in the diffusion current of the anodic wave due to the decrease in the uncomplexed EDTA, CyDTA, or DTPA concentration with the time. In the kinetic study, all the measurements were conducted in solutions with an ionic strength of 0.30 ($NaClO_4$) and containing large excesses of complexed and uncomplexed EN, NTA, or HIDA over EDTA, CyDTA, or DTPA at 25°C. Therefore, all the substitution reactions could be treated as pseudo-first-order reactions. In this study, no buffer reagent was required to keep the solution's pH constant over the entire pH range covered ($7.50<pH<9.00$), because all the solutions contained a large excess of uncomplexed EN, NTA, or HIDA. All the experimental procedures employed in the kinetic study were the same as have previously been described.[3] In the spectrophotometric determination of the solution equilibrium, sample solutions with an ionic strength of 0.50 were used.

Results and Discussion

Spectrophotometric Determination of Solution Equilibria between the Nickel(II)-Nitrilotriacetate Complex and Ethylenediamine. Thermodynamically, when the product of the conditional formation constant of a 1:1 nickel(II)-NTA complex, K_{NiX}' ($=K_{NiX}/(\alpha_H)_X$), and the total concentration of the nickel(II) ion is larger than 1.0×10^6, the nickel(II) ion in the solution containing an equimolar NTA can be expected to exist exclusively in the form of NiX^-. Furthermore, when the concentration of the nickel(II)-NTA complex is nearly equal to that of uncomplexed EN and the $K_{NiX}'/(1+K_{NiA_2}^{A'}[A]_f)K_{NiA}'$ value is larger than 1.0×10^4, EN can not displace the NTA anion from its nickel(II) complex. Here, K_{NiA}' and $K_{NiA_2}^{A'}$ mean conditional first and second formation constants of nickel(II)-EN complex, and $[A]_f$, the concentration of the uncomplexed EN. Therefore, if the above conditions are fulfilled, the addition of EN to the nickel(II)-NTA complex solution will necessarily result in the formation of a mixed nickel (II)-NTA-EN complex according to the following equation:

$$NiX^- + A^0 = NiXA^-; \quad K_{NiX}^{A} = \frac{[NiXA^-]}{[NiX^-]\cdot[A_0]} \qquad (1)$$

The nickel(II)-NTA complex in an aqueous solution gives an absorption spectrum with two absorption maxima, at 395 and at 635 mμ. By the addition of EN to the nickel(II)-NTA solution, its absorbance was increased remarkably and the absorption curve's maxima were shifted to shorter wavelengths (365 and 585 mμ). These facts can be interpreted in terms of the formation of a mixed ligand complex involving an EN. As was discussed in the spectrophotometric determination of the formation constants of nickel(II)-ethylenediaminemonoacetate complexes, the following relation can be derived for the above solution equilibrium:[6]

3) M. Kodama, This Bulletin, **42**, 2532 (1969).

$$\log \frac{1}{[A]_t - \frac{A - A_{NiX}}{\varepsilon_{NiXA} - \varepsilon_{NiX}}} = \log \frac{A_{NiXA} - A}{A - A_{NiX}} + \log \frac{K^{A}_{NiX}}{(\alpha_H)_A} \quad (2)$$

where ε's and $[A]_t$ mean the molar extinction coefficients and the total concentration of EN, and where A, A_{NiXA}, and A_{NiX} are, respectively, the absorbance of the solutions in which NiX^- and $NiXA^-$ coexist, in which all the nickel(II)-NTA complex exists in the form of $NiXA^-$ and in which there is no EN. With the aid of Eq. (2), the experimental data were analyzed. The results obtained are reproduced in Fig. 1. From the $\log [1/([A]_t - (A - A_{NiX})/(\varepsilon_{NiXA} - \varepsilon_{NiX}))]$ value at $\log [(A_{NiXA} - A)/(A - A_{NiX})] =$ zero, the $\log K^{A}_{NiXA}/(\alpha_H)_A$ value was estimated to be 1.84. This corresponds to the $\log K^{A}_{NiXA}$ value of 5.84.

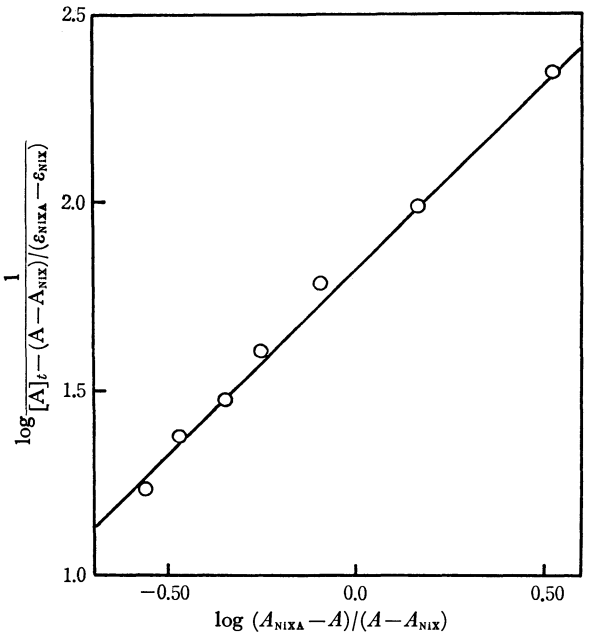

Fig. 1. The relation between $\log [1/[[A]_t - (A - A_{NiX})/(\varepsilon_{NiXA} - \varepsilon_{NiX})]]$ and $\log (A_{NiXA} - A)/(A - A_{NiX})$.
The concentration of Ni(II)-NTA complex=24.0 mM
pH=6.50, μ=0.50, λ=550 mμ
The EN concentration ranged from 30 to 300 mM

The Kinetic Study of the Substitution Reaction of the Nickel(II)-Nitrilotriacetate Complex with Diethylenetriaminepentaacetic Acid in the Presence of Ethylenediamine. As was found in the substitution reaction of the nickel(II)-NTA complex with DTPA in the absence of EN,[3] a linear relation passing through the point of origin could be obtained by plotting the $\log (i_0/i_t)$ against the time, t, in the present substitution reaction (the results are not shown here). Here, i_0 and i_t denote the wave heights of DTPA at times $t=0$ and $t=t$ respectively. When the other experimental conditions were kept constant, the slope of the above linear relation was not influenced by the addition of the nickel(II)-DTPA complex and was independent of the initial concentration of DTPA (Table 1). These facts clearly indicate that the forward reaction is much faster than the backward reaction, and that the dissociation of the nickel(II)-NTA complex is not involved in the present reaction. Therefore, the log-plot slope multiplied by 2.303 should be equal to the apparent rate constant of the forward reaction, k^{+}_{ap}. Furthermore, the log-plot slope was found to be exactly proportional to the total concentration of the nickel(II) ion (Table 2). As was shown in Fig. 2, the substitution reaction of the nickel(II)-NTA complex with DTPA in the presence of EN gave the linear relation between the log-plot slope multiplied by $(1 + K^{X'}_{NiX_2}[X]_f/K^{A'}_{NiXA}[A]_f)$ and the reciprocal of the uncomplexed EN concentration, $[A]_f^{-1}$. Here, $K^{X}_{NiX_2}$ denotes the second successive formation constant of the nickel(II)-NTA complex. By plotting the intercept of the above linear relation multiplied by the $(\alpha_H)_Z K^{X'}_{NiAX}[X]_f/[Ni]_t$ value or the slope multiplied by the $(\alpha_H)_Z K^{A'}_{NiXA}/[Ni]_t$ value against the hydrogen ion concentration, we could also obtain the straight line with the intercept of a finite value. The linear relations thus obtained are shown in Figs. 3 and 4. These facts

evidently imply that the substitution reaction of the nickel(II)-NTA complex with DTPA in the presence of EN proceeds through the following four reaction pathways:

$$NiX_2^{2-} \overset{\text{rapid}}{\rightleftharpoons} \begin{matrix} NiX^- \\ NiXA^- \\ NiA^{2+} \end{matrix} + \begin{cases} Z^{5-} \overset{k_1^+}{\rightleftharpoons} NiZ^{3-} + X^{3-} \\ HZ^{4-} \overset{k_2^+}{\rightleftharpoons} NiZ^{3-} + HX^{2-} \\ Z^{5-} \overset{k_3^+}{\rightleftharpoons} NiZ^{3-} + A^0 \\ HZ^{4-} \overset{k_4^+}{\rightleftharpoons} NiZ^{3-} + HA^+ \end{cases}$$

For the above reaction mechanism, k^+_{ap} is given by this relation (3):

$$k^+_{ap} = \left(\frac{k_X^+}{K^{A'}_{NIXA}[A]_f} + \frac{k_A^+}{K^{X'}_{NIXA}[X]_f}\right) \times \frac{[Ni]_t}{(\alpha_H)_Z \cdot \left(1 + \frac{K^{X'}_{NIX_1}[X]_f}{K^{A'}_{NIXA}[A]_f}\right)} \quad (3)$$

Here, k_X^+ and k_A^+ are given by (4a) and (4b) respectively.

$$k_X^+ = k_1^+ + k_2^+ \frac{[H^+]}{K_5} \quad (4a)$$

$$k_A^+ = k_3^+ + k_4^+ \frac{[H^+]}{K_5} \quad (4b)$$

where K_5 means the fifth dissociation constant of DTPA.

From the slopes and intercepts of the linear relations in Figs. 3 and 4, k_1^+, k_2^+, k_3^+, and k_4^+ were determined; they are listed in Table 3. Although the precision is not satisfactory, the k_3^+ and k_4^+ values determined in this study agree well with those obtained in the kinetic study of the substitution reaction of the nickel(II)-EN complex with DTPA (μ=0.30, $k_3^+=4\times10^6$, $k_4^+=3.5\times10^5$).[7] If the substitution reaction of the nickel(II)-NTA complex with DTPA in the presence of EN proceeds through the above four reaction pathways, the k_1^+, k_2^+, k_3^+, and k_4^+ values obtained in this study should explain satisfactorily the effect of the concentration of the uncomplexed NTA on the reaction rate. Equation (3) clearly indicates that, provided that the other experimental conditions are kept constant, a plot of the log-plot slope multiplied by the $(1+K^{X'}_{NIX_2}[X]_f/K^{A'}_{NIXA}[A]_f)$ value against the reciprocal of the uncomplexed NTA concentration, $[X]_f^{-1}$, should yield a straight line, the slope and the intercept of which are $2.303\times k_A^+[Ni]_t/$

$K^{X'}_{NiXA}(\alpha_H)_Z$ and $2.303 \times k^+_A[Ni]_t/K^{A'}_{NiXA}[A]_f(\alpha_H)_Z$ respectively. A typical linear relation between the product of the log-plot slope and the $(1+K^{X'}_{NiX_2}[X]_f/K^{A'}_{NiXA}[A]_f)$ and the reciprocal of the concentration of uncomplexed NTA is reproduced in Fig. 5. The slope and intercept of the above linear relation were compared with those calculated with the aid of Eq. (3) by using the k_1^+, k_2^+, k_3^+, and k_4^+ values listed in Table 3. The calculated values agreed well with those obtained (Table 3). This agreement strongly supports the reaction mechanism proposed by the present authors.

The Kinetic Study of Substitution Reactions of the Nickel(II)-N-(2-Hydroxyethyl)-Iminodiacetate Complex with Ethylenediaminetetraacetic Acid and with Cyclohexane-1,2-diamine-N,N,N',N'-tetraacetic Acid. In the substitution reaction of the nickel(II)-HIDA complex, quite similar results to those obtained in the substitution reactions of the nickel(II)-iminodiacetate (IDA) complex with EDTA and CyDTA were obtained. The plot of log-(i_0/i_t) against t invariably gave a straight line passing through the point of origin. Its slope was independent of the initial concentration of EDTA or CyDTA and was not influenced by the addition of the nickel(II)-EDTA or CyDTA complex (the results will not be given here). It was also found that the log-plot slope is exactly proportional to the concentration of the 1:1 nickel(II)-HIDA complex in solutions of a given pH (Table 4), and that the plot of the product of the log-plot slope and $2.303 \times (\alpha_H)_Y(1+K^{X'}_{NiX_2}[X]_f)/[Ni]_t$ against the concentration of the hydrogen ion gives a linear relation (Fig. 6) corresponding to the following relation:

$$\frac{k^+_{ap}(\alpha_H)_Y(1+K^{X'}_{NiX_2}[X]_f)}{[Ni]_t} = k_\alpha{}^+ + k_\beta{}^+[H^+] \qquad (5)$$

where $(\alpha_H)_Y$ denotes the (α_H) value of EDTA or CyDTA, $K^{X'}_{NiX_2}$, the conditional second successive formation constant of the nickel(II)-HIDA complex, and $[X]_f$, the concentration of the uncomplexed HIDA. Therefore, we can safely propose the following reaction mechanism for the substitution reaction of the nickel(II)-HIDA complex with EDTA or CyDTA.

i) $NiX_2{}^{2-}$
$\downarrow\uparrow$ rapid
$NiX^0 + Y^{4-} \overset{k_1^+}{\rightleftharpoons} NiY^{2-} + X^{2-}$

ii) $NiX_2{}^{2-}$
$\downarrow\uparrow$ rapid
$NiX^0 + HY^{3-} \overset{k_2^+}{\rightleftharpoons} NiY^{2-} + HX^-$

where Y^{4-} denotes the completely-deprotonated EDTA or CyDTA anion, and X^{2-}, the completely-deprotonated HIDA anion. If the reaction of the nickel(II)-HIDA complex with EDTA or CyDTA has the above reaction mechanism, k_α^+ and k_β^+ in Eq. (5) should be equal to k_1^+ and k_2^+/K_4 respectively. Here, K_4 corresponds to the fourth dissociation constant of EDTA or CyDTA. Thus, we can determine the k_1^+ and k_2^+ values for the reactions of the nickel(II)-HIDA complex with EDTA and CyDTA from the intercepts and slopes of the linear relations in Fig. 6. The k_1^+ and k_2^+ values thus determined are listed in Table 5, together with the k_1^+ and k_2^+ values of the substitution reactions of the nickel(II)-IDA complex with EDTA and CyDTA.[5]

We can mention here that the rate for the substitu-

tion reaction of the nickel(II)-EN complex with DTPA is much larger than that for the dissociation of the nickel(II)-EN complex.[8] This can be explained in terms of the formation of the mixed ligand complex reaction intermediate involving the DTPA anion.[1,9] As was attempted in the substitution reaction of the nickel(II)-EDMA complex with DTPA,[6] we can also estimate the structure of the reaction intermediate in the substitution reaction of the nickel(II)-EN complex with DTPA by comparing its rate constant with that for the dissociation of the nickel(II)-EN complex. If the reaction of the nickel(II)-EN complex proceeds through the reaction intermediate I_a, the rate constant, k_3^+, should be about 3×10^7 times larger than the dissociation constant of a 1:1 ratio nickel(II)-EN complex. Here, we used the nickel(II)-*N*-ethyl-glycinate complex as a model. In the estimation of the relative rate constant, the electrostatic contribution to the stability of the reaction intermediate, K_{etec}, and the statistical factor were also taken into account. Similarly, when the reaction intermediate is given by I_b or I_c (Fig. 7),

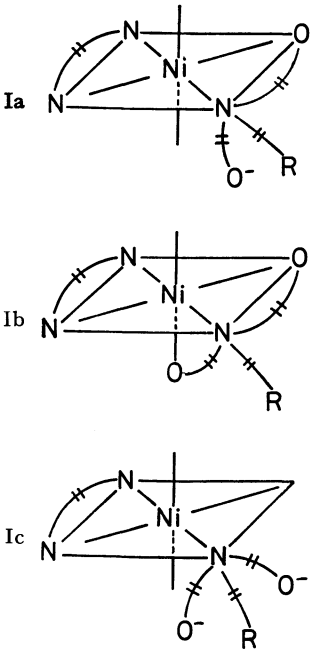

Fig. 7. Reaction intermediates for the substitution reaction of nickel(II)-EN complex with DTPA.

the ratio of the rate constant, k_3^+, to the dissociation rate constant of a 1:1 nickel(II)-EN complex should be 3×10^9 or 1×10^9. The k_3^+ and k_d^{EN} values in Table 3 clearly indicate that the reaction intermediate I_a fits best. From a comparison of the k_1^+ value with the dissociation rate constant of a 1:1 ratio nickel(II)-NTA complex, we can also estimate the structure of the reaction intermediate in the reaction of the nickel(II)-NTA complex with DTPA. The rate constant for the dissociation of a 1:1 nickel(II)-NTA complex was reported by Kimura (3.0×10^{-5} sec^{-1}, μ=0.10, 25°C).[10]

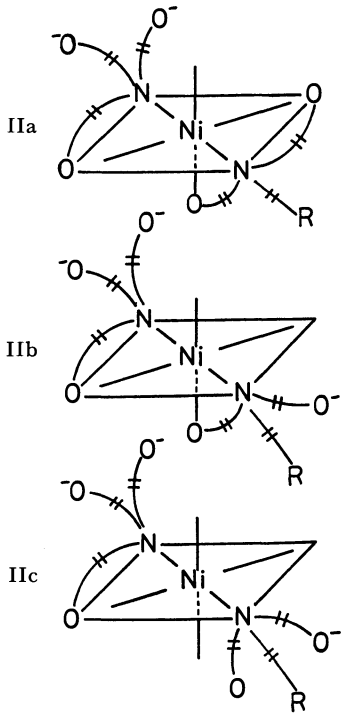

Fig. 8. Reaction intermediates for the substitution reaction of nickel(II)-NTA complex with DTPA.

As was discussed in connection with the dissociation of nickel(II)-aspartate complex,[11] by comparing this value with the rate constant calculated on the basis of the reaction intermediate proposed, we can determine the detailed structure of the reaction intermediate. The rate constant reported by Kimura agrees well only with that calculated on the basis of a glycinate reaction intermediate.[12] Consequently, the following are considered to be the possible reaction intermediate in the substitution reaction of the nickel(II)-NTA complex with DTPA (Fig. 8). The k_1^+ value determined in this study is 7.7×10^7 times larger than the dissociation rate constant of the nickel(II)-NTA complex. As is shown in Fig. 8, the rate constant ratio estimated on the basis of the reaction intermediate, II_a, agreed best with that determined experimentally. In general, the substitution reaction of the nickel(II)-aminopolycarboxylate complex proceeds through the reaction intermediate in which the attacking aminopolycarboxylate anion is bonded to the nickel(II) ion through the iminodiacetate chelate ring. Therefore, the above conclusion must be reasonable.

Previously,[2] we had reported that even in the presence of ammonia the substitution reaction of nickel(II)-EDTA complex with BT proceeds only through the normal nickel(II)-EDTA complex, NiY^{2-}. Theo-

11) M. Kodama, H. Nunokawa, and N. Oyama, This Bulletin, **44**, in Press.
12) The glycinate reaction intermediate means the reaction intermediate in which the leaving NTA anion is bonded to the nickel(II) ion through a glycinate chelate ring. The rate constant calculated with the aid of Eq. (16) in Ref. (11) was 1.6×10^{-5} sec^{-1}. In the calculation, the electrostatic contribution to the stability of the reaction intermediate and the statistical factor were also taken into consideration.

retically, the substitution reaction of the nickel(II)-EDTA complex with BT in the presence of ammonia can be expected to proceed also through the nickel(II)-ammonia complex. However, the reaction pathway which involves a mixed-ligand 1:1:1 ratio ammonia, EDTA nickel(II) complex, $NiY(NH_3)^{2-}$, is unlikely, because the mixed-ligand complex is much less favorable for the formation of a reaction intermediate, which is essentially a mixed-ligand complex involving a BT anion. On the basis of the reaction intermediate, we can estimate the contribution of the reaction pathway involving the nickel(II)-ammonia complex to the whole reaction. If we apply Eq. (5) in Ref. (13) or Eq. (17) in Ref. (9) to the substitution reaction of the nickel(II)-EDTA complex with BT, the contribution ratio of the reaction pathway involving the ammonia complex to that involving the EDTA complex can be calculated approximately by using the following relation:

$$\text{Ratio} = \frac{k_d^{NH_3} \cdot K_{Ni(NH_3)} \cdot (\alpha_H)_Y \cdot [NH_3]_f}{4 \cdot k_d^{gly} \cdot K_{Ni-gly} \cdot (\alpha_H)_{NH_3} \cdot [Y]_f}$$

where $k_d^{NH_3}$[14] and k_d^{gly}[15] are the rate constants for the dissociation of ammonia and glycinate anions respectively from the nickel(II) ion in the reaction intermediate, $[NH_3]_f$ and $[Y]_f$, the concentrations of uncomplexed ammonia and of uncomplexed EDTA, and $K_{Ni(NH_3)}$ and K_{Ni-gly}, the formation constants of 1:1-ratio nickel(II)-ammonia and -glycinate complexes respectively, and where the (α_H)'s indicate the (α_H) values of ammonia and EDTA, and 4, the statistical factor for the formation of a nickel(II)-glycinate chelate ring between the nickel(II) ion and the tetravalent EDTA anion. In the derivation of the above equation, we assumed that the nickel(II)-BT segments in the reaction intermediates of both reaction pathways have the same structure and that the reaction pathway involving the nickel(II)-EDTA complex proceeds via a glycinate reaction intermediate.[13] With the aid of the above relation, the ratio was calculated to be about 0.01 by using the reported numerical values. This small contribution ratio clearly supports the present author's explanation that the substitution reaction of the nickel(II)-EDTA complex with BT in the presence of ammonia proceeds exclusively through the normal nickel(II)-EDTA complex, NiY^{2-}. Similarly, on the basis of the proposed reaction intermediates, we can also estimate the contribution of the reaction pathway involving the normal nickel(II)-NTA complex to the whole reaction. If the reaction pathway involving the nickel(II)-EN complex proceeds through the reaction intermediate I_a, and that involving the nickel(II)-NTA complex, through II_a, under the conditions where the concentration of the uncomplexed EN is nearly identical with that of the uncomplexed NTA, the ratio of the contribution of the former reaction pathway to that of the latter reaction pathway will be given by the following relation:

$$\text{Ratio} = \frac{4 \times k_d^{EN} K'_{Ni-EN}}{6 \times k_d^{gly} K_{Ni-IDA}}$$

where 4 and 6 are statistical factors; k_d^{EN} the rate constant for the dissociation of the nickel(II)-EN complex with a 1:1 ratio,[8] and K_{Ni-EN} and K_{Ni-IDA}, the formation constants of 1:1-ratio nickel(II)-EN and -IDA complexes. The ratio calculated with the aid of the above relation was nearly equal to unity. This also supports the reaction mechanism proposed by the present authors for the substitution of the nickel(II)-NTA complex with DTPA in the presence of ethylenediamine.

As is clear from the data shown in Table 5, the k_1^+ and k_2^+ values for the substitution reaction of the nickel(II)-HIDA complex with EDTA are nearly identical with those for the corresponding substitution reaction of the nickel(II)-IDA complex. If the above two substitution reactions proceed through the reaction intermediates in which both HIDA and IDA anions are bonded to the nickel(II) ion through one nitrogen and two oxygen atoms, the k_1^+ value for the former reaction should be nearly equal to the k_1^+ value for the latter reaction, for the relative stabilities of the reaction intermediates for both reactions must be the same. Already, we have established that the substitution reaction of the nickel(II)-IDA complex with DTPA has the glycinate mechanism,[16] and also that the rate constants for the reaction of the nickel(II)-IDA complex with DTPA are nearly identical with those for the reaction with EDTA.[5] These facts clearly imply that the reaction of the nickel(II)-IDA complex with EDTA also proceeds through the reaction intermediate in which the displaced IDA anion is bonded to the nickel(II) ion through one nitrogen and one oxygen atoms (the glycinate mechanism). Thus, in the substitution reaction of the nickel(II)-IDA complex with EDTA, the reaction intermediate in which the displaced IDA anion is bonded to the nickel(II) ion through one nitrogen and two oxygey atoms should be eliminated. If the reactions of both nickel(II)-IDA and -HIDA complex with EDTA have the glycinate mechanism, the rate constant for the substitution reaction of the nickel(II)-HIDA complex should be approximately 17 times smaller than that for the reaction involving the nickel(II)-IDA complex, because the formation constant of the nickel(II)-HIDA complex with a 1:1 ratio is 17 times larger than that of the 1:1 nickel(II)-IDA complex. Therefore, the finding that the k_1^+ and k_2^+ values for the reaction of the nickel(II)-HIDA complex are nearly equal to those for the reaction of the nickel(II)-IDA complex should be ascribed to the fact that the hydroxyethyl group in the HIDA anion effectively helps the dissociation of the HIDA anion from the nickel(II) ion in the reaction intermediate. Furthermore, the k_1^+ value for the substitution reaction of the nickel(II)-IDA complex with EDTA is about 1×10^8 times larger than the rate constant for the dissociation of a 1:1-ratio nickel(II)-IDA complex.[11,17]

If the reaction of the nickel(II)-IDA complex with EDTA proceeds through the reaction intermediate in which the EDTA anion is bonded to the nickel(II) ion through the iminodiacetate chelate ring, the ratio of the rate constant between the substitution and dissociation reactions of the nickel(II)-IDA complex should be 2.1×10^8. Here, we used the nickel(II)-HIDA complex as a model of the nickel(II)-EDTA segment. In the above calculations, the statistical factor and the electrostatic contribution were also taken into account. The rate-constant ratio calculated on the basis of the reaction intermediate in which the EDTA anion is bonded to the nickel(II) ion through the iminodiacetate chelate ring agreed well with that observed. From the above results and the discussion of them, we can safely conclude that the substitution reaction of the nickel(II)-HIDA complex with EDTA proceeds through the following reaction intermediate (Fig. 9). As is shown in Table 5, the k_1^+ and k_2^+ values for the substitution reaction of the nickel(II)-HIDA complex with CyDTA are appreciably smaller than those of the other substitution reactions studied. This may be attributed mainly to the steric hindrance resulting from the interaction between the cyclohexane

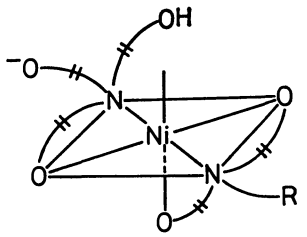

Fig. 9. Reaction intermediate for the substitution reaction of nickel(II)-HIDA complex with EDTA.

ring of CyDTA anion and the hydroxyethyl group of the HIDA anion. Finally, it should be noted that the k_2^+ value, especially, for the reaction with CyDTA is much smaller than the k_1^+ value. Since the protonation of the CyDTA anion bonded to the nickel(II) ion will reduce the electrostatic repulsion between the un-coordinated carboylate groups, and will stabilize the reaction intermediate, the above fact suggests the importance of the deprotonation of the attacking group in the formation of the reaction intermediate. In order to describe the precise nature of the effect of the protonation of the attacking group, a further, systematic investigation is necessary

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1822—1826 (1971)

Hydrolysis of Nickel(II) Ion in Aqueous 3 M Sodium Chloride Medium

Hitoshi OHTAKI and Georg BIEDERMANN*

**Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm, Sweden*

(Received December 25, 1970)

The hydrolytic reaction of nickel ion was studied at 25°C in an aqueous 3M sodium chloride medium. In the range of the total nickel concentration of 0.0145—1.000M, the emf data obtained could be explained in terms of the formation of the complex $Ni_4(OH)_4$ (the charge is omitted), the formation constant of the species being found to be $\log {}^*\beta_{4,4} = -28.5_5 \pm 0.1_0$, together with some minor species NiOH ($\log {}^*\beta_{1,1} \leq -10.5$) and Ni_2OH ($\log {}^*\beta_{1,2} \leq -10.5$).

The hydrolytic reaction of nickel ion has been studied by a number of workers and the results are summarized.[1] A brief survey of these studies has been made by Burkov, Lilič, and Sillén[2] in their paper on the hydrolytic reaction of nickel ion in the 3 M sodium perchlorate medium. In addition to these studies some recent works should be mentioned.[3,4]

Most of these workers, except Burkov *et al.*,[2] reported formation of the mononuclear complex $NiOH^+$ as the main product of hydrolytic reaction. Burkov *et al.* showed that the main hydrolyzed species of nickel ion is the tetramer $Ni_4(OH)_4^{4+}$, and only negligible amounts of mononuclear complexes are formed in solutions of relatively high concentrations of nickel and perchlorate ions.

The present study deals with the hydrolytic reaction of nickel ion in the 3 M sodium chloride medium.

The hydrolytic reaction of nickel ions may, in general, be written as

$$qNi^{2+} + pH_2O + rCl^- = Ni_q(OH)_pCl_r^{(2q-p-r)+} + pH^+ \quad (1)$$

and the equilibrium constant of the reaction (1) is defined by

$${}^*\beta^\circ_{p,q,r} = [Ni_q(OH)_pCl_r^{(2q-p-r)+}][H^+]^p/[Ni^{2+}]^q[Cl^-]^r \quad (2)$$

Taking into account the formation of chloro complexes, the concentration of nickel ions which are not hydrolyzed $[Ni^{2+}]_f$, can be written as follows.

$$\begin{aligned}[Ni^{2+}]_f &= [Ni^{2+}] + \sum_m\sum_n m[Ni_mCl_n^{(2m-n)+}] \\ &= [Ni^{2+}](1 + \sum_m\sum_n m\beta_{m,n}[Ni^{2+}]^{m-1}[Cl^-]^n) \\ &= [Ni^{2+}]\alpha_{Ni(Cl)} \end{aligned} \quad (3)$$

where $\beta_{m,n}$ denotes the overall formation constant of

1) L. G. Sillén and A. E. Martell, "Stability Constants," 2nd. Ed., Chem. Soc., London (1964).

2) K. A. Burkov, L. S. Lilič, and L. G. Sillén, *Acta Chem. Scand.*, **19**, 14 (1965).

3) J. Shanker and B. C. De Souza, *Aust. J. Chem.*, **16**, 1119 (1963).

4) D. D. Perrin, *J. Chem. Soc.*, **1964**, 3644.

the complex $Ni_mCl_n^{(2m-n)+}$ and $\alpha_{Ni(Cl)}$ the side reaction coefficient of nickel ion with respect to chloride ions.

If we define $*\beta^\circ_{p,q}$ by

$$*\beta^\circ_{p,q} = [H^+]^p \sum_r [Ni_q(OH)_pCl_r^{(2q-p-r)+}]/[Ni^{2+}]^q \quad (4)$$

$*\beta^\circ_{p,q}$ is related to $*\beta^\circ_{p,q,r}$ through the equation

$$*\beta^\circ_{p,q} = \sum_r *\beta^\circ_{p,q,r}[Cl^-]^r \quad (5)$$

If we use $[Ni^{2+}]_f$, insted of $[Ni^{2+}]$ in Eq. (4), the conditional equilibrium constant $*\beta_{p,q}$ is given by

$$*\beta_{p,q} = [H^+]^p \sum_r [Ni_q(OH)_pCl_r^{(2q-p-r)+}]/[Ni^{2+}]_f^q = \alpha_{Ni(Cl)}^{-q} \sum_r *\beta^\circ_{p,q,r}[Cl^-]^r \quad (6)$$

$*\beta_{p,q}$ will be a constant in the whole range of the nickel concentrations provided that the concentration of chloride ions remains practically unchanged and that only the mononuclear chloro complexes ($m=1$) are formed.

Symbols;

- h Hydrogen ion concentration at equilibrium.
- H Analytical excess of hydrogen ions$=[Cl^-]-2B-[Na^+]$.
- B Total concentration of nickel.
- b Concentration of unhydrolyzed nickel ions.
- Z Average number of hydrogen ions set free per nickel atom$=(h-H-K_wh^{-1})/B$.
- p Number of OH groups bound to hydrolyzed species.
- q Number of nickel atoms bound to hydrolyzed species.
- r Number of chlorine atoms bound to hydrolyzed species.
- $*\beta_{p,q}$ Conditional equilibrium constant of the hydrolytic reaction of nickel ion, defined by Eq. (6).
- [ ] Concentration.
- E Emf.

Method of Measurement

Titration procedures are similar to those adopted in other systems in which cations are very weak acids and solubilities of metal hydroxides are very low.[5,6] Thus, a test solution containing nickel hydroxide precipitates was filtered, and the clear solution was titrated with an acid solution at constant B. The studied range of B values was from 0.0145 M to 1.000 M. Sodium chloride was used as an ionic medium and the total concentration of chloride ions was kept constant (3M).

Titration was performed under an atmosphere of nitrogen, which was free from carbon dioxide and was pre-equilibrated with the solvent.

The hydrogen ion concentration h was measured by means of the cell

$$\text{Ref}\,|\,\text{Solution}\,|\,\text{GE} \quad (A)$$

where GE denotes a glass electrode and Ref the reference half-cell (B):

$$\text{Ag-AgCl}\,|\,\text{3M NaCl saturated with AgCl}\,|\,\text{3M NaCl}\,| \quad (B)$$

The emf of cell (A) can be written at 25°C as

$$E = E^{\circ\prime} + 59.15 \log h + E_j \quad (7)$$

constant activity coefficient of hydrogen ions being assumed. Since pH range studied is 6—7.7, the liquid junction potential E_j is practically independent of the hydrogen ion concentration at constant concentration of total nickel and chloride ions. Thus, Eq. (7) can be rewritten in a simpler form as

$$E = E^\circ + 59.15 \log h \quad (8)$$

and E°, a constant, is determined by means of the Gran plot[7] at each titration procedure.

The average number of OH groups bound to hydrolyzed species, Z, is obtained as

$$Z = \frac{\sum_p\sum_q\sum_r p*\beta^\circ_{p,q,r}[Ni^{2+}]^q[H^+]^{-p}[Cl^-]^r}{[Ni^{2+}] + \sum_m\sum_n m\beta_{m,n}[Ni^{2+}]^m[Cl^-]^n + \sum_p\sum_q\sum_r q*\beta^\circ_{p,q,r}[Ni^{2+}]^q[H^+]^{-p}[Cl^-]^r} = \frac{\sum_p\sum_q p*\beta_{p,q}[Ni^{2+}]_f^q[H^+]^{-p}}{[Ni^{2+}]_f + \sum_p\sum_q q*\beta_{p,q}[Ni^{2+}]_f^q[H^+]^{-p}} = \frac{h - H - K_wh^{-1}}{B} \quad (9)$$

Experimental

Reagents. *Sodium chloride* (reagent grade, E. Merck Co.) was mixed with a small amount of water and hydrochloric acid and the slurry was dried and finally ignited at about 500°C in an electric oven.

Nickel chloride (reagent grade, E. Merck Co.) was recrystallized from water by addition of dried HCl gas and crystals were washed with hydrochloric acid solution. The crystals were then dried in a desiccator over potassium hydroxide pellets *in vacuo*. The crystals were dissolved in distilled water in order to prepare a stock solution of nickel chloride. pH of the stock solution was about 3.

Other chemicals were prepared by methods described elsewhere.[2,5,6]

Apparatus. *Glass electrodes*: Beckman (No. 40498) glass electrodes were used in combination with *a Radiometer PHM 4 (Copenhagen)*.

Silver-silver chloride electrodes set in *the "Wilhelm" type of half-cell*[8] were prepared according to Brown.[9]

Preparation of Test Solution. Test solutions containing hydrolyzed nickel species were prepared by means of two different methods.

(1) Thallium(I) perchlorate solution, prepared from thallium carbonate and perchloric acids, was electrolyzed in a cell in which the cathode of platinum gauze was separated from the anodic platinum foil with a sintered glass membrane. Metallic thallium was deposited on the cathode by electrolysis in an atmosphere of nitrogen. After washing thoroughly the cathode and the electrolytic cell with distilled water in a nitrogen atmosphere, the electrode and the cell vessel were dried with the stream of dried nitrogen. Slightly acid nickel

6) H. Ohtaki, *Inorg. Chem.*, **7**, 1205 (1968).
7) G. Gran, *Analyst*, **77**, 661 (1952).
8) W. Forsling, S. Hietanen, and L. G. Sillén, *Acta Chem. Scand.*, **6**, 901 (1952).
9) A. S. Brown, *J. Amer. Chem. Soc.*, **56**, 646 (1934).

chloride in 3M sodium chloride medium was then introduced, and oxygen gas was bubbled at the platinum gause electrode. With dissolution of metallic thallium by oxidation, pH of the solution increased to form nickel hydroxide precipitates. Thallium(I) ions thus formed were also precipitated as chloride. The amount of thallium ions remaining in the solution was so small and the thallium ions are such weak acid that the effect of thallium ions remaining in the medium on emf measurements is negligible. Nickel hydroxide and thallium chloride precipitates were filtered off through G4 glass filters with layers of finely divided platinum powder. Thus, a clear solution was obtained and used for titration.

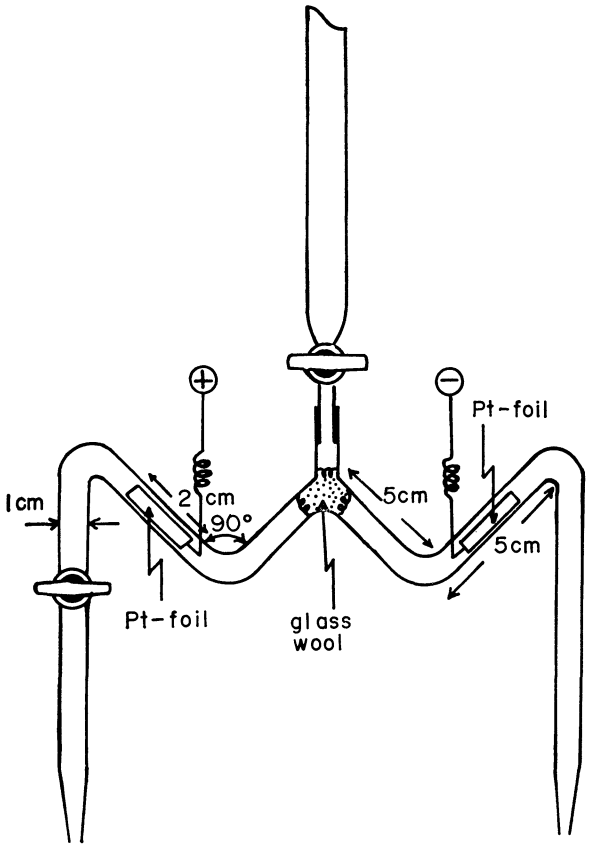

Fig. 1. Apparatus for preparation of sodium hydroxide from sodium chloride solution by electrolysis.

(2) Into the nickel chlodide solution was added a sodium hydroxide solution, prepared by electrolysis of 3M sodium chloride solution with an apparatus depicted in Fig. 1. From a buret 3M sodium chloride solution was flowed and a part of the solution was decomposed at the platinum foil cathode to sodium hydroxide and hydrogen by electrolysis. The solution was introduced to a nickel chloride solution to prepare nickel hydroxide precipitates. The flow rate of the solution was controlled by means of stop cocks. Contact of sodium hydroxide solution with glass wall of the apparatus was short (2–3 seconds), and the dissolution of any significant impurity from the apparatus could be avoided. Filtration and introduction of the solution to a titration vessel were performed in the same way as described.[5,6]

The total concentration of nickel in the test solution was determined gravimetrically by means of electrolysis and weighing as metallic nickel when the concentration of nickel was high, or as nickel dimethylglyoximate when the concentration was low.

A clear solution was titrated with an acid solution at the constant total concentration of nickel at 25.00±0.01°C in a paraffin oil thermostat, placed in a room thermostated at 25±0.2°C. Emf measurements were performed with an accuracy of ±0.1 mV at each point of measurements.

In supplementary titrations, made for testing the reversibility of the hydrolytic reaction of nickel ions, pH of a test solution was varied in the opposite direction of that in the titration described above. In these titrations a clear solution in which nickel hydroxo complexes had been present was diluted by addition of 3M sodium chloride. Thus, the total concentration of nickel *decreased*, whereas pH of the solution *increased*.

Results and Discussion

Values of Z and $-\log h$ for each value of B are represented in Fig. 2 together with those obtained by supplementary titration.

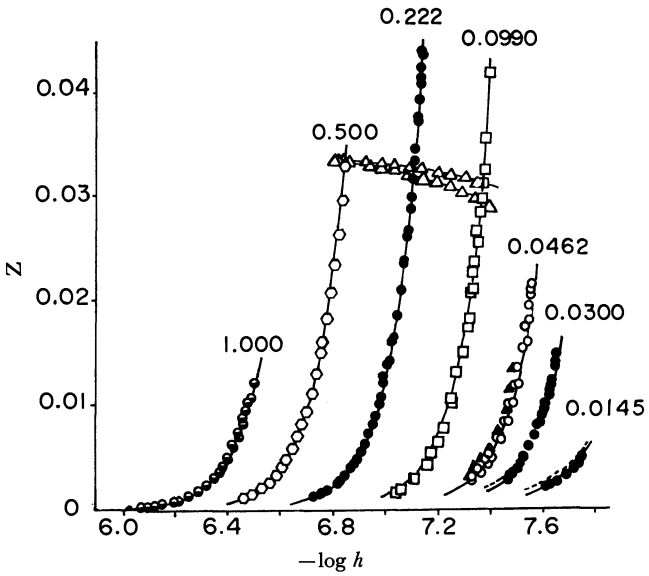

Fig. 2. Z *vs.* $-\log h$. Solid lines are those calculated with values of $\log {}^*\beta_{4,4} = -28.55$, $\log {}^*\beta_{1,1} = -10.5$, and $\log {}^*\beta_{1,2} = -10.5$. Broken lines show curves calculated with values of $\log {}^*\beta_{4,4} = -28.55$ and $\log {}^*\beta_{1,1} = -10.3$.

The concentration of hydrogen ion set free by hydrolysis, BZ, is given by the general formula as

$$BZ = \sum_p \sum_q \sum_r p {}^*\beta^{\circ}_{p,q,r} [Ni^{2+}]^q [H^+]^{-p} [Cl^-]^r$$
$$= \sum_p \sum_q p {}^*\beta_{p,q} [Ni^{2+}]_f^q [H^+]^{-p} = \sum_p \sum_q p {}^*\beta_{p,q} b^q h^{-p} \quad (10)$$

In cases where the maximum value of Z is very low, we may, without introduction of any appreciable error, simplify the preliminary calculations by employing the approximation

$$[Ni^{2+}]_f = b \simeq B \quad (11)$$

Substituting this relation into Eq. (10) and rearranging, we obtain

$$Z = \sum_p p K_p h^{-p} \quad (12)$$

where

$$K_p = \sum_q {}^*\beta_{p,q} B^{q-1} \quad (13)$$

Under an assumption of the constant chloride ion concentration, ${}^*\beta_{p,q}$ may become constant and thus K_p may also be given as a constant for a constant B.

Curves of Z plotted against $-\log h$ fitted very well

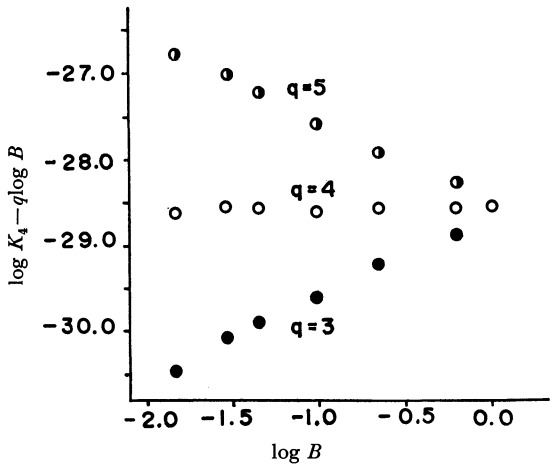

Fig. 3. Variations of log $K_4 - q\log B$ with log B at various q.

with a normalized curve, $y=px^p=f(\log x)$ with $p=4$. Values of K_4 thus found at each B were plotted against log B with various values of q. Results are shown in Fig. 3. It is seen that values of log $K_4 - q \log B$ are independent of B at $q=4$. Thus, the composition of the main species formed by hydrolysis of nickel ion and the equilibrium constant, $*\beta_{4,4}$, is evaluated. The composition of the main species may be written as $Ni_4(OH)_4Cl_r^{(4-r)+}$, although the value of r is not known.

Existence of other minor complexes was examined from data of low Z values, where small discrepancies of experimental results from the normalized curves were observed.

If the composition of minor species is written as $Ni_{q'}(OH)_{p'}Cl_{r'}^{(2q'-p'-r')+}$, Eq. (12) may be written as

$$Z = 4K_4h^{-4} + \sum_{p'} p'K_{p'}h^{-p'} \tag{14}$$

or

$$Zh^4 - 4K_4 = \sum_{p'} p'K_{p'}h^{(4-p')} \tag{15}$$

If we plot log (Zh^4-4K_4) against log h, all points would fall on a straight line with a slope of $4-p'$, provided that only homoligandic complexes are formed. The plot gave a straight line with a slope of 3, *viz.*, $p'=1$. Values of homoligandic constant K_1 at various B were plotted against log B, and are shown in Fig. 4. At $q'=1$ values of log $K_1 - \log B$ are almost independent of B, but a slight systematic deviation is observed, which can be interpreted in terms of formation of another homoligandic complex with $q'=2$, *i.e.*, $Ni_2(OH)Cl_{r''}^{(3-r'')+}$.

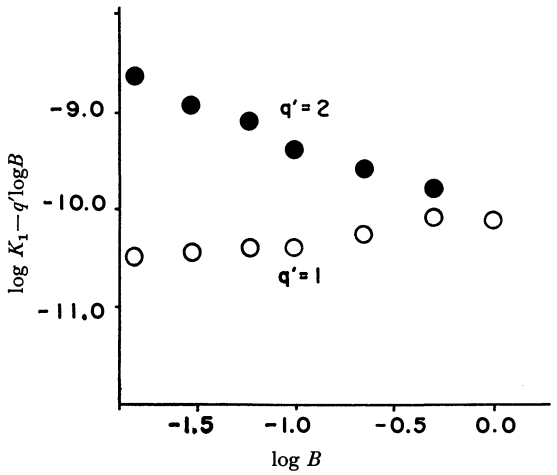

Fig. 4. Variations of log $K_1 - q'$ log B with log B at various q'.

This shows that the composition of the predominant species formed by the hydrolytic reaction of nickel ion is $Ni_4(OH)_4Cl_r$, and complexes $Ni(OH)Cl_{r'}$, and $Ni_2(OH)Cl_{r''}$ may also be formed as minor components, although no information was available for values of r.

In order to obtain more reliable information of compositions of complexes and values of $*\beta_{p,q}$, the totality of the experimental data was compared with the normalized projection maps.[10]

The computation procedure was as follows. Values of log B and $\frac{3}{4}\log B - \log h$ were calculated by graphical interpolation of Z *vs.* $-\log h$ curves at constant Z. Plots of the log B values against $\frac{3}{4}\log B - \log h$, covering the Z range from 0.002 to 0.035, have been compared with a graph of normalized functions, log $B^*(X)_{z,\gamma}$, where

$$\log B^* = \log B + \frac{1}{3}\log *\beta_{4,4} - \frac{4}{3}\log *\beta_{1,1} \tag{16}$$

$$X = \frac{3}{4}\log B - \log h + \frac{1}{4}\log *\beta_{4,4} \tag{17}$$

and

$$\log \gamma = \log *\beta_{1,2} + \frac{1}{3}(\log *\beta_{1,1} - \log *\beta_{4,4}) \tag{18}$$

The log $B^*(X)_{z,\gamma}$ functions are based on the fundamental equations

$$B = b(1 + *\beta_{1,1}h^{-1} + 2*\beta_{1,2}bh^{-1} + 4*\beta_{4,4}b^3h^{-4}) \tag{19}$$

and

$$Z = \frac{*\beta_{1,1}h^{-1} + *\beta_{1,2}bh^{-1} + 4*\beta_{4,4}b^3h^{-4}}{1 + *\beta_{1,1}h^{-1} + 2*\beta_{1,2}bh^{-1} + 4*\beta_{4,4}b^3h^{-4}} \tag{20}$$

with the assumption that complexes $Ni(OH)Cl_{r'}^{(1-r')+}$, $Ni_2(OH)Cl_{r''}^{(3-r'')+}$, and $Ni_4(OH)_4Cl_r^{(4-r)+}$ are formed.

Introducing new variables

$$\eta = *\beta_{1,1}h^{-1} \text{ and } \xi = *\beta_{4,4}^{1/3} \cdot *\beta_{1,1}^{-1/3} \cdot h^{-1}b \tag{21}$$

two of the three constants can be eliminated from Eqs. (19) and (20) which then will take the form

$$B^* = \xi\eta^{-1}(1 + \eta + 2\gamma\xi + 4\xi^3\eta) \tag{22}$$

$$Z = \frac{\eta + \gamma\xi + 4\xi^3\eta}{1 + \eta + 2\gamma\xi + 4\xi^3\eta} \tag{23}$$

Eqs. (22) and (23) show that when Z and γ are kept constant, η becomes a function of only ξ, consequently log $B^*(X)_{z,\gamma} = \log B^*(\frac{3}{4}\log B^* + \log \eta)_{z,\gamma}$ can be evaluated by assigning a series of values of ξ. If no $Ni_2(OH)Cl_{r''}^{(3-r'')+}$ complex forms, experimental data would better fit normalized curves with $\gamma=0$ than those calculated with any finite value of γ.

Solid lines in Fig. 5 show calculated curves with values of log $*\beta_{4,4} = -28.55$, log $*\beta_{1,1} = -10.5$, and log $*\beta_{1,2} = -10.5$. Broken lines show "best fitted" curves with the assumption $*\beta_{1,2}=0$. The former set of curves clearly gave better results than the latter.

Finally the data have been treated by the generalized least squares method with a computer program, "LETAGROP," in which the set of $*\beta_{1,1}$, $*\beta_{1,2}$, and

10) L. G. Sillén, *Acta Chem. Scand.*, **10**, 803 (1956).

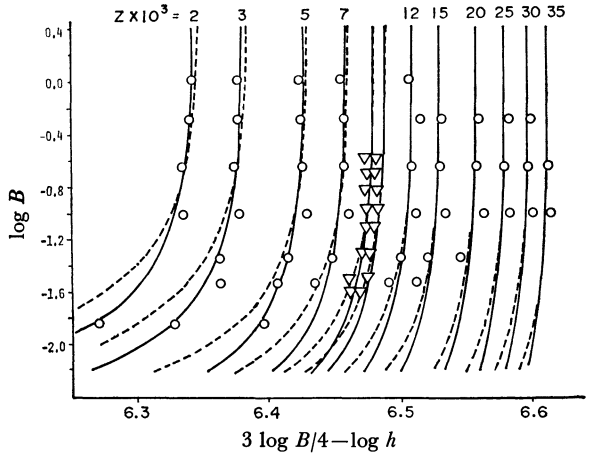

Fig. 5. Comparison of data at constant Z with normalized projection maps. Solid lines are calculated normalized projection maps with values given in (D) and broken lines are calculated "best fitted" curves with assumption of formation of only the $Ni_4(OH)_4$ and NiOH complexes.

$*\beta_{4,4}$ values were chosen to make the error square sum, $(U=\sum(Z-Z_{calc})^2)$ a minimum. Z_{calc} denotes the value of the function (20) for a particular set of the constants. The values of log $*\beta_{1,1}$, log $*\beta_{1,2}$, and log $*\beta_{4,4}$ thus calculated are

$$\left.\begin{aligned}\log *\beta_{4,4} &= -28.55 \pm 0.02\\ \log *\beta_{1,1} &= -10.5 \pm 0.1\\ \log *\beta_{1,2} &= -10.5 \pm 0.5\end{aligned}\right\} \quad (C)$$

Values of $*\beta_{p,q}$ obtained by Burkov *et al.*[2] in 3 M sodium perchlorate medium were log $*\beta_{4,4}=-27.37\pm 0.02$ and log $*\beta_{1,2}\approx -10$. Recent studies of hydrolytic reactions of nickel ion showed that log $*\beta_{1,1}=-10.12$[4] (at $\mu=0.04$, 25°C) and -10.01[3] (at $\mu=1.0$, 28°C). Funahashi and Tanaka[11] evaluated the formation constant of the $NiOH^+$ complex to be log $*\beta_{1,1}=-9.7$ (at $\mu=0.1$, 25°C) by means of a kinetic method. Agreements of our data with these results may support the formation of the $NiOH^+$ complex in 3 M sodium chloride medium, although the number of chloride atoms which may be contained in the complex is not evaluated.

Formation of chloro complexes must be taken into consideration in a chloride medium. Many workers have reported that nickel ions form the $NiCl^+$ complex[12-18] and even $NiCl_2$ in aqueous solutions. The formation constant of the latter complex is so small and even erroneous that only the former complex is taken into account in the following discussion.

If we take the value of log $\beta_{1,1}$ for the $NiCl^+$ complex as -0.55 (a simple average of spread values of log $\beta_{1,1}$ from -0.24[15] to -0.85[17]), log $\alpha_{Ni(Cl)}$ changes by 0.03 when the concentration of nickel ion varies from 0.0145 to 1.0 M, *viz.*, the value of log $*\beta_{4,4}$ possibly changes by about 0.1_2. Since about 13% of the decrease of the concentration of free chloride ions may be estimated in the solution of $B=1.0$, the conditional equilibrium constant for the formation of $Ni_4(OH)_4Cl_r^{(4-r)+}$ may decrease by 0.06 in the logarithmic unit for contribution of each chloride ion in the complex.

Calculations of conditional equilibrium constants at each B were performed by means of the "LETAGROP" computation, but no systematic trend of values of $*\beta_{p,q}$ was found. Thus, we finally propose the values of the equilibrium constants of the complex formation as follows.

$$\left.\begin{aligned}\log *\beta_{4,4} &= -28.5_5 \pm 0.1_0\\ \log *\beta_{1,1} &\leq -10.5\\ \log *\beta_{1,2} &\leq -10.5\end{aligned}\right\} \quad (D)$$

The maximum Z value at each B increases with decreasing h and then decreases after passing through the maximum at about $B=0.2$. The decrease of Z_{max} with decreasing h may be interpreted in terms of the formation of $Ni(OH)_2$ as the precipitate. If we denote the hydrogen ion concentration at Z_{max} as h_{max}, the following equation can be derived at a given B;

$$Z_{max} \simeq 4*\beta_{4,4}B^3h_{max}^{-4} \quad (24)$$

The solubility product $*K^s_{Ni(OH)_2}$ is defined as

$$*K^s_{Ni(OH)_2} = [Ni^{2+}][H^+]^{-2} \quad (25)$$

Insertion of Eq. (25) into Eq. (24) and rearrangement lead to

$$Z_{max} \simeq 4*\beta_{4,4}(*K^s_{Ni(OH)_2}\cdot\alpha_{Ni(Cl)})^3h_{max}^2 \quad (26)$$

Thus, Z_{max} may decrease with decreasing h_{max}, provided that $\alpha_{Ni(Cl)}$ remains practically unchanged.

On the other hand, the decrease of Z_{max} with increasing h_{max} in the region of higher B may be interpreted in terms of the formation of Ni(OH)Cl as the precipitate. With a similar method of calculation as that described above, the solubility product of the Ni(OH)Cl precipitate being defined as

$$*K^s_{Ni(OH)Cl} = [Ni^{2+}][H^+]^{-1}[Cl^-] \quad (27)$$

and the constant $[Cl^-]$ being assumed, the following equation can be derived;

$$Z_{max} \simeq 4*\beta_{4,4}(*K^s_{Ni(OH)Cl}\cdot\alpha_{Ni(Cl)})^3[Cl^-]^{-3}h_{max}^{-1} \quad (28)$$

and thus, Z_{max} may decrease with increasing h_{max}.

The authors wish to thank the late Professor Lars Gunnar Sillén for his valuable advice.

Solvolysis of Organic Phosphates. IV.[1] 3-Pyridyl and 8-Quinolyl Phosphates as Effected by the Presence of Metal Ions

Yukito MURAKAMI and Junzo SUNAMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received December 26, 1970)

Influence of nickel(II), copper(II), and thorium(IV) ions on the hydrolysis of 3-pyridyl and 8-quinolyl phosphates was investigated at $\mu=0.10$ in a lower pH region. The reaction in the presence of the bivalent metal ions followed apparent first-order kinetics with respect to the phosphates in homogeneous phase. The copper ion showed a positive catalytic effect only on the hydrolysis of 8-quinolyl phosphate, and such effect increased markedly as pH was raised. The nickel ion, however, did not show any significant effect on the hydrolysis of both phosphates. The requisites for effective catalysis of bivalent metals have been postulated previously: *(1) preliminary chelate formation,* and *(2) transitional chelate formation.* Accordingly, complex formation of the present phosphates with copper(II) and nickel(II) was studied by means of potentiometric measurements. The results strongly suggest the importance of (1) for yielding catalytic efficiency. The presence of the thorium ion resulted in a profound acceleration of hydrolysis of both phosphates in a relatively lower temperature range. The reaction rate did not follow the simple kinetic law although the reaction system was kept homogeneous under the present experimental conditions. The complex formation with the phosphate moiety, which would provide effective charge neutralization for the substrate, is most likely the necessary cause for the thorium-catalysis. Plausible reaction mechanisms and the corresponding potential energy correlations were postulated for the present catalysis.

The influence of metal ions on the hydrolysis reactions of phosphate monoesters has been extensively studied up to the present time in connection with the biochemical interest. Among such studies, some efforts have been made by a limited number of research groups to clarify the reaction mechanisms of catalysis which has possibly arisen through the complex-forming interaction of metal ions with organic phosphates in the transition state.

In our previous work,[2,3] the hydrolysis of pyridylmethyl phosphates was investigated in the presence of bivalent and polyvalent metal ions. Of the bivalent metal ions, only the copper ion promoted the hydrolysis rate of 2-pyridylmethyl phosphate to a considerable extent in a moderate pH range. Its presence, however, did not cause any rate enhancement for the hydrolysis of 3- and 4-pyridylmethyl phosphates. We have proposed from these studies[2-4] that the two successive interactions are required for bivalent metals to yield catalytic efficiency: (1) A metal ion must demonstrate a significant chelate-forming affinity for an organic phosphate. Both the neighboring functional group in the leaving alcohol group (*e.g.*, the pyridyl nitrogen for 2-pyridylmethyl phosphate and the carboxyl group for salicyl phosphate) and the phosphate group, in which one of the oxygen atoms may act as a donor atom, may participate in such coordination interaction. This is the requirement of the preliminary chelate formation. (2) A metal ion must demonstrate an appropriate affinity for the ester oxygen in the transition state, so that the chelate ring involving both the neighboring functional group and the ester oxygen is to be formed in the excited state. This affinity can be judged from the chelating tendency of a metal ion with the alcohol, a hydrolysis product. This may be called the requirement of the transitional chelate formation.

Among polyvalent metal ions, the thorium ion accelerated the hydrolysis of pyridylmethyl phosphates, irrespective of the difference in isomeric structures, to a remarkable extent. However, we failed to find a satisfactory explanation for the profound catalysis although the primary interaction with the phosphate moiety seems to result in such rate enhancement.

The present work as well as the subsequent investigations has been designed to accumulate kinetic and mechanistic data for the confirmation of the above requisites established for the bivalent metal catalysis.

We also intend to investigate the role of polyvalent metal ions, particularly the thorium ion, in the hydrolysis reactions from the mechanistic viewpoint. In this work, the hydrolysis of 3-pyridyl and 8-quinolyl phosphates was studied in the presence of copper(II), nickel(II), and thorium(IV) ions in aqueous media at various temperatures. The complex-forming interaction between these metal ions and the phosphates has also been investigated to obtain key information on the catalytic reaction mechanism.

Experimental

Materials. Preparation of 3-pyridyl and 8-quinolyl phosphates has been described in our previous paper.[5] Other materials of analytical grade were commercially obtained and used without further purification. The stock solutions of metal ions were prepared from their nitrate salts. These solutions were standardized by means of the usual chelatometric titration.

Kinetic Measurements. The apparatus and experimental procedures were essentially the same as those employed pre-

viously.[1c,2,3] In the case of the thorium-ion-catalyzed reactions, the procedure for kinetic measurements had to be slightly modified because of its extreme rate enhancement relative to the spontaneous hydrolysis. Two different aqueous solutions were initially prepared, the one containing the substrate and the other the catalyst species. A 50-m*l* solution which contained the phosphate ester, an inorganic salt for maintaining the ionic strength constant, and an appropriate amount of acid or base for adjusting the initial pH of an experimental solution was placed in a thermostated reaction cell. Another 50-m*l* solution containing a specified amount of the thorium ion and perchloric acid for minimizing a partial hydrolysis of the metal ion was placed in a thermostated bath controlled at a desired temperature. After both solutions attained an equilibrated temperature, the catalyst solution was quickly transferred into the reaction cell. The resulting solution was so controlled that the initial concentration of the substrate and the ionic strength were maintained at 2×10^{-3}M and 0.10, respectively. The subsequent procedure for kinetic measurements was essentially the same as those described previously.[2,3]

Potentiometric Measurements. A jacketed glass cell of approximately 100-m*l* capacity, which was equipped with a magnetic stirrer, nitrogen inlet and outlet tubes, a microburet delivery tube and electrodes, was adopted. A set of a Beckman glass electrode No. 39099 and a Beckman reference electrode No. 39170 was used in combination with a Horiba-Hitachi Model P pH meter for measurements at 25.0±0.1°C and the ionic strength of 0.10 (KNO_3). The initial concentration of the phosphate was maintained at 2.0×10^{-3}M, while those of the metal ions were varied in a range 1.0—2.0×10^{-3}M. Each titration was carried out under a nitrogen atomosphere and checked by duplicate or triplicate runs. The method of establishing $-\log[H^+]$ values at the constant ionic stength was the same as those employed in a series of our previous studies.

Mathematical Treatment of Equilibrium Data

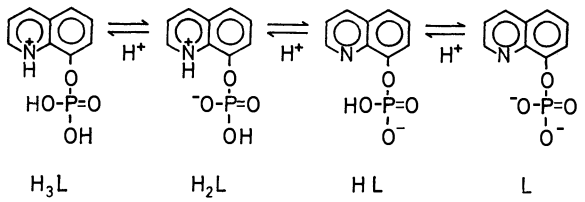
Since 8-quinolyl phosphate and 3-pyridyl phosphate are tribasic acids, the acid dissociation constants are defined as follows:

$$K_{H_3L} = \frac{[H_2L][H^+]}{[H_3L^+]} \quad (1)$$

$$K_{H_2L} = \frac{[HL^-][H^+]}{[H_2L]} \quad (2)$$

$$K_{HL} = \frac{[L^{2-}][H^+]}{[HL^-]} \quad (3)$$

where H_3L^+, H_2L, HL^-, and L^{2-} refer to monocation, neutral zwitterion, monoanion, and dianion, respectively. As an example, the acid diassociation processes for 8-quinolyl phosphate are shown in Scheme 1.



Scheme 1

These phosphate molecules have two coordination sites, an aromatic nitrogen and a phosphate group. On the basis of the results and discussion for the complex-forming interaction of 2-pyridylmethyl phosphate with various bivalent metal ions,[6] we consider that the following reaction scheme may suffice to cover the probable solution equilibria responsible for the present experimental conditions:

$$M^{2+} + L^{2-} \rightleftharpoons ML$$

$$K_1 = \frac{[ML]}{[M^{2+}][L^{2-}]} \quad (4)$$

$$M^{2+} + H^+ + L^{2-} \rightleftharpoons M(HL)^+$$

$$K_a = \frac{[M(HL)^+]}{[M^{2+}][H^+][L^{2-}]} \quad (5)$$

If these two solution equilibria take place to a significant extent, the following relationships are derived under the consideration of ionic neutrality and mass balance for ligand and metal:

$$T_M = [M^{2+}] + [ML] + [M(HL)^+] \quad (6)$$

$$T_L = [L^{2+}] + [HL^-] + [H_2L] + [H_3L^+] + [ML] + [M(HL)^+] \quad (7)$$

$$T_{OH} + [H^+] + [H_3L^+] + 2[M^{2+}] + [M(HL)^+] = [OH^-] + 2[L^{2-}] + [HL^-] + 2T_M + T_H \quad (8)$$

Then, the following two equations are derived from Eqs. (6), (7), and (8) in conjunction with Eqs. (1), (2), and (3) for the acid dissociation constants:

$$RS[L^{2-}]^2 + (T_MS + R - T_LS)[L^{2-}] - T_L = 0 \quad (9)$$

$$QS[L^{2-}]^2 + (PS + Q - T_MJ)[L^{2-}] + P = 0 \quad (10)$$

where

$$R = \frac{[H^+]^3}{K_{H_3L}K_{H_2L}K_{HL}} + \frac{[H^+]^2}{K_{H_2L}K_{HL}} + \frac{[H^+]}{K_{HL}} + 1$$

$$Q = \frac{[H^+]}{K_{HL}}\left(\frac{[H^+]^2}{K_{H_3L}K_{H_2L}} - 1\right) - 2$$

$$S = K_1 + K_a[H^+]$$

$$J = 2K_1 + K_a[H^+]$$

$$P = T_{OH} + [H^+] - [OH^-] - T_H$$

T_L, T_M, T_{OH}, and T_H refer to the total concentrations of ligand, metal ion, base, and acid added to the system, respectively. Since the concentration of the ligand dianion $[L^{2-}]$ can not become zero, the following relation is obtained through division of Eq. (10) by Eq. (9):

$$[L^{2-}] = \frac{T_M(T_LS + T_LK_1 - PS) - (PR + T_LQ)}{(PR + T_LQ)S} \quad (11)$$

Equations (9) and (10) are nonlinear with respect to equilibrium constants K_1 and K_a. In order to obtain the unknown equilibrium constants cited above, Rubin's method[7] was applied to our present system. An iterative calculation was performed to minimize the residual sum of squares (U)

$$U = \sum_{i=1}^{N}\{T_L(\text{obs})_i - T_L(\text{calc})_i\}^2 \quad (12)$$

until

$$\max_j \left|\frac{A_j^{(1)} - A_j^{(0)}}{A_j^{(0)}}\right| < \varepsilon$$

6) Y. Murakami and M. Takagi, *J. Phys. Chem.*, **72**, 116 (1968).
7) D. I. Rubin, *Chem. Eng. Progr. Symp. Ser.*, **59**, 90 (1963).

holds, where N is the number of observations and the subscript i is the observation-number index; $A_j^{(0)}$ and $A_j^{(1)}$ refer, respectively, to the approximation at one stage and to the next approximation to the jth parameter to be determined in the course of iterative calculation. The ε-value is a convergence criterion preassigned and was set at 1×10^{-4} in the present calculation.

All the calculation processes were programmed by means of the Fortran language for use with a FACOM 230-60 electronic computer of the Computation Center of Kyushu University.[8]

Results

Effects of Copper(II) and Nickel(II) Ions. The hydrolysis reactions of 8-quinolyl and 3-pyridyl phosphates were investigated in the presence of the copper(II) ion and the nickel(II) ion under various conditions. The reaction followed apparent first-order kinetics with respect to the total concentration of unreacted phosphate in homogeneous phase over the whole pH region and the metal concentration range studied. However, the nickel ion did not show any significant effect on the hydrolysis of both phosphates as can be seen in Table 1. On the other hand, the copper ion showed a positive catalytic effect only on the hydrolysis of 8-quinolyl phosphate. Such catalytic efficiency was subjected to a significant pH-dependency as shown in Table 2. The reaction rate increased markedly with the rise of pH-value of the solution. As for the concentration effect on the catalytic efficiency of the copper ion, the observed overall reaction rate was found to be consistent with Eq. (13).

$$k_{obs} = k_{H_2L}X_{H_2L} + k_{H^+}[H^+]X_{H_2L} + k_{Cu}[Cu^{2+}] \qquad (13)$$

where k_{obs} is the observed overall rate constant and X_{H_2L} is the mole fraction of the zwitterion species:

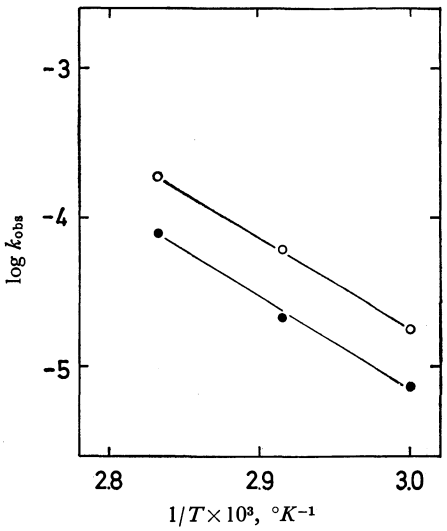

Fig. 1. Arrhenius plots of the first-order reaction rates for the hydrolysis of 8-quinolyl phosphate: ○, copper(II)-catalyzed reaction; ●, spontaneous reaction; rate constant (k_{obs}) in sec^{-1}.

k_{H_2L}, k_{H^+}, and k_{Cu} refer to the specific rate constants for the hydrolysis of zwitterion, acid catalysis, and copper-ion catalysis, respectively. The validity of this equation was checked by varying the T_M/T_E value from 0.2 to 2.0 at a particular pH-value ($-\log[H^+]=2.01\pm0.02$) as listed in Table 2. The k_{Cu} value for the hydrolysis of 8-quinolyl phosphate was estimated at 80°C and at this pH: $k_{Cu}=5.55\times10^{-2}M^{-1}$ sec^{-1}. Figure 1 illustrates the Arrhenius plots for the spontaneous and copper(II)-ion catalyzed reactions measured at 60°, 70°, and 80°C with the T_M/T_E value of 1.0, the $-\log[H^+]$ value being maintained at 2.01 ± 0.02. The temperature-dependence of the catalytic reaction rate has a close resemblance to that of the spontaneous one. Thus, the activation energy for the true catalytic reaction, which corresponds to the third term on the right hand side of Eq. (13), is almost negligible relative to that for the spontaneous reaction.

The presence of the copper(II) ion did not result in

any enhancement of the reaction rate in the hydrolysis of 3-pyridyl phosphate, as seen in Table 3.

Effect of Thorium(IV) Ion. The presence of the thorium(IV) ion resulted in a profound acceleration of the hydrolysis of both phosphates, although the reaction rate did not follow the simple kinetic law. During the course of reaction, formation of any insoluble materials was not detected and a good homogeneous system was maintained. Figure 2 shows the rate plots for the hydrolysis of 3-pyridyl and 8-quinolyl phosphates in terms of the first-order kinetic law under the identical experimental conditions, where the corresponding spontaneous reactions did not proceed to any appreciable extent. The extent of catalytic efficiency in both reactions is nearly the same, and thus the apparent difference in reaction rates in Fig. 2, for example,

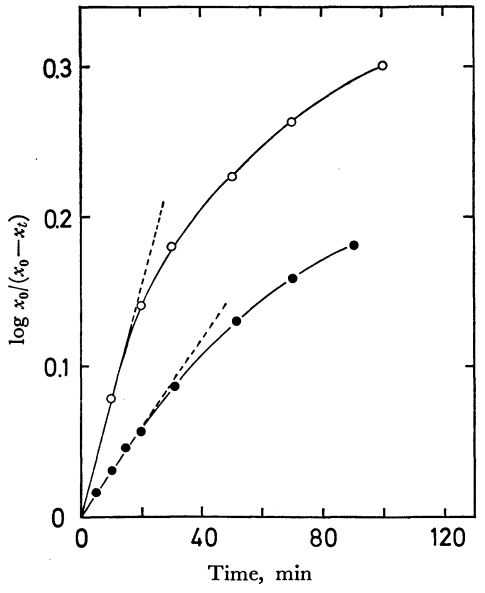

Fig. 2. Rate plots in terms of first-order kinetics for the thorium(IV)-catalyzed hydrolysis of 8-quinolyl phosphate (●) and 3-pyridyl phosphate (○) at 25°C, $-\log[H^+]=1.88$, $T_M/T_E=1.0$, and $\mu=0.10$ ($NaClO_4$). Broken lines stand for the first-order rate relation extrapolated from the initial reaction rate.

can be ascribed to the nature of the leaving alcohol groups. For both phosphates, the catalyzed reactions appear to be largely controlled by concentrations of the hydrogen ion and the thorium ion as well as the reaction temperature as illustrated in Figs. 3 and 4. The increase of these controlling factors, *i.e.*, pH, metal-concentration, and temperature, caused a significant rate enhancement. In these thorium-ion catalysis, the slow but appreciable liberation of proton was always observed before the hydrolysis proceeded to any detectable extent: this became more apparent in lower concentration of the thorium ion at lower temperature. The sluggish formation of some thorium complexes with the substrates appears to be responsible for this phenomenon. The reaction rate in the presence of the thorium ion deviated downward significantly from the first-order plot; this deviation increased as the reaction proceeded further. In order to examine whether the rate deceleration effect is due to the removal of the thorium ion from the reaction system through the complex-formation with the yielded alcohol, 3-pyridinol and 8-quinolinol were added in a half of the equimolar amount of the corresponding substrates into the corresponding reaction systems at the beginning of the reaction. However, the addition of such alcohols did not result in any significant change in reaction rate.

Potentiometric Titration. In order to obtain a

clue to understanding the catalytic mechanism in the hydrolysis of organic phosphates and to examine a correlation between the catalytic efficiency and the complex-forming tendency of metal ions with the phosphates, we have carried out potentiometric measurements of these chelate systems, in which copper(II), nickel(II), and thorium(IV) ions were included, in aqueous media at 25°C and $\mu=0.1$ (KNO_3). An attempt was made to carry out some quantitative measurements and analysis for the thorium chelate system. This was not successful, however, due to the markedly rapid hydrolysis even in a temperature range as low as 10°C. The titration curves for 8-quinolyl phosphate with copper(II) and nickel(II) are shown in Fig. 5, and for 3-pyridyl phosphate with the same metal ions in Fig. 6. Solution equilibria

Fig. 5. were attained shortly after addition of base in a relatively low a-region (a being the degree of neutralization of the ligand). Beyond a certain a-value for each titration of the chelate systems, pH-reading became

unsteady on standing probably because of the hydrolytic tendencies of the metal ions. These non-equilibrated regions are shown in Figs. 5 and 6 by broken lines. The nickel ion obviously exhibited lower complex-forming ability toward the phosphates than the copper ion. The difference is apparent for the 8-quinolyl phosphate systems in particular. The formation of the copper complex is already appreciable in a region below $a=1.0$ while that of the nickel complex is not significant. Stability constants for metal complexes of a 1:1 ratio of ligand to metal and for the corresponding protonated complexes were calculated by means of the computational method described in the preceding section: the results are summarized in Table 4.

TABLE 4. STABILITY CONSTANTS OF METAL COMPLEXES OF SOME HETERO-AROMATIC PHOSPHATES AT 25±0.1°C AND $\mu=0.1$ (KNO_3)[a]

Discussion

Bivalent Metal Catalysis. In earlier papers, the effects of various metal ions on the hydrolysis of pyridylmethyl phosphates[2,3] and of salicyl phosphate[9,10] have been reported. Catalytic mechanism and efficiency for these hydrolysis reactions have been discussed from the viewpoint of complex-forming ability of metal ions at various stages of the reaction process.[2-4] 8-Quinolyl phosphate has a structural similarity to 2-pyridylmethyl phosphate although the former has a more rigid structure due to the presence of fused rings. Therefore, a comparison of the catalytic efficiency of metal ions in these phosphate hydrolyses is particularly interesting.

For the hydrolysis of 2-pyridylmethyl phosphate, only the copper ion was significantly effective among various bivalent metal ions.[2] The hydrolysis of 8-quinolyl phosphate was promoted appreciably with copper(II), but not at all with nickel(II), as shown in Tables 1 and 2. On the other hand, both metal ions were almost ineffective in the hydrolysis of 3-pyridyl phosphate as can be seen in Tables 1 and 3. Stability order among the copper complexes formed with the above three phosphates is in the following sequence (log K_1) with respect to the ligands: 8-quinolyl phosphate>2-pyridylmethyl phosphate>3-pyridyl phosphate. The former two phosphates appear to form a chelate ring for which the hetero-aromatic nitrogen and the terminal phosphate-oxygen act as donor atoms, judging from the magnitude of stability constants for 1:1 complexes.[6] The catalytic efficiency of copper(II) in terms of k_c/k_o, where k_c and k_o refer, respectively, to the overall rate constant for metal-ion-catalyzed hydrolysis and that for the spontaneous reaction, follows the sequence with respect to the phosphates: 8-quinolyl phosphate ($k_c/k_o=8.4\times10^2$; 40°C $-\log[H^+]=3.56$)>2-pyridylmethyl phosphate (1.65; 90°C, 3.67)>3-pyridylmethyl phosphate (0.96; 90°C, 3.49)~4-pyridylmethyl phosphate (1.07; 90°C, 3.59)~3-pyridyl phosphate (1.11; 70°C, 3.82). The latter three phosphates can not form a chelate ring with a metal ion but rather act as unidentate ligands, due to their structural nature. In order to clarify the correlation between the catalytic efficiency and the initial formation of metal chelate species with the substrate, the concentrations of metal species involved in the copper chelate systems, the free metal ion (M^{2+}), the 1:1 complex (ML), and its protonated complex ($M(HL)^+$), were

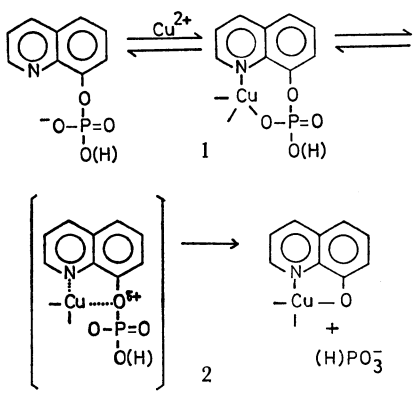
calculated for the systems of 8-quinolyl, 2-pyridylmethyl, and 3-pyridyl phosphates from the data given in Table. 4. The results for the limited pH range of present interest are listed in Table 5. It is apparent that the catalytic efficiency is sensitively affected by the formation of chelate species, ML and $M(HL)^+$. With the increase of concentrations of these chelate species, a significant rate enhancement was observed accordingly for the hydrolyses of 8-quinolyl and 2-pyridylmethyl phosphates. On the other hand, 3-pyridyl phosphate does not secure a catalytic efficiency of similar trend in its hydrolysis due to the lack of chelate-ring formation. The hydrolysis of salicyl phosphate was accelerated by the presence of copper(II) as investigated previously.[10] Since this phosphate was found to form a 1:1 chelate with copper(II) (log $K_1=3.64$ at 10.0°C and $\mu=0.10$), the catalytic mechanism was considered to start with the initial formation of such a complex followed by the intramolecular rearrangement to form a chelate ring with the ester oxygen and the carboxylate group as donor groups in the transition state.[4] On the other hand, the potentiometric study on the interaction of nickel(II) with the present phosphates indicated that this metal ion does not form complexes to any detectable extent in a relatively low pH region. The difference between copper(II) and nickel(II) in such interaction is more apparent with 8-quinolyl phosphate. This is quite consistent with the inert character of nickel(II) for the hydrolysis of the phosphates.

Judging from the results obtained for the bivalent metal catalysis, the following interaction is required at the initial stage of reaction to secure an effective catalytic action of metal ions in the hydrolysis. An organic phosphate must demonstrate a significant chelate-forming tendency toward a metal ion at the initial stage. In order to make this interaction possible, a phosphate molecule must possess at least one more functional group besides the phosphate moiety, which shows a satisfactory donating affinity for a metal ion. In the present case, a hetero-aromatic nitrogen atom is considered to be such an extra donor goup. Both the phosphate group and another functional group must be situated in a molecule, so that a chelate formation becomes favored. The nitrogen atom in 3-pyridyl phosphate is not suitably oriented for chelation with a metal ion in conjunction with the phosphate moiety, while that in 8-quinolyl phosphate

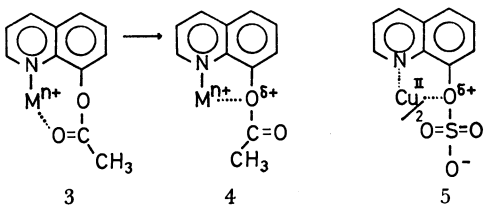


Scheme 2

is placed in a desired manner. Meanwhile, in the course of such a chelate-forming interaction the copper ion demonstrated enough coordination affinity for the nitrogen atom to secure an effective catalytic action. The nickel ion, however, does not seem to have a satisfactory affinity for the nitrogen atom as the stability data indicate. We thus invoke to postulate the reaction mechanism shown in Scheme 2 for an elucidation of significant catalytic effect of copper(II) on the hydrolysis of 8-quinolyl phosphate. This mechanism has a close similarity to that for the hydrolysis of 2-pyridylmethyl phosphate,[2] although the copper ion appears to be less active in the latter reaction.

The mechanism is also understood as an analogy to the intramolecular proton transfer mechanism in the corresponding spontaneous hydrolysis,[1c,2] since an effective metal ion for this type of reaction in general tends to act as a pseudo-proton. Chelate formation would consequently require participation of the nitrogen atom in a manner as shown by **1** and **2** (Scheme 2). If the role of a metal ion is only to neutralize the charge of the substrate as postulated for the magnesium-catalyzed hydrolysis of acyl phosphate,[11] the nitrogen atom would not necessarily be required to participate in coordination with a metal ion. As to the ground state in the copper-catalyzed hydrolysis of 8-quinolyl phosphate, the formation of the initial intermediate **1** is of no doubt judging from the relatively large stability constants listed in Table 4. Although the activation energy for the copper-catalyzed hydrolysis of 8-quinolyl phosphate is negligibly small relative to that for the spontaneous reaction as can be seen in Fig. 1, we can not eliminate the initial process of complex formation prior to the transition state for hydrolysis. Furthermore, a large negative value of apparent activation entropy ($\Delta S^{\ddagger}_{Cu}=-67$ e.u. at 80°C and $-\log[H^+]=2.01\pm0.02$) was obtained for the copper-catalyzed reaction of 8-quinolyl phosphate. This suggests that the activated complex formed in the transition state becomes considerably rigid due to the presence of the metal ion.

A similar mechanistic elucidation has been proposed to account for the copper-catalyzed hydrolysis of 8-actoxyquinoline;[12] the formation of an activated complex, either **3** or **4**, was suggested. With reference to our studies on the phosphate hydrolysis, we rather suggest that the weak interaction forming complex **3** at the initial stage is followed by the formation of complex **4** in the transition state. Hay and Edmonds[13]



11) C. H. Oestreich and M. M. Jones, *Biochem.*, **6**, 1515 (1967).
12) R. H. Barca and H. Freiser, *J. Amer. Chem. Soc.*, **88**, 3744 (1966).
13) R. W. Hay and J. A. G. Edmonds, *J. Chem. Soc., D*, **1967**, 969.

reported that the hydrolysis of 8-hydroxyquinoline sulfate was accelerated by copper(II). They suggested the formation of complex **5** as an activated intermediate.

In case of the catalytic hydrolysis of 2-pyridylmethyl phosphate, the alcohol product (2-pyridylmethanol) forms the stable complexes only with copper(II), among various bivalent ions, upon liberation of the alcohol-proton at 1:1 and 2:1 molar ratios of ligand to metal ion;[14] thus, the copper ion has a profound affinity for the alcohol-oxygen of 2-pyridylmethanol. In the present work, 8-quinolinol, the hydrolysis product of 8-quinolyl phosphate, yields quite stable complexes with copper(II) and nickel(II): log K_1=13.49 for the copper complex and log K_1=11.44 for the nickel complex at 25°C in 50% aqueous dioxane.[15] Therefore, an affinity of these metal ions for the leaving alcohol group does not primarily control the catalytic efficiency in this instance. Rather, interaction of these metal ions with the substrate at the initial stage through pre-equilibrated complex-formation appears to be the necessary cause of the catalysis.

Thorium(IV) Catalysis. Since the extent of catalytic efficiency does not show large structural dependency, as was the case in the hydrolysis of pyridylmethyl phosphates,[3] the catalytic action must involve primarily the interaction between the thorium ion and the phosphate moiety of the substrate. The hydrolysis rate tends to level off after a while as shown in Figs. 3 and 4. Since addition of the alcohols did not result in any significant change in hydrolysis rate as mentioned in the preceding section, the rate retardation does not appear to be due to the produced alcohol but to the liberated inorganic phosphate. Judging from the relatively large stability constants for the thorium complexes formed with inorganic phosphate,[16] the potent interaction of thorium(IV) with the phosphate moiety at the initial stage of reaction and with the liberated inorganic phosphate in hydrolysis is to be expected. We observed the slow but appreciable liberation of proton at the initial stage. This finding definitely indicates the formation of certain thorium complexes in the early stage of reaction.

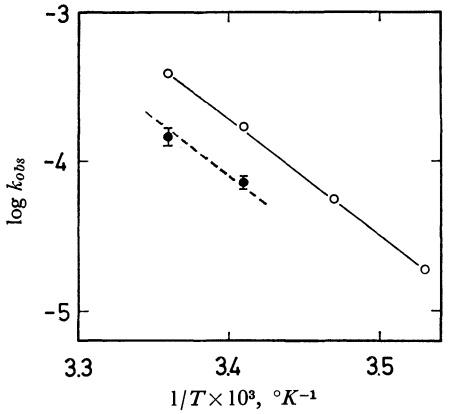


Fig. 7. Arrhenius plots of the apparent first-order reaction rates evaluated at the initial stage for the thorium(IV)-catalyzed hydrolysis of 3-pyridyl phosphate (○) and 8-quinolyl phosphate (●); rate constant (k_{obs}) in sec^{-1}.

Figure 7 shows the temperature dependence of an overall rate constant for the hydrolysis of 3-pyridyl phosphate in the presence of thorium(IV) at $-\log[H^+]=2.0$.[17] An apparent activation energy graphically estimated was 40 cal mol^{-1}. The hydrolysis reaction appears to be almost entirely due to the thorium-ion catalysis, since the spontaneous hydrolysis does not proceed to any detectable extent under these experimental conditions. This activation energy is almost in the same order of magnitude as that for the copper-catalyzed reaction described above. Therefore, a similar mechanistic elucidation may be applied to both cases: the hydrolysis reaction needs to pass through potential energy maxima forming two kinds of reaction intermediates as shown in Fig. 8.

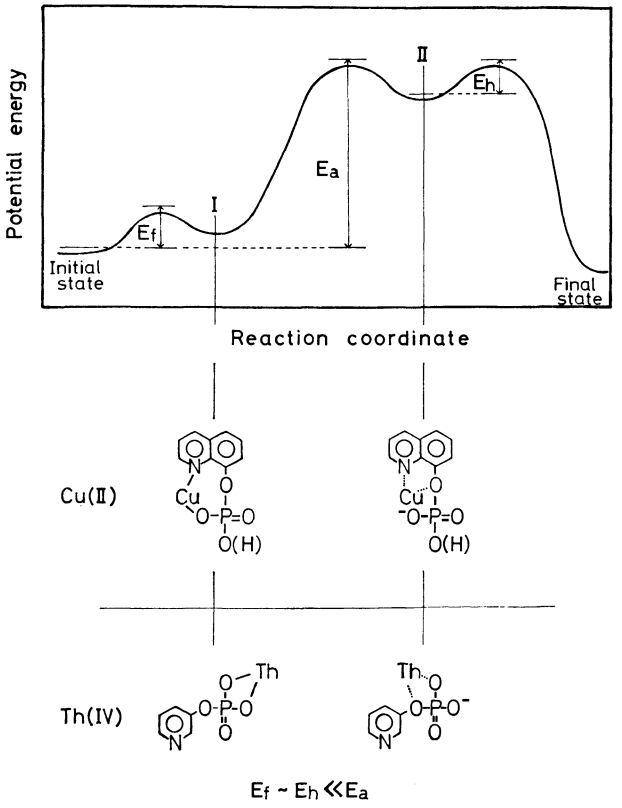

Fig. 8. Schematic representation of reaction mechanisms in terms of potential energy *vs.* reaction coordinate correlation.

In conclusion, the chelate-forming ability is the most important factor for the catalytic efficiency of bivalent metal ions, but this is not necessarily required for the thorium ion. Judging from the relatively large stability constants for the thorium(IV) complexes formed with inorganic phosphate, complex formation with the phosphate moiety is most likely the necessary cause for the catalysis. This interaction would provide effective charge neutralization for the substrate.

17) When the deviation from the first-order plot was observed, the apparent first-order rate constant was evaluated from the initial part of reaction.

Studies of the Solvent Extraction of Potassium by Nitrobenzene in the Presence of Organic or Inorganic Acids

Tadashi IWACHIDO

College of Liberal Arts, Okayama University, Tsushima, Okayama

(Received December 28, 1970)

Aromatic compounds with an acidic group, such as –OH, –SH, –COOH, $-SO_3H$, >NH, >CH, and $\equiv B^-$ (tetraphenylborate) were tested as extracting agents for potassium. The first four acids showed an extractability lower by far than that of the last three. Most inorganic acids exhibited no signs of extraction. Bulky and electron-attracting substituents, such as nitro or halogen group, were proved to be effective in enhancing the extractability. The addition of iodine was also effective. A few kinds of surfactants showed considerably high extractability. Some factors influencing the extraction were speculated upon.

In recent years, the solvent extraction of alkali metals by utilizing ion-pairing agents has attracted growing attention. The first and most extensive works were carried out by researchers engaged in the treatment of radioactive fission products, especially ^{137}Cs. Tetraphenylborate,[1,2] hexanitrodiphenylamine,[3,4] and some phenols[5,6] are typical reagents. Nitrobenzene, a dipolar aprotic solvent with a high dielectric constant, has been frequently used as a solvent of these ion-pairs. However, there has been no systematic explanation of the reasons why these compounds are good for the extraction of alkali metals. This paper will establish some factors affecting potassium extraction by examining a number of organic and inorganic acids and will give some indications on how to obtain good extractions in the future.

Experimental

Reagents. The reagents used were, for the most part, commericial reagents of the purest quality; some were purified when the necessity arose. The amine derivatives were synthesized by a method described in a series of works by Tôei.[7-9] All of the potassium or sodium salts of organic and inorganic acids were dissolved in water to give a 2.5×10^{-2}M aqueous solution. Organic compounds of the acid-form were made up into either a 2.5×10^{-2}M aqueous or a 1.0×10^{-2}M nitrobenzene solution, according to the solubility of the acids. Some of the remaining organic compounds with which a high extractability was obtained were made up into a 10^{-3}M nitrobenzene solution except in a few cases (10^{-4}M).

The pH's of the aqueous solutions were adjusted when necessary by adding a 0.1M citrate buffer (pH 2 and 3), a 0.1M acetate buffer (pH 4 and 5), a 0.1M phosphate buffer (pH 6,7, and 8), or a 0.1M carbonate buffer (pH 9 and 10). The pH of the solution was also adjusted to pH 11 and 12 with 0.1M lithium carbonate and 0.1M lithium hydroxide solutions respectively. The solutions were made so that they all contained equal amounts of lithium ions.

Extraction. Into a 50-m*l* separatory funnel, 1 m*l* of a 0.1M potassium chloride solution was transferred, and then 4 m*l* of a 2.5×10^{-2}M aqueous reagent solution and 5 m*l* of water or a buffer solution were added. The resultant 10 m*l* of a 10^{-2}M potassium solution was gently shaken with 10 m*l* of nitrobenzene for 2 hr at room temperature. Some alterations were made according to the type of stock solution employed, keeping both the molar ratio of potassium to the reagent and the volume ratio of the aqueous to the organic phase at unity. In order to prevent the extraction of lithium ions with the reagent, buffers were not employed except in the cases where reagent anions were expected to hydrolyze to a great extent and where the knowledge of the dependence of the extractability on the pH was necessary for further discussions.

Determination of Potassium. After the extraction mixture had been allowed to stand for half an hour, the nitrobenzene phase was separated and subsequently subjected to atomic absorption spectrophotometry (Nippon Jarrell Ash, Type AA-1). About 0.2×10^{-6}M of potassium was detected.

Results

Extraction Curves. Figure 1 and 2 show the extraction curves obtained with several acids.

With acids having one functional group, the curve will be sigmoidal in shape, but the location of the curve shifts toward a higher or a lower pH region according to the magnitude of the acid dissociation constant and the distribution coefficient of the acid (Fig. 1).

Different types of extraction curves were obtained with acids having two or more functional groups, as is shown in Fig. 2. The form and the location of the curve may be instructive in estimating what kind of ion-pair is dominantly extractable by nitrobenzene.

Extractability. The values of the percent extractions of many kinds of acids are listed in Tables 1 to 9. The results may be summarized as follows: 1). The highest extraction of potassium was attained with the acids of amine derivatives and tetraphenylborate (8-X), as is shown in Tables 4 and 8. The values of the percent extractions of some typical acids, such as phenols, sulfonic acids, and carboxylic acids (Tables 1 to 3), were all less than 0.1, except for some nitro- or halogeno-substituted acids. Such a situation was also encountered with acids of different types, as is shown in Tables 5 to 9.

1,2-Naphthoquinone-4-sulfonic acid	3-V		2.75	0.060
Anthraquinone-2-sulfonic acid	3-VI	−0.38	6.24	0.11

of that which can be observed between 2-naphthyl mercaptan (8-IX) and 1-naphthol (1-XI); this might be due to the hydrolysis of the former in the aqueous phase. Mercaptans (8-VII, -VIII) showed much higher extractabilities than imidazoles (8-IV, -V), although all of them are similar in size.

2) Acids having a bulky nucleus were desirable as extraction agents. This was well shown by sulfonic acids as follows: Anthraquinone-2-sulfonic acid (0.11) >2-naphthalenesulfonic acid (0.035)>benzenesulfonic acid (0.006). The same sequence was also observable with phenols and carboxylic acids (Tables 1 and 2). The insertion of a CH_2 group between the nucleus and the functional group reduced the effect, as was shown with 1-naphthylacetic acid (2-V).

3) The introduction of a bulky, electron-attracting

b) Reagent concentration, 10^{-4}M.

substituent, such as a nitro group or halogen atoms, was highly effective in improving the extractability. In general, the extractability increases rapidly with the number of the substituents. The effect was obvious with phenols (Table 1) and amine derivatives (Table 4).

4) Compounds which have two or more functional groups in a molecule showed a characteristic extraction curve. With phthaleins (6-I, -III) and sulfonphthaleins (6-XI) we obtained a curve with a maximum at a certain pH value, and with alizalinsulfonic acid (5-III), a monotonously-descending curve. In both cases, the percent extraction begins to decrease at a somewhat higher pH value than that to be expected from the first dissociation constant of the acid. The fact may show that, among the possible species existing in the aqueous phase, the neutral ion-pair composed of equimolecular amounts of potassium and the monovalent, reagent anion is dominantly extractable by nitrobenzene. Styphnic acid (5-I) may be a good illustration. Molybdate (9-VIII) and tungstate (9-IX) may be the same.

5) The addition of iodine greatly improved the extractability (Tables 6 and 9). It is well known that the iodine combines with iodide to form a bulky I_3^- anion. Therefore, it seems likely that the KI_3, ion-pair, is extractable by nitrobenzene. For the other cases encountered, a different explanation must be given.

6) A few surfactants showed quite good results, whereas polyvinylsulfate (8-XIII) exhibited no extraction. It must be noted that the separation of the nitrobenzene phase from the aqueous phase becomes increasingly difficult as the amount of the surfactant used increases. This may prevent their practical use.

7) Many kinds of inorganic compounds were tested by varying the pH of the aqueous solution, but only a few were capable of extracting only a small amount of potassium. Bulky, monovalent peroxyacid anions were the best; divalent anions were all incapable of extracting potassium, except for a few compounds which are known as precipitants of potassium.

Extractability and Solubility. In Fig. 3 the solubility of potassium salts in water, S, is plotted against the distribution ratio, q, of these compounds between

Potassium can not be extracted by the following reagent.
IO_3^-, ClO_3^-, BrO_3^-, NO_3^-, NO_2^-, F^-, Cl^-, Br^-, N_3^-, OCN^-, CrO_4^{2-}, SO_4^{2-}, HPO_4^{2-}, SeO_4^{2-}, TeO_4^{2-}, $HAsO_4^{2-}$, CO_3^{2-}, SiF_6^{2-}, $S_2O_7^{2-}$, $S_2O_8^{2-}$, $H_2Sb_2O_7^{2-}$, $B_4O_7^{2-}$, $Cr_2O_7^{2-}$, BO_3^-, BiO_3^-, VO_3^-, AlO_2^-, AsO_2^-, $Fe(CN)_5NO^{2-}$, $Fe(CN)_6^{3-}$, $Fe(CN)_6^{4-}$

the aqueous and nitrobenzene phases. Because of the lack of the solubility data, most of the results obtained can not be shown in this figure. This figure indicates that the solubility is closely related to the extractability. It is of much interest to note that this relation holds not only for nitro compounds, which are similar in chemical constitution to nitrobenzene, the solvent, but also even for inorganic compounds. Such a correlation will be helpful for further extractions.

Discussion

In a previous paper,[10] it has been reported that the extraction of alkali metals with organic acids into nitrobenzene can be well understood by recognizing that nitrobenzene helps the ionic dissociation of the ion-pairs extracted. The paper also has stated that the extractability of the ion-pair increases with the association constant in the aqueous phase and with the dissociation constant in nitrobenzene.

Some chemical constitutional factors influencing such equilibria will be considered below.

Ion Size. Ion association in organic solvents has been extensively studied by Kraus and his collaborators by means of conductometry.[11] As might be expected from a long-range electrostatic force, ion association generally increases with a decrease in the ion size. This may be true for a simple binary electrolyte. The estimation of the energy of charge separation, however, becomes increasingly more difficult as the structural complexity of the anions increases. In general, large anions from loosely associated ion-pairs, and the resultant ion-pairs can easily be dissociated in nitrobenzene.

On the other hand, in an aqueous solution Bjerrum's theory[12] is not always helpful for the study of ion-pairing. According to the theory, the distance of the closest approach of free ions is 3.57 Å for 1:1 electrolytes in water at 25°C. This distance roughly corresponds to that of potassium iodide. Hence, anions which are larger than iodide should not make stable ion-pairs in the aqueous solution. Diamond[13] has indicated the formation of an ion-pair of a different type between bulky and poorly hydrated ions, the distance of the separation being much greater than 3.57 Å. He also suggested that, with regard to such ion-pairs, the hydrogen-bonded structure of water enforces the association of the oppositely-charged ions to minimize the disturbance of the water structure. This type of ion-pairing or the water structure-enforced ion-pairing has a dependence on the distance of charge separation the reverse of that of the ion-pairing of the Bjerrum type. From the above considerations of the behavior of ion-pairs in both the aqueous and nitrobenzene phases, it might be expected that ion-pairing between large organic anions and a potassium cation is facilitated in the aqueous phase and suppressed in the nitrobenzene phase. Accordingly, it can be concluded that large anions favor the extraction.

Steric Factors. In tetraphenylborate (8-X), hexanitrotriphenylmethane (8-VI), and diaryl-substituted amines (Table 4), a formal, negative charge is located on the boron, carbon, and nitrogen atoms respectively, and they are all sterically hindered by large, bulky phenyl groups from coming in contact with the potassium cation. Nitro-group or halogen atoms also help to keep the oppositely-charged ions apart.

On the other hand, anions with no steric hindrance can contact the potassium cation directly, even though they have a residual bulky group. This results in a strong ion-pairing. The fact that the association constant of potassium picrate in nitrobenzene[10] is 1200, about 120-times than that of hexanitrodiphenylamine,[14] can be considered as a good illustration of the effect. Such examples may easily be seen in the remaining compounds.

Charge Dispersal. The concept of charge dispersal has been developed on the basis of the discussion of the acid-base strength. Electrons in an extended π bond are free to move anywhere within the region of the charge cloud; this promotes the delocalization of electrons through a π-molecular orbital system. Thus, the negative charge located at first on the atom from which the hydrogen atom is released as the hydrogen ion is delocalized or dispersed on the whole molecule. As a consequence, the resultant anions are stabilized by the amount corresponding to the delocalization energy. The stabilization of anions will result in the enhancement of the acidity of the corresponding conjugate acids. A similar effect might be expected as well in the case of ion-association; that is, the charge dispersion of anions weakens the interaction with cations and helps the dissociation of such ion-pairs in the organic phase. If atoms of a high electronegativity are assumed to resist the dispersion of the charge located on them, it can be expected that the anions suitable for potassium extraction by nitrobenzene are such that the negatively-charged atoms are less electronegative. The electronegativities of the atoms in question decrease in the following order: O>N>C, S>B. Therefore, the ion-pair of tetraphenylborate should strongly dissociate, and oxy-acids or phenols

in nitrobenzene should weakly dissociate. Such a sequence has already been verified with tetraphenylborate[15] and picrate.[10] The sequence may also be supported by the fact that, in liquid ammonia, the dissociation constant decreases in the following order:

$$NaSPh > NaNHPh > NaOPh,^{11}$$

where Ph denotes the phenyl radical.

Inductive Effect. The introduction of substituents which can attract electrons away from the negatively-charged atoms decreases the electron density on them. As the nitro group and halogen atoms will exert an electron-attracting inductive effect, it can be expected that, with these compounds, a highly enhanced extractability will be obtained. It is, however, difficult to discuss the effect of ion size and the inductive effect separately, because these substituents are very bulky themselves. Acrydone (4—IV) and phenothiazine (4-V) can clearly be differentiated from phenoxazine (4-VII). This fact may also suggest the inductive effect of $\geq C{=}O$, $\geq SO_2$, and $\geq O$ groups.

15) Unpublished work.

Conclusion

From the above discussion and the experimental results, it can be concluded that bulky, charge-dispersible anions with electronegative groups in adjacent positions of the functional group are the best for the extraction of potassium by nitrobenzene.

The author wishes to express his gratitude to Professor Kyoji Tôei for his guidance throughout the course of this work.

The Carbon-catalyzed Oxidation of Co(II)-Ethylenediaminetetraacetate by Molecular Oxygen

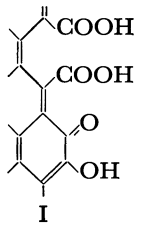
Akira TOMITA

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai

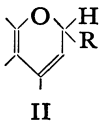
(Received January 20, 1971)

The kinetics of the oxidation of a cobaltous complex of ethylenediaminetetraacetic acid (EDTA) is determined volumetrically at 50.0°C in the presence of several kinds of carbon as catalysts. One mole of oxygen was used to oxidize four Co(II) ions, and all the Co(II) ions were oxidized to Co(EDTA)$^-$ ions quantitatively. The rate of oxygen uptake was found to change from zeroth order to first order with respect to the complex ion during the course of oxidation; it was also found to be first order with the oxygen pressure and the amount of the carbon catalyst. The catalytic activity of the carbon was correlated to the quantity of surface basic oxides of the carbon. A possible mechanism which can account for the above results is proposed.

Many reactions have been known to be catalyzed by carbons or metals supported on carbon.[1] Several works[2-4] have also described the catalytic effect of the carbon on the reaction of coordination compounds, but no mechanistic details have been investigated. Recently, the functional groups on the carbon surface have been characterized by various methods. The presence of acidic oxides I[5] and basic oxides II[6] has been reported. As a first step to studying the interaction between metal complex ions and the carbon, we previously studied[7] the adsorption of a $Co(NH_3)_6^{3+}$ ion onto carbon and the base hydrolysis



I



II

of the same complex ion catalyzed by the carbon. In that paper, we concluded that the active site was the acidic oxide on the carbon surface I, and suggested that the electrostatic force between the complex ion and the acidic oxides is one of the most important factors in their interaction. It then appeared of interest to investigate whether or not the active site for the reaction of complex *anions* was also the acidic oxide. The oxidation of a Co(II)-EDTA complex was undertaken for this purpose.

A Co(II)-EDTA complex ion has been known to be oxidized by various oxidants, such as H_2O_2, PbO_2,[8] and $Fe(phen)_3$.[9] It cannot be oxidized in an aqueous

solution by bubbling oxygen or air. During the course of the previous investigation, we found the catalytic activity of the carbon for the air-oxidation of this complex ion. The catalytic effect of the carbon on the oxidation reaction has been reported in the cases of a $Co(NH_3)_6^{2+}$ ion[10] and a Fe^{2+} ion[11] with no explanation of the role of the catalyst. This paper will report the results of a kinetic study of the oxidation of the Co(II)-EDTA ion, and a tentative mechanism for the oxidation will be discussed in relation to the functional groups on the carbon surface.

Experimental

Reagents. A solution of Co(II)-EDTA was prepared from cobaltous nitrate and disodium salt of EDTA unless otherwise stated; the pH of the solution was about 0.7. The predominant chemical species under these conditions has been identified as $Co(HL)(H_2O)^-$, where L indicates the ethylenediaminetetraacetate ion.[12] The effect of the initial pH of the solution was determined in a medium with an ionic strength of 1.0 μ ($NaNO_3$). The hydrogen ion concentration was adjusted by the addition of a dilute sodium hydroxide solution.

Two kinds of carbons with different surface areas were used: a carbon black (HAF) and an active carbon (AC). These carbons were modified by the method of Boehm.[5] The surface area (N_2 adsorption) and the surface acidity (NaOH consumption) are listed in Table 1. The pretreatment of the carbon is designated by an appended "n" or "o" for oxidation by HNO_3 or O_2 respectively.

Kinetic Measurement. We used a general type of apparatus, incorporating a constant-pressure gas buret with a volume of 50 m*l* and a reaction flask with a stirrer driven magnetically. The reaction flask held 40 m*l* of the reacting solution. The flask had a side chamber containing 10 g of soda lime to absorb the carbon dioxide produced. After the aqueous solution had been saturated with oxygen and allowed to come to the desired temperature, the reaction was started by plunging the carbon catalyst under a stream of oxygen and adjusting the pressure of oxygen. The gas buret was placed in a constant-temperature bath which was held at 30.0°C, while the reactor was kept in a bath maintained at 50.0°C. They were then placed in a room which was also thermostated at 27.2°C. The rate of oxidation was measured by the amount of oxygen absorbed during the course of oxidation.

Results

Typical profiles of the oxygen absorption are shown in Fig. 1. The plateau region of these curves corresponds to 95—102% of complete oxidation calculated on the basis of:

$$4Co(HL)(H_2O)^- + O_2 \longrightarrow 4CoL^- + 6H_2O \quad (1)$$

The absorption spectrum of the solution corresponding to this stage also shows that all the cobalt ions are present as forms of the CoL^- ion. These curves were obtained in the presence of soda lime in the side compartment of the flask. Otherwise, the gas absorption curve falls again due to the evolution of carbon dioxide after the absorption of oxygen of this molarity. The evolution of carbon dioxide may be attributed to the formation of the CoL^- ion in the first step, because this phenomenon was also observed when we used the CoL^- ion instead of the $Co(HL)(H_2O)^-$ ion as the starting material. Figure 1 illustrates the effect of the initial concentration of the complex ion on the rate. The initial slopes of all the curves are equivalent, in spite of the different initial concentrations. This fact and the linearity over the initial range indicate that the reaction is of the zeroth order. Deviation from linearity occurs later, since the kinetics approaches first-order behavior.

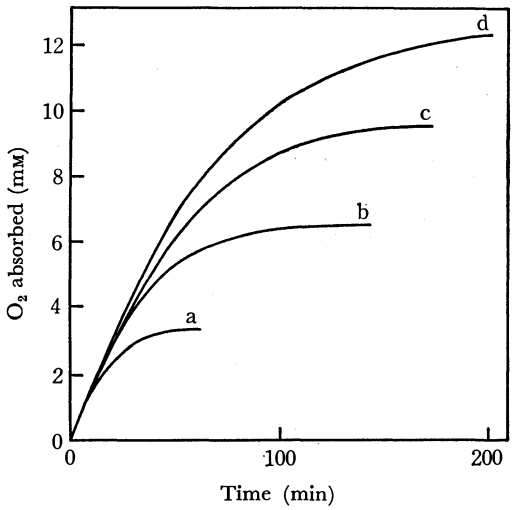

Fig. 1. Effect of initial concentration of Co(II)-EDTA: (a) 12.5 mM; (b) 25 mM; (c) 37.5 mM; (d) 50 mM. Carbon, AC 200 mg; Temperature, 50.0°C; Oxygen, 700 mmHg.

The zeroth-order rate constant as a function of the amount of the carbon was found to vary linearly in the range of 0—500 mg (Fig. 2). Such a dependence is expected for a solid catalyst, the rate being a function of the number of active sites on the surface. The rate

in the absence of the carbon was extremely low. Figure 3 shows the linear variation of the rate constant with the oxygen pressure. No oxidation was observed when the atmospheric gas was replaced by nitrogen.

The effect of the initial pH of the solution was determined in the pH region from 0.7 to 1.2, and the observed zeroth-order rate constant was represented by:

$$k_{obs} = k_a + k_b/[H^+] \quad (2)$$

and $k_a = 7 \times 10^{-4}$ (M·min^{-1}) and $k_b = 0.3 \times 10^{-4}$ (M^2·min^{-1}) are obtained at 50.0°C.

The rate constants given in Table 1 were obtained by using carbons with different surface acidities or basicities. In these runs, some experimental conditions were different from those mentioned above: cobaltous chloride was used for preparing the starting material, and the reaction temperature was 30.0°C. The catalytic activity of carbons is well correlated with the surface basicity (see also Fig. 4), but not with the surface acidity. This tendency is quite in contrast with the case of the *cationic* complex ion.[7] Under these conditions, the effect of the temperature was investigated only briefly. One oxidation run catalyzed by AC was made at 50.0°C; we found that k_{obs} was 8.6×10^{-4} (M·min^{-1}). The apparent activation energy was calculated to be about 9 kcal/mol.

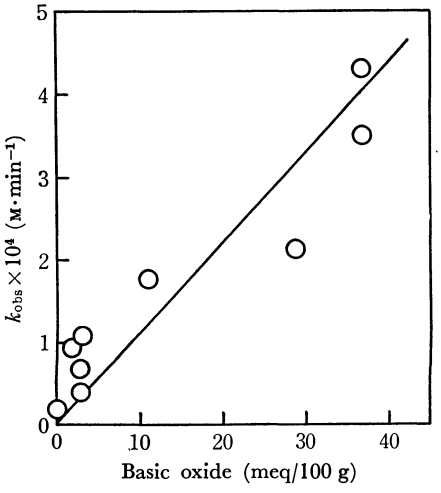

Fig. 4. Relationship between the rate constant and the basicity of the carbon surface.

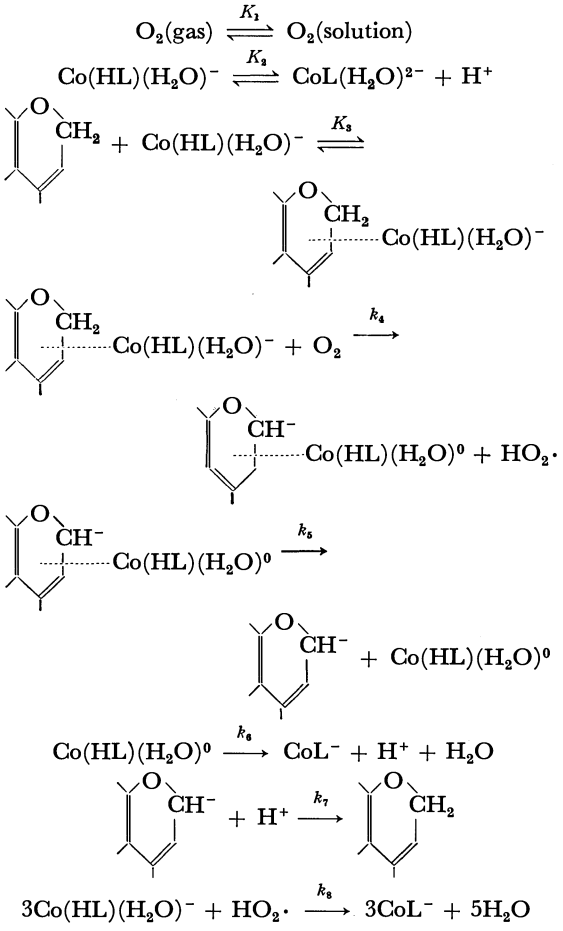
Discussion

Carbon dioxide evolution after the formation of the CoL^- ion may be considered to arise from the oxidation of carbon or from the decarboxylation of the EDTA complex. We regard the former as unlikely. Evidence in favor of the latter was adduced from the experiments in gas evolution starting from the CoL^- ion: (1) carbon dioxide was also observed to evolve under a nitrogen atmosphere, (2) the absorbance at 537 mμ corresponding to the CoL^- ion decreased upon the evolution of carbon dioxide, and (3) the amount of carbon dioxide evolved was closely related to the initial concentration of the CoL^- ion. As a more detailed mechanism is not clear from the data now available, we would like to limit our discussion to the first step of oxidation, where the side reaction is considered to be slow enough.

Any mechanism proposed for the carbon-catalyzed oxidation of a Co(II)-EDTA complex must explain, or be in accord with, the dependences of the rate on the following: (1) the amount of the carbon, (2) the oxygen pressure, (3) the initial concentration of a Co(II) complex, (4) the pH of the solution, and (5) the surface acidity or basicity of the catalysts. As there is an inverse correlation between the acidity of the carbon and the activity, the adsorption of a Co(II) complex on the acidic-surface oxides I is unlikely. Although this inverse correlation can be explained by the electrostatic repulsion between the dissociated acidic groups (*i.e.*, the -COO^- or -O^- group) and the complex anions, this interpretation is inadequate because these acidic groups are not dissociated because of the low pH value of the solution. On the other hand, the activity of carbon was well correlated with the quantity of basic surface oxides, and it seems reasonable to conclude that the active sites for this oxidation are those basic oxides (*i.e.*, with the chromene-type structure II). The following scheme may be proposed to account for the catalytic action of these functional groups:



The oxidation reaction seems to proceed through two simultaneous reaction paths, one of which involves the oxidation of the protonated chelate as described above, while the other involves the oxidation of the unprotonated chelate, $CoL(H_2O)^{2-}$. The corresponding constants for $CoL(H_2O)^{2-}$ will be marked K_3', k_4', k_5', and k_6' in the following discussion. Although the presence of a sexidentate CoL^{2-} has been suggested,[9] it seems reasonable to consider only two quinquedentate anions represented by the K_2 equilibrium in a strongly acidic solution.[9,12] Letting the fraction of the surface sites covered with $Co(HL)(H_2O)^-$ and $CoL(H_2O)^{2-}$ be θ and θ', and letting the total concentration of Co(II) complexes be represented by $[Co]_T$, one obtains:

$$K_3 = \frac{\theta}{(1-\theta-\theta')\cdot[Co(HL)(H_2O)^-]} = \frac{\theta\cdot([H^+]+K_2)}{(1-\theta-\theta')\cdot[H^+]\cdot[Co]_T} \quad (3)$$

and:

$$K_3' = \frac{\theta'\cdot([H^+]+K_2)}{(1-\theta-\theta')\cdot K_2\cdot[Co]_T} \quad (4)$$

where K_3 and K_3' are the equilibrium constants for the adsorption of complex ions on the carbon. The adsorption is followed by an attack of oxygen; this is the rate-determining step, k_4 or k_4'. Assuming that the rate of $[Co(II)]_T$ consumption equals four times the rate of oxygen consumption, we can express the rate of oxidation by the above pathway as:

$$-d[Co]_T/dt = -4d[O_2]/dt = (k_4\theta+k_4'\theta')\cdot[C]\cdot K_1\cdot P \quad (5)$$

where [C] is the "concentration" of the carbon catalyst and where P is the oxygen pressure in the gas phase. Combining Eqs. (3), (4), and (5) gives:

$$-d[Co]_T/dt = \frac{(k_4\cdot K_3\cdot[H^+]+k_4'\cdot K_3'\cdot K_2)\cdot[Co]_T}{[H^+]+K_2+(K_3\cdot[H^+]+K_3'\cdot K_2)\cdot[Co]_T} \times[C]\cdot K_1\cdot P \quad (6)$$

This equation can explain the fact that the reaction is zeroth-order with respect to $[Co]_T$ at the beginning of the oxidation and is first-order at lower concentrations of the cobaltous ion. Equation (6) also shows a simple dependence of the rate of oxidation on the oxygen pressure and the amount of the carbon catalyst. The validity of this relationship may be seen by the same dependences shown in Figs. 2 and 3. The effect of the pH on the zeroth-order rate constant shown in Eq. (6) may be expressed in the form:

$$k_{obs} = K\cdot\frac{k_4\cdot K_3\cdot[H^+]+k_4'\cdot K_3'\cdot K_2}{K_3\cdot[H^+]+K_3'\cdot K_2} \quad (7)$$

where K is $[C]\cdot K_1\cdot P$, which was kept constant in these runs. In a strongly acidic solution, where $K_3'\cdot K_2$ is small compared to $K_3\cdot[H^+]$, Eq. (7) simplifies to:

$$k_{obs} = K\cdot\left(k_4+\frac{k_4\cdot K_2\cdot K_3'/K_3}{[H^+]}\right) \quad (8)$$

This theoretical equation agrees with the experimental equation (2). The dissociation constant, K_2, was reported[12] to be approximately 10^{-3}. Using this value and the constants presented in Eq. (2), we can estimate the $k_4\cdot K_3/k_4'\cdot K_3'$ ratio to be 0.023. The fact that this ratio is smaller than unity may be understood if one considers that the rate of the electron transfer to produce a pair of anions (k_4') might be faster than k_4. The oxidized complex ions may then be dissociated from the carbon surface in a fast step (k_5 and k_5'). The dehydration of the quinquedentate complex ion into the sexidentate CoL^- ion may then take place in a subsequent fast step (k_6). Considering the data reported[13] below 25°C, we can estimate the rate of this step to be very large compared to the preceeding steps. The $HO_2\cdot$ radical produced in the rate-determining step oxidizes the other three ions of Co(II)-EDTA accoring to the Weiss mechanism[14] (k_8). Thus, four ions of Co(II)-EDTA complexes are oxidized by one molecule of oxygen.

In conclusion, it should be emphasized that the catalytic behavior of the carbon in connection with the oxidation of Co (II)-EDTA was quite different from that for the adsorption or the hydrolysis of the $Co(NH_3)_6^{3+}$ ion. The active sites for the former case were surface basic oxides, II, whereas those for the latter were surface acidic oxides, I. Whether this difference has arisen from the electric charge of the complex ions, from the choice of different types of reactions, or from other reasons is not yet clear; it is advisable to investigate other reactions[15] in order to elucidate this point.

The author is grateful to Professor Yasukatsu Tamai for his helpful discussions.

The Fluorine, Chlorine, Bromine, and Iodine Contents of Volcanic Rocks in Japan[1]

Minoru YOSHIDA, Kazuyoshi TAKAHASHI, Norinobu YONEHARA,*
Takejiro OZAWA, and Iwaji IWASAKI[2]

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
** Department of Chemistry, Faculty of Science, Kagoshima University, Kamoike-cho, Kagoshima-shi*

(Received January 23, 1971)

The halogen contents of 49 Japanese volcanic rocks are; F: 50—1700 (average 410), Cl: 17—1220 (av. 270), Br: 0.09—8.10 (av. 0.85), I: 0.011—0.32 (av. 0.088) μg/g. The fluorine and chlorine were determined by usual photometric methods, and the bromine and iodine, by photometric methods based on their catalytic action, after decomposition and separation procedures suitable for each case. The bromine and iodine contents are appreciably lower than the values generally accepted for igneous rocks. The bromine content agrees with Sugiura's value. The frequency distribution of each halogen content shows an approximate lognormality. The chlorine and bromine contents are strongly correlated, and the Br/Cl atomic ratio is in a narrow range $(0.66—3.7)\times10^{-3}$ (av. 1.5×10^{-3}). No other correlation is observed among the halogen contents at all. Each halogen content has no marked relation to the type of rock. A regional difference is seen in the F/Cl and I/Br ratios. Three ultrabasic rocks have very low fluorine (≦20) and chlorine contents (≦50 μg/g). On the other hand, they have a slightly lower bromine content (0.15—0.34 μg/g) than, and almost the same iodine content (0.07—0.13 μg/g) as, the volcanic rocks.

Data on the halogen contents of igneous rocks are important in discussing the relation between igneous rocks and magmatic emanations. The investigation of the halogens is also interesting in connection with the "geochemical balance" of the elements. The origin of the oceans has often been discussed on the basis of the volatilization of the halogens and some other elements.[3-8] Since Correns[9] reviewed "the geochemistry of the halogens" in 1956, the fluorine and chlorine contents of igneous rocks have been reported by many investigators. The data on fluorine were compiled by Fleischer and Robinson (1963),[10] and those on chlorine, by Johns and Huang (1967),[11] although the latter authors did not quote the results of the studies by Japanese investigators.[12,13] On the other hand, data on bromine and iodine, especially those on iodine, are scarce.

Behne's results[14] of a systematic investigation of bromine in rocks were long accepted as reliable. In 1964, however, Filby[15] reported that the bromine content of two standard rock samples, G1 and W1, prepared by the U. S. Geological Survey, as determined by neutron activation analysis, was appreciably lower than Behne's average value. He confirmed this conclusion by analyzing some other standard rock samples.[16] The results of the recent determinations[17-19] of the bromine content of meteorites also show that Behne's values are too high. Recently, Sugiura[20] determined the bromine content of igneous rocks by a photometric method. His values were also lower than those of Behne; indeed, some rocks have a bromine content lower than the limits of determination of the method (0.2 ppm).

The iodine contents of igneous rocks have not yet been studied systematically so far as is known. The classical values determined titrimetrically by Fellenberg and Lunde[21] are widely used for many discussions, even at present,[7,22] in spite of doubts raised by several investigators. Noddacks' value[23] on the iodine in the earth's surface material is appreciably lower than Fellenberg's value; Urey[5] used the former value in his discussion of the concentration of certain elements at the earth's surface. Goles and Anders[24] determined

the iodine content of several meteorites by the neutron activation method and concluded that most of the iodine data in Fellenberg's study are systematically too high by factors of 5 to 30. Brown and Wolstenholme[25] could not detect iodine in their attempt to determine the minor components in G1 and W1 by spark-source mass spectrometry (limit of detection: 0.05 ppm). Crouch[26] investigated the applicability of a spectrophotometric method for the determination of iodine in silicate rocks and gave some data somewhat lower than Fellenberg's value, but his work has not been continued.

In our opinion, ordinary photometric methods, to say nothing of titrimetric methods, have too low sensitivities to be used in the determination of bromine and iodine in igneous rocks. The neutron activation method has, indeed, a very high sensitivity, but it requires special equipment and time-consuming procedures. The present authors have previously established photometric methods for the determination of bromine[27] and iodine[28] in silicate rocks based upon their catalytic effects on certain redox reactions. The bromine and iodine contents of about fifty volcanic rocks are here determined using these methods. Their fluorine and chlorine contents are also determined. The relations among the abundances of halogens themselves and those between the halogen contents and the other properties of rocks are discussed. The only report which has dealt with the contents of our halogens in the same rock is that of Kogarko and Gulyayeva[29] on the rocks in Lovozero alkalic massif. These rocks are, however, of a specific type and have unusually high halogen contents.

Experimental

The samples used for the present study cover various types of Japanese volcanic rocks. Three ultramafic rocks obtained from New Zealand and New Guinea were also analysed. All the samples were crushed in a steel Ellis mortar and finely pulverized in an agate mortar, with special caution taken against the contamination of the halogens.

The method of analysis will be described only briefly here; the details are given in the papers cited. The fluorine was determined as follows:[30] About 1 g of a sample was fused with sodium peroxide in a nickel crucible. After cooling, the cake was treated with a small amount of water, taking precautions against a violent reaction. The resultant solution and residue were transferred into a distillation flask. After the addition of about 30 m*l* of conc. sulfuric acid and a small amount of hydrazine sulfate, the fluorine was steam-distilled at about 140°C. The fluorine in the distillate (1 *l*) was determined by the photometric method, using zirconium and *p*-dimethylaminoazophenylarsonic acid.[31] The fluorine content of rocks can be determined with a precision of about ± 20 μg/g by this method.

The chlorine was determined by the method of Iwasaki *et al.*,[32] with some improvements.[33] About 0.2 g of a sample was fused with anhydrous sodium carbonate in a platinum crucible. After cooling, the chlorine was extracted with hot water and was determined by the photometric method, using mercuric thiocyanate. The chlorine content of rocks can be determined with a precision of about ± 10 μg/g by this method.

The bromine was determined by the method of Takahashi *et al.*[27] After 0.25—0.5 g of a sample had been fused with potassium hydroxide in a nickel crucible, the resulting cake was leached with water. The bromine in the solution was converted to the elementary form and extracted with benzene. Then, it was back-extracted into the aqueous phase by shaking it with a sodium hydroxide solution; it was determined by the photometric method on the basis of its catalytic action on the oxidation of iodine to iodate by potassium permanganate. The error in this method is about ± 0.03 μg at bromine of 0.50 μg and less at lower amounts.

The iodine was determined by the method of Yonehara *et al.*[28] After 0.5—1 g of a sample had been fused with potassium hydroxide in a nickel crucible, the resulting cake was treated with water and sulfuric acid. The iodine in the solution was converted to the elementary form and extracted with carbon tetrachloride. Then it was back-extracted into the aqueous phase by shaking it with a sodium hydroxide solution and determined by the photometric method on the basis of its catalytic action on the color-fading of a ferric thiocyanate complex. The iodine content of rocks can be determined with a precision of about ± 0.005 μg/g.

The water-soluble halogens in some rocks were determined by methods similar to that described by Iwasaki and Katsura.[13]

All the chemicals used were of analytical-reagent quality or were specially purified. Redistilled water was used throughout the analytical procedures. Blank tests were made on all the procedures of each analytical method.

Results and Discussion

Table 1 gives the results of the determination and some atomic ratios among halogens. The fluorine contents of these volcanic rocks range from 50 to 1700 μg/g; the arithmetic mean is 410 μg/g. The chlorine contents range from 17 to 1220 μg/g; the arithmetic mean is 270 μg/g. The F/Cl ratio is scattered over a wide range, from 0.43 to 45 (average 7.8). These results are consistent with those of the previous reports summarized in Table 2. The bromine contents range from 0.09 to 8.10 μg/g; the arithmetic mean is 0.85 μg/g. The Br/Cl ratio falls within a narrow range from 0.66×10^{-3} to 3.7×10^{-3} (average 1.5×10^{-3}). These values agree with those of Sugiura[20] and are lower than Behne's value.[14] The iodine contents range from 0.011 to 0.32 μg/g; the arithmetic mean is 0.088 μg/g. The

a) Numerical values in parentheses are contents of the water-soluble halogens

I/Cl ratio is scattered over a wide range, from 0.41×10^{-5} to 130×10^{-5} (average 23×10^{-5}). These values are appreciably lower than Fellenberg's value,[21] which is generally accepted. The rocks in Lovozero alkalic massif have very high halogen contents, as is shown in Table 2d.[29] The ratios among halogens are, however, in good agreement with those of the present study.

The amounts of the water-soluble halogens are usually small as compared with those of the total halogens. Some specimens (No. 12, No. 45) contain unusually large amounts of the water-soluble chlorine and bromine. They were obtained at localities near the sea and are possibly contaminated. The data on these specimens are excluded from the calculation of the ratios and the mean values. However, we do not think that all the water-soluble halogens have their origin in contamination.

The abundance of each halogen does not show any marked relationship to the type of rock, as many authors

TABLE 2. HALOGEN CONTENTS OF IGNEOUS ROCKS IN THE LITERATURE

a) F in Volcanic Rocks (mainly from Fleischer and Robinson[10])

Rock Name	No. of Samples	F (μg/g) Range	F (μg/g) Average

have pointed out.[8-12,20] All we can say is that some glassy rocks have high chlorine and bromine contents, and that some rocks from alkaline rock provinces have high fluorine contents.

Figures 1—4 give the frequency distribution of each halogen content of the volcanic rocks analysed in this study. They show approximate lognormalities.

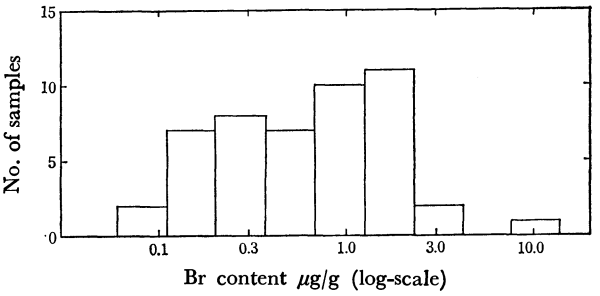

Fig. 3. Frequency distribution of bromine content in volcanic rocks.

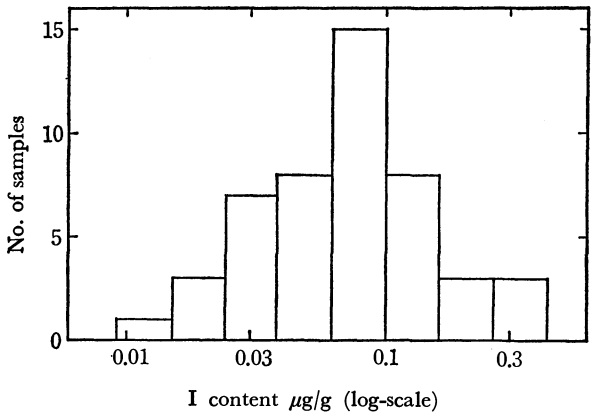

Fig. 4. Frequency distibution of iodine content in volcanic rocks.

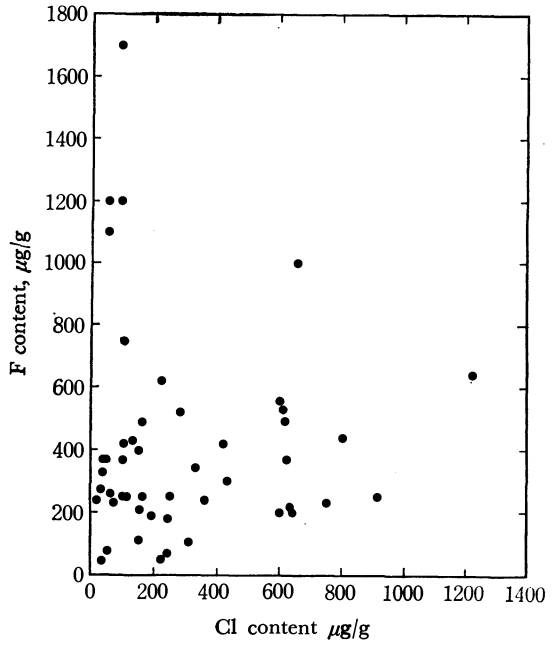

Fig. 5. Relation between chlorine content and fluorine content.

Strictly speaking, the fluorine and chlorine contents show deviations from the log-normal type distribution when they are plotted on cumulative frequency diagrams. The number of samples are, however, insufficient for a further discussion of the distribution of the halogens.

The correlations among halogens are shown in Figs. 5—9: F—Cl in Fig. 5, Br—Cl in Fig. 6, I—Cl in

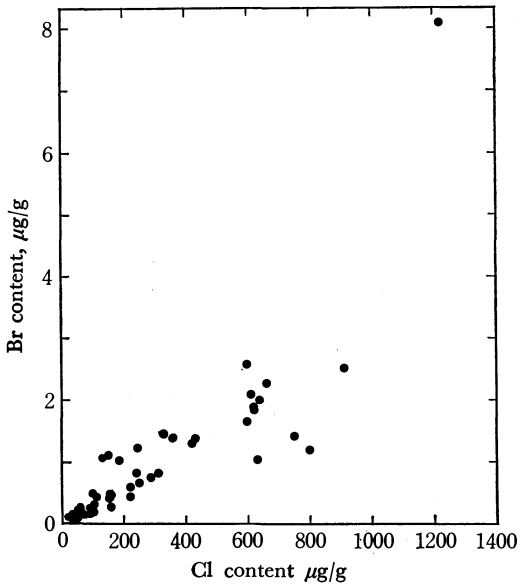

Fig. 6. Relation between chlorine content and bromine content.

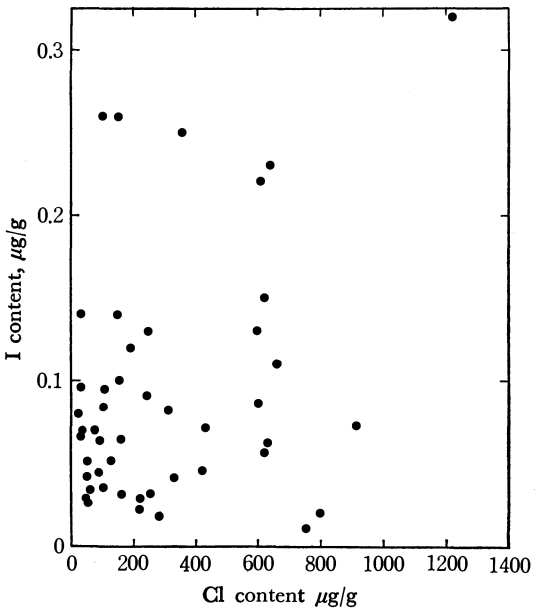

Fig. 7. Relation between chlorine content and iodine content.

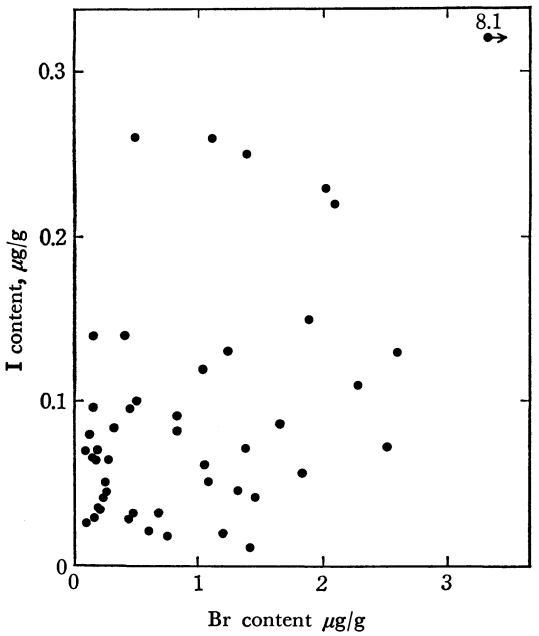

Fig. 8. Relation between bromine content and iodine content.

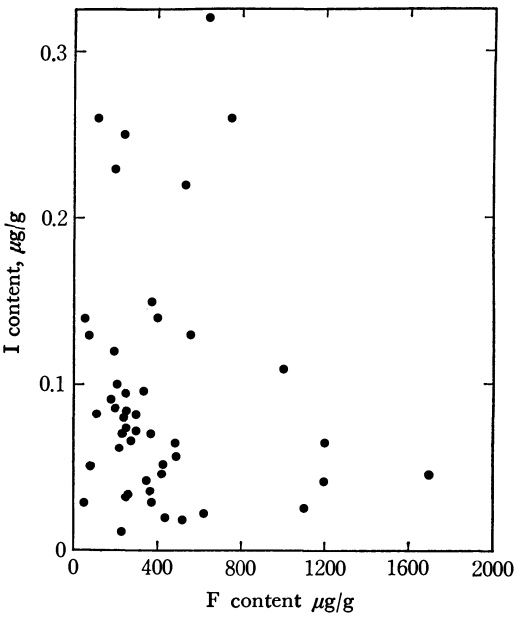

Fig. 9. Relation between fluorine content and iodine content.

Fig. 7, I—Br in Fig. 8, and I—F in Fig. 9. The chlorine and bromine contents are strongly correlated, as may be seen in Fig. 6. On the contrary, the other figures show no correlation at all. These findings indicate that in the process of the formation of volcanic rocks halogen behave in markedly different ways except for the similarity between chlorine and bromine. According to recent investigations, a primary factor governing their halogen contents is thought to be the distribution of volatile halogen compounds between the molten silicate phase and the gas phase. Kuroda and Sandell[34] stated that much of the chlorine escapes as hydrogen chloride formed by the reaction: $Cl^- + H_2O \rightleftharpoons HCl + OH^-$. Kogarko and Ryabchikov[35] discussed the relation between the fluorine and chlorine contents in gas and the chemical composition of the condensed phases in equilibrium with the gas on the basis of this reaction: $2X^-_{melt} + H_2O_{gas} = O^{2-}_{melt} + 2HX_{gas}$. Iwasaki and Katsura[36] discussed the chlorine content of volcanic rocks on the basis of the solubility of hydrogen chloride in rock melts. All the volatile components in the igneous rock have usually been regarded in the same light despite the distinctive chemical property of each of them. If the distribution of the four halogens was controlled mainly by the same mechanism

the halogen contents of volcanic rocks should be intimately correlated with each other. From our results, chlorine and bromine may be taken as an illustration of this. On the other hand, the behavior of fluorine and iodine must be controlled by other factors. The ratios among halogens in natural volcanic gases are listed in Table 3.[37-40] A comparison between the data in Table 3 and the data of the present study shows that the F/Cl ratio in the gases is appreciably lower than that of volcanic rocks, as was stated in our previous reports.[39-42] The Br/Cl and I/Cl ratios in the gases are nearly equal to, or a little smaller than, those of the volcanic rocks. The same relations concerning F/Cl, Br/Cl, and I/Cl can be observed between gases evolved from volcanic rocks on heating and the original rocks used in the experiments.[40-43] The difference in behavior between fluorine and chlorine may be attributed to the formation of stable metal-fluorine complexes in rock melts, as was suggested by Kogarko *et al.*[35] Several factors which may control the distribution of iodine have been suggested: its large ionic size, its possible occurence as an elemental form, its chalcophile properties, *etc.* At present, we have no way to decide which of them is the main factor.

A regional difference is observed with regard to some ratios among halogens. The rocks from the Izu Seven Islands have low F/Cl and I/Br ratios; on the contrary, the rocks from the Circum-Japan Sea Province have high F/Cl and I/Br ratios, with a few exceptions. These two petrographic provinces have already been said to be in marked contrast to one another.[44]

The ultra-basic rocks analysed have very low chlorine and fluorine contents as compared with volcanic rocks. The results agreed with those of Stueber *et al.*[45] The bromine content is slightly lower than those of volcanic rocks, while the iodine content is almost the same as those of volcanic rocks. As a result, their Br/Cl and I/Cl ratios are appreciably higher than those of the volcanic rocks. This fact is interesting for showing the difference in the behavior of bromine and iodine from that of fluorine and chlorine duing the formation of magma in the mantle.

The authors wish to express their thanks to the Research Fund of the Kawakami Memorial Foundation for a research grant partly used in this work.

^{55}Mn Nuclear Magnetic Resonance Studies of the Compounds with Manganese-Tin Bonds

Satoru ONAKA,* Takeshi MIYAMOTO, and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received February 3, 1971)

The nature of Mn–Sn bonds has been studied by ^{55}Mn-NMR and IR spectroscopies of a series of compounds, $R_{3-x}X_xSn-Mn(CO)_5$, where R is C_6H_5 or CH_3 and where X is Cl or Br. Molecular orbital considerations have shown that the chemical shift of the ^{55}Mn-NMR spectra is a measure of the σ-polarity of the L–Mn bond in L–$Mn(CO)_5$-type complexes, and that the linewidth is mainly determined by the π-interaction between Mn and Sn. The π-interaction (back-donation from Mn to Sn) seems to be most pronounced in $Br_3Sn-Mn(CO)_5$ in the series of $(CH_3)_{3-x}Br_xSn-Mn(CO)_5$ compounds. The relationships among the chemical shift, the wave numbers of CO stretching modes, and the eqQ are also shown.

The aim of the present report is to ascertain, by the aid of the ^{55}Mn-NMR, the σ-character and the π-character of metal-metal bonds in the complexes, $R_{3-x}X_xSn-Mn(CO)_5$, which have been studied using Mössbauer spectroscopy,[1] where X and R stand for Cl, Br and C_6H_5, CH_3 respectively.

The L–$M(CO)_5$-type compounds, where L and M represent a ligand and a metal atom respectively, have been extensively investigated, since the octahedral symmetry around the metal atom permits the independent treatment of the σ- and the π-characteristics of the chemical bonds in these complexes.[2–9] The most successful method thus far employed to study these complexes is to measure the CO stretching frequencies in the infrared region and to interpret the data in terms of the σ- or the π-electron donation from L to M or the back donation from M to L, including cases of M–M′ bonds.[10] According to Graham,[10] these two donation powers can be quantitatively expressed by the two parameters, σ and π, which can be calculated from the CO stretching data. We have found that the NMR spectra of ^{55}Mn offer useful information concerning these two characteristics.

Some NMR data on organometallic compounds containing the Mn atom have been reported by Calderazzo, Lucken, and Williams[11] and by Miles *et al.*,[12] but no compound containing metal–metal bonds has thus far been subjected to similar study.

The NQR techniques were also introduced by Brown to the study of metal–metal bonds in cobalt complexes with a C_{3v} symmetry.[13,14]

Experimental

Materials. All the compounds except $(CH_3)Cl_2Sn-Mn(CO)_5$, $(CH_3)_2BrSn-Mn(CO)_5$, and $(CH_3)Br_2Sn-Mn(CO)_5$ were prepared by the methods of Gorsich[15] and Graham.[16] All the reactions were carried out under a dried nitrogen atmosphere.

$(CH_3)_2BrSn-Mn(CO)_5$: A solution of $NaMn(CO)_5$ was prepared from 5.9 g (0.015 mol) of $Mn_2(CO)_{10}$ in 100 m*l* of anhydrous tetrahydrofuran (THF) by stirring the mixture over an excess of 1% sodium amalgam; it was then slowly dropped into a stirred solution of 9.24 g (0.03 mol) of $(CH_3)_2SnBr_2$ in 100 m*l* of THF. The THF solution was kept overnight in a refrigerator. The organic layer separated from fine precipitates by using a centrifugal separator was condensed under reduced pressure. The yellow residue thus obtained was recrystallized from hexane at 0°C; yellow crystals were then obtained by filtration (yield, 80%).

Found: C, 19:96; H, 1.25%. Calcd for $C_7H_6O_5BrMnSn$: C, 19.84; H, 1.43%.

$(CH_3)Cl_2Sn-Mn(CO)_5$: A mixture of 2.1 g (0.005 mol) of $Cl_3Sn-Mn(CO)_5$ and an equimolar amount of $(CH_3)_2ClSn-Mn(CO)_5$ was heated at 130°C for 10 min. The crude product was recrystallized from hexane to give 2.9 g of pale yellow crystals (yield, 50%).

Found: C, 18.18; H, 0.68%. Calcd for $C_6H_3O_5Cl_2MnSn$: C, 18.03; H, 0.76%.

$(CH_3)Br_2Sn-Mn(CO)_5$: A mixture of 1.95 g (0.0035 mol) of $Br_3Sn-Mn(CO)_5$ and 0.63 g (0.00175 mol) of $(CH_3)_3Sn-Mn(CO)_5$ was heated at 130°C for an hour. The crude product was then recrystallized from hexane to give 0.71 g of yellow crystals (yield, 28%).

Found: C, 14.77; H, 0.45%. Calcd for $C_6H_3O_5Br_2MnSn$: C, 14.75; H, 0.62%.

The purities were determined by carbon and hydrogen analyses and by melting-point or decomposition-point measurements.

NMR Spectra. The ^{55}Mn-NMR spectra were registered as derivative curves at 10 KOe and 10.55 MHz on a Varian

Associates VF-16 NMR spectrometer at room temperature. The manganese samples were sealed, as 0.25 mol solutions in methylene chloride, into glass tubes 8 mm in diameter under a nitrogen atmosphere. An aqueous solution of potassium permanganate (10% concentration) was used as the external standard. The linewidth, ΔH, was represented by the interval between the points of the maximum slopes.

Infrared Spectra. The spectra in the CO-stretching region were recorded with a Hitachi EPI-G2 spectrometer in hexane solutions (2—3 mg/m*l* except Cl_3Sn–$Mn(CO)_5$) with a 0.1-mm KBr liquid cell. The spectra of Cl_3Sn–$Mn(CO)_5$ were measured with a KBr variable-path-length liquid cell in a hexane solution because of its low solubility in the solvent.

All the results of the NMR and IR measurements are listed in Table 1, together with some data cited from the report by Calderazzo *et al.*[11]

Discussion

Infrared Spectra. Graphs presenting the linear relationship between the infrared wave numbers of A_1^2, A_1^1, and E modes and the chemical shift are shown in Fig. 1. The force constants, not found in the literature, of $R_{3-x}Br_xSn$–$Mn(CO)_5$ were obtained by the method of Cotton and Kraihanzel[4]; the results are listed in Table 2, along with the values of k_2, k_1, k_i and σ- and π-parameters[10] for the compounds $R_{3-x}Br_xSn$–$Mn(CO)_5$ (R is CH_3 and C_6H_5).

NMR Data. The NMR data in Table 1 show that the successive substitution of the halogen atoms on the tin atom by phenyl or methyl groups results in changes in the chemical shift of ^{55}Mn as large as 600 ppm. The chemical shift increases almost linearly with the number of the organic group on the tin atom, as

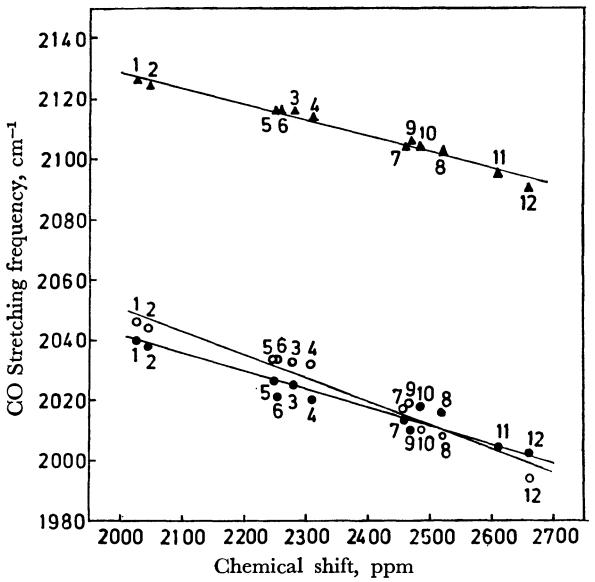

Fig. 1. Stretching frequency of A_1^2, A_1^1, and E bands *versus* ^{55}Mn-chemical shift. Upper series assigned as A_1^2 and lower series as E and A_1^1. Points labeled by ○ and ● correspond to E and A_1^1 bands respectively. The numbers in the graphs represent the compounds in Table 1.

TABLE 2. CO STRETCHING FORCE CONSTANTS AND GRAHAM'S σ- AND π-PARAMETER

Compound	Force constant, mdyn/Å			Graham's σ- and π-parameter, mdyn/Å	
	k_1	k_2	k_i	σ	π
$Br_2PhSn-Mn(CO)_5$	16.67	17.14	0.21	0.08	0.24
$Br_2(CH_3)Sn-Mn(CO)_5$	16.59	17.13	0.21	0.14	0.17
$BrPh_2Sn-Mn(CO)_5$	16.62	16.85	0.19	−0.45	0.48
$Br(CH_3)_2Sn-Mn(CO)_5$	16.60	16.80	0.24	−0.53	0.51

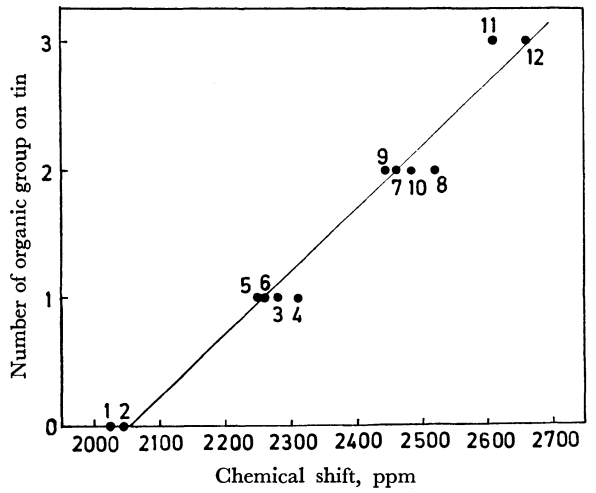

Fig. 2. Effect of organic groups on ^{55}Mn-chemical shift.

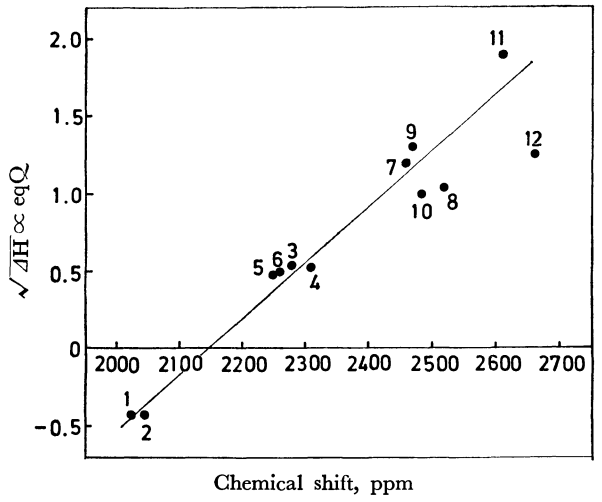

Fig. 3. The relationship between chemical shift and quadrupolar coupling constant. The signs of $\sqrt{\Delta H} \propto eqQ$ for $X_3Sn-Mn(CO)_5$ are chosen as minus signs.

is shown in Fig. 2.[17] On the other hand, the change in halogen atoms in $X_xR_{3-x}Sn-Mn(CO)_5$ from Cl to Br causes only a slight shift, as is shown in Table 1. All the NMR data can be most conveniently presented on the $\sqrt{\Delta H}$ *versus* chemical-shift graph given in Fig. 3. A remarkable feature of the graph, which is a characteristic of the compounds containing Sn–Mn bonds, is that the linewidth narrows drastically from $Ph_3Sn-Mn(CO)_5$ to $X_3Sn-Mn(CO)_5$, along with the change in the ligands on the tin atom. In the $CH_xF_{3-x}-Mn(CO)_5$ series, no such abrupt narrowing has been reported.[11] The sign of $\sqrt{\Delta H}$ is not obtained from the experiments described in this paper, but a change in the sign of the field gradient between $X_3Sn-Mn(CO)_5$ and $X_2RSn-Mn(CO)_5$ in the present series of compounds is suggested by the data shown in Fig. 3.

As we have reported previously,[1] the plotting of the NMR chemical shift of ^{55}Mn against the isomer shift of the ^{119}Sn-Mössbauer spectra suggests that the ^{55}Mn-chemical shift can be interpreted in terms of the σ-electron transfer from Mn to Sn. This finding that the ^{55}Mn-chemical shift can be interpreted in terms of the σ-character of the L–Mn bond is substantiated by the following relationship. As is shown in Fig. 4, the ^{55}Mn-chemical shift is linear to the σ-parameters[18] which are concerned with the σ-character of the L–Mn bond.[19] For these reasons, the following molecular orbital considerations are acceptable.

According to Ramsey,[21] the so-called paramagnetic shift, which mainly determines the variations in the chemical shift of transition elements, is given by the

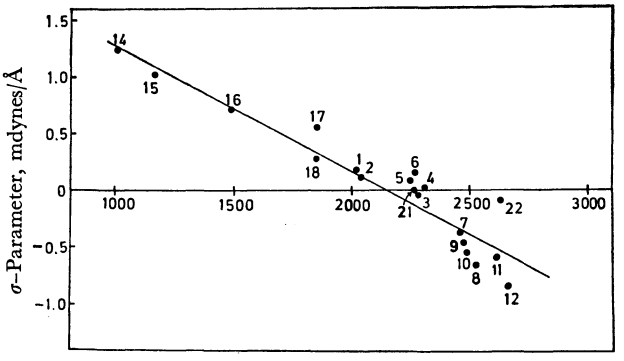

Fig. 4. The relationship between ^{55}Mn-chemical shift and Graham's σ-parameter. Graham's σ-parameters are cited from the literature, (W. A. G. Graham, *Inorg. Chem.*, **7**, 315 (1968).), and from Table 2.

17) The linearity of the chemical shift with the sum of the electronegativity of the halogen atoms on tin is also observed. The analogous linearity of the CO stretching frequencies with the sum of the electronegativity of the halogen atoms on tin has been already reported by Patmore, Thompson, and Graham in cases of the complexes $R_{3-x}X_xGe-Co(CO)_4$ and $R_{3-x}X_xSn-Mn(CO)_5$: D. J. Patmore and W. A. G. Graham, *Inorg. Chem.*, **6**, 981 (1967), J. A. J. Thompson and W. A. G. Graham, *ibid.*, **6**, 1875 (1967).

18) Graham's σ-and π-parameters are obtained by the use of these formulae: $k_1=\sigma+2\pi+c_1$, $k_2=\sigma+\pi+c_2$. He rather arbitrarily assumed that $\sigma=\pi=0$ for the $CH_3-Mn(CO)_5$ complex in order to fix the two constants c_1 and c_2.

19) The correspondence of σ-bond polarity with the "σ-parameter" calculated from infrared data has been reported for many cases.[7,17,20]

20) F. R. Dean and J. C. Green, *J. Chem. Soc.*, *A*, **1968**, 3047.

21) N. F. Ramsey, *Phys. Rev.*, **78**, 699 (1950).

expression:

$$\sigma_p = -\frac{e^2}{2m^2c^2}\sum_{n\neq 0}(E_n-E_0)^{-1}[\langle\psi_0|\sum_i l_i|\psi_n\rangle\langle\psi_n|\sum_k l_k r_k^{-3}|\psi_0\rangle + \langle\psi_n|\sum_i l_i|\psi_0\rangle\langle\psi_0|\sum_k l_k r_k^{-3}|\psi_n\rangle]$$

where ψ_0 and ψ_n denote wave functions of, respectively, the ground and excited states of the atom in question, and where l_i and r_i are angular operators and the distance from the metal nucleus to the i-th electron. Single-electron molecular energy schemes for L–Mn-$(CO)_5$ have been reported by Gray and Billing[22] and by Anderson and Brown.[23] The one-electron d-d transitions from the ground state ($^1A_1$) are:

$$b_2\ (\pi, 3d_{xy}) \longrightarrow b_1\ (\sigma^*, 3d_{x^2-y^2}),\ (^1A_1-{}^1A_1),\ \Delta E_1$$
$$b_2\ (\pi, 3d_{xy}) \longrightarrow a_1\ (\sigma^*, 3d_{z^2}),\ (^1A_1-{}^1B_2),\ \Delta E_2$$
$$e\ (\pi, 3d_{xy,yz}) \longrightarrow b_1\ (\sigma^*, 3d_{x^2-y^2}),\ (^1A_1-{}^1E_u),\ \Delta E_3$$
$$e\ (\pi, 3d_{xz,yz}) \longrightarrow a_1\ (\sigma^*, 3d_{z^2}),\ (^1A_1-{}^1E_v),\ \Delta E_4$$

The second transition does not contribute to the shift in the case of the present molecular symmetry, and ligand-charge transfer transitions from e (π, L and CO) to the upper σ-antibonding levels are disregarded because of very low values of both r^{-3} and ΔE_n^{-1}. The values of ΔE may be obtained by measuring the d-d transition spectra, but, in the present case, no data are available because of the intense charge-transfer bands in this region. When this approach is used, the following expression is obtained for the paramagnetic shift:

$$\sigma_p = -\frac{e^2\hbar^2}{2m^2c^2}\langle r^{-3}\rangle C_{a_1 g}\left[\frac{8C_{a_2}}{\Delta E_1}+\frac{4C_{E_u}}{\Delta E_3}+\frac{12C_{E_v}}{\Delta E_4}\right]$$

where C_n denotes the coefficient of the metal d-orbital in the molecular orbitals.[20,24] However, it is characteristic of the octahedral L–Mn$(CO)_5$-type compounds that the b_2 (π, $3d_{xy}$) and e (π, $3d_{xz,yz}$) levels are virtually non-bonding, so the values of ΔE_1, ΔE_3, and ΔE_4 are mainly determined by the b_1 (σ^*, $3d_{x^2-y^2}$) and a_1 (σ^*, $3d_{z^2}$) levels, which are correlated only with the σ-bonding between manganese and tin atoms or carbon atoms of carbonyl groups. As the strength of the σ-bond between Sn and Mn increases, the value of ΔE_n increases. The molecular antibonding orbital constants, C_n, increase from $Mn(CO)_5^-$ to $Mn(CO)_5^+$ through R_3Sn–$Mn(CO)_5$, X_3Sn–$Mn(CO)_5$, and X–Mn$(CO)_5$. The increase in ΔE_n causes the paramagnetic shift to decrease, while an increase in C_n causes the paramagnetic shift to increase. Thus, changes in C_n rather than in ΔE_n or in $\langle r^{-3}\rangle$ must be mainly responsible for the observed trend in the chemical shift, as has been reported in the case of platinum complexes.[22] Therefore, the following order of the values of the chemical shift may be a good measure of the σ-bond polarity of the L–Mn bonds:[11]

$Cl<Br<I<CF_3=CF_3CO<CH_3CO<CHF_2<Cl_3Sn\leqq Br_3Sn<CH_2F<PhBr_2Sn\leqq(CH_3)Br_2Sn\leqq CH_3\leqq PhCl_2Sn\leqq(CH_3)Cl_2Sn\leqq Mn(CO)_5<Ph_2ClSn\leqq Ph_2BrSn\leqq(CH_3)_2BrSn<(CH_3)_2ClSn<Ph_3Sn\leqq H\leqq(CH_3)_3Sn$

The L–Mn bond may be most ionic in $Cl^{\delta-}$—$^{\delta+}Mn(CO)_5$ and in $(CH_3)_3Sn^{\delta+}$—$^{\delta-}Mn(CO)_5$ and "covalent" at $(CO)_5Mn$–$Mn(CO)_5$.

The linewidth of the ^{55}Mn-NMR absorption is expressed by this formula:[25]

$$\Delta H = \frac{9}{500\sqrt{2}}\cdot\left(1+\frac{\eta^2}{3}\right)\cdot\left(\frac{eQ}{\hbar}\cdot\frac{\partial^2 V}{\partial z^2}\right)^2\cdot\tau_c$$

In the present type of complex, the asymmetry parameter, η, is of zero value because of the C_{4v} symmetry around the Mn nucleus. Accordingly, the linewidth of $LMn(CO)_5$ complexes is determined by two factors, the principal field gradient, $\partial^2V/\partial z^2$, and the correlation time, τ_c. However, the changes in the linewidth in a series of complexes of the $(CH_3)_{3-x}Br_xSn$–Mn-$(CO)_5$ type, as is shown in Table 1, are attributable to the change in the field gradient, because these complexes, being similar in molecular size, will give almost the same τ_c value.[26,27] Following the molecular orbital treatment of $LMn(CO)_5$ by Gray and Billing,[22] it may be deduced that the energy difference, ΔE_0, between two π-orbitals, b_2 (π, $3d_{xy}$) and e (π, $3d_{xz,yz}$) localized on Mn determines the field gradient at the Mn nucleus, or that the field gradient at the Mn nucleus is sensitive to the π-interaction between Mn and Sn. The contributions from other orbitals may be of secondary importance because of their small r^{-3} values. From the above consideration, we obtain the following order of the π-interaction between manganese and tin atoms from the linewidths:

Br_3Sn–$Mn(CO)_5>(CH_3)Br_2Sn$–$Mn(CO)_5>(CH_3)_2$-$BrSn$–$Mn(CO)_5>(CH_3)_3Sn$–$Mn(CO)_5$

The fact that the π-accepting tendency of the X_3Sn-group is stronger than that of the $(CH_3)_3Sn$-group[28] is well expressed by the larger differences in the linewidth, but Graham's π-parameters of Br_3Sn–$Mn(CO)_5$, $Br_2(CH_3)Sn$–$Mn(CO)_5$, $Br(CH_3)_2Sn$–$Mn(CO)_5$, and $(CH_3)_3Sn$–$Mn(CO)_5$ all have practically the same values within the limits of experimental error.[10] The linewidth of the ^{55}Mn-NMR spectra can, then, be thought to be a better measure of the π-interaction than the π-parameter proposed by Graham, at least in the present case.

The authors wish to express their deep gratitude to Mr. Fumikazu Yajima for his interest in this work and to Dr. Kazutaka Kawamura for his kind permission to use the NMR spectrometer. The authors are also grateful to the Ministry of Education for its financial support.

The Synthesis of Phosphonophenylazochromotropic Acids and the Stability Constants of Its Alkaline Earth Metal Chelates

Kenyu KINA, Haruo MIYATA, and Kyoji TÔEI

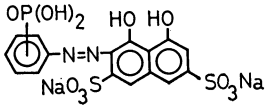
Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received February 15, 1971)

The acid dissociation constants of the three isomeric phosphonophenylazochromotropic acids and their chelate stability constants with alkaline earth metals have been measured by the pH titration method at an ionic strength of 0.10 and at 25.0±0.1°C. The stability order with respect to the ligands is as follows: *ortho-*>*meta-*>*para-*, and the stability constant of each ligand decreases in the order: Mg>Ca>Sr>Ba; this order is parallel to the reciprocal of the ionic radii of the metal ions. From a comparison between the chelate stability of *o*-phosphonophenylazochromotropic acid and that of Neo-Thorin, it has been concluded that the magnesium ion forms a more stable chelate bond with the phosphonic group than with the arsonic group.

A large number of azo compounds were synthesized and used as metal indicators. As a phenylazo derivative of chromotropic acid, Neo-Thorin, which has an arsonic group adjacent to the azo link, is well-known as a colorimetric reagent for thorium, zirconium, and uranium.

The present authors synthesized the *o*-phosphonophenylazochromotropic acid, which has a phosphonic group in place of the arsonic group of the Neo-Thorin, and two isomers (*m*-, *p*-) of this one. The structural formula for phosphonophenylazochromotropic acid disodium salt is given below:



Phosphonophenylazochromotropic acid

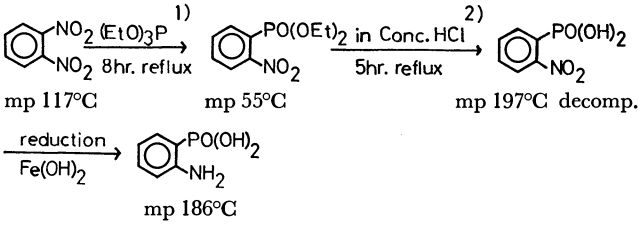
The measurement of its chelate stability constants with alkaline earth metals was carried out by means of the pH titration method.

Experimental

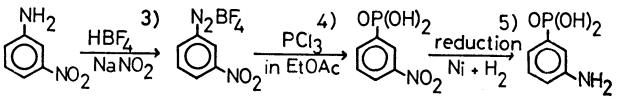
Synthesis of Phosphonophenylazochromotropic Acid. Three isomeric phosphonophenylazochromotropic acids were obtained form the corresponding diazonium salt by coupling with chromotropic acid dissolved in a sodium hydroxide solution. After the coupling reaction, the reaction mixture was added, drop by drop, to well-chilled concentrated hydrochloric acid; a reddish precipitate was thus obtained. This precipitate was recrystallized several times from an acidic solution by the salting-out method. These reagents, which are obtained as disodium salt, are all fine, reddish needles. Figure 1 shows the synthetic routes of the three isomeric diazo components.

o-Aminophenylphosphonic acid has been prepared by the use of the method of Route I. Triethylphosphite (25 g) and *o*-dinitrobenzene (16.8 g) were refluxed in acetonitrile for 8 hr.[1] After releasing the solvent under reduced pressure, diethyl *o*-nitrophenylphosphonate (mp 55°C) can be obtained as yellow needles by letting it stand over-night in an ice-box; then it was hydrolyzed in boiling concentrated hydrochloric acid (5 hr).[2] The *o*-nitrophenylphosphonic acid thus obtained was reduced with the use of ferrous hydroxide. After the precipitated ferric hydroxide was removed by

I. *o*-Aminophenylphosphonic acid



II. *m*-Aminophenylphosphonic acid



III. *p*-Aminophenylphosphonic acid was also prepared in a similar manner as above

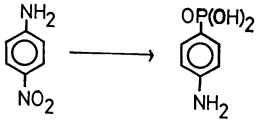


Fig. 1. Synthetic routes of diazo components.

filtration, *o*-aminophenyl-phosphonic acid, mp 186°C, rapidly crystallized as white needles when the alkaline filtrate was acidified with concentrated hydrochloric acid. Two other isomers, *m*- and *p*-aminophenylphosphonic acids, were prepared by the use of the methods of Routes II, and III; the details of the procedure have been described in a previous paper.[6]

Reagent Solutions. The stock solutions of these ligand were standardized by potentiometric titration with standard 0.10N potassium hydroxide. Carbonate-free 0.10N potassium hydroxide was prepared by the method of ion exchange and was standardized by potassium hydrogen phthalate titrimetrically. The stock solutions of the metal ion were prepared by dissolving $Mg(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$, $Sr(NO_3)_2$, and $Ba(NO_3)_2$ of a guaranteed reagent grade in distilled water. The concentrations of the Mg(II) and Ca(II) solutions were determined by chelatemetric titration, while the concentrations of the Ba(II) and Sr(II) solutions were determined by the usual gravimetric method.

pH Titration Method. The acid dissociation and the chelate stability constants were calculated from titration

curves obtained by titrating solutions (5 m*l*) in the presence and in the absence of metal ions, with 0.10N potassium hydroxide in a double-walled glass vessel with a 5-m*l* capacity, and maintained at 25.0±0.1°C by the circulation of water from a thermostat bath. All the measurements were carried out by the use of the micro-titration apparatus, presented in Fig. 2, and the alkali was added by means of a calibrated 0.50-m*l* micrometer syringe.

Solutions under titration were kept in a nitrogen atmosphere by the circulation of carbon dioxide-free nitrogen through the titration vessel. The ionic strength was adjusted to 0.10 with potassium nitrate. The hydrogen-ion concentration was measured by means of an HRL-Model P pH meter (Horiba Instruments Co., Ltd.) with a combined glass electrode (Metrohm, EA-125 U type, Herisaw, Switzerland). The observed pH meter readings were converted into the actual hydrogen-ion concentration by comparison with the stoichiometric dissociation constant of acetic acid. The pH (−log[H+]) region above 11.0 was calibrated by measurements in the KOH solution.

Calculation of Acid Dissociation Constants and Chelate Stability Constants. The dissociation constants of the triprotic acid are defined as follows:

$$K_{a1}=[H][H_2L]/[H_3L],$$
$$K_{a2}=[H][HL]/[H_2L],$$
$$K_{a3}=[H][L]/[HL],$$

where the ionic charge was neglected for the sake of convenience. In general, the following relationship holds among the step-by-step acid dissociation constants of the polyprotic acid:

$$\sum_{i=1}^{n}\frac{iT_L-f}{f[H]^i}K_{a1}\cdot K_{a2}\cdots K_{ai}=1,$$
$$f=T_{OH}+[H]-[OH],$$

where T_L represents the total concentration of ligand species, and T_{OH} the total concentration of the base added to the system. T_L, T_{OH}, and f are entirely of known or measurable quantities; therefore, K_{a1}, K_{a2}, and K_{a3} can be obtained by solving the simultaneous equation in principle. In practice, the ligands were treated as monoprotic acid until $a=1$, and treated as diprotic acid after $a=1$; since a clear inflection is observed, the first dissociation process can be separated from the subsequent dissociation. The chelate stability constants were calculated by the following equation:

$$K_{ML}=(T_L-F)/[L](F+T_M-T_L),$$

where:

$$[L]=(3T_L-T_{OH}-[H]+[OH])/\{[H]/K_{a3}+2[H]^2/K_{a3}K_{a2}+3[H]^3/K_{a3}K_{a2}K_{a1}\},$$
$$F=[L]\{1+[H]/K_{a3}+[H]^2/K_{a3}K_{a2}+[H]^3/K_{a3}K_{a2}K_{a1}\},$$

where T_M represents the total concentration of the metal species.

Results and Discussion

Titration Curves. The titration curves are illustrated in Figs. 3—5 for phosphonophenylazochromotropic acid in the presence and in the absence of alkaline earth metal ions. According to the results of the measurement of the pK_a of phenylphosphonic acid, the first dissociation constant was not obtained because of

L, Ligand only, [Ligand]$=1.374\times10^{-3}$M, [Mg]$=2.216\times10^{-3}$M, [Ca]$=2.256\times10^{-3}$M, [Sr]$=2.078\times10^{-3}$M,
a=moles of base added per mole of ligand

the very strong acid; however, the second dissociation constant, pK_{a2}, is 6.90. Therefore, the inflections at $a=1$ and $a=2$ on the ligand-only titration curve were identified with the dissociation of two phosphonic protons. The third dissociation step corresponds to the naphtholic hydroxyl proton.

As is shown in Figs. 3—5, a depression of the pH on the titration curves is observed in the presence of the metal ion when compared with that of the ligand only; this depression is due to the formation of a chelate. Therefore, the stability order can be judged by the extent of the pH drop. The order with respect to metal ions is as follows: Mg>Ca>Sr>Ba; that is, the stability constants, log K_{ML}, increase with a decrease in the ionic radii. Therefore, the order with respect to ligands is as follows: *ortho-*>*meta-*>*para-*. The ligand-only titration curve of *o*-phosphonophenylazochromotropic acid has a well-defined inflection at $a=2$ in comparison with those of the two isomers, and the third dissociation step is separated from the second dissociation step; therefore, the calculation of pK_{a3} can be performed like that of monoprotic acid after $a=2$.

Acid-dissociation Constants. The acid-dissociation constants of phosphonophenylazochromotropic acid are listed in Table 1. The pK_{a1} and pK_{a2} values correspond to the dissociation of the phosphonic group; the pK_{a3} value corresponds to the dissociation of the naphtholic hydroxyl group. The pK_{a1} values were not obtained in practice, because the first dissociation is almost complete, as in the case of the sulfonic group. Phenylazochromotropic acid derivatives have two naphtholic protons; however, one proton is not dissociated under ordinary conditions because of the very strong hydrogen bond between the oxygen atoms.[7] Another proton is also combined with one of the nitrogen atoms of the azo link by a hydrogen bonding; that is, in spite of the fact that the pK_a value of the naphtholic proton of chromotropic acid is 5.44,[8] those of the azo derivatives are increased to an order of magnitude of 9—10. The *o*-phosphonophenylazochromotropic acid has a higher pK_{a3} value (=10.12) than the other *m*- and *p*-isomers. This is attributed to the ortho effect of the phosphonic group. Such phenomena have been also observed with regard to *o*-sulfophenylazochromotropic acid.

Table 1. Acid-dissociation constants of phosphonophenylazochromotropic acids and stability constants of their chelates ($t=25$°C; $\mu=0.10$ by KNO_3)

Ligand	Acid-dissociation constants			Stability constants, log K_{ML}			
	pK_{a1}	pK_{a2}	pK_{a3}	Mg	Ca	Sr	Ba
ortho-	a)	6.43	10.12	5.71	4.95	4.34	4.15
meta-	a)	6.78	9.46	4.34	3.48	2.72	a
para-	a)	6.88	9.42	3.93	3.04	1.8	a
Neo-Thorin				5.57	5.20	4.39	4.22

a) not measurable owing to very strong acid or unstable chelate

Stability Constants. The chelate stability constants are also listed in Table 1. The chelate stability constants, log K_{ML}, decrease with respect to metal ions as follows: Mg>Ca>Sr>Ba. This order is parallel to the reciprocal of the ionic radii of the metal ions. *o*-Phosphonophenylazochromotropic acid forms a more stable chelate than the *m*- and *p*-isomers; this stabilization is due to the increase in the coordination number produced by the phosphonic group. The log K_{ML} values of Neo-Thorin (*o*-arsonophenylazochromotropic acid) with respect to Mg, Ca, Sr, and Ba are 5.57, 5.20, 4.39, and 4.22 respectively. The calcium, strontium, and barium chelate stability constants of Neo-Thorin are greater than those of *o*-phosphonophenylazochromotropic acid, while the magnesium chelate of *o*-phosphonophenylazochromotropic acid is more stable than that of Neo-Thorin; therefore, it may be concluded that the coordination bond of Mg with the phosphonoic group is stronger than that with the arsonic group.

Intramolecular Hydrogen Bonds. XVII.[1] Intramolecular Hydrogen Bonding Involving the Mercapto Group as a Hydrogen Donor

Nobuo MORI, Shinichi KAIDO, Koichi SUZUKI, Mikio NAKAMURA, and Yojiro TSUZUKI

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received October 12, 1970)

The SH stretching absorption spectra of some mercapto compounds in dilute carbon tetrachloride solutions and also in acetonitrile solutions have been measured at 20°C. Alkyl mercaptans show absorption bands which are suggestive of the rotational isomerism around the C–S bond. The spectral data indicate that benzyl mercaptan, ω-ethoxyalkyl mercaptans, and ethyl α- and β-mercaptoalkanoates form practically no intramolecular hydrogen bond between the SH group and the hydrogen-acceptor group. In thiosalicylic acid and its ethyl ester, the hydrogen-bonding to the carbonyl group is partially possible even in acetonitrile. On the other hand, the corresponding free carboxylic acids are not hydrogen-bonded between the S atom and the carboxyl group.

The mercapto group is well known[2,3] to form hydrogen bonds with oxygen, nitrogen, carbon, and sulfur atoms, and possibly with aromatic π-electrons as well, but it is apparently not capable of hydrogen bonding to such an extensive degree as occurs with the hydroxyl group. On the dilution of neat mercaptans with non-polar solvents, the stretching frequencies of the S–H bonds are only slightly shifted to the lower-frequency side and the chemical shifts of the proton magnetic resonance of the SH groups are extraordinarily small.

The literature contains scant information on the intramolecular hydrogen bonding involving the mercapto group. In ω-*N*,*N*-dialkylamino-alkyl mercaptans,[4] there is no evidence for the expected lowering of the SH-stretching frequency by hydrogen bonding. However, only a few thiols, such as ethyl β-mercapto-β-phenylacrylates,[5] *o*-amino- and *o*-hydroxy-thiophenols,[6] and ethyl thiosalicylate,[7] show relatively large spectral shifts of the bonded SH bands. More recently, Hirota and his co-workers[8] have suggested that, in *o*-substituted thiophenols, the hydrogen bonding may be indicated by an increased intensity of the SH stretching band and also by an increased downfield-shift of the SH proton resonance, even if no lowering of the SH stretching frequency is observed.

In previous papers,[9,10] it has been reported that α- and β-hydroxyalkanoic esters form an intramolecular hydrogen bond, predominantly between the hydroxyl and the ester-carbonyl groups. These results have prompted us to examine the corresponding mercapto compounds as well.

The present paper will deal with the intramolecular hydrogen bonding in benzyl mercaptan, ω-ethoxyalkyl mercaptans, ethyl α- and β-mercaptoalkanoates, and ethyl thiosalicylate, as studied by means of infrared spectroscopy. Furthermore, the SH spectra of alkyl mercaptans in dilute carbon tetrachloride solutions have also been measured, since there have been no detailed and systematic studies of them, although the SH frequencies of many thiols have been reported.[11]

Experimental

Samples. All the compounds examined were prepared in the usual manner except for commercially-available alkyl and benzyl mercaptans. The new *o*-mercaptobenzyl methyl ether was prepared form *o*-aminobenzyl methyl ether[12] by way of its diazonium salt. Their melting and/or boiling points were equal, or very close, to those previously reported, and their purity was established by gas chromatograms and/or NMR spectra. The unknown compounds had the analytical data shown in Table 1. Carbon tetrachloride and acetonitrile were fractionally distilled over phosphours pentoxide.

Infrared Measurement. This was carried out at *ca.* 20°C by the method previously described,[9] using a grating infrared spectrophotometer, Model DS-403G, of the Japan Spectroscopic Co. The concentrations used were 0.006 mol/*l* (SH spectra; cell-thickness: 5.0 cm) and 0.01 or 0.001 mol/*l* (CO spectra; cell-thickness: 1.1 or 10.0 mm), unless otherwise noted. The calculated spectral slit width was 1.5 cm^{-1} at the wave number of 1700 cm^{-1} and 0.8 cm^{-1} at 2600 cm^{-1}. Some of the unsymmetrical bands with relatively high intensities were graphically[9] divided into their components, particularly when the intensity ratios were desired.

Results and Discussion

Alkyl mercaptans. The spectra of some alkyl mercaptans in carbon tetrachloride are shown in Fig. 1, while the apparent spectral data are summarized in Table 2. The SH bands of *prim-* and *t*-alkyl mercaptans are practically symmetric, while those of *s*-alkyl mercaptans are unsymmetric; the shapes and the frequencies

o-$C_6H_4(SH)(CH_2OCH_3)$	88/ 5.5	62.43	6.44	62.32	6.54

of the bands vary with the type of the alkyl group (R). This variation can not be due to any molecular association, since thiols are generally already monomeric even in a concentration of 0.1 mol/l in the same solvent. By analogy with the case of the corresponding alkanols,[13] it is probably attributable to the rotational isomerism around the C–S bond.

Figure 3 shows three possible steric environments around the S–H group, which are projected along the C–S bond, where C denotes an alkyl group, and X, a hydrogen atom or an alkyl group, depending on the type of R. If the molecule takes a staggered conformation, but not an eclipsed one, the mercapto-hydrogen atom of methyl and t-butyl mercaptan always exists in the environment, I or III respectively, in any rotational position about the C–S bond to be favoured. Hence, the frequency-lowering by 14 cm^{-1} of t-butyl mercaptan can be attributed to the presence of the two methyl groups *skew* to the SH. The spectral pattern of isopropyl mercaptan changed with the temperature; the intensity of the stronger band-component relative to the shoulder decreases at a higher temperature. Therefore, the band consists of at least two band-components, which can probably be assigned to the SH species in the environments, I and II respectively. The practically symmetrical bands of ethyl and n-butyl mercaptan probably consist of two bands corresponding to the two environments, I and II, because there is a possibility that they exist in these environments and also because the half-band widths are relatively wide.

Table 2. The spectral data of alkyl, benzyl and ω-ethoxyalkyl mercaptans in CCl_4

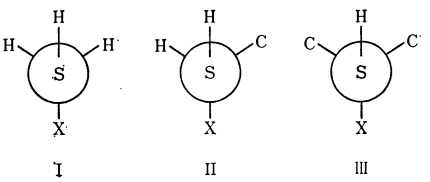

Fig. 3. Three steric environments around the SH group (X=H or C).

13) M. Ōki and H. Iwamura, This Bulletin, **32**, 950 (1959).

Benzyl mercaptan shows a complicated spectral pattern in the SH stretching region, but a simple unsymmetrical band can be obtained by subtracting the spectral curve of benzyl methyl thioether from it (Fig. 2); the peak frequency and intensity are very close to those of *prim*-alkyl mercaptans. It thus appears that the SH group is practically incapable of the interaction with the aromatic π-electrons which occurs with benzyl alcohols[14] and benzylamines.[15]

2- and 3-ethoxyalkyl mercaptans show, in carbon tetrachloride, single SH bands which are complicated by overlapping with other absorption bands on the higher-frequency side; the peak frequencies are rather close to that of methyl mercaptan, and the intensities are similar to those of alkyl mercaptans. Accordingly, the hydrogen bonding to the ethoxy group appears to be practically absent.

Furthermore, the SH frequencies of the above mercaptans are very close to those of thiophenols; hence, the electronic effects of substituents on them seem negligible. However, substituents have electronic effects on the intensities, as is indicated by the ε values of thiophenol and ethyl *p*-mercaptobenzoate (Table 5).

Ethyl α- and β-mercaptoalkanoates. Their SH spectra in carbon tetrachloride are shown in Fig. 4, while the apparent spectral data are summarized in Table 3. The bands of ethyl α-mercapto-acetate and -isobutyrate are almost symmetric, while ethyl α-mercaptopropionate shows an unsymmetric band. The frequencies and half-band widths are very close to those of the corresponding alkyl mercaptans; it thus appears that all the α-esters form no hydrogen bond. On the other hand, the high intensities, as compared with those of alkyl mercaptans, do not provide evidence for the hydrogen bond formation, because such an increase in intensity may also be caused by the electronic effects of the ethoxycarbonyl group. In order to clarify this

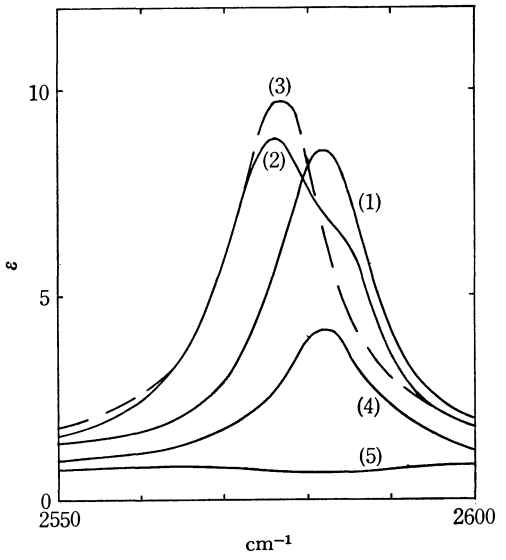

Fig. 4. The spectra of ethyl mercaptoacetate (1), α-mercaptopropionate (2), α-mercaptoisobutyrate (3), β-mercaptopropionate (4), and α-ethylthiopropionate (5).

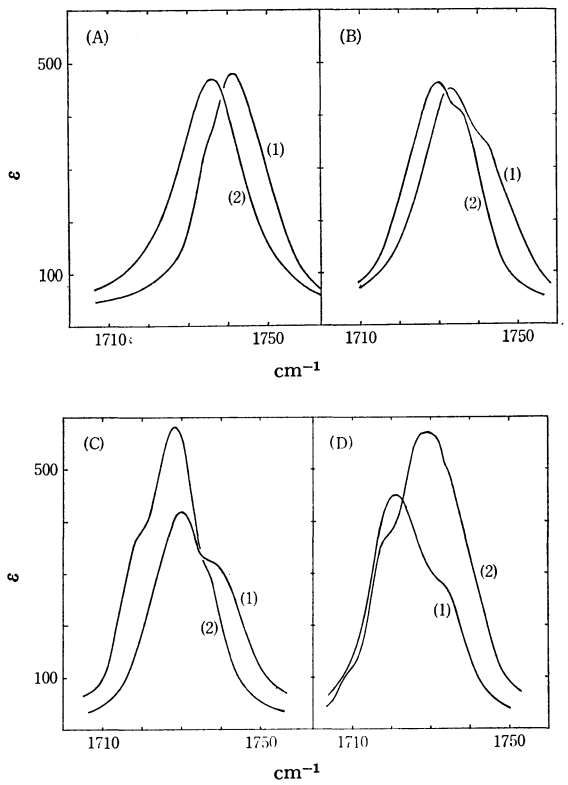

Fig. 5 (A)—(D). The CO spectra of ethyl mercaptoacetate (A) and its *S*-ethylated compound (B), α-ethylthiopropionate (C) and α-ethylthioisobutylate (D) in carbon tetrachloride (1) and acetonitrile (2).

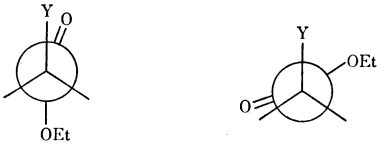
point, the carbonyl data will be discussed further on the basis of a comparison with those of the corresponding *S*-ethylated compounds.

Ethyl α-ethylthioalkanoates show, in carbon tetrachloride, two overlapped carbonyl bands with a spacing of about 10 cm,$^{-1}$ and the intensity of the higher-frequency band increases in acetonitrile relative to that of the lower-frequency band (Fig. 5A—5D). By analogy with the cases of α-halogeno-[16] and α-alkoxycarbonyl compounds,[10,17] as well as in view of the relatively high dipole moment of a C–S bond (*cf.* μ_{C-S}: 1.2 D; μ_{C-O}: 0.9 D; μ_{C-Cl}: 1.7 D), this phenomenon can be suitably explained in terms of the rotational isomerism around the C_1–C_2 bond. Thus, the two bands can be assigned, in the usual manner, to the *cis* and *gauche* forms respectively:



cis-Form with a higher ν_{CO} *gauche*-Form with a lower ν_{CO}

On the other hand, ethyl α-mercaptoalkanoates show, in carbon tetrachloride, a strong band, with a weak shoulder centered at a position lower by about 6 cm^{-1} than the peak position, and the frequencies of

a) The values in parentheses, obtained by band reflection, are approximate.

the two band-components are close to those of their *S*-ethylated compounds. In acetonitrile (Fig. 5A), ethyl mercaptoacetate shows a single, symmetric band at the same frequency as that of the *cis* form of the corresponding *S*-ethylated compound, suggesting that the ester exists exclusively in the *cis* form. Accordingly, the two bands which appear in carbon tetrachloride can probably be associated with the same rotational isomers, *cis* and *gauche*, as has been suggested in the case of ethyl α-ethylthioalkanoates. If this is true, it should be noticed, from the relative intensities of the bands, that the proportion of the *cis* form of ethyl α-mercaptoalkanoates in carbon tetrachloride is much higher than those which have hitherto been observed in α-halogeno- and α-alkoxy-carbonyl compounds (the intensities being taken as approximately indicative of the concentrations). The equilibrium between the *cis* and the *gauche* form is considered to be determined by two factors: (1) the electrostatically repulsive interaction between the C_α–Y and C=O dipoles (Y: an electronegative atom or group), which increases with the increasing polarity of the C–Y bond,[18] and (2) the sterically repulsive interaction between the Y and carbonyl-oxygen atoms[17,19] and between the Y and alkoxy-oxygen atoms,[18] both of which increase with the increasing bulkiness of Y. Since the dipole-dipole interaction should raise the double bond character of the carbonyl group and increase the stretching frequency of the C=O group, the fact that the spacing between the two carbonyl bands of ethyl ethylthioacetate (*ca.* 10 cm^{-1}) is lower than those of ethyl halogeno- and ethoxy-acetates (*ca.* 20 cm^{-1})[17] seems to indicate that the electrostatic interaction between the C–S and the C=O dipole is lower than those in the latter esters. From this, a higher proportion of the *cis* form may be expected in the former. On the other hand, the steric repulsion of Y exerting on the C=O group in the *cis* form and also exerting on the alkoxy group in the *gauche* form should be more highly operative in the ethylthioacetate than in the ethoxyacetate, because of the larger van der Waals radius of the sulfur atom.[20] Consequently, judging from the observation that the relative intensity (*cis* to *gauche*) of ethyl ethylthioacetate (*ca.* 0.8) is lower than the 1.94 of ethyl ethoxyacetate,[17] the steric repulsion between the Y and the carbonyl group must be much more important than the other electrostatic and steric repulsions. This is consistent with the conclusion by Brown[17] that the size, rather than the polarity, of Y in acetates is the determining factor.

In the case of ethyl mercaptoacetate, the mercapto group may be expected to be equal in size to, or smaller than, the ethylthio group.[21] If it is smaller, the steric repulsion between the Y and the carbonyl group should become lower, and the proportion of the *cis* form should be higher than that of the corresponding *S*-ethylated acetate. This expectation agrees with our observation that the *cis*-to-*gauche* ratio is *ca.* 8, but this ratio seems too high to be attributable to the decreased steric repulsion only, because no such high ratio has been observed even when the Y group has a bulkiness as small as the ethoxy group or the fluorine atom. In this connection, an attractive interaction between the SH and the carbonyl group may further be considered; it is not evident, however, whether this interaction is the usual hydrogen bonding or the electrostatic attraction, but it is probably the latter because no lowering of the SH and CO frequencies is observed. In this connection, it must be mentioned that ethyl glycolate

18) S. Mizushima, T. Shimanouchi, I. Ichishima, T. Miyazawa, I. Nakagawa, and T. Araki, *ibid.*, **78**, 2038 (1956).

20) The van der Waals radius (r) of an atom (Y) is approximately equal to the C–Y bond distance: r=1.40 Å for O, 1.85 for S, and 1.35 for F; O–Y distance=1.43 Å (Y:O), 1.81 (S), and 1.38 (F); hence, the r value may be considered as a function of the steric interaction.

21) In the cyclohexane system, the steric size of the SH group is close to, or somewhat lower than, that of the SCH_3 or SC_6H_5 group (*cf.* E. L. Eliel, N. L. Allinger, S. J. Angyal, and G. A. Morrison, "Conformational Analysis," Interscience Publishers, New York (1965), p. 438).

exists exclusively in the *cis* form with the hydrogen bonding between the OH and CO group; thereby, both OH and CO frequencies are very much lowered.[9,10]

Ethyl β-mercaptopropionate may be internally unbonded, since both the frequency and the intensity of the SH band are comparable to those of *prim*-alkyl mercaptans, and the carbonyl data are very close to that of the corresponding *S*-ethylated compound.

α- and β-Ethylthioalkanoic Acids. The spectral data are summarized in Table 4. The α-acids show, in carbon tetrachloride, two split carbonyl bands in the monomer region (Fig. 6). Since only one OH band of the *cis*-carboxyl structure is observed, the band-splitting is not attributable to a hydrogen bond formation between the S atom and the *trans*-carboxyl group such as occurs in α-alkoxyalkanoic acids.[22] The reason for this is not clear at the present time, but at least two reasons can be considered: (1) the Fermi resonance or other absorptions and (2) the rotational isomerism, as has been suggested above in accounting for a similar phenomenon in the corresponding esters. A further study of this problem is in progress.

β-Ethylthiopropionic acid shows only single OH and CO bands in the monomer region, both corresponding to the *cis*-carboxyl structure. These findings agree with the conclusion, confirmed in ω-methylthioalkanols,[23] that the hydrogen-accepting ability of a sulfur atom is lower than that of an oxygen atom.

Thiosalicylic Acid and Related Compounds. In carbon tetrachloride, the free SH bands of aromatic thiols generally appear near 2585 cm^{-1} (*e.g.*, thiophenol, *o*-thiocresol, and ethyl *p*-mercaptobenzoate in Table 5), indicating that the steric and electronic effects on the SH frequency are not significantly operative. Ethyl *p*-mercaptobenzoate shows two bands in the SH region (Fig. 7); the higher-frequency band can be assigned to the SH group on the basis of a comparison with the spectrum of the corresponding *S*-methylated compound. Therefore, the band (ε=20; $\Delta\nu_{1/2}$=40 cm^{-1}) at 2560 cm^{-1} of *o*-mercaptobenzyl methyl ether can be assigned to the bonded SH group,[24] but this ether shows no free SH band. This fact is very interesting which differs from the case of *o*-hydroxybenzyl methyl ether in which a weak free OH band is observed apart from a strong bonded OH band.[25] The two split bands of ethyl thiosalicylate observed in the SH region (Fig. 8) can likewise be assigned to the SH species bonded to the ethoxy- and the carbonyl-oxygen atoms respectively; this assignment is consistent with the observation of two carbonyl bands which can be assigned to the free and bonded carbonyl groups (Fig. 9A).

$CH_2(SEt)CH_2COOH$	3527	72	1762	200	1713	480

Thiosalicylic acid and its *S*-methylated compound show, in carbon tetrachloride, only single OH bands of the *cis*-carboxyl structure in the monomer region; hence, they form no hydrogen bond between the sulfur atom and the carboxyl group, although such a bonding occurs in *o*-alkoxybenzoic acids.[26] The two monomeric CO bands and the two SH bands of the former acid can probably be assigned much like those of its ester, because the spectral data of the two compounds are almost the same.

Ethyl *S*-methyl thiosalicylate shows, in carbon tetrachloride, two overlapped CO bands. In acetonitrile, the higher-frequency band is much weaker, with the frequency remaining almost unchanged, while the lower-frequency band shifts towards the lower-frequency side (Fig. 9B). This band-splitting is probably attributable to the Fermi resonance, but not to rotational isomerism or other absorptions, for the following reasons: (1) a band-splitting ascribed to the Fermi resonance is generally subject to a similar solvent effect,[27] while that ascribed to rotational isomerism

shows a reverse trend of solvent effect,[28] and (2) even in the other *p*-substituted benzoates where rotational isomers are not expected, a similar band appears near 1720 cm^{-1}.

It is further interesting that, in acetonitrile, thiosalicylic acid and its ethyl ester show, apart from the band ascribed to the Fermi resonance, two carbonyl bands; the relative intensities of the lower-frequency bands are much lower than those in carbon tetrachloride. There are at least two possibilities for the band-splitting: (1) absorptions due to groups other than the carbonyl or due to rotational isomers, and (2) intramolecular hydrogen bonding. The first one can probably be rejected since the other aromatic compounds, even those *o*-substituted, show no splitting. The second possibility should thus be considered. The basicity of acetonitrile is so strong as to allow benzoic acid to be practically monomeric even in a concentration of 1 mol/*l*.[28] Further, it has now been found that acetonitrile is a base so strong that the aliphatic and aromatic carboxylic acids examined in the present work show negligible dimer absorptions at 0.01 mol/*l* in carbon

tetrachloride containing 20% by volume of acetonitrile. Nevertheless, the intramolecular hydrogen bond between the OH and CO groups in salicylic acid and also in its methyl ester can not be broken at all in acetonitrile, while the dimer formation of the acid through intermolecular hydrogen bonding is practically completely prevented.[29] Accordingly, the intramolecular hydrogen bonding in thiosalicylic acid and its ester is probably possible to some extent even in acetonitrile; however, this is not expected at all because of the very poor hydrogen-donating property of the mercapto group.

29) N. Mori, unpublished results: for salicylic acid, $\nu_{CO}=1695$ (monomer) and 1662 cm^{-1} (dimer) in CCl_4 and 1682 cm^{-1} in CH_3CN; for the methyl ester, $\nu_{CO}=1680$ cm^{-1} in both solvents. On the other hand, ethyl glycolate is internally bonded in CCl_4, but not in CH_3CN.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1864—1868 (1971)

The Preparation and Properties of Mesoionic 5-Iminothiazole Derivatives

Toshie SHIBA and Hiroshi KATO[1)]

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received October 28, 1970)

Mesoionic 5-iminothiazoles were prepared by the cyclization of *N*-thiobenzoyl-methylaminoacetonitriles with hydrogen chloride or acyl chlorides. The reaction between a 5-aminothiazolium chloride and acyl chlorides, isocyanate, sulfonyl chloride, and nitrous acid gave the corresponding *N*-substituted mesoionic 5-iminothiazole derivatives. The spectral data of these compounds as well as the ready bromination of the ring support the view that this ring system is aromatic.

Although the chemistry of mesoionic thiazole derivatives in general has been widely investigated,[2)] only a single derivative of mesoionic 5-iminothiazole (3,5-dihydro-5-iminothiazole or anhydro 3-substituted 5-aminothiazolium hydroxide) has been described in the literature.[3)] That paper concerns the formation of mesoionic 3-methyl-2,4-diphenyl-5-phenyliminothiazole by the proton-catalyzed rearrangement of mesoionic 1-methyl-2,3,5-triphenylimidazole-4-thione. This rearrangement has been found to be difficult to reproduce and no properties of the mesoionic 5-iminothiazole have been described. Unsuccessful attempts to prepare this ring system by the action of amines on 5-methylmercaptothiazolium salts have been reported earlier.[4)]

The preparation of some 3-substituted 5-aminothiazolium salts by the alkylation of the corresponding 5-aminothiazoles has been described earlier.[5,6)] In one case, even treatment with methyl iodide of 5-acetamido-2-thio-3-isopropylthiazoline in aqueus sodium hydroxide has been studied.[6)] It is reported, however, that this treatment, instead of affording the corresponding mesoionic compound or inner salt, gave the corresponding thiazolium hydroxide.

We wish to report here a more reliable method of

synthesizing mesoionic 5-iminothiazoles, a method promising a wider synthetic applicability, and also some properties of the ring system thus prepared.

Results and Discussion

Preparation and Recations. The thiobenzoylation of two acetonitriles, Ia and Ib, gave *N*-thiobenzoylmethylaminoacetonitriles (IIa and IIb). The two nitriles, IIa and IIb, showed only a very weak absorption of a cyano group in the infrared region, suggesting the possibility that II may partly tautomerized to cyclic mesoionic iminothiazoles, II'. However, the lack of any infrared bands assignable to an NH group, and the fact that II did not react with acetic anhydride, eliminate such a possibility.

The treatment of thiobenzoylaminoacetonitriles, IIa and IIb, with hydrogen chloride in aprotic solvents gave 5-aminothiazolium hydrochlorides, IIIa and IIIb, as hygroscopic compounds. The hydrochlorides were characterized by conversion to the corresponding perchlorates and picrates. The structures of these salts were determined by elemental analyses, spectroscopic data, and the reactions to be described below. On heating the hydrochlorides, IIIa and IIIb, with acetyl and benzoyl chloride, the corresponding *N*-acetyl- and *N*-benzoyl-aminothiazolium chlorides, IVa—d,HCl, were formed. Alternatively, the same *N*-acylaminothiazolium chlorides, IVa—d,HCl, were prepared by the reaction of thiobenzoylaminoacetonitriles, IIa and IIb, with acetyl and benzoyl chloride in benzene. The mode of the formation of these compounds is analogous to that of sydnone imines.[7]

The treatment of the salts, IVa—d,HCl, with alkali afforded mesoionic 5-acyliminothiazoles, IVa—d. In a similar manner, the corresponding phenylcarbamoyl- and phenylthiocarbamoyl-iminothiazole, Va and Vb, were prepared by the treatment of 5-amino-3-methyl-2,3,4-diphenylthiazolium chloride (IIIa) with phenyl isocyanate and phenyl isothiocyanate respectively. Thiazolium chloride, IIIa, reacted with benzenesulfonyl chloride in the presence of a base to afford mesoionic 5-benzenesulfonyliminothiazole, VI. By the action of sodium nitrite on IIIa, *N*-nitroso-iminothiazole VII was formed slowly. It was anticipated that the elimination of a molecule of nitrogen from VII, in a fashion analogous to that with *N*-nitroso-sydnone imines,[8] would give the corresponding mesoionic 5-oxothiazole.[2,9] However, both the pyrolysis and photolysis of the *N*-nitroso derivative, VII, in aprotic solvents resulted in a polymer formation, and no nitrogen evolution was observed.

In order to obtain chemical support concerning the aromatic nature of the mesoionic 5-iminothiazole ring, the bromination of IVd was carried out. Bromination took place readily at the 4-position of IVd to afford 4-bromo-5-benzoylimino-3-methyl-2-phenylthiazole VIII. The structure of the bromide was assigned on the basis of elemental analyses, the lack of an NMR signal around τ 2.7, and the lack of an infrared band at 3080 cm^{-1} (*vide infra*).

The hydrochlorides III and acyliminothiazoles IV

are quite stable to acid, and were recovered unchanged after having been heated with 10% hydrochloric acid for one hour. It appears that the iminothiazoles have a considerable basicity because the hydrochloride IIIa was unchanged by treatment with aqueous sodium hydrogen carbonate. Even the *N*-acyl derivatives IV readily form hydrochlorides and picrates.

Spectral Properties (Cf. Tables 1 and 2). The large hypsochromic shifts of the ultraviolet absorption maxima of IV at the longest wave length with an increase in the solvent polarity show that they are n→π transitions; they may also suggest that there is a considerable charge separation between the heterocyclic ring and the exocyclic acylimido group.[10]

The infrared spectra of 5-iminothiazoles unsubstituted at the 4-position show a medium intensity peak at 3100 cm^{-1} (hydrochlorides) or 3080 cm^{-1} (free bases) which may be assigned as the C–H stretching band of the 4-position. None of the free bases of *N*-acyl (IVa—d) and *N*-carbamoyl (Va) derivatives shows an infrared absorption band of the carbonyl group in a region normally expected for an amide group. The infrared spectra of the corresponding salts (IVa—d, HCl, Va,HCl) show an absorption at 1630—1680 cm^{-1}, but this absorption is weaker than that expected for a normal amide carbonyl band. Moreover, they usually show both the absorption bands assignable to a hydroxyl and an ammonium (and/or amino) group.

The NMR signal of the 3-methyl group of mesoionic iminothiazoles, IV, appears at τ 6.05—6.25, a position which is higher by *ca.* 0.2 ppm than that of the corresponding aminothiazolium chlorides, IV,HCl. The signal of the proton at the 4-position of IVc and IVd appears at *ca.* τ 2.7, whereas that of thiazolium hydrochloride, IVc,HCl, is shifted considerably to a lower magnetic field and appears at τ 1.15. This shift of the proton signal with the hydrochloride may partly be due to a solvent effect, because this spectrum had to be taken in a mixture of deuteriochloroform and deuteriodimethyl sulfoxide. In fact, the position of the proton signal of the 4-position of IVb is fairly much dependent upon the solvent employed (Table 2). This shift is probably due to the formation of a hydrogen bond with the solvent.[11] The chemical shift values of the

3-methyl group and the 4-hydrogen atom are those usually encountered with common aromatic azoles[12] and many other mesoionic ring systems.[2]

From the properties of IV described above, one may infer that this ring system shows a certain degree of aromaticity, that there is a considerable charge separation between the ring and the exocyclic acylimido group, and that the acyl group is considerably polarized.

Experimental[13]

The Attempted Proton-catalyzed Isomerization of 1-Methyl-2,3,5-triphenylimidazole-4-thione.[3] *a*) A solution of 1 g of 1-methyl-2,3,5-triphenylimidazole-4-thione (imidazolethione) in 50 m*l* of chloroform was saturated with dry hydrogen chloride with cooling. After stirring for four hours at 20°C, the solvent was distilled off and the colorless residue of the hydrochloride (mp 195—197°) was collected. On treatment with aqueous sodium bicarbonate or even with water, 0.8 g of imidazolethione was recovered.

Imidazolethione was recovered in 75—100% yields, after treatment with bicarbonate or with water, when the chloroform solution was treated with: *b*) a slow stream of hydrogen chloride for fifteen hours at 20—30°C, *c*) with an equivalent amount of hydrogen chloride for five hours or overnight, or *d*) with conc. hydrochloric acid for two hours, or *e*) when a solution of imidazolethione in tetrahydrofuran was treated as has been described in procedure *a*). In every case, the crude hydrochloride or the recovered crude imidazolethione showed no infrared absorption at 1670 cm^{-1}.

1,3-Dimethyl-2,5-diphenylimidazole-4-thione[4] was also recovered unchanged when it was treated by methods similar to those described above.

N-Thiobenzoyl-α-phenyl-methylaminoacetonitrile (IIa) Into a solution of 3 g (0.019 mol) of thiobenzoyl chloride in 20 m*l* of triethylamine, there was dropwise added with stirring at 0°C, 2.8 g (0.019 mol) of α-phenyl-methylaminoacetonitrile. After thirty minutes' stirring, the solvent was removed under reduced pressure and the residue was extracted with benzene. The benzene extract was washed with water and dried over sodium sulfate. After the solvent had been distilled off, an oily residue remained; this solidified upon the addition of isopropanol, Recrystallization from isopropanol gave 2 g (54% yield) of yellow prisms melting at 79—81°C. IR: 2230 (CN), 1380, 1068 (C=S); NMR: 7.05 (3H, s, Me), 2.30—2.80 (10H ,m, Ph), 1.55 (1H, s, CH).

Found: C, 71.93; H, 5.32; N, 10.54%. Calcd for $C_{16}H_{14}N_2S$: C, 72.16; H, 5.30; N, 10.52%.

N-Thiobenzoyl-methylaminoacetonitrile (IIb). This was prepared in a 50% yield, by a method similar to that described above, from 2 g (0.028 mol) of methylaminoacetonitrile and 4.4 g (0.028 mol) of thiobenzoyl chloride. Colorless needles (from isopropanol); mp 123—124°C. IR: 2240 (CN), 1375, 1084 (C=S); NMR 6.70 (3H, s, Me), 4.92 (2H, s, CH_2), 2.60 (5H, s, Ph).

Found: C, 62.87; H, 5.43; N, 14.53%. Calcd for $C_{10}H_{10}N_2S$: C, 63.15; H, 5.30; N, 14.73%.

5-Amino-3-methyl-2,4-diphenylthiazolium Chloride (IIIa). Hydrogen chloride was saturated to a solution of 1 g of IIa in 40 m*l* of anhydrous ether. The white powder which slowly separated out was recrystallized from ethanol-acetone (2:5) to give 1 g (91% yield) of colorless prisms melting at 206—207°C.

Found: C, 63.32; H, 5.12; N, 9.52%. Calcd for $C_{16}H_{15}N_2SCl$: C, 63.57; H, 4.97; N, 9.27%.

Perchlorate. Colorless prisms [from ethanol-acetone (1:4)]: mp 302—303°C.

Found: C, 52.77; H, 4.05; N, 7.24%. Calcd for $C_{16}H_{16}N_2O_4SCl$; C, 52.48; H, 4.38; N, 7.61%.

Picrate. Yellow needles (from ethanol): mp 200—201.5°C. Found: C, 53.63; H, 3.26; N, 13.81%. Calcd for $C_{22}H_{17}N_5O_7S$: C, 53.33; H, 3.45; N, 14.13%.

5-Amino-3-methyl-2-phenylthiazolium Chloride (IIIb). This was prepared by the saturation of hydrogen chloride in a

12) *Cf. e.g.*, "NMR Spectra Catalog," Vol. I and II, Varian Associates, Palo Alto, Calif, (1962, 1963); H. A. Szymanski and R. E. Yelin, "NMR Band Handbook," IFI/Plenum, New York (1968).

13) The melting points were determined on a micro hot stage, and are not corrected. The ultraviolet spectra were recorded on a Hitachi model ESP-2U spectrophotometer and the infrared spectra were recorded as KBr disks on a Hitachi model EPI-SII spectrophotometer. The NMR spectra were measured using a JEOLCO JNM-4H-100 (100 MHz) spectrometer in deuteriochloroform solutions containing tetramethylsilane as internal standard, and the chemical shifts are given in τ values. The mass spectra were measured at 75 eV using a direct inlet technique.

benzene solution of IIb. Since it was very hygroscopic, it was characterized by converting it to the corresponding perchlorate and picrate. The yields were in the range of 80—95%.

Perchlorate. White prisms; mp 132—133°C. Found: C, 41.52; H, 3.58; N, 9.48%. Calcd for $C_{10}H_{11}N_2O_4SCl$: C, 41.38; H, 3.79; N, 9.65%.

Picrate. Yellow needles (from ethanol); mp 125—126°C. Found: C, 45.98; H, 3,37; N, 16.89%. Calcd for $C_{16}H_{13}N_5O_7S$: C, 45.83; H, 3,13; N, 16.70%.

5-Acetylamino-3-methyl-2,4-diphenylthiazolium Chloride (IVa, HCl). (*a*) A solution of 5 g (0.02 mol) of nitrile IIa and 3.1 g(0.04 mol) of acetyl chloride in 50 m*l* of benzene was allowed to stand for two days at room temperature. The white precipitate was recrystallized from acetone-isopropanol (4:1) to give 4.8 g (70% yield) of fine, colorless needles melting at 207—208°C (dec.).

Found: C, 62.43; H, 5.10; N, 7.72%. Calcd for $C_{18}H_{17}N_2OSCl$: C, 62.69; H, 4.97; N, 8.12%.

(*b*) A mixture of 0.22 g of thiazolium chloride, IIIa, and 3 m*l* of acetyl chloride was heated under reflux on a water bath for two hours. After cooling, the solid precipitate was collected, washed with ether, and recrystallized from acetone-isopropanol (4:1) to give the same product, IVa,HCl, in a 84% yield.

Picrate of IVa. Yellow needles (from ethanol); mp 166—167°C. Found: C, 58.19; H, 3.73; N, 11.42%. Calcd for $C_{29}H_{21}N_5O_8S$: C, 58.09; H, 3.51; N, 11.68%.

5-Acetylimino-3-methyl-2,4-diphenylthiazole (IVa). An aqueous solution of IVa,HCl was made alkaline with sodium hydrogen carbonate and was then extracted with benzene. The benzene extract was dried over sodium sulfate, the solvent was distilled off, and the residue was recrystallized from acetone to give yellow prisms; mp 229—230°C. Mass *m/e* (rel. intensity): 308(33,P), 293 (65, P—Me), 265 (1, P—Ac), 121 (100, PhC=S), 118 (37, PhC=MMe), 77 (43, Ph), 43 (27, Ac).

Found: C, 69.83; H, 5.12; N, 8.80%. Calcd for $C_{18}H_{16}N_2OS$: C, 70.10; H, 5.22; N, 9.08%.

By procedures similar to those described above, the following compounds were prepared.

5-Benzoylamino-3-methyl-2,4-diphenylthiazolium Chloride (IVb, HCl). Colorless prisms [from acetone-ethanol (4:1)]; mp 187—188°C, yield 74%.

Found: C, 67.60; H, 4.68; N, 6.68%. Calcd for $C_{23}H_{19}N_2OSCl$: C, 67.90; H, 4.71; N, 6.89%.

Picrate of IVb. Yellow needles (from ethanol); mp 166—167°C.

Found: C, 58.19; H, 3.73; N, 11.42%. Calcd for $C_{29}H_{21}N_5O_8S$: C, 58.09; H, 3.51; N, 11.68%.

5-Benzoylimino-3-methyl-2,4-diphenylthiazole (IVb). Yellow prisms (from acetone); mp 259—260°C; yield, 82%.

Found: C, 74.79; H, 4.87; N, 7.25%. Calcd for $C_{23}H_{18}N_2OS$: C, 74.58; H, 4.90; N, 7.56%.

5-Acetylamino-3-methyl-2-phenylthiazolium Chloride (IVc,HCl). Colorless prisms (from isopropanol); mp 243—244°C (dec); yield, 87%.

Found: C, 53.36; H, 5.02; N, 10.16%. Calcd for $C_{12}H_{13}N_2OSCl$: C, 53.63; H, 4.88; N, 10.42%.

5-Acetylimino-3-methyl-2-phenylthiazole (IVc). Colorless needles (from acetone); mp 219—220°C; yield, 75%. Mass *m/e* (rel. intensity): 232 (35, P), 217 (100, P—Me), 189 (1, P—Ac), 121 (74, PhC=S), 118 (28, PhC=NMe), 77 (very intense, Ph), 43 (very intense, Ac).

Found: C, 61.92: H, 5.29; N, 12.24%. Calcd for $C_{12}H_{12}N_2OS$: C, 62.06; H, 5.21; N, 12.06%.

5-Benzoylamino-3-methyl-2-phenylthiazolium Chloride (IVd,HCl). Colorless prisms (from isopropanol); mp 237—238°C; yield, 91%.

Found: C, 61.40; H, 4.56; N, 8.24%. Calcd for $C_{17}H_{15}N_2OSCl$: C, 61.72; H, 4.57; N, 8.46%.

5-Benzoylimino-3-methyl-2-phenylthiazole (IVd). Yellow leaflets (from acetone-ethanol); mp 261—262°C; yield, 90%.

Found: C, 69.18; H, 4.74; N, 9.73%. Calcd for $C_{17}H_{14}N_2OS$: C, 69.37; H, 4.80; N, 9.52%.

5-Phenylcarbamoylimino-3-methyl-2,4-diphenylthiazole (Va). This was prepared from IIa and phenyl isocyanate by heating them on a water bath for 2 hr, and then treating them with sodium hydrogen carbonate. Yellow prisms (from acetone-ethanol); mp 245—246°C; yield, 75%.

Found: C, 72.10; H, 4.75; N, 11.17%. Calcd for $C_{23}H_{19}N_3OS$: C, 71.67; H, 4.97; N, 10.90%.

Hydrochloride of Va. White prisms (from acetone); mp 230—231°C (dec.).

Found: C, 65.07; H, 4.52; N, 9.63%. Calcd for $C_{23}H_{20}N_3OSCl$: C, 65.47; H, 4.77; N, 9.95%.

5-Phenylthiocarbamoylimino-3-methyl-2,4-diphenylthiazole (Vb). Yellow leaflets (from aceton-ethanol); mp 241—242°C; yield, 82%.

Found: C, 68.50: H, 4.54; N, 10.10%. Calcd for $C_{23}H_{19}N_3S_2$: C, 68.82; H, 4.77; N, 10.47%.

5-Benzenesulfonylimino-3-methyl-2,4-diphenylthiazole (VI) To a solution of 0.5 g of IIIa in 5 m*l* of water, 0.3 g of benzenesulfonyl chloride and then two molar equivalents of aqueous potassium hydroxide were slowly added with cooling and stirring. The precipitate was recrystallized from ethanol to give 0.25 g (37% yield) of yellow prisms melting at 242—243°C. IR: 1130 (SO_2).

Found: C, 64.76; H, 4.23; N, 6.77%. Calcd for $C_{22}H_{18}N_2O_2S_2$: C, 65.02; H, 4.46; N, 6.89%.

5-Nitrosoimino-3-methyl-2,4-diphenylthiazole (VII). To a cooled solution of 1.0 g of IIIa in 6 m*l* of water, a solution of 0.3 g of sodium nitrite in 4 m*l* of water was added, after which the mixture was allowed to stand for two days at room temperature. The yellow precipitate which slowly separated out was recrystallized from ethanol to give 0.5 g (51% yield) of yellow prisms melting at 187—188°C (dec.). IR: 1110, 1190 (N-O-?).

Found: C, 64.85; H, 4.51; N, 13.99%. Calcd for $C_{16}H_{13}N_3OS$: C, 65.08; H, 4.44; N, 14.23%.

5-Benzoylamino-4-bromo-3-methyl-2-phenylthiazolium Bromide (VIII,HBr). To a suspension of 0.5 g of IVd in 20 m*l* of ether, 0.1 m*l* of bromine was added with stirring and cooling. After twenty minutes, the newly-formed precipitate was recrystallized from ethanol to give 0.5 g (80% yield) of white prisms melting at 184—185°C (dec.). IR: 3340, 1660, 1570, 1455, 1305, 1270.

Found: C, 44.60; H, 2.94; N, 5.96%. Calcd for $C_{17}H_{14}N_2OSBr_2$: C, 44.96; H, 3.11; N, 6.17%.

The Free Base VIII was formed by the treatment of the hydrobromide with aqueous sodium hydrogen carbonate. Yellow prisms (from ethanol); mp 235—236°C. IR: 1460, 1380.

Found: C, 54.84; H, 3.31; N, 7.22%. Calcd for $C_{17}H_{13}N_2OSBr$: C, 54.71; H, 3.51; N, 7.51%.

We wish to thank Professor Masaki Ohta of Tokyo Institute of Technology and Professor Kameji Yamane of this Department for discussions and encouragement. We are also indebted to Kyorin Chemical Laboratories for performing the elemental analyses and the mass-spectral determination.

Isolation and Characterization of Pteridines from *Pseudomonas ovalis*

Akira SUZUKI and Miki GOTO

Department of Chemistry, Gakushuin University, Toshima-ku, Tokyo

(Received October 29, 1970)

Four ribityllumazine compounds were isolated from the cultured medium of *Pseudomonas ovalis*. Three of them were characterized as 6-methyl-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine, 6-(3-indolyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine and 6-(*p*-hydroxyphenyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine by comparison with synthetic samples. The fourth compound, named *putidolumazine*, was supposed to be a new compound (2-carboxyethyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine from its chemical and spectroscopic properties. This was confirmed from the identity of both natural and synthetic products.

6,7-Dimethyl-8-(1-D-ribityl)-2,4-dioxohexahydropteridine (Compound G)[1] and 6-methyl-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (Compound V) (IV)[2] were isolated from *Eremothecium ashbyii* as a green and a purple fluorescent materials, respectively. Recently, two new ribityllumazines were isolated from *Achromobacter petrophilum* by Takeda and Hayakawa.[3] One of them was identified as 6-(3-indolyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (III)[4] and the other was supposed to be 6-(*p*-hydroxyphenyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (II), the structure being proposed on the basis of biosynthesis.[5]

The function of ribityllumazines was recently clarified; *i.e.* Compound G is an intermediate of riboflavin and Compound V functions as an inhibitor.[6] Tyrosine and tryptophan have been found to be effectively incorporated into II and III.[5]

This paper describes the isolation of four ribityllumazine compounds from cultures of *Pseudomonas ovalis*. Three of them have been identified as compounds II, III, and IV. The last compound (*Putidolumadine*) is assumed to be a new ribityllumadine compound, 6-(2-carboxyethyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (I), from spectroscopic and chemical data. This was confirmed by the synthesis from 2,6-dihydroxy-5-nitro-4-D-ribitylaminopyrimidine and α-ketoglutaric acid.

Experimental

Isolation of Ribityllumazines. *Pseudomonas ovalis* (IAM 1506) was cultivated for 10 days in a fermentation jar (capacity: 20 *l*) at 32°C with aeration. The medium used was 0.75% casein enzymatic hydrolysate (10 *l*); the solution was adjusted to pH 7.0 with ammonia. After centrifugation the culture was concentrated to about 100 m*l* *in vacuo* below 40°C. Ribityllumazines were separated by conventional chromatographic methods using a cellulose column (7×25 cm) and isopropyl alcohol-1% ammonia (2:1) as a solvent. The fluorescent compounds were separated into two bands, *i.e.* a band containing green, purple and blue fluorescent compounds (Fraction 1), and a band containing a greenish-blue fluorescent compound (Fraction 2). The two fluorescent bands were eluted and the eluates were evaporated to dryness *in vacuo* at below 40°C. The residues were again purified chromatographically using a cellulose column (5×12 cm; solvent: water) for Fraction 2 and a DEAE-cellulose column (5×22 cm; solvent: 1 *l* of water, followed by 0.003 N hydrochloric acid) for Fraction 1. The greenish-blue fluorescent compound from Fraction 2 was eluted and eluate was evaporated to dryness *in vacuo*. The residue was dissolved in a small amount of water, and acetone was added. The precipitate was washed with cold water and dried over P_2O_5; yield, 3 mg (UV: $\lambda_{max}^{0.1N\ NaOH}$ mμ, 260, 307, 403; $\lambda_{max}^{H_2O}$ mμ, 215, 299, 377; $\lambda_{max}^{0.1N\ HCl}$ mμ, 240, 295, 365). This compound was identified as 6-(*p*-hydroxyphenyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (II) by comparison with synthetic material (see blow) and also with Compound GB, which was isolated from *Achromobacter petrophilum*[3].

Table 1. Paper chromatography and electrophoresis of pteridines

Substance	Solvents[a] A	B	C	D	Electrophoresis[b]
Greenish-blue fluorescent compound	0.23	0.19	0.11	0.10	7
After KIO_4 oxidation and $NaBH_4$ reduction	0.37	0.26	0.09	0.22	6
Compound GB	0.23	0.19	0.11	0.10	7
II	0.23	0.19	0.11	0.10	7
VI	0.37	0.26	0.09	0.22	6

a) Solvents: A. isopropyl alcohol: 2% ammonium acetate (1:1)
B. isopropyl alcohol: 1% ammonia (2:1)
C. 3% aqueous ammonium chloride
D. *n*-butyl alcohol: acetic acid: water (4:1:1)
b) Distance (in mm) to anode after paper electrophoresis at pH 4.65 (sodium acetate buffer) for 60 min at 18V/cm.

The compound thus obtained (*ca.* 1 mg) was dissolved in 0.2 m*l* of water and 4 mg of potassium periodate was added. After one hour the product was purified by paper chromatography using water as a solvent. The oxidation product was then reduced with a small amount of sodium borohydride in 0.1 m*l* of 1% ammonia. The solution was kept standing at room temperature for 30 min, then adjusted to pH 1 with hydrochloric acid. The product was again purified by paper chromatography using water as a solvent. The final product was identified as 6-(*p*-hydroxyphenyl)-8-(2-hydroxyethyl)-2,4,7-trioxohexahydropteridine (VI) by comparison with synthetic material (see Table 1).

The material from Fraction 1 was separated into two purple fluorescent and one greenish-yellow fluorescent bands on a DEAE-cellulose column. The greenish-yellow compound was further purified by column chromatography using a cellulose column (7×25 cm) and isopropyl alcohol-1% ammonia (2:1) as solvent; yield, *ca.* 30 mg. The material was recrystallized twice from 50% acetic acid to give yellow crystals; yield, 15.3 mg, mp 285—286°C (decomp.) (UV: $\lambda_{max}^{0.1N\ NaOH}$ mμ, 271, 308, 401; $\lambda_{max}^{H_2O}$ mμ, 213, 312, 398; $\lambda_{max}^{0.1N\ HCl}$ mμ, 216, 317, 390).

Found: C, 50.40; H, 4.39; N, 14.50%. Calcd for $C_{19}H_{19}O_7N_5 \cdot H_2O$: C, 51.00; H, 4.73; N, 15.65%.

The compound was identified as 6-(3-indolyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (III) by comparison with synthetic material (see below) and also with Compound GY, which was isolated from *Achromobacter petrophilum* by McNutt and Takeda[4] (Table 2). The purple fluorescent compound was identified as 6-methyl-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (IV) by comparison with Compound V of Masuda[2] (Table 2). The yield was *ca.* 2 mg.

Table 2. Paper chromatography and electrophoresis of pteridines

Substance	Solvents[a] A	B	C	D	Electrophoresis[b]
Greenish-yellow fluorescent compound	0.13	0.13	0.02	0.11	2
Purple fluorescent Compound	0.57	0.35	0.62	0.14	23
Compound GY	0.13	0.13	0.02	0.11	2
III	0.13	0.13	0.02	0.11	2

a) and b): See the footnote in Table 1.

Another purple fluorescent compound (putidolumazine) was further purified by conventional chromatographic methods using the following column and solvent: 1. a cellulose column (7×25 cm); developer: isopropyl alcohol-1% ammonia (2:1), and 2. a Sephadex G-25 column (5.5×25 cm); developer: water. The crude product (30 mg) from 30 *l* of the cultured medium was recrystallized twice from water to give colorless needles; yield, 8 mg; mp >265°C (decomp.).

Found: C, 42.27; H, 4.44; N, 14.08%. Calcd for $C_{14}H_{18}O_9N_4 \cdot H_2O$: C, 41.58; H, 4.95; N, 13.86%, The compound contained neither S nor P. The sample was dried over P_2O_5 for 10 hr at 100—110°C and 3 Torr. *Rf*-values and UV-spectra of putidolumazine are given in Table 3 and Fig. 1.

Reaction of Putidolumazine. Esterification. Putidolumazine (15 mg, recovered from mother liquid) dissolved when it was suspended in absolute ethanol and saturated with dry HCl gas. The reaction mixture was concentrated *in vacuo* below 40°C and purified by chromatography using a cellulose column (5×25 cm; developer: 50% isopropyl alcohol). The eluate was evaporated to dryness *in vacuo* below 40°C, and pale brown precipitate was obtained by recrystallization from a ethanol - ether; yield, 12.4 mg. Recrystallization of the product from ethanol gave a faint yellow product; yield, 5.4 mg, mp 117—120°C; additional crops (*ca.* 5 mg) were also obtained from the mother liquid.

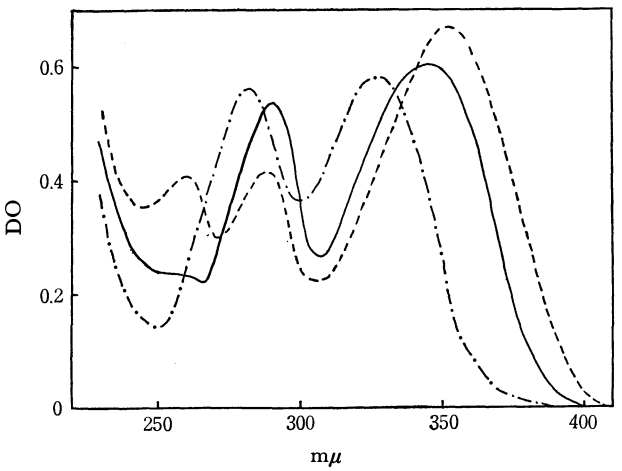

Fig. 1. Ultraviolet absorption spectrum of putidolumazine.
------: In 0.1N NaOH
——: In water
– · –: In 0.1N HCl

Found: N, 14.06%. Calcd for $C_{16}H_{22}O_9N_4$: N, 13.52%.

Acetylation of the Esterified Product: To a mixture of 1 m*l* of pyridine and 1 m*l* of acetic anhydride, 10 mg of the esterified product was added, and the whole was left standing at room temperature. After 2 days the reaction mixture was concentrated to dryness *in vacuo* below 40°C. Pale brown material was obtained by recrystallization from ethyl acetate-ether; yield, 6 mg. Mass spectrum of this compound is shown in Fig. 2.

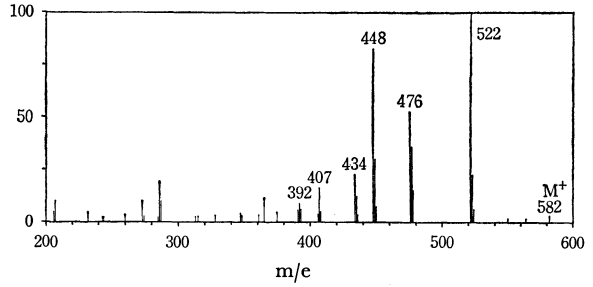

Fig. 2. Mass spectrum of acetylated putidolumazine-ester.

Periodate Oxidation: One milliliter of aqueous solution of putidolumazine (3.85×10^{-5} M) was treated with 2 m*l* of aqueous potassium metaperiodate solution (12.9×10^{-5} M, pH 4.2) at room temperature. At intervals the amount of understroyed periodate was estimated from UV-absorption (223 mμ) by the method of Dixon and Lipkin.[7] The compound (M, 386) consumed 4.70 mol of periodate per mole. For the sake of comparison, an authentic sample of Compound V of Masuda was subjected to periodate oxidation; it consumed 4.25 mol of periodate per mole.

$NaBH_4$ Reduction of the Periodate Oxidation Product: Putidolumazine (*ca.* 2 mg) was dissolved in 0.4 m*l* of water and 4 mg of KIO_4 was added. After 1 hr, the oxidation

7) J. S. Dixon and D. Lipkin, *Anal. Chem.*, **26**, 1092 (1954).

product was purified by paper chromatography using *n*-butyl alcohol-acetic acid-water (4:1:1) and isopropyl alcohol-water (2:1) as solvents. The periodate oxidation product was dissolved in 0.3 m*l* of warm water. The solution was cooled and a small amount of $NaBH_4$ was added. After standing at room temperature for 30 min, the solution was adjusted to pH 1 with hydrochloric acid and chromatographed on paper with a solvent of isopropyl alcohol-1% ammonia (2:1); the product was indistinguishable from synthetic 6-(2-carboxyethyl)-8-(2-hydroxyethyl)-2,4,7-trioxohexahydropteridine (V) (see below) (Table 3).

Photodecompositon: Putidolumazine (2.5 mg) was dissolved in 3 m*l* of 0.6 N NaOH. After addition of 0.3 m*l* of 30% H_2O_2, the solution was irradiated in a glass tube with an electric lamp of 100 W from a distance of 15 cm for 20 hr. The decomposition product was purified by paper chromatography using *n*-butyl alcohol-acetic acid-water (4:1:1) and isopropyl alcohol-1% ammonia (2:1) as solvents. The product was identified as 6-(2-carboxyethyl)-2,4,7-trioxohexahydropteridine (VII) by comparison with synthetic material (Table 3).

6-(2-Carboxyethyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (I). 2,6-Dihydroxy-5-nitro-4-D-ribitylaminopyrimidine[8] (0.4 g) in water (50 m*l*) was hydrogenated over a platinum oxide catalyst (0.2 g). After the theoretical amount of hydrogen was taken up, the catalyst was removed by filtration. The solution was acidified with acetic acid. (1 m*l*). α-Ketoglutaric acid (0.4 g) was added and the mixture was heated for 30 min on a steam bath. The solution was concentrated *in vacuo* to about 10 m*l* below 40°C, and acetone was added to the residue. The resulting pale yellow precipitate (280 mg) was purified by chromatography using a DEAE-cellulose column (3.5×18 cm; developer: 0.01 N HCl). A purple fluorescent band was eluted and the eluate was concentrated *in vacuo* below 40°C. The residue was recrystallized twice from water-ethanol to give colorless needless, yield, 130 mg (25.8%), mp >265°C (decomp.).

Found: C, 40.96; H, 4.73; N, 14.03%. Calcd for $C_{14}H_{18}O_9N_4 \cdot H_2O$: C, 41.58; H, 4.95; N, 13.86%.

6-(p-Hydroxyphenyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (II). 2,6-Dihydroxy-5-nitro-4-ribitylaminopyrimidine[8] (0.4 g) in water (50 mg) was hydrogenated over platinum oxide (0.2 g). After the theoretical amount of hydrogen was absorbed, the catalyst was removed. After acidification with acetic acid (1 m*l*), *p*-hydroxyphenylglyoxlic acid[9] (0.4 g) was added to the solution and the mixture was heated for 30 min on a steam bath. The solution was filtered and the filtrate was left standing overnight at 4°C. The yellow precipitate (250 mg) was recrystallized twice from water to give pale yellow crystals, yield, 140 mg (26.4%), mp 272—273°C (decomp.).

Found: C, 47.75; H, 4.77; N, 12.64%. Calcd for $C_{17}H_{18}O_8N_4 \cdot H_2O$: C, 48.11; 4.75; N, 13.20%.

6-(3-Indolyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (III). 2,6-Dihydroxy-5-nitro-4-D-ribitylaminopyrimidine[8] (0.2 g) in water (25 m*l*) was hydrogenated over platinum oxide (0.1 g). After the theoretical amount of hydrogen was taken up, the catalyst was removed. The solution was acidified with acetic acid (0.2 m*l*) and warmed. 3-Indolylglyoxylic acid[10] (0.12 g) in ethanol (3 m*l*) was added drop by drop, and the mixture was heated on a steam bath for 30 min. The solution was left standing overnight at 4°C. The brown product (96 mg) was recrystallized twice from 2 N HCl to give a pale yellow substance, yield, 60 mg (21.4%), mp 285—286°C (decom.).

Found: C, 50.77; H, 4.46; N, 15.61%. Calcd for $C_{19}H_{19}O_7N_5 \cdot H_2O$: C, 51.00; H, 4.73; N, 15.65%.

6-(2-Carboxyethyl)-8-(2-hydroxyethyl)-2,4,7-trioxohexahydropteridine (V). 5-Nitroso-6-(β-hydroxyethylamino)-2,4-dihydroxypyrimidine[11] (300 mg) was suspended in 5 m*l* of water, and sodium hydrosulfite (0.8 g) was added. When the solution became pale yellow, acetic acid (1 m*l*) and α-ketoglutaric acid (0.3 g) were added; the reaction mixture was heated on a steam bath for 1 hr. The solution was filtered and the filtrate was left standing overnight at 4°C. The needles (200 mg) thus obtained were further recrystallized from 50% acetic acid, yield, 125 mg (28.2%), mp 262—265°C.

Found: C, 45.07; H, 4.25; N, 19.17%. Calcd for $C_{11}H_{12}O_6N_4$: C, 44.60, H, 4.08; N, 18.91%.

6-(p-Hydroxyphenyl)-8-(2-hydroxyethyl)-2,4,7-trioxohexahydropteridine (VI). 5-Nitroso-6-(β-hydroxyethylamino)-2,4-dihydroxypyrimidine[10] (70 mg) was suspended in 1 m*l* of water and sodium hydrosulfite (150 mg) was added. When the solution became pale yellow, acetic acid (1 m*l*) and *p*-hydroxyphenylglyoxylic acid[9] (85 mg) were added and the solution was heated on a steam bath for 1 hr. The solution was filtered and the filtrate was left standing overnight at 4°C. The pale yellow product (79 mg) was recrystallized twice from 70% ethanol, yield, 32 mg (28.9%), mp>300°C.

Found: C, 50.74; H, 3.95; N, 16.54%. Calcd for $C_{14}H_{12}O_5N_4 \cdot H_2O$: C, 50.30; H, 4.22; N, 16.76%.

6-(2-Carboxyethyl)-2,4,7-trioxohexahydropteridine (VII). 4,5-Diaminouracil sulfate (250 mg) was dissolved in 20 m*l* of 1N NaOH by warming. α-Ketoglutaric acid (150 mg) was added and the mixture was heated on a steam bath for 1 hr. The solution was adjusted to pH 1 with concd. HCl and left standing at room temperature. The yellow precipitate (200 mg) was recrystallized from 1 N HCl to give pale yellow plates, yield, 50 mg (20.9%), mp 259—263°C (decomp.).

Found: C, 42.82; H, 2.68; N, 22.15%. Calcd for $C_9H_8O_5N_4$: C, 42.86; H, 3.20; N, 22.22%.

6-Ethoxycarbonyl-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (VIII). Zinc powder (150 mg) was added to a suspension of

Results and Discussion

Four pteridine compounds were isolated from the culture of *Pseudomonas ovalis*. Three of them were the pteridines already described, *i.e.* a purple fluorescent compound was identified as 6-methyl-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine[2] (Table 2), a greenish-yellow fluorescent compound as 6-(3-Indolyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine[4] (Table 2) and a greenish-blue fluorescent compound as 6-(*p*-hydroxyphenyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine[5] (Table 1) by comparison with natural and synthetic samples.

The fourth compound, designated as putidolumazine ($C_{14}H_{18}N_4O_9$), was supposed to be a new pteridine. UV-Spectra of this compound suggested that it was a 2,4,7-trioxohexahydropteridine with alkyl side chains at N-8 and C-6 positions (Fig. 1). Putidolumazine was stable against Al-Hg treatment[13] suggesting that it has $-CH_2-$ group at position 6. On photoirradiation in the presence of H_2O_2 it gave 6-(2-carboxyethyl)-2,4,7-trioxohexahydropteridine (VII); This compound was synthesized by condensation of 4,5-diaminouracil and α-ketoglutaric acid (Table 3). On oxidation with periodate followed by reduction with sodium borohydride, putidolumazine yielded 6-(2-carboxyethyl)-8-(2-hydroxyethyl)-2,4,7-trioxohexahydropteridine (V); this was identified by comparison with synthetic material (Table 3). Periodate consumption of putidolumazine suggests the presence of four neighboring hydroxy groups. Finally, acetylated putidolumazine ethyl ester gave a molecular peak of *m/e* 582 on mass spectrum.

From these results the structure of 6-(2-carboxyethyl)-8-(1-D-ribityl)-2,4,7-trioxohexahydropteridine (I) was postulated for putidolumazine. This compound was synthesized by condensation (reduction) of 2,6-dihydroxy-5-nitro-4-D-ribitylaminopyrimidine and α-ketoglutaric acid. Its identity with the natural product was confirmed (Table 3, 4; Fig. 1).

We thought that putidolumazine was produced by enzymic condensation with 4-ribitylamino-5-aminouracil and α-ketoglutaric acid produced from glutamic acid and the possible formation of putidolumazine has been implicated in the enzymic production of riboflavin.

We wish to thank Dr. T. Masuda and Dr. I. Takeda for the generous supply of natural compounds for comparison. Thanks are also due to Dr. T. Naito, Bristol-Banyu Research Institute, for microanalyses and Mr. T. Kinoshita, Sankyo Co., for obtaining mass spectrum.

Studies on the Interaction of Isocyanides with Transition-metal Complexes. VII.[1] Insertion Reactions of Isocyanide into Alkyl-platinum Sigma Bonds[2]

Yasuhiro YAMAMOTO and Hiroshi YAMAZAKI

The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received October 29, 1970)

The reactions of *trans*-iodobis(phosphine)aklylplatinum(II) compounds with isocyanide were carried out. The reactions of isocyanide with the methyl and benzyl derivatives of platinum(II) with triphenylphosphine or dimethylphenylphosphine gave salt-like complexes [*trans*-$Pt(PR_3)_2(CNR')CH_3]I$ (**1**) ($PR_3=PPh_3$, $PPhMe_2$; $R'=C_6H_{11}$, $C(CH_3)_3$). When **1** was refluxed in benzene or toluene, an insertion of isocyanide took place, affording *trans*-iodobis(phosphine)(1-cyclohexylimino)alkylplatinum(II). Two P-CH_3 proton resonances were observed in the NMR spectrum of *trans*-$Pt(PPhMe_2)_2I[C(CH_3)=NC_6H_{11}]$, indicating that the two methyl groups on the same phosphorus atom are magnetically nonequivalent. It was deduced from this NMR behavior that all the iminoacyl complexes prepared have a five-coordinate structure.

We have reported that the reactions of cyclohexyl isocyanide with the metal alkyls, such as triphenylphosphine-π-cyclopentadienylnickel and tricarbonyl-π-cyclopentadienylbenzylmolybdenum, inserted isocyanide into a carbon-to-metal bond to give π-cyclopentadienyl(cyclohexyl isocyanide)(1-cyclohexylimino)ethylnickel[3] and tricarbonyl-π-cyclopentadienyl(1-cyclohexylimino)(2-phenyl)ethylmolybdenum.[4] Recently we also found that the reaction of isocyanide with *trans*-iodobis(phosphine)alkylpalladium(II) took place with successive insertions of isocyanide molecules, thus affording the iminoacyl complexes of palladium(II) with five-coordinate structures.[5,6]

In our extensive studies of the alkyl complexes of platinum(II), we found that isocyanides react with methyl and benzyl complexes of platinum(II) to produce five-coordinate iminoacyl complexes.

A recent note[7] on the reaction of methyl isocyanide with *trans*-halobis(triphenylphosphine)alkylplatinum(II) to give the iminoacyl complexes of platinum(II) has prompted us to report on other iminoacyl complexes obtained from isocyanides and alkyl complexes of platinum(II). We found that this type of iminoacyl complexes has a five-coordinate structure with a platinum atom bound to imino-nitrogen.

Results and Discussion

The treatment of cyclohexyl isocyanide with *trans*-iodobis(phosphine)methylplatinum(II) in a 1 : 1 molar ratio in benzene at room temperature gave colorless crystals formulated as a 1 : 1 adduct $Pt(PR_3)_2(CNC_6H_{11})(CH_3)I$ (**1**), based on its elemental analysis. The compounds (**1**) are soluble in methyl alcohol, methylene chloride, and chloroform, and are insoluble in nonpolar solvents such as benzene and hexane.

The IR spectrum of each compound showed a characteristic band in the range from 2178 to 2210 cm^{-1}, this spectrum was attributable to the coordinated isocyanide group. The value of the $\nu_{N\equiv C}$ bond of the coordinated isocyanide group was approximately 70 cm^{-1} higher than the corresponding value of the uncoordinated one. The formation of $[Pt(PPh_3)_2(CNC_6H_{11})(CH_3)]BPh_4$ from the reaction of **1a** with sodium tetraphenylborate in ethanol suggests an ionic nature for the (**1**) complexes.

In the NMR spectrum of **1a** measured in $CDCl_3$, the methyl resonance centered at 9.95 τ appears as a set of three triplets; it is interpreted to give $J_{P,H}=7.5$ Hz and $J^{195}_{Pt,H}=60$ Hz, the central one with an intensity approximately four times that of the outer triplets. The triplet resonance implies that the two phosphorus ligands are in mutually *trans*-positions.

It may be deduced from these results that the (**1**) complexes have an ionic square-planar structure.

When the **1a** complex in benzene was kept at 80°C for 2 hr, the migration of the methyl group to the isocyanide ligand took place, affording *trans*-iodobis(triphenylphosphine)(1-cyclohexylimino)ethylplatinum (II) (**2a**), *trans*-$Pt(PPh_3)_2I[C(CH_3)=NC_6H_{11}]$, characterized by the presence of an infrared band due to carbon-nitrogen double bond at 1604 cm^{-1}, as is seen in the IR spectrum. This structure was supported by the formation of *N*-cyclohexylacetoamide from the degradation of 2a with moist air.

$$\mathbf{2a} \longrightarrow CH_3CONHC_6H_{11}$$

An analogous complex, *trans*-$Pt(PPh_3)_2Cl[C(CH_2Ph)=NC_6H_{11}]$ (**2d**), was obtained from the reaction of *trans*-chlorobis(triphenylphosphine)benzylplatinum(II) with cyclohexyl isocyanide in a 1:1 molar ratio at 80°C. In this case, no attempts were made to isolate an intermediate ionic complex.

We had already reported that the insertion reaction of cyclohexyl isocyanide into the corresponding pal-

ladium(II) complex occurred at 0°C.[5,6] In the present reactions, the initial formation of a salt-like complex, accompanied by the insertion of isocyanide into a platinum-carbon sigma bond at an elevated to temperature, suggests that the reactivity of the Pt–CH_3 bond is lower than that of the Pd–CH_3 one.

When **1b** was handled in a way similar to that in the above-mentioned reaction (**1a**→**2a**), the unconverted starting materials were recovered without undergoing an insertion. On the refluxing of **1b** in toluene for 5 hr, the insertion of isocyanide proceeded, ultimately affording the iminoacyl complex (**2b**), *trans*-Pt $(PPhMe_2)_2I[C(CH_3)=NC_6H_{11}]$.

It was presumably the electronic effect of the phosphine ligands that the migration of the methyl group to the isocyanide ligand in the **1a** complex containing triphenylphosphine occurred more easily than that in **1b** containing dimethylphenylphosphine.

In the NMR spectrum of **2b** in $CDCl_3$, the C–CH_3 proton resonance showed a well-defined 1:4:1 triplet at 7.73 τ, arising from the coupling of ^{195}Pt–H ($^3J_{^{195}Pt,H}$ =33 Hz). The long-range coupling of $^4J_{P,H}$ was not observed, although it was noted in the analogous complexes of Pd(II).[5,6] The P–CH_3 proton resonances

a) Recorded by Varian HA-100B. Other samples were measured by JEOL C-60.
b) a set of three triplets.
c) α-proton of cyclohexyl group.
d) Benzene contained in the complexes.

appeared as two sets of three triplets centered at 8.01 and 8.07 τ respectively. The two P–CH_3 resonances are interpreted to arise from $J_{P,H}$[8]$=7$ Hz and $J_{^{195}Pt,H}=38$ Hz. The triplet resonance indicated that the two phosphorus ligands were coordinated to a metal in mutual *trans*-positions.[9] The presence of the two triplets also indicated that the two methyl groups on the same phosphorus atom were magnetically nonequivalent. If the **2b** complex has a square-planar structure, the magnetic nonequivalence will not be observed. Therefore, it seems reasonable to assume that the origin of nonequivalence is the absence of a plane of symmetry resulting from the coordination of lone-pair electrons of imino nitrogen to the platinum atom, thus giving the five-coordinate structure.

It may be concluded from the NMR spectrum of **2b** that these types of iminoacyl complexes of platinum (II), including those prepared in another recent paper,[5] have the five-coordinate structure.

Experimental

All the reactions were carried out under a nitrogen atmosphere. All the melting points are uncorrected; they were measured by a micro-melting-point apparatus, Yanagimoto Model MP-S2. The IR spectra were obtained by a Perkin-Elmer 521 spectrometer. The NMR spectra were recorded in $CDCl_3$ by means of JEOL C-60 and Varian HA-100B instruments, using tetramethylsilane as the internal standard. Isocyanides were prepared according to the procedures described in the literature.[10] *Trans*-iodobis(triphenylphosphine)methylplatinum(II) was prepared by Chatt and Shaw's method.[11] The elemental analyses, melting points, yields, and IR and NMR spectra of all the complexes prepared here are summarized in Tables 1 and 2.

Preparation of trans-*Pt(PPhMe$_2$)$_2$(CH$_3$)*. *Trans*-iodobis(dimethylphenylphosphine)methylplatinum was obtained by the reaction of *trans*-diiodobis(dimethylphenylphosphine)-platinum(II) with methylmagnesiumiodide.

Found: C, 33.17; H, 3.95; I, 20.12%. Calcd for $C_{17}H_{25}IP_2Pt$: C, 33.29; H, 4.11; I, 20.69%. Mp 146—150°C (decomp).

Preparation of trans-*Pt(PPh$_3$)$_2$Cl(CH$_2$Ph)*. A mixture of tetrakis (triphenylphosphine)platinum(II) (1 g, 0.98 mmol) and benzylchloride (10 ml) was kept at 75°C. After 5 hr, white crystals were observed. The evaporation of benzyl-chloride and recrystallization from benzene-hexane gave *trans*-chlorobis(triphenylphosphine)benzylplatinum(II) (0.6 g, 73%; mp 208—211°C (decomp.).)

Found: C, 61.03; H, 4.41; Cl, 4.18%. Calcd for $C_{43}H_{37}ClP_2Pt$: C, 61.41; H, 4.64; Cl, 14.29%. NMR ($CDCl_3$,τ): 7.69 (a set of three triplets, $J_{^{195}Pt,H}=99$Hz, $J_{P,H}=7.5$ Hz, CH_2), 2.1—3.5 (broad, P-Ph and Ph).

Preparation of [trans-*Pt(PPhMe$_2$)$_2$(CNC$_6$H$_{11}$)CH$_3$]I*. Cyclohexyl isocyanide (0.065 g, 0.6 mmol) in benzene (0.6 m*l*) was added, drop by drop to a solution of *trans*-Pt(PPhMe$_2$)$_2$I(CH$_3$) (0.36 g 0.59 mmol) in benzene (15 m*l*) at room temperature, and the solution was kept overnight. Colorless crystals (0.39 g, 93%) were filtered, washed by benzene-hexane, and identified as [*trans*-Pt-(PPhMe$_2$)$_2$(CNC$_6$H$_{11}$)-CH$_3$]I.

The other ionic complexes were obtained by the procedures described above.

Preparation of trans-*Pt(PPh$_3$)$_2$[C(CH$_3$)=NC$_6$H$_{11}$]*. [*trans*-Pt-(PPh$_3$)$_2$(CNC$_6$H$_{11}$)CH$_3$]I (0.2 g, 0.21 mmol) in benzene (25 m*l*) was kept at 80°C. After 2 hr, the reaction mixture was evaporated almost to dryness under a reduced pressure. Recrystallization from a benzene-hexane mixture gave colorless crystals, *trans*-iodobis(triphenylphosphine)(1-cyclohexylimino)ethylplatinum(II) (0.18 g, 90%).

Preparation of trans-*Pt(PPh$_3$)$_2$Cl[C(CH$_2$Ph)=NC$_6$H$_{11}$]*. Cyclohexyl isocyanide (0.05 g, 0.45 mmol) in benzene (0.45 m*l*) was added to a soluton of *trans*-chlorobis(triphenylphosphine)benzylplatinum(II) (0.38 g, 0.49 mmol). After the evaporation of the solvent almost to dryness, the viscous residue was kept at 80°C for 4 hr. Colorless crystals obtained were washed with benzene and identified as *trans*-chlorobis(triphenylphosphine)(1-cyclohexylimino)(2-phenyl)ethylplatinum (II).

Preparation of trans-*Pt(PPhMe$_2$)$_2$I[C(CH$_3$)=NC$_6$H$_{11}$]*. [*trans*-Pt(PPhMe$_2$)$_2$(CNC$_6$H$_{11}$)CH$_3$]I (0.22 g, 0.31 mmol) in toluene (3 m*l*) was refluxed for 5 hr. The reaction mixture was evaporated almost to dryness. Recrystallization from benzene-hexane gave colorless crystals, *trans*-iodobis(dimethylphenylphosphine)(1-cyclohexylimino)ethylplatinum(II) (0.19 g, 88%).

Preparation of trans-*Pt(PPhMe$_2$)$_2$I(CN)*. [*trans*-Pt(PPhMe$_2$)$_2$(CNC(CH$_3$)$_3$[CH$_3$]I (0.16 g, 0.24 mmol) in toluene (3 m*l*) was refluxed for 4 hr. The reaction mixture was evaporated almost to dryness. Recrystallization from benzene-hexane gave colorless crystals, iodo-cyanobis(dimethylphenylphosphine)platinum(II) (0.12 g, 82%; mp(decomp.) 150—153°C).

Found: C, 34.38; H, 3.68; N, 2.77; I, 21.89%. Calcd for $C_{17}G_{22}NP_2IPt$; C, 34.41; H, 3.74; N, 2.36; I, 21.39%. IR(KBr): 2122 cm^{-1} (N≡C). NMR($CDCl_3$, τ): 7.84 (a set of three triplets, $J_{^{195}Pt,H}=30$ Hz, $|^2J_{P,H}+{}^4J_{P,H}|=7.5$ Hz, P-CH_3), 2.1—2.7 (broad, C_6H_5).

Restricted Rotation Involving the Tetrahedral Carbon. I. Some Diels-Alder Adducts Derived from 9-Substituted Anthracenes

Michinori Ōki and Minoru Suda

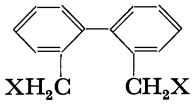
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received November 10, 1970)

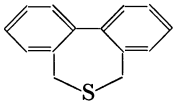
9-*t*-Butylanthracene was treated with dimethyl acetylenedicarboxylate and benzoquinone to give Diels-Alder adducts. The NMR spectra of these adducts suggest that the internal rotation about the C_1–C_{Bu} bond is not taking place on the NMR time scale. On the other hand, a Diels-Alder adduct prepared from 9-isopropylanthracene and dimethyl acetylenedicarboxylate shows the coalescence phenomenon of the NMR signals when the temperature is raised. The possibility of optical resolution due to hindered rotation about the sp^3–sp^3 carbon bond is pointed out.

There have been numerous examples of restricted rotations about the carbon-carbon single bonds. However, since the confirmation of the restricted rotation depends on the optical resolution, the identified examples have been limited to fairly stable isomers; in other words, a highly restricted rotation was necessary in order to note the hindered rotation. Optical resolutions of numerous biphenyl derivatives[1] and ansanoid compounds[2] are examples of this.

In recent years, it has become possible to study the internal rotation by means of NMR spectroscopy. This method has enabled us to study the exchange of protons as fast as 10^0—10^3 sec^{-1}. Prior resolution is not now necessary to study fairly fast internal rotation. Biphenyls[3], ketones[4] and ansanoids[5] have thus been studied by virtue of either the presence of dissymmetric protons of methylene, isopropyl, or other groups (*e.g.* **1**) or the different chemical shifts in the ring system (*e.g.* **2**).

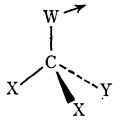


(1)

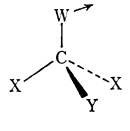


(2)

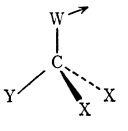
In the biphenyls and ketones, the pivot bond in question is the C_{sp^2}–C_{sp^2}, whereas in ansanoids the pivot bond is C_{sp^2}–C_{sp^3}. A very important point should be raised here. That is, in the tetrahedron theory of carbon, it is assumed that the rotation about the C–C single bond is free; otherwise, even a compound which has no asymmetric carbon could be resolved into optical isomers. Let us consider a molecule, C_{WXXY}, in which W is not spherically symmetric and is directed.[6] We can then write three stable conformations for the molecule, **3**, **4**, and **5**, where the arrow attached to W represents the direction of W. If the



(3)



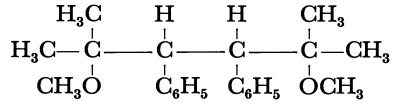
(4)



(5)

rotation about the W–C bond is free in the sense of classical organic chemistry, the molecule will not have any isomer, as the tetrahedron theory predicts. However, if the rotation about the W–C bond is slow, there will be three isomers for the C_{WXXY} molecule. The mirror image of **5** is identical with **5**, whereas **3** and **4** are mirror images of each other and are not identical. It will be proper to call **5** the *meso*-form, and **3** and **4** *dl*-form.

Since W can involve either sp^2- or sp^3-hybridized carbon in connecting with the C_{XXY} group, the restricted rotation in either the sp^2–sp^3 or the sp^3–sp^3 C–C bond could cause the isolation of the afore-mentioned isomers. There have been several papers concerning the above phenomena, but not much notice has been taken of the importance of the phenomenon.[7] As early as 1961, Brownstein[8] reported the NMR results of *meso*- and *dl*-forms of 2,5-dimethoxy-2,5-dimethyl-3,4-diphenylhexane (**6**) and pointed out the possibility of the presence of rotational isomers from the appearance of two sets of signals. However,



(6)

the close examination of the spectra of the pairs led the present authors to doubt the presence of the conformers. Rather, the spectra can best be interpreted by assuming the contamination by the other isomers, the *meso*- and *dl*-forms. Therefore, in our opinion, these data are not conclusive in establishing the restricted rotation about the central C_{sp^3}–C_{sp^3} bond.

There are, of course, many cyclic compounds, the

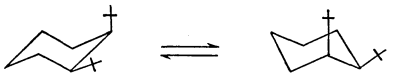
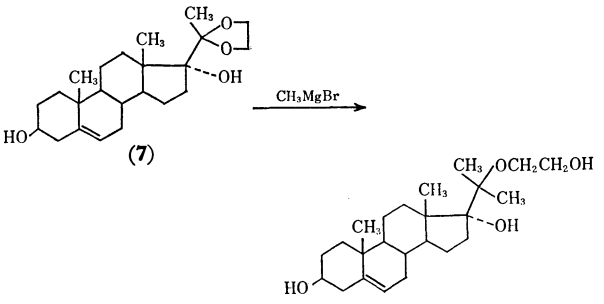
conformations of which are frozen at the lower temperature, and even the equatorial isomer of chlorocyclohexane[9] has been isolated. However, these isomers are unstable at room temperature. *cis*-1,2-Di-*t*-butylcyclohexane has been reported by Kessler *et al.*[10] to have nonequivalent *t*-butyl groups in its NMR spectrum at room temperatur , and the two signals coalesce at 35°C. These results indicated that two *t*-butyl groups on the cyclohexane ring are not good enough to isolate the rotational isomers about the C_{sp^3}–C_{sp^3} bond, although the cyclohexane ring and the bulkiness of the *t*-butyl groups are considered to be favorable for freezing the conformations.



(or twisted boat conformations)

Recently Scheer *et al.* isolated a pair of isomers on treating the ethylene ketal (**7**) with methylmagnesium bromide.[11]



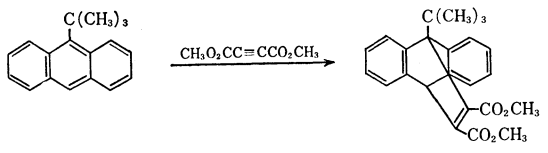
(**7**) (**8**)

They claim that these isomers (**8**) result from the restricted rotation about the C_{17}–C_{20} bond. The present authors have a feeling that this example is too complicated to demonstrate the presence of the isomers clearly and that simpler examples are needed.

We wish to report our findings about the restricted rotation in the Diels-Alder adducts of 9-substituted anthracene and point out the possibility of isolating the rotational isomers.

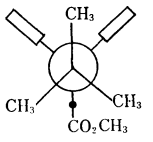
Results and Discussion

The treatment of 9-*t*-butylanthracene (**9**) with dimethyl acetylenedicarboxylate gave dimethyl 1-*t*-butyldibenzo[*b*,*e*]bicyclo[2.2.2]octatriene-7,8-dicarboxylate



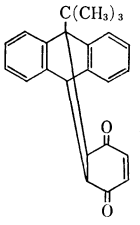
(**9**) (**10**)

(**10**). The NMR spectrum of **10** at room temperature is given in Fig. 1. As will be seen, the signal of the *t*-butyl group is split into two, the relative area being 1:2. This result can best be interpreted by assuming the restricted rotation about the C_1-C_{Bu} bond. Namely, the Newman projection (**11**) through the C_1-C_{Bu}

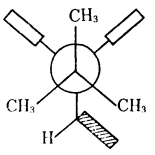


(**11**)

bond clearly explains why the *t*-butyl group should show two signals at the different chemical shift: the two methyls are equivalent, but the last methyl is located in a magnetically non-equivalent environment. Additional support for the above assignment can be obtained by looking at the NMR spectrum of 1-*t*-butyl-9,10:11,12-dibenzotricyclo[6.2.2.$0^{2,7}$]dodeca-4,9,11-triene-3,6-dione (**12**), which was prepared from **9** and *p*-benzoquinone. The Newman projection (**13**) of this compound shows that no pair of the three methyl groups are equivalent to each other; indeed, the NMR spectrum (Fig. 2) shows three methyl signals.



(**12**)



(**13**)

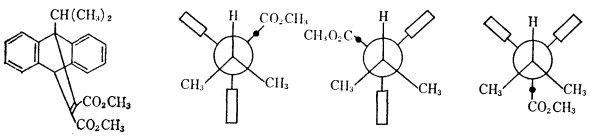
The shaded rectangle indicates the cyclohexenedione ring.

The two methyl signals of **10** are found not to coalesce even at 132°C. Thus, using the chemical-shift difference ($\Delta\nu_0$) and putting 405°K into Eq. (1), the free energy ($\Delta G^{\ddagger}$) of the activation for rotation is estimated to be not lower than 25 kcal/mol.

$$\Delta G^{\ddagger} = -RT\ln\frac{\pi h(\Delta\nu_0)}{\sqrt{2kT}} \qquad (1)$$

It will be possible to isolate isomers of this kind, since, if the free energy of activation is 20—30 kcal/mol, the isolation of isomers is possible at room temperature in biphenyl derivatives. Study along these lines is now in progress.

In an attempt at isolating the *meso*- and *dl*-forms of **3**—**5** type, the *t*-butyl group is now switched to the isopropyl goup: W, X, and Y are 2,3-dimethoxycarbonyl-5,6:7,8-dibenzobicyclo[2.2.2]octa-2,5,7-trien-1-yl, methyl, and hydrogen respectively. The isopropyl derivative (**14**) was prepared analogously with the other compounds.



(**14**) (**15**) (**16**) (**17**)

The NMR spectrum (Fig. 3) of **14** at room temperature shows a pair of doublets for the methyl groups

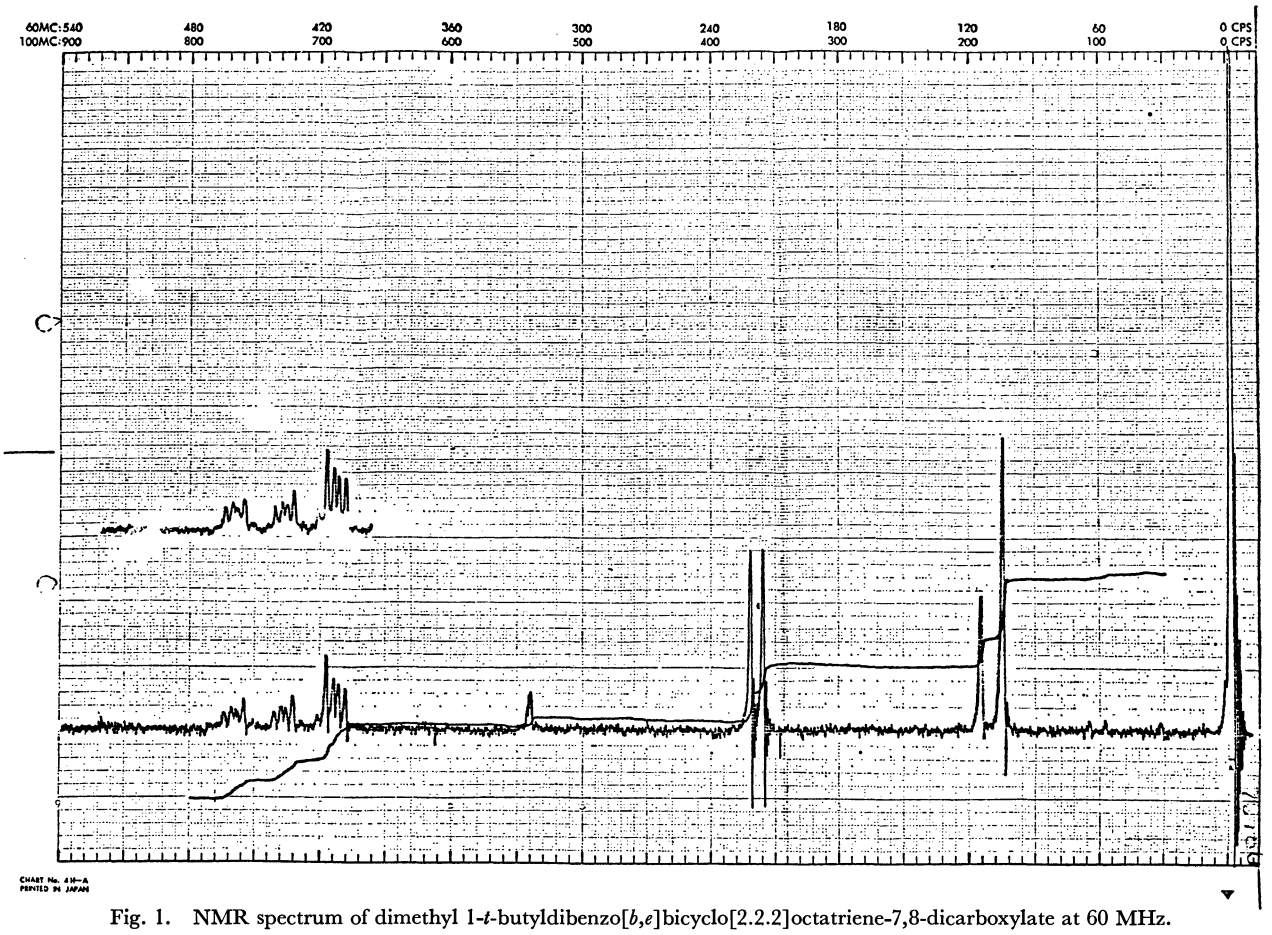

Fig. 1. NMR spectrum of dimethyl 1-*t*-butyldibenzo[*b*,*e*]bicyclo[2.2.2]octatriene-7,8-dicarboxylate at 60 MHz.

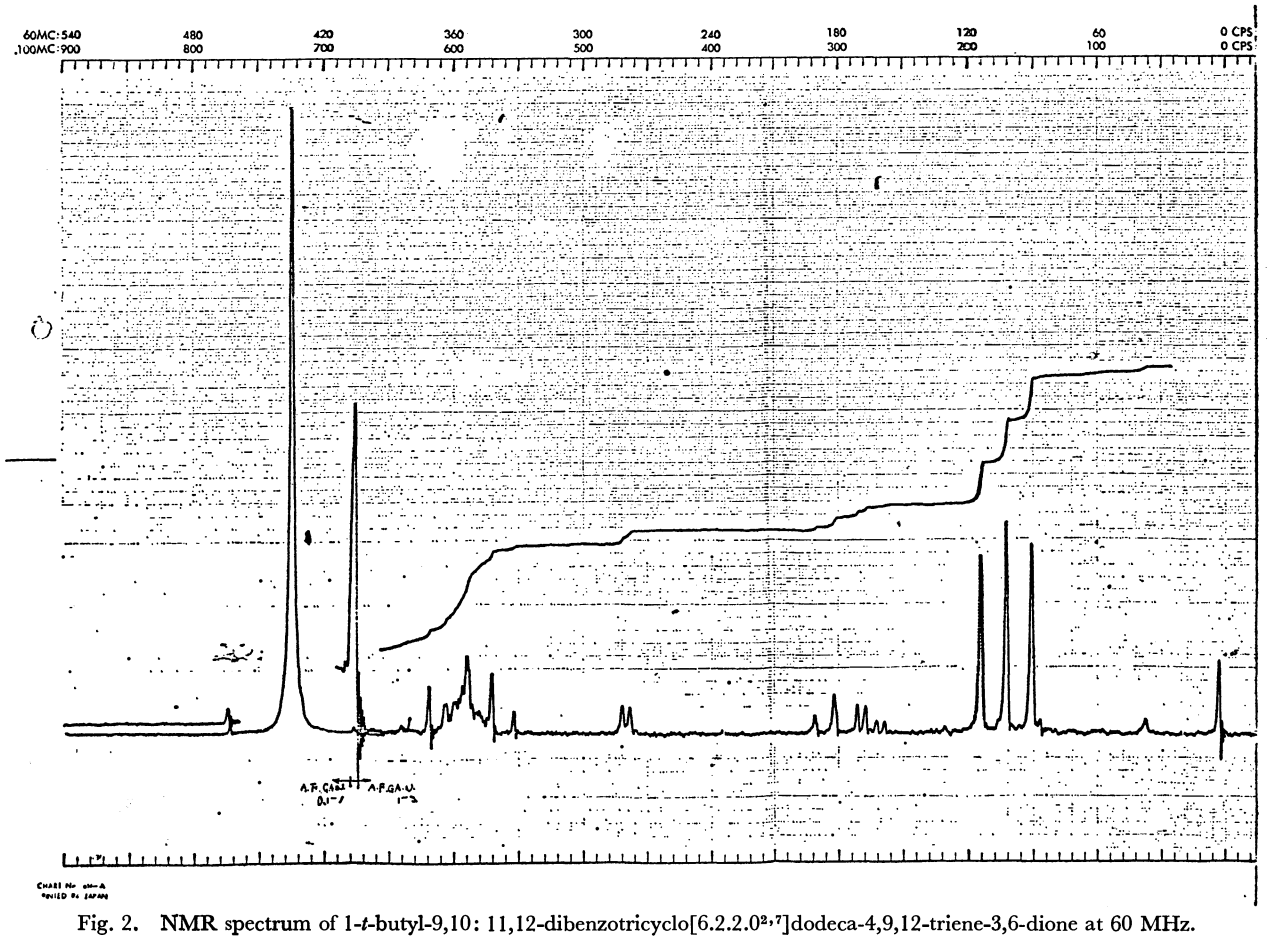

Fig. 2. NMR spectrum of 1-*t*-butyl-9,10: 11,12-dibenzotricyclo[6.2.2.0^{2,7}]dodeca-4,9,12-triene-3,6-dione at 60 MHz.

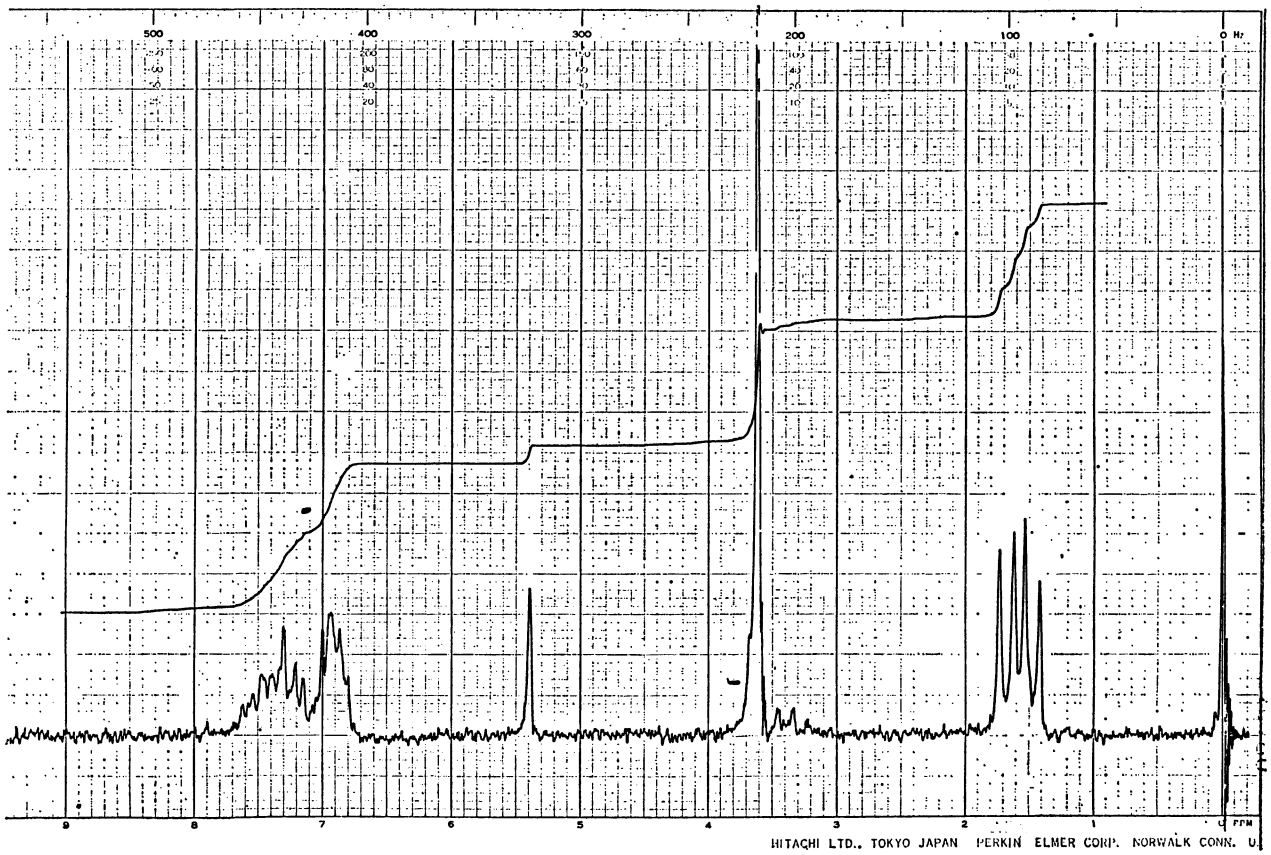

Fig. 3. NMR spectrum of dimethyl 1-isopropyldibenzo[*b*,*e*]bicyclo[2.2.2]octatriene-7,8-dicarboxylate at 60 MHz at room temperature.

in the isopropyl. The intensities are identical within the range of error. Since it may be assumed that methyl signals of the *meso*-form (**17**) are very close to one of the methyl groups in the *dl*-form (**15** and **16**), if the *meso*-form were present in a substantial amount, one of the methyl signals would have been stronger than the other. Thus, the absence of the other signals for the methyl groups of the isopropyl and the almost identical intensities of the pair of doublets indicate that the population of the *meso*-form will be very small, if present at all.

This can be interpreted by assuming that either the *meso*–form is thermodynamically less stable than the *dl*–form or the formation of the former is kinetically less favored than the latter. Either case is possible at the present stage, since the group carrying the methoxycarbonyl group is expected to be larger than the benzo group and the approach of the dimethyl acetylenedicarboxylate molecule from the side where two methyl groups are present will be disfavored relative to the side where a methyl and a hydrogen are present.

When the temperature is raised, the coalescence of the pair of doublets in the NMR spectra is observed. The T_c is 64°C in tetrachloroethane. The free energy of activation for the rotation about the C_{Pr}-C_1 bond is now obtained as 17.7 kcal/mol, using Eq. (1). From the temperature dependence of the half-band width of the signals the rate constants (k) can be obtained by Eq. (2):

$$k = \frac{\pi(\Delta\nu_0)^2}{2(W-W_0)} \tag{2}$$

where W_0 is the half-band width with an infinitely fast exchange rate and W, the half–band width at the observed temperature. The Arrhenius plot of $\log k$ *vs.* $1/T$ afforded E_a of 15.4±1.0 kcal/mol.

On the other hand, the free energy of activation ($\Delta G_c^{\ddagger}$) at the coalescence temperature is obtained by Eqs. (3) and (4):

$$k_c = \frac{\pi}{2}\Delta\nu_0 \tag{3}$$

$$\Delta G_c^{\ddagger} = -RT\ln\frac{hk_c}{k_BT} \tag{4}$$

where k_B is the Boltzmann constant.

It is, then, possible to derive $\Delta H_c^{\ddagger}$ and $\Delta S_c^{\ddagger}$ by putting these values into Eyring's equations, (5) and (6):

$$\Delta H_c^{\ddagger} = E_a - RT \tag{5}$$

$$\Delta S_c^{\ddagger} = \frac{1}{T}(\Delta H_c^{\ddagger} - \Delta G_c^{\ddagger}) \tag{6}$$

$\Delta H_c^{\ddagger}$=14.4±1.0 kcal/mol and $\Delta S_c^{\ddagger}$=−10±1 e. u. are thus obtained. These values suggest that, at 20°C, the rate constant is 0.78 sec^{-1} or the half-life time is 0.9 sec. Thus, in order to resolve this compound (**14**) into optically active isomers, the compound will have to be handled at the lower temperature.

The chemical shift of the methyl signal is 1.49 ppm from TMS at 130°C, whereas the average of the chemical shift of the methyl signals at room temperature is 1.55. This small change in the average chemical shifts may mean that the contribution of the conformation (**17**) is very little, even at 130°C. It could also

be deduced that the internal rotation occurring in **14** is not the full rotation, but the movement to and fro, in which the transition state is the eclipsing of the hydrogen of the isopropyl group and the methoxycarbonyl group. This assumption readily explains why the internal rotation in the *t*-butyl compound (**10**) is so much restricted, while that in the isopropyl compound (**14**) occurs with fair ease, for the methoxycarbonyl group is bulkier than the benzo group, as judged from the isomer distribution of **14**.

Experimental

Spectral Measurement. The NMR spectra were recorded on either a JEOL C-60H or Hitachi R-20A spectrometer. The temperature reading was calibrated by measuring the chemical shift difference between methylene and hydroxyl protons of ethylene glycol.

Dimethyl 1-t-Butyldibenzo[b, e]*bicyclo*[2.2.2]*octatriene-7,8-dicarboxylate (**10**).* An equimolar mixture of 9-*t*-butylanthracene[12] and dimethyl acetylenedicarboxylate was heated slowly until all the solid fused; the heating was then continued for several more minutes. The recrystallization of the product from either methanol or ethanol gave the desired product; mp 182—183°C.

Found: C, 76.65; H, 6.65%. Calcd for $C_{24}H_{24}O_4$: C, 76.57; H, 6.43%.

Dimethyl 1-Isopropyldibenzo [b, e] *bicyclo* [2.2.2] *octatriene-7,8-dicarboxylate* (***14***) was similarly prepared; mp 143.5—144.5°C

Found: C, 75.95; H, 6.20%. Calcd for for $C_{23}H_{22}O_4$: C, 76.22; H, 6.12%.

1-t-Butyl-9,10,11,12-dibenzotricyclo [6.2.2.$0^{2,7}$] *dodeca-4,9,12-triene-3,6-dione* (***12***). 9-*t*-Butylanthracene (4 g) and 3 g of benzoquinone in xylene were heated under reflux. The crystals obtained on cooling were recrystallized from ethanol; mp 161—166° (dec.).

Found: C, 83.93; H, 6.73%. Calcd for $C_{24}H_{22}O_2$; C, 84.17; H, 6.47%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1880—1885 (1971)

Restricted Rotation Involving the Tetrahedral Carbon. II. 2-Substituted 4,6,8-Trimethylazulenes[1]

Michinori Ōki and Nobuo Nakamura

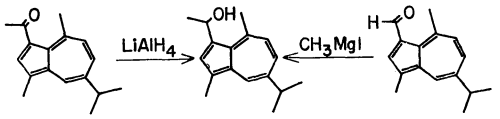
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received November 10, 1970)

1-(1-Hydroxyethyl)-4,6,8-trimethylazulene (**3**) was prepared by the lithium aluminum hydride reduction of 1-acetyl-4,6,8-trimethylazulene, and by the reaction of methylmagnesium iodide with 1-formyl-4,6,8-trimethylazulene. **3** showed various melting points according to its crystallization conditions and the reaction solvent. Their IR spectra both in solid states and in solutions, the NMR spectra at various temperatures, and the results of X-ray diffraction studies led to a conclusion that this phenomenon is attributable to polymorphism. From the temperature dependence of the NMR spectra of the *t*-butyl protons of 1-*t*-butyl-4,6,8-trimethylazulene, the internal rotation around the C_{Bu}–$C_{azulene}$ was concluded to be slow only at the lower temperature.

In the preceding paper,[2] the restricted rotation about the sp^3–sp^3 carbon-carbon bond was discussed and the possibility of isolating a pair of optical isomers and a *meso*-form of some triptycene-type compounds was mentioned. In the light of this consideration, the sp^2–sp^3 C–C bond should be able to supply another example of resolution into optical isomers provided that the rotation around the bond in question is really restricted and the group involving the very sp^2 carbon atom is directed in relation to the sp^3 part.

A search of the literature revealed that 3-(1-hydroxyethyl)-*s*-guaiazulene has been reported to show two different melting points and different dehydrative reactivities according to the methods of preparation: the lithium aluminum hydride reduction of 3-acetyl-*s*-guaiazulene and the Grignard reaction of methyl iodide with 3-formyl-*s*-guaiazulene.[3] These phenomena have been suggested to originate from "the isomerism caused by restricted rotation" around the azulene-to-3-substituent bond.



(1)

[70-71°], [72-73°]

If this were really the case, this should be a good example of restricted rotation around the sp^2–sp^3 carbon bond. Thus, we have undertaken an investigation of the isolation of three possible pairs of optical isomers of the afore-mentioned type of compound, which should exist as visualized by the following six models, where

Ar is the azulene ring and where the arrow indicates the direction of the azulene group.

The purpose of this paper is to report the results of this investigation which indicate that the rotation around the bond in question is fast and that optical resolution is not possible.

Results and Discussion

4,6,8-Trimethylazulene derivatives were chosen as the model compounds, for the ring system is readily accessible[4] and has the same stereochemical environment as that studied by Ukita and his co-workers.

1-Acetyl-4,6,8-trimethylazulene (**1**) was obtained by the action of acetic anhydride and phosphorus pentoxide on 4,6,8-trimethylazulene and 1-formyl-4,6,8-trimethylazulene (**2**) by the action of the Vilsmeyer-Haak reagent.

Lithium aluminum hydride reduction of **1** in ether afforded blue needles of 1-(1-hydroxyethyl)-4,6,8-trimethylazulene (**3**-L), which melted at 93.5—95.0°C before recrystallization. When recrystallized from petroleum ether, two modifications of the alcohol showing different melting points were obtained according to the crystallization conditions. That is, when the hot solution was chilled quickly to about 0°C, blue granular **3**-L with a mp of 68—78°C was precipitated, while blue crystalline **3**-L with a mp of 81.0—81.1°C was formed when the hot solution was allowed to cool slowly to room temperature.

The reduction of **1** in 1:1 ether-tetrahydrofuran also yielded **3**-L as a dark blue crystalline mass, which changed to tiny violet needles after recrystallization; their melting points were 75.0°C and 87.5—88.5°C before and after recrystallization, respectively.

The reaction of **2** with the methyl Grignard reagent in 1:1 ether-tetrahydrofuran gave **3**-G as a dark blue crystalline mass melting at 80.5—81.5°C before recrystallization. However, the alcohol again changed to tiny violet needles melting at 87.5—88.5°C when the hot solution of the alcohol in petroleum ether was cooled slowly to room temperature.

These phenomena may be accounted for in two different ways. The first is, as has been suggested by Ukita *et al.*, the rotational isomerism, while the second is the polymorphism caused by the different packings in the crystal lattice. Since it is expected that the attacking reagent approaches the reaction site from the least-hindered side, the hydride reduction of **1** will yield **3**-L or its mirror image, as is shown schematically in Fig. 1. Similarly, **2** will afford **3**-Gb or its mirror image and in the case of **3**-Gb the rotation around the C_{α}–$C_{azulene}$ may be possible at room temperature because of the smaller barrier formed by the hydrogen atom; thus **3**-Gc will exist also.

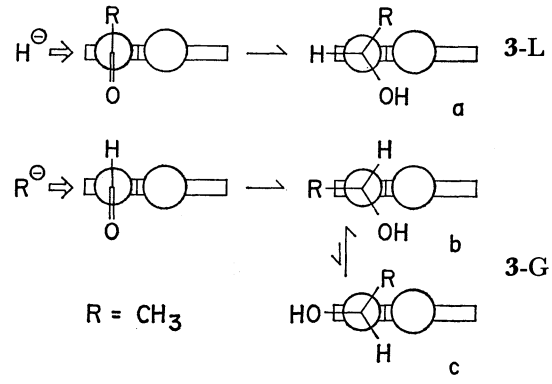

Fig. 1. Possible conformations of **3**-L and **3**-G (Newman type projection). C-1 carbon atom within 5-membered ring and C-8 methyl group attached to 7-membered ring are indicated by circles.

These considerations lead to the idea that, if the rotational isomer is the cause, there should be some differences in IR and NMR spectra among these modifications, because, for example, the force constants of C–O in **3**-Gb and **3**-Gc and the magnetic environments for the methyl protons are considered to be different. Thus, the following spectral studies have been undertaken.

The IR spectra of these compounds were recorded both with solid states and with carbon disulfide solutions, the former being shown in Figs. 2, 3, and 4, and the latter, in Fig. 5.

The correlations of their origins with the mp and IR spectra are summarized in Table 1.

A comparison of Figs. 2 and 4 reveals that, in solid states the difference between **3**-L and **3**-G appears in the spectral ranges of 1340—1260, 1080—1010, and 890—830 cm^{-1} if the reaction solvents differ from each other. When the same solvent is used for the reactions, the spectral difference, as judged by a comparison of

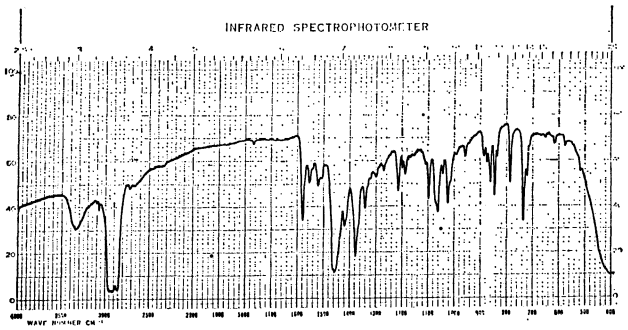

Fig. 3. IR spectrum of **3**-L (Nujol), mp 75.0°C.

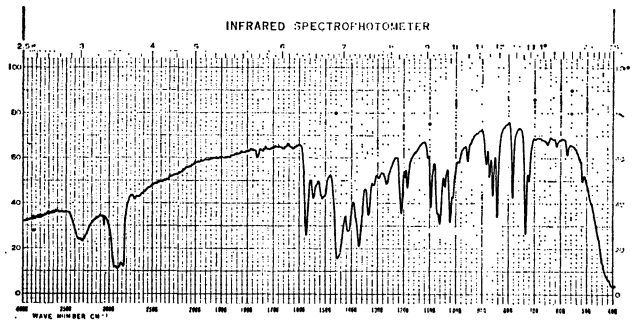

Fig. 4. IR spectrum of **3**-L (Nujol), mp 68—78, 81.0—81.1, 87.5—88.5°C, and **3**-G (Nujol), mp 80.5—81.5, 87.0—89.0°C.

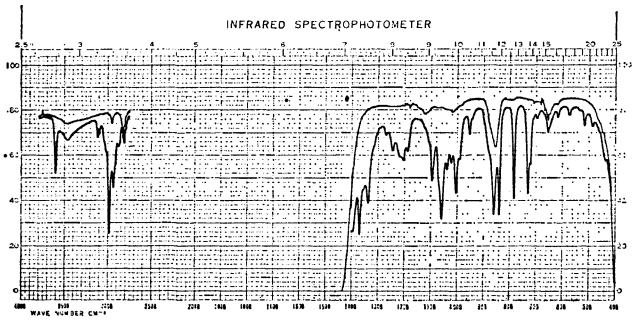

Fig. 5. IR spectrum of **3**-L and **3**-G (CS_2 soln, 0.109 mm KBr cell). The upper line is CS_2 and the lower the CS_2 soln.

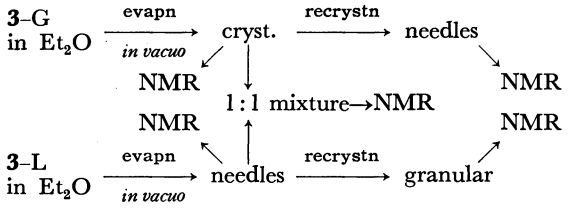
Figs. 3 and 4, is confined to around 830 cm^{-1}. The IR spectra of the solution of **3**-L in carbon disulfide, however, were superimposable on those of **3**-G in every respect, one of them being illustrated in Fig. 5.

Some rotational behavior of these compounds is expected to be observable by recording the NMR spectra at various temperatures, since $R_{(a)}$ and $R_{(b)}$ ($R=CH_3$) are in different magnetic environments and a chemical shift difference between them is expected (Fig. 1). Though the NMR sampling was carried out according to Scheme 1, all the NMR spectra are superimposable upon each other; one of them is shown in Fig. 6 (a 1:1 **3**-L-**3**-G mixture in carbon disulfide).



Scheme 1

These results, together with the IR results, may be interpreted by considering that a rapid exchange among the conformers, a, b, and c, is taking place at room temperature.

The NMR spectra of the alcohol, **3**, in carbon disulfide-pyridine was recorded at low temperatures. The methyl proton signal of CH_3-CH< appeared as a sharp doublet ($J=7$ Hz) at room temperature, but as the probe temperature was lowered, the signal decreased in height and increased in width. The changes in signal shape (as in Fig. 7) in the temperature range of −70——90°C apparently indicate that the internal rotation in question becomes sufficiently slow to be observed at these temperatures. Conversely, the internal rotation in question is very rapid, at least at room temperature.

Further evidence supporting the implication that the rotation around the C_α-to-azulene bond was slow at low temperature was obtained from variable-temper-

Table 1. Correlations of reactions with mp and IR

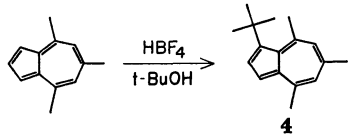
ature NMR studies of 1-*t*-butyl-4,6,8-trimethylazulene (**4**), which had been prepared by the reaction of 4,6,8-trimethylazulene with *t*-butyl alcohol in the presence of anhydrous tetrafluoroboric acid. The NMR spec-



(4)

4

tral data of the *t*-butyl protons are shown in Table 2. Though the *t*-butyl signal was a sharp singlet at room temperature, it became somewhat broader as the temperature was lowered, and below 0°C apparent changes in both its height and half-width were observed. When the temperature reached −80°C, the relative height and the relative half-width were 2.4 and 1.4 respectively, with respect to the ring-methyl signal of the greatest height, and below −80°C there was little change in these figures.

Although no chemical-shift difference among the methyl groups of the *t*-butyl residue was observed in this experiment, those facts given above can be best accounted for by the theory that the internal rotation around the *t*-butyl-to-azulene bond is sufficiently slow only at −80°C on the NMR time scale and that it is too rapid at room temperature for the stable rotamers to be isolated.

Table 2. NMR spectral data of 1-*t*-butyl-4,6,8-trimethylazulene

Temp. °C	Rel. values of *t*-butyl signal[a]	
	height	half-width
23	3.8_4	0.56

−80	2.3_6	1.3_6
−90	2.3_0	1.2_4

Spectrum was taken with CS_2 solution.
a) Relative values to the ring-methyl group of the greatest height

Thus, it is most probable to ascribe the many modifications of 1-(1-hydroxyethyl)-4,6,8-trimethylazulene to the polymorphism derived by the difference in the mode of crystal packing into the lattice. Indeed, the X-ray diffraction patterns (Fig. 8), whose angles and relative intensities have been obtained with good reproducibilities, show a difference supporting the conclusion.

Experimental[5]

The NMR spectra were taken with JEOL 3H-60 and C-60H spectrometer equipped with variable-temperature accessories, the IR spectra, with a HITACHI EPI-G2 grating infrared spectrophotometer, and the X-ray diffraction lines, with a diffractometer, Geigerflex, of the Rigaku Denki Co., Ltd.

The reduction and Grignard reaction were carried out under dry nitrogen, and the solvents were distilled over lithium aluminum hydride just before use.

1-Acetyl-4,6,8-trimethylazulene (1). From 11.3 g of 4,6,8-trimethylazulene,[4] 200 m*l* of acetic anhydride, and 5.3 g of phosphorus pentoxide, 7.0 g of 1-acetyl-4,6,8-trimethylazulene were formed; mp 72—73°C (reported mp 72—73°C[6]).

5) All the melting points are uncorrected.
6) K. Hafner, H. Pelster, and J. Schneider, *Ann. Chem.*, **650**, 74 (1961).

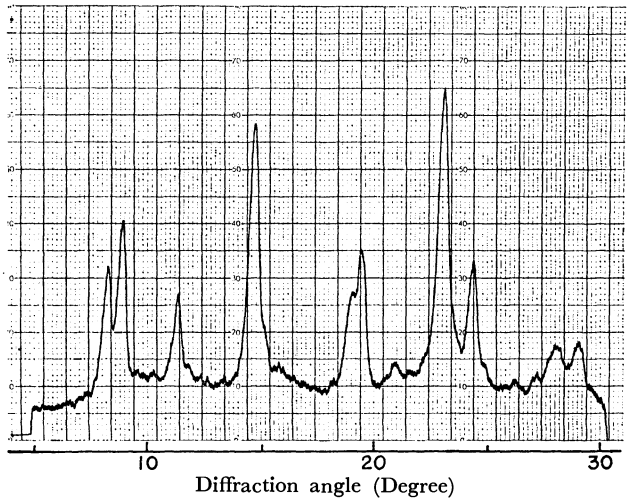
b) **3**-L, whose IR spectrum corresponds to Fig. 3



c) **3**-G, whose IR spectrum corresponds to Fig. 4

Fig. 8. X-ray diffraction patterns of **3**-L and **3**-G.

1-Formyl-4,6,8-trimethylazulene (2). 4,6,8-Trimethylazulene (17.0 g) was formylated with a Vilsmeyer-Haak reagent prepared from 45 m*l* of *N*,*N*-dimethylformamide and 17.0 g of phosphorus oxychloride to yield 13 g of 1-formyl-4,6,8-trimethylazulene; mp 105°C (reported mp 106—107°C[7]).

1-(1-Hydroxyethyl)-4,6,8-trimethylazulene (3-L): Reduction of 1 with Lithium Aluminum Hydride. a) Reduction in Ether: To a well-stirred suspension of 0.2 g of lithium aluminum hydride in 30 m*l* of anhydrous ether was added a solution of 1.5 g of **1** in 70 m*l* of anhydrous ether at 0°C; the reaction mixture was then stirred at this temperature for 30 min. At the end of this time, 10 m*l* of methanol and then 20 m*l* of water were added. The mixture was poured into a saturated sodium chloride solution and extracted with ether. The combined ether extracts were washed with water and dried over sodium sulfate. The solvent was evaporated *in vacuo* below 20°C. The blue needles so obtained melted at 93.5—95.0°C and had the IR absorption shown in Fig. 2 (Nujol). Found: C, 84.50; H, 8.81%; Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%.

3-L was recrystallized from petroleum ether (50—60°C fraction). When the hot solution was cooled quickly with ice water, blue granular solid was obtained; mp 68—78°C. However, when it was allowed to cool slowly to room temperature, a blue crystalline product was formed; mp 81.0—81.1°C. These **3**-L's showed identical IR spectra, as is shown in Fig. 4. NMR (δ from TMS in CS_2): 1.50 (3H, doublet, J=6.0 Hz), 1.82 (1H, singlet), 2.53 (3H, singlet), 2.73 (3H, singlet), 2.94 (3H, singlet), 5.44 (1H, quartet, J=6.0 Hz), 6.82 (2H, singlet), 7.05 (1H, doublet, J=4.0 Hz), 7.57 (1H, doublet, J=4.0 Hz).

b) Reduction in 1:1 Ether-Tetrahydrofuran: To a mixture of 0.2 g of lithium aluminum hydride and 30 m*l* of ether, was added a solution of 1.5 g of **1** in 20 m*l* of ether and 50 m*l* of tetrahydrofuran at 0°C. The reaction mixture was then treated as described in a). The blue product, mp 75°C before recrystallization, showed the IR spectrum given in Fig. 3 (Nujol). After recrystallization from petroleum ether, tiny violet needles, mp 87.5—88.5°C, were obtained. The IR spectrum (Nujol) is shown in Fig. 4.

Found: C, 84.36; H, 8.80%; Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%.

1-(1-Hydroxyethyl)-4,6,8-trimethylazulene (3-G): Reaction of 2 with Methylmagnesium Iodide. To an ethereal solution of methylmagnesium iodide prepared from 2.2 g of methyl iodide, 0.37 g of magnesium ribbon, and 30 m*l* of anhydrous ether, was added, drop by drop, a soluion of 1.98 g of **2** in 20 m*l* of anhydrous ether and 50 m*l* of anhydrous tetrahydrofuran at 0°C; the reaction mixture was stirred at this temperature for a further 30 min. The mixture was treated with 10 m*l* of methanol and then 20 m*l* of water, poured into a saturated sodium chloride solution, and extracted with ether. The combined extracts were washed with water and dried over sodium sulfate. The solvent was evaporated *in vacuo* below 20°C to yield a dark blue crystalline product, mp 80.5—81.5°C before recrystallization, whose IR spectrum (Nujol) is shown in Fig. 4.

After recrystallization from petroleum ether (50—60°C fraction), it was obtained as tiny violet needles; these needles melted at 87.0—89.0°C (reported mp 87—88°C[8]) and showed the IR spectrum illustrated in Fig. 4 (Nujol).

Found: C, 83.70; H, 8.93%; Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%.

1-t-Butyl-4,6,8-trimethylazulene (4). To a well-stirred mixture of 5.1 g of 4,6,8-trimethylazulene, 68 g of *t*-butyl alcohol, and 150 m*l* of anhydrous ether, 60 m*l* of a 54%

7) K. Hafner and C. Bernhard, *Ann. Chem.*, **625**, 116 (1959).
8) K. Hafner and C. Bernhard, *ibid.*, **625**, 122 (1959).

ethereal solution of anhydrous tetrafluoroboric acid[9] was added, drop by drop under nitrogen. The reaction mixture was allowed to stand at room temperature for 12 days and then poured onto crushed ice. The mixture was extracted three times with ether to recover the starting material. The aqueous layer was made alkaline with a 5% sodium hydroxide solution and extracted with ether. The extracts were washed with water and dried over sodium sulfate-potassium carbonate (2:1). The solvent was then evaporated *in vacuo*, and the residual dark blue oil was chromatographed on alumina to yield *ca.* 1 g of 1-*t*-butyl-4,6,8-trimethylazulene as a dark blue oil.

Found: C, 90.17; H, 9.99%; Calcd for $C_{17}H_{22}$: C, 90.20; H, 9.80%.

NMR (δ from TMS in CS_2): 1.54(9H, sharp singlet), 2.45 (3H, singlet), 2.69 (3H, singlet), 2.95 (3H, singlet), 6.72 (1H, broad singlet), 6.81 (1H, broad singlet), 7.00 (1H, doublet, J=5 Hz), 7.57 (1H, doublet, J=5 Hz). The two protons attached to the seven-membered ring of 1-*t*-butyl-4,6,8-trimethylazulene showed different positions of absorption from each other in their NMR spectra in carbon disulfide. This phenomenon was observed only in the case of **4**. In the case of the other 1-substituted 4,6,8-trimethylazulenes studied, including 1-benzoyl and 1-hydroxymethyl derivatives, the ring protons attached to the seven-membered ring appeared as a broad singlet in the 60 MHz MNR spectra in carbon disulfide.

We are deeply indebted to Dr. Yutaka Kawazoe and Dr. Mitsuhiro Tsuda, National Cancer Center Research Institute, Japan, for measuring the NMR spectra, and also to Dr. Isao Ikemoto, The University of Tokyo, for recording the X-ray diffraction lines.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1885—1891 (1971)

Reactions of Tosylhydrazide Derivatives Having Olefinic Groups[1)]

Tadashi SATO and Itomi HOMMA*[1]

Department of Applied Chemistry, Waseda University, Shinjuku-ku, Tokyo

(Received December 7, 1970)

When α,β-unsaturated ketone tosylhydrazones (**5**) were heated in 85% aqueous acetic acid, a smooth decomposition was induced and β-tosylketones (**4**) were obtained in fair yields. Tosylhydrazones, devoid of an olefinic group in the specified position, failed to undergo the present reaction. When allyl halides (**17**) were reacted with the anion of tosylhydrazide in DMSO, substitution occurred on the N-1 of tosylhydrazide, unlike as in the case of the reaction of chlorides with tosylhydrazide in pyridine, which effected the substitution on N-2. On warming in acetic acid, these 1-allyltosylhydrazides (**18**) afforded olefins (**19**) in fair yields, with a complete allylic rearrangement. A concerted cyclic mechanism was proposed for the **5**→**4** and **18**→**19** reactions.

It has been remarked that compounds derived from tosylhydrazide undergo many interesting reactions, and many of these reactions have been used for synthetic purposes.[2)] The present paper will deal with two new types of reactions, one with α,β-unsaturated ketone tosylhydrazones, and the other with 1-allyltosylhydrazides.

a) α,β-Unsaturated Ketone Tosylhydrazone System. Since the article of Bamford and Stevens,[3)] the base-induced thermal reactions of ketone tosylhydrazones have been extensively studied, but the reactions under acidic conditions have not attracted so much interest. Henry and Moore[4)] thermolyzed several ketone tosylhydrazones in acetic acid, but the reaction proceeded in a complicated way and the product was a mixture of several compounds.

In connection with our studies of α,β-unsaturated ketone tosylhydrazones,[5)] we carried out the reactions of these tosylhydrazones under acidic conditions. It has previously been established that these hydrazones afford pyrazole derivatives on treatment with alkoxides,[5-7)] and conjugated dienes on treatment with alkyllithium.[8)]

Henry and Moore[4)] obtained β-tosylketone **4a** in a 29% yield by heating benzalacetophenone (**1**) and tosylhydrazide (**2**) in acetic acid. They proposed a mechanism of: (1) the decomposition of **2** into *p*-toluenesulfinic acid (**3**) and diimide, and (2) the 1,4-addition of **3** to benzalacetophenone to afford the product. The mechanism is reasonable because each step, both (1)[9)] and (2)[10)], is a known reaction. We thermolyzed benzalacetone tosylhydrazone (**5b**) in acetic acid and

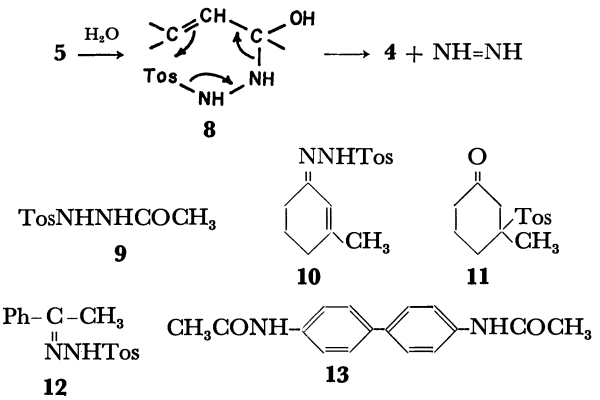
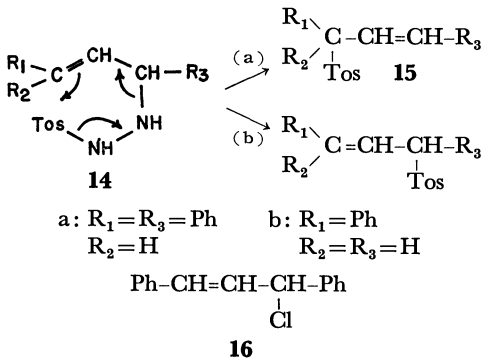
thus obtained Compounds **4b**, **6**, and **7** and the starting tosylhydrazone in 16%, 47% (stoichiometrically), 2.5%, and 5% yields, respectively. The formation of **6** is evidence that *p*-toluenesulfinic acid might intervene in the reaction.

We observed that a smooth decomposition was effected when the thermolysis was carried out in acetic acid *containing* 15% *of water*. The tosylhydrazones **5a**—**5c** afforded *β*-tosylketones **4a**—**4c** in yields of 76%, 68%, and 42%, respectively, no other products being isolated in the pure state. A concerted transfer of electrons in an intermediate **8** was presumed as the probable mechanism for the formation of **4** in view of the following observations. First, when **2** was heated under the present reaction conditions, a quantitative amount of 2-acetyltosylhydrazide (**9**) was obtained and no decomposition into diimide and *p*-toluenesulfinic acid was observed. 2-Acetyltosylhydrazide was a stable compound and was recovered unchanged on refluxing in an acetic acid-water mixture in the presence of benzalacetophenone. Second, when 3-methyl-2-cyclohexenone tosylhydrazone (**10**) was heated under the present reaction conditions, a quantitative amount of **9** was obtained. As 3-methyl-2-cyclohexenone and **3** afforded the *β*-tosylketone **11**, the failure of the **10**→**11** reaction could be ascribed to the incapability for **10** to take the cyclic configuration, as represented in **8**, which might be requisite for the tosyl migration. Acetophenone tosylhydrazone (**12**) also afforded **9** quantitatively under the same conditions. The formation of diimide in the reaction was evident because, when the reaction was carried out in the presence of



azobenzene, 27% (on the basis of **5b**) of diacetylbenzidine (**13**) was obtained. It has been established that azobenzene is reduced by diimide to hydrazobenzene,[11] which then affords **13** by the reaction sequence of benzidine rearrangement and acetylation in acetic acid.[12]

As a model for the intermediate **8**, a tosylhydrazide derivative, **14a**, was prepared from chloride **16** and **2** in pyridine. Although **14a** actually afforded **15a** on refluxing in ethanol, it was not possible, because of the symmetrical carbon skeleton of **14a**, to differentiate between the proposed cyclic mechanism (a) and the elimination-recombination mechanism on the same carbon atom (b). As an attempt to synthesize compound **14** with an unsymmetrical carbon skeleton, cinnamyl chloride (**17a**) and **2** were allowed to react under various reaction conditions, but the reaction mostly proceeded with nitrogen elimination, and cinnamyl *p*-tolyl sulfone resulted. In one case, when **17a** was treated with sodium salt of **2** in DMSO, nitrogen-elimination was avoided and a tosylhydrazide derivative was obtained. The product, however, proved not to be the expected **14b**, but an isomer, **18a**, as proved by



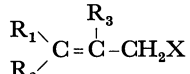
the following observations. The IR spectrum of the compound showed a sharp band at 3400 cm^{-1} for NH_2, and two strong bands, at 1340 and 1150 cm^{-1}, for the tosyl group. The NMR spectrum showed a singlet at δ 3.5 corresponding to two protons for NH_2. The structure was further confirmed by deriving it to the benzal derivative **20a** by treatment with benzaldehyde. It is conceivable that the substitution occurred on the N-1 of **2** because the hydrogen on this nitrogen would be the most acidic and would ionize first when treated with sodium hydride. The reaction presented a sharp contrast to that of **2** with chlorides in pyridine, in which case substitution occurred on the more basic N-2,as in the case of **16**→**14a**. Although our attempts to synthesize **14b** were thus unsuccessful, we observed instead that compound **18a** underwent an interesting fragmentation when treated with acetic acid.

b) 1-Allyltosylhydrazide System.[13] When **18a** was heated in acetic acid at 60°C, allylbenzene, **19a**, was unexpectedly obtained in a 66% yield. Allylbenzene was also obtained when **18a** was pyrolyzed at 110°C, but the yield was much lower in this case and

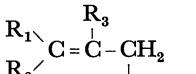
11) E. E. vanTamelen, R. S. Dewey, and R. J. Timmons, *J. Amer. Chem. Soc.*, **83**, 3725 (1961).
12) F. Sachs and C. M. Whittaker, *Ber.*, **35**, 1435 (1902).
13) The authors are indebted to Mr. Shohei Nakamura for his helpful assistance.

the product was contaminated with toluene and other minor unidentified compounds. As an extension of this type of reaction, some allyl halides, **17b—17e**, were reacted with **2** by the NaH/DMSO method. The resulting compounds (**18b—18e**) were shown to have primary amino group from the IR and NMR spectra and by deriving them to benzalamino derivatives **20b—20d**. Compounds **18b—18d**, when warmed at 30—60°C in acetic acid, afforded **19b—19d** in 55—70% yields.

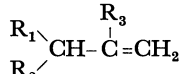
Two features of the acid fragmentation of the tosylhydrazides are noteworthy: 1. The reaction proceeds so as to isolate double bond from conjugation with the phenyl group or to cause the endocyclic double bond to migrate to the thermodynamically more unfavorable exocyclic double bond. 2. The reaction proceeds with a complete allylic rearrangement, no other double-bond isomers being detected in any product on analysis by gas chromatography and by a study of the NMR spectrum.



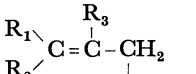
17



18



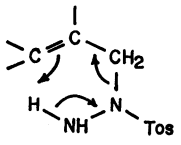
19



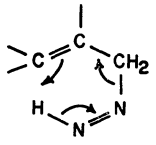
20

a: $R_1=Ph$, $R_2=R_3=H$, $X=Cl$
b: $R_1=R_2=Ph$, $R_3=H$, $X=Br$
c: $R_1=R_3=Ph$, $R_2=H$, $X=Br$
d: R_1, $R_3=-(CH_2)_4-$, $R_2=H$, $X=Cl$
e: $R_1=R_2=R_3=H$, $X=Cl$

The complete allylic rearrangement in the present reaction can be explained in terms of a concerted fragmentation of 1-allyltosylhydrazide **21**, or of the allyldiimide **22** formed *in situ* from **21**, by the elimination of *p*-toluenesulfinic acid.



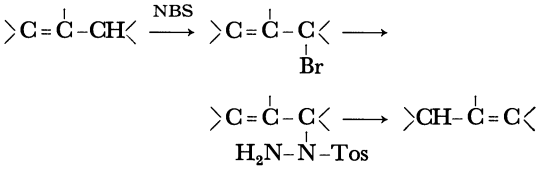
21



22

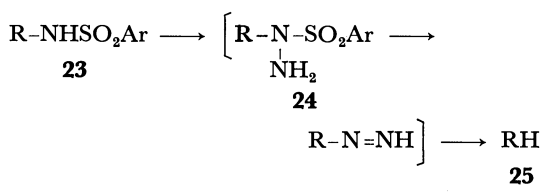
Similar types of double-bond migrations have been reported in the cases of: (1) the reaction of allylamines with difluoroamine,[14] (2) the unusual Wolff-Kishner reduction of α,β-unsaturated carbonyl compounds,[15] and (3) the reaction of allylmercuric derivatives with hydrogen chloride.[16] However, reactions (1) and (2) have limited general applicability because, in the former case, a special experimental technique is necessary for handling difluoroamine and, in the latter case, the reaction frequently gives the product as a mixture of double-bond isomers or proceeds in another directions.

The present reaction could be used for causing the double bond to migrate by the sequence of reactions shown in Scheme 1:

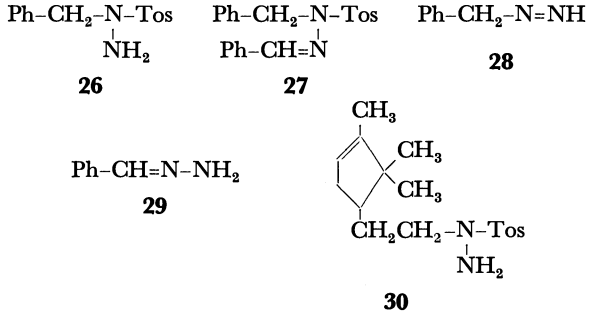


Scheme 1

Nickon and Hill[17] showed that the treatment of *N*-substituted sulfonamides, **23**, with an excess of hydroxylamine-*O*-sulfonic acid in the presence of aqueous alkali yielded the corresponding hydrocarbons, **25**, and proposed a scheme involving 1-substituted arylsulfonylhydrazides (**24**) as the possible pathway. As an example, they obtained toluene from *N*-benzyltosylamide, **23** (Ar=*p*-C_7H_7, R=$PhCH_2$), in a good yield. Similar types of reactions under alkaline conditions were



also reported by Cram.[18] With the intention of comparing the present reaction (in acetic acid) with the reaction under alkaline conditions, the base-induced decomposition of **18a** and **18b** was investigated. When **18a** was treated with sodium methoxide, allylbenzene and 1-phenylpropene were obtained in a ratio of 71:29, as determined from the relative area under each peak on the gas chromatogram. In the same way, **18b** gave a 55:45 mixture of 3,3-diphenylpropene (**19b**) and 1,1-diphenylpropene. As it was confirmed in a separate experiment that allylbenzene (**19a**) was isomerized to 1-phenylpropene to an extent of only 12.5% under the same conditions, it was evident that a portion of the 1-phenylpropene was formed directly from **18a**, instead of *via* allylbenzene (**19a**), under alkaline conditions. Presumably, fragmentations with and without the allylic rearrangement of **18a** occur competitively.



30

It is most probable that an olefinic group in the specified position is requisite for this type of fragmen-

tation to occur. When 1-benzyltosylhydrazide (**26**) was treated with acetic acid, a benzalamino derivative **27** was obtained in a 54% yield (calculated stoichiometrically). Obviously, the lack of an olefinic group in **26** forced the reaction to proceed in a way other than the one described above. A reasonable scheme for the formation of **27** would involve three steps: a) the elmination of *p*-toluenesulfinic acid from **26**, thus affording benzyldiimide (**28**), b) the tautomerization of the diimide into benzaldehyde hydrazone (**29**), and c) the reaction of the hydrazone, or the benzaldehyde formed therefrom, with the starting material, **26**. No smooth reaction proceeded with a compound in which the olefinic group was located in a position remote from the tosylhydrazide group, as in **30**. Under severer conditions, **30** afforded an unidentifiable mixture as the product.

Experimental

*Tosylhydrazones, **5a**, **5b**, **10**, and **12**.* The hydrazones were prepared by refluxing equivalent quantities of the ketones and tosylhydrazide (**2**) in methanol containing a trace amount of conc. hydrochloric acid for 1 hr. The details are summarized in Table 1.

*Mesityl Oxide Tosylhydrazone **5c**.* The compound was prepared according to the method reported by Closs.[19] Mp 118—122°C, Lit[19]: mp 105—110°C.

*Thermolysis of Tosylhydrazones **5a**, **5b**, **5c**, **10**, and **12** in Aqueous Acetic Acid.* A solution of 1g of hydrazone in 15 m*l* of 85% aqueous acetic acid was heated as specified in Table 2 for 3 hr. The subsequent evaporation of the solvent and the recrystallization of the residual solid afforded the product.

*β-Tosylketones **4a**, **4b**, **4c**, and **11**.* An aqueous solution of sodium *p*-toluenesulfinate was neutralized with dilute hydrochloric acid and shaken with ether. To the resulting ether solution was added an equivalent amount of ketone, and the separated solid was recrystallized. The details are summarized in Table 3.

*Thermolysis of Benzalacetone Tosylhydrazone (**5b**) in Acetic Acid.* A solution of 2g of benzalacetone tosylhydrazone (**5b**) in 25 m*l* of freshly-distilled acetic acid was refluxed for 3 hr. The solvent was removed *in vacuo*. The resulting oil solidified on treatment with a small amount of ether. The solid was washed with ether several times (ether-insoluble solid: named A). The ether washings were combined and the ether was removed. The residual solid (0.3 g) afforded crystals of mp 142°C when recrystallized from methanol. The compound was identified as **4b** by comparison with an authentic sample (IR spectrum, mp, and mixed mp). When

the solid A was recrystallized from ethanol, 0.7 g of crystals with a mp of 140—142°C was obtained. The compound was identified as **6** by comparison with an authentic samle (IR spectrum, mp and mixed mp). From the mother liquor of the recrystallization process, 0.1 g of the starting tosylhydrazone, **5b**, and 0.05 g of crystals of **7** (mp 156—157°C) were obtained. On recrystallization from ethanol, the mp rose to 159—159.5°C (Lit[6]: mp 164—165°C).

Found: C, 64.72; H, 5.68; N, 8.89%. Calcd for $C_{17}H_{18}N_2O_2S$: C, 64.95; H, 5.77; N, 8.91%.

2-Acetyltosylhydrazide (9). An acetic-acid solution of tosylhydrazide (**2**) was refluxed for 2 hr. The solvent was then removed *in vacuo*, and the solid was recrystallized from water. Mp 146—147°C (Lit[21]: mp 151°C).

Found: C, 47.19; H, 5.01; N, 12.36%. Calcd for $C_9H_{12}N_2O_3S$: C, 47.37 ; H, 5.30; N, 12.28%.

4-Phenyl-4-tosyl-2-butanone Tosylhydrazone (6). a) An aqueous solution of 1 g of sodium *p*-toluenesulfinate was neutralized with dilute hydrochloric acid, and free *p*-toluenesulfinic acid was extracted with ether . To the resulting ether solution, we then added 1.6 g of benzalacetone tosylhydrazone (**5b**). The solid was filtered and recrystallized from ethanol. Mp 144—146°C. b) A methanol solution containing 1.5 g of **4b**, 1 g of tosylhydrazide (**2**), and a trace amount of conc. hydrochloric acid was refluxed for 2 hr. On cooling, a solid separated which was then recrystallized from ethanol. Mp 144—146°C. The compounds obtained from the two processes, a) and b), were identical.

Found: C, 61.41; H, 5.55; N, 6.01%. Calcd for $C_{24}H_{26}N_2O_4S_2$: C, 61.27; H, 5.57; N, 5.96%.

Thermolysis of Benzalacetone Tosylhydrazone (5b) in Aqueous Acetic Acid in the Presence of Azobenzene. A solution of 3g of benzalacetone tosylhydrazone (**5b**) and 1.7 g of azobenzene in 27 m*l* of acetic acid and 3 m*l* of water was refluxed for 5 hr. The solvent was evaporated *in vacuo*, and the residue was washed with petroleum ether (the petroleum ether-insoluble oil: named B). From the petroleum-ether washing, 0.7 g of azobenzene was recovered. The oil B partially crystallized when a small amount of chloroform was added. The solid was filtered (mother liquor: named C), and recrystallized from acetic acid. Crystals of diacetylbenzidine (**13**) (0.7 g) were thus obtained. Mp 328°C (Lit[12]: mp 330—331°C). Found: C, 71.62; H, 6.11; N, 10.21%. Calcd for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44%. The work-up of the mother liquor of the recrystallization process of **13** afforded other crystals. Recrystallization from ethanol afforded a pure sample of 4-tosylazobenzene (0.3 g); mp 218—220°C. (Lit[22]: mp 224—225°C). Mixed mp with the authentic sample: 220°C. From the mother liquor, C, **4b** was obtained.

1,3-Diphenyl-2-propen-1-ol. To a solution of 20 g of benzalacetophenone in 50 m*l* of ethanol, we added, portion by portion, 1 g of sodium borohydride. The solution was stirred at room temperature for 3 hr, and then the ethanol was evaporated *in vacuo*. A small amount of acetic acid was added to decompose the excess borohydride, and water was added. The solution was shaken with ether and dried over sodium sulfate. The evaporation of the solvent afforded crystals which were recrystallized from ether-petroleum ether. Mp 56°C (Lit[23]: mp 58—59°C).

2-(1,3-Diphenyl-2-propen-1-yl)tosylhydrazide (14a). Thionyl chloride (7.5 m*l*) was added, drop by drop, to 18 g of 1,3-diphenyl-2-propen-1-ol with cooling by ice water, after which the resulting mixture was warmed at 80°C. After gas evolution had ceased, the excess thionyl chloride was removed *in vacuo*. The resulting oil (**16**) was added to a solution of 16 g of tosylhydrazide in 100 m*l* of pyridine with cooling by ice water, and the solution was stirred for 2 hr at room temperature. When the solution was poured into a cold hydrochloric acid (1:1), a solid separated. This was filtered, washed with ether, and recrystallized from ethanol. Prolonged heating in ethanol caused decomposition. Crystals of **14a** were obtained (8 g). Mp 132°C.

Found: C, 69.78; H, 5.84; N, 7.48%. Calcd for $C_{22}H_{22}N_2O_2S$: C, 69.82; H, 5.86; N, 7.40%.

Thermolysis of 14a. A small amount of **14a** was dissolved in ethanol and refluxed for 20 min. On cooling, a solid crystallized out; it was identified as **15a** by comparison with an authentic sample (IR spectrum, mp, and mixed mp).

1,3-Diphenyl-3-tosylpropene (15a). The crude chloride **16** obtained above and an equivalent quantity of *p*-toluenesulfinic acid was dissolved in benzene and refluxed for 2 days. The solvent was removed *in vacuo*, and the residual solid was recrystallized from ethanol. Mp 157—158°C.

Found: C, 75.87; H, 5.77%. Calcd for $C_{22}H_{20}O_2S$: C, 75.84; H, 5.79%.

The reaction of Cinnamyl Chloride with Tosylhydrazide. A solution of 2 g of tosylhydrazide and 0.5 g of cinnamyl chloride in 10 m*l* of pyridine was warmed to 70°C. The evolution of gas was observed. After the gas evolution had ceased, the solution was poured into a cold hydrochloric acid (1:1). The solid filtered and recrystallized from aqueous methanol (0.8 g). Mp 112—113°C. The compound was identified as cinnamyl *p*-tolyl sulfone by comparison with an authentic sample (IR spectrum, mp, and mixed mp).

Cinnamyl p-Tolyl Sulfone. Equivalent quantities of sodium *p*-toluenesulfinate and cinnamyl chloride in DMSO were kept at 80°C for 5 hr. Water was then added, and the mixture was shaken with ether. Thereafter ether was removed, and a mixture of benzene and ligroin was added. A solid separated on standing in a refrigerator; it was recrystallized from aqueous methanol. Mp 118—119°C (Lit[24]: mp 126—126.5°C).

Found: C, 70.03; H, 5.83%. Calcd for $C_{16}H_{16}O_2S$: C, 70.57; H, 5.92%.

1-Chloromethylcyclohexene (17d).[25] Into a solution of 5.2 g of 2-methylenecyclohexanol (bp 82—85°C/23 mmHg, prepared from ethyl 2-cyclohexanonecarboxylate[26]) in 100 m*l* of ether, we stirred 3.4 m*l* of thionyl chloride. When the solution was refluxed for 10 hr and poured into ice water, an ether layer was separated. The ether solution was washed with cold water and dried over calcium chloride. The ether was removed, and the residue was distilled. Bp 62—64°C/11 mmHg. The IR spectrum showed no band assignable to exo-methylene ($>C=CH_2$).

1-Allyltosylhydrazides 18a, 18b, 18c, 18d, and 18e, and 1 Benzyltosylhydrazide (26). To a solution of 1.86 g of tosylhydrazide (**2**) in 20 m*l* of DMSO, we added 0.5 g of sodium hydride (50%) with stirring and external cooling. After the gas evolution had subsided, an equivalent amount of halide was added, little by little, with cooling. The reaction mixture was then stirred for an additional 10 min and poured into ice water. The solid was filtered, washed with cold water several times, and recrystallized from benzene-

ligroin. The details are summarized in Table 4.

*Benzal Derivatives **20a**, **20b**, **20c**, **20d**, and **17**.* An ethanol solution of equivalent amounts of 1-substituted tosylhydrazide (**18a**—**18d**, and **26**) and benzaldehyde was kept at 70°C for 1 hr, and then at room temperature overnight. The crystals which thus separated were filtered and recrystallized from methanol. The details are summarized in Table 5.

*Thermolysis of 1-Allyltosylhydrazides **18a**, **18b**, **18c**, and **18d**, and 1-Benzyltosylhydrazide (**26**) in Acetic Acid.* Two grams of the hydrazide were dissolved in 15 m*l* of acetic acid, and the solution was heated. A gas evolution started at 30°C and became vigorous at 40—70°C. The solution was kept at the temperature specified in Table 6 until the gas evolution ceased. Excess water was then added, and the solution was shaken with ether. The ether layer was washed with an aqueous solution of sodium bicarbonate and dried over sodium sulfate. On the evaporation of the ether, an oil remained; it was then distilled. A gas-chromatographic investigation of the crude oil indicated that this oil was not contaminated with any of the isomers.

*Base-induced Decompositon of **18a**.* A solution of 0.8 g of **18a** and 2 g of sodium methoxide in 50 m*l* of ethanol was refluxed until no gas evolution was observed (40 min). Most of the ethanol was evaporated *in vacuo*, and water was added. The mixture was shaken with ether, and the ether solution was washed with water and dried over sodium sulfate. The oil which remained on the evaporation of ether was distilled under a vaccum (20 mmHg). All the materials which had distilled at the bath temperature of 70—80°C were collected and analyzed by gas chromatograpy. From the retention time and the relative area of each peak in the gas chromatogram, it was determined that the oil consisted of allylbenzene and 1-phenylpropene (71% and 29% respectively).

*Base-induced Decompositiom of **18b**.* A solution of 1 g of **18b** and 2 g of sodium methoxide in 50 m*l* of ethanol was refluxed for 5 hr. After the evaporation of the ethanol *in vacuo*, water was added and the mixture was shaken with ether. The ether layer was washed with water, and the ether was removed. The oil which remained was distilled under a vacuum (3 mmHg). All the materials which had been distilled before the bath temperature reached 170°C were collected and analyzed by gas chromatography. It was determined that the oil consisted of 3,3-diphenylpropene (**19b**) and 1,1-diphenyl-1-propene (55% and 45% respectively).

Base Treatment of Allylbenzene. A solution of allylbenzene (0.6 g), sodium *p*-toluenesulfonate (0.91 g), and sodium methoxide (4 g) in 100 m*l* of ethanol was refluxed for 40 min. A work-up of the reaction mixture in the way described above, and subsequent gas-chromatographic analysis, indicated that the reaction product consisted of two components (Fractions 1 and 2) (87.5% and 12.5% respectively). Each fraction was then collected. Fraction 1 was found to be allylbenzene by comparison with an authentic

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1891—1895 (1971)

The Trialkylborane-initiated Graft Copolymerization of Methyl Methacrylate onto Hemoglobin[1)]

Koichi KOJIMA, Susumu IWABUCHI, and Kuniharu KOJIMA*,
Department of Applied Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba
and Niro TARUMI
Institute for Medical and Dental Engineering, Tokyo Medical and Dental University, Kanda-Surugadai, Chiyoda-ku, Tokyo

(Received December 14, 1970)

The graft copolymerization of methyl methacrylate by trialkylborane onto hemoglobin has been studied at 37°C. In aqueous media, graft copolymers were obtained in the form of a light brown powder or granules, while no grafting occurred in organic solvents, such as cyclohexanone, *n*-hexane, tetrahydrofuran, and toluene. The presence of water seems to be essential to the grafting. The hydrogen peroxide-decomposing property of hemoglobin was well preserved in the graft copolymers so obtained. The mechanism of the initiation is discussed.

Since the pioneering works by Furukawa *et al.*[2)] and by Kolesnikov and Klimentova,[3)] it has been shown that trialkylboranes can initiate the polymerization of various vinyl monomers in the presence of oxygen or oxygen-containing compounds.[4-9)] On the other hand, some reports on the preservation of blood by chemical treatment have appeared. Suzuki and Hachimori[10)] tried to protect blood by the reaction of aldehyde with hemoglobin in vain. Kondo[11)] disclosed that blood can be stabilized by enclosing or "wrapping" it with colloidal gelatin.

We have previously described the cocatalytic effects of pyridine and its derivatives on the polymerization of methyl methacrylate (MMA) by tri-*n*-butylborane (Bu_3B) in organic solvents.[12)] We have also studied the graft copolymerization of vinyl monomers

by trialkylborane initiators onto collagen,[13] proteins, and fibers.[14] In another previous paper,[15] we reported the graft copolymerization of MMA by Bu_3B in blood; MMA was found to be grafted onto blood components in the following order:

blood cells > hemoglobin > blood plasma.

In order to elucidate the MMA-grafting in blood, we tried to graft MMA by Bu_3B directly onto hemoglobin. This paper will report some interesting results on the subject.

Experimental

Materials. *Methyl Methacrylate*: One liter of commercial MMA was washed with three 100-m*l* portions of a saturated sodium hydrosulfite solution in a separatory funnel, and then with three 100-m*l* portions of a 20% sodium chloride solution. The MMA so washed was allowed to stand over silica gel overnight and then filtered and distilled in a nitrogen atmosphere under reduced pressure; bp 46°C/100 mmHg.[16]

Tri-n-butylborane (Bu_3B): Commercial Bu_3B (Callery Chemical Co., USA) was distilled under nitrogen just before use; bp 108—110°C/20 mmHg.[17]

Commercial *hemoglobin* and an isotonic sodium chloride solution were used without further treatment. All the *other materials used* were purified in the usual manner and were distilled just before use.

Graft Copolymerization. *Typical Procedure*: A mixture of 0.5 g of hemoglobin and 10 m*l* of an isotonic sodium chloride solution was placed in a stoppered glass tube (inner volume: *ca.* 60 m*l*). In another, smaller glass tube we added 0.10 m*l* of Bu_3B to 5.0 m*l* of MMA. This mixture was immediately poured into the first glass tube. Then, the glass tube was shaken in a thermostatted shaking apparatus at 37°C. The reaction was stopped by pouring the mixture into 200 m*l* of methanol. The precipitate was filtered, washed with methanol, and dried *in vacuo* to a constant weight. The dry precipitate was extracted with acetone in a Soxhlet extractor for 50—80 hr. The acetone-soluble extracts were reprecipitated with methanol to yield a homopolymer. Both the acetone-insoluble residue (graft copolymer) and the homopolymer were dried *in vacuo* to constant weights.

The infrared speatra were obtained with a Hitachi Model EPI-3T spectrophotometer.

Calculation

The total conversion, the percentage of grafting, and the efficiency of grafting were calculated as follows:

$$\text{total conversion} = \frac{\text{weights of poly (MMA) grafted and homopolymer}}{\text{weight of MMA charged}} = \frac{II+III}{I}$$

$$\text{percentage of grafting} = \frac{\text{weight of poly (MMA) grafted}}{\text{weight of MMA charged}} = \frac{II}{I}$$

$$\text{efficiency of grafting} = \frac{\text{weight of poly (MMA) grafted}}{\text{weights of poly (MMA) grafted and homopolymer}} = \frac{II}{II+III}$$

where

I: weight of MMA charged

II: (weight of the acetone-insoluble component) minus (weight of the backbone polymer)

III: weight of the acetone-soluble component (homopolymer)

The hydrogen Peroxide-decomposing Properties of hemoglobin and of the graft copolymer were determined as follows: To 50 m*l* of a 1% hydrogen peroxide solution were added 2 g of hemoglobin or the graft copolymer obtained from 2 g of hemoglobin. The mixture was well stirred. After 1/2, 1, 2, 3, and 5 hr, 1.0 m*l* portions of the hydrogen peroxide solution were taken up by means of a syringe and titrated with a 0.1 N potassium permanganate solution.

Results and Discussion

Effects of Solvents. The graft copolymerization of MMA by Bu_3B onto hemoglobin was carried out at 37°C in various solvents, both in aqueous and organic solvents. The results are listed in Table 1. The percentage of grafting was 7.8 in the isotonic sodium chloride solution and 12.1 in water, while no weight increase of the final product was observed in cyclohexa-

none, *n*-hexane, tetrahydrofuran (THF), and toluene. This means that, in the presence of water only, MMA was grafted by Bu_3B onto hemoglobin. Similar results were also obtained in the graft copolymerization of MMA by Bu_3B onto proteins, such as albumin and casein.[14]

When the graft copolymerization of MMA by Bu_3B onto hemoglobin was carried out in aqueous media, the acetone-soluble parts of the products were obtained in the form of a light brown powder or granules. The infrared spectra are given in Figure 1. The spectrum of the acetone-insoluble part (I in Fig. 1) showed characteristic absorption bands at 1730, 1450, 1150, and 990 cm^{-1}. Since none of these bands were seen in the spectrum of hemoglobin (II), while all of them were found in the spectrum of poly (MMA) (III), the bands may be assigned to the MMA-grafted hemoglobin. The acetone-insoluble parts may, therefore, be believed to be graft copolymers.

Figure 2 shows an electron micrograph of the acetone-insoluble part (graft copolymer).

For purposes of comparison, the same grafting procedure was done in the absence of Bu_3B. The spectra of the acetone-insoluble parts entirely agreed with that of hemoglobin (II), which means that no grafting occurred in the absence of Bu_3B.

Both di-*n*-butylzinc and the well-known benzoyl peroxide/dimethyl-*p*-toluidine system were incapable of initiating the graft copolymeriaztion of MMA onto hemoglobin under the same conditions. This would suggest that the graft copolymerization of MMA onto hemoglobin is specific for tri-*n*-butylborane under these conditions.

Fig. 2. An electron micrograph of the acetone-insoluble part (graft copolymer), ×500, (viewed in a JELCO JSM-U3 electron microscope).

Reaction Time. The effects of the reaction time on the grafting were also studied. Figure 3 indicates that the grafting proceeded very rapidly in the initial

(○): total conversion; (●): weight increase of hemoglobin; (△): percentage of grafting;
Hemoglobin: 0.5 g; MMA: 5.0 m*l*; Bu_3B: 0.10 m*l*; Solvent: 10 m*l*; 37°C.

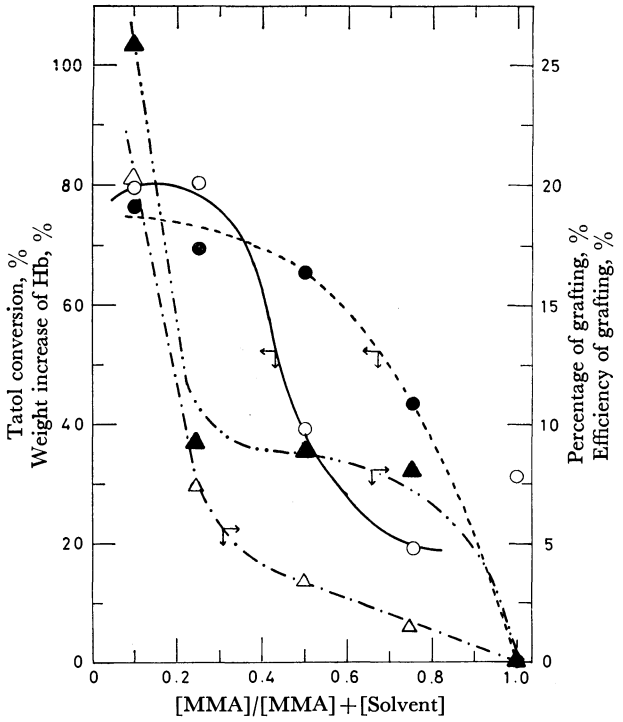

Fig. 4. Effects of monomer concentration.
(○): total conversion; (●): weight increase of hemoglobin; (△): percentage of grafting; (▲): efficiency of grafting.
Hemoglobin: 0.5 g; (MMA + solvent): 20 m*l*; Bu_3B: 0.10 m*l*; 37°C; 2 hr.

stage and then reached the saturation point in about an hour at 37°C.

Concentration of MMA. The concentration of MMA influenced the grafting (Figure 4). The total conversion was minimal when the concentration of MMA was 70—80%. The weight increase, the percentage of grafting, and the efficiency of grafting decreased with the increase in the concentration of MMA, so that at last no grafting was observed when the concentration of MMA was 100%, that is, in MMA itself and in the absence of water. This also shows that water is essential to the grafting.

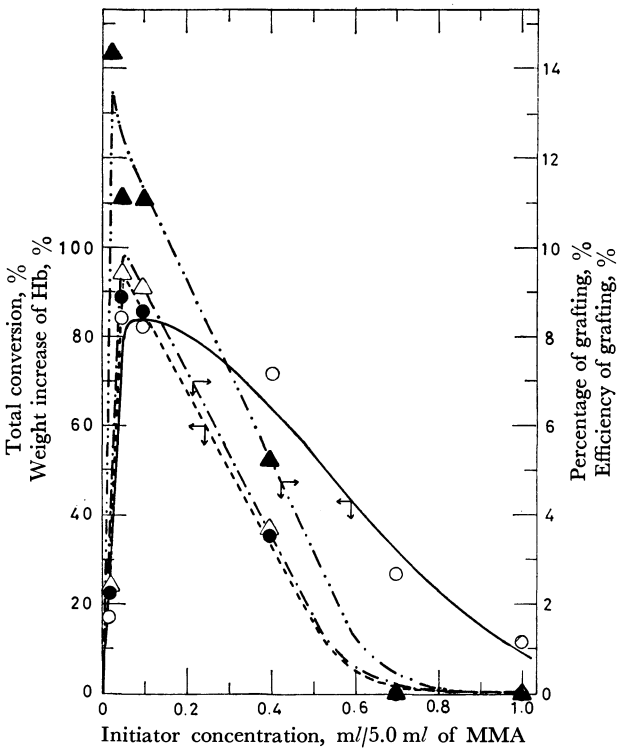

Fig. 5. Effects of initiator concentration.
Hemoglobin: 0.5 g; MMA: 5.0 m*l*; solvent: 10 m*l*; 37°C; 2 hr.

Concentration of Bu_3B. The dependence of the grafting on the concentration of Bu_3B is given in Fig. 5. There was an optimum concentration of 0.05—0.1 m*l* of Bu_3B/5.0 m*l* of MMA for the total conversion, the percentage of grafting, and the efficiency of grafting. All of these values decreased considerably when the concentration of Bu_3B increased much above the optimum concentration. A similar tendency was also observed in the system without hemoglobin.

Concentration of Hemoglobin. Figure 6 presents the relationship between the grafting and the concentration of hemoglobin. So long as the concentration was low, the total conversion was practically constant; when the former was higher than 0.4—0.5 g/5.0 m*l* of MMA, the latter decreased. Both the weight increase and the percentage of grafting had their optimum concentration of hemoglobin; especially, the weight increase gave relatively high values of 130—500% in the range of 0.05—0.30 g/5.0 m*l* of MMA. The higher the concentration of hemoglobin, the higher was efficiency of grafting.

On the Grafting Site. It is known that hemoglobin can accelerate the decomposition of hydrogen peroxide.

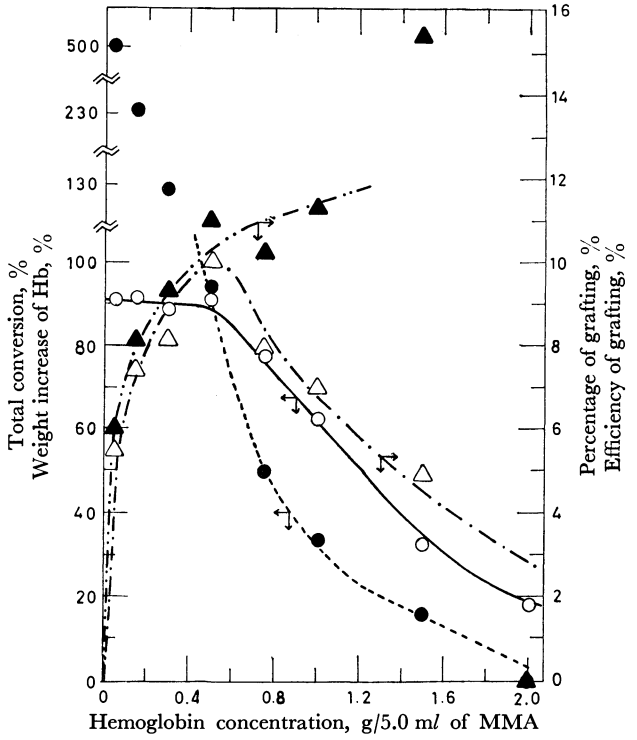

Fig. 6. Effects of homoglobin concentration.
(○): total conversion; (●): weight increase of homeglobin; (△): percentage of grafting; (▲): efficiency of grafting; MMA: 5.0 m*l*; Bu_3B: 0.10 m*l*; Solvent: 10 m*l*; 37°C; 2 hr.

This characteristic property remained practically unchanged after the graft copolymerization, as is shown in Fig. 7. This fact would suggest that MMA was not grafted onto the very part of the hemoglobin which possesses the hydrogen peroxide-decomposing ability. Fe^{2+} is known to be responsible for the decomposition of hydrogen peroxide. Therefore, Fe^{2+} may be supposed to be preserved without any change.

On the Reaction Mechanism. It is interesting to note again that the graft copolymerization of MMA by Bu_3B proceeded well only in aqueous media, although

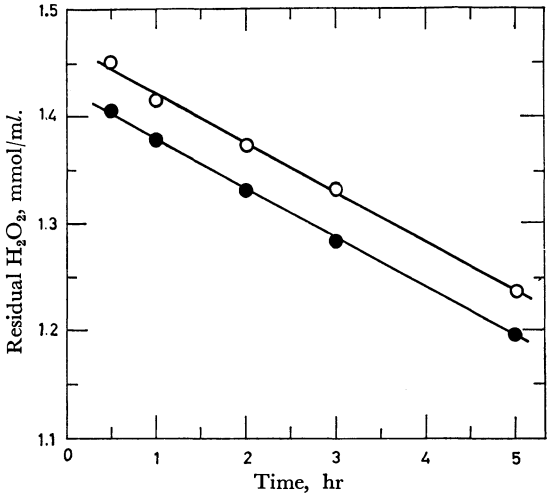

Fig. 7. Hydrogen peroxide-decomposing properties of hemoglobin and graft copolymer.
(○): hemoglobin; (●): graft copolymer. Initial concentration of H_2O_2: 1.46 mmol/m*l*; hemoglobin: 0.3 g; graft copolymer: 0.6 g.

water reacts with trialkylboranes to form hydroxy derivatives (*e.g.*, R_2BOH[18]) and, at last, inactive boric acid.[19] On the other hand, trialkylboranes can initiate the polymerization of MMA in ordinary organic solvents.[4-9] This dicrepancy could be explained by assuming the following three reaction steps:

Solvation:

$$Hb + n\cdot H_2O \longrightarrow (solv.\ Hb) \quad (1)$$

Formation of the complex:

$$(solv.\ Hb) + Bu_3B \longrightarrow complex \quad (2)$$

Formation of the active center:

$$complex \longrightarrow active\ center \quad (3)$$

to initiate the graft copolymerization

(Hb: hemoglobin)

Step 1 is supported by the fact that water is essential to the graft copolymerization and that no grafting occurred in the usual organic solvents. When proteins (such as albumin and casein) and fibers (such as wool, silk, and cotton) were treated similarly, the same phenomenon was also observed.[14]

We previously proposed the following reaction mechanism for the polymerization of MMA by the Bu_3B/pyridine system:[12]

$$pyridine + Bu_3B \longrightarrow complex \quad (4)$$

$$complex \longrightarrow radical \quad (5)$$

to initiate the polymerization

Steps 2 and 3 could be compared with Equations 4 and 5 respectively. The solvated hemoglobin seems to act as an electron donor in Step 2, just like pyridine in Eq. (4). All these backbone polymers contain hydrophilic groups such as amino and hydroxyl groups. The electron-donative property of the hydrophilic groups in hemoglobin is, therefore, believed to play an important role in the formation of the complex. Step 3 could be interpreted analogously in agreement with Eq. (5). In the Bu_3B/pyridine system, our ESR study suggested that the polymerization of MMA involves a free-radical mechanism.[12] Since (1) it is well known that the polymerization of vinyl monomers by trialkylboranes in the presence of oxygen or oxygen-containing compounds proceeds *via* a free-radical mechanism[6-8] and (2) radical polymerization is less sensitive to water than ionic polymerization, Step 3 may be supposed to involve a free-radical mechanism.

However, if an olefinic monomer is polymerizable by the free-radical mechanism, they can usually be polymerized with every other peroxide and azo initiator, too.[20] On the contrary, the benzoyl peroxide/dimethyl-*p*-toluidine system was ineffective on the graft copolymerization under the same conditions.

We thank Professor Eiichi Masuhara for his encouragement throughout this work. We are indebted to Mr. Akihiko Watanabe, Tokyo Medical and Dental University, for taking the electron micrograph.

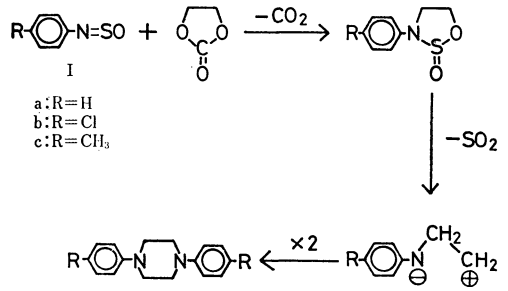
Studies of *N*-Sulfinyl Compounds. IV.[1] The Reactions of *N*-Sulfinylanilines and -phenylhydrazines with Styrene Oxide

Otohiko Tsuge and Shuntaro Mataka
Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka
(Received December 15, 1970)

The reaction of *p*-substituted *N*-sulfinylanilines with styrene oxide in the presence of tetraethylammonium bromide gave the corresponding 1,2,4,5- and 1,2,4,6-tetraarylpiperazines, whose configurations were established on the basis of the NMR spectral studies. On the other hand, while a similar reaction of *p*-substituted *N*-sulfinylphenylhydrazines with the oxide in benzene gave the corresponding diaryl disulfide, diaryl sulfide, and *p*-substituted biphenyl, the reaction in acetonitrile did not give the biphenyl. The pathways for these reactions are suggested.

It is known that *N*-sulfinylaniline reacts as a 1,3-dipolarophile with benzonitrile oxide[2] and diphenylnitrilimine.[3] Recently, Etlis *et al.*[4] found that the reaction of *N*-sulfinylaniline with 1,2-epoxides such as ethylene oxide, propylene oxide, and epichlorohydrin, in the presence of tetraethylammonium bromide (TEABr) gave the corresponding 1,2,3-oxathiazolidine-2-oxides.

In a previous paper,[5] we reported that *p*-substituted *N*-sulfinylanilines (I) reacted with ethylene carbonate in the presence of lithium bromide or TEABr, to afford the corresponding *N,N'*-diarylpiperazine. The pathway for the formation of the piperazine may be illustrated by the dimerization of the intermediate derived from the expected 1,2,3-oxathiazolidine-2-oxide with the elimination of sulfur dioxide, as is shown in Scheme 1.



Scheme 1

On the basis of the above facts, the reaction of I with styrene oxide (II) which can behave like a 1,3-dipolar reagent, can be considered to result in the formation of either diaryl-1,2,3-oxathiazolidine-2-oxides or tetraarylpiperazines. However, little attention has been paid to the reaction of I with II.

When *N*-sulfinylaniline (Ia) and three molar amounts of II were heated with a small amount of TEABr in an atmosphere of nitrogen at 120°C for 7 hr, two crystalline compounds, IIIa (mp 204°C) and IVa (mp 219°C), were obtained. Both IIIa and IVa had molecular formula, of $C_{28}H_{26}N_2$ (M^+ *m/e* 390), which was equivalent to that of a dimer of an intermediate derived from an 1:1 adduct of Ia and II with the elimination of sulfur dioxide.

The IR spectra of IIIa and IVa did not show any bands due to the NH group, and the mass spectrum of IIIa was very similar to that of IVa. On the basis of the above observations and NMR spectra (Fig. 1), it may be deduced that IIIa and IVa are isomeric tetraphenylpiperazines.

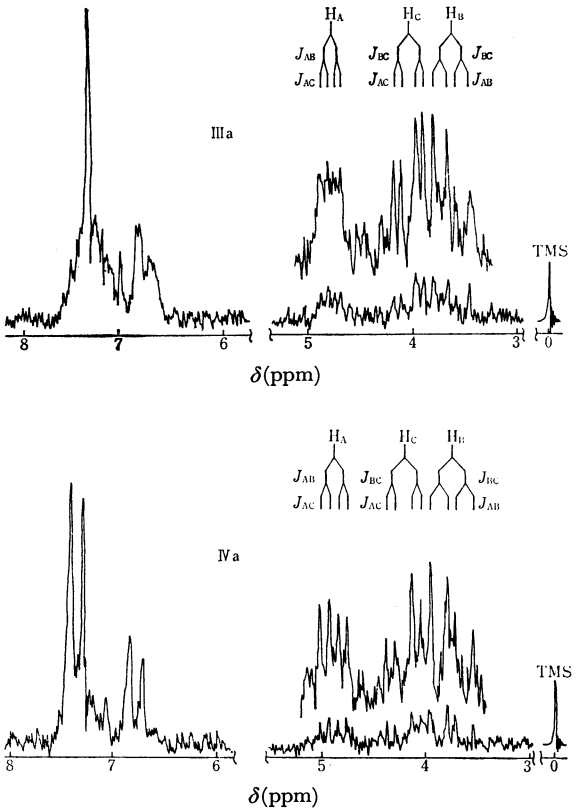


Fig. 1. NMR spectra of IIIa and IVa in $CDCl_3$

Recently, Hoberg[6] reported that the reaction of benzylidenaniline with diazomethane in the presence of diethylaluminum iodide gave 1,2,4,5- and 1,2,4,6-tetraphenylpiperazines, but their structural evidences were not given.

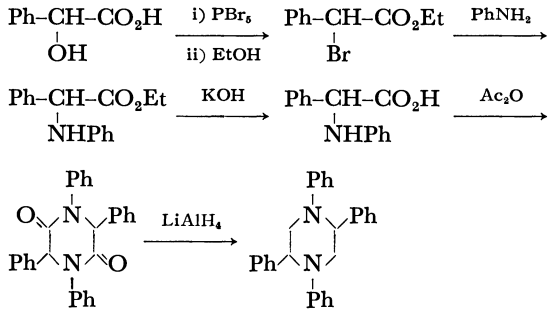

Scheme 2

1,2,4,5-Tetraphenylpiperazine was synthesized by the reduction of the tetraphenylpiperazine-3,6-dione[7] prepared unequivocally from mandelic acid, as is shown in Scheme 2. The melting points of 1,2,4,5- and 1,2,4,6-tetraphenylpiperazines reported by Hoberg[6] were 214 and 202°C respectively, but the 1,2,4,5-tetraphenylpiperazine prepared by the method shown in Scheme 2 melted at 204°C. Therefore, it is clear that tetraphenylpiperazines were erroneously identified by Hoberg;[6] it seems reasonable to assume that the compound melting at 202°C is 1,2,4,5-tetraphenylpiperazine and that melting at 214°C is 1,2,4,6-isomer.

The compound IIIa was proved, by the admixed melting point and by a study of its IR spectrum, to be identical with the authentic sample of 1,2,4,5-tetraphenylpiperazine prepared by the above method. In view of the reaction process (Scheme 3) and of the melting point reported by Hoberg,[6] the compound IVa was assumed to be 1,2,4,6-tetraphenylpiperazine.

A similar reaction of *N*-sulfinyl-*p*-chloro- (Ib) or -*p*-methylaniline (Ic) with II gave the corresponding tetraarylpiperazines, IIIb and IVb or IIIc and IVc. The yields, physical properties, results of elemental analyses, and NMR spectral data of III and IV are summarized in Tables 1 and 2 respectively.

The compounds IIIb—IIIc and IVb—IVc were assigned, by a comparison of their NMR and IR spectra (Fig. 2) with those of IIIa and IVa, to be the corresponding 1,2,4,5- and 1,2,4,6-tetraarylpiperazines respectively.

7) H. Henze, *Ber.*, **32**, 3058 (1899).

Table 2. NMR spectral data of tetraarylpiperazines

a) d.d: double-doublet.

In connection with a previous paper,[5] the pathway for the formation of III and IV is illustrated in Scheme 3. That is, 3,5- (A) and 3,4-diaryl-1,2,3-oxathiazolidine-2-oxides (B) are formed by the (2+3) cycload-

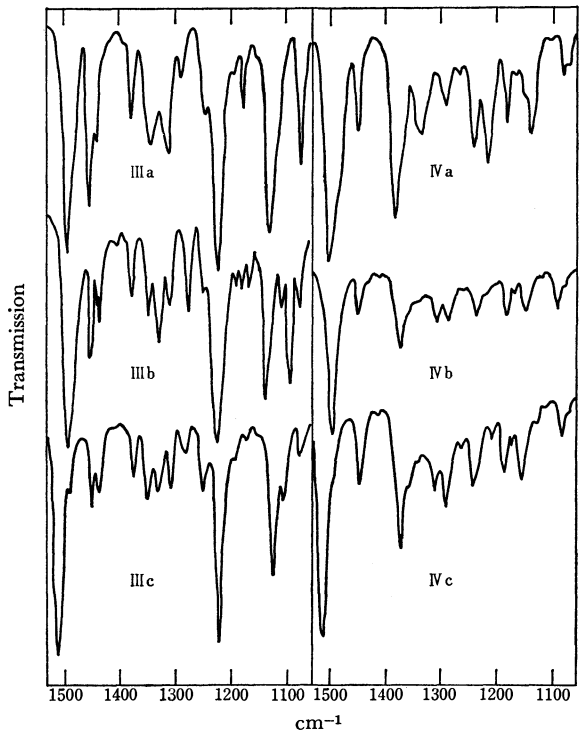

Fig. 2. IR spectra of III and IV (KBr).

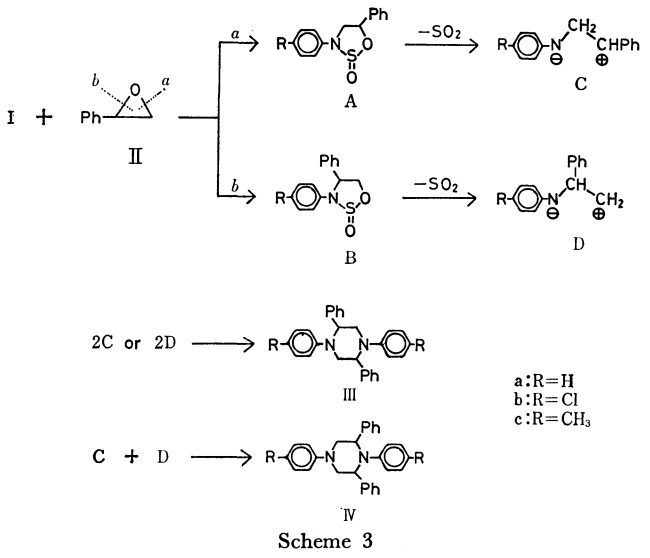
dition of I to the 1,3-dipoles arising from the cleavage of *a* or *b* bond in II.



Scheme 3

The subsequent elimination of sulfur dioxide from A and B yields the 1,3-dipolar intermediates C and D respectively. The dimerization of C or D leads to the formation of III, while the (3+3) cycloaddition of C to D gives IV.

Three conformational isomers, III-1—III-3, and IV-1—IV-3, are possible for the respective structures of III and IV (Fig. 3).

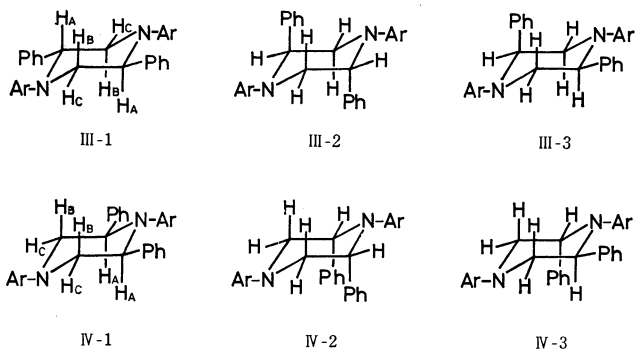


Fig. 3

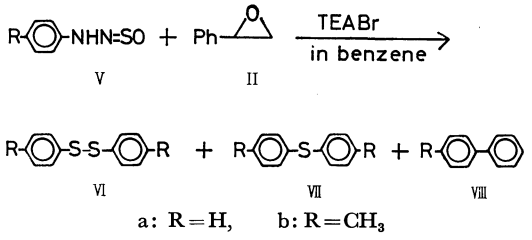
As is shown in Fig. 1 and Table 2, the NMR spectra of all the III and IVisomers showed only one double-doublet (1H+1H) and two double-doublets (each 2H) in the methine and methylene regions respectively; these facts exclude the possibility of III-3 or IV-3 for the structure of III or IV. It is well known that, in cyclohexane derivatives, the values of the vicinal axial-axial ($J_{a,a}$) and axial-equatorial coupling constants ($J_{a,e}$) are 8—13 and 2—6 Hz, and that the value of the vicinal equatorial-equatorial coupling constant ($J_{e,e}$) is invariably and significantly smaller than that of $J_{e,e}$.[8]

Consequently, it may be deduced that the most reasonable structures for III and IV are the conformers, III-1 and IV-1, in which the two phenyl groups are in equatorial positions.

There has been no study of the reaction of *N*-sulfinylphenylhydrazines (V) with a 1,3-dipole, because V is less reactive than I. It appeared of interest to investigate the reaction of V with II.

When equimolar amounts of *N*-sulfinylphenylhydrazine (Va) and II were heated with a small amount of TEABr in refluxing benzene for 16 hr, diphenyl disulfide (VIa), diphenyl sulfide (VIIa), biphenyl (VIIIa), and colorless prisms (IX), mp 156—157°C, were obtained, accompanied with a large amount of tars.

A similar reaction of *N*-sulfinyl-*p*-tolylhydrazine (Vb) with II gave *p,p'*-ditolyl disulfide (VIb), *p,p'*-ditolyl sulfide (VIIb) and 4-methylbiphenyl (VIIIb), but no 4,4'-dimethylbiphenyl was formed.



On the basis of these data, it is evident that the benzene used as the solvent participates in the formation of VIII.

When acetonitrile was used as the solvent in place of benzene, Vb reacted with II in the presence of TEABr to give only VIb and VIIb, but here the formation of VIIIb or 4,4'-dimethylbiphenyl was not observed. The products, VI, VII, and VIII, were isolated in pure forms by gas chromatography and were identified by comparison with authentic samples. Also, quantitative analyses were carried out on the basis of the areas of the individual peaks on the respective chromatograms.

The results are summarized in Table 3.

Table 3. Reactions of V with II in the presence of TEABr

V		II	TEABr	Solvent	Reaction time	Product: Total yield	Product: Composition (ratio)		
R	(g)	(g)	(mg)		(hr)	(mg)	VI	VII	VIII
H	1.0	0.78	70	benzene	16	200	14	4	1

CH_3	1.0	0.68	60	CH_3CN	7	190	2	1	0

8) L. M. Jackman and S. Sternhell, "Applications of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry," 2nd Ed., Pergamon Press, Oxford, London, Edinburgh, New York, Toronto, Sydney, Paris, Braunshweig (1969), p. 286.

The reaction of Va with TEABr, or the reaction of Va with II in the absence of TEABr, did not take place, but Va was recovered quantitatively.

Many years ago, Michaelis and Ruhl[9] found that Va reacted with thionyl or acetyl chloride at a low temperature to give benzenediazonium chloride; they suggested the following reaction scheme:

$$\mathrm{PhNHN{=}SO} \longrightarrow \mathrm{PhN{=}N{-}SOH} \xrightarrow{\text{Y-Cl}} \mathrm{PhN{=}N{-}SO{-}Y} + \mathrm{HCl} \longrightarrow \mathrm{PhN_2^{\oplus}Cl^{\ominus}} + \mathrm{S} + \mathrm{YOH}\ (\mathrm{Y{=}SOCl\ or\ CH_3CO})$$

However, the formation of sulfur was not observed in the reaction of V with II. On the other hand, *N*-sulfinyl-α-methylphenylhydrazine, PhN(Me)N=SO, which does not show the tendency to isomerize to the azo compound, did not react with II under the influence of TEABr, but was recovered quantitatively; this suggests that the tautomerism of the *N*-sulfinyl compound (ArNHN=SO) to the azo compound (ArN=NSOH) plays an important role in the formation of products.

On the basis of the above facts and the formation of the symmetrical diaryl sulfide VII and asymmetrical biphenyl VIII, the reaction pathway for the formation of the products, VI—VIII, can tentatively be assumed to be that shown in Scheme 4.

$$\underset{\mathrm{V}}{\mathrm{ArNHN{=}SO}} \longrightarrow \underset{\mathrm{E}}{\mathrm{ArN{=}N{-}SOH}} \xrightarrow{\text{II+TEABr}} \underset{\mathrm{F}}{\mathrm{ArN{=}N{-}SO{-}Z}} + \mathrm{Et_4N^{\oplus}Br^{\ominus}}$$

$$\mathrm{F} \begin{cases} \longrightarrow \mathrm{Ar\cdot} + \mathrm{N_2} + \mathrm{\cdot SO{-}Z} \\ \longrightarrow \mathrm{ArS\cdot} + \mathrm{N_2} + \mathrm{ZO\cdot} \end{cases}$$

$$\mathrm{2ArS\cdot} \longrightarrow \underset{\mathrm{VI}}{\mathrm{ArS{-}SAr}}, \qquad \mathrm{Ar\cdot} + \mathrm{ArS\cdot} \longrightarrow \underset{\mathrm{VII}}{\mathrm{ArSAr}}$$

$$\mathrm{Ar\cdot} + \mathrm{PhH(solvent)} \longrightarrow \mathrm{ArPhH\cdot} \xrightarrow{\text{-H·}} \underset{\mathrm{VIII}}{\mathrm{Ar{-}Ph}}$$

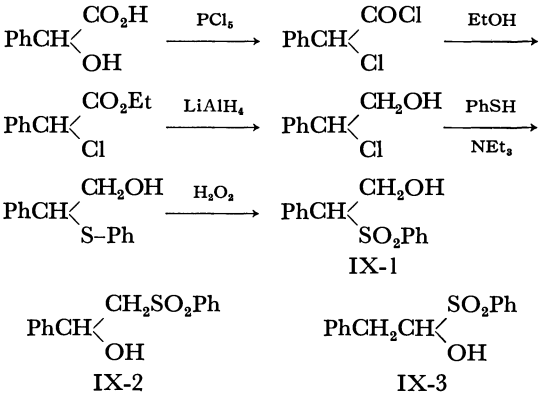
$$(\mathrm{Z{=}PhCHCH_2OH\ or\ PhCH(OH)CH_2{-}})$$

Scheme 4

The intermediates (F) which are formed by the attack of 1,3-dipoles from II on the tautomer (E) of V are decomposed in two ways under these reaction conditions to yield aryl and arylthio radicals respectively. The formation of VI, VII, and VIII can be well understood in terms of the reactions shown in Scheme 4.

On the other hand, the molecular formula of compound IX (mp 156—157°C), which was obtained in a trace amount in the reaction of Va with II, was established from the molecular ion (M^+ *m/e* 262) in the mass spectrum and by elemental analysis, which showed the empirical formula to be $C_{14}H_{14}O_3S$. The IR spectrum of IX showed characteristic bands at 3480 (ν_{OH}) and at 1290 and 1140 cm^{-1} (ν_{SO_2}), while the NMR spectrum exhibited signals at 2.62 (1H, broad singlet, O*H*, exchanged with D_2O), 3.90—4.90 (3H, multiplet, >C*H* and -CH_2-), and 7.00—7.70 ppm (10H, multiplet, aromatic protons).

On the basis of the above observations, three isomers of benzenesulfonyl-phenylethanols, IX-1—IX-3, are possible for the structure of IX. However, it has been reported[10] that β-benzenesulfonyl-α-phenylethanol (IX-2) melts at 93—94°C, and the mass spectrum of IX seems to support the structure of IX-1; the fragment ion peaks appeared at *m/e* 244 (M^+-H_2O), 232 (M^+-CH_2O), 143 ($232^+-C_7H_5$), 121 (M^+-PhSO_2, base peak), 103 (121^+-H_2O, 87.7[11]), 91 ($C_7H_7^+$), and 77 (Ph^+) in the mass spectrum.



The compound IX was confirmed, by its admixed melting point and by a study of its IR spectrum, to be identical with β-benzenesulfonyl-β-phenylethanol (IX-1), mp 156—157°C, which was unequivocally prepared by the reaction of β-chloro-β-phenylethanol[12] with thiophenol and by subsequent oxidation with hydrogen peroxide.

However, the course of the formation of IX in the reaction of Va with II is not clear.

Experimental

All the melting and boiling points are uncorrected. The IR spectra were measured in KBr disks, and the NMR spectra were determined in deuteriochloroform at 60 MHz with a Hitachi R-20 NMR spectrometer, using TMS as the internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer, using a direct inlet and an ionization energy of 70eV.

Materials. The *N*-sulfinyl compounds were prepared by the reported methods[12-15] and were purified by fractional distillation or by recrystallization. *N*-sulfinylaniline (Ia), bp 80°C/12 mmHg (lit,[13] bp 80°C/12 mmHg); *N*-sulfinyl-*p*-chloroaniline (Ib), 101—102°C/5 mmHg (lit,[13]bp 237°C); *N*-sulfinyl-*p*-toluidine (Ic), bp 91.5—92°C/6 mmHg (lit,[13] bp 224°C); *N*-sulfinylphenylhydrazine (Va), mp 104.5—105.5°C (lit,[14] mp 105°C); *N*-sulfinyl-*p*-tolylhydrazine (Vb), mp 112—113°C (lit,[14] mp 112°C); *N*-sulfinyl-α-methylphenylhydrazine, mp 78°C (lit,[15] mp 77°C). The styrene oxide (II) was purified by distillation, bp 191°C.

The Reaction of Ia with II in the Presence of TEABr. After a mixture of 2.0 g of Ia and 5.2 g of II had been stirred

with 0.45 g of TEABr under a slow stream of dry nitrogen at 120°C for 7 hr, the reaction mixture was allowed to stand overnight. A benzene solution of the mixture was then chromatographed on alumina, affording 0.75 g of colorless crystals and a large amount of resinous materials. Several fractional recrystallizations of the crystals from ligroin (bp 80—110°C) gave 0.12 g (4%) of 1,2,4,5-(IIIa), (mp 204°C) and 0.45 g (14%) of 1,2,4,6-tetraphenylpiperazines (IVa), mp 219°C.

Similar reactions of Ib and Ic with II in the presence of TEABr gave the corresponding 1,2,4,5- (IIIb and IIIc) and 1,2,4,6-tetraarylpiperazines (IVb and IVc) respectively. The yields, physical properties, and elemental analysis results are summarized in Tables 1 and 2.

The Preparation of 1,2,4,5-Tetraphenylpiperazine. *i)* Ethyl α-bromophenylacetate: A mixture of 20 g of mandelic acid and 100 g of phosphorus pentabromide was stirred at 100°C for 2 hr, and then the reaction mixture was cooled. After 20 m*l* of ethanol had been added to the mixture, it was refluxed for 10 min. The mixture was subjected to steam distillation, and then the distillate was extracted with 150 m*l* of chloroform. After the extract had been dried over anhydrous sodium sulfate, the solvent was distilled off to give a residue. The vacuum distillation of the residue gave 12 g (36%) of ethyl α-bromophenylacetate, bp 108—115°C/2 mmHg (lit,[16] bp 175°C/25 mmHg).

ii) Ethyl α-Anilinophenylacetate: After a mixture of 10.9 g of ethyl α-bromophenylacetate and 7.0 g of aniline had been stirred at 100°C for 4 hr, the reaction mixture was extracted with hot ligroin. The extract was concentrated *in vacuo* affording 9.4 g (83%) of ethyl α-anilinophenylacetate, mp 81—83°C (lit,[17] mp 83—84°C) as colorless needles.

iii) 1,2,4,5-Tetraphenylpiperazine-3,6-dione: A suspension of 8.4 g of ethyl α-anilinophenylacetate in 50 m*l* of 10% aqueous potassium hydroxide was refluxed for 3 hr, and then it was cooled. The resulting solution was neutralized with 1 N hydrochloric acid to afford a white precipitate. Filtration gave 5.6 g (75%) of crude α-anilinophenylacetic acid, mp 177—180°C (lit,[18] mp 181°C).

A mixture of 5.6 g of the acid and 2.8 g of acetic anhydride was stirred at 155°C (oil bath) for 2 hr, and then the mixture was filtered to give crystals. The crystals were washed with dilute aqueous ammonia and then diethyl ether, leaving 1.1 g (21%) of 1,2,4,5-tetraphenylpiperazine-3,6-dione, mp 258°C (decomp.) (lit,[7] mp 260°C (decomp.)).

iv) Reduction of 1,2,4,5-Tetraphenylpiperazine-3,6-dione: After a mixture of 0.1 g of 1,2,4,5-tetraphenylpiperazine-3,6-dione and 50 mg of lithium aluminum hydride in 30 m*l* of diethyl ether had been refluxed for 5 hr, the mixture was poured into water. The mixture was extracted with chloroform, and then the extract was evaporated *in vacuo*, leaving a yellowish-green, viscous oil. Purification by chromatography on alumina, using benzene as the eluent, followed by recrystallization from ligroin (bp 80—110°C), gave 10 mg (11%) of 1,2,4,5-tetraphenylpiperazine (IIIa), mp 204°C. This compound was proved, by the admixed melting point and by a study of its IR spectrum, to be identical with the compound (mp 204°C) obtained in the reaction of Ia with II.

The Reaction of Va with II in the Presence of TEABr. A solution of 1.0 g of Va and 0.78 g of II in 10 m*l* of benzene was refluxed with 70 mg of TEABr for 16 hr. The reaction mixture was then concentrated *in vacuo* to leave a red oil, which was chromatographed on alumina using benzene and then ethanol as eluents. The benzene-eluent gave 0.2 g of a pale green liquid, which was found, by gas chromatographic analysis, to be a mixture of diphenyl disulfide (VIa), diphenyl sulfide (VIIa), and biphenyl (VIIIa) (Table 3). The compounds, VIa—VIIIa, were isolated by gas chromatography, and were identified by a comparison of the IR spectra with those of respective authentic samples.

The ethanol-eluent was concentrated *in vacuo*, and the resulting residue was purified by chromatography on silica gel, using chloroform as the eluent, to give 30 mg of colorless crystals and intractable tars. The recrystallization of the crystals from benzene gave β-benzenesulfonyl-β-phenylethanol (IX), mp 156—157°C, as colorless prisms.

Found: C, 64.41; H, 5.36%. Calcd for $C_{14}H_{14}O_3S$: C, 64.11; H, 5.38%.

Similar reaction of Vb with II in benzene and acetonitrile were carried out; the results are given in Table 3. *p,p'*-Ditolyl disulfide (VIb), *p,p'*-ditolyl sulfide (VIIb), and 4-methylbiphenyl (VIIIb) formed in the reaction were isolated by gas chromatography, and were proved, by a comparison of the IR spectra, to be identical with the respective samples of VIb, VIIb, and VIIIb prepared by the reported methods.

The Preparation of β-Benzensulfonyl-β-phenylethanol. The reduction of ethyl α-chlorophenylacetate prepared by Walden's method[22] with lithium aluminum hydride in diethyl ether gave crude β-chloro-β-phenylethanol,[12] bp 164—166°C/4 mmHg.

A solution of 1.0 g of β-chloro-β-phenylethanol, 0.62 g of thiophenol, and 0.57 g of triethylamine in 10 m*l* of benzene was refluxed for 1.5 hr, and then the precipitated triethylamine hydrochloride was filtered off. The filtrate was concentrated *in vacuo* to leave 1.4 g of a yellow oil, which was used without further purification. A solution of 0.9 g of the oil and 2 m*l* of 30% hydrogen peroxide in 10 m*l* of acetic acid was stirred at room temperature for 4 days. After the reaction mixture had been poured into 50 ml of water, it was extracted twice with 50 m*l* of chloroform. The extracted was concentrated *in vacuo* to leave a viscous oil, which crystallized on standing at room temperature for a long while. Recrystallization from benzene gave 50 mg of β-benzenesulfonyl-β-phenylethanol, mp 156—157°C, as colorless prisms. This compound was proved, by the admixed melting point and by a study of its IR spectrum, to be identical with the compound (mp 156—157°C) obtained in the reaction of Va with II.

Kinetics and Equilibrium Positions of *cis-trans* Isomerization of 1,2-Bis(phenylthio)ethylene and Its Exchange with Benzenethiyl Radicals

Atsuyoshi OHNO, Tomo'o SAITO, Akio KUDO, and Gen-ichi TSUCHIHASHI
Sagami Chemical Research Center, Ohnuma, Sagamihara-shi, Kanagawa
(Received December 7, 1970)

Kinetics of the *cis-trans* isomerization of 1,2-bis(phenylthio)ethylene induced by benzenethiyl radicals and the exchange of phenylthio group have been studied by using thiophenol-*phenyl*-^{14}C. Pseudo-first order rate constants for the isomerization and the exchange are $2.08\pm0.22\times10^{-5}$ sec^{-1} and $2.03\pm0.26\times10^{-5}$ sec^{-1} at 50°C, respectively. The *cis/trans* ratio of this olefin is 55—58/45—42 at the completion of the reaction, which differs from the value obtained from the reaction induced by iodine (48—49/51—52). The difference has been interpreted with the idea that the isomer composition in the *cis-trans* isomerization is determined by kinetic factors when the reaction is initiated by thiyl radicals.

Many studies have been carried out on the *cis-trans* isomerization of olefins. We know that there are generally two types of equilibria, thermal and photochemical. The thermodynamically more stable isomer is favored by thermal or catalytic isomerization, while the unstable isomer is favored by photochemical isomerization. In the course of our studies on the photocycloaddition of thiobenzophenone to propenylbenzene, we have found that *cis-trans* isomerization of the olefin takes place during the reaction, but the equilibrium compositions of the isomers are completely different from those of thermal and photochemical ones. Thus thermal equilibrium of propenylbenzene forms (at 27°C) 21.8% of *cis*- and 78.2% of *trans*-isomers,[1] while direct photo-irradiation to this olefin produces an equilibrium mixture of about 60—68% *cis*- and 40—32% *trans*-isomers.[2] On the other hand, when thiobenzophenone is present in the photo-irradiated system, the *cis/trans* ratio changes to 3.1/96.9, which is the same as that when thiyl radicals are employed for the catalysts of the thermal isomerization of the olefin (*cis/trans*=4.1/95.9 at 52.3°C[2]). Since it is known that photo-irradiation to thiobenzophenone yields its n,π^* triplet state and this species behaves like a thiyl-radical,[3,4] there is no doubt that thiyl radicals play a different role form that of other radical catalysts in *cis-trans* isomerizations of olefins.

These findings prompted us to study the *cis-trans* isomerizations of 1,2-bis(phenylthio)ethylene induced by benzenethiyl radicals and iodine, and the exchange reaction of this olefin with isotopically labeled benzenethiyl radicals.

Results

All experiments were carried out in *p*-xylene at 50.0± 0.05°C. Isomerization of 1,2-bis(phenylthio)ethylene was initiated by benzenethiyl radicals derived from benzenethiol and azobisisobutyronitrile. The *cis-trans* ratios of the olefin at desired time intervals were determined by vpc and the equilibrium composition was found to be 55% and 45% for *cis*- and *trans*-olefins, respectively. Similar results were also obtained by isotope-labeling technique (*cis/trans*=57.6/42.4). Results are illustrated in Figs. 1 and 2. When 1,2-bis(phenylthio)ethylene was isomerized with the aid of iodine atoms, the composition of the olefin approached the asymptote of 48.5% *cis*- and 51.5% *trans*-isomers.

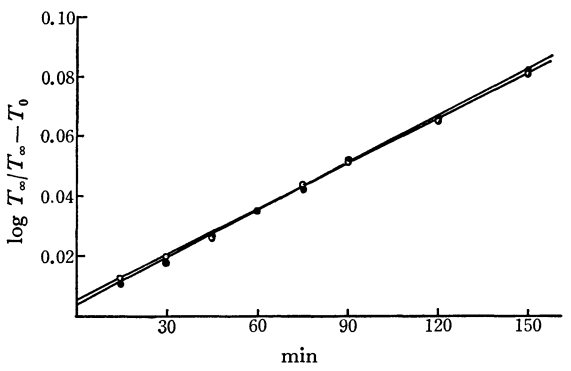

Fig. 4. The pseudo-first order rate plots for the isomerization and the exchange of 1,2-bis(phenylthio)ethylene (The first run of Table 1).
○: *cis*-isomer ●: *trans*-isomer

However, in this case, the composition does not change smoothly, and has a maximum point as shown in Fig. 3.

Pseudo-first order kinetics of the isomerization and exchange were followed by using benzenethiyl-*phenyl*-^{14}C radicals,[5] and rate constants k_i and k_e were found to be $2.08\pm0.22\times10^{-5}$ sec^{-1} and $2.03\pm0.26\times10^{-5}$ sec^{-1}, respectively.[6] The rate constants were calculated by the least-squares method using the data in Table 1. An example of the pseudo-first order rate plots is shown in Fig. 4.

Substantial amounts of diphenyl disulfide were formed during the reactions, but the yield was larger in the reaction with iodine than with benzenethiyl radicals. About 10% of 1,2-bis(phenylthio)ethane was also obtained from the reaction with iodine.

Discussion

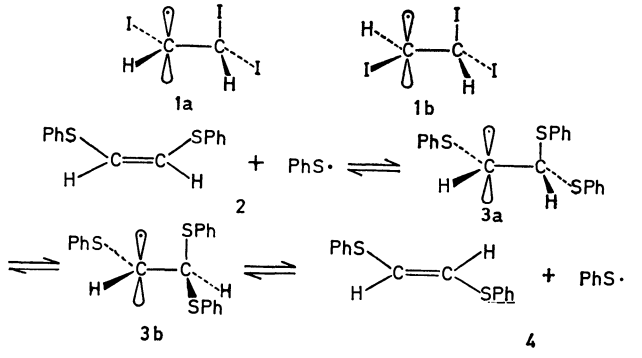
As has been observed with propenylbenzene, benzenethiyl radical shifts the equilibrium composition of 1,2-bis(phenylthio)ethylene from that given by iodine. The latter constant is thought to be thermodynamically controlled.[7]

5) Since the rate of isomerization must be followed during the very early stage of the reaction in order to avoid complexity caused by the other isomer produced, the vpc-method is inadequate as it includes comparison of very small and very large peak areas which inevitably leads to large errors.

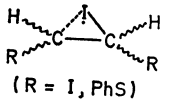
6) The *true* rate constants for the isomerization k'_i and the exchange k'_e should be calculated by $k'_i=\alpha k_1$ and $k'_e=\alpha k_0$ ($1\leq\alpha\leq2$). The value of α changes according to relative rates of the rotation of the central carbon-carbon bond in the intermediate radicals **3**, and the elimination of benzenethiyl radical from it. However, since both rate constants have the same factor, we will employ the observed rate constants k_i and k_e for discussions.

7) For example, E. L. Eliel, "Stereochemistry of Carbon Compounds," McGraw-Hill Book Co., New York, N. Y. (1962). pp. 337—346.

The kinetics of the *cis-trans* isomerization of diiodoethylene and its exchange with iodine have been studied extensively by Noyes and his co-workers.[8] The rate constants for the isomerization and the exchange with this system are, on an average, 1.5×10^{-3} sec^{-1} and 1.4×10^{-1} sec^{-1}, respectively, at 144°C. Thus, the exchange is one hundred times faster than the isomerization in this system. On the other hand, the kinetics with the system of 1,2-bis(phenylthio)ethylene and benzenethiyl radicals has revealed that the isomerization and the exchange proceed at the same rate. This is the main difference in the behavior of iodine and thiyl radicals.



A greater exchange rate than that of isomerization in the case of diiodoethylene has been interpreted in terms of restricted rotation around the carbon-carbon bond[9] in the common intermediates, **1**.[7] If **3** had the life-time of the same order of magnitude as **1**, we should conclude that the energy barrier of the rotation in **3** must be lower than that in **1** in order to interpret the same rate of exchange and isomerization. This is, however, highly unlikely, since the volume of a phenylthio group is supposed to be large enough to form a barrier comparable to that of **1**. If one assumes the structure **5** only for the intermediate of the reaction



with iodine, the exchange should not be as fast as the isomerization considering the microscopic reversibility of the reaction. Consequently, we believe that the intermediates **3** have a life-time long enough to rotate the carbon-carbon bond freely, or that they are fairly stable and can be regarded as only one species instead of two distinct radicals. In other words, **3a** and **3b** are conformational but not configurational isomers. Thus, 1,2-bis(phenylthio)ethylene has a different equilibrium composition, when treated with benzenethiyl radicals, from that expected from thermodynamics, which can be seen from the reaction diagram schematically shown in Fig. 5. Since the intermediate **3** is energetically more stable than systems of **2** and **4**, thermodynamic stabilities of olefin isomers no longer

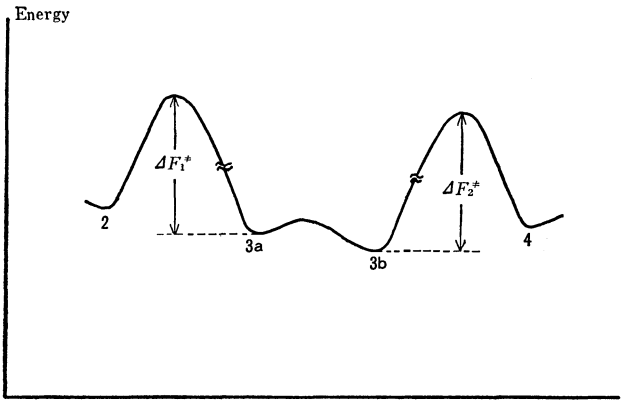


Fig. 5. Schematic energy diagram for reactions of 1,2-bis(phenylthio)ethylene with benzenethiyl radicals.

control the equilibrium composition, but free energies of activation of reactions **3**→**2** and **3**→**4** determine the amounts of isomers at the equilibrium state:

$$\frac{[2]}{[4]}=\frac{[cis\text{-olefin}]}{[trans\text{-olefin}]}=\exp\left(\frac{\Delta F_2^*-F_1^*}{RT}\right)$$

This explanation includes one ambiguous assumption that *cis-* and *trans*-olefins are produced only from conformations **3a** and **3b**, respectively. This possibility is discussed in terms of the angle of the rotation around the carbon-carbon bond at the transition state.[8]

The diagram in Fig. 5 can be explained by the fact that the addition of methanethiyl radical to ethylene is an exothermic reaction with $\Delta H=-14$ kcal/mol, while that of iodine atom to ethylene is an endothermic one with 7 kcal/mol.[10]

It should be noted that the third reaction, the formation of diphenyl disulfide by the combination of benzenethiyl radicals, takes place from **2** and **4** competitively during the isomerizations and exchanges, or leakage from the systems **2** and **4** occurs concurrently and the whole system is in dynamic equilibrium. In this connection, the term "equilibrium" composition may be inadequate, but it could be said that *the final compositions of isomers are determined by kinetic factors when the cis-trans isomerization of an olefin is catalyzed by thiyl radicals.*

It has been mentioned that the composition of isomers of 1,2-bis(phenylthio)ethylene does not approach the asymptote smoothly when the isomerization is catalyzed by iodine (Fig. 3). This indicates that the *true* or thermodynamic equilibrium composition should possess a larger proportion of the *trans*-isomer (smaller proportion of the *cis*-isomer) than that observed here. Since benzenethiyl radicals are produced, as can be seen by the formation of a large amount of diphenyl disulfide during the reaction, they also act as catalysts and the observed composition of isomers changes as the reaction proceeds. This may be an additional proof for the different catalytic behavior of a thiyl radical and an iodine atom in *cis-trans* isomerizations of olefins.

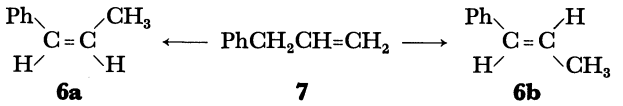
proposal given above and previously,[2] we claim that the *cis-trans* isomerization of an olefin does not give a true or thermodynamically proposed equilibrium constant, when it includes a very stable intermediate and both isomers cannot equilibrate directly. Thus, it is reasonable to expect that such kind of phenomena could be observed from systems other than thiyl radical-catalyzed reactions.[11]

When allylbenzene is treated with potassium *tret*-butoxide in dimethylsulfoxide at 25°C, propenylbenzen with *trans/cis* ratio of 44.4 is formed.[12] However, if the reaction is



6a **7** **6b**

carried out starting form allylbenzene with potassium *tert*-butoxide in *tert*-butyl alcohol at 25°C, the *trans/cis* ratio in propenylbenzene changes to 12.9. Kinetically controlled equilibrium clearly exists in the latter case, since under the conditions the reactions **6a** to **7** and **6b** to **7** do not take place.

Another example can be seen in the isomerization of **7** to **6** catalyzed by palladium(II) chloride. Here again the reverse reactions are very slow and the final *trans/cis* ratio of 19.0 in **6** is controlled kinetically.[13]

These observations support our assumption that the isomer ratio in *cis-trans* isomerization of propenylbenzene induced by thiyl radicals are kinetically controlled.[2]

Experimental

Materials. The isomers of 1,2-bis(phenylthio)ethylenes were prepared after Parham and Herberling[14]; mp 31.5—32.0°C (lit,[14] 32.0—32.5°C) for the *cis*-isomer and 63.5—64°C (lit,[14] 64°C) for the *trans*-isomer. Azobisisobutyronitrile was purified by recrystallizations and used at the longest within 3 days. Thiophenol-*phenyl*-^{14}C was prepared from benzene-^{14}C and chlorosulfuric acid[15] followed by reduction with Zn-H_2SO_4[16] and purified as described previously[17]. The same procedure was employed for the purification of non-radioactive thiophenol. Iodine was purified by sublimations and used immediately. The solvent, *p*-xylene, was once distilled and carefully redistilled over sodium chips. All materials were stored at −18°C under an atomosphere of nitrogen and purities were confirmed by vpc prior to use.

Procedures. Reaction mixtures were prepared in a vacuum-dry box under an atomosphere of nitrogen or argon. An example for the experiment with vpc-method is as follows: 1 m*l* solutions of 0.10 M olefin, 0.056 M thiophenol, and 9.7×10^{-4} M of azobisisobutyronitrile each were combined and diluted to 5 m*l*. Aliquots of 50 μl were sealed in capillaries and immersed in a thermostat of 50.0±0.05°C. At desired intervals, compositions of aliquots were detected by vpc on a Hitachi K-53 (FID) with a column of XE-60 at 200°C. Peak areas of olefins were calculated by the half-height-width method and *cis/trans* ratios were calculated with the aid of a calibrating curve.

In experiments with thiophenol-*phenyl*-^{14}C, 22 m*l* solutions each prepared as described above were placed in ampuls and vacuum-sealed. After being immersed in the thermostat and picked up, two portions of 10 m*l* solutions were pipetted from the aliquot. To each solution, 700 mg of *cis*- and *trans*-1,2-bis(phenylthio)ethylene were added, respectively. The mixtures were washed immediately once with 20 m*l* of 10% aq-Na_2CO_3 and three times with 100 m*l* of water. After evaporation of the solvent, *cis*- and *trans*-olefins thus obtained were recrystallized from ethanol, vacuum dried, and subjected to activity-measurements on a Beckmann LS-250 Liquid Scintillation Counter. Activities were corrected with the aid of calibrating curves for each isomer. The total activity of the reaction mixture was obtained by pipetting 20 μl of solution from the aliquot after the reaction and subjecting to the activity countings.

The procedure for reactions with iodine was the same as described above except for the use of iodine in place of thiophenol.

The ESR Spectra of 2- and 6-Methoxyazulene Anion Radicals

Yusaku IKEGAMI and Shuichi SETO

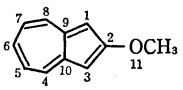
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2-chome, Sendai

(Received December 21, 1970)

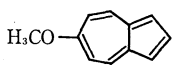
The electron spin resonance spectra of 2- and 6-methoxyazulene anion radicals have been examined. The radicals were generated from neutral species either by electrolytic reduction in *N,N*-dimethylformamide or by the reduction with alkali metals in ethereal solvents. The experimental splitting constants are explained satisfactorily in terms of the calculated spin densities by McLachlan's procedure.

The electron spin resonance (ESR) spectrum of azulene anion radical was first reported by Bernal *et al.*[1] The calculations of the π-electron spin density ρ_i for the anion radical were used with the experimental splitting constants a_i to make a comparison with the predicted bond angle variation of the parameters Q^{H}_{CH} in the McConnell relation, $a_i = Q^{H}_{CH}\rho_i$.[2] Among the relatively few studies on the anion radicals of azulene derivatives, a recent result on 2,2'-biazulenyl[3] has shown that the observed splitting constants are related to the calculated spin densities by rather larger Q^{H}_{CH} values (23—28 gauss) than that suggested by Bernal *et al.* Reddoch[4] has found the anomalous effects of temperature and concentration on the splitting constants for azulene anion radical. This is of interest in connection with the fact that azulene is a non-alternant hydrocarbon. Since only a few ESR works on azulene derivatives have been reported, more systematical studies are desired for elucidation of ESR spectroscopic properties of azulenes.

The present authors attempted to prepare the anion radicals of azulene derivatives. Two methoxy derivatives, 2- and 6-methoxyazulenes, were first chosen because the presence of the substituent at 2- or 6-position does not lower the structural symmetry of azulene, and also the affinity of methoxy substituent with ethereal solvents might favor the generation of relatively stable anion radicals. The ESR spectra of the radicals will be reported in this paper.



I



II

Experimental

Both of the materials, 2-methoxyazulene, mp 82—83°C[5], and 6-methoxyazulene, mp 112—113°C[6], were recrystallized from methanol and finally purified by sublimation in a vacuum. All solvents were degassed by at least five freezing-pumping cycles after being purified. 1,2-Dimethoxyethane (DME) and tetrahydrofuran (THF) were each preserved as solutions of sodium anthracenide in a flask connected with a high vacuum apparatus. *N,N*-Dimethylformamide (DMF) was distilled on to a molecular sieve (4A, small pellet) which had been flame dried in a vacuum. The solvent was moved usually by distillation into the reaction vessels connected with the sample tube for measurement.

The technique employed in the electrolytic generation of free radical is similar to that used by Hirayama.[7] A cell with platinum electrodes was designed so that electrolysis could be performed within the cavity for the preparation of radicals unstable at room temperature. Tetra-*n*-propylammonium perchlorate was used as the supporting electrolyte for the electrolysis in DMF. The alkali metal reduction was performed by the usual method, using lithium, sodium, and potassium metals as the reducing agents.

The ESR spectra were measured with a Hitachi X-band ESR spectrometer, Model MPU-3B or Model 771, using a field modulation of 100 kHz. Analysis of the spectra was confirmed by simulation for which a JEOL spectrum computer, JRA-5, was used.[8] Numerical calculations were carried out on the NEAC 2230 at the Computer Centre, Tohoku University.

Results and Discussion

2-Methoxyazulene Anion Radical. *a) Generation and Spectrum of the Radical*: Treatment of 2-methoxyazulene (I) solution with an alkali metal in degassed DME or THF at −5°C usually resulted in an immediate disappearance of its pink color. This is similar to the case of formation of azulene anion radical in which a deep

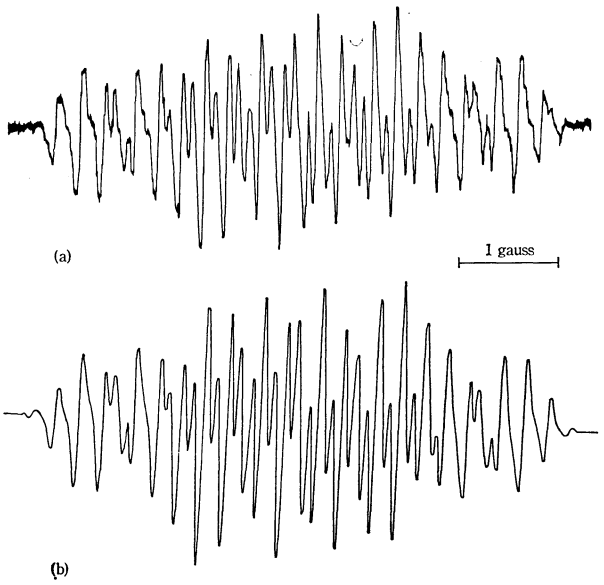

Fig. 2. (a) Enlarged spectrum for the lower 6 gauss of Fig. 1. (b) Simulated spectrum of the above ($\Delta H_{1/2}$=90 milligauss).

purple-blue color of the neutral species changed into a pale greenish yellow.[1] The colorless solution exhibited a strong ESR signal. Although the anion radical is stable for a long period at room temperature, careful procedure was required to obtain it, since a crystalline product was formed at times if the solution was kept in contact with the metal for a long period at room temperature.

Na—THF: The spectrum of the anion radical generated by the reduction of I with sodium metal in THF is shown in Fig. 1. Complicated hyperfine structure of the spectrum suggests the presence of splittings due to the coupling of the radical with a sodium cation. It is easy to read the two splitting constants, 8.598 and 6.133 gauss, from the spectrum, one of which represents the coupling with one hydrogen atom and the other that with two equivalent hydrogen atoms. The enlarged spectrum shown in Fig. 2a for the lower 6 gauss of Fig. 1 is analyzed with three splitting constants, 1.252 (2H), 0.237 (5H) and 0.567 gauss (1Na). A combination of these three constants with eight nuclear spins afforded the simulated spectrum shown in Fig. 2b, confirming the analysis.

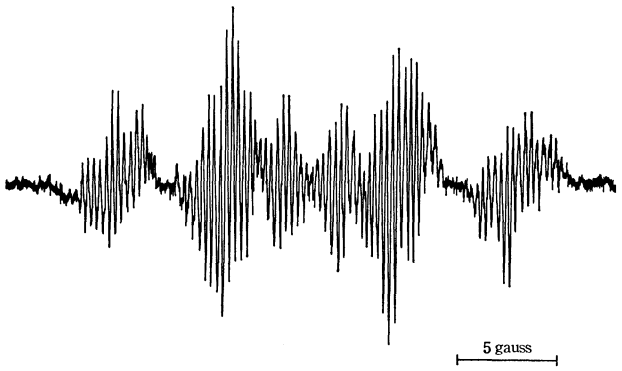

Fig. 3. ESR spectrum of the anion radical generated by the reduction of 2-methoxyazulene with sodium metal in DME (g=2.0030).

Na—DME: Figure 3 shows the spectrum of the anion radical formed by the reduction of I with sodium metal in DME. Hyperfine structure of the spectrum can be interpreted assuming that there are metal splittings with the coupling constant comparable to the least constant in the anion radical. Four splitting constants listed in Table 1 and rather large line-width ($\Delta H_{1/2}$, *ca.* 0.27 gauss) permit analysis of the hyperfine structure.

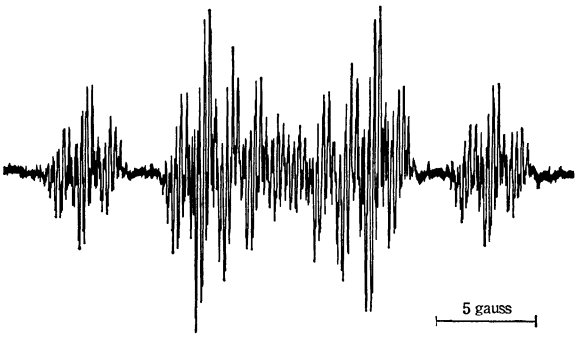

Fig. 4. ESR spectrum of the anion radical generated by the reduction of 2-methoxyazulene with potassium metal in THF (g=2.0017).

K—THF: Generation of the radical with potassium metal in THF afforded the spectrum shown in Fig. 4. It is easy to read three splitting constants, 8.359 (1H), 5.862 (2H) and 1.149 gauss (2H), from the spectrum. Final splittings are explained as those consisting of seven bands of relative intensities 1:4:7:8:7:4:1, each splits into three lines (a_i, *ca.* 0.1 gauss). Relative intensities of the seven bands should be due to the fact that the two constants for potassium metal and methoxy protons are close to each other.

K—DME, Li—THF and Li—DME: Hyperfine structures of the ESR spectra of the radical generated by these systems are simpler than those of Figs. 1 and 3, and the analysis of each spectrum revealed that the metal splitting constant is comparable to that of the least constant for the radical. The hyperfine lines are comparatively broad because of the large line-width close to the least splitting constant. The observed constants are included in Table 1.

Electrochemical Reduction: Electrolytic reduction of I in DMF at *ca.* 1.9V produced the anion radical, which exhibited the ESR spectrum shown in Fig. 5. Hy-

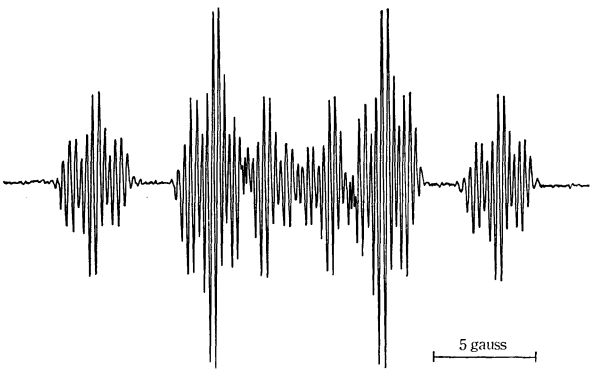

Fig. 5. ESR spectrum of 2-methoxyazulene anion radical generated by the electrolytic reduction in DMF (g=2.0038).

Table 1. Observed hyperfine splitting constants (a_i) for 2-methoxyazulene anion radical

1, 3 (2H)	0.26	0.1	0.29	0.24		0.23_7	0.23
4, 8 (2H)	5.804	5.862	5.670	5.96	6.02	6.133	6.21
5, 7 (2H)	1.097	1.149	1.163	1.17	1.21	1.252	1.31
6 (1H)	8.326	8.359	8.529	8.55	8.62	8.598	8.76
OCH_3(3H)	0.26	0.27	0.29	0.24	0.27	0.23_7	0.23
Metal		0.27	0.29	0.24	0.27	0.56_7	0.23

perfine structure of the spectrum can be readily analyzed with four splitting constants included in Table 1. The analysis was confirmed by spectral simulation.

The observed constants are summarized in Table 1. Assignments for the constants were given according to the type of splitting and by comparing them with the calculated spin densities.

b) Calculation of Spin Density. Calculations of unpaired spin densities (ρ_i) for the anion radical were carried out by employing the Hückel MO theory and the approximate configuration interaction treatment proposed by McLachlan.[9] The Coulomb and resonance integral parameters for C–OCH_3 group were chosen from the values suggested by Streitwieser.[10] The results are given in Table 2. As generally known for many aromatic anion radicals[9] including some azulene anion radicals,[1,3] the McLachlan's procedure gave much more satisfactory results than the Hückel MO calculations. The application of some other parameters for the 9,10-bond ($\beta_{9,10}$:1β) and the C–OCH_3 group (β_{C-O}: 0.6—1.0β, α_O: α+0.5—2.0β) did not alter the assignments for the observed constants shown in Table 2. The Q^H_{CH} values obtained by the McConnell relation are also shown in the table.

6-Methoxyazulene Anion Radical. a) Generation and Spectrum of the Radical: The anion radical of 6-methoxyazulene (II) is not so stable as that of 2-isomer. The solution of II in degassed DME or THF reacted readily with an alkali metal at room temperature losing its pink color, but no ESR signal has been observed.

Table 2. Calculated spin densities(ρ_i) for 2-methoxyazulene anion radical[a]

b) Q^H_{CH} values in the relation of $a_i = Q^H_{CH}\rho_i$, in which the observed a_i in an electrolytic reduction and the McLachlan spin densities were used.

9) A.D. McLachlan, *Mol. Phys.*, **3**, 233 (1960).

10) A. Streitwieser, Jr., "Molecular Orbital Theory for Organic Chemists," John Wiley & Sons, New York (1962), p. 120.

The anion radical was identified when the pink solution came into contact with an alkali metal at −78°C and was measured at a temperature lower than −20°C. The radical generated with sodium metal in DME exhibited the ESR spectrum shown in Fig. 6, which was measured at −100°C. Three splitting constants, 6.63 (2H), 3.67 (1H) and 1.53 gauss (2H), are obtained from the hyperfine structure of the spectrum. The signal intensity decreases with increasing temperature and disappears completely at −10°C. Other systems, Li—THF, Na—THF and K—THF, also showed the ESR signals, each of which consists of broad hyperfine lines.

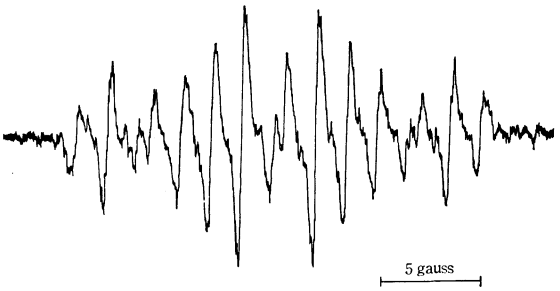

Fig. 6. ESR spectrum of the anion radical generated by the reduction of 6-methoxyazulene with sodium metal in THF, measured at −100°C.

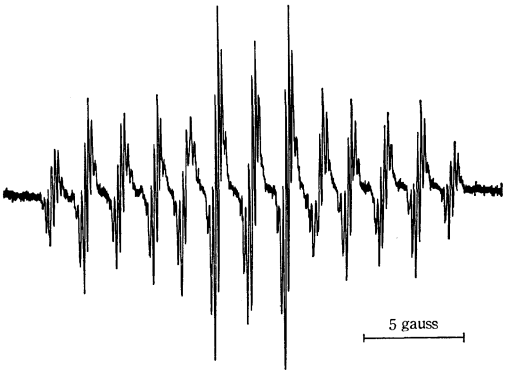

Fig. 7. ESR spectrum of 6-methoxyazulene anion radical generated by the electrolytic reduction in DMF at room temperature (g=2.0029).

In contrast to the above, electrolytic reduction of II produced the stable radical at room temperature. Electrolysis of the solution of II in DMF at *ca.* 1.9V resulted in a pale brown solution which exhibited an ESR spectrum shown in Fig. 7. No decay of the intensity of the spectrum is observed during the course of a few hours. Hyperfine structure of the spectrum is analyzed with four splitting constants listed in Table

3 and the assignments for the constants are reasonably made by comparing them with the calculated spin densities.

TABLE 3. OBSERVED HYPERFINE SPLITTING CONSTANTS (a_i) AND CALCULATED SPIN DENSITIES (ρ_i) FOR 6-METHOXYAZULENE ANION RADICAL

Position	a_i, gauss		ρ_i[a]		$\lvert Q_{CH}^{H}\rvert$[b]
	Na-DME	Electrolysis in DME	Hückel	McLachlan	
1, 3(2H)		0.16	0.0061	−0.0206	7.8

5, 7(2H)	1.53	1.701	0.0032	−0.0890	19.1
6			0.2480	0.3509	
9, 10			0.0806	0.0582	
OCH_3(3H)		0.16	0.0257	0.0236	

a) Parameters for the calculation: $\alpha_{11}=\alpha+2\beta$, $\beta_{6,11}=0.8\beta$, $\beta_{9,10}=0.9\beta$ and $\lambda=1.2$.
b) See footnote b in Table 2.

b) Calculation of Spin Density. Calculations of unpaired spin densities for the anion radical were carried out in a similar way as those for 2-isomer. The results are listed in Table 3 together with the Q_{CH}^{H} values obtained by the McConnell relation.

Discussion. Both 2- and 6-methoxyazulenes produced the stable anion radicals through their electrolytic reductions in DMF. The formation of radicals is consistent with the suggestion by polarographic study on azulene, which showed the first reversible reduction potential ($E_{1/2}$) at −1.10 V in DMF.[11] In the generation of 2-methoxyazulene anion radical by alkali metal reduction, the radical was identified as a rather unstable form sometimes producing solid precipitates. The instability might be due to the further reduction of the radical with alkali metal leading to the decomposition of 2-methoxyazulene structure in ethereal solvent. The solution did not reproduce the pink color of neutral species by exposure to air, while it is known that the complex of guaiazulene with sodium in ethereal solvent shows the immediate reappearance of the original blue color by exposure to air.[12]

The spectra of 2-methoxyazulene anion radical generated by the reduction with alkali metals all showed the coupling with the cation, indicating that the radical species exist mostly as ion pairs. For the radical solutions of Na—DME (Fig. 3), Li—DME and Li—THF systems, co-existence of the ion pairs and the solvent-separated ion pairs might be assumed to explain the asymmetric feature of the splittings observed within the outer 6 gauss of their spectra.

In Table 1, the splitting constants at 4(8)-, 5(7)- and 6-positions are smallest for a case of the generation of the radical by electrolytic reduction, and each of the constants increases for the reductions with alkali metals roughly in the order K—THF, Na—DME, K—DME, Li—DME, Na—THF and Li—THF systems. This is similar to the observation by Reddoch,[13] who pointed out the empirical correlation for proton coupling constants of azulene anion radical in various solvents with various cations. The variation of the constants can be ascribed to the electrostatic perturbation of the cation as stated by him.

The Q_{CH}^{H} values in Tables 2 and 3, which are given for the free radical in DMF, are reasonable if the variation of the value with bond angle in an aromatic ring is assumed as estimated by Bernal *et al.*[1] The value for each position is close to that at the same position for azulene anion radical.[1] However, the values on the carbon atoms in the seven-membered ring are clearly smaller than those for 2,2′-biazulenyl anion which is a very stable radical with deep blue color.[3]

We wish to express our appreciation to Profs. T. Toda and T. Asao for the supply of materials. We are also grateful to Prof. T. Isobe and Dr. H. Yokoi for their helpful discussions.

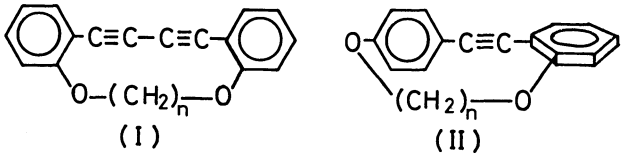
Cyclic Acetylenes. XIII. The Syntheses and Properties of *p,p'*-Bridged Cyclic Diphenyldiacetylenes

Mutsuo KATAOKA, Takashi ANDO, and Masazumi NAKAGAWA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
(Received December 23, 1970)

Concerning the studies on the effect of ring strain on the electronic spectra of cylcic acetylenes, a series of polymethylene ether derivatives of *p,p'*-dihydroxydiphenyldiacetylene (VI_n, $n=13$, 14, 15, and 18) has been prepared by the oxidative coupling of *p*-hydroxyphenylacetylene polymethylene ethers (V_n, $n=13$, 14, 15, and 18) under a high dilution condition. A slight bathochromic shift accompanied by hypochromism was observed in the electronic spectra of VI_n resulting from the increase of the ring strain. The same trend has been observed in the *p,p'*-bridged cyclic tolans.[1] However, the bathochromic shift observed in the *p,p'*-series makes a contrast with the hypsochromic shift in the strained *o,o'*-bridged cyclic diphenyldiacetylene (I)[2] and *o,p'*-bridged cyclic tolans (II).[3] The NMR and IR spectra of VI_n were discussed.

As has been pointed out in previous papers, the increase of strain in the cyclic polymethylene ether derivatives of *o,o'*-dihydroxydiphenyldiacetylene (1)[2] and *o,p'*-dihydroxytolan (II)[3] brought about hypsochromic shift of their electronic spectra. In contrast, bathochromic shift was observed in the spectra of strained cyclic polymethylene ether derivatives of *p,p'*-dihydroxytolan.[1] We hoped to synthesize another series of *p,p'*-bridged cyclic acetylenes to get further insight into the effect of the ring strain on the electronic spectra of cyclic acetylenes. The present paper deals with the syntheses and the properties of *p,p'*-bridged cyclic diphenyldiacetylenes (VI_n).



Syntheses. Alkylation of methyl 4-hydroxycinnamate with polymethylene dibromide gave the biscinnamic ester (III_n). Ester (III_n) was converted into bis-phenylpropiolic acid (IV_n) *via* bromination followed by dehydrobromination. Propiolic acid (IV_n) was decarboxylated without isolation to give *p*-hydroxyphenylacetylene polymethylene ether (V_n). α,ω-Diethynyl compounds (V_n) thus obtained was purified by means of chromatography on alumina. It is to be noted that a minor amount of hydration product, 1,14-bis(*p*-acetylphenoxy)tetradecane and 1-(*p*-ethynylphenoxy)-13-(*p*-acetylphenoxy)tridecane are obtained from the fractions eluted with benzene-ether in the case of $n=14$ and 13, respectively. The oxidative coupling of V_n according to the method of Eglinton under a high dilution condition using ether as an entraining agent afforded *p,p'*-bridged diphenyldiacetylene (VI_n) as colorless crystals. A solution of V_n in pyridine-ether (6:1) was added slowly into a refluxing solvent (pyridine-ether, 6:1) containing cupric acetate monohydrate. The temperature of the refluxing solvent was 83—84°C. The reaction conditions, the yields and the melting points of VI_n are summarized in Table 1. The monomeric nature of VI_n was confirmed by elemental analyses and molecular weight determination.

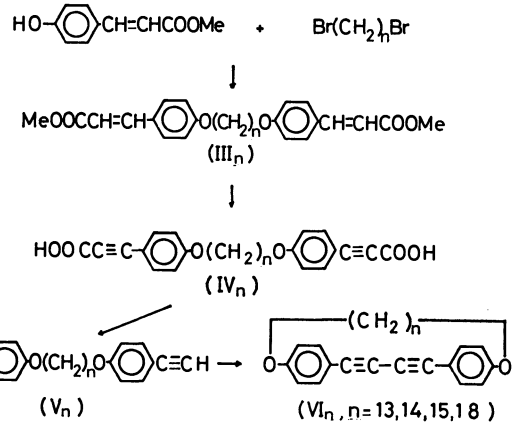


Table 1. The reaction conditions, yields and melting points of VI_n

n	Amount of V_n (mmol)	Amount of solvent (m*l*)	Period of addition of V_n (hr)	Yield of VI_n (%)	Mp of VI_n (°C)
18	1.52	280	7.5	60	138.8—140.0
15	1.70	350	7.5	53	168.8—169.2[a]
					174.7—176.0
14	1.19	210	6.0	37	167.2—169.2
13	1.72	400	5.5	0.8	151.2—153.0
	2.03	2500	8.0	2.0	

a) Dimorphism.

Preparation of VI_{14} by means of the alkylation of *p*-hydroxyphenylacetylene with 1,14-dibromotetradecane was found to be less satisfactory as compared with the above method presumably owing to the instability of the hydroxyacetylene.

Electronic Spectra. The electronic spectral data of *p,p'*-bridged diphenyldiacetylene (VI_n) measured in *n*-hexane and the absorption curves are recorded in Table 2 and Fig. 1 together with those of the open chain analog, *p,p'*-di-*n*-butoxydiphenyldiacetylene.

The absorption band at long-wavelength region consists of four distinct vibrational peaks (A~D) which are considered to arise from the stretching vibration of poly-yne linkage. All of these vibrational sub-

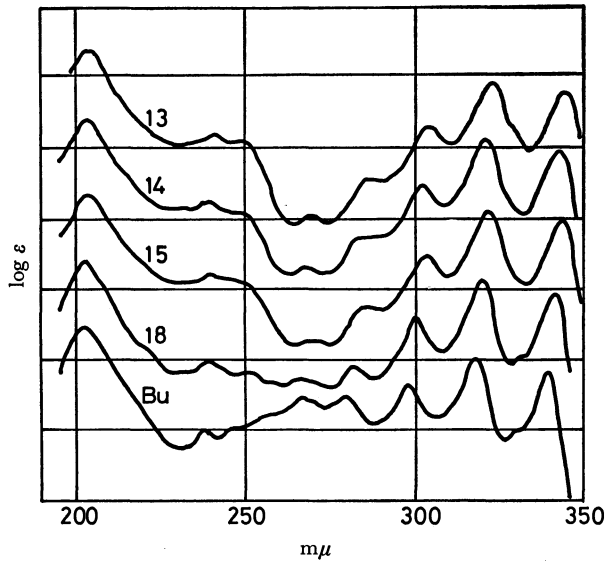

Fig. 1. The absorption curves of VI_n and p,p'-di-n-butoxydiphenyldiacetylene. The curves, with the exception of the di-butoxydiphenyldiacetylene at the bottom, are displaced upward on the ordinate axis by 1/3 log ε unit increments from the curve immediately below, and each horizontal line corresponds to log ε=4. (in n-hexane)

peaks exhibit bathochromic shift due to the decrease in the ring size making a sharp contrast with the hypsochromic shift observed in the strained o,o'-bridged diphenyldiacetylene (I)[1]

An inspection of molecular model of compound VI_n reveals that a chain of fifteen methylene groups is of the minimum length to link p,p'-position of dihydroxydiphenyldiacetylene without ring strain and the two phenyl groups are held almost in a coplanar fashion owing to the restricted rotation.

The absorption intensities of the four vibrational peaks exhibited an interesting change with that of the length of polymethylene bridge. As illustrated in Fig. 2, ε-values of the peaks A and B diminish monotonously with the decrease of the number of n. On the other hand, the absorption intensities of C and D attain maximum in the case of n=15, and then rapidly fall with the increase of ring strain. The nature of the transition corresponding to each of the vibrational peaks has not been clarified yet, and it is difficult to deduce a precise correlation between the ring strain and the above-mentioned intensity change. However, the spectral behavior of VI_n seems to be the result of the effects of coplanarity of the benzene rings (hyperchromism of C and D observed in VI_{15} and VI_{18}), the strain of the diacetylenic linkage caused by the short bridging chain (hypochromism of C and D observed in VI_{13} and VI_{14}) and the diminish of population of molecules in high vibrational sub-levels according to the decrease of the ring size (hypochromism of A and B according to the decrease of the number of n).

Nuclear Magnetic Resonance Spectra. As illustrated in Fig. 3, the protons on the benzene rings exhibit two AB pattern doublets at τ 2—3. The down field

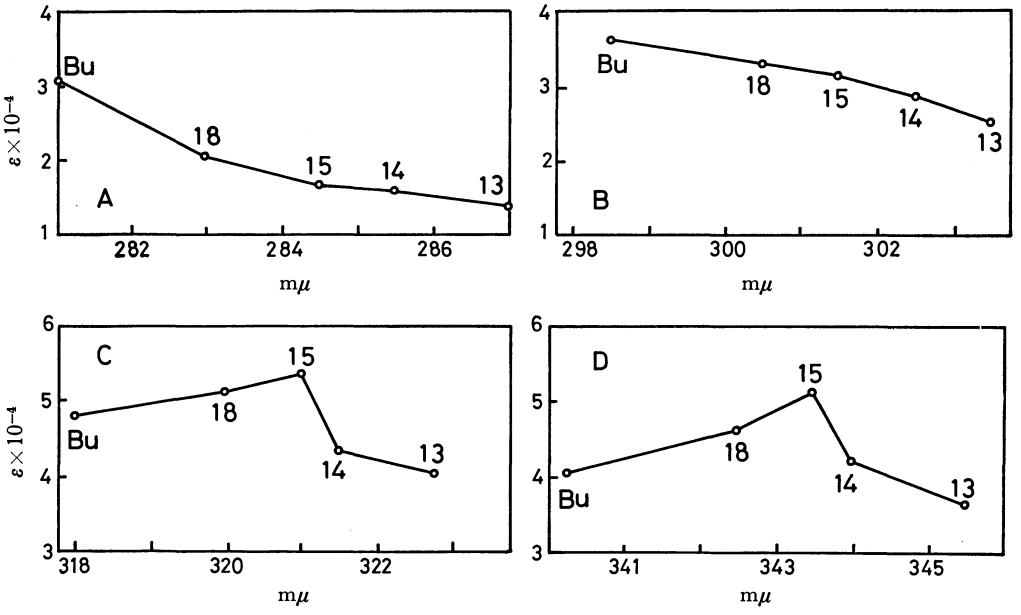

Fig. 2. Change in absorption intensities of the long-wavelength bands of VI_n.

Table 3. Assignment of NMR spectra of VI_n, 60 MHz in $CDCl_3$ (τ-value)

VI_n	Aromatic	α-Methylenes	β-Methylenes	Other methylenes
18	2.53 (4H), 3.08 (4H)	5.72 (4H)	8.37 (5H)[a]	8.84, 9.10 (27H)[a]
15	2.57 (4H), 3.06 (4H)	5.73 (4H)	8.42 (4H)	9.01 (22H)
13[b]	2.54 (4H), 3.04 (4H)	5.72 (4H)	8.47 (7H)[a]	9.04 (16H)
n-BuO	2.54 (4H), 3.14 (4H)	6.02 (4H)	8.0—8.3 (8H)	9.03 (6H)

a) Accurate intensity was not obtained owing to the poor resolution.
b) Measured on a 100 MHz spectrometer.

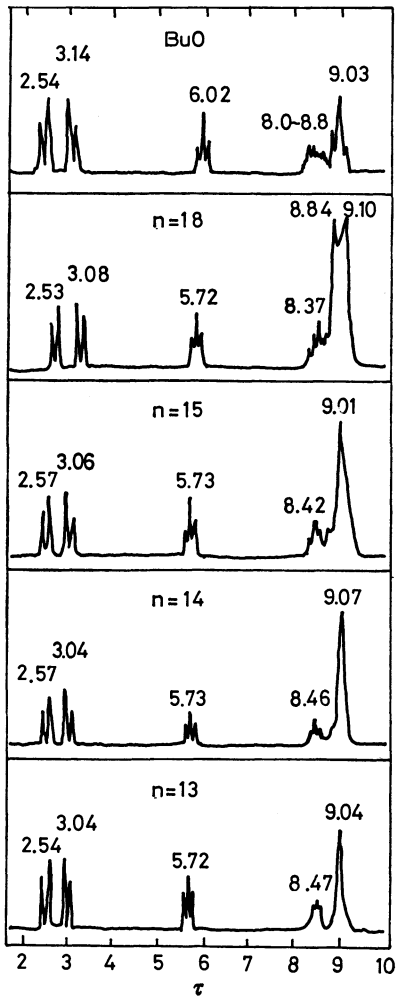

Fig. 3. NMR spectra of VI_n and *p,p'*-di-*n*-butoxydiphenyldiacetylene. The spectrum of VI_{13} was obtained on a 100 MHz spectrometer and the others were measured with a 60 MHz spectrometer (in $CDCl_3$).
(I_n) n=3,4,5,6 (III_n) n=13,14,15,16
(II_n) n=7,8,9,10,11,12 (IV_n) n=11,12,13,14,18

doublet was assigned to the ortho protons to the ethereal oxygen. The protons on the α-methylene groups adjacent to the ethereal oxygen exhibit distinct triplet at τ *ca.* 5.7. Another triplet was observed at around τ 8.4. A decoupling technique was applied for VI_{14} in which the centers of the two triplets were found at τ 5.73 and τ 8.46. The high field triplet was assigned to the methylene protons at the β-position to the ethereal oxygen, because the triplet at τ 5.73 was changed to a sharp singlet by the irradiation at τ 8.46. Therefore, the broad and intense peaks at τ *ca.* 9 should be assigned to the protons on other methylene groups. This indicates that an almost uniform magnetic environment is formed in the vicinity of the *p,p'*-bridged diphenyldiacetylene system as in the case of *p,p'*-bridged cyclic tolans.[1] The assignments are summarized in Table 3 together with that of *p,p'*-di-*n*-butoxydiphenyldiacetylene. The NMR spectroscopic feature of VI_n was found to be closely related to those of *p,p'*-bridged cyclic tolans, however, the slight down field shift of the τ-values of VI_n as compared with those of *p,p'*-bridged tolans seems to indicate that the diacetylenic unit in VI_n exerts more enhanced effect than the acetylenic linkage in the cyclic tolans.

Table 4. IR spectra of VI_n KBr-disk (cm^{-1})

VI_n	$\nu_{C=O}$	$\nu_{C=C}$ (arom.)	δ_{C-H} (arom.)
18	2120 (w)	1600 (s)	835 (s)
15	2120 (w)	1595 (s)	840 (m)
14	2130 (w)	1595 (s)	845 (m)
13	2120 (w), 2200 (w)	1600 (m)	835 (s)
n-BuO	2120 (w)	1959 (s)	830 (s)

(w): weak, (m): medium, (s): strong

Infrared Spectra. The characteristic peaks in the IR spectra of VI_n are tabulated in Table 4 with that of the open-chain analog, *p,p'*-di-*n*-butoxydiphenyldiacetylene. A decrease of intensity of the absorption band due to skeletal in-plane vibration of aromatic ring conjugated with the lone pair electrons in the substituent was observed in the spectra of VI_n as compared with that of the open-chain analog. The same trend has been observed in the IR spectra of *p,p'*-bridged tolans.[1] This seems to be attributable to a resonance inhibition of the oxygen with the benzene owing to a fixation of conformation by the spanning of the bridging chain. The splitting of $\gamma_{C\equiv C}$ band into two peaks (2120 and 2200 cm^{-1}) in the spectra of the strained VI_{13} may be pertinently attributed to some restriction of stretching vibration mode due to the ring strain. The same phenomenon has been observed in the spectrum of 2,4-hexadiynylene ether of 1,5-bishydroxymethylnaphthalene.[4]

Experimental

All melting points are uncorrected. The IR spectra were obtained with a Hitachi EPI-2 spectrophotometer by KBr-disk method, the electronic spectra with a Hitachi EPS-2 spectrophotometer and the NMR spectra with Varian A60 and Jeol JMN-4H-100 spectrophotometers. The molecular weights were measured on a Hitachi Perkin-Elmer 115 vapor osmometer.

Ethyl p-n-*butoxycinnamate.* To a refluxing mixture of methyl *p*-hydroxycinnamate (6.98 g, 39 mmol), *n*-butyl

4) T. Ando and M. Nakagawa, This Bulletin, **40**, 363 (1967).

bromide (11 g, 80 mmol), and anhydrous ethanol (120 ml) was added 56 ml of 0.70 M solution of potassium hydroxide in anhydrous ethanol over a period of 100 min. After further stirring for 2.5 hr, the reaction mixture was poured into water and extracted with ether. The extract was washed successively with a dilute sodium hydroxide and water, and dried. Evaporation of the solvent gave colorless crystals (7.48 g, 98%). This was recrystallized twice from *n*-hexane to give pure ethyl *p*-*n*-butoxycinnamate, mp 35.3—38.0°C.

Ethyl p-n-*butoxycinnamate dibromide.* Thirty six ml of 0.902 M solution of bromine in carbon tetrachloride was added under stirring over a period of 50 min to an ice-cooled solution of slightly crude ethyl *p*-*n*-butoxycinnamate (7.48 g, 31 mmol) in the same solvent (70 ml). Stirring was continued for 40 min at room temperature and then for 40 min at 50°C. The reaction mixture was washed with dilute sodium hydroxide and water successively and dried. The crystals (9.46 g, 74%) obtained by evaporation of the solvent were recrystallized twice from *n*-hexane to give pure dibromide, colorless prisms, mp 105.3—106.3°C. Found: C, 43.95; H, 4.94; Br, 39.47%. Calcd for $C_{15}H_{20}O_3Br_2$: C, 44.14; H, 4.94; Br, 39.16%.

p-n-*Butoxyphenylacetylene.* Anhydrous methanol (95 ml) was added to an ice-cooled intimate mixture of ethyl *p*-*n*-butoxycinnamate dibromide (5.44 g, 14 mmol) and powdered potassium hydroxide (21.4 g).[5] After a vigorous exothermic reaction had subsided, the mixture was refluxed for 4 hr. The reaction mixture was mixed with 6N hydrochloric acid (40 ml) and extracted with ether. The extract was washed with a saturated aqueous solution of sodium chloride and dried. The violet amorphous solid (2.84 g) obtained by the evaporation of the solvent was dissolved in anhydrous pyridine (28 ml). The pyridine solution was refluxed for 50 min in the presence of copper powder (280 mg). Petroleum benzine (100 ml) was added to the reaction mixture and washed thoroughly with 2N hydrochloric acid. After the usual washing and drying procedures, distillation of the solvent furnished a dark brown oily material (1.77 g). The IR spectrum of this substance indicates the presence of carbonyl function (1670 cm^{-1}) presumably owing to the formation of a minor amount of *p*-butoxyacetophenone. The crude material was chromatographed on alumina (15 g). The fractions eluted with petroleum benzine gave crude *p*-*n*-butoxyphenylacetylene (light brown liquid, 1.26 g, 53%) free from carbonyl compound. This was used without further purification for the following reaction.

p,p'-*Di*-n-*butoxydiphenyldiacetylene.* To a stirred mixture of cupric acetate monohydrate (1 g) and anhydrous pyridine (80 ml), was added a solution of *p*-*n*-butoxyphenylacetylene (2.26 g, 13 mmol) in pyridine (20 ml) over a period of 10 min at 50—55°C.[6] Stirring was continued for 4 hr at the same temperature. Benzene (100 ml) was added to the reaction mixture and washed thoroughly with 2N hydrochloric acid. The crude diacetylene (yellow crystals, 1.06 g, 47%), obtained by the usual washing, drying and evaporating procedures, was recrystallized twice from benzene to afford pure *p*,*p*'-di-*n*-butoxydiphenyldiacetylene, mp 154.7—155°C, colorless prisms. Found: C, 83.29; H, 7.64%. Calcd for $C_{14}H_{26}O_2$: C, 83.20; H, 7.56%.

1,13-Dibromotridecane, 1,14-Dibromotetradecane, and 1,18-Dibromooctadecane. The dibromoalkanes were prepared according to the method previously reported.[3]

1,15-Dibromopentadecane. To a stirred and refluxing solution of diethyl sodiomalonate in ethanol [from sodium (7.8 g, 0.34 g atom), diethyl malonate (53 ml, 0.35 mol) and anhydrous ethanol (170 ml)], was added 1,11-dibromoundecane (50 g, 0.16 mol)[3,7] over a period of 40 min. After stirring for further 2 hr, the solvent was removed under reduced pressure. The residue was mixed with ether, washed with water and dried. The crude reddish brown oily tetraethyl ester obtained by the evaporation of the solvent was added over 15 min-period to a stirred solution of potassium hydroxide (50 g) in water (100 ml). The mixture was refluxed for 13 hr under stirring. The reaction mixture was mixed with hot water (800 ml) and concentrated hydrochloric acid (200 ml). The oily material deposited crystallized on cooling under stirring. The tetracarboxylic acid thus obtained was heated to 160—180°C for 70 min to give 1,15-pentadecanedioic acid. The dioic acid in anhydrous methanol (160 ml) containing concentrated sulfuric acid (16 ml) was refluxed for 3 hr to give the dimethyl ester (bp 168—175°C/4 mmHg, 25.6 g, 53% based on dibromoundecane). The dimethyl ester was converted to 1,15-pentadecanediol by means of lithium aluminum hydride reduction.[3] 1,15-Dibromopentadecane (bp 147—150°C/10^{-3} mmHg, 71%) was obtained from the diol according to the method previously reported.[3]

α,ω-Bis-[p-(*2-methoxycarbonylvinyl*)*phenoxy*]*alkanes* (*III*n). As the alkylation of methyl *p*-hydroxycinnamate with α,ω-dibromoalkane was carried out under almost the same reaction conditions, the preparation of 1,15-bis[*p*-(2-methoxycarbonylvinyl)phenoxy]pentadecane (III_{15}) will be described as a representative example.

A solution of methyl *p*-hydroxycinnamate was mixed with a solution of sodium methoxide in methanol [prepared from sodium equivalent to the ester], and the solvent was removed under reduced pressure. The sodium salt of the ester (13.3 g, 67 mmol, yellow powder), thus obtained, was mixed with

H: *n*-hexane B: benzene, M: methanol

1,15-dibromopentadecane (11.6 g, 31 mmol). The mixture was heated on an oil-bath maintained at 165—170°C for 8 hr with occasional shaking. Benzene (100 m*l*) was then added to the reaction mixture and refluxed. The insoluble material was removed by filtration and filtrate was concentrated to *ca.* 50 m*l*. The yellow crystals deposited were recrystallized from benzene to afford pure III_{15} (6.71 g, 37%).

The results of the preparation of III_n are summarized in Table 5.

α,ω-Bis(p-*ethynylphenoxy*)*alkanes* (V_n). The bromination of III_n was carried out in chloroform at room temperature by the addition of a slight excess of 1N solution of bromine in the same solvent. Tetrabromides were obtained as viscous liquids and were subjected to the following reactions without purification. The procedures of dehydrobromination and decarboxylation used in the preparation of *p-n*-butoxyphenylacetylene were applied for the crude tetrabromides and the crude bis-phenylpropiolic acids (IV_n). After copper powder was removed by filtration, pyridine was distilled off under reduced pressure. The residue was mixed with ether and washed with dilute hydrochloric acid. The ether layer was dried over potassium carbonate. The crude material obtained by evaporation of the solvent was chromatographed on alumina. The fractions eluted with benzene afforded V_n as colorless crystals.

In the case of V_{14}, the fractions eluted with benzene-ether gave a minor amount of yellow crystals, mp 107—112°C (3% based on III_{14}). The substance was proved to be identical with bis(*p*-acetylphenoxy)tetradecane by comparison with an authentic sample which was prepared by the method described below. Also, in the case of $n=13$, a small amount of colorless solid (2% based on III_{13}, mp 86—92°C) was obtained from the fractions eluted with benzene-ether. This was recrystallized from *n*-hexane 5 times and from benzene-methanol 4 times to give colorless solid, mp 89—95°C. The structure of 1-*p*-ethynylphenoxy-13-*p*-acetylphenoxytridecane was assigned to this substance on the basis of NMR and IR spectroscopic evidences. Found: C, 80.34; H, 8.75%. Mol. wt. 438. Calcd for $C_{22}H_{38}O_3$: C, 80.14; H, 8.81%. Mol. wt. 435.

The results of the preparation of V_n are summarized in Table 6.

p,p'-*Dihydroxydiphenyldiacetylene Polymethylene Ether* (VI_n).

The preparation of VI_{14} is described as a typical example. A solution of the diethynyl compound (V_{14}, 515 mg, 1.2 mmol) in pyridine-ether (6:1, 60 m*l*) was slowly added over a period of 6 hr to a vigorously stirred refluxing solution of cupric acetate monohydrate (2 g) in pyridine-ether (6:1, 210 m*l*) employing a high dilution apparatus. The change of color of the reaction mixture from blue to greenish brown was observed. After the addition had been completed, the mixture was stirred for 30 min under reflux. The solvent was removed under reduced pressure and the residue was dissolved in ether. The ether layer was successively washed with dilute hydrochloric acid, dilute sodium hydroxide, and a saturated sodium chloride solution, and dried. The reddish brown solid obtained by evaporation of the solvent was subjected to a chromatography on alumina (20 g). Recrystallization of the yellow crystals obtained from the fractions eluted with benzene furnished the cyclic diacetylene, (187 mg, 37%). The reaction conditions, yields and the melting points are given in Table 1, the analytical data and molecular weights are summarized in Table 7.

Table 7. Elemental analysis and molecular weight of VI_n

VI_n	Elemental analysis (%)[a]	C	H	MW
18	Found	84.09	9.17	503[b]
	Calcd	84.25	9.15	485
15	Found	84.31	8.69	484[b]
	Calcd	84.12	8.65	443
14	Found	83.78	8.47	409
	Calcd	84.07	8.47	429
13	Found	83.90	8.29	411
	Calcd	84.01	8.27	415

a) Recrytallized from benzene –*n*-hexane.
b) Measured by the Rast method.

The crystals of VI_n are colorless needles and development of brown color was observed at the temperature around its melting point.

Another Preparation of 1,14-bis(p-*ethynylphenoxy*)*tetradecane* (V_{14}). p-*Hydroxyphenylacetylene.* A mixture of *p*-hydroxyacetophenone (5.0 g, 37 mmol), phosphorus pentachloride (8.5 g, 42 mmol) and benzene (7.5 m*l*) was stirred at 45°C for 10 min and then at 60°C for 20 min. Anhydrous ether (150 m*l*) was added to the reaction mixture. The ethereal solution was added over a period of 20 min to a solution of sodamide [from sodium 5.5 g, 0.24 g atom] in liquid ammonia (250 m*l*).[8] After stirring for 3.5 hr, ammonium chloride (17 g) was added to the reaction mixture, and the ammonia was allowed to evaporate. The residue was mixed with water and extracted with ether. The extract was washed with a saturated aqueous solution of sodium chloride and dried. The reddish brown extract was passed through a short column of alumina (20 g). The yield of *p*-hydroxyphenylacetylene was estimated to be *ca.* 1.5 g (35%), since an

8) I. L. Kotlyarevskii and M. I. Bardamova, *Izv. Akad. Nauk SSSR, Ser. Khim.*, **1964**, 2073.

aliquot (6 ml) of pale yellow filtrate (250 ml) gave 35 mg of a liquid which changed immediately to violet materials. Owing to the instability of *p*-hydroxyphenylacetylene, the ethereal solution was used for the subsequent reaction without isolation of acetylene.

Alkylation of p-*hydroxyphenylacetylene with 1,14-dibromotetradecane.* The aforementioned ethereal solution was evaporated *in vacuo* under the addition of anhydrous ethanol. The resulting ethanol solution of *p*-hydroxyphenylacetylene was mixed with 1,14-dibromotetradecane (1.20 g, 3.4 mmol). The mixture was refluxed, and to it was added over a period of 25 min, with stirring, 1N solution of potassium hydroxide in anhydrous ethanol (8.0 ml). After refluxing for further 2 hr, water was added to the reaction mixture and extraction was carried out with ether. The extract was successively washed with dilute sodium hydroxide and a saturated sodium chloride solution and dried. The deep brown solid (1.77 g) obtained by evaporation of the solvent was chromatographed on alumina (50 g). The fractions eluted with petroleum benzine gave 1,14-dibromotetradecane (283 mg, 24%). The substance (148 mg) obtained from petroleum benzine-benzene (1:4—1:1) fractions gave positive Beilstein's test. The substance was recrystallized from *n*-hexane to yield colorless prisms, mp 78.5—79.5°C. The structure of *p*-*ω*-bromotetradecanoxyphenylacetylene was assigned to this substance on the basis of IR spectroscopy and analytical data. Found: C, 67.22; H, 8.50; Br, 20.14%. Calcd for $C_{22}H_{33}OBr$: C, 67.16; H, 8.45; Br, 20.32%.

The fractions eluted with benzene afforded 40 mg (3%) of V_{14}. This was recrystallized from *n*-hexane to give pure V_{14}, mp 93.0—94.2°C, colorless leaflets.

*α,ω-Bis(*p-*acetylphenoxy)alkanes.* The reaction of 1,14-dibromotetradecane with *p*-hydroxyacetophenone according to the procedure for the preparation of α,ω-bis[*p*-(2-methoxycarbonylvinyl)phenoxy]alkanes (III_n) gave bis(*p*-acetylphenoxy)tetradecane in a yield of 57%, colorless prisms, mp 112.0—113.2°C (from benzene-ethanol). Found: C, 77.43; H, 9.18%. Calcd for $C_{30}H_{42}O_4$: C, 77.21; H, 9.07%.

Similarly, the reaction of *p*-hydroxyacetophenone with 1,18-dibromooctadecane gave bis(*p*-acetylphenoxy)octadecane in a yield of 1.3% colorless leaflets, mp 115.4—117.0°C (from benzene-ethanol). Found: C, 78.19; H, 9.76%. Calcd for $C_{34}H_{50}O_4$: C, 78.12; H, 9.64%.

Hydrogenation of V_{15} and V_{18}. The cyclic diacetylene, V_{15} (127 mg) in benzene was hydrogenated over palladium-carbon. A theoretical amount of hydrogen was absorbed over a 70 min period. The reduction product was chromatographed on alumina (5 g). The fractions eluted with *n*-hexane-benzene (4:1) gave 95 mg (75%) of colorless prisms, mp 59.8—60.3°C. Found: C, 82.89; H, 10.31%. Calcd for $C_{31}H_{46}O_2$: C, 82.61; H, 10.29%.

The hydrogenation of V_{18} gave colorless prisms, mp 102.3—102.7°C (from benzene-methanol). Found: C, 82.50; H, 10.62%. Calcd for $C_{34}H_{52}O_2$: C 82.87; H 10.64%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1914—1916 (1971)

Cyclic Acetylenes. XIV. The Effects of Ring Strain on the Electronic Spectra of Cyclic Tolans and Cyclic Diphenyldiacetylenes

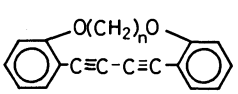
Fumio TODA, Takashi ANDO, Mutsuo KATAOKA, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

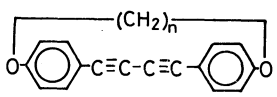
(Received December 23, 1970)

Characteristic features of the electronic spectra of *o,o'*-bridged cyclic diphenyldiacetylenes (I_n), *o,p'*-bridged cyclic tolans (II_n), *p,p'*-bridged cyclic diphenyldiacetylenes (III_n) and *p,p'*-bridged cyclic tolans (IV_n) are compared. The hyperchromism observed in the longest-wavelength absorption maxima (λ_{max}) in the higher homologues of I_n, III_n, and IV_n as compared with the absorption intensities of the respective open-chain analogues is explained in terms of the coplanarity of the chromophore system, and the marked hypochromism observed in the lower homologues of these cyclic acetylenes is attributed to ring strain. The hypochromism observed in the series of II_n is ascribed to the superposition of the effects of ring strain and the twisting of phenyl groups. The bathochromic shifts of λ_{max} with the increase of ring strain in the *p,p'*-bridged series (III_n and IV_n) are explained by the pronounced increase of the energy of the ground state of the strained molecule of this series. On the other hand, the hypsochromic shifts of λ_{max} of *o,o'*-bridged series (I_n) are regarded as the result of the minor increase of energy of the ground state along with the increase of the ring strain.

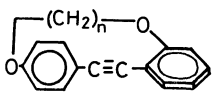
In previous papers we reported the syntheses and properties of *o,o'*-bridged cyclic diphenyldiacetylenes (I_n),[1] *o,p'*-bridged cyclic tolans (II_n),[2] *p,p'*-bridged diphenyldiacetylenes (III_n)[3] and *p,p'*-bridged cyclic tolans (IV_n).[4] In the present paper, we wish to summarize the characteristic features of the electronic



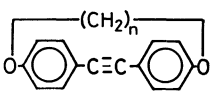
(I_n) n=3, 4, 5, 6



(III_n) n=13, 14, 15, 18



(II_n) n=7, 8, 9, 10, 11, 12



(IV_n) n=11, 12, 13, 14, 18

1) F. Toda and M. Nakagawa, This Bulletin, **34**, 862 (1961).
2) M. Kataoka, T. Ando, and M. Nakagawa, *ibid.*, **44**, 177 (1971).
3) M. Kataoka, T. Ando, and M. Nakagawa, *ibid.*, **44**, 1909 (1971).
4) T. Ando and M. Nakagawa, *ibid.*, **44**, 172 (1971).

spectra of these four series of cyclic acetylenes.

The locations of the longest-wavelength absorption maxima (λ_{max}) and their absorption intensities (ε) of I_n, III_n, and IV_n along with those of the open-chain reference substances are summarized in Tables 1, 3, and 4. A rough molecular geometry which is revealed by an examination of the molecular models of these compounds is also shown in the Tables. Since the longest-wavelength absorption maxima of *o,p'*-bridged cyclic tolans (II_n) disappear as the ring size decreases, the wavelength of the absorption peaks at *ca.* 300 nm along with the ε-values and the molecular geometry are recorded in Table 2.

Table 1. Molecular geometry and electronic spectral data of *o, o'*-bridged diphenyldiacetylenes (I_n)

The change of absorption intensities with that of the chain length is illustrated in Figs. 1 and 2. The hyperchromism of λ_{max} observed in the higher homologues of I_n, III_n, and IV_n as compared with the ε-values of the respective open-chain analogues can be reasonably ascribed to the enhanced coplanarity of the two phenyl groups as a result of the ring formation. The fact that the maximum ε-values are attained in I_5, III_{15}, and IV_{13} is consistent with the above-mentioned argument, because as indicated in Tables 1, 3, and 4, the molecular models indicate that these molecules are strain free and keep rigid and planar structures due to the presence of bridging chain of adequate length. However, the absorption intensities rapidly decrease with the decrease of chain length. The marked hypochromism of λ_{max} in the lower homologues of I_n, III_n, and IV_n should, therefore, be attributed to the increase of the ring strain.

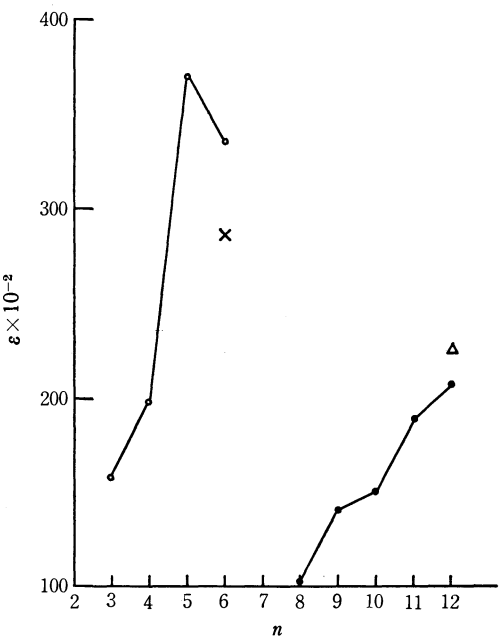

Fig. 1. The ε-values of *o,o'*-bridged diphenyldiacetylenes (I_n, ○——○), *o, p'*-bridged tolans (II_n, ●——●) and the the open-chain analogs (× = *o,o'*-dimethoxydiphenyldiacetylene; △ = *o,p'*-dimethoxytolan).

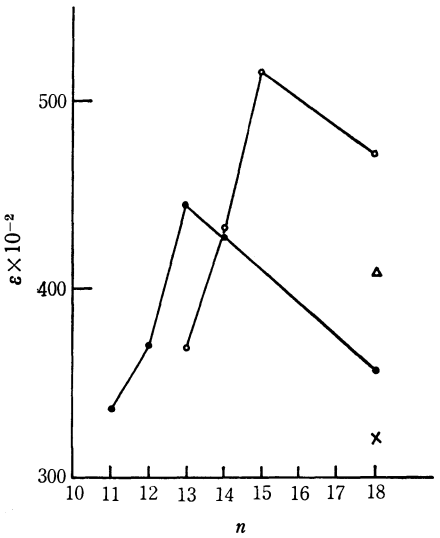

Fig. 2. The ε-values of *p,p'*-bridged diphenyldiacetylenes (III_n, ○——○), *p,p'*-bridged tolans (IV_n, ●——●) and the open-chain analogs (△ = *p,p'*-di-*n*-butoxydiphenyldiacetylene; × = *p,p'*-di-*n*-butoxytolan).

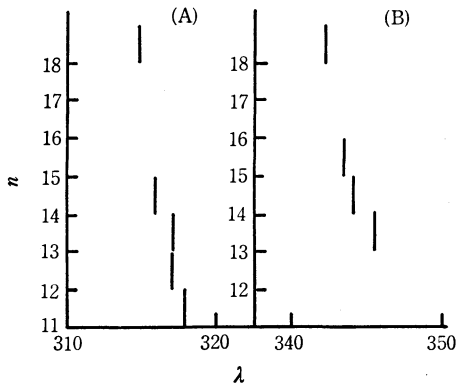

Fig. 3. The bathochromic shifts of the λ_{max} in the *p,p'*-bridged series. (A)=*p,p'*-bridged tolans (IV_n); (B)=*p,p'*-bridged diphenyldiacetylenes (III_n).

In the case of *o,p'*-bridged cyclic tolans (II_n), the decrease of chain length should increase the twisting of the two phenyl groups, *e.g.*, the molecular model of II_7 shows that the interplanar angle of the two phenyl groups should be almost rectangular. Therefore, the hypochromism observed in II_n should be regarded as the superposition of the effect of ring strain and the effect of twisting of the two phenyl groups.

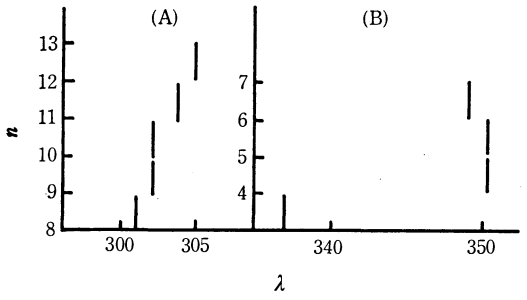

Fig. 4. The hypsochromic shifts of the λ_{max} in the *o,p'*- and *o,o'*-bridged series. (A)=*o,p'*-bridged tolans (II_n); (B)=*o,o'*-bridged diphenyldiacetylenes (I_n).

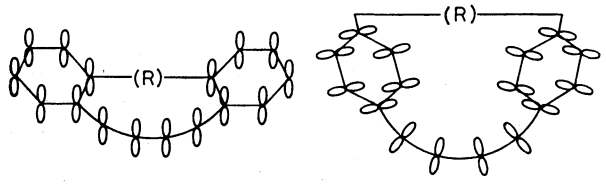
With regard to the effect of ring strain on the location of λ_{max}, the above-mentioned four series of cyclic acetylenes (I_n, II_n, III_n, and IV_n) exhibit striking contrast. As illustrated in Fig. 3, the increase of ring strain resulted in the bathochromic shifts of the λ_{max} of *p,p'*-bridged tolans (IV_n) and *p,p'*-bridged diphenyldiacetylenes (IV_n). On the contrary, as is shown in Fig. 4, the decrease of the ring size exerts hypsochromic effects on the λ_{max} of *o,o'*-bridged diphenyldiacetylenes



Strained *o,o'*-bridged series Strained *p,p'*-bridged series

Fig. 5. A schematic illustration of the *p*-orbitals of the strained *o,o'*- and the strained *p,p'*-bridged diphenyldiacetylenes.

(I_n) and that of *o,p'*-bridged tolans (II_n). The hypsochromism observed in the latter compounds (II_n) can not be ascribed only to the increase of ring strain, because the afore-mentioned twisting of the phenyl groups should also result in the increase of the transition energy of the long-wavelength bands of II_n. However, the difference in spectral behavior between the *o,o'*-series (I_n) and the *p,p'*-series (III_n and IV_n) seems to reflect the difference of the mode of ring strain in these two series of cyclic acetylenes.

The strained molecules of I_n are held in planar conformation regardless of the magnitude of the ring strain as illustrated in Fig. 5. The diacetylenic linkage in I_3 seems to be forced to bend due to the short bridging chain. However, the two phenyl nuclei should be held still in a coplanar position. Therefore, the *p*-orbitals which contribute to the conjugation of the entire chromophore system are also held in a parallel position independent of the magnitude of the ring strain.

In the *p,p'*-series (III_n and IV_n), as illustrated in Fig. 4, the two benzene nuclei should deviate from the coplanar position according to the increase of ring strain. Consequently, the *p*-orbitals which contribute to the conjugation of the entire chromophore should deviate from the parallel position in the strained members of III_n and IV_n.

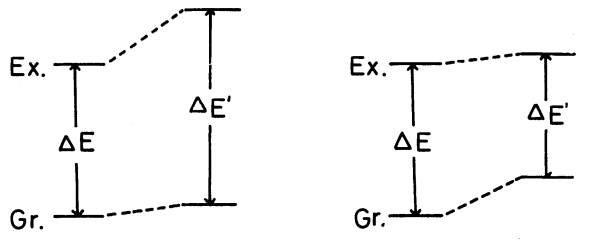


Fig. 6. The transition energies of the *o,o'*-bridged and the *p,p'*-bridged cyclic acetylenes.

Thus, it seems pertinent to assume that the increase of energy of the ground state of the strained molecule of *o,o'*-series (I_n) is smaller than that of the *p,p'*-series (III_n and IV_n), whereas, the increase of energy of its excited state is larger than or almost the same as that of *p,p'*-series (III_n and IV_n). This is illustrated schematically in Fig. 6. Thus, the transition energy $\Delta E'$ of the strained *o,o'*-bridged molecule (I_n) becomes larger than that of the strain free molecule ΔE. Consequently, in the case of *o,o'*-bridged series (I_n), the increase of ring strain produces a hypsochromic shift. Inversely, the transition energy $\Delta E'$ of the strained *p,p'*-bridged molecule (III_n and IV_n) becomes smaller than that of the strain free molecule ΔE, *i.e.*, the increase of ring strain in the series of *p,p'*-bridged cyclic acetylenes (III_n and IV_n) results in a bathochromic shift.

The Catalytic Dehydrogenation, Dehydroxylation, and Dehydroxymethylation of Benzyl Alcohol. III. The Effect of Metal Chlorides as Additives

Masayoshi ISHIGE,* Koji SAKAI, Masatoshi KAWAI, and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received December 28, 1970)

This paper will describe the reaction of benzyl alcohol in the presence of various kinds of modified stabilized nickel catalysts, which had been prepared from the mother catalyst by treating it with solutions of appropriate metal chlorides. The catalytic activities of each modified catalyst for the formation of benzene, toluene, and benzaldehyde were compared in terms of the f_H, f_{CH_3}, and f_{CHO} values; the selectivities for the formation of benzene and toluene against that of benzaldehyde, S_H and S_{CH_3}, were also evaluated. In general, the formation of toluene and benzene was greatly affected both by the kind and by the amount of metal chlorides used as additives. The reaction was promoted by the addition of a proper quantity of alkali metal chloride. In the cases of the reactions by lowly-modified catalysts, the decreasing order of the f_H and f_{CH_3} values according to the kind of metal ion adsorbed on the catalyst was as follows: $Na^+ \geqq K^+ > Co^{2+} > Ca^{2+} > Cd^{2+} > Ba^{2+} > Hg^{2+} > Cu^{2+}$. On the other hand, in the higher degrees of modification, the corresponding order of the f_H and f_{CH_3} values was altered to be as follows: $K^+ > Na^+ > Co^{2+} > Cd^{2+} > Ba^{2+} \geqq Ca^{2+} > Cu^{2+} > Hg^{2+}$. With regard to the modified nickel catalysts treated with 0.08 N solutions, it was found that the sequence of the f_H and f_{CH_3} values due to the kind of metal ion was roughly correlated with that of the atomic numbers of the corresponding metals. The results are discussed in connection with the general concept of catalytic chemistry.

Preceding papers[1,2] have described the catalytic reactions of benzyl alcohol in the presence of various nickel catalysts and of modified stabilized nickel catalysts treated with solutions of sodium compounds. The reaction products mainly consisted of benzaldehyde, toluene, and benzene, sometimes accompanied by the formation of small quantities of certain hydrocarbons and carbon dioxide. The composition of the product was found to be variable under the influence of the chemical nature of the catalysts employed. Numerous papers on the hydrogenation of benzyl alcohol over various metal catalysts[3] have described the formation of toluene as a hydrogenolysis product of the alcohol. The palladium and nickel catalysts were proved to be especially preferable for the hydrogenolysis of benzyl alcohol to toluene. On the other hand, it has been shown that benzyl alcohol is converted to benzaldehyde, toluene, and benzene in the redox reaction of unsaturated organic compounds, with benzyl alcohol as the hydrogen donor and in the presence of nickel catalysts.[4]

In general, the behavior of benzyl alcohol adsorbed on the catalyst surface is so complex that this catalysis cannot be simply comprehended. Garbisch *et al.*[5] have discussed the mechanism of the hydrogenolysis of benzyl alcohols. Mitsui *et al.*[6] have reported that the hydrogenolysis of optically-active benzyl-type alcohols proceeds either with the retention or the inversion of the configuration through sterically-different adsorbed transition states of substrates, depending upon the kind of catalyst metal. On the other hand, Khan *et al.*[7] have offered another proposal regarding the configurational behavior in the catalytic hydrogenolysis of benzyl alcohols.

However, relation between the behavior of benzyl alcohol and the surface nature of the catalysts has not yet been explored clearly. In order to get further information on the operative factor of the catalytic reactions of benzyl alcohol, the present investigation was carried out into the reaction of benzyl alcohol catalyzed by modified nickel catalysts, which had been prepared by the treatment of the surface of a nickel catalyst with solutions of various metal chlorides.

Results

In all the experiments, we employed a stabilized nickel catalyst (hereafter abbreviated as S–Ni)(S 10),[8] from which various kinds of modified nickel catalysts were prepared by treating it with solutions of proper metal chlorides. By a procedure similar to that described in the preceding paper, the degree of modification for each modified S–Ni was controlled by using metal chloride solutions of varying concentrations.

When a given amount of the S–Ni catalyst was treated with aqueous NaCl, KCl, and $CaCl_2$ solu-

tions of given concentrations, the amount of metal chlorides adsorbed on the catalyst surface was measured by the titration of the residual solution with a standard solution of silver nitrate. The amount of adsorbate determined in a 0.16N solution was found to be 0.15 meq per 1 g of the catalyst; this value was independent of the kind of metal chloride within about a 4% error: a linear relation between the amount of adsorbate and the initial concentrations of the metal chloride solutions was also observed.

The modified-nickel-catalyzed reaction of benzyl alcohol was practiced in a sealed tube by heating it at 162°C for 24 hr, then, the composition of the reaction mixture was evaluated by gas chromatography. It was previously found by kinetic observation[2] that the reaction proceeds as a first-order one, with the diminution of benzyl alcohol during the initial period of the reaction, but becomes complicated when more than 30% of benzyl alcohol is transformed. Thus, in order to avoid the difficulty of the kinetic analysis, the calculation of the rate was generally based upon the time required within the period before 30% of the alcohol reacted.

The f_H, f_{CH_3}, and f_{CHO} values, which had previously been defined as representing the catalytic activity for the formation of benzene, toluene, and benzaldehyde respectively, were calculated both from the observed rate constant of the alcohol, k_{alc}, and from the composition of the reaction products. The S_H and S_{CH_3} values, which indicate the selectivity factors for the formation of benzene and toluene with regard to that of benzaldehyde, were also estimated much as in the preceding report. The results obtained are summarized in Table 1. The plots of the f and S values *vs.* the degrees of the modification[9] for each modified S–Ni are also given in Figs. 1 and 2 respectively.

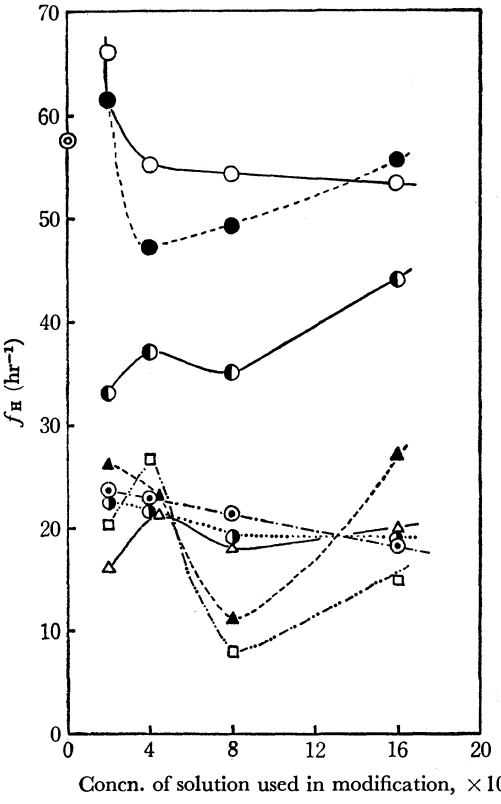
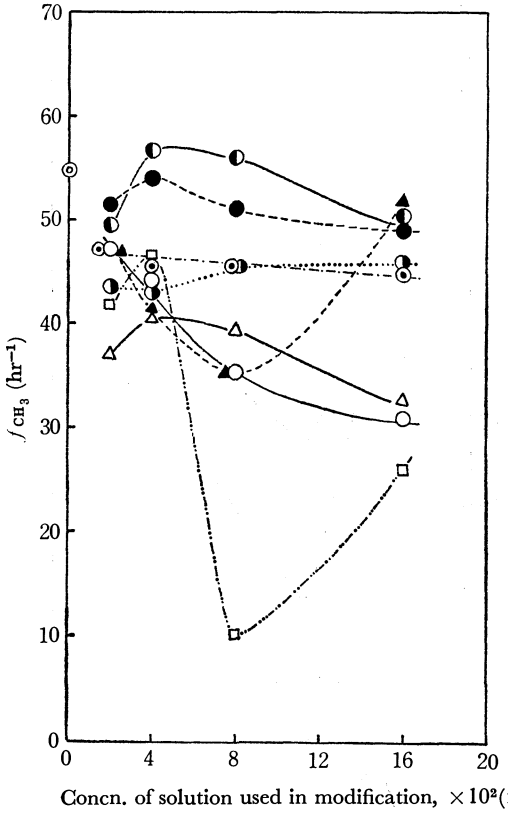
9) The degrees of the modification are tentatively represented by the initial concentrations of the solution used on treatment.





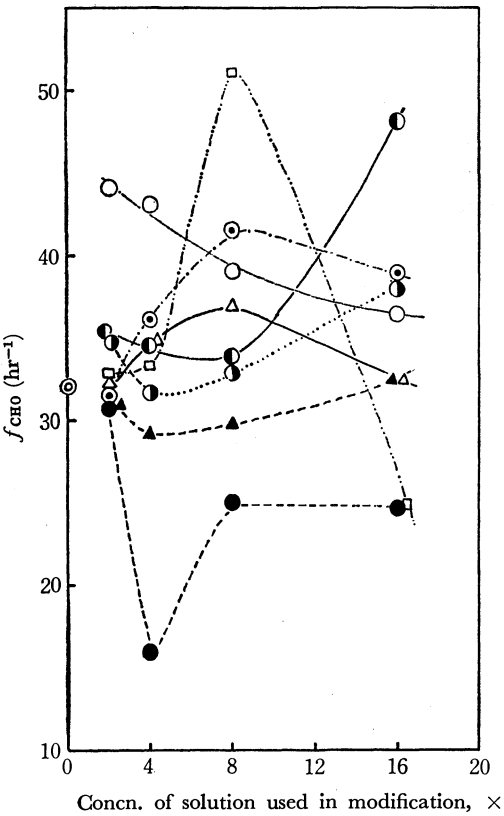


Fig. 1. The activities of modified catalysts for the formation of benzene, toluene, and benzaldehyde.
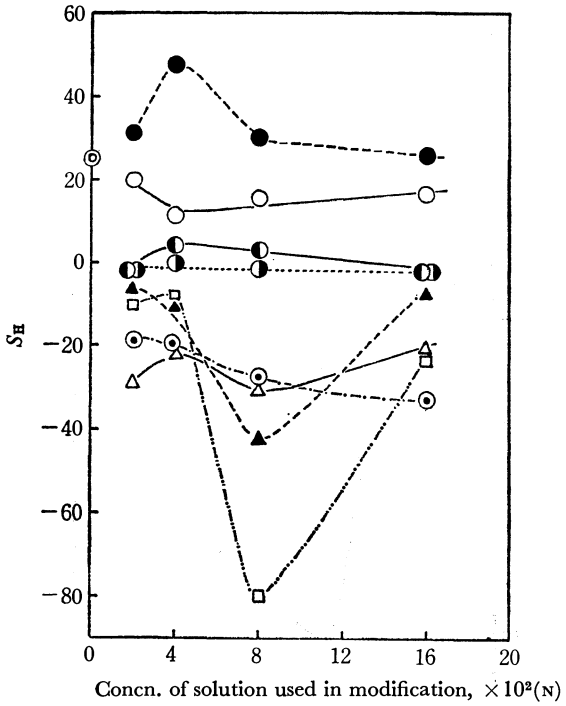
○ NaCl, ● KCl, ⊙ $CaCl_2$, ◑ $BaCl_2$, ◐ $CoCl_2$, △ $CuCl_2$, ▲ $CdCl_2$, □ $HgCl_2$, ◎ Control (unmodified S–Ni catalyst)

As may be seen in Fig. 1, the effects of metal chlorides as additives appear somewhat complicated; yet we can find some features of the additives in the catalysis: (1) A proper amount of alkali metal chloride acts as a promotor. (2) Alkaline earth metal chlorides are less influential than alkali metal chloride on the f value change with the increase in the amounts of the metals adsorbed on the catalyst. (3) The formation of toluene and benzene is largely influenced by both the kind and the amount of the adsorbate. (4) A remarkable change in the f values is observed when a varied amount of mercury(II) chloride is used as the additive.

On the basis of the f values for various modified S–Ni, it is noticeable that the effect of the additives is in a remarkably different order on lowly modified catalysts from that on more highly modified ones. In the reations with lowly modified catalysts, the f_H and f_{CH_3} values decrease generally according to the kind of metal cation used as additives in the following order: $Na^+ \geqq K^+ > Co^{2+} > Ca^{2+} > Cd^{2+} > Ba^{2+} > Hg^{2+} > Cu^{2+}$. This order is somewhat like the decreasing order of the heat of hydration of a metal complex.[10]

On the other hand, when modified catalysts with the same metal chlorides but in higher degrees were used, the f_H and f_{CH_3} values were observed to decrease in the following order on the average: $K^+ > Na^+ > Co^{2+} > Cd^{2+} > Ba^{2+} \geqq Ca^{2+} > Cu^{2+} > Hg^{2+}$. The correlation between the f values and the normal electrode potentials of corresponding metals was examined;

10) F. Basolo and R. G. Pearson, "Mechanisms of Inorganic Reactions," 2nd Ed. John Wiley & Sons, Inc. N. Y. (1967), p. 81; $-\Delta H$, (kcal): $K^+(79) > Na^+(100) > Ba^{2+}(316) > Ca^{2+}(382) > Cd^{2+}(437) > Hg^{2+}(441) > Co^{2+}(497) > Cu^{2+} \approx Ni^{2+}(507)$.



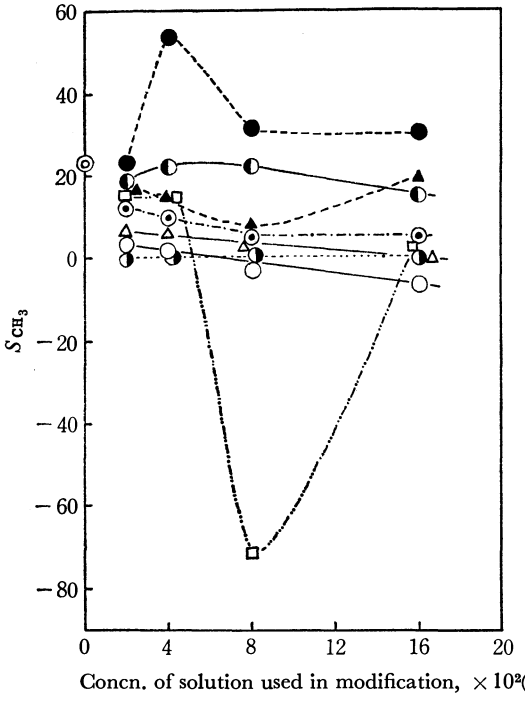


Fig. 2. The selectivities of modified catalysts for the formation of benzene and toluene against that of benzaldehyde. (The notations are the same as in Fig. 1).

the results are shown in Fig. 3. As may be seen in Fig. 3, the formation of benzene is assumed to be approximately correlated with the potential change in the catalyst surface caused by the addition of metal chlorides to the catalyst. However, it was found that the cobalt ion promotes the formation of benzene exceptionally, more than would be predicted from its electrode potential, whereas calcium and barium ions have the opposite effect on the reaction. The relation of the formation of toluene and benzaldehyde is not

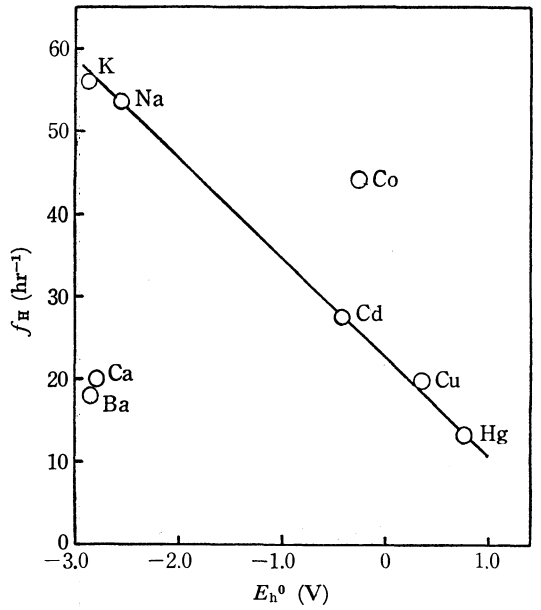

Fig. 3(a). The plots of f_H in the higher modification degree *vs.* the electrode potential of metal ($M^0 \rightleftarrows M^{n+} + ne^-$, 25°C).

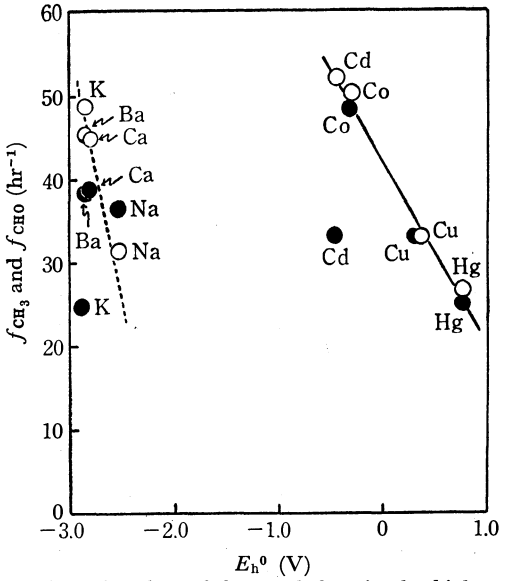

Fig. 3(b). The plots of f_{CH_3} and f_{CHO} in the higher modification degree *vs.* the electrode potential of metal ($M^0 \rightleftarrows M^{n+} + ne^-$, 25°C).
○ toluene, ● benzaldehyde

so clearly correlated with the electrode potential of metal as it is in the case of benzene. We can readily recognize that the relations between the f value and the electrode potential of the metal used as the additive may be roughly divided into two groups: the lower-electrode-potential group and the higher-electrode-potential group. The alkali and alkaline earth metals belong to the former group, whereas the transition metals belong to the latter one. Within each group, there is a tendency for the f values to vary in correlation with the electrode potential of the metals adsorbed on the catalyst.

With regard to the modified nickel catalysts treated with a 0.08N solution of each metal chloride, it is found that the decreasing sequence of the f_H and f_{CH_3}

values due to the kind of metal chloride is roughly associated with that of the atomic number of the corresponding metals. This finding leads to a consideration that the promoting and poisoning effects by metal chlorides may partially result from the polarizability of the metals as additives.

It is interesting that the general order of the decrease in the f_{CHO} values observed in the presence of the modified catalysts treated with 0.08N solutions of metal chlorides is roughly reversed for the formation of benzene and toluene (f_H and f_{CH_3} values). This observation implies that highly polarizable metal ions adsorbed on the catalyst are preferable to the dehydrogenation of benzyl alcohol.

The tendency of the changes is S_H and S_{CH_3} values brought about by the addition of metal chlorides is generally similar to that of the changes in f_H and f_{CH_3} values respectively. The general features of the change in selectivity caused by the adsorption of metal chlorides may be summarized as follows: (1) KCl can characteristically serve to increase the selectivity for the formation of benzene and toluene. (2) The S-value changes due to NaCl, $CaCl_2$, $BaCl_2$, and $CoCl_2$ are almost independent of their amounts. (3) A considerably large variation in S value is observed as a result of the addition of the mercury(II) ion.

Discussion

It is assumed that the change in selectivity for the formation of toluene and benzene in the presence of each modified S–Ni may come from the change in the catalytic activity for the formation of the corresponding products. Thus, with the purpose of examining the correlation between f and S values for the formation of toluene and benzene, log f was plotted against the S values. The results are shown in Fig. 4. In the case of the formation of benzene, the plots are distributed on nearly a straight line. For the production of toluene, the relation is not so clear as in the case for benzene, thought a faint linear relation is also observed.

A large amount of experimental evidence has already revealed the non-uniformity of the surface of the nickel catalyst.[11] A properly-devised poisoning experiment can often provide information on the possible presence of areas or centers on the catalyst surface possessing different degrees of catalytic activity. This consideration can be demonstrated when a suitable catalyst poison is selectively adsorbed first on the sites of greater activity and then upon less active sites. However, the reaction of benzyl alcohol catalyzed by modified S–Ni catalysts treated with metal chlorides cannot be explained simply by such a poisoning effect of the metal chlorides, because there is a promoting effect on the reaction from a proper kind and amount of metal chlorides,[12] and also because a regular variation in the catalytic activity is brought about on the modified S–Ni, depending on the property of the added metal cation. It is reasonable to conclude that the electrode

potentials of the additive metals may play an important role in the promoting and retarding effects on the reaction, and that the polarizability of the metal ions adsorbed on the catalyst surface may be partially responsible for the change in f and S values. These observations suggest that this catalytic reaction of benzyl alcohol takes place in association with the acid and base functions of the catalyst surface.

It is known that the catalytic activity and selectivity are considerably correlated with the acid strength of heterogeneous metal catalysts,[13] and that the heterogeneous catalysis can be extensively elucidated by means of the acid-base concept.[14] In the formation of toluene and benzene from benzyl alcohol, it was found that the larger f values are mainly brought about by the addition of a hard metal ion, such as Na^+ and K^+, whereas the smaller f values are associated with the addition of a soft metal ion, *e.g.*, Hg^{2+}. Furthermore, the medium f values often result from the metals which belong on the borderline of the soft-hard classification. In the formation of benzaldehyde by dehydrogenation, the relation between the f_{CHO} values and the hardness of metal ions as additives tends to be opposed to that in the cases of the formation of toluene and benzene. Though a plausible explanation for this cannot yet be proposed, it seems that either the reaction path or the rate-determining step in the formation of benzaldehyde is different from that in the formation of toluene and benzene; that is, the more favorable formation of benzaldehyde is related to the change in the acid strength of the nickel catalyst by the addition of soft metal, whereas the formation of toluene and benzene is unfavorable under the same conditions.

Since the surface structure of the nickel catalyst is not sufficiently clear, it is very difficult to consider in what manner the substrate interacts with the active sites on the catalyst. However, according to the rule of the SHAB concept[13-15] that hard acids prefer hard bases and soft acids prefer solft bases, the hydroxyl group of the alcohol possessing a hard-base character will interact more strongly with the harder acid sites, and the phenyl group, as a soft base, will favorably coordinate to the softer acid sites. If the newly-formed coordination bond of each group to a metal is sufficiently strong, this should contribute to the cleavage of the C–O and C–C bonds of benzyl alcohol.

It can reasonably be inferred that the C–C bonds is more durable than the C–O bond in the catalytic fission, because the former bond is in a stable soft-soft combination, while the latter one is in a unstable hard-soft combination. This consideration is consistent with the finding of the present experiments that the f_{CH_3} values are generally larger than the f_H values.

Experimental

Material. *Benzyl Alcohol*: Benzyl alcohol used in all the experiments was purified by the previously-described procedure.[2] Its purity was confirmed by gas chromatography.

Catalyst: A commercial stabilized nickel (S 10) (supplied by the Nikko Shokai Co. Ltd.), containing 50% of kieselguhr, was used as a catalyst.

Preparation of Modified S–Ni. Various kinds of modified S–Ni catalysts were prepared by treating the S–Ni with aqueous solutions of various metal chlorides in the same manner as was described previously.[1] The degree of modification was controlled by adjusting the concentration of the aqueous solutions of each metal chloride to 0.02, 0.04, 0.08, and 0.16 N.

Reaction. Benzyl alcohol (2.00 m*l*) and a modified S–Ni catalyst (0.333 g) were heated at 162°C for 24 hr in a sealed tube. After the reaction was over, the tube was cooled with ice, then the reaction mixture was analyzed by gas chromatography.

The authors wish to express their hearty thanks to Dr. Ken-ichi Watanabe for his helpful encouragement.

Studies of the Synthesis of Furan Compounds. XXIV.[1] The Synthesis of 5-[2-(5-Nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazole and Its Related Compounds[2]

Ichiro HIRAO, Yasuhiko KATO, and Toshiyuki HIROTA

Laboratory of Organic Synthesis, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-kyushu

(Received December 31, 1970)

5-[2-(5-Nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazoles and -1,3,4-thiadiazoles have been prepared from 3-(5-nitro-2-furyl)-2-(4-nitrophenyl)acrylic acid. All of these compounds exhibited strong antibacterial activities against *Staphylococcus aureus*.

A series of systematic investigations concerning the synthesis of 5-[2-(5-nitro-2-furyl)-1-substituted]vinyl-1,3,4-oxadiazole derivatives has been undertaken in order to obtain information on their chemical properties and on the relations between the chemical structures and the antibacterial activities. With the aim of establishing the influence of the β-substituents of the –C=C– chain upon the antibacterial activities in a continuation of a series of studies concerning the antibacterial properties of nitrofuran derivatives,[3–10] the present work has studied the introduction of a 4-nitrophenyl group into β-carbon, namely, 5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazole (III) and its related compounds.

Results and Discussion

3-(5-Nitro-2-furyl)-2-(4-nitrophenyl)acryloylhydrazine (I) was prepared from the chloride of 3-(5-nitro-2-furyl)-2-(4-nitrophenyl)acrylic acid[11] in the usual method.[3–10] The preparation of I using trichloroethylene or dioxane as a solvent was unsuccessful, but it was achieved by using methylene chloride as the solvent, although 1,2-bis[3-(5-nitro-2-furyl)-2-(4-nitrophenyl)acryloyl]hydrazine was not formed as the by-product.

5-[2-(5-Nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazolone (II) was obtained by the introduction of phosgene into a solution of I in dioxane-water (3:2,

a) 3-(5-Nitro-2-furyl)-2-(2-furyl)acrylic amide was used in the test.

v/v) at 15—20°C. This compound was found, from the infrared absorptions[12] at 3360 cm^{-1} (N–H) and 1765 cm^{-1} (C=O), to take the keto structure, at least in the solid state. The treatment of II with a large excess of acid anhydrides or with 2—3 times as many moles of acid anhydrides in dioxane afforded the corresponding monoacyl derivatives, the 3-acetyl (IIa), 3-propionyl (IIb), and 3-butyryl (IIc) derivatives. These acyl derivatives commonly showed two C=O absorptions, near 1780 and 1740 cm^{-1}, but not the absorption at 3360 cm^{-1} characteristic of N–H in the mother compound, II.

As a N–H in an oxadiazolone ring is known to undergo the Mannich reaction to form an *N*-aminomethyl derivative, 3-aminomethyl derivatives (IId—h) were prepared by treating II with 37% formaldehyde and secondary amines (*N*-methylaniline, *N*-ethylaniline, pyrrolidine, pyperidine, and morpholine) in methanol or dioxane in the presence of *N,N*-dimethylformamide. The 3-hydroxymethyl derivative (IIi) was also obtained in a good yield from II and 37% formaldehyde.

When treated with refluxing ethyl orthoformate, I afforded 5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazole (III). 2-Amino-5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazole (IV) was prepared by the reaction of I with cyanogen bromide in refluxing methanol or by the cyclization of 1-[3-(5-nitro-2-furyl)-2-(4-nitrophenyl)acryloyl]-*S*-methylisothiosemicarbazide (V) in boiling ethanol, both in satisfactory yields. The similar treatment of 4-alkyl (or aryl)-1-[3-(5-nitro-2-furyl)-2-(4-nitrophenyl) acryloyl]-*S*-methylisothiosemicarbazides (Va—c) gave the 2-R-substituted amino-5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)-vinyl]-1,3,4-oxadiazole, IVa, IVb, and IVc, in which R was methyl, ethyl, and phenyl. The treatment of IV with 37% formaldehyde afforded the 2-hydroxymethylamino derivative (IVd), and that with acid anhydrides gave the 2-acetylamino (IVe), 2-propionylamino (IVf), and 2-butyrylamino (IVg) derivatives. V and Va—Vc were each obtained by the reaction of methyl iodide with 1-[3-(5-nitro-2-furyl)-2-(4-nitrophenyl)acryloyl]thiosemicarbazide (VI) or its 4-substituted derivatives (VIa—c), which had been prepared from the acid chloride and thiosemicarbazide or from I and isothiocyanates.

When heated in phosphoryl chloride, VI was cyclized to 2-amino-5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)-vinyl]-1,3,4-thiadiazole (VII). 2-Substituted amino derivatives were also obtained by the similar treatment of VIa—VIc in phosphoryl chloride and of VII with 37% formaldehyde or acid anhydrides. Thus, the 2-methylamino (VIIa), 2-ethylamino (VIIb), 2-anilino (VIIc), 2-hydroxymethylamino (VIId), 2-acetylamino (VIIe), 2-propionylamino (VIIf), and 2-butyrylamino (VIIg) derivatives were obtained. All of these compounds are listed in Tables 1 and 2.

Microbiological Assays.[13] The antibacterial activities of these compounds toward ten microorganisms were examined. The minimum amount of the compounds necessary for the complete inhibition of the growth was determined by the dilution method, using the usual bouillon agar medium (pH 7). Some of the results are shown in Table 3. The compounds of this group exhibited weak antibacterial activity against Gram-positive bacteria, but not against Gram-negative bacteria. In particular, all the compounds tested showed strong activity against *Staphylococcus aureus*. Ultimately, it was found that the introduction of a 4-nitrophenyl group instead of a 2-furyl group[10] into β-carbon lowered the activity greatly.

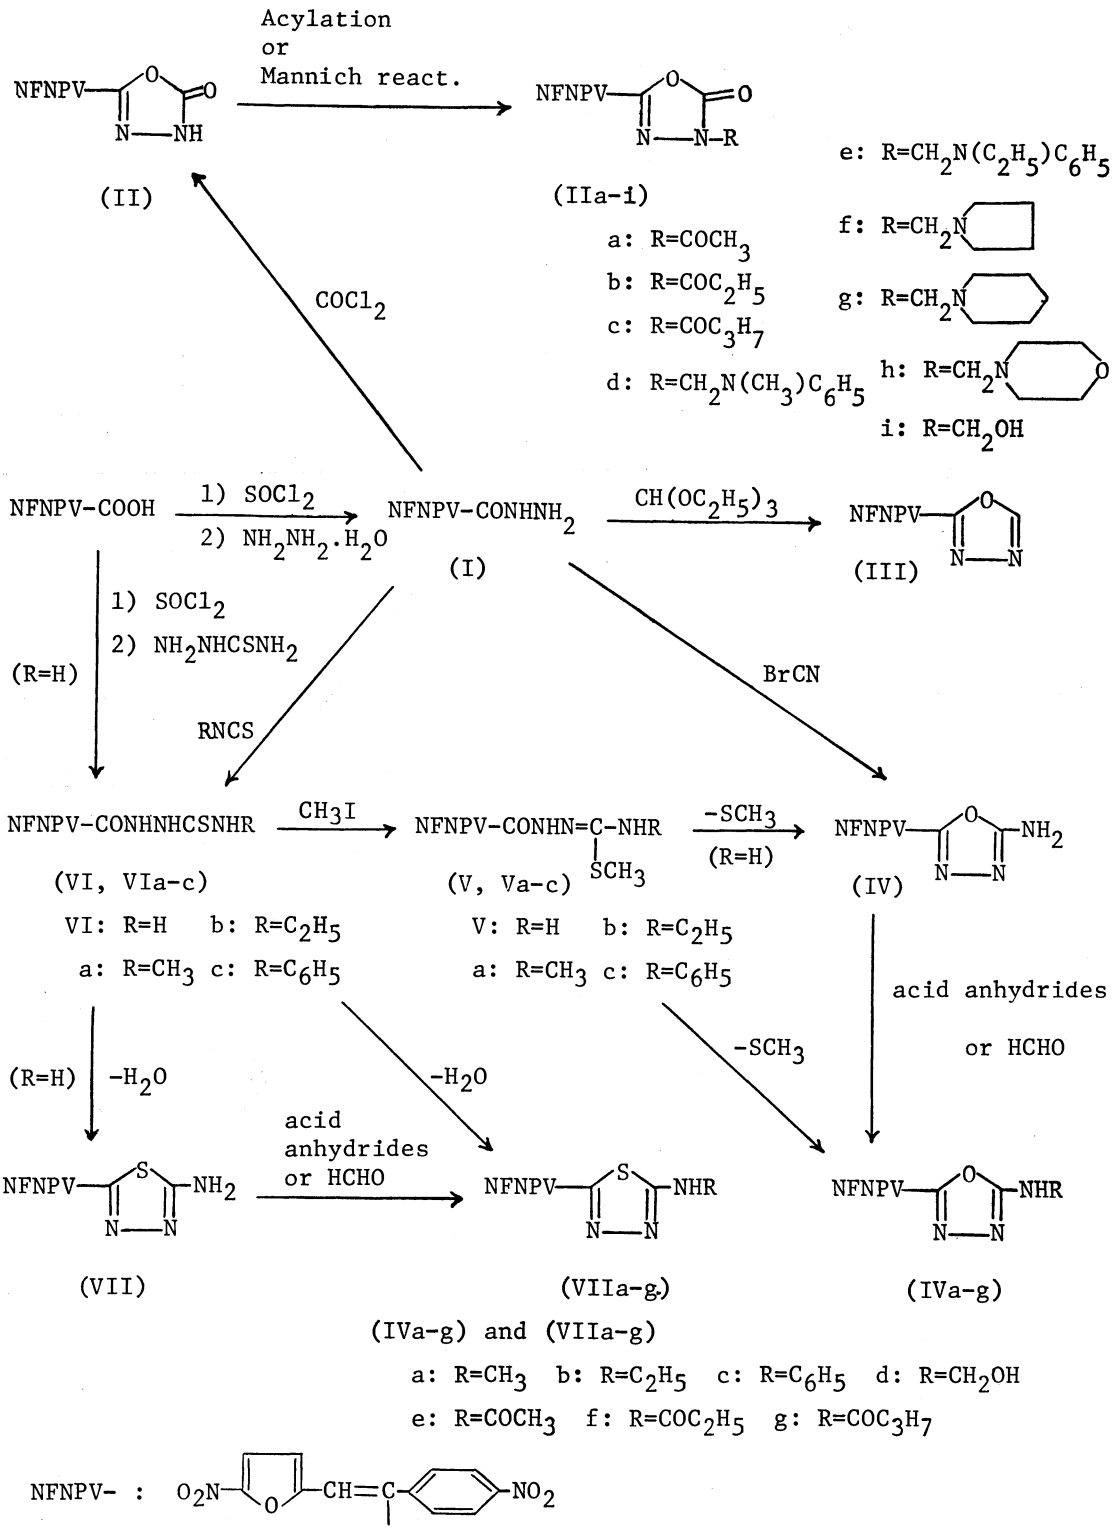
Experimental[14]

3-(5-Nitro-2-furyl)-2-(4-nitrophenyl)acryloyl chloride. A mixture of 3-(5-nitro-2-furyl)-2-(4-nitrophenyl)acrylic acid[11] (60.8 g, 0.2 mol), thionyl chloride (36 g, 0.2 mol), *N,N*-dimethylformamide (2 g), and 200 m*l* of monochlorobenzene was stirred at 65—70°C for 1 hr. The resulting solution was cooled with an ice-salt bath; the acid chloride was then separated as yellow crystals, filtered, washed with dry ether, and used in the next experiments without further purification.

12) The infrared absorption spectra in this experiments were obtained with a Shimadzu IR-27S spectrophotometer with KBr method.

13) The authors are indebted to Dr. R. Ueno and his staff of the Ueno Pharmaceutical Company, Ltd., for the assay.

14) All melting and decomposition points are uncorrected. Microanalyses were carried out with a Yanagimoto C. H. N. Corder MT-2 type.



3-(5-Nitro-2-furyl)-2-(4-nitrophenyl)acryloylhydrazine (I). To a stirred, ice-salt, cooled (−5—0°C) mixture of 80% hydrazine hydrate (20.2 g, 0.4 mol), water (60 m*l*) and methylene chloride (140 m*l*), we added, drop by drop, a solution of the acid chloride (32.3 g, 0.1 mol) in 700 m*l* of methylene chloride during a period of 1.5 hr. After the addition had been completed over, the temperature was allowed to rise to room temperature and stirring was continued for an additional 2 hr. The resulting suspension was filtered, and the residue was washed with 50% aqueous methanol and then dried. This afforded 21.6 g (67.9%) of yellow crystals melting, with decomposition, at 165—168°C. Recrystallization from methanol gave ochreous prisms; mp 182—184°C dec. The yield was 20.4 g (64.2%).

Found: C, 49.16; H, 3.09; N, 17.79%. Calcd for $C_{13}H_{10}N_4O_6$: C, 49.06; H, 3.14; N, 17.62%.

1-[3-(5-Nitro-2-furyl)-2-(4-nitrophenyl)acryloyl]thiosemicarbazide (VI). A solution of the acid chloride (32.3 g, 0.1 mol) in dry dioxane (200 m*l*) was added slowly to a stirred suspension of thiosemicarbazide (18.2 g, 0.2 mol) and sodium bicarbonate (45 g, 0.54 mol) in 80 m*l* of dioxane. The suspension was stirred for 2 hr at room temperature and then

heated on a steam bath for 1 hr. After cooling, yellow precipitates were filtered out and poured into aqueous hydrochloric acid. The insoluble product was collected on a filter, washed with water, and then dried. In this way we obtained 29.4 g (78%) of a crude product melting at 143—148°C dec. Crystallization from methanol gave yellow leaflets.

4-Substituted 1-[3-(5-nitro-2-furyl)-2-(4-nitrophenyl)acryloyl]-thiosemicarbazides (VIa—c). A mixture of I (3.18 g, 10 mmol), alkylisothiocyanate (12 mmol), and methanol (140 m*l*) was refluxed for 2 hr. The resulting solution was cooled, and the precipitated product was collected by filtration. Recrystallization from methanol gave a pure product (Table 1).

1-[3-(5-Nitro-2-furyl)-2-(4-nitrophenyl) acryloyl]-S-methylisothiosemicarbazide (V) and Its 4-Substituted Derivatives (Va—c). To a stirred mixture of 5 mmol of VI (or VIa—c), methyl iodide (15 mmol), and ethanol (10—20 m*l*), we added, drop by drop, a solution of potassium hydroxide (5 mmol) in 20 m*l* of ethanol. After the addition, stirring was continued for 12 hr at room temperature. The resulting suspension was filtered, and the residue was washed with a small amount of ethanol and dried. If the product were heated in solvents, decomposition occurred and methyl mercaptane was evolved. Therefore, recrystallization from solvents could not be achieved, but these products were pure enough for elemental analyses.

5-[2-(5-Nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazol-2-one (II). To a stirred solution of I (7.9 g, 25 mmol) in 360 m*l* of dioxane-water (3:2, v/v), phosgene was introduced under cooling at 15—17°C. After 3 hr, the product was collected and washed with water to give 7 g (81.4%) of crude II, mp 161—163°C dec. Recrystallization from ethanol gave II, melting at 217—218°C dec and weighing 5.95 g (69.2%).

3-Acyl-5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazol-2-ones (IIa—c). A mixture of II (0.7 g, 2.30 mmol) and 13 m*l* of acid anhydride or 0.7 g of acid anhydride in 13 m*l* of dioxane was heated on a steam bath for 1—2 hr. The resulting solution was taken to dryness *in vacuo*, and the residue was washed with water, dried, and recrystallized. The yield and mps of products are given in Table 2.

3-Aminomethyl-5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazol-2-ones (IId—h). To a stirred solution of II (1.72 g, 5 mmol) in 40 m*l* of dioxane or 100 m*l* of methanol containing *N,N*-dimethylformamide (0.5 g), 37% formaldehyde (0.5 g, 6 mmol), and secondary amine (6 mmol) were added. The solution was stirred for 30 min at room temperature and warmed at 50—65°C for 1 hr. After cooling, the precipitate was filtered. When no precipitate appeared, water was added to the soltuion and the precipitated product was filtered. The yields and mps of the products are given in Table 2.

Hydroxymethylation of II, IV, and VII. A suspension of II, IV, or VII (each 3 mmol) in 37% formaldehyde (10 m*l*) was heated on a steam bath for 2—3 hr. After cooling, water (50—100 m*l*) was added, and the precipitated product was collected by filtration, washed with water, and dried. The product was purified by recrystallization.

5-[2-(5-Nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazole (III). A suspension of I (3.18 g, 10 mmol) in ethyl orthoformate (40 m*l*) was heated under reflux for 12 hr. The resulting solution was concentrated *in vacuo*, and the product was filtered and washed with cold ethanol. Recrystallization from ethanol gave III as yellow prisms; mp 218°C dec. The yield was 2.25 g (69%).

Found: C, 51.27; H, 2.12; N, 17.17%. Calcd for $C_{14}H_8N_4O_6$: C, 51.22; H, 2.44; N, 17.08%.

2-Amino-5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-oxadiazole (IV). *Procedure A*: A mixture of I (2 g, 6.3 mmol), cyanogen bromide (1.05 g, 9.4 mmol), and 60 m*l* of methanol was heated under reflux for 1 hr. Cooling provided 2 g, (92.8%) of a yellow powder: mp 236—238°C dec. Crystallization was carried out from ethanol.

Procedure B: A suspension of V (1.6 g, 4.1 mmol) in ethanol (50 m*l*) was refluxed until the evolution of methyl mercaptane had ceased (*ca.* 3—4 hr). The resulting solution was taken to dryness *in vacuo*, and the residue was crystallized from ethanol to give 1 g (71.5%) of IV as yellow leaflets; mp 246—247°C dec, undepressed on admixture with a sample by *Procedure A* as above for IV.

2-Substituted amino-5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)-vinyl]-1,3,4-oxadiazoles (IVa—c). These substances were prepared in the same way as IV above (*Procedure B*) using 5 mmol of 4-substituted *S*-methylisothiosemicarbazide derivatives (Va—Vc).

2-Amino-5-[2-(5-nitro-2-furyl)-1-(4-nitrophenyl)vinyl]-1,3,4-thiadiazole (VII) and 2-Substituted Amino Derivatives (VIIa—c). A mixture of 5 mmol of V (or Va—c) and phosphoryl chloride (10 m*l*) was heated under reflux for 2—3 hr. The solution was poured onto crushed ice, and the solidified product was filtered, washed with water, and dried. Two or three recrystallizations gave a pure product.

2-Acylamino Derivatives of IV and VII. Compound IV (or VII) (1.4 mmol) was covered with acid anhydride (5 m*l*) and heated on a steam bath for 2—3 hr. Water (30—40 m*l*) was added to the resulting solution to decompose the surplus acid anhydride. The product was filtered, washed with water, and dried. In this way the corresponding acyl products were obtained; recrystallizations were achieved from solvents or solvent pairs, as is shown in Table 2.

Electrochemical Reduction of Aza-heteroaromatic Compounds. IV.[1] Stabilities of Neutral Free Radicals Electrolytically Derived from 1-Methylcyanoquinolinium Perchlorates

(Received December 28, 1970)

Three isomers of 1-methylcyanoquinolinium perchlorates were reduced by controlled potential electrolysis for one-electron transfer, and the reduction products were identified in order to clarify their reduction mechanisms and the effect of the cyano group on the stabilities of cyanoquinolinyl radicals. The 1-methyl-4-cyanoquinolinyl radical was stable enough to survive at room temperature under anaerobic conditions. The 1-methyl-2- and 1-methyl-3-cyanoquinolinyl radicals were short-lived and were subsequently dimerized to the 1,4-dihydrotype. The 1-methyl-4-cyanoquinolinyl radical was autoxidized to 1-methyl-4-cyanoquinolinium salts in an electrolyte solution and to 1-methyl-4-cyano-2-quinolone in an ethanol solution.

The mechanisms of the reduction of aromatic compounds containing cyano groups have been studied by many investigators, even if the discussion has been limited to the field of electrochemistry. For example, in acidic media 4-cyanopyridine is reduced to 4-aminomethylpyridine through a four-electron transfer;[2,3] in alkaline media, to pyridine through a two-electron transfer accompanied by decyanation reaction,[4] and in aprotic solvents, to the 4-cyanopyridinyl radical anion through a one-electron transfer.[5] As for phthalonitrile, a reductive decyanation reaction occurs.[6,7] Moreover, in benzonitrile derivatives which have substituents such as carbonyl groups, it is possible for two reduction pathways, the reduction of the cyano and carbonyl groups, to occur.[7,8]

A cyano group with a great resonating effect as well as a great electron-attracting effect would be expected to play an important role in stabilizing a pyridinyl radical. Actually, Schwartz, Kosower, and Shain[9] have detected a relatively stable 1-ethyl-4-cyanopyridinyl radical by means of cyclic voltammetry.

It may be easily suggested that the first polarographic reduction step of quaternary ammonium salts of aza-heteroaromatic compounds (R^+) is a one-electron transfer which does not involve protonation, even in aqueous solutions.

$$R^+ \xrightarrow{e} R\cdot \xrightarrow{e} (R^- \xrightarrow{H^+}) RH$$

The overall process thus contrasts to the case of free bases (R).

$$R \xrightarrow{e} (R^{\cdot-} \xrightarrow{H^+}) RH\cdot \xrightarrow{e} (RH^- \xrightarrow{H^+}) RH_2$$

A one-electron transfer to a quaternary ammonium salt should produce a neutral free radical, which may be able to avoid the disproportionation.

In the present paper, we will discuss the characteristics of the cyano group. We chose the following quinolinium compounds for study: 1-methyl-4-cyanoquinolinium perchlorate (Ia), 1-methyl-3-cyanoquinolinum perchlorate (IIa), and 1-methyl-2-cyanoquinolinium perchlorate (IIIa). These compounds are reduced by controlled potential electrolysis for one-electron transfer, and the structures of the reduction products are identified in order to clarify the mechanisms of electrochemical reduction, the effect of the cyano group on the stabilities of radicals or dimers produced by one-electron reduction, and the coupling sites of the dimers.

Results

Polarography. 1-Methyl-3-cyanoquinolinium perchlorate (IIa) and 1-methyl-2-cyanoquinolinium perchlorate (IIIa) give complicated polarograms in a buffered solution, while 1-methyl-4-cyanoquinolinium perchlorate (Ia) gives well-defined polarograms over a wide pH range of 2—10. The dependence of the half-wave potential ($E_{1/2}$) of Ia on pH clearly indicates that the first reduction does not involve a protonation step, in contrast with the second ($\Delta E_{1/2}/\Delta pH = -4$ mV for the first and -51 mV for the second).

The 1-methylcyanoquinolinium perchlorates are sensitive to nucleophiles. The height of the polarographic waves appreciably decreases with the passage of time. IIIa is the most sensitive of the three compounds; it is readily changed to 1-methyl-2-ethoxyquinolinium perchlorate by refluxing in aqueous ethanol for about 20 min. Such nucleophilic substitution reactions by solvents are known with respect to some heteroaromatic quaternary ammonium salts. The behavior of the hydrolysis is similar to that of 1-methyl-4-cyanopyridinium perchlorate reported by Kosower and Patton.[10]

In aprotic solutions, all the cyanoquinolinium salts give well-difined polarographic waves. Table 1 shows

the $E_{1/2}$ values of the quinolinium salts. It is clear that the cyano group has an effect on the positive shift of the reduction potential compared with quinolinium salts[1] by *ca.* 0.47 V.

General Electrolysis. The coulometric data (Table 2) suggest that Ia absorbs one electron per molecule by controlled potential electrolysis corresponding to the first wave, and two electrons per molecule, by the electrolysis corresponding to the second wave. As for IIa and IIIa, one-electron reduction also occurs by the electrolysis at the potential corresponding to the first wave.

One-electron reduction products formed by electrolysis precipitate in buffered solutions. A reduction wave is not observed when electrolysis is completed.

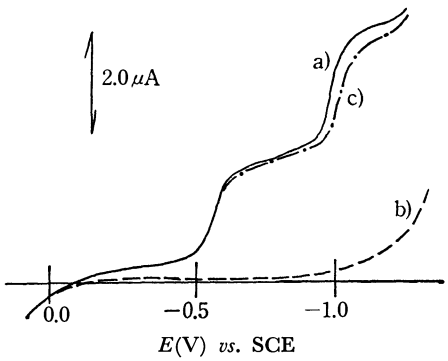

Fig. 1. Polarographic behavior of 1-methyl-4-cyanoquinolinium perchlorate (I_a), before and after one-electron electrolysis (pH 7).
a) before b) just after c) 15 min. after

Table 3. The recovery[a] of reduction products

Material	Reduction Product	pH	Time (min)	Yield (%)
Ia	1 e	7	3	90
Ia	2 e	7	15	trace
IIa	1 e	2	20	87
IIIa	1 e	2	20	29

a) The yields were measured polarographically after stirring at room temperature under aerobic condition.

However, it becomes observable at the original position after stirring at room temperature under aerobic conditions (Fig. 1). The recovery yield becomes larger in the order of IIIa<IIa<Ia (Table 3). On the contrary, the recovery yield of the two-electron reduction product of Ia is very slight; therefore, it may be concluded that the two-electron reduction product is not so sensitive to air as the one-electron reduction product.

When the quinolinium salts are subjected to one-electron electrochemical reduction in aprotic solvents under the same conditions as in the polarographic measurement, oxidation waves appear in all the cases (Table 1). In the case of Ia, an oxidation and a reduction wave are observed at the potentials identical with those of the first and the second waves of Ia respectively. Moreover, the heights of the oxidation and the reduction waves are almost identical with those of the first and the second waves of Ia (Fig. 2). On the other

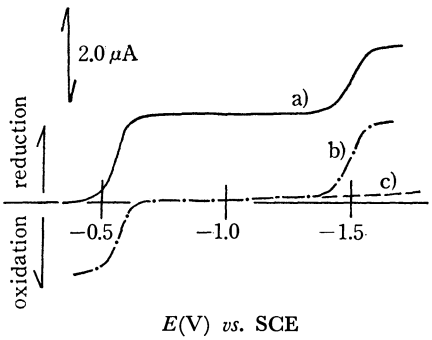

Fig. 2. Polarographic behavior of 1-methyl-4-cyanoquinolinium perchlorate (I_a), before and after electrolysis (in DMF).
a) before electrolysis
b) just after one-electron reduction
c) just after two-electron reduction

hand, both the solutions after the one-electron reduction of IIa and IIIa have oxidation waves at potentials less negative than those of the original reduction waves. The discordance in potential in those cases suggests the formation of the dimers. The two-electron reduction product of Ia shows no oxidation wave; this serves to confirm the lower oxidizability of two-electron reduction products.

Structure of the One-electron Reduction Product of 1-Methyl-4-cyanoquinolinium Perchlorate (Ia). Kosower and his co-worker[11] reported that 1-alkyl-4-cyanopyridinyl radicals are relatively stable, but that subsequent dimerizations cause decyanation reduction, thus forming alkylviologen radicals. As has been shown above, Ia shows an oxidation wave at the same potential as does the original reduction wave. Moreover, Ia is almost quantitatively recovered by the autoxidation, and the electron required for the reduction of one molecule of Ia is no more than unity. Moreover, the solution after the one-electron reduction of Ia shows a considerably different UV spectrum from the corresponding two-electron reduction product (Fig. 3). Hence, the one-electron reduction product of Ia seems to be a stable neutral radical which involves no decyanation reaction.

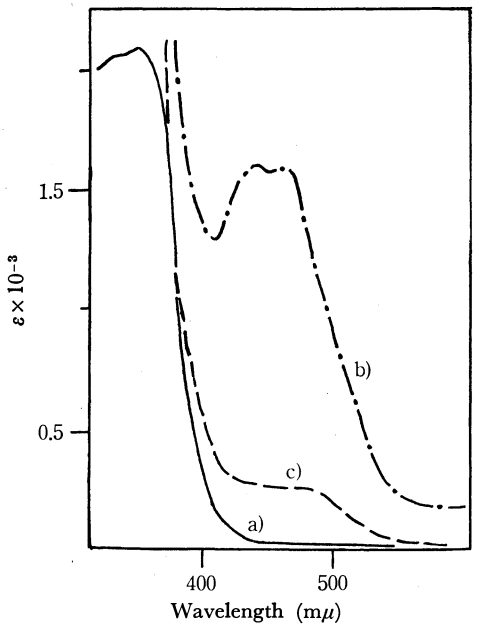

Fig. 3. Electronic spectra of 1-methyl-4-cyanoquinolinium perchlorate (I_a), before and after electrolysis (in DMF).
a) before electrolysis
b) just after one-electron reduction
c) just after two-electron reduction

During and after the electrolysis of an acetonitrile solution of Ia at the potential corresponding to the one-electron reduction (−0.9 V *vs.* $Ag/AgClO_4$), an ESR signal with a hyper-fine structure of $19 \times 5 = 95$ lines is observale (Fig. 4). The deep yellow crystalline precipitates obtained by the one-electron reduction of Ia also show an ESR signal in the solid state or in a

11) E. M. Kosower and J. L. Cotter, *J. Amer. Chem. Soc.*, **86**, 5524 (1964).

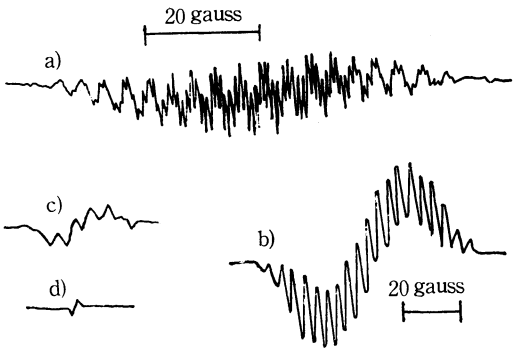

Fig. 4. ESR spectra of the one-electron reduction product of 1-methyl-cyanoquinolinium perchlorates in acetonitrile solution.

c) III_a, intermediate
d) II_a, intermediate

solution. The solution, after reduction with zinc powder, also shows the ESR spectrum. When the 5w/v-% acetonitrile solution of Ia is reduced by zinc dust, no signal is observed in its NMR spectrum (Fig. 5). The removal of zinc dust from the solution causes a quantitative recovery of the signals of Ia. Therefore, it is obvious that the one-electron electrochemical reduction product of Ia is a stable radical, one which is identical with the reduction product with zinc dust, and that the radical is stable even at high concentrations or in the solid state.

a) before b) after

Autoxidation of 1-Methyl-4-cyanoquinolinyl Radical (Ib). When the solution after the electrolysis of Ia is exposed to air, Ib is autoxidized to Ia almost quantitatively. When Ib is refluxed in ethanol, 1-methyl-4-cyano-2-quinolone (IV) is isolated from the solution by means of recrystallization or sublimation. Accordingly, Ib seems to react with oxygen at the 2-position in the quinoline ring under aerobic conditions, forming a peroxide with a 1,2-dihydro structure which may decompose to IV. This spectrophotometric behavior further supports the idea that Ib intermediately produces the peroxide with the 1,2-dihydro structure. The ethanol solution of Ib shows the same UV maximum (360 mμ) as that of 1-methyl-4-cyano-1,2-dihydroquinoline (Ic), and Ib shows a strong band at

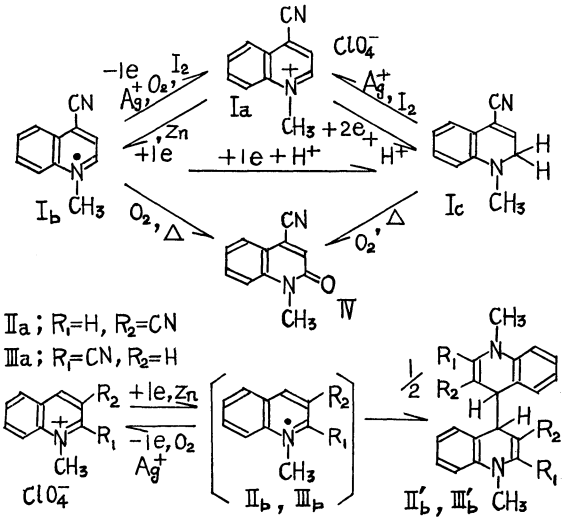
Table 4. UV-and IR-spectra of reduction products

Material	Reduction product	λ_{max}(mμ)	ν_{max}^{KBr}(cm^{-1})
Ia	1 e	447, 465 (DMF) 360 (EtOH)	2200, 2300 (C≡N) 1665 (C=C)
Ia	2 e	360 (EtOH) 361 (CH_3CN)	2230, 2300 (C≡N) 1645 (C=C)
IIa	1 e	330 (EtOH)	2200 (C≡N) 1645 (C=C)
IIIa	1 e	326 (EtOH) 344 (DMF)	2230 (C≡N) 1636 (C=C)

1665 cm^{-1} due to an absorption of cyclic amide and two bands due to the cyano group in its IR spectrum (Table 4).

Structure of the Two-electron Reduction Product of Ia. The two-electron reduction product of Ia has a UV maximum at about 360 mμ whether the solvent is protic or not; this indicates the formation of Ic. The fact that IV is obtained by the autoxidation of Ic also supports the 1,2-dihydro structure.

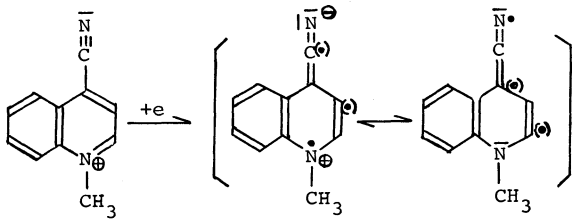
One-electron Reduction Products of 1-Methyl-3-cyanoquinolinium Perchlorate (IIa) and 1-Methyl-2-cyanoquinolinium Prechlorate (IIIa). The one-electron reduction products of IIa and IIIa show UV maxima at 330 and 326 mμ respectively, and IR maxima at 1648 and 1636 cm^{-1} due to ethylenic stretching vibration. These data support the idea that both products are the dimers of a 1,4-dihydro type structure. That they are dimers is proved by the results of elemental analysis and the molecular-weight determination. When the one-electron reduction of IIa or IIIa is performed in an ESR cavity, the ESR signal is detectable only by the *in situ* method (Fig. 4). Each signal intensity is extraordinarily small in comparison with that of Ia under identical conditions. Moreover, the intensity of the intermediary radical derived from IIa is smaller than that of IIIa. These results suggest that the rate of dimerization of the radical (IIb) is greater than that of the radical (IIIb). The fact that the one-electron electrochemical reduction product of IIa and the reduction product with zinc dust are the same dimer (IIb′), one which is oxidizable to IIa with silver perchlorate, is confirmed by UV and NMR spectroscopy.



The reduction mechanisms of Ia—IIIa and the oxidation reaction of their reduction procucts are summarized in the following scheme.

Discussion

Stability of the Radical. As has been mentioned above, only Ia was able to stay as the radical in the solution. This is because the cyano group at the 4-position sufficiently resonates with the quinoline ring, and the unpaired electron can delocalize on each atom in the pyridine ring. On the other hand, IIb has a



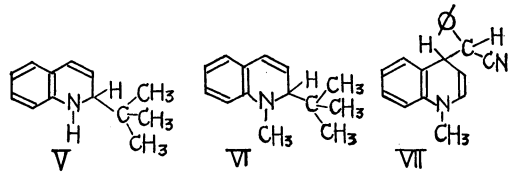
Ia Ib

cyano group at the position *meta* to ring nitrogen; as a result, the unpaired electron is difficult to delocalize. In the case of IIIb, the neighboring *N*-methyl group may sterically prevent it from keeping the co-planarity between the cyano group and the quinoline ring. Therefore, neither IIb nor IIIb is sufficiently stable, and so each radical dimerizes. The fact that the conjugated nitrile (>C=C<CN) of IIIb′ has a higher frequency than that of IIb′ in the IR spectrum (Table 4) suggests steric hindrance by the *N*-methyl group. However, the mighty radical-stabilizing effect of the cyano group is supported by the fact that even IIb or IIIb can be detected intermediately by ESR spectroscopy, though it is rather short-lived.

Elimination of the Cyano Group. Ib does not lead to a decyanation reaction in an aprotic or buffered solution. The stability of Ib is explanined in terms of the great conjugated system which causes the delocalization of the unpaired electron in comparison with the 1-ethyl-4-cyanopyridinyl radical.[11] The 1-methyl-2-cyanoquinolinyl radical, IIIb, does not lead to decyanation because it dimerizes at the 4-position, where the cyano group is not attached.

Oxidation of the One-electron Reduction Product. The fact that the recovery yield of the one-electron reduction product or the reactivity for oxygen decreases in the order of Ib>IIb′>IIIb′ is reasonable in view of the structures of the reduction products. Ib is somewhat resistant to dimerization, but since its unpaired electron is in the antibonding molecular orbital, it is very reactive to oxidizing agents. Though IIb′ and IIIb′ are dimers and the covalent bonds are formed by the reduction, the 4-4′ single bond of the dimers is not very resistant to oxidants because of the hindered resonance of the dihydroquinoline ring and the steric effect. The cyano group may sterically affect the stability of the bonding, and so IIb′ seems to be more reactive than IIIb′. The oxidative cleavage of such a single C–C bond has been reported for several dihydro-

quinoline derivatives, such as V,[12] VI,[13] and VII.[14]



As has been described previously, Ib is autoxidized to the 1-methyl-4-cyanoquinolinium ion in electrolyte solution, while it is autoxidized to 1-methyl-4-cyano-2-quinolone in ethanol. Accordingly, the peroxide initially formed by air-oxidation is considered to have two ways of decomposition: the ionic way (in a buffered solution) and the radical one (in a solution which contains no electrolyte).

Experimental

The polarographic measurements (Yanagimoto Polarograph, Model P8-AP) and controlled potential electrolysis (Nichiakeiki Potentiostat Type NP-1A) for the coulometry were performed with a concentration of 5×10^{-4}M. In the case of the isolation of reduction products, the electrolysis were performed on solutions ranging in concentration from 5×10^{-3}M to 2×10^{-2}M. The IR spectra of the precipitates obtained from electrolyzed solutions were measured as KBr tablets or chloroform solutions. The molecular-weight was determined in benzene with an Hitachi Molecular-Weight Measuring Apparatus, Model 115.

The Nuclear Magnetic Resonance spectra were recorded with a Hitachi Perkin-Elmer R-20 High Resolution NMR Spectrometer at 60 MHz, using tetramethylsilane as the reference. The spectra of Ia were measured at a concentration of about 5w/v-% in acetonitrile, hydrogen oxide, deuterium oxide, and d_6-dimethyl sulfoxide (d_6-DMSO). After the first spectroscopic measurements, a sufficient amount of zinc powder or sodium dithionite was added to the solution, and the solution was warmed for a few minutes. Then the NMR spectra of the resulting deep red solution were again recorded.

The Electronic Spin Resonance spectra were recorded with a Hitachi ESR Spectrometer, Model MES-4001. Twenty ml of a 1-mM acetonitrile solution of a sample containing 0.1 M of TBAP was electrolyzed both *in situ* and in macroscale, using a platium cathode and a platium anode. The nitrogen used to degas the solution was previously passed over a hot copper gauze. The reference electrode used in in this experiment was an $Ag/AgClO_4$ electrode.

1-Methyl-4-cyanoquinolinium Perchlorate (Ia). In a 300-ml three-necked round-bottomed flask fitted with a dropping funnel and a reflux condenser, we placed 14.9 g of 4-cyanoquinoline (0.097 mol) and 80 ml of benzene, and then 12.3 g of dimethyl sulfate (0.098 mol) were added, drop by drop. The mixture was refluxed for about 12 hr on an oil bath. The precipitates thus formed were filtered, washed with benzene, and dried. The precipitates were added to an aqueous solution of 13.5 g (0.097 mol) of potassium perchlorate. The mixture was warmed on a water bath and then cooled. The resulting white precipitates (22.0 g, 0.082 mol, 85%) were recrystallized twice from 200 ml of 50 percent ethanol to give 19.7 g of Ia, mp 200—201°C.

Found: C, 48.96; H, 3.28; N, 9.86%. Calcd for $C_{11}H_9N_2O_4Cl$: C, 49.17; H, 3.38; N, 10.43%.

As will be described below, the conversion to the quinolinium perchlorate was possible by the used of hydrogen perchlorate instead of potassium perchlorate.

1-Methyl-3-cyanoquinolinium Perchlorate (IIa). 3-Cyanoquinoline (2.0 g, 0.013 mol) was dissolved in 50 ml of benzene, and then 1.8 g (0.014 mol) of dimethyl sulfate were added, drop by drop. The mixture was refluxed for 20 hr. The precipitates thus formed were filtered, washed with benzene, and dried to give 2.9 g (0.010 mol, 79%) of 1-methyl-3-cyanoquinolinium methylsulfate (IIa').

To a solution of 2.8 g (0.010 mol) of IIa' in 50 ml of water, we added 1.55 g (0.011 mol) of 70 percent hydrogen perchlorate. White precipitates were filtered out, washed with water and dried. The recrystallization of 2.2 g (0.008 mol, 82%) of the precipitates from 45 mol of 70% ethanol furnished 2.05 g of white needles of IIa, mp 200—202°C.

Found: C, 49.28; H, 3.31; N, 10.47%. Calcd for $C_{11}H_9N_2O_4Cl$: C, 49.17; H, 3.38; N, 10.43%.

1-Methyl-2-cyanoquinolinium Perchlorate (IIIa). 2-Cyanoquinoline (5.0 g, 0.0324 mol) was dissolved in 50 ml of benzene, and to the solution there were then added, drop by drop, 10.0 g (0.0794 mol) of dimethyl sulfate. The mixture was worked up as above. The aqueous solution (100 ml) of 7.0 g of 1-methyl-2-cyanoquinolinium methylsulfate was decolorized with Norit and then filtered. To the filtrate was added 4.5 g (0.027 mol) of 60 percent hydrogen perchlorate. The resulting white crystallines were filtered by suction, washed with water, and dried to give 4.25 g (0.016 mol, 63%) of IIIa, mp 204—205.5°C.

Found: C, 49.53; H, 3.36; N, 10.17%. Calcd for $C_{11}H_9N_2O_4Cl$: C, 49.17; H, 3.38; N, 10.43%.

1-Methyl-2-ethoxyquinolinium Perchlorate. A solution of 1.4 g (0.0052 mol) of IIIa in 32 ml of 90% ethanol was refluxed for a few hours and then cooled to give 0.66 g (0.0023 mol, 44%) of 1-methyl-2-ethoxyquinolinium perchlorate as white needles, mp 182—183°C.

Found: C, 49.74; H, 4.58; N, 4.82%. Calcd for $C_{12}H_{14}NO_5Cl$: C, 49.92; H, 4.90; N, 4.85%.

NMR spectrum (d_6-DMSO, τ): 0.86 (d,1, J=9.75Hz, H_4), 1.58—2.14 (m, 5, H_3 and aromatic H), 5.18 (q,2, J=5.94Hz, $-OC\underline{H}_2CH_3$), 5.81 (s,3, N-CH_3), 8.43 (t,3, J=5.94Hz, $-OCH_2C\underline{H}_3$).

One-electron Reduction of 1-Methyl-4-cyanoquinolium Perchlorate (Ia). In a 500-ml electrolytic cell were placed 2.00 g (0.0075 mol) of Ia, 3.80 g of sodium sulfate, 320 ml of Britton-Robinson buffered solution (pH 7), and 80 ml of distilled water. The solution was then deaerated by a stream of nitrogen while being continuously stirring with a magnetic stirrer. After complete deaeration, electrolysis was carried out at the cathodic potential of −0.70V *vs.* SCE with successive stirring under nitrogen. The electrolysis was stopped when almost no appreciable current passed through. The deep yellow precipitates thus produced were filtered by suction, washed with water, and dried. The precipitates were easily soluble in ether, ethanol, ethyl acetate, and benzene, but insoluble in water and ligroin. Immediately after the precitates were dissolved in solvents, the solutions assumed a dark yellow color; there after they turned light yellow.

Autoxidation of One-electron Reduction Product of Ia. The deep yellow precipitates obtained by the one-electron electrochemical reduction of 2.00 g of Ia were dissolved in ethanol, and the filtrate was evaporated to dryness. The light brown residue was recrystallized from 22 ml of ethanol to give 0.290 g

12) H. Staudinger, H. W. Klever, and P. Kober, *Ann. Chem.*, **374**, 1 (1910).
13) W. Bradley and S. Jeffrey, *J. Chem. Soc.*, **1954**, 2770.
14) J. Leonard and R. L. Foster, *J. Amer. Chem. Soc.*, **74**, 3671 (1952).

(0.0016 mol, 21%) of 1-methyl-4-cyano-2-quinolone. The melting point, the results of elemental analysis, and the UV, IR, and NMR spectra were in agreement with those of the authentic sample.

When the residue of the ethanol solution was sublimed under reduced pressure, 1-methyl-4-cyano-2-quinolone was also obtainable in a 34% yield.

Autoxidation of Two-electron Reduction Products of Ia. A buffered solution (pH 7) of 2.00 g of Ia was electrolyzed at the potential of −1.50V *vs.* SCE in the same way as in the one-electron reduction. The solution of resulting solid in ethanol was filtered, and the filtrate was evaporated to dryness. The residue was sublimed under reduced pressure to give 0.166 g (0.001 mol, 12%) of 1-methyl-4-cyano-2-quinolone.

Oxidation of the Two-electron Reduction Product of Ia with Iodine. Ia (2.00 g) was electrolyzed at −1.50V, and the resulting precipitates were dissolved in 30 m*l* of pyridine. A solution (40 m*l*) of 1.89 g (0.0075 mol) of iodine in methanol was added to this solution. The solvent was evaporated off, and the red-brown, oily material was extracted with water. The water was evaporated, and the residue was recrystallized twice from ethanol to give 0.057 g (3%) of 4-cyanoquinoline methiodide. The melting point, the results of elemental analysis, and the IR and UV spectrum were identical with those of the authentic sample.

One-electron Reduction of 1-Methyl-3-cyanoquinolinium Perchlorate (IIa). The solution of 0.806 g (0.003 mol) of IIa in 200 m*l* of a buffered solution (pH 5) was electrolyzed at −0.80V. The resulting precipitates were dissolved in 40 m*l* of methanol. The solution was poured into 500 m*l* of water after it had been filtered. The mixture was allowed to stand overnight, filtered, and dried to give 0.301 g (0.0009 mol, 59%) of a yellow dimer.

Found: C, 78.18; H, 5.42; N, 16.55%; mol wt, 342. Calcd for $C_{22}H_{18}N_4$: C, 78.07; H, 5.37, N, 16.56%; mol wt, 338.

The solution of 0.201 g (0.00075 mol) of IIa and 1.48 g of potassium perchlorate in 100 m*l* of DMF was electrolyzed at −0.80V. The resulting yellow solution was poured into water and allowed to stand overnight in a refrigerator to give 0.081 g (0.00024 mol, 64%) of the yellow dimer.

One-electron Reduction Product of 1-Methyl-2-cyanoquinolinium Perchlorate (IIIa). The solution of 0.537 g (0.002 mol of IIIa in 200 m*l* of a buffered solution (pH 5) was electrolyzed at −0.70V. The resulting gray reduction product was extracted with ether, and the extract was dried with sodium carbonate. The ether was evaporated to dryness at room temperature under reduced pressure to give an unidentified red-brown resin.

Iminodithiocarbonates. III.[1] Reactions with Some Electrophiles and the Structural Effect on Nucleophilic Reactivities and Basicities[2]

Yoshio UENO, Takeshi NAKAI, and Makoto OKAWARA

Research Laboratory of Resouces Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo

(Received January 13, 1971)

With a view toward demonstrating the structural effect on the reactivity of iminodithiocarbonates, the reactions of some electrophilic reagents with the following four iminodithiocarbonates have been studied; 2-methylimino- (IVa) and 2-phenylimino-1,3-dithiolane (IVb) and *S,S'*-dimethyl-*N*-methyl-(Va) and *S,S'*-dimethyl-*N*-phenyl-iminodithiocarbonate (Vb). Cyclic IVa and its *N*-ethyl homologue reacted with an equimolar amount of phenyl isocyanate at room temperature giving 1:2 cycloadducts. However, the other imino compounds (IVb, Va, and Vb) did not react at all even at elevated temperature. All these imino compounds reacted with acid chlorides to afford the corresponding *N*-acyliminium salts which could, in some cases, be isolated; however the rate of formation of the salts varied significantly with the structure of the imino compound. Some reactions with alkyl halides and phenyl isothiocyanate were also attempted. From the present results and those previously obtained on their reactions with epoxides and with ketenes, it has been concluded that the nucleophilic reactivity of the imino compounds increases in the order Vb<Va<IVb<IVa. Furthermore, it was found that the basicity of the imino compounds increased in the order Vb<IVb<Va<IVa. The observed ring effect and *N*-substituent effect on the reactivity and basicity of the imino compounds are discussed in connection with similar effects on the stability of closely related tri(hetero)carbonium ions, *i.e.*, bis(alkylthio)-dialkylaminocarbonium ion (I).

In our previous paper on tri(hetero)-substituted carbonium ions,[3–5] we reported that the electrophilic reactivity of tri(hetero)substituted carbonium ions (I) depends upon their structural factors, *e.g.*, whether they are cyclic or open-chain. On the other hand, the reaction of iminodithiocarbonates (II) with an electrophile ($^+$E) should involve an initial formation of tri(hetero)-substituted carbonium ions (III). Thus it could be expected that the nucleophilic reactivity of

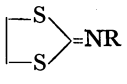
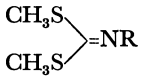
the imino compound (II) is closely related to the stability of the tri(hetero)carbonium ion formed (III).

However, little information has been available on the reaction of II with electrophilic reagents although there are a few papers reporting the reaction of II with epoxides[6] and with ketenes.[7] In order to obtain more elaborate information on the structural effect on the nucleophilic reactivity of iminodithiocarbonates (II), reactions of various types of II with some electrophilic reagents have been studied. Iminodithiocarbonates studied are: 2-methylimino-(IVa) and 2-phenylimino-1,3-dithiolane (IVb) and *S,S'*-dimethyl-*N*-methylimino-(Va) and *S,S'*-dimethyl-*N*-phenyliminodithiocarbonate (Vb). Furthermore, the basicity of these imino compounds has been measured. In this paper we will describe the results of the investigation and discuss the structural effect on nucleophilic reactivity and basicity.



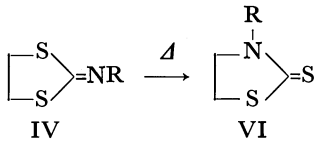
IVa, R=CH_3
b, R=C_6H_5



Va, R=CH_3
b, R=C_6H_5

Results

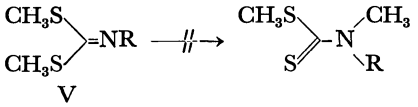
Thermal Isomerization. We reported that 2-methylimino-1,3-dithiolane (IVa) and *N*-ethyl homologue are ring-isomerized at 200°C to the corresponding thiazolidine-2-thione (VI), but 2-phenylimino compound (IVb) is not isomerized even under more drastic conditions.[6]



IV VI

R=CH_3, C_2H_5

Attempts to isomerize the open-chain compounds (Va and Vb) were made under various conditions. However, the two compounds were not isomerized to dithiocarbamates even at 250—270°C.

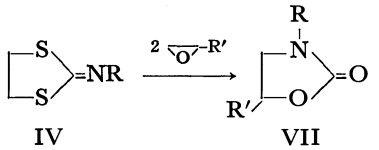


V

R=CH_3, C_6H_5

Harley-Mason has reported that *S,S'*-diphenyl-*N*-phenyliminodithiocarbonate remains unchanged on heating at 330°C.[8]

Reactions with Epoxides. We reported that the cyclic compounds (IVa and IVb) react with epoxides at 140—160°C to give the 2-oxazolidone derivatives (VII) in good yields and suggested that the initial process of this reaction is a cycloaddition of epoxides to the C=N bond of IV.[6,9]

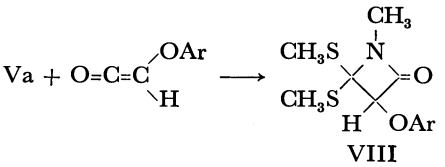


IV VII

R=CH_3, C_6H_5

The reactions of open-chain Va and Vb with propylene oxide were carried out under various conditions. It was found that neither Va nor Vb reacted with epoxide even at 170—180°C, but the starting materials were recovered.

Cycloaddition Reactions with Heterocumulenes. Metzger reported that *o*-chlorophenoxyketene or diphenylketene reacts with numerous iminodithiocarbonates including 2-propylimino-1,3-dithiolane and open-chain Va to afford the corresponding 1:1 cycloadduct (VIII),[7] *e.g.*



VIII

The reactions of the four iminodithiocarbonates with phenyl isocyanate were attempted. It was found that methylimino-dithiolane (IVa) reacted with an equimolar amount of phenyl isocyanate at room temperature to produce the 1:2 cycloadduct (IXa) in 65% yield. Similarly, ethylimino-dithiolane (IVa') and the isocyanate gave the 1:2 cycloadduct (IXa') in 16% yield in the presence of a small amount of lithium chloride; however, in the absence of the catalyst no reaction proceeded appreciably. In contrast to this observation, the other iminodithiocarbonates (IVb, Va, and Vb) did not react with the isocyanate even at elevated temperature and the starting materials were recovered almost quantitatively.

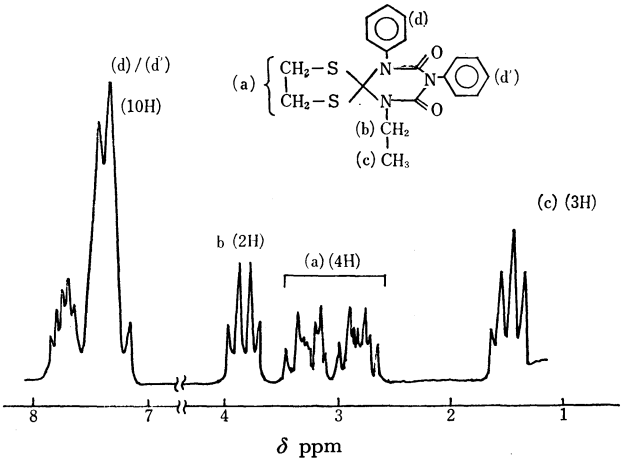


Fig. 1. The NMR spectrum of 1:2 cycloadduct IXa' in $CDCl_3$

Products IXa and IXa' were identified by means of elemental analyses and spectral data (IR and NMR). The IR spectra of IXa and IXa' showed two strong absorption bands at 1703 and 1668—1670 cm^{-1} indicating the presence of two kinds of carbonyl groups. The structure of IXa' was confirmed by the NMR spectrum (Fig. 1) which showed a triplet at δ 1.42

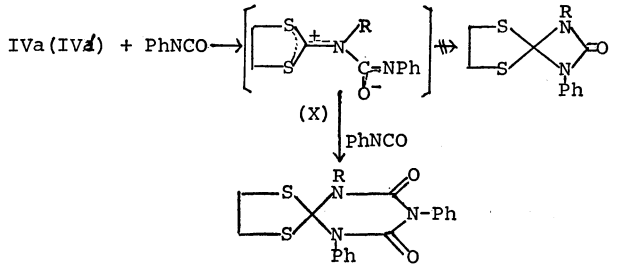
($N-CH_2C\underline{H}_3$), a quartet at δ 3.83 ($N-\underline{C}H_2CH_3$), two multiplets centered at δ 3.28 and 2.28 ($S-\underline{C}H_2\underline{C}H_2-S$), and a multiplet centered at δ 7.45 (two phenyls). Unequivalence of the two ring-methylenes is noteworthy. It suggests that the phenyl nucleus would significantly deshield the methylene protons situated near the phenyl nucleus.

Product IXa is best explained as a result of an initial formation of the ionic 1:1 adduct (X) which then reacts with additional isocyanate, finally yielding the six-membered ring compound (IXa) instead of the formation of the more hindered four-membered 1:1 cycloadduct.



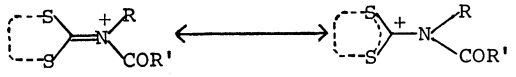
IXa, R=CH_3
a', R=CH_3CH_2

The formation of the 1:2 cycloadduct in equimolar condition is in direct contrast to the reaction of the isopropyl analog of IVa with ketenes described above, and to the reactions of mono-substituted azomethines with phenyl isocyanate only at elevated temperature giving six-membered 2:1 cycloadducts.[10]

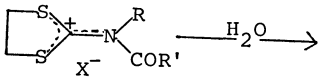
Reactions of the four imino compounds with phenyl isothiocyanate were attempted; however, no significant reactions were observed.

Reactions with Acid Chlorides. The acylating reactions with acid chlorides have been carried out in the presence of tertiary amine. In these cases existance of acylammonium salts as reactive intermediates has been postulated. However, the acylammonium salts were so unstable that only a few salts have been successfully isolated. Acyliminium salts such as acylpyridinium salt are also too unstable to be isolated.

If the iminodithiocarbonates reacts with an acid chloride, the acyliminium salt formed would be greatly stabilized through delocalization of the positive charge by the two sulfur atoms as shown below.



Reactions of imino-dithiolane IVa and IVb with acetyl chloride, benzoyl chloride, and methacryloyl chloride were carried out at room temperature in inert solvents such as ether or benzene. The reaction proceeded immediately to completion yielding crystalline adducts XI quantitatively. In the reaction of IVa with acetyl chloride it was necessary to cool the reaction mixture with dry ice-acetone bath because of violent heat evolution. On the other hand, in the reaction of IVb with benzoyl chloride, the reaction proceeded slowly. The acyliminium salts obtained were stable white solids in inert solvent, but they were hygroscopic in air. An exchange of the counter anion of Cl^- with $SbCl_6^-$ or $B(C_6H_5)_4^-$ was successful in the case of XIb and XIe. However, in other cases, the salts were easily hydrolyzed giving rise to the formation of HX salts of iminodithiocarbonates, XVI.



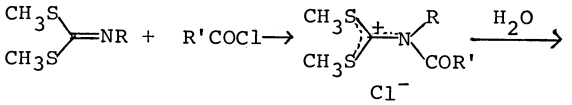
XIa,c,d.

XVI

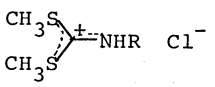
TABLE 1. *N*-ACYLIMINIUM SALTS XI

	R	R'	X	IR (KBr) ($\nu_{C=O}$) cm^{-1}	Mp (°C)
XIa	CH_3	CH_3	Cl	—	—
b	CH_3	C_6H_5	Cl	1700	126—129
b'	CH_3	C_6H_5	$SbCl_6$	1700	134—135
c	C_6H_5	CH_3	Cl	—	—
d	C_6H_5	C_6H_5	Cl	—	—
e	CH_3	$CH_2=C(CH_3)$	$B(C_6H_5)_4$	1740	110

Similarly, open-chain iminodithiocarbonates Va and Vb reacted with acetyl chloride to give very hygroscopic *N*-acethyliminium chlorides (XII) which were easily hydrolyzed with the moisture in air.



V XII



Stability of N-*Acyliminium Salts (XI, XII).* Cyclic iminium salts XI were more stable than open-chain analogs XII. This is in agreement with the fact that 2-dimethylamino-1,3-dithiolanium salt XIII in more stable than its open-chain analog XIV.[12]

XIII XIV

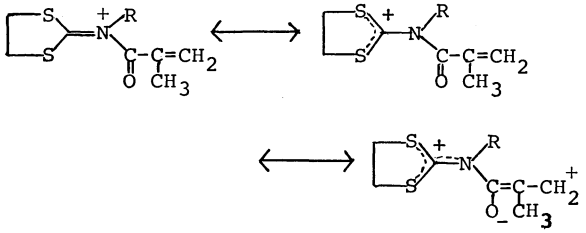
XIb and XIe in particular, were stable enough to be isolated and characterized by IR spectra and elemental analyses.

Thus, stabilization of XI is increased by the *N*-sub-

10) H. Ulrich, "Cycloaddition Reactions of Heterocummulenes," Academic Press, New York (1967), pp. 153—155.

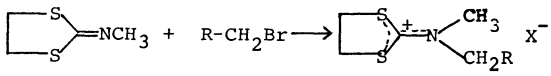
stituent in the order $CH_3<C_6H_5<CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}-$.

This was rationalized by the following resonance effect, which caused the decrease in the positive charge on the nitrogen atom.



Acylation of Amine by N-*Acyliminium Salt XI.* The strong acylating ability of the *N*-acyliminium salt XI was demonstrated using the IVb acetyl chloride adduct, XIc. The solution of aniline in benzene was added to the suspension of XIc in the same solvent and the mixture was warmed in a water-bath for one minute to produce acetanilide in 52% yield.

Reactions with Alkyl Halides. Alkylation of imino-1,3-dithiolane IVa with active halides such as α-haloketone, α-haloester and benzyl halide easily took place, producing the *N,N*-dialkyliminium salts XV in acetonitrile or under neat conditions at room temperature. Thus, IVa reacted with phenacyl bromide, ethyl bromoacetate and *p*-nitrobenzyl bromide to give the iminium salts XVa, b, and c in 92, 93, and 92% yield, respectively.



XVa, R=C_6H_5CO X=ClO_4
b, R=EtOCO X=ClO_4
c, R=p-$NO_2C_6H_4$ X=Br

In the case of XVa and XVb, the counter anion was exchanged into perchlorate anion by treating the salts with sodium perchlorate. Similarly, methylation of IVa with methyl iodide occurred to produce 2-dimethylamino-1,3-dithiolanium salt XIII in good yield.

On the other hand, 2-phenylimino-1,3-dithiolane (IVb) or *S,S'*-dimethyl-*N*-methyliminodithiocarbonate (Va) reacted with phenacyl bromide to give unidentified products and no simple alkylation products were obtained.

Determination of the Basicities of the Iminodithiocarbonates (IV and V) by Spectrophotometry. Basicities of IV and V were calculated using the following equation,[11]

$$pK_a = pK_{HAc} + \log (C_{Ac^-}/C_{HAc}) + \log (D - D_{B^-}/D_{HB} - D)$$

where D_{B^-}, D_{HB}, and D refer to the absorption coefficient of the iminodithiocarbonates measured in water

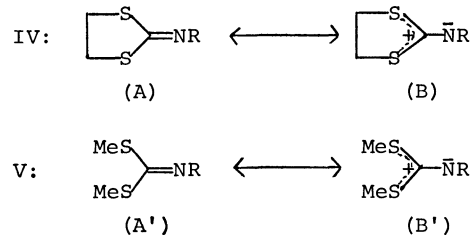
(curve 1), in aqueous sulfuric acid (curve 2), and in acetic acid-sodium acetate buffer solution (curve 3), respectively. For the calculation, values of D_{B-}, D_{HB}, and D were taken from the curves 1, 2, and 3, respectively, at some wave lengths omitting than those in the neighborhood of the isobestic point. The value of pKa of acetic acid was taken as 4.76. Complete protonation of IVa was observed in over 18.2 wt% of aqueous sulfuric acid. The values of pKa of IVb, Va, and Vb were calculated in a similar manners. The pKa values are summarized in Table 2.

Correlation between Nucleophilic Reactivities and Structures of Iminodithiocarbonates. The nucleophilic reaction data of the iminodithiocarbonates including the previous results[6] are summarized in Table 2. We see that 1) nucleophilic reactivites of iminodithiocarbonates decrease in the order IVa>IVb>Va>Vb, and 2) this order is almost in agreement with that of basicities of the imino groups.

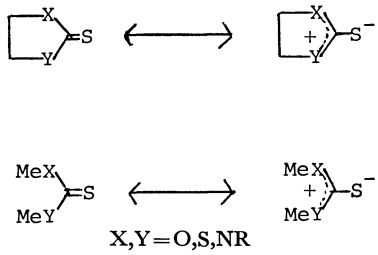
These observations indicate that the nucleophilic reactivities of iminodithiocarbonates may qualitatively be explained in terms of the basicities of the imino groups.

Ring Effect. The greater reactivities and basicities of cyclic IV than those of open-chain V show that the polarized structure (B) significantly contributes to the ground state of the former, and that the structure (B′) in the latter is less important.



In other words, resonance stabilization of the polarized structure (B and B′) by the two sulfur atoms is greater in cyclic than open-chain analog.

A similar ring effect was observed in the greater basicities and reactivities toward epoxides of various cyclic thione compounds than in those of open-chain analog.[9]



Moreover, the ring effect has also been observed in the stability of tri(hetero)substituted carbonium ion; thus cyclic cation XIII was more stable than open-chain analog XIV.[12] This is also true for the stability of N-acyliminium salts. In general, ring effects such as enhanced reactivity, basicity, and stability of the cyclic compounds might be recognized in the following compounds as compared with open-chain analogs.

(X, Y, Z=O, S, NR′)

The ring effect is probably attributed to a much greater overlap between the lone pairs of the heteroatoms and 2p orbital of sp^2 center carbon in the ring compounds than in the analogous open-chain compounds.

N-*Substituents.* In both cases of IV and V, the difference of pKa between the N-methyl and the N-phenyl derivatives is 2.0—2.1. This shows that a pair of electrons on the iminonitrogen of IV and V are delocalized over the phenyl nucleus to the same extent. Thus the smaller reactivities of N-phenyl derivatives can be explained by this electron delacalization. In summary, the nucleophilic reactivities of iminodithiocarbonates are explained in terms of the ring effect and the N-substituents.

Experimental

General. All melting and boiling points are uncorrected. IR and UV spectra were recorded with Hitachi EPI-S-2 and EPS-2 spectrometers, respectively. NMR spectra were obtained with a Japan Electron Optics JNL 4H-100 spectrometer. Chemical shifts are given in ppm from tetramethylsilane as an internal standard.

Materials. All iminodithiocarbonates were prepared by the methods previously reported: methylimino-1,3-dithiolane (IVa), bp 79—81°C/0.45 mmHg; ethylimino-1,3-dithiolane (IVa′), bp 85—87°C/0.30 mmHg; phenylimino-1,3-dithiolane (IVb), mp 47—48°C; N-methylimino-dithiocarbonate (Va), bp 110—112°C/70 mmHg; N-phenyliminodithiocarbonate (Vb), mp 34—35°C. Other reagents were either commercially available materials or prepared by a standard method.

Reaction of Methylimino-dithiolanes with Phenyl Isocyanate. Methylimino-dithiolane IVa (1.3 g, 0.01 mol) and phenyl isocyanate (1.2 g, 0.01 mol) were mixed at room temperature. A vigorous exothermic reaction occurred and crystals were immediately formed. After standing the reaction mixture at room temperature overnight, the precipitates were collected by filtration to give 1.2 g (65%) of the 1:2 cycloadduct (IXa). To remove the impurities (diphenylurea), the precipitates were washed several times with warm ether and recrystallized from acetonitrile: mp 231.5—232.5°C; IR (KBr) 1703 and 1670 cm^{-1} (C=O).

Found: C, 58.34; H, 4.39; N, 11.53%. Calcd for $C_{18}H_{17}N_3O_2S_2$: C, 58.22; H, 4.61; N, 11.32%.

The reaction of imino-dithiolane IVa′ with phenyl isocyanate was carried out under similar conditions in the presence of lithium chloride (0.10 g) to produce the cycloadduct IXa′ in 16% yield: mp 202—203°C (recrystallized from a mixture of ethanol and ether): IR (KBr) 1703 and 1668 cm^{-1} (C=O),

Found: C, 59.01; H, 5.00; N, 10.94%. Calcd for $C_{19}H_{19}N_3O_2S_2$: C, 59.21; H, 4.97; N, 10.90%.

The IR spectrum of IXa′ closely resembled that of IXa. The NMR spectrum of IXa′ is given in Fig. 1.

Reaction of Iminodithiocarbonates (IV or V) with Acid Chlorides. General Procedure: The iminodithiocarbonate was mixed with the acid chloride listed in Table 1 at room temperature in inert solvent (benzene, ether) or under neat conditions. Acyliminium salts were obtained as crystalline solids.

12) T. Nakai, Y. Ueno, and M. Okawara, This Bulletin, **43**, 3175 (1970).

Reaction of Imino-dithiolane IVa with Benzoyl Chloride. IVa (1.3 g, 0.01 mol) and benzoyl chloride (1.4 g, 0.01 mol) were mixed. A white crystalline precipitate XIb started to separate almost immediately. The acyliminium salt XIb was obtained in quantitative yield, mp 126—129°C (recrystallized from benzene); IR (KBr): 1700 cm^{-1} (C=O).

Found: N, 5.12%. Calcd for $C_{11}H_{12}NOS_2Cl$: N, 5.18%.

Conversion of the counter anion of the salt XIb into antimony hexachlorate anion by the addition of antimony pentachloride gave *N*-benzoyliminium antimony hexachlorate XIb′: mp 134—135°C; IR (KBr): 1700 cm^{-1} (C=O).

On the other hand, treatment of the reaction mixture with aqueous sodium tetraphenylborate gave only the hydrolyzed product, XVI (X=$B(C_6H_5)_4$: mp 157—158°C;

Found: C, 73.61; H, 6.29; N, 2.80%. Calcd for $C_{28}H_{28}BNS_2$: C, 74.16; H, 6.22; N, 3.09%.

Reaction of Imino-dithiolane IVa with Methacryloyl Chloride. The crystalline adduct was treated with aqueous sodium tetraphenylborate to give XIe in quantitative yield: mp 110°C (recrystallized from acetonitrile);

Found: N, 2.69%. Calcd for $C_{32}H_{32}NOS_2B$: N, 2.65%.

In other cases, the resulting adducts (XIa, c, and d) were difficult to isolate. They were solids stable only in inert solvents.

Acetylation of Aniline with Iminium Salt XI. To the suspension of XIc (prepared from 1.0 g of acetyl chloride and 1.0 g of IVb) in benzene, was added 0.48 g of aniline in benzene. After warming the reaction mixture for one minute on water-bath, the reaction mixture was poured into the cold water to give 0.35 g (52%) of acetanilide: mp 110—112°C (lit., 114°C) (recrystallized from water). The IR spectrum of this product was identical with that of authentic sample of acetanilide.

Reaction of Imino-dithiolane IVa with Alkyl Halides. General Procedure: 2-Methylimino-1,3-dithiolane IVa was mixed with the equimolar amount of alkyl halide in acetonitrile or under neat conditions at room temperature. The iminium salts were isolated as perchlorates by treating with aqueous sodium perchlorate.

Reaction of IVa with Phenacyl Bromide. The imino-dithiolane (11.2 g, 0.084 mol) IVa was mixed with phenacyl bromide (16.8 g, 0.084 mol) in acetonitrile (30 m*l*) at room temperature. Heat evolution took place with the addition of solid sodium perchlorate to the reaction mixture. After about 30 min, the reaction mixture was treated with excess aqueous sodium perchlorate to give the solid, which was washed with water and then with ether: (27 g, 92%); mp 194—195°C, IR (KBr); 1700 cm^{-1} (C=O), 1080 cm^{-1} (ClO_4^-); UV $\lambda_{max}^{H_2O}$ 257.5 mμ.

Found: C, 40.98; H, 4.00; N, 4.02%. Calcd for $C_{12}H_{14}NO_5S_2Cl$: C, 40.98; H. 4.01; N, 3.98%.

Reaction of IVa with Ethyl Bromoacetate. Similarly, IVa (1.3 g, 0.01 mol) was allowed to react with ethyl bromoacetate (1.7 g, 0.01 mol) under neat conditions to give salt (93%). The bromide anion was converted into perchlorate anion by treatment with aqueous sodium perchlorate to give XVb: mp 119.5—120.5°C (recrystallized from ethanol).

Found: C, 29.64; H, 4.31; N, 4.40%. Calcd for $C_8H_{14}NO_6S_2Cl$: C, 30.06; H, 4.41; N, 4.38%.

Reaction of IVa with p-*Nitrobenzyl Bromide.* IVa (6.5 g, 0.03 mol) and *p*-nitrobenzyl bromide (6.5 g, 0.03 mol) in acetonitrile (10 ml) were warmed on a water bath for 1 hr. Cooling the reaction mixture gave the iminium salt XVc containing one mole of water of crystallization. (10.1 g, 92%): mp 84—85°C (recrystallized from acetonitrile).

Found: C, 35.90; H, 4.02; N, 7.62%. Calcd for $C_{11}H_{13}N_2O_2S_2Br\cdot H_2O$: C, 35.98; H, 3.29; N, 7.63%.

Reaction of IVa with Methyl Iodide. A slight excess of methyl iodide was added to a solution of IVa in acetonitrile. Dithiolanium salt XIII was obtained in 90% yield: mp 184—186°C (recrystallized from acetonitrile).

Found: C, 22.08; H, 3.56; N, 5.30%. Calcd for $C_5H_{10}NS_2I$: C, 21.82; H, 3.66; N, 5.09%.

Determination of the pKa of Iminodithiocarbonates. The buffer solution was a mixture of acetic acid (0.35 mol/*l*) and sodium acetate (0.10 mol/*l*). As both IVb and Vb did not completely dissolve in water or in buffer solution, a small amount of ethanol (1—2%) was added to obtain in a clear solution. Concentration of the samples was approximately $1.0—1.7\times10^{-4}$ mol/*l*. The concentrations of sulfuric acid for complete protonation of iminodithiocarbonates were 18.2, 45.5, 57.5, and 57.5 wt % for IVa, IVb, Va, and Vb, respectively. The p*K*a values thus obtained are summarized in Table 3.

Solvolysis of Organic Phosphates. III[1] 3-Pyridyl and 8-Quinolyl Phosphates in Spontaneous Reaction[2]

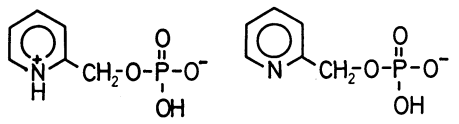
Yukito MURAKAMI and Junzo SUNAMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received January 13, 1971)

The spontaneous hydrolysis of 3-pyridyl and 8-quinolyl phosphates was investigated at 60, 70, and 80°C over the $-\log[H^+]$ range from 1 to 7 in aqueous media with an ionic strength of 0.10. The reactions followed apparent first-order kinetics with respect to the unreacted phosphate species, and the maximum rate was observed around $-\log[H^+]=2.5$. Reactive species of each phosphate in hydrolysis were the neutral zwitterion and the monoanion, the former being found to be more labile. In a moderately acidic region ($-\log[H^+]<2.0$), an apparent enhancement of the reaction rate was detected for both phosphates, which was attributed to the acid catalysis acting on the zwitterion species. The activation enthalpy for hydrolysis of the zwitterion and the monoanion falls near 30 kcal mol^{-1}. This is consistent with the reaction mechanism expected for hydrolysis of ordinary monoalkyl or monoaryl phosphate, in which the P–O bond cleavage takes place. The activation entropy data also provide an evidence for the unimolecular nature of the transition state. The kinetic solvent isotope effect k^{H_2O}/k^{D_2O} for the hydrolysis of both phosphates falls near unity. The isotope effect in this magnitude is consistent with the intramolecular proton-transfer mechanism. The results are, therefore, consistent with a mechanism for the hydrolysis of the zwitterion species of 8-quinolyl phosphate in which the quinolinium group donates a proton intramolecularly to the leaving ester oxygen atom in the transition state.

In an earlier study[3] dealing with the hydrolysis of pyridylmethyl phosphates in the presence and the absence of metal ions, we elucidated the correlation between reaction rate and structural specificity of the leaving alcohol group of the phosphates. As a result, the extent of participation of the pyridyl nitrogen in their reaction processes was discussed. The neutral zwitterion form of 2-pyridylmethyl phosphate **1** was



1 **2**

found to be more labile than the corresponding monoanion species **2**. The profound reactivity of the former was attributed to the unique intramolecular proton-transfer mechanism, in which the pyridinium group donates a proton to the leaving ester-oxygen in the transition state. In the hydrolysis reactions of 3- and 4-pyridylmethyl phosphates no such unique behavior was detected.

In the present work, the spontaneous hydrolysis of 3-pyridyl and 8-quinolyl phosphates has been investigated in conjunction with kinetic solvent isotope effect as well as activation entropy and enthalpy effects. The former phosphate has no pyridinium proton available for an intramolecular proton-transfer mechanism, while the latter has a structural analogy to 2-pyridylmethyl phosphate. It is expected that some aspects, such as an intramolecular proton-transfer mechanism, participation of a water molecule in the transition state, and the electronic effect of the hetero-aromatic nitrogen on reactivity may be clarified.

Experimental

Materials. Preparation and purification of 2-pyridylmethyl phosphate have been described previously.[4] 3-Pyridyl and 8-quinolyl phosphates were prepared by the reaction of 3-pyridinol and oxine respectively with phosphorous oxychloride, and purified by the column chromatographic technique with cation exchange resin. Detailed synthetic methods and purification procedures have been described elsewhere.[5] Heavy water was obtained from Mallinckrodt Chemical Works (99.8%, Deuter AR), and from E. Merck Ag. Darmstadt (99.75%, Uvasol^R) and used without furhter purification. Use of either of these reagents gave no noticeable difference in reaction kinetics. Sodium deuteroxide solution (0.1 N) was obtained by diluting 40% concentrated sodium deuteroxide (G.R.) purchased from Merck with deuterium oxide. Deuteroperchloric acid (0.1 N) was prepared by diluting 60% aqueous solution with deuterium oxide. Other solution in deuterium oxide were prepared directly by dissolving the anhydrous compounds. Other materials were of analytical grade and used without any particular purification.

Apparatus. The reaction vessel used for kinetic and potentiometric measurements was the same as that designed and use for the reactions of pyridylmethyl phosphates.[3] Electrodes used for pH measurements in kinetic runs were a set of glass electrode HG-6005 and reference electrode HC-605 of TOA Electronics, Ltd., Tokyo, or a set of Beckman glass electrode No. 39099 and Beckman reference electrode No. 39402. When the Beckman electrodes were adopted, a Beckman SS-2 pH meter was used in place of TOA HM-5A. Both of these pH meters were incorporated with TOA pH-stat HS-1B and TOA EPR-2T recorder in order to maintain pH-value constant during each run.

Kinetic Measurements. The reaction rate was determined by measuring the amount of inorganic orthophosphate liberated in the course of reaction. When an aqueous system was investigated, the experimental technique generally followed the procedure described previously.[2] When the

reaction was carried out in deuterium oxide, the solution was made up initially to 35 m*l* in total volume and a 1.00-m*l* sample was drawn out from the vessel by a syringe at an appropriate time interval.

pD Measurements. The pH-meter was first calibrated with two standard aqueous buffer solutions, phthalate and phosphate buffers, and then potentiometric titration of deuteroperchloric acid with sodium deuteroxide of known concentration was carried out at a given temperature and a constant ionic strength. The difference (ΔpD) between the negative logarithm of a real concentration of deuterium ion, established by the titration of deuteroperchloric acid with sodium deuteroxide, and the apparent pH-meter reading is represented by the equation:

$$\Delta\text{pD} = -\log[\text{D}^+] - \text{"pH-meter reading"}$$

For example, at an ionic strength of 0.10 (KNO_3) and 70°C, ΔpD was determined to be 0.276. It was assumed that the ΔpD value was valid at the same temperature and ionic strength over the whole pD range studied. In this way, $-\log[\text{D}^+]$ values were established from pH-meter readings. Before determining ΔpD, the electrodes used were preequilibrated in deuterium oxide for 2 days or more. In each run, thereafter, the electrode system was conveniently checked with 0.05 M potassium biphthalate in deuterium oxide. The pH-meter reading of this reference solution corresponds to 4.21 in pD value at 70°C, 4.32 at 80°C, and 4.30 at 90°C.

Determination of Acid Dissociation Constants. The acid dissociation constants of 3-pyridyl and 8-quinolyl phosphates in aqueous solution at low temperature (25°C) were determined by titrating 2.0×10^{-3} M solution of the phosphates with a standard alkaline solution according to standard procedures. However, the acid dissociation constants obtained by this method at higher temperatures, especially the second one (K_{H_2A}), were suspected to involve a little uncertainty. The possible errors can be caused by trace hydrolysis of the phosphates during the course of measurements. Thus, under these circumstances as well as in the runs in heavy water at elevated temperatures, the kinetic (or dynamic) acid dissociation constants of each ionic species were evaluated by means of the equation:

$$k_0 = k_{H_2A}X_{H_2A} + k_{HA}X_{HA} + k_AX_A \qquad (1)$$

where k_0 is the over-all rate constant and ks stand for the specific rate constants of ionic species suffixed to them; H_2A, HA, and A refer to neutral, monoanionic, and dianionic species of the phosphate, respectively. Mole fraction X of each ionic species is related to the corresponding acid dissociation constant in terms of the following relationships:

$$T_E = [H_3A] + [H_2A] + [HA] + [A]$$

$$[H_3A] = \frac{[A]}{K_{H_2A}K_{H_2A}K_{HA}}[H^+]^3$$

$$[H_2A] = \frac{[A]}{K_{H_2A}K_{HA}}[H^+]^2$$

$$[HA] = \frac{[A]}{K_{HA}}[H^+]$$

Ks are acid dissociation constants of various ionic species suffixed to them, and T_E is the total phosphate concentration. In spite of the above general expression for reaction rate, the dianionic species of the present phosphates, as well as those of the pyridylmethyl phosphates,[3] were not reactive in the spontaneous hydrolysis. Thus, we could eliminate the last term in the right side of Eq. (1). The first approximation of the remaining four constants K_{H_2A}, K_{HA}, k_{H_2A}, and k_{HA} were carried out by solving the corresponding matrix of four rows and four columns, based on the data obtained in a pH range 3.0—6.0. The calculation was then iterated with the use of these evaluated four constants as a starting set until the best fit of the calculated values to the observed over-all rate constants was attained over the appropriate pH range studied ($-\log[H^+]=2.5$—7.0). All the calculation processes were programmed by means of Kyushu Daigaku Fortran and carried out on a FACOM 230-60 electronic computer of the Computer Center of Kyushu University.

Results

Acid Dissociation Constants. As mentioned in the experimental section, acid dissociation constants at elevated temperatures were evaluated by potentiometric method and/or by kinetic method. They are listed in Table 1, along with the values previously reported for 2-pyridylmethyl phosphate.[3]

Table 1. Acid dissociation constants of 8-quinolyl, 3-pyridyl, and 2-pyridylmethyl phosphates at various temperatures and $\mu=0.10$ (KNO_3)

Temp. °C	pK_{H_2A}	pK_{HA}
	8-Quinolyl phosphate	
25	4.17[a]	6.42[a]
80	4.16[a]	6.29[a]
80	4.09[b]	6.24[b]
80	4.05[c]	6.50[c]
	3-Pyridyl phosphate	
25	3.86[a]	5.64[a]

70	3.87[b]	5.76[b]
70	4.28[c]	5.71[c]
	2-Pyridylmethyl phosphate	
25	4.42[d]	6.29[d]
80	4.15[d]	6.54[d]
90	4.03[b]	6.46[b]
90	4.46[c]	6.46[c]

a) Determined by potentiometric titration.
b) Estimated by kinetic method using Eq. (1).
c) Estimated by kinetic method using Eq. (1) in deuterium oxide.
d) Reported previously[3] (determined by potentiometric titration).

Spontaneous Hydrolysis in Aqueous Media. 3-Pyridyl and 8-quinolyl phosphates were hydrolyzed at 60, 70, and 80°C in aqueous media for which an ionic strength was maintained at 0.10. The reactions followed apparent first-order kinetics with respect to the total concentration of the unreacted phosphate. The over-all rate constants, k_{obs}, thus obtained are listed in Table 2, together with the results in deuterium oxide as well as those for 2-pyridylmethyl phosphate in deuterium oxide.

The pH-rate profiles for 8-quinolyl, 3-pyridyl, and 2-pyridylmethyl phosphates are shown in Figs. 1, 2, and 3, respectively, along with the corresponding pD-rate profiles.

For the hydrolysis of 3-pyridyl phosphate, there is a narrow plateau on its experimental pH-rate profile

in the pH region 2—3, where the major fraction of the phosphate is in the neutral zwitterion form. A similar observation was made for the hydrolysis of 8-quinolyl phosphate. Thus, we may propose that the neutral zwitterion and the monoanionic species of these phosphates are reactive as was confirmed to be the case for pyridylmethyl phosphates. To evaluate the specific rate constants for these reactive ionic species, fractional molar concentrations of various ionic species of each substrate were calculated by the aid of acid dissociation constsnts listed in Table 1. The following equation can be used for the calculation of the specific rate constants for these active species.

$$k_{obs} = k_{H_2A}X_{H_2A} + k_{HA}X_{HA}$$

where k_{obs} refers to the observed over-all rate constant. On the other hand, employment of Eq. (1) results in a simultaneous evaluation of rate constants and acid dissociation constants as mentioned in the previous section. The results are listed in Table 3.

In a moderately acidic region ($-\log[H^+]<2.0$), a good linear relationship between $k_{obs}-(k_{H_2A}X_{H_2A}+k_{HA}X_{HA})$ and the stoichiometric concentration of hydrogen ion exists for both phosphates. From the slope of the straight line, we tentatively estimated a specific rate constant for acid-catalyzed reaction, K_H^+: 8-quinolyl phosphate, $k_H^+=4.79\times 10^{-4}M^{-1}sec^{-1}$ at 80°C; 3-pyridyl phosphate, $k_H^+=5.00\times 10^{-4}M^{-1}sec^{-1}$ at 70°C.

Activation Parameters. Activation parameters for the hydrolysis of 8-quinolyl and 3-pyridyl phosphates are listed in Table 4. They were evaluated from the specific rate constants for the hydrolysis reactions of the neutral and monoanionic species (Table 3).

Discussion

In general, organic phosphates are polybasic acids and various ionic species with different degree of protonation exist in solution. The reactivity of these ionic species varies from one species to another, depending upon the structural property of the leaving alcohol group. In a series of solvolysis studies of

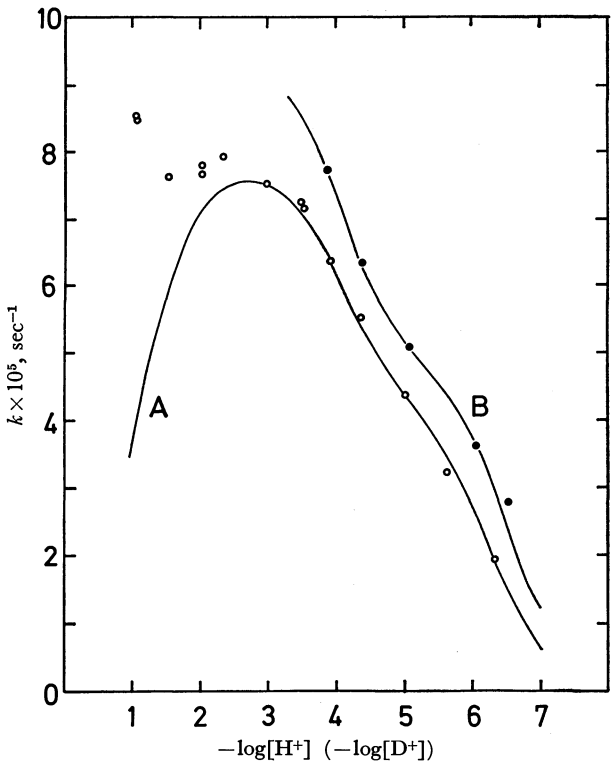

Fig. 1. Rate profiles for the spontaneous hydrolysis of 8-quinolyl phosphate in water (curve A) and in deuterium oxide (curve B) at 80°C and $\mu=0.10$.

The curves were calculated from the experimemtal data by means of Eq. (1) with the following constant: aqueous system, $pK_{H_3A}=1.0$, $pK_{H_2A}=4.09$, and $pK_{HA}=6.24$; $k_{H_3A}=0$ sec^{-1}, $k_{H_2A}=7.84\times10^{-5}$sec^{-1}, and $k_{HA}=4.19\times10^{-5}$sec^{-1}: deuterium oxide system, $pK_{H_2A}=4.05$ and $pK_{HA}=6.50$; $k_{H_2A}=9.65\times10^{-5}$sec^{-1} and $k_{HA}=4.83\times10^{-5}$sec^{-1}.

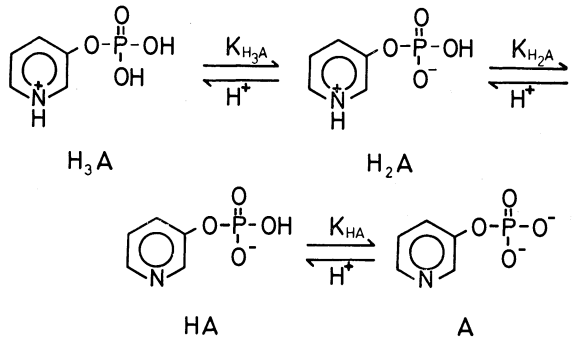
3-Pyridyl	28.0	27.3	+2	30.7	30.0	+7

a) Value at 70°C.



Scheme 1

Pyridyl phosphate affords, for example, four ionic species of different protonation degree due to the dissociation process shown in Scheme 1. Throughout this study we refer H_3A to the monocationic form, H_2A to the neutral zwitterion, and HA to the monoanionic form. Both H_2A and HA, however, involve the monoanionic phosphate group.

Hydrolysis of Neutral Zwitterion Species. In the kinetic and mechanistic studies of hydrolysis of the pyridylmethyl phosphates,[3] the species involving a monoanionic phosphate moiety, zwitterion form (H_2A) and monoanionic form (HA), were confirmed to be reactive toward hydrolysis, although the corresponding acidic hydrolysis did not proceed to any detectable extent in the pH range studied. In addition, irrespective of the phosphate species, the activation energies for the hydrolysis of zwitterion forms were approximately 30 kcal mol^{-1} and the corresponding Arrhenius' A values were in the same order of magnitude as other ordinary alkyl phosphates.[3] Thus, we proposed that the zwitterion species of the pyridylmethyl phosphates follow the same hydrolytic pathway, accompanied with the P–O bond cleavage, as expected for the monoanionic form of an ordinary alkyl phosphate. The reactivity of the zwitterion was much greater than that of the corresponding monoionic species. This trend was marked for 2-pyridylmethyl phosphate; 2.5 times as large as those for its 3- and 4-isomers in terms of the rate ratio k_{H_2A}/k_{HA} as listed in Table 3. This facile hydrolytic tendency of the zwitterion species of 2-pyridylmethyl phosphate was explained in terms of interamolecular proton-transfer mechanism.

The same mechanistic argument can be applied to the elucidation of the facile hydrolysis of H_2A species of 8-quinolyl phosphate in the light of its structural analogy to 2-pyridylmethyl phosphate, activation parameters, and kinetic solvent isotope effect. First, the zwitterion species of 8-quinolyl phosphate has a quinolinium proton at a suitable position for attacking the ester-oxygen atom. The phosphate moiety is constrained more effectively in the neighborhood of nitrogen due to the quinolyl ring structure than expected in 2-pyridylmethyl phosphate. The proton is, therefore, readily transferred in the transition state to the oxygen atom. The activation parameters listed in Table 4 may further qualify for this similarity of the hydrolytic pathway among the zwitterion species of 2-pyridylmethyl and 8-quinolyl phosphates. The activation energy for the H_2A species of 8-quinolyl phosphate is very close to that for the corresponding species of 2-pyridylmethyl phosphate; the former is 27.0 kcal mol^{-1} and the latter is 28.2 kcal mol^{-1}, respectively. This equality must be attributed to the similarity in their hydrolytic pathways. Also, the small and positive entropy of activation for the H_2A species of 8-quinolyl phosphate, +3, is consistent with the unimolecular nature of the transition state, and rules out the possibility of participation of a water molecule. Similar observation has been made in many hydrolysis reactions of the monoanionic phosphate species; *e.g.*, in the hydrolysis of glucose-6-,[6] isopropyl,[7] and nitrophenyl phosphates.[8]

Table 5. Kinetic solvent isotope effect in hydrolysis reactions of some organic phosphates containing an acidic group

Species	k^{H_2O}/k^{D_2O}	Reference
8-Quinolyl phosphate zwitterion	0.81	a)

Further additional evidence for the intramolecular proton-transfer mechanism is provided for the neutral zwitterion species of both 8-quinolyl and 2-pyridylmethyl phosphates in terms of the kientic solvent isotope effect as listed in Table 5. As suggested by Westheimer[9] the deuterium oxide solvent isotope effect (k^H/k^D)

3 4

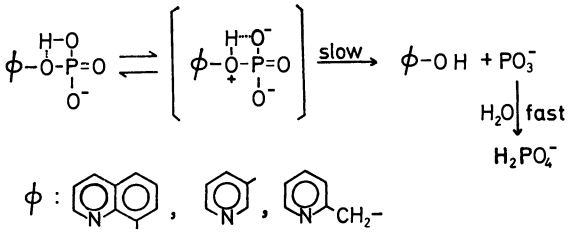
Scheme 2

reaches its maximum when the symmetric transition state is attained. On the other hand, if a transition state becomes asymmetric with respect to the position of a proton, without transfer or complete transfer of a proton to the ester oxygen (**3** or **4** in Scheme 2) in the transition state, the isotope effect (k^H/k^D) decreases markedly. A large deuterium oxide isotope effect was observed in none of the reactions including hydrolysis of salicyl phosphate dianion and methyl phosphate monoanion as shown in Table 5. Since the kinetic isotope effects for 8-quinolyl and 2-pyridylmethyl phosphates in their zwitterion forms are smaller than unity, a certain proton-transfer mechanism seems to be engaged in some analogy to A1 and A2 mechanisms. On the other hand, the small entropy of activation must eliminate the possibility of bimolecular process in the transition state. On the basis of the above arguments, the solvolysis mechanism for 8-quinolyl and 2-pyridylmethyl phosphates is closely related to A1 mechanism, even though the proton-transfer would not be as complete as expected in the A1 process. As a result, the most plausible reaction mechanism must involve the pre-equilibrium intramolecular proton-transfer (Scheme 2) in a manner similar to that suggested by Bender and Lawlor for the solvolysis of salicyl phosphate dianion.[10]

On the other hand, the value of deuterium kinetic solvent isotope effect for the zwitterion species of 3-pyridyl phosphate is approximately unity. As the molecular structure indicates, 3-pyridyl phosphate does not possess any proton suitably placed for an intramolecular hydrogen bonding. Such a kinetic isotope effect, therefore, must be attributed to another hydrolytic pathway. The data of activation parameters and of kinetic isotope effect are, however, consistent with the unimolecular and intramolecular proton-transfer mechanism. Thus, the zwitterion of 3-pyridyl phosphate seems to hydrolyze through the transition state similar to those for the monoanionic species as described below.

Hydrolysis of Monoanionic Species. 3-Pyridyl and 2-pyridylmethyl phosphates in their monoanionic forms seem to hydrolyze thourgh the same mechanistic path as proposed for the hydrolysis of methyl phosphate monoanion[11,12] in the light of the activation parameters and the kinetic solvent isotope effects.

The hydrolysis of 8-quinolyl phosphate monoanion provided relatively large activation parameters; a large positive entropy term in particular, $\Delta S^{\neq}=+22$. So far, such a large positive entropy term for solvolysis reactions does not seem to have been previously reported. We have not obtained any reliable activation parameters for the hydrolysis of 2-pyridylmethyl phosphate monoanion, which is analogous in structure to the 8-quinolyl phosphate monoanion. We are not ready to give a plausible explanation at present for the kinetic entropy effect. In any case, however, both kinetic deuterium oxide solvent isotope effect and activation entropy effect are in favor of unimolecular and intramolecular proton-transfer mechanism (Scheme 3).



Scheme 3

Hydrolysis in Lower pH Region. The hydrolysis rates of 8-quinolyl and 3-pyridyl phosphates increase in the moderately acidic region ($-\log[H^+]=1.0$—2.0) in proportion to the stoichiometric concentration of acid. This rate enhancement is primarily due to the acid-catalyzed hydrolysis of the neutral zwitterion species. The increase of electron-withdrawing power of the alcohol moiety may cause the deficiency of charge density on the ester oxygen atom, and consequently the electrophilic attack by the hydronium ion would be less favored. Contrary to what would be expected, the zwitterion species of pyridylmethyl phosphates do not undergo acid-catalyzed hydrolysis to any detectable extent in a moderately acidic region. We believe, therefore, that the favorable acid catalysis for 3-pyridyl and 8-quinolyl phosphates is due to electron-withdrawing effect caused by the pyridinium proton, which results in the weakening of P–O bond. Resonance stabilization effect given to the yielded alcohol of phenolic nature may facilitate the hydrolysis reaction.

Relative Reactivities in the Addition of Free Trichloromethyl Radicals to Substituted Styrenes. An Attempt to Separate Polar and Resonance Effects[1]

Hideki SAKURAI, Shun-ichi HAYASHI, and Akira HOSOMI
Department of Chemistry, Faculty of Science, Tohoku University, Sendai
(Received January 20, 1971)

Relative reactivities in dibenzoyl peroxide-catalyzed addition of bromotrichloromethane to nine nuclear-substituted styrenes have been investigated with unsubstituted styrene. The effect of *meta* substituents upon the relative rates was correlated with the simple Hammett equation using either σ or σ^+ constants. The relative rates of *para*-substituted styrenes, however, did not obey the simple Hammett relation, with the results best explained on the basis of polar ($\rho\sigma^+$) and resonance (E_D) terms. All *para* substituents examined increase the reactivity.

$$\log (k/k_H) = \rho\sigma^+ + E_D$$

The E_D term shows a striking correlation with log$Q$ of the corresponding *para* styrene in Alfrey-Price's Q-e scheme of free-radical copolymerization. That the polar term originates in charge-transfer interactions between the olefin and the electrophilic trichloromethyl radical and can be expressed by $\rho\sigma^+$ is further supported by the evidence that charge-transfer energies of substituted styrenes showed good correlation with σ^+. Factors influencing the reactivity have been discussed.

There are few reactions of free-radical chemistry more extensively studied than addition to olefins, yet some of the basic problems of structure and reactivity remain unresolved. The substituent effects of styrenes, which should be studied as one of the most fundamental substrates, have not yet been investigated systematically in addition reactions except in copolymerization.[2]

Martin and Gleicher[3] have reported the addition of the trichloromethyl radical to substituted allylbenzenes, 3-butenylbenzenes and other 1-olefins where they observed linear correlations of the rate data by the Hammett-Taft equation.[4] More recently, Cadogan and Sadler[5] have reported the relative reactivities of addition of trichloromethyl and thiyl radicals to variously substituted olefins; in their report it was disclosed that the rate constant rations of substituted stilbenes and α-methylstyrenes toward these radicals obey the Hammett-Brown relation.[6]

$$\log (k/k_H) = \rho\sigma^+ \quad (1)$$

However, only three substituents were chosen, *i.e.* methoxy, methyl and bromo, all at the *para* position, no *meta* or other appropriate substituent being included to check the possibility that enhanced delocalization of the odd electron in the free radical was increasing the reactivity. They noted at the same time, however, that the reactivity of 4-nitro-*trans*-stilbene was greater than that predicted from the proposed relation (eq. (1)).

Numerous studies[7] of hydrogen abstraction from substituted toluenes and other alkylbenzenes have demonstrated that the relative reactivities are generally correlated by the Hammett equation, and sometimes better by the Hammett-Brown equation. We have also reported recently examples in which the importance of polar effects was demonstrated.[8] As part of a program directed toward the relations of structure and reactivity in the homolytic process, we have investigated the relative reactivities of substituted styrenes toward the trichloromethyl radical derived from bromotrichloromethane. Our special interest was to separate the factors influencing the reactivity: both resonance and the polar effects should be operating in homolytic addition to conjugated olefins.

Results

Competitive Reactions. Addition of bromotrichloromethane to olefins by a free-radical mechanism has been well established.[3,5,9-11] Kharasch, Reinmuth, and Urry reported in their chassical study that styrene afforded the 1:1 adduct in 78% yield at 70°C using 2.3 wt% diacetyl peroxide as an initiator. Formation of a 1:1 adduct of styrene and bromotrichloromethane in photochemically induced reactions[12] and even in an uncatalyzed thermal reaction[13] have also been reported.

Kinetic investigations of the photochemical telomerization of styrene[14,15] also showed that at sufficiently low molar ratios of styrene to bromotrichloromethane, only a 1:1 adduct was formed. In our hands, the high yields of a 1:1 adduct from styrene are also confirmed under the conditions employed in competitive reactions. Therefore, any error originating in the possible comsumption of styrenes by polymerization can be ignored.

Cadogan and Sadler[5] published a very elaborate analysis to establish a valid competitive method of measuring the relattve reactivities of olefins toward thiyl and trichloromethyl radicals. We empolyed a procedure essentially the same as theirs[3,5] (see Experimental).

A reactant ratio of bromotrichloromethane: X:Y of 4:1:1 was empolyed generally in the competitive addition of the trichloromethyl radical derived from bromotrichloromethane to styrenes. Effects of variation of both the bromotrichloromethane ratios and the degree of conversion of the styrene into adduct were examined in some detail for *p*-chlorostyrene-styrene system, as shown in Table 1.

The reactivity of *p*-chlorostyrene relative to styrene was found to be fairly constant, regardless of experimental conditions. The value for k_{Cl}/k_H of 1.06±0.03 is consistent with the value 1.0, by Kharasch *et al.*[12]

b) Calculated by Eq. (2).

In Table 2 are indicated the relative reactivities of nine nuclear-substituted styrenes toward the addition of the trichloromethyl radical.

Charge-transfer Spectra of Styrenes with Tetracyanoethylene. The charge-transfer spectra were taken in dichloromethane solution at an ambient temperature with tetracyanoethylene as an electron acceptor by the standard method.[16] The results are listed in Table 3. Ionization potentials (IP) were calculated from equation 2, and are also tabulated in the last column of the Table.

$$IP = (IP)_0 + (h\nu_{CT}) - (h\nu_{CT})_0 \quad (2)$$

The charge-transfer energies are plotted against σ^+ parameters as shown in Fig. 1. A reasonably good (r=0.98)linear relationship was obtained omitting the point for *m*-methoxystyrene.

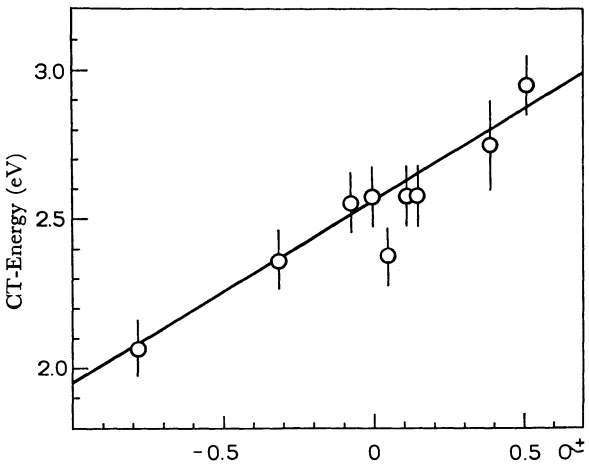

Fig. 1. Plots of charge-transfer energies of substituted styrenes-tetracyanoethylene complexes against σ^+ of the substituents.

Discussion

Figure 2 plots logarithm of the relative rates of additions against σ^+ constants. No very linear Ham-

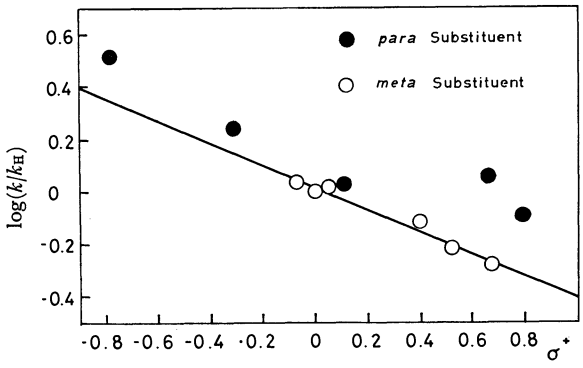

Fig. 2. Correlation of $\log(k/k_H)$ and σ^+ for addition of free trichloromethyl radicals to substituted styrenes in benzene at 80.0°.

mett correlation is found for the data as a whole, but clearly, the data for *meta*-substituted styrenes afford a nice linear relationship with σ or a somewhat better one with σ^+(*vide infra*).

$$\log (k_X/k_H) = -0.425\sigma + 0.019 \quad (r = 0.9689) \tag{3}$$

$$\log (k_X/k_H) = -0.418\sigma^+ + 0.018 \quad (r = 0.9847) \tag{4}$$

(r = correlation coefficient)

The ρ-values were calculated by the method of least squares, the negative ρ-value being consistent with the view that the trichloromethyl radical is of an electrophilic nature. In *meta*-substituted styrenes, the odd electron of the 1-phenyl-3,3,3-trichloropropyl radicals is conjugated not with the substituent but only with the π-electrons of the benzene ring. Thus further resonance stabilization of the resulting radicals due to the presence of the *meta*-substituent does not occur, and it is quite natural that the second-order substituent effect, seen in the relative rates, is polar for the *meta* series

The ρ-value obtained here is considerably lower than that of ionic reactions such as hydration of styrenes ($\rho = -3.42$ with σ^+ including *para* substituents).[17] This fact indicates that the polar effect in the addition of the trichloromethyl radicals is much smaller than in ionic reactions, although the polar effect is the crucial factor in determining the relative rates in *meta* styrenes.

The rate constant ratios of *para*-substituted styrenes, however, do not obey the Hammett relation. These data deviate considerably upward from the line of *meta* series. All *para* substituents examined increase the reactivity.

We have tried to get the relative rate for *p*-methoxystyrene, but the tendency of this monomer toward spontaneous polymerization was too high to obtain a reliable value. However, there is a close resemblance in the relative reactivity sequences of styrenes, α-methylstyrenes and *trans*-stilbene toward the trichloromethyl radical. Thus, the increase in reactivity toward the trichloromethyl radical due to the interaction of a given substituent group in the *para* position, as shown in Table 4, is the same within the limits of experimental error for these.[5] Therefore we

Table 4. Relative reactivities toward trichloromethyl radicals in olefins

a) Present study
b) Cadogan and Sadler[5]

may assume the relative rate for *p*-methoxystyrene to be around 3. 3.

It is an unlikely assumption that these *para*-substituent effects are due entirely to the stabilization of the somewhat electron-deficient free-radical in the transsition state by an inductive effect, since the reactivities of substrates containing a deactivating substituent group such as *p*-nitro- and *p*-cyanostyrene are far greater than those predicted on the basis of this polar effect alone. Therefore, the high observed relative rates for *para*-substituted styrenes are certainly due, at least in part, to the extra delocalization of the odd electron in the radicals.

Investigations of homolytic arylation by Simamura and co-workers[18] have shown that the influence of a substituent may be divided into resonance and inductive effects. Since in substitution at the *meta*-position of the substituted benzenes the conjugation of the odd electron dose not extend into the substituent group, as for *meta*-styrenes, the partial rate factors for arylations at the *meta* position are correlated only with the polar term; thus the Hammett relation holds. On the other hand, partial rate factors for *para* substitution are expressed by

$$\log (k_p/k) = \rho\sigma_p + \tau_p \tag{5}$$

where τ_p is a term for additional stabilization due to the conjgaution of the substituent group correlated with the difference of the extra resonance energy. That τ_p is a constant dependent only on the nature of the substituent group in the substrate is also demonstrated.

If it is assumed that the free-energy changes for the *para*-substituted styrense in free-radical addition can be also divided into polar and delocalization terms, with the former expressed by $\rho\sigma$ or $\rho\sigma^+$, the relative rates may be formulated as

$$\log (k_p/k_H) = \rho\sigma_p(\text{or } \rho\sigma_p^+) + E_D \tag{6}$$

where E_D is a term for additional stabilization due to extra delocailzation by the *para* substituent group.

Combining this equation with eqs. 3 and 4, numerical values of E_D are calculated with σ and σ^+ -parameters, respectively. The results are listed in Table 5.

Meanwhile, Alfrey and Price[19] proposed an empirical formula that expresses the monomer reactivity ratios, r, in free-radical copolymerization in terms of Q and e. Table 5 contains also log Q for the respective styrenes. There is a striking resemblance between the

b) Estimated values.

values of log Q and E_D calculated with σ^+.

$$\log Q_p = 1.022E_{D(\sigma^+)} - 0.067 \quad (r=0.9995) \qquad (7)$$

The correlation of log Q with the value of E_D calculated with σ is less satisfactory (r=0.7090).

Therefore, if we assume that the E_D term in eq. 6 can be given by log Q log(k_m/k_H) of *meta* styrenes and log(k_p/k_H) —log Q of *para* derivatives should express the free-energy change of the reaction corrected for extra-resonance effect of the substituents. As shown in Fig. 3, these are plotted against σ^+ to give a nicely linear relation even with the hypothetical value of *p*-methoxystyrene.

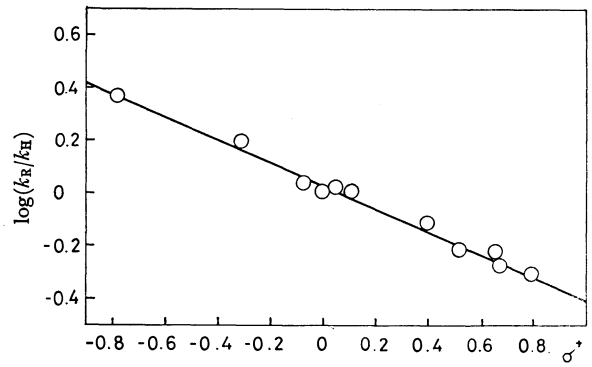

Fig. 3. Correlation of log(k_R/k_H) and σ^+ for addition of free trichloromethyl radicals to substituted styrenes in benzene at 80.0°. Reduced rates, k_R, are defined as k_m for *meta*-substituted styrenes, whereas k_p/Q for *para* series.

These findings now raise the question of why the polar term is given by $\rho\sigma^+$ instead of $\rho\sigma$ and/or why the resonance term should be log Q.

In the case of free-radical addition to olefins there is good indication that in the absence of any specific polar effects the rate of addition and the orientation are governed primarily by the localization energy of the substrate.[20] However, when an electrophilic radical such as the trichloromethyl radical is approaching to an olefinic double bond, the electrostatic interaction leads to a lowering of the potential energy of the system, and this should be an origin of the polar effect in addition reaction. It is not clear that electrophilic radicals can form a π-complex with olefin, but such interaction must originate in the charge-transfer interaction between the free radical and olefin. Therefore, the more developed the charge-transfer interaction at the transition state, the more the lowering of the potential energy of the system, and the relative extent of such a lowering effect of the free energy may be evaluated by ionization potential difference of olefins.

We have measured the charge-transfer frequencies of substituted styrene-tetracyanoethylene complex, and as seen in Fig. 1, there is a good correlation between the charge-transfer energy or ionization potential and σ^+ substituent constants. This correlation implies that the substituent effect in the charge-transfer interaction, *viz.*, the polar effect of the addition reaction, is governed by the $\rho\sigma^+$ relation.

It is established that in hydrogen abstraction reaction at non-benzylic position rates are correlated with σ, and that rates of abstraction of benyzlic and phenolic hydrogen by electron-seeking radicals follow generally the $\rho\sigma^+$ relation.[21] It should be emphasized that the latter $\rho\sigma^+$ relation is concerned with the polar effect of the substituent in stabilization of the benzylic carbonium ions and not with the extra stabilization of the benzylic radicals due to the delocalization of unpaired electron by the substituent. For addition reaction, the $\rho\sigma^+$ relation should be also recognized as a result of the charge-transfer interaction responsible for the polar effect.

The "Q and e" treatment must be regarded as empirical, but there is a good deal of evidence showing a satisfactory correlation of the localization energy with log Q of various types of vinyl monomers.[22] It is still a matter of question whether the E_D term observed in the present study can be equated to log Q. We might propose a new set of parameters equated directly to E_D. However, considering our basis for representing the polar effect as $\rho\sigma^+$, and the fact that the calculated E_D values based on the $\rho\sigma^+$ relation resemble nicely log Q, relative rates of addition of the trichloromethyl radical to substituted styrenes are best expressed by the following equation.

$$\log (k/k_H) = \rho\sigma^+ + \log Q_p \qquad (8)$$

Experimental

Materials. Bromotrichloromethane was of reagent grade purchased from Aldrich Chemical Co. and was used after distillation through a 35-cm column packed with glass helicoils. Styrene and *m*-nitrostyrene were commercial samples. *p*-Methoxy- and *m*-methoxystyrenes were prepared by decarboxylation of the corresponding cinnamic acids. *p*-Methyl-, *m*-methyl-, *p*-chloro, *m*-chloro-, *p*-bromo-, *p*-cyano-, and *m*-trifluoromethylstyrenes were obtained by dehydration of the corresponding secondary alcohols. *p*-Nitrostyrene was prepared by dehydrobromination of 2-(4′-nitrophenyl)ethyl bromide with triethanolamine. All samples were stored in a freezer and distilled under reduced pressure immediately before use. All physical constants and glpc analyses confirmed the purity of the materials used.

Procedure for Kinetic Runs. Samples of substituted

styrene (X), styrene (Y, standard olefin), and an internal standard were accurately weighed into a flask, to which 5 m*l* of bromotrichloromethane and 10 m*l* of benzene containing dibenzoyl peroxide were added. A reactant ratio of bromotrichloromethane/styrene/substituted styrene/internal standard/dibenzoyl peroxide of 4:1:1:0.75:0.012 was employed. The reaction mixture was then placed in a glass tube and degassed by repeated freezing and melting in a vacuum. The tube was then sealed in a vacuum and immersed in a constant-temperature bath kept at 80° for 0.5—1 hr. The extent of total olefin consumption varied from 30—60%. The mixtures were analyzed by glpc on a column packed with polyethylene glycol 20 M or Apiezon L using helium as a carrier gas. In each run, the amount of chloroform was negligibly small, and hardly detectable, indicative of the absence of hydrogen abstraction by the trichloromethyl radical as a side reaction.

A survey of the literature and arguments above indicated that side reactions other than addition could be ignored and that the rate determining step should be the addition of the trichloromethyl radical to the olefins. The relative rates were thus followed by the disappearance of the styrenes. The ratio of rate constants for disappearance of the two styrenes was calculated from the usual expression

$$(k_X/k_Y) = \log([X_0])/[X_f])/\log([Y_0]/[Y_f]) \quad (6)$$

where $[X_0]$ and $[X_f]$ were the initial and final concentrations of styrene X-$C_6H_4CH=CH_2$(X), respectively, and $[Y_0]$ and $[Y_f]$ have a similar significance for Y-$C_6H_4CH=CH_2$(Y).

Charge-transfer Spectra. Charge-transfer spectra were run on a Shimadzu Model SV-50A automatic recording spectrophotometer using 10 mm quartz cell. Dichloromethane was used as the solvent throughout the experiment, concentrations of tetracyanoethylene and styrenes being kept at 10^{-4}—10^{-3} and 10^{-2}—10^{-1} mol/*l*, respectively. The solutions were made up and mixed immediately before measurements. These solutions decolorize fairly rapidly, but were stable enough to record the charge-transfer maxima two or three times.

A part of the work was done at the Department of Synthetic Chemistry, Kyoto University. We thank Professor M. Kumada for his help and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1949—1951 (1971)

The Preparation and Thermal Decomposition of Alkyl Acyl Dithiol- and Trithiocarbonates. A Convenient Method for the Synthesis of Thiolesters

Hiroshi YOSHIDA, Tsuyoshi OGATA, and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received January 21, 1971)

New alkyl acyl dithiol- and trithiocarbonates (**1** and **2**) were prepared from acid chlorides and tetramethylammonium alkyl dithiol- and trithiocarbonates (**3** and **4**). **1** and **2** decomposed at around 100°C to give the corresponding thiolesters in good yields. The kinetic studies of the decomposition of **1** and **2** showed that, in *o*-dichlorobenzene, the decomposition reaction was first order and that it proceeded *via* a four-membered intramolecular cyclic mechanism.

The decomposition of mixed carbonic carboxylic anhydrides (or alkyl acyl carbonates)[1] has been known to lead to two concurrent paths, A and B:

$$ROCO_2COAr \longrightarrow \begin{cases} ROCO_2R + (ArCO)_2O & (A) \\ ROCOAr + CO_2 & (B) \end{cases}$$

In contrast to these anhydrides, *p*-nitrobenzoic alkyl thiolcarbonic anhydrides (or *p*-nitrobenzoyl *S*-alkyl monothiocarbonates) (**5**) gave solely the corresponding thiolesters and carbon dioxide.[2]

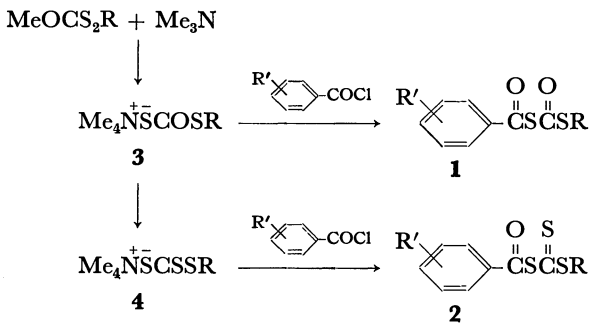
$$O_2N\text{-}C_6H_4\text{-}CO_2COSR \longrightarrow O_2N\text{-}C_6H_4\text{-}COSR + CO_2$$

However, no other system of thiolcarbonates has been studied.

The present authors have found a convenient route for the preparation of *S*-alkyl *S*-acyl dithiol- and trithiocarbonates (**1** and **2**). In this report the thermal decompostion of **1** and **2** will be described.

Results and Discussion

In the course of the studies of the reaction of xanthates with tertiary amines, tetramethylammonium alkyl



dithiol- and trithiocarbonate (**3** and **4**) were found to be prepared in good yields.[3] The action of acid chlorides on **3** and **4** at −10—0°C gave **1** and **2** (Table 1).

2h	Et	H	41—43	49.17(49.55)	4.09(4.16)		

Compounds **1** and **2** decomposed gradually at temperatures above their melting points and vigorously at about 160°C, with the evolution of gases. The decomposition products were analyzed by vpc with known samples (Table 2). These results indicate that **1** and **2** decompose solely by sulfur-acyl bond fission to yield the corresponding thiolesters (path B).

Table 2. Thermal decomposition products of **1** and **2** without solvent

2h	110—120	87	4	CS_2

Table 3. First-order rate constants for the thermal decomposition of **1** and **2** in *o*-dichlorobenzene

Compound	Temp.(°C)	$k\times10^4$ sec^{-1}
1a	100.0	1.85
	96.0	1.25
	90.1	0.74
1b	100.0	1.35
1c	100.0	1.38
1d	100.0	1.06
1e	100.0	0.76
2a	105.8	2.38
	100.0	1.45
	96.0	1.02
2b	100.0	1.30
2c	100.0	1.05
2d	100.0	1.14
2e	105.8	2.23
	100.0	1.36
	94.7	0.83
2f	100.0	1.09
2g	100.0	0.887

The decomposition of the carbonates **1** and **2** in *o*-dichlorobenzene gave good first-order constants (k) up to 75% completion, as followed by NMR spectroscopy, and the constants were independent of the concentration of **1** and **2** at 0.5—3 weight% (Table 3). At these concentrations the crossed dialkyl dithiol- and trithiocarbonate were found to be produced in yields of less than 1%. Thus the decomposition of **1** and **2** seems to proceed practically *via* an intramolecular mechanism.

Compound **5** (R=*i*-Pr and *t*-Bu) has been suggested[2] to decompose *via* an intramolecular cyclic mechanism judging from activation parameters and the small solvent effect on the reaction. However the effect of the substituents of the acyl group has not yet been made clear.

Table 4. Activation parameters for the decomposition of **1** and **2** in *o*-dichlorobenzene

Compound	ΔE(kcal/mol)	ΔS(e. u.)
1a	24.0	−9.9
2a	23.8	−12.6
2e	24.5	−10.8
5(R=*t*-Bu)[a]	30.3	−5.1
5(R=*i*-Pr)[a]	30.6	−3.7

a) Taken from Ref. 2.

There are no marked difference in the activation parameters between **1** and **2**, as Table 4 shows, but the values considerably deviate from those of **5**.[2] This observation may be attributed to the nature of the bridge atoms, sulfur (**1** and **2**) and oxygen (**5**). The difference in the activation energies may come from the fact that, in bond energies, C–O>C–S. In going from the ground state to the transition state, a relatively larger loss in degree of freedom would occur in the **1** and **2** system than in the **5** system due to desolvation (bond length, C–S>C–O). This is consistent with the larger loss of entropy in the **1** and **2** system than in the **5** system. The samll negative values of the activation entropy seem to indicate that **1** and **2** decompose *via* a four-membered cyclic mechanism similarly to **5**.

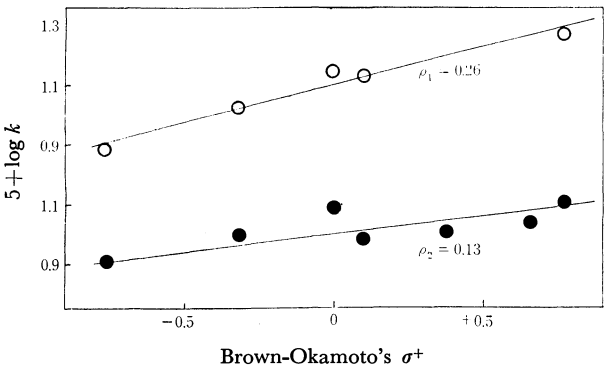

Fig. 1. Hamett relationship for the decomposition of **1** and **2** in *o*-dichlorobenzene at 100°C.
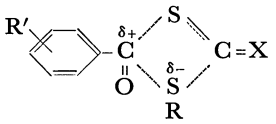
○ for **1**. ● for **2**.

Although an ordinary Hammett's plot of log*k* *vs* σ did not give a linear relationship, plots of log*k* *vs*. Brown-Okamoto's σ^+ gave relatively good straingh lines (Fig. 1). The small positive ρ values seem to indicate that, in the transition states of the decomposition of **1** and **2**, a partial charge on the reacting sites is not highly developed, and that the *S*-alkyl group, as a nucleophile, attacks the carbonyl carbon of the acyl group. The difference in ρ values, ρ_1 and ρ_2, may then, be attributed to the difference in nucleophilicity of *S*-alkyl groups of **1** and **2**, resulting from the difference in mesomeric effects of the carbonyl and the thiocarbonyl groups.

Thus the transition state may be pictured as in **6** with a partial negative charge on the sulfur, and a partial positive charge on the carbonyl carbon.



6 (X=O or S)

Experimental

Materials. Tetramethylammonium alkyl dithiol- and trithiocarbonate (**3** and **4**) were prepared according to the previously-described method.[3] To a dry ether suspension of **3** or **4**, we added, drop by drop at −10—0°C, an ether solution of acid chloride. After the removal of the tetramethyl ammonium chloride, the solution was concentrated *in vacuo*. The residual **1** or **2** was recrystalized from ligroin for **1** or from carbon tetrachloride for **2**. The physical constants of the products are collected in Table 1.

Thermal Decomposition of 1 and 2 without a Solvent. (*Table* 2). This reaction was carried out in a test tube at 100—160°C. At higher temperatures, a vigorous evolution of gas was observed. The decomposition products were analysed by vpc using known samples.

Kinetic Studies of the Decomposition of 1 and 2. Kinetic runs were carried out at a constant temperature in an oil bath. A solution of **1** or **2** in *o*-dichlorobenzene was sealed in an NMR sample tube. The rate was followed at suitable time intervals by analyzing the NMR spectra of *S*-methyl groups using a Hitachi Parkin-Elmer R-20 60 MHz spectrometer.

The authors wish to thank Mr. K. Adachi, K. Ishii, K. Unno, and S. Ishizuka for their assistance in the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1951—1956 (1971)

Some Oxidation and Reduction Products of 4-Acetyltropolone and Its Methyl Ethers

Tetsuo NOZOE, Kahei TAKASE,* Kohei SHIMIZU, and Masafumi YASUNAMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-2-chome, Sendai

(Received February 9, 1971)

The chemical properties of the acetyl side-chain of 4-acetyltropolone and its methyl ethers in relation to some oxidizing and reducing reagents were examined. The selenium-dioxide oxidation of one of the methyl ethers afforded a glyoxyloyl derivative in its hydrate form. The catalytic reduction of 4-acetyltropolone gave a mixture of 4-(1-hydroxyethyl)- and 4-ethyltropolones. The reduction of two isomeric methyl ethers with sodium borohydride gave 4-(1-hydroxyethyl)-2-methoxy- and 6-(1-hydroxyethyl)-2-methoxytropones respectively, from which two isomeric methyl ethers of 4-ethyltropolone were prepared in pure states.

Considering the reactivity of the acetyl group, 4-acetyltropolone (I), which has been obtained by the oxidation of 4-isopropenyltropolone (β-dolabrin),[1] should be expected to be one of the most important materials for the synthesis of troponoid compounds, since no acyltropolone except for formyltropolones[2] has yet been prepared by the direct acylation of tropolones because of the impossibility of the Friedel-Crafts

reaction and the related acylation of tropolones.[3] The chemical properties of I, especially those of its acetyl side-chain have been investigated for some reactions — the condensation with arylaldehyde,[1] the Huang-Minlon reduction,[4] the Schmidt reaction,[5] and the ketal formation.[6] The present paper will describe the syntheses of some alkyl ethers of I and the results of the examination of the chemical properties of the acetyl side-chain of I and its methyl ethers in relation to some oxidizing and reducing reagents.

Results and Discussion

It is known that the tropolone nucleus is broken oxidatively by oxidizing reagents, such as potassium permanganate or chromic acid.[3] On the other hand, although selemium dioxide acts at the tropolone nucleus to give diselenide compounds,[7] this reagent is known to oxidize effectively the methyl side-chain of the methyl ethers of 4-methyltropolone, giving formyl derivatives.[2a] Now, some alkyl ethers of 4-acetyltropolone (I) have been synthesized for the first time and their oxidation with selenium dioxide has been examined.

Because of the highly mobile tautomerism in the tropolone nucleus,[3] tropolones which have substituents at the unsymmetric positions generally should give two kinds of isomeric ethers on *O*-alkylation. The same is true in the case of 4-acetyltropolone (I). Thus, the treatment of silver salt of I with methyl iodide gave a mixture of two isomeric methyl ethers, from which 4-acetyl-2-methoxy- (IIa) and 6-acetyl-2-methoxytropones (IIb) respectively were isolated in crystalline forms. The structures of these ethers were established from the infrared spectral data, showing the characteristic absorptions[8] due to the out-of-plane deformations at 834 and 785 cm^{-1} respectively. The chemical evidence to be presented later also supports these structures. The methylation of I with diazomethane was very complicated; the use of an excess amount of the reagent gave a resinous product, whereas the use of an equimolar amount of the reagent afforded a mixture of IIa and IIb. Two isomeric ethyl ethers, 4-acetyl-2-ethoxy- (IIIa) and 6-acetyl-2-ethoxytropones (IIIb), were also obtained by the treatment of silver salt of I with ethyl iodide. The infrared spectra of these ethers show the characteristic absorptions[8] at 817 and 784 cm^{-1} respectively. Furthermore, isopropyl ethers of I were obtained by the treatment of silver salt of I with isopropyl iodide, but only an isomer, 4-acetyl-2-isopropoxytropone (IVa), was isolated in a crystalline form. Its infrared spectrum shows the characteristic absorption[8] at 825 cm^{-1}. Another isomer, 6-acetyl-2-isopropoxytropone (IVb), was not isolated, but its existence was shown from an absorption at 790 cm^{-1}[8] in the infrared spectrum of the reaction mixture. In the case of the benzylation of I with benzyl chloride, a benzyl ether was isolated in a crystalline form, but its structure could not be determined because of the difficulty in assigning the characteristic absorption due to the out-of-plane deformation in the infrared spectrum.

The oxidation of IIa with selenium dioxide in aqueous dioxane gave a compound (V), $C_{10}H_{10}O_5$. The ultraviolet absorption spectrum of V is very similar to that of IIa. The infrared spectrum shows absorptions at 3360, 1096, 1057, and 1037 cm^{-1} associable with the hydroxyl group, in addition to an absorption at 1704 cm^{-1} corresponding to the carbonyl group. From these spectral data, as well as the results of the elementary analysis, V was assigned the structure of 4-(ω,ω-dihydroxyacetyl)-2-methoxytropone, a hydrate form of 4-glyoxyloyl-2-methoxytropone. The further oxidation of V with metaperiodic acid afforded 4-carboxy-2-methoxytropone (VI),[2c] which gave 4-carboxytropolone[2b,9] on hydrolysis with a sodium hydroxide solution. This finding shows that the acetyl side-chain of IIa was oxidized effectively with selenium dioxide. The hydrate, V, was so stable that it did not show any change upon heating at 110°C *in vacuo*. This stability of V is probably due to the inductive effect of the electron-withdrawing tropolone nucleus. In the case of the other isomeric ether, IIb, the treatment with selenium dioxide deposited selenium powder, but no identifiable product could be isolated.

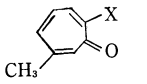
It is known that the tropolone nucleus generally resists catalytic hydrogenation with the palladium-carbon catalyst.[3] The same is true in the case of I. Thus, under similar conditions, the tropolone nucleus of I was not hydrogenated; only the acetyl group was hydrogenated, giving a mixture of 4-(1-hydroxyethyl)- (VII) and 4-ethyltropolone (VIII).[4] The ultraviolet spectrum of VII is similar to that of tropolone, and the infrared spectrum shows an absorption at 3370 cm^{-1} due to the hydroxyl group. The dehydroxylation of VII to VIII was performed effectively by treatment with iodine and red phosphorous in acetic acid. 4-(1-Chloroethyl)tropolone (IX) was derived from VII by treatment with thionyl chloride in the presence of pyridine. The chloro substituent in IX was very sensitive to nucleophilic attack; that is, the treatment of IX with potassium hydroxide in methanol or ethanol afforded 4-(1-methoxyethyl)-(Xa) and 4-(1-ethoxyethyl)-tropolones (Xb) respectively, whose structures were determined from their NMR spectral data. The azocoupling of VII with *p*-toluenediazonium chloride gave an azo compound (XI), which then afforded a 5-hydroxy-6(2*H*)-cyclohepta[*c*]pyrazolone derivative (XII)[10] by cyclization when heated over its melting point or when heated in an alcoholic solution in the presence of hydrochloric acid.

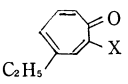
The reaction of I with sodium borohydride gave water-soluble products, but no identifiable compound was isolated from the reaction mixture; this may be a mixture of boron-complexes of the reduction products. On the other hand, the reduction of the methyl ethers, IIa and IIb, with sodium borohydride in aqueous methanol gave the corresponding alcohols, (XIIIa) and (XIIIb) respectively, in good yields. The infrared spectra show absorptions due to the hydroxyl groups at 3360 and 3380 cm^{-1} respectively, and no absorption corresponding to an acetyl carbonyl. On alkaline hydrolysis, both XIIIa and XIIIb gave the same compound, VII, in good yields. Consequently, in oredr to prepare VII conveniently from I, a mixture of the methyl ethers, IIa and IIb, without the separation of each component, could be treated with sodium borohydride and then hydrolyzed with alkali.

The methylation of 4-ethyltropolone (VIII) with diazomethane gave a mixture of two isomeric methyl ethers, 4-ethyl-2-methoxy-(XIVa) and 6-ethyl-2-methoxytropone (XIVb), but the separation of each component from this mixture could not be achieved effectively. However, XIVa and XIVb could be prepared in pure states from XIIIa and XIIIb respectively as follows. The treatment of XIIIa or XIIIb with thionyl chloride in the presence of pyridine gave 4-(1-chloroethyl)-2-methoxy- (XVa) or 6-(1-chloroethyl)-2-methoxytropones (XVb) respectively. Their reductive dechlorinations afforded XIVa and XIVb respectively in good yields.

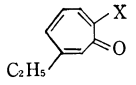
The structures of two series of methyl ethers, IIa, XIIIa, XIVa, and XVa, and IIb, XIIIb, XIVb, and XVb, described above have been presumed only on the basis of a consideration of the infrared spectral data. Now, some chemical evidence for the structural proof of these ethers will be presented. It is known that the reaction of 2-methoxytropones and hydrazine proceeds in the mode of the normal substitution; for example, 2-methoxy-6-methyltropone (XVI) is known to react with hydrazine, giving 2-hydrazino-6-methyltropone (XVII).[11] Moreover, it has now been observed that 6-methyl-2-(*p*-tolylsulfonyloxy)tropone (XVIII)[12] also reacts with hydrazine in a similar manner, giving the same hydrazino compound, XVII.



XVI: X=OCH_3
XVII: X=$NHNH_2$
XVIII: X=OTs



XIXa: X=OTs
XXa: X=$NHNH_2$



XIXb: X=OTs
XXb: X=$NHNH_2$

This close relation in the reaction mode between 2-methoxytropone, XVI, and 2-(*p*-tolylsulfonyloxy)-tropone, XVIII, could also be applicable to the structural correlation between the methyl ethers, XIVa and XIVb, and the *p*-tolylsulfonyl derivatives, (XIXa) and (XIXb), of 4-ethyltropolone (VIII) (the structures of the latter have been established).[13] Thus, on treatment with hydrazine, XIVa and XIXa gave the same hydrazino compound (XXa), whereas XIVb and XIXb gave another kind of the same hydrazino compound (XXb). From these facts, the structures of the methyl ethers, XIVa and XIVb, and, consequently, the structures of IIa and IIb were determined by chemical means.

Experimental

All the melting points are uncorrected. The ultraviolet absorption spectra were determined on a Beckman DU spectrophotometer, and the infrared spectra were recorded on a Shimadzu IR-27 infracord apparatus.

Silver Salt of 4-Acetyltropolone (I). Into a solution which had been prepared by the neutralization of I (5.0 g) in water (20 m*l*) with a 0.2 N potassium hydroxide solution (*ca.* 150 m*l*), a solution of silver nitrate (5.1 g) in water (20 m*l*) was stirred. A reddish-orange silver salt immediately precipitated; it was collected by filtration, washed with water, and dried *in vacuo*. Yield, 8.1 g.

Found: C, 38.27; H, 2.44%. Calcd for $C_9H_7O_3Ag$: C, 38.88; H, 2.60%.

4-Acetyl-2-methoxytropone (IIa) and 6-Acetyl-2-methoxytropone (IIb). a) To a suspension of silver salt (8.1 g) of I in dry benzene (150 m*l*), methyl iodide (10 g) was added, and then the mixture was refluxed for 1.5 hr. The silver

iodide thus formed was filtered off, and the benzene filtrate was washed with a 5% sodium hydrogen carbonate solution. After drying over anhydrous sodium sulfate, the evaporation of the solvent left crystals (2.5 g), mp 79—87°C. The sodium hydrogen carbonate solution was extracted with chloroform; the subsequent evaporation of the solvent gave further crops of crystals (2.8 g), mp 76—85°C. The fractional recrystallization of these crystals from ethyl acetate gave IIa as light brown micro-crystals, mp 122.5°C, and IIb as yellow needles, mp 107°C.

Found for IIa: C, 67.64; H, 5.33%. Found for IIb: C, 67.38; H, 5.39%. Calcd for $C_{10}H_{10}O_3$: C, 67.40; 5.66%. UV (MeOH) for IIa: λ_{max} nm (log ε); 250 (4.46), 309 (3.69), 322 (3.68), 369 (3.26). UV (MeOH) for IIb: λ_{max} nm (log ε); 245 (4.44), 310 (3.77), 372 (3.68).

b) To a stirred suspension of I (328 mg) in ether (5 m*l*), we added a slight excess of an ethereal solution of diazomethane at 0—5°C. The crystals thus formed were collected by filtration, affording a mixture (258 mg) of IIa and IIb.

4-Acetyl-2-ethoxytropone (IIIa) and 6-Acethyl-2-ethoxytropone (IIIb). Silver salt (1.36 g) of I was treated with ethyl iodide (1.56 g) in a manner similar to that described above; the crystals (901 mg), mp 55—62°C, thus obtained were fractionally recrystallized from ether, giving IIIa as yellow needles, mp 88.5—89°C and IIIb as yellow needles, mp 91—92°C.

Found for IIIa: C, 68.52; H, 6.01%. Found for IIIb: C, 68.69; H, 6.05%. Calcd for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%. UV (MeOH) for IIIa: λ_{max} nm (log ε); 250 (4.52), 310 (3.74), 370 (3.82). UV (MeOH) for IIIb: λ_{max} nm (log ε); 247 (4.49), 315 (3.87), 377 (3.74).

4-Acetyl-2-isopropoxytropone (IVa) and 6-Acetyl-2-isopropoxytropone (IVb). Silver salt (2.71 g) of I was treated with isopropyl iodide (2.2 g) in a manner similar to that described above, and the oily mixture (1.32 g) thus obtained was dissolved in ether, passed through an alumina column, and eluted with ether. The fractions crystallized were collected and recrystallized from petroleum ether, giving IVa as yellow prisms, mp 71—72°C.

Found: C, 69.91; H, 6.80%. Calcd for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84%. UV (MeOH): λ_{max} nm (log ε); 252 (4.52), 310 (3.78), 325 (3.76), 370 (3.84).

The mother liquor of recrystallization did not crystallize, but its infrared spectrum shows an absorption at 790 cm^{-1}, corresponding to the characteristic absorption[8] for 6-acetyl-2-isopropoxytropone (IVb).

Benzyl Ether of I. Silver salt (820 mg) of I was treated with benzyl chloride (460 mg) in a manner similar to that described above; the crystals (230 mg) thus obtained were recrystallized from ethyl acetate, giving benzyl ether as orangish yellow prisms, mp 177°C.

Found: C, 75.85; H. 5.39%. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55%. UV (MeOH): λ_{max} nm (log ε); 237 (4.44), 320 (2.83).

4-(ω,ω-Dihydroxyacetyl)-2-methoxytropone (V). A mixture of IIa (712 mg) and selenium dioxide (490 mg) in dioxane (3 m*l*) containing a small amount of water (0.1 m*l*) was refluxed for 5 hr. The selenium thus deposited was filtered off, and the filtrate was allowed to stand at room temperature. The crystals thus formed were collected by filtration and recrystallized from dimethylformamide, giving V as fine, organish-yellow leaflets, mp 144—146°C.

Found: C, 56.93; H, 4.48%. Calcd for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%. UV (MeOH): λ_{max} nm (log ε); 248 (4.41), 322 (3.76), 350 (3.77).

4-Carboxy-2-methoxytropone (VI). To a suspension of V (105 mg) in a mixture of ethanol (4 m*l*) and water (0.5 m*l*), metaperiodic acid dihydrate (125 mg) was added. After being stirred for 3 hr at room temperature, the mixture was diluted with water and allowed to stand at room temperature. The crystals thereby formed were collected by filtration to give crude VI (19 mg). The extraction of the filtrate with ethyl acetate gave further crops of VI (77 mg). Recrystallization from 25% aqueous methanol afforded light brown micro-crystals, mp 245°C. The melting point reported[2c] is 254°C.

Found: C, 60.04; H, 4.57%. Calcd for $C_9H_8O_4$: C, 60.00; H, 4.48%. UV (MeOH): λ_{max} nm (log ε); 245 (4.45), 323 (3.82), 360 (3.83). The infrared spectrum shows sbsorptions at 2700—2500 and 1721 cm^{-1} (carboxyl).

The hydrolysis of VI by warming it with a dilute sodium hydroxide solution gave 4-carboxytropolone, mp 215°C. The melting point reported [2b] is 217°C.

Catalytic Reduction of 4-Acetyltropolone (I). A solution of I (3.0 g) in methanol (50 m*l*) was shaken, in the presence of 5% palladium-carbon, under a hydrogen atmosphere; 850 m*l* of hydrogen gas were consumed in a period of 15 hr at 18°C. The removal of the palladium catalyst and of the solvent left an oily material, to which a small amount of benzene was added; the mixture was then allowed to stand. The crude crystals (1.07 g), mp 85—89°C, thereby formed were collected by filtration. Recrystallization from ethyl acetate afforded 4-(1-hydroxyethyl)tropolone (VII) as pale yellow prisms, mp 97—98°C.

Found: C, 65.30; H, 6.21%. Calcd for $C_9H_{10}O_3$: C, 65.05; H, 6.07%. UV (MeOH): λ_{max} nm (log ε); 240 (4.45), 322 (3.86), 350 (3.77).

The filtrate was passed through a silica gel column and eluted with benzene. The removal of the solvent from the effluent gave an oily substance (600 mg). Distillation *in vacuo* and then recrystallization from petroleum ether gave 4-ethyltropolone (VIII) as colorless rhombic prisms, mp 42—43°C.

4-Ethyltropolone (VIII) from 4-(1-Hydroxyethyl)tropolone (VII). A mixture of VII (160 mg), iodine (50 mg), and red phosphorous (150 mg) in acetic acid (2 m*l*) containing a small amount of water (0.5 m*l*) was refluxed for 4 hr. A precipitate was filtered off, and the filtrate was diluted with water and then extracted with chloroform The removal of the solvent left an oily substance, which was distilled *in vacuo* and crystallized on being allowed to stand, giving VIII (130 mg). Recrystallization from petroleum ether gave colorless rhombic prisms, mp 42—43°C.

4-(1-Chloroethyl)tropolone (IX). To a solution of VII (340 mg) and pyridine (160 mg) in dry dioxane (3 m*l*), we added a solution of thionyl chloride (400 m*l*) in dry dioxane (2 m*l*); the mixture was then stirred for 5 hr at room temperature. After the removal of the solvent, the residue was recrystallized from petroleum ether, giving IX (260 mg) as yellow needles, mp 82—83°C.

Found: C, 58.53; H, 4.65%. Calcd for $C_9H_9O_2Cl$:C, 58.55; H, 4.91%. UV (MeOH): λ_{max} nm (log ε); 341 (4.48), 324 (3.85), 355 (3.75).

4-(1-Methoxyethyl)tropolone (Xa). A solution of IX (185 mg) in methanol (2 m*l*) containing a 6 N potassium hydroxide solution (1 m*l*) was refluxed for 2.5 hr. The reaction mixture was then diluted with water (20 m*l*), acidified with 6 N hydrochloric acid, extracted with benzene, and dried over anhydrous sodium sulfate. The evaporation of the solvent left crystals (185 mg) which were subsequently recrystallized from cyclohexane, giving Xa (150 mg) as colorless prisms, mp 65—66°C.

Found: C, 66.91; H, 6.41%. Calcd for $C_{10}H_{12}O_3$; C, 66.65; H, 6.71%. UV (MeOH): λ_{max} nm (log ε); 238 (4.46),

325 (4.17), 367 (3.98). NMR ($CDCl_3$): δ ppm; 1.42 (3H,d, J=6.5 Hz, $C\underline{H}_3$–CH), 3.27 (3H, s, CH_3O–), 4.20 (1H, q, J=6.5 Hz, CH_3–$C\underline{H}$–O), 6.93-7.46 (4H, m, ring protons).

4-(1-Ethoxyethyl)tropolone (Xb). To a solution of IX (550 mg) in ethanol (2 m*l*) we added a potassium hydroxide solution (6 m*l*) which had been prepared by dissolving potassium hydroxide (10 g) in a mixture of water (10 m*l*) and ethanol (40 m*l*), and then the mixture was refluxed for 2 hr. The reaction mixture was diluted with water (10 m*l*), acidified with 6 N hydrochloric acid, extracted with chloroform, and dried over anhydrous sodium sulfate. The evaporation of the solvent left a light brown, oily material (270 mg). This was dissolved in ether and chromatographed on a silica gel column. The first fraction, when eluted with ether, gave Xb (193 mg), mp 58—62°C. The second fraction gave the same compound (50 mg), mp 56—60°C. Recrystallization from cyclohexane afforded colorless prisms, mp 63—64°C.

Found: C, 68.00, H, 7.06%. Calcd for $C_{11}H_{14}O_3$, C, 68.02. H, 7.27%. UV (CH_3OH), λ_{max} nm (log ε); 238 (4.45), 325 (3.97), 365 (3.75). NMR ($CDCl_3$): δ ppm, 1.34 (3H, t, J=7.0 Hz, $C\underline{H}_3$–CH_2), 1.42 (3H, d, J=6.5 Hz, $C\underline{H}_3$–CH), 3.42 (2H, q, J=7.0 Hz, $CH_3C\underline{H}_2$–O–), 4.34 (1H, q, J=6.5 Hz, CH_3–$C\underline{H}$–O), 6.93—7.46 (4H, ring protons).

4-(1-Hydroxyethyl)-5-(p-tolylazo)tropolone (XI). To a solution of VII (160 mg) in pyridine (0.7 m*l*) we added a solution of *p*-toluenediazonium chloride which had been prepared by the diazotization of a solution of *p*-toluidine (120 mg) in water (1 m*l*) containing a 6N hydrochloric acid (0.5 m*l*) with a solution of sodium nitrite (80 mg) in water (0.5 m*l*), with stirring under cooling with ice-water. Water was added to the mixture, and the crystals thereby deposited were collected by filtration and recrystallized from benzene, giving XI (240 mg) as orange needles. These needles evolved gas at 123—126°C and melted at 202—204°C.

Found: C, 67.19; H, 5.34; N, 9.61%. Calcd for $C_{16}H_{16}O_3N_2$: C, 67.59; H, 5.67; N, 9.85%. UV (MeOH): λ_{max} nm (log ε); 232 (4.37), 300 (3.99), 397 (4.41).

5-Hydroxy-3-methyl-2-(p-tolyl)-6(2H)-cyclohepta[c]pyrazolone (XII). A mixture of XI (100 mg) in ethanol (10 m*l*) containing 6N hydrochloric acid (0.3 m*l*) was refluxed for 2 hr and then allowed to cool, giving XII (70 mg) as pale yellow needles, mp 203—204°C.[10]

4-(1-Hydroxyethyl)-2-methoxytropone (XIIIa). To a solution of IIa (160 mg) in 10% aqueous methanol (2 m*l*), sodium borohydride (40 mg) was added; the mixture was stirred for 1 hr at room temperature, and then diluted with water and extracted with ethyl methyl ketone. The extract was dried over anhydrous sodium sulfate; the subsequent evaporation of the solvent left crystals (150 mg), mp 118—120°C. Recrystallization from ethyl acetate gave XIIIa as colorless micro-needles, mp 121—122°C.

Found: C, 66.60; H, 6.42%. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%. UV (MeOH): λ_{max} nm (log ε); 241 (4.46), 320 (3.88), 345 (3.92).

6-(1-Hydroxyethyl)-2-methoxytropone (XIIIb). The treatment of IIb (270 mg) in a manner similar to that described above gave XIIIb (180 mg) as colorless micro-needles, mp 139°C.

Found: C, 66.25; H, 6.43%. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%. UV (MeOH): λ_{max} nm (log ε); 239 (4.43), 319 (3.70).

Hydrolysis of XIIIa and XIIIb. A solution of XIIIa (180 mg) in a 2N potassium hydroxide solution (2 m*l*) was refluxed for 1 hr; then it was diluted with water, acidified with 6N hydrochloric acid, and extracted with ethyl methyl ketone. The evaporation of the solvent gave VII (160 mg), mp 93—96°C. A similar treatment of XIIIb (180 mg) gave VII (160 mg), mp 95—97°C.

4-(1-Chloroethyl)-2-methoxytropone (XVa). To a solution of XIIIa (360 mg) in chloroform (3 m*l*) containing pyridine (180 mg), a solution of thionyl chloride (260 mg) in chloroform (1 m*l*) was added, drop by drop, at room temperature. After being stirred for 3 hr and then allowed to stand overnight, the mixture was washed with water and dried over anhydrous sodium sulfate. The evaporation of the solvent gave an oily XVa (311 mg). A sample for the elementary analysis was prepared by distillation *in vacuo*.

Found: C, 59.98; H, 5.36%. Calcd for $C_{10}H_{11}O_2Cl$: C, 60.46; H, 5.58%. UV (MeOH): λ_{max} nm (log ε); 243 (4.26), 330 (3.72).

6-(1-Chloroethyl)-2-methoxytropone (XVb). The treatment of XIIIb (180 mg) in a manner similar to that described above gave XVb (158 mg). Recrystallization from ethyl acetate gave colorless prisms, mp 85—86°C.

Found: C, 60.90; H, 5.39%. Calcd for $C_{10}H_{11}O_2Cl$: C, 60.46; H, 5.58%. UV (MeOH): λ_{max} nm (log ε); 242 (4.38), 325 (3.76).

4-Ethyl-2-methoxytropone (XIVa). A mixture of XVa (202 mg), 5% palladium-carbon (10 mg), and sodium acetate (90 mg) in methanol (6 m*l*) was subjected to hydrogenolysis at room temperature. The reaction was stopped when an equimolar amount of hydrogen gas had been uptaken. After the removal of the catalyst and of the solvent, the mixture was diluted with water and extracted with chloroform. The organic layer was dried over anhydrous sodium sulfate, and the solvent was evaporated, giving XIVa (168 mg) as a pale yellow oil. A sample for the elementary analysis was prepared by distillation *in vacuo*.

Found: C, 69.67; H, 7.10%. Calcd for $C_{10}H_{12}O_2 \cdot \frac{1}{2}H_2O$: C, 69.34; H, 7.57%. UV (MeOH): λ_{max} nm (log ε); 242 (4.38), 325 (3.76).

6-Ethyl-2-methoxytropone (XIVb). A mixture of XVb (90 mg), 5% palladium-carbon (20 mg), and sodium acetate (45 mg) in methanol (5 m*l*) was treated as has been described above, giving XIVb (73 mg). Recrystallization from petroleum ether afforded colorless needles, mp 53—55°C.

Found: C, 73.26; H, 7.10%. Calcd for $C_{10}H_{12}O_2$; C, 73.14; H, 7.37%. UV (MeOH): λ_{max} nm (log ε); 239 (4.44), 325 (3.86).

Picrate: Yellow crystals (from ethanol); mp 140—141°C.

Found: C, 48.70; H, 3.77; N, 10.80%. Calcd for $C_{16}H_{15}O_9N_3$: C, 48.86; H, 3.84; N, 10.68%.

2-Hydrazino-6-methyltropone (XVII). *a) From 2-Methoxy-6-methyltropone (XVI)*: A mixture of XVI (300 mg) and 80% hydrazine hydrate (250 mg) in water (0.5 m*l*) was heated for 5 min at 100°C, and then allowed to cool, giving XVII (250 mg) as yellow needles, mp 123—124°C. The melting point reported[11] is 134—135°C.

b) From 6-Methyl-2-(p-tolylsulfonyloxy)tropone (XVIII): A similar treatment of XVIII (290 mg) with 80% hydrazine hydrate (250 mg) in methanol gave yellow needles, mp 123—124°C, which were identical with XVII.

4-Ethyl-2-hydrazinotropone (XXa). *a) From 4-Ethyl-2-(p-tolylsulfonyloxy)tropone (XIXa)*: A mixture of XIXa (218 mg) and 80% hydrazine hydrate (1 m*l*) in methanol (1 m*l*) was heated for 10 min at 100°C. The mixture was diluted with water and extracted with ether, and then the ether solution was passed through an alumina column. The evaporation of the solvent from the effluent gave XXa (100 mg) as a reddish oil.

Found: C, 65.80; H, 7.25; N, 17.42%. Calcd for $C_9H_{12}ON_2$: C, 65.83, H, 7.37; N, 17.06%.

b) From 4-Ethyl-2-methoxytropone (XIVa): A similar treatment of XIVa (40 mg) with 80% hydrazine hydrate (0.5 m*l*) gave a reddish oily material (35 mg) which was identical with XXa.

6-Ethyl-2-hydrazinotropone (XXb). a) From 6-Ethyl-2-(p-tolylsulfonyloxy)tropone (XIXb): A mixture of XIXb (218 mg) and 80% hydrazine hydrate (1 m*l*) in methanol (1 m*l*) was treated as has been described above. The crystals (16 mg), mp 64—67°C, thus obtained were recrystallized from ether, giving XXb as orange needles, mp 71—72°C.

Found: C, 65.72; H, 7.18; N, 16.86%. Calcd for $C_9H_{12}O$-N_2: C, 65.83; H, 7.37; N, 16.06%.

b) From 6-Ethyl-2-methoxytropone (XIVb): A similar treatment of XIVb (20 mg) with 80% hydrazine hydrate gave yellow crystals (18 mg), mp 69—72°C. Recrystallization from ether gave yellow prisms, mp 71—72°C, which were identical with XXb.

The authors wish to thank the Takasago Perfumery Co., Ltd., for its assistance in the preparation of the β-dolabrin.

A Novel Cyclodimerization of Butadiene. A Synthetic Route to 2-Methylenevinylcyclopentane

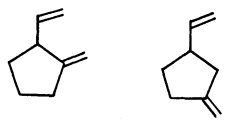
Jitsuo KIJI, Kazuo MASUI,* and Junji FURUKAWA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received February 12, 1971)

In the presence of a controlled amount of alcohol, the dimerization of butadiene to produce 2-methylenevinylcyclopentane has been shown to occur by means of several nickel catalysts. The most effective nickel catalysts are: (1) $(Bu_3P)_2NiX_2$ (X=Cl and Br) and organolithium, (2) (*o*-tolyl)$NiX(PEt_3)_2$ (X=Cl, Br, and I), and (3) π-allylnickel bromide and tri-*n*-butylphosphine. A detailed study of the role of alcohol during the reaction by the arylnickels is presented. In the presence of butadiene, the aryl-nickel bond of (*o*-tolyl)$NiX(PEt_3)_2$ is reductively cleaved by methanol to give toluene, and then the dimerization of butadiene occurs. With CH_3OD as the reducing reagent, toluene is not deuterated, but with CD_3OD the aromatic ligand is deuterated on the carbon originally bonded to nickel to give monodeuterotoluene.

The dimerizations of butadiene in the presence of transition metals to cyclic or linear products have been extensively studied in the last decade by many workers.[1] The principal products are isomeric *n*-octatrienes, methylheptatrienes, 4-vinylcyclohexene, 1,5-cyclooctadiene, and 1,2-divinylcyclobutane. Until now, however, no effective catalysts have been reported to convert butadiene into a five-membered cyclic dimer, 2-methylenevinylcyclopentane (I) or 3-methylenevinylcyclopentane (II), except for the works of Müller[2] and Feldman,[3] who isolated the five-membered cyclic dimers of butadiene in low yields as a by-product.



I II

The formation of intermediates which give several different products is expected when butadiene is allowed to react under the influence of transition-metal catalysts. Therefore, it is of considerable interest to compare the courses of the dimerization of butadiene by the different transition metals. The critical importance of appropriate auxiliary ligands to the catalytic effectiveness of Ziegler-Natta polymerization catalysts is well known. From our interest in the mechanism of transition-metal-catalyzing oligomerization and polymerization, we have examined the effects of appropriate ligands, using the reaction of butadiene by means of nickel catalysts as a model system. In the course of this work, we have confirmed the formation of 2 methylenevinylcyclopentane (MVCP) from the dimerization of butadiene by several nickel catalysts. A part of this study has already been reported in preliminary reports.[4,5] The new route to MVCP from butadiene is of interst in connection with certain synthetic problems and with the catalysis of transition metals.

In this paper we wish to report on the formation of MVCP and on some mechanistic studies of the cyclodimerization.

Results and Discussion

The following types of nickel catalysts in the presence of alcohol were effective for the cyclodimerization of butadiene to MVCP: (1) bis(trialkylphosphine)dihalo-

20	$(Bu_3P)_2NiCl_2$	(1.3)	*n*-BuLi	(1.3)	CF_3COOH	(10)	100	——

a) All reactions were carried out in benzene (1.8—5 ml) solution at 60—75°C for 40—50 hr.
b) *n*-BuLi, *n*-butyllithium; DMBALi, *o*-lithio-*N*,*N*'-dimethylbenzylamine.
c) MVCP, 2-methylenevinylcyclopentane; VCH, 4-vinyl-1-cyclohexene; COD, 1,5-cyclooctadiene; OT, octatriene.
d) Crystalline compound could not be obtaind.
e) In low yield.

nickel and organolithium, (2) *trans*-bis(triethylphosphine)halo-(*o*-tolyl)nickel, and (3) π-allylnickel bromide and tributylphosphine. The dimerization with these catalysts proceeded smoothly at 60—70°C, and MVCP free from significant by-products was easily obtained by distillation. No obvious dimerization was observed at room temperature. We have not tried to carry the reaction out above 100°C because the Diels-Alder reaction is expected to occur at higher temperatures. The most characteristic features of these catalysts are that they contain a halogen atom and should be used in the presence of a considerable and controlled amount of alcohol. Without alcohol, 4-vinylcyclohexene (VCH) and 1,5-cyclooctadiene (COD) were formed in low yields. The infrared spectrum of MVCP showed strong absorptions at 910 and 990 cm^{-1} due to a vinyl group and at 880 cm^{-1} due to a terminal methylene group. The absorption band at 1370 cm^{-1} for the methyl group was absent in the spectrum. The main product of hydrogenation over palladium-carbon was identical with *trans*-1-methyl-2-ethylcyclopentane.

Bis(tertiaryphosphine)dihalonickel Compounds and Organolithium. The results are summarized in Table 1. An inspection of Table 1 leads to the following conclusions concerning the factors which affect this cyclodimerization.

(a) It is essential to add alcohol in a 25—40 molar amount. In an experiment in which an amount of methanol equimolar to the nickel catalyst was added, no MVCP was formed except that vinylcyclohexene and cyclooctadiene were formed in low yields. On the other hand, the use of too large an amount of methanol resulted in the formation of higher-boiling products in addition to MVCP. Alcohols other than methanol can be used, but acids, phenols, and amines were less effective.

(b) The cyclodimerization proceeds satisfactorily in the presence of strong σ-donor phosphines without a bulky substituent. Strong electron donors, such as triethylphosphine and tri-*n*-butylphosphine, were effective as auxiliary ligands. On the contrary, bis(tricyclohexylphosphine)dichloronickel catalyzed not the cyclodimerization, but the linear dimerization, as is indicated by No. 17. Presumably, the marked difference in the behavior of $(Bu_3P)_2NiCl_2$ and $(Cy_3P)_2NiCl_2$ is a consequence of the difference in the bulkiness of the substituents on phosphorus, because the electron donor-acceptor properties of these two phosphines are similar; *i.e.*, no indication of any significant difference is provided by a comparison of the infrared CO stretching frequencies of $Ni(CO)_2(Phosphine)_2$ for tricyclohexylphosphine, 1973 cm^{-1}, with that for tri-*n*-butylphosphine, 1976 cm^{-1}.[6]

TABLE 2. DIMERIZATION WITH (*o*-TOLYL)NiX(PEt_3)$_2$ IN THE PRESENCE OF PROTONIC COMPOUNDS[a]

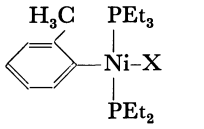
Expt No.	Catalyst	(mmol)	Protonic compd.	(mmol)	Butadiene (mmol)	Dimer distribution (%) MVCP	VCH	COD	OT
1	IIIa X=Cl	(0.85)	CH_3OH	(20)	60	86	9	5	—
2	IIIb X=Br	(2.4)	CH_3OH	(40)	100	95	4	1	—
3	IIIc X=I	(0.5)	CH_3OH	(12)	50	92	5	3	—
4	IIId X=NO_2	(0.3)	CH_3OH	(12)	50	—	6	22	72
5	IIIe X=NCS	(1.1)	CH_3OH	(25)	70	—	14	16	70
6	IIIb X=Br	(1.4)		(17)	100	29	46	25	—
7[b]	IIIb X=Br	(0.4)	CH_3OD	(15)	15	—	—	—	—

a) All reactions except No. 7 were carried out in benzene (1—5 m*l*) solution at 70—75°C for 40 hr; yield of dimers, 50—70%.
b) Reaction at 70°C for 3 hr. Butadiene was recovered unchanged (not deuterated) and decomposition of the catalyst was not observed.

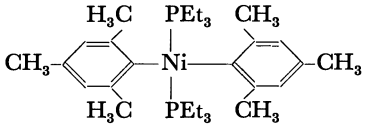
(c) The substituent, X, in $(R_3P)_2NiX_2$ is very important, although its behavior is obscure. It is essential for the nickel complex to contain a chlorine or bromine atom. No MVCP was formed, but linear dimers were formed in low yields when the substituents, the X's, were I, NO_2, CO, and SCN.

(d) *o*-Substituted aryllithium such as *o*-lithio-*N*,*N*′-dimethylbenzylamine[7] was effective, as was *n*-butyllithium. The other alkylation reagents, such as alkylaluminums, were ineffective.

Arylnickel Compounds. It is generally agreed that the first step in the reaction of transition metal halides and alkylmetals (*i.e.*, the first step in the preparation of Ziegler-Natta-type catalysts) is an alkylation. This mechanistic concept prompted us to examine the catalytic properties of the stable *o*-substituted arylnickels (III and IV) prepared by Chatt and Shaw,[8] because an arylnickel is presumed to be formed on the reaction of *o*-lithio-*N*,*N*′-dimethylbenzylamine with $(Bu_3P)_2NiCl_2$.



III



IV

a: X=Cl d: X=NO_3
b: X=Br e: X=NCS
c: X=I

These arylnickels (III and IV) are so stable that they can be handled in the open air. In spite of their chemical stability, they readily dimerized butadiene in the presence of alcohol.[5] The results are summarized in Table 2.

The iodine complex (IIIc) effected the cyclodimerization, while $(Bu_3P)_2NiI_2$ and organolithium catalyzed a linear dimerization. Interestingly, nitrironickel (IIId), isothiocyanatonickel (IIIe), and bis(triethylphosphine)-di(mesityl)nickel (IV) no longer brought about the cyclodimerization, but effected linear dimerization. Thus, in this catalytic system only halogen-bearing arylnickels were effective for the dimerization to the five-membered cycle (I). In the present study, however, the role of the halogen atom in the cyclodimerization has not been well understood so we cannot here discuss its behavior.

Bis(triethylphosphine)halo-(*o*-tolyl)nickels were recovered unchanged after heating the solution of methanol if butadiene was absent. Under the dimerization conditions in the presence of butadiene, the *o*-tolylnickels were decomposed to give toluene almost quantitatively, and were converted to a substance possessing the catalytic activity. In the working state of the catalysts, the aryl group originally attached to nickel is eliminated. Therefore, the presence of the aryl-nickel bond is not essential for the cyclodimerization, though the initiation of the dimerization may be affected by the aryl group. When the reaction with IIIb was stopped at an early stage (after three hours), toluene and the dimer, I, were not detected. Thus, the elimination of the aryl group and the cyclodimerization are associated with each other. This is consistent with the fact observed in the case of diethylbis(dipyridyl)iron, which catalyzes the dimerization of butadiene after the elimination of the ethyl group as butane, ethane, or ethylene.[9]

Of considerable importance is the observation that no deuterium was incorporated in toluene even if CH_3OD and CD_2=CH–CH=CD_2 were used instead of CH_3OH and CH_2=CH–CH=CH_2 respectively. The results are summarized in Table 3. This observation suggests that the cleavage of the arylnickel σ-bond in the presence of butadiene is not due to simple methanolysis. Since the use of CD_3OD resulted in the formation of monodeuterotoluene, it is clear that a hydrogen (deuterium) is transferred from a methoxide group to the coordinated *o*-tolyl group originally attached to nickel, thus liberating toluene. Accordingly, we began to consider the reductive cleavage of the aryl-nickel bond. Indeed, we have observed that the aryl-nickel bond of IIIb is cleaved by molecular hydrogen. Though the reaction was slow and a considerable amount of IIIb was recovered unchanged after the reaction, toluene was isolated in a 33% yield (based on the IIIb used); the complex under the influence of hydrogen showed a catalytic activity toward the dimerization of butadiene similar to that of IIIb combined with methanol.

X=Cl	1.5	CD_3OD	24	85[e]	*ca.* 95	C_4H_6	10	80
X=Br	0.4	H_2	30 (kg/cm²)	33[e]	0	C_4H_6	10	5

a) All reactions were carried out in benzene solution (1 m*l*) at 70—75°C for 24—48 hr.
b) Yield based on nickel complex used.
c) Isolated yield after distillation.
d) Not determined.
e) Gas chromatographic analysis using benzene as an internal standard.
f) Yield based on butadiene used.

While, in the cleavage of the aryl-nickel bond, no products other than toluene have been identified, the reaction evidently proceeds, by analogy to that of palladium,[10] through an oxidation of methanol, thus producing toluene and an active nickel catalyst which is effective for the dimerization to MVCP. The reduction of IIIb with molecular hydrogen also gives toluene and the active nickel catalyst. The dimerization using molecular hydrogen as the reducing agent is interesting in the point that a hydrogen migration during the dimerization is involved even in an aprotic solvent. In addition, dimers other than MVCP were not formed, though the formation of vinylcyclohexene and cyclooctadiene has been anticipated, because vinylcyclohexene and cyclooctadiene are the usual products of the dimerization of butadiene using nickel catalysts in an aprotic solvent.[1] In order to cyclodimerize butadiene to MVCP, the migration of one hydrogen must be involved. To our knowledge, for the dimerization of butadiene using nickel catalysts, protonic solvents such as alcohol,[2] phenol[3] and amine[11] must be always used for the formation of linear dimers. The experiment with molecular hydrogen suggests that alcohol is not necessary to the migration of hydrogen during the dimerization.

Bis(triethylphosphine)di(mesityl)nickel showed a different catalytic behavior from that of III (Table 4);

Table 4. Catalysis of $(mesityl)_2Ni(PEt_3)_2$[a]

Catalyst (mmol)	Reducing agent (mmol)	Butadiene (mmol)	Products (%)	
0.3	——	9	Vinylcyclohexene	50
			Cyclooctadiene	27
1.0	Methanol 25	100	1,3,6-*n*-Octatriene	14
			Higher boiling products[b]	
0.4	H_2 30 (kg/cm²)	10	Butane	*ca.* 30
			Ethylcyclohexane	33
			Cyclooctane	24

a) All reactions were carried out in benzene solution at 70—75°C for 24 hr.
b) The yields were not determined.

10) D. A. White and G. W. Parshall, *Inorg. Chem.*, **9**, 2358 (1970).
11) P. Heimbach, *Angew. Chem.*, **80**, 967 (1968).

even in the absence of the reducing agent, IV catalyzed the dimerization of butadiene to give 4-vinylcyclohexene and 1,5-cyclooctadiene in high yields.

Similarly, the aryl-nickel bond of bis(triethylphosphine)di(mesityl)nickel (IV) was cleaved by molecular hydrogen to form mesitylene. The mesityl complex, IV, was also an excellent catalyst precursor for the dimerization of butadiene described below, though the reaction catalyzed by IV differed from that by III. The catalytic behavior of IV would be consistent with the catalysis of $Fe(dipyl)_3$[9] or "naked nickel" combined with an electron-donating ligand[12] in the points that the distribution of the products is similar and IV is the precursor of an active catalyst containing no halogen atom.

On the other hand, if the mesityl complex, IV, was treated with hydrogen in the presence of butadiene, mesitylene was liberated and the reaction of butadiene was observed. In this case, however, instead of 4-vinylcyclohexene and 1,5-cyclooctadiene, only butane, ethylcyclohexane, and cyclooctane were formed as hydrogenated products. This is in marked contrast to the catalysis of III, which is inactive for hydrogenation.

π-Allylnickel Halide and Electron Donors. It is well known that π-allylic complexes are converted to dynamic σ-allylic ones.[13]

$$\pi\text{-Allyl}\cdot M\cdot X\cdot PR_3 + PR_3 \rightleftharpoons \sigma\text{-Allyl}\cdot M\cdot X\cdot (PR_3)_2$$

M: Ni and Pd. X: Halogen.

Thus, the π-allylnickel complex combined with strong electron donors was expected to show catalytic activities similar to those of the arylnickels described above. In fact, π-allylnickel bromide combined with tri-*n*-butylphosphine converted butadiene catalytically to MVCP. The results are summarized in Table 5. It is noteworthy that π-allylnickel iodide gave no MVCP but *trans*-1,4-polybutadiene. We examined the effect

Table 5. Dimerization by π-allylnickel bromide and electron donors[a)]

Expt No.	Catalyst (π-$C_3H_5NiBr)_2$ (mmol)	Donor	(mmol)	Products yield (%)
1	0.75	PBu_3	3	MVCP, 50
2	0.75	PPh_3	3	MVCP, 5; 1,3,6-OT,9
3	0.75	$P(OPh)_3$	3	——
4	0.75	NEt_3	3	——

a) All reactions were carried out in 5 ml of benzene at 70—75°C for 40 hr. 80 mmol of butadiene was used.

of some other electron donors. Phosphite and tertiary amine were ineffective.

Reaction Mechanism. The catalysts studied by us are different from the conventional nickel catalysts, which give linear dimers in protonic solvents.[1)] The essential features of our nickel catalysts giving the five-membered cycle (I) are that they contain a halogen atom and are to be used in the presence of a controlled amount of alcohol. The cyclodimerization involves a hydrogen migration caused by a protonic compound. This is confirmed by the reaction using deuteromethanol. The dimerization was duplicated using deuteromethanol (CH_3OD) in place of methanol (CH_3OH). A monodeuterated dimer was thus obtained. Fig. 1B shows a part of the NMR spectrum. The absorptions of 3.9 to 5.3 τ were unaffected by the deuteration. The signal centered at 7.6 τ is assigned to the hydrogens on the 3-carbon atom. The analysis of this dimer using mass spectrometry and the NMR technique demonstrated that it is about 50% deuterated in the 3 position.

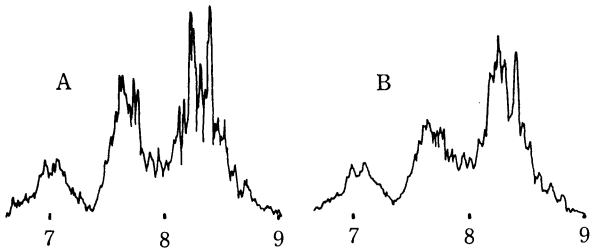

Fig. 1. NMR spectra of (A) normal- and (B) monodeuterated-MVCP.

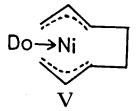
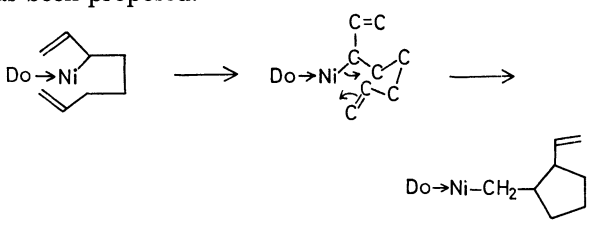
Dimerization with nickel catalysts to cyclic or linear dimers is believed to proceed through a bis-π-allylic intermediate (V).[12)]



V

In our case, the internal insertion of a double bond into the nickel-carbon σ-bond to form a five-membered cycle has been proposed.[4)]



However, since halogen is essential to this catalyst, the structure of the intermediate of the dimerization may be more complicated.

Experimental

trans-Bis(tertiaryphosphine)dichloronickel and the bromo analog were prepared by adding the phosphine (2 mol) to a solution of the nickel halide (1 mol) in methanol. The derivatives of NO_2, SCN, and I were afforded by displacement reactions in which the appropriate metal salt was mixed with the dihalocomplex in acetone.[14)] Arylnickel complexes were prepared from a Grignard reagent according to the method of Chatt and Shaw.[8)] π-Allylnickel halides were prepared from the reaction of allyl halide with nickel carbonyl.[15)] Commercially-available *n*-butyllithium in hexane was used. *o*-Lithio-*N*,*N*′-dimethylbenzylamine was prepared from *N*,*N*′-dimethylbenzylamine and *n*-butyllithium in benzene.[7)] Commercially-available deuteromethanol was used without further purification. Tetradeuterobutadiene was prepared by H–D exchange between butadiene-β-sulfone and deuterium oxide.[9)] Commercially-available butadiene was used after drying with a 3 Å molecular sieve.

Gas-chromatographic analyses were carried out on a column, Silicon DC 550 on Celite, 1 m, at 100°C. The identification of vinylcyclohexene, cyclooctadiene, and *n*-octatrienes was done by comparing the retention time on the gas chromatogram and the infrared and NMR spectra with those of authentic samples. The identification of 2-methylenevinylcyclopentane was done by comparing the retention time and the infrared and NMR spectra of the hydrogenation product over palladium-carbon with those of *trans*-1-methyl-2-ethylcyclopentane.[16)]

*Dimerization by Bis(tri-*n*-butylphosphine)dichloronickel and* n*-Butyllithium.* Bis(tri-*n*-butylphosphine)dicloronickel, 0.67 g (1.3 mmol), was placed in a glass tube (20 mm in diameter). The tube was immediately fitted with a three-way stopcock through which solvent and reagents were introduced through a syringe. The system was placed under argon by evacuating it and filling it with argon several times. At room temperature, 5 ml of benzene and 1.3 mmol of *n*-butyllithium in 0.54 ml of *n*-hexane were added. The reaction mixture became warm and turned dark red. It was then stirred at room temperature for 30 min, and this was followed by the addition of 1.5 ml (40 mmol) of methanol. The solution was cooled to −78°C in a dry ice-acetone bath; then, 3.9 g (70 mmol) of liquefied butadiene was added and the tube was sealed with a flame. The reaction mixture was heated at 65—70°C for 40 hr. Distillation without separation of the catalyst gave 2.7 g (70%) of MVCP as a colorless liquid; bp 121—122°C, n_D^{24} 1.4553. (lit,[17)] n_D^{27} 1.4557)

General Procedure for Dimerization by Various Nickel Catalysts and Organolithium. The above procedure is illustrative. The amounts of reagents used and the reaction conditions are shown in Table 1. The reactions were carried out in the glass tube described above. The yields of the products were determined gas-chromatographically. The separation of the products, if necessary, was carried out by preparative gas chromatography, and the structure of the products was confirmed by comparing the NMR and infrared spectra of the products with those of authentic samples.

Dimerization by trans-*Bis(triethylphosphine)chloro-(o-tolyl)-nickel.* In the glass tube, 0.36 g (0.85 mmol) of *trans*-bis(triethylphosphine)chloro-(*o*-tolyl)nickel was dissolved in 1.5 m*l* of benzene under an argon atmosphere; this was followed by the addition of 0.85 m*l* of methanol. The solution was cooled to −78°C in a dry ice-acetone bath, and then 3.5 g of liquefied butadiene were added. The sealed tube was heated at 70—75°C for 40 hr. Distillation gave 2.4 g of dimers. Gas-chromatographic analysis showed the presence of MVCP (86%), VCH (9%), and COD (5%).

The above procedure is illustrative. Reactions by other arylnickels are summarized in Table 2.

Reaction of Ia with CD_3OD and Dimerization of Butadiene. In a glass tube 0.61 g (1.5 mmol) of IIIa was placed. Under a nitrogen atmosphere 0.9 g of benzene and 1 m*l* of CD_3OD were added. The mixture was cooled in a dry ice-acetone bath to −78°C, and then 10 mmol of liquefied butadiene were added. The tube was heated at 70—75°C for 42 hr. Gas-chromatographic analysis (2 m Apiezon, 100°C), using benzene as an internal standard, showed the formation of 0.11 g (85% based on IIIa) of toluene and 0.48 g of MVCP. After the removal of the catalyst by distillation, toluene was separated by preparative gas chromatography. Mass spectroscopic analysis showed C_7H_7D of *ca.* 95% isotopic purity.

Reaction of IIIb with Hydrogen and Dimerization of Butadiene. In a 30-m*l*, stainless-steel pressure reactor, 0.21 g (0.41 mmol) of IIIb was dissolved in 2 m*l* of benzene. The reactor was cooled to −78°C, and then 10 mmol of liquefied butadiene was added under a nitrogen atmosphere. Hydrogen was charged up to 30 kg/cm² at that temperature. The mixture was heated at 70—75°C for 24 hr. Gas-chromatographic analysis showed the formation of toluene (33% yield on IIIb) and MVCP (5% yield on butadiene). From the reaction mixture, a yellow-brown solid was obtained. Recrystallization from methanol gave 0.03 g of the pure IIIb as yellow-brown needles, mp 102—103°C (lit,[8] mp 102—103°C).

Reaction of IV and Reaction of Butadiene Catalyzed by IV. All reactions using methanol (or without methanol) or hydrogen were carried out in ways similar to those described above in the glass tube or the stainless-steel pressure reactor respectively. The products were identified by comparing the infrared spectra and retention time with those of authentic samples. The formation of butane, ethylcyclohexane, and cyclooctane was confirmed by a study of the infrared and mass spectra.

Dimerization by π-Allylnickel Halide and an Electron Donor. The following procedure is a typical one. To 5 m*l* of benzene solution containing 0.75 mmol of π-allylnickel bromide, 0.61g (3 mmol) of tri-*n*-butylphosphine, 25 mmol of methanol and 80 mmol of liquefied butadiene were added, in this order. The glass tube was then sealed and heated at 70—75°C for 40 hr. Distillation gave MVCP in a 50% yield.

Dimerization by other π-allylnickel compounds were carried out in a similar way. The reaction conditions are summarized in Table 5.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1961—1964 (1971)

Methylation of Phenol over Metallic Oxides

Takeshi KOTANIGAWA, Mitsuyoshi YAMAMOTO, Katsuyoshi SHIMOKAWA, and Yuji YOSHIDA

The Government Industrial Development Laboratory, Hokkaido, Higashi-Tsukisamu, Sapporo

(Received December 24, 1970)

Methylation took place only at *ortho* position of phenol under an atmospheric pressure at 350°C when the reaction was carried out over an MO–Fe_2O_3 catalyst containing Cu, Mg, Ca, Ba, Zn, Mn, Co, or Ni each as M. The aromatic fraction in liquid products was only *o*-cresol and 2,6-xylenol and products substituted at *para* and *meta* positions could not be obtained. However, gasification of methanol took place simultaneously as a side reaction. From the relation between methylation and gasification, the catalytic activity was found to be effective in the order Cu>Zn>Ba>Ca>Co>Mn>Mg>Ni. Deactivation of these catalysts was observed before the reaction reaches a steady state. The thermogravimetric curve of the used catalyst was measured. From thermal analysis the reduction of the catalyst seems to be a cause of deactivation in addition to deposition of carbonaceous materials onto the catalyst surface. The used catalysts were reclaimed through the process of Scheme 1.

The catalytic alkylation of phenols by vapor phase reaction with alcohols is well known and is used for preparation of alkyl phenols.[1-3] However, because of its low selectivity for a desired alkyl phenol, application of the reaction is limited.

Since poly(2,6-dimethyl)phenylene oxide, the so-called PPO resin, has been introduced as a new thermo-resistant polymer,[4-5] the synthesis of its monomer, 2,6-xylenol, has attracted special attention in industry. A large number of related patents and papers have appeared on synthetic methods using vapor phase or liquid phase reaction. It has been reported that the vapor phase reaction of phenol with methanol over magnesium oxide gives 2,6-xylenol in an exellent yield.[6] A vapor phase synthetic method using Ce_2O_3-MnO-MgO as a catalyst has also been reported.[7] This demonstrates that magnesium oxide is most favorable in the synthesis of 2,6-xylenol as compared

with other catalysts which are used in the methylation of phenol.

We found that methylation occurs only at *ortho* position of phenol under an atmospheric pressure at 350°C when the reaction is carried out over an MO-Fe_2O_3 catalyst containing Cu, Mg, Ca, Ba, Zn, Co, Mn, or Ni each as M. This synthetic method of 2,6-xylenol using these types of catalysts is not found in literature. It is, therefore, of particular interest to selectively synthesize 2,6-xylenol without using magnesium oxide as the main component of catalyst. We wish to report on the methylation of phenol over a new type of catalyst.

Experimental

Materials. Phenol and methanol were of analytical reagent grade. They were free from any impurities as ascertained by gas chromatography. Cupric, magnesium, calcium, barium, zinc, manganese, nickel, cobalt, and ferric nitrate were also analytical reagent grade.

Preparation of Catalysts. The catalysts were prepared as follows: 1) After dissolution of 0.2 mol of ferric nitrate and 0.1 mol of magnesium, calcium, barium, or zinc nitrate in water, 14% aqueous ammonium solution was added to the solution until it gave a pH of 6.4 at room temperature. 2) After dissolution of 0.2 moles of ferric nitrate and 0.1 mol of cupric, manganeses, nickel or cobalt nitrate in water, 3N aqueous sodium hydroxide solution was added to the solution until it gave a pH of 9.6 at room temperature. The coprecipitate consisting of an individual metallic hydroxide and ferric hydroxide was washed several times with water and calcined in an electric furnace at 400°C for 3 hr with air pumped into the container. These catalysts were crushed and sieved to 12—14 mesh size particles.

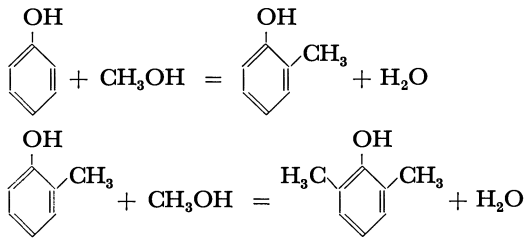
Thermal Analysis of the Used Catalysts. A Rigaku Denki "Thermoflex 8002D" was employed in the differential thermogravimetric analysis.

Analysis of Products. Carbon dioxide in gaseous products was determined by means of the Hempel gas analytical method. Other gases were identified by comparing their respective retention time on the gas chromatogram against authentic samples, after which they were determined quantitatively by gas chromatography (Column: molecular sieve 13X, carrier gas: Ar gas). Liquid products were identified by gas chromatography and infrared spectrometry. Respective quantitative analysis was performed by gas chromatography (Column: Silicone DC 550 at 170°C and Porapak Q at 110°C, carrier gas: He gas).

Apparatus. A Pyrex glass tubular reactor (500 mm length, 20 mm o.d., 18 mm i.d.) was connected with a micro pump which feeds reactants, vertically supported and externally heated in an electric furnace. A vaporizer above the catalyst bed was surrounded by an electric heater and maintained at temperatures 250—280°C. The reactant vapors carried with nitrogen gas were led over the catalyst bed through the vaporizer. The reaction temperature was measured with an IC thermocouple placed in the middle of the catalyst bed. The product vapors were led through an air-cooled condenser and two dry ice traps, and non-condensable products were determined with a wet gas meter.

Results and Discussion

Phenol is methylated consecutively to 2,6-xylenol *via* *o*-cresol by the following processes.



At a high temperature, however, it is decomposed to form benzene, toluene, and xylene. To avoid this, the optimal reaction condition was selected as follows. One mole of phenol is reacted with 10 moles of methanol at 350°C. Partial pressure of nitrogen gas carrier is 0.38 atom. The contact time is 1.6 sec at 350°C.

We see from Table 1a that phenol is selectively methylated at *ortho* position. Even with a large

excess of methanol, the aromatic fraction in liquid products is only *o*-cresol and 2,6-xylenol except for the case in which $NiO-Fe_2O_3$ catalyst is used. In contrast, methanol reacts through two simultaneous pathways, the methylation of phenol and the gasification of methanol itself. Using gaseous components in Table 1b, the gasification of methanol can be demonstrated by

$$CH_3OH = CO + 2H_2 \quad (1)$$

$$CO + 3H_2 = CH_4 + H_2O \quad (2)$$

$$CO + H_2O = CO_2 + H_2 \quad (3)$$

These pathways can be expected from the fact that the Fe_2O_3 catalyst promotes reactions (2) and (3). Thus, this type of catalyst promotes the selective methylation at *ortho* position of phenol and simultaneously the gasification of methanol. Effectiveness of these catalysts should be discussed from the relation between the main reaction and the undesired side reaction. Figure 1 shows the relation between the methylation and gasification. The upper-right region in Fig. 1 denotes where the methylation only takes place and lower-left region denotes where the gasification only takes place. Thus, it can be said that these catalysts are effective in the order Cu>Zn>Ba>Ca>Co>Mn>Mg>Ni.

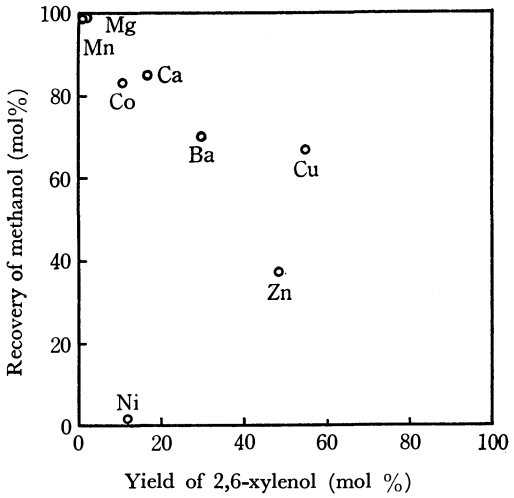

Fig. 1. Relation between methylation and gasification.

Tables 1a and 1b show the data which were obtained around six or seven hours after the commencement of the reaction. However, deactivation of the catalysts is observed before the reaction reaches a steady state. Figure 2 shows the course of deactivation.

The surface area and the differential thermogravimetric curve of the used catalysts were determined in order to estimate the degree of deactivation of catalyst which is said to depend on decrease of surface area caused by sintering of catalyst and also on the contamination of active sites by carbon deposition. The

a) Measured from coprecipitates of hydroxides.

surface area of the fresh and the used catalysts is shown in Table 2 and a typical differential thermogravimetric curve is shown in Fig. 3.

Figure 3 is divided into three parts, (I) exothermic with a weight increase, (II) exothermic with a weight decrease, and (III) exothermic without a weight change. (I) is due to the oxidation of the used catalyst which has been reduced during the reaction. As would be expected from molar free energies in Table 3a,[8] hematite in the fresh catalyst is reduced to magnetite. This was confirmed through the thermal analysis of the mixture of MO and Fe_3O_4. (II) is due to the combustion of carbonaceous materials which deposited during the course of reaction. (III) is due to the following solid reaction.

$$MO + Fe_2O_3 = M(Fe_2)O_4$$
$$MO + Fe_2O_3 = Fe(MFe)O_4$$

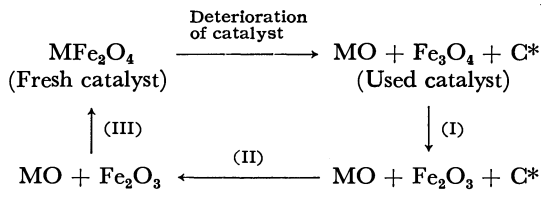
It is expected from molar enthalpies of formation in Table 3b that (III) is exothermic except for CuO-Fe_2O_3.[9-10] The solid reaction was confirmed by means of X-ray diffractometry before and after the exothermic peak. Behaviors of the used catalyst in differential thermogravimetric analysis can be summerized as follows.

The result of thermal analysis is shown in Table 4.

Here, the degree of reduction in the case all catalysts except CuO–Fe_2O_3 does not exceed the calculated value which is given by the following expression.

$$[1 - (3MO, 2Fe_3O_4/3MO\text{-}Fe_2O_3)] \times 100$$

However, in the case of CuO-Fe_2O_3, it exceeds the calculated value (2.24%) because the reduction takes place not only in hematite, but also in cupric oxide. Thus, the reduction of the catalyst would give rise to the deactivation of the catalyst besides the decrease of the surface area and deposition of carbonaceous materials onto the catalyst surface. Thermal analysis was carried out in order to discuss deactivation of the catalyst, and Scheme 1 can be regarded as a process for the reclamation of the used catalyst.



Scheme 1

C* shows carbonaceous materials.

A large number of studies, by the reaction of phenol with methanol over magnesium oxide or modified magnesium oxides, are mainly concerned with the ring substitutive reaction of phenol. However, this paper deals with not only the ring substitutive reaction, but also the thermal analysis of the used catalyst.

Thus, we may conclude that the present catalyst gives an excellent catalytic activity for selective methylation at *ortho* position of phenol and its activity is effective in the order Cu>Zn>Ba>Ca>Co>Mn>Mg>Ni, and the used catalyst is reclaimed through the process of Scheme 1.

Mass Spectra of Phenyl *p*-Toluates and Toluanilides Substituent Effect in Fragmentation. II

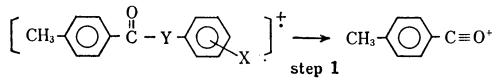
Seizi KOZUKA, Hideo TAKAHASHI, and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 5, 1970)

The effect of substituent on mass spectra has been investigated considerably in recent years. In our previous work,[1] the Hammett correlation was observed in the three steps of fragmentation of *p*-substituted phenyl-*p*-toluenesulfonates; a positive ρ-value for the initial step and negative ρ-values for the succeeding two steps. We have extended our study to two classes of compounds, phenyl-*p*-toluates and toluanilides, since the fragmentation is considered to be similar to that of the sulfonates.

As expected, their mass spectra show the following similar three fragmentation steps.



step 1

step 2 step 3

Y=O X: *p*-NO_2 *m*-NO_2, *p*-Cl, H, *m*-CH_3, *p*-CH_3, *p*-OCH_3, *p*-CN

Y=NH X: *p*-NO_2, *m*-NO_2, *p*-Cl, H, *m*-CH_3, *p*-CH_3, *p*-OCH_3

The relative peak heights (Z-value) of the fragmentation of these compounds are nicely correlated with the Hammett constants as shown in Figs. 1 and 2.

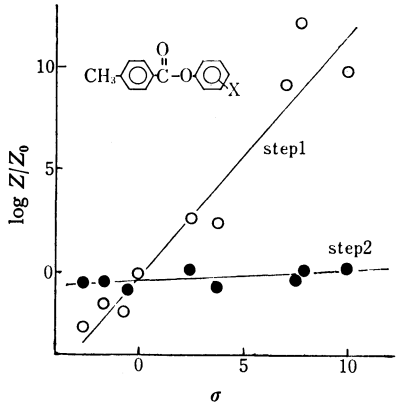


Fig. 1. Hammett plot of the relative peak height obtained in the fragmentation of phenyl *p*-toluates.

The positive ρ-values of the first steps of fragmentation are reasonable. However, no noticeable effect of substituent was found in the second and third steps unlike the case of sulfonates where negative ρ-values were obtained in the suceeding steps.

A possible rationale is that the internal energies

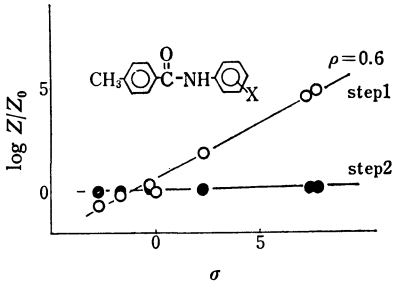

Fig. 2. Hammett plot of the relative peak height obtained in the fragmentation of *p*-toluanilide.

resulting from various activation energies of the decompositions of these compounds with different substituents were retained not in the fragment ions but in the leaving groups that depart from the molecular ions, and all acylinium ions resulting from different molecular ions would retain nearly identical internal energies and give rise to no substituent effect in the succeeding steps.

Another possibility is derived from the assumption that the parent and acylinium ions are formed from a common intermediate (super-excited state) as accepted in the usual treatment of fragmentation in terms of molecular orbital theory.[2] If this is the case, the observed substituent effect at the initial step could derived from the two competing reactions, leading to the parent ion and acylinium ion. At present, we have no definite evidence to make a choice between the two possibilities.

It is worthy to note that the acylinium ion formed

from the ester undergoes more facile decomposition than that derived from the anilide (Table 1). This suggests that the acylinium ions derived from different molecules would retain different internal energies even in the individual fragmentation of those compounds which show no noticeable effect of substituent in the succeeding steps.

The difference of ρ-values observed for the esters and anilides can be ascribed to the difference of bond strengths. As shown in Fig. 3, the deviation of the carboxyl stretching frequency with various substituents is apparently smaller with the esters than with the anilides. This suggests that the effect of substituent is more enhanced in the strength of C–O bond of the ester than that in the C–N bond of the anilide. A similar effect has also been observed in the usual reactions such as alkaline hydrolyses.[3,4]

Experimental

Mass spectra were recorded with a Hitachi RMU-6E single forcus spectrometer. The spectra are shown in Table 1. Infrared spectra were obtained in chloroform solution with 1 mm NaCl cell using JASCO IR-G.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1966—1967 (1971)

Oligomerization of Isoprene by the Catalyst Systems Consisting of Tetraallylzirconium and Aluminum Compounds

Yasuzo UCHIDA, Ken-ichi FURUHATA, and Shohei YOSHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 5, 1970)

Recently, we have reported on the oligomerization of isoprene by zirconium bases catalysts.[1] In this paper, we report on the oligomerization of isoprene by the catalyst systems consisting of tetraallylzirconium and aluminum compounds.

Tetraallylzirconium itself was not a good catalyst for the oligomerization of isoprene and 12% of isoprene was converted into 2,6-dimethyl-1, *trans*-3,6-octatriene (selectivity, 36%) in the reaction at 100°C for 2 hr. Ethylaluminium sesquichloride was found to be a particularly good co-catalyst and 66% of isoprene was converted into the dimer (selectivity, 78%; Al/Zr molar ratio, 2) under the same conditions.

Results and Discussion

We examined five aluminum compounds, triethylaluminum, diethylaluminum chloride, ethylaluminum sesquichloride, ethylaluminum dichloride, and aluminum trichloride as co-catalyst.

Effect of Et_3Al. When triethylauminum was used as a co-catalyst, the dimer yield was less than 3% in the region of the Al/Zr molar ratio between 1 and 11. The conversion of isoprene decreased at lower molar ratios and reached a minimum at 4.2. The conversion increased at Al/Zr molar ratios higher than 4.2.

Effect of Et_2AlCl. The effect of diethylaluminum chloride on the oligomerization of isoprene by tetraallylzirconium has been reported.[1] The dimer yield was about 40% in the region of the Al/Zr molar ratio between 4.5 and 10. The yield of trimers was less than 10%.

Effect of $Et_{1.5}AlCl_{1.5}$. The effect of the molar ratio of ethylaluminum sesquichloride on the oligomerization of isoprene is shown in Fig. 1. The maximum yield of the dimer was attained at the Al/Zr molar ratio

1) A. Misono, Y. Uchida, K. Furuhata, and S. Yoshida, This Bulletin, **42** 2330 (1969).

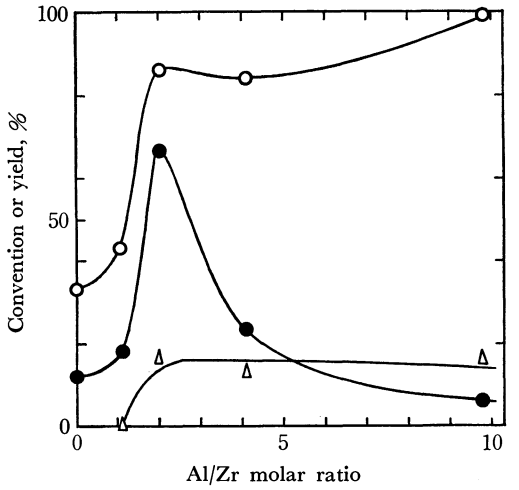

Fig. 1. Effect of $Et_{1.5}AlCl_{1.5}/Zr(C_3H_5)_4$ molar ratio.
—○—: Conversion of isoprene, %
—●—: Yield of the dimer, %
—△—: Yield of trimers, %
100°C, 2 hr, isoprene/$Zr(C_3H_5)_4$=100

of 2.

Effect of $EtAlCl_2$. Ethylaluminum dichloride showed a similar effect to that of ethyaluminum sesquichloride on the oligomerization of isoprene and the maximum yield of the dimer was attained at the Al/Zr molar ratio of 1. The conversion of isoprene was 66% and the dimer yield was 51% at this molar ratio. In contrast, isoprene was cyclopolymerized at room temperature by the catalyst system consisting of zirconium (IV) *n*-butoxide and ethylaluminum dichloride.[1]

Effect of $AlCl_3$. The conversion of isoprene and the dimer yield increased by the addition of aluminum trichloride to tetraallylzirconium. The maximum yield was observed at the Al/Zr molar ratio of 0.46 but both the conversion and the yield decreased at higher molar ratios. The maximum conversion was 48% and the maximum yield was 17%.

The results are summarized in Table 1. The acidity of aluminum compounds increases in the order $Et_3Al < Et_2AlCl < EtAlCl_2$.[2]

Absorption peaks of tetraallylzirconium in the nuclear magnetic resonance spectrum were shifted to lower field in the presence of diethylaluminum chloride. The difference of chemical shifts between methyl and methylene protons of diethylaluminum chloride in the mixed system was −1.0 ppm, while that of free diethylaluminum chloride was −0.9 ppm. This suggests that diethylaluminum chloride receives electrons from tetraallylzirconium.[3]

Table 1. Dimerization of isoprene by $Zr(C_3H_5)_4$ and aluminum compounds

Aluminum compound	Best Al/Zr[a] mol. ratio	Best yield of the dimer
Et_3Al[b]	×	×
Et_2AlCl	4.5—10	40%
$Et_{1.5}AlCl_{1.5}$	2	66%
$EtAlCl_2$	1	51%
$AlCl_3$	0.46	17%
none	—	12%

a) Al/Zr molar ratio where the yield of the dimer reached a miximum.
b) Yield of the dimer was less than 3%.
Reaction conditions: 100°C, 2 hr; Isoprene/$Zr(C_3H_5)_4$ molar ratio, 100.

The presence of a second component with adequate acidity seems to be necessary for the dimerization of isoprene by tetraallylzirconium.

Experimental

Reagents. Isoprene was dried over anhydrous sodium sulfate, distilled and deoxygenated by the freeze-thaw method with pumping.

Tetraallylzirconium was synthesized according to the reported method[4] and was stored at −78°C as an isoprene solution (3.29 wt% or 1.0 mole%). Isoprene hardly reacted at all under this condition.

Alkylaluminum compounds were diluted in dry benzene before use.

Aluminum trichloride was purified by sublimation.

Reaction Procedure. In a typical reaction, to a glass ampule filled with dry nitrogen, 2.36 g of benzene, 0.66 mmol of tetraalllylzirconium, 66 mmol of isoprene and 2.91 mmol of diethylaluminum choride (19.9 wt% benzene solution) were charged with syringes under a nitrogen stream. The ampule was then sealed and kept at 100°C for 2 hr.

Analysis. The dimer was determined to be 2,6-dimethyl-1,*trans*-3,6-octatriene by comparing its infrared spectrum with that of the authentic sample.[1]

Gas chromatography was used for calculating the conversion percentage of isoprene and the quantitative analysis of products. A 2 m stainless steel column, 4 mm in diameter and packed with poly(diethylene glycol succinate) on Shimalite was used. Operation conditions: column temperature, 112°C and 180°C for dimers and trimers, respectively; flash evaporator temperature, 300°C; carrier gas (helium) speed, 30 m*l*/min. Benzene was used as the internal standard.

Nuclear magnetic resonance spectra were recorded on a Nihon Denshi Model C-60.

Dispersion State of Platinum on Zeolite and Hydrogenation of Ethylene

Toshihiko KUBO, Hiromichi ARAI, Hiroo TOMINAGA, and Taiseki KUNUGI

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 8, 1970)

Some metal cations loaded on a zeolite by ion exchange are readily reduced by heating in a hydrogen stream. The reduced metals are highly disperesed in the cavities of the zeolite and show high catalytic activity for hydrogenation of unsaturated compounds. Strel'nikova and Lebedev[1] proposed a hypothesis that the catalytic hydrogenation is carried out on a "mixed ensemble" consisting of a metallic atom and an active center of the carrier. However, this is not in line with the findings that the reduction of cations in the cavities of zeolite gives tiny crystallites with diameters ranging 5—30 Å.[2]

A number of papers[3,4] have reported that catalytic behaviors of supported metal are dependent on the crystallite size or the degree of dispersion. Rabo[5] showed that zeolite catalyst loaded with platinum by ion exchange was less affected by sulfur compounds than similar catalysts prepared by impregnation.

We studied the behavior catalysis of the zeolite catalyst loaded with metals in a given dispersion state. Zeolite(NaY)-supported platinum catalysts were prepared either by ion exchange or impregnation method. After reduction with hydrogen, the platinum subjected to ion exchange was supposed to exist mainly in the cavity. While the impregnation method gave rather large platinum crystallites exclusively on the outer surface of zeolite. The two different catalysts were compared for their activities for the hydrogenation of ethylene.

Experimental

Two types of catalysts, (A) and (B), were prepared from zeolite–NaY with Si/Al ratio of 2.5. (A) was prepared by ion exchange with $Pt(NH_3)_4^{2+}$ aqueous solution, followed by drying at 100—110°C in the air and reduction with hydrogen at 200°C for 3 hr. (B) was prepared by impregnation with ($PtCl_6^{2-}$) aqueous solution, followed by drying and reduction under the same conditions as for (A).

Platinum content was 0.2 or 0.5 wt%. The catalytic activities were tested for hydrogenation of ethylene by use of pulse-technique. In the reactor, 0.1 g of catalyst was placed, and 0.15 m*l* of ethylene gas was injected into a large excess of hydrogen stream continuously flowing down the reactor. The product stream was analyzed by gas chromatography. Hydrogen was supplied from a commercial cylinder after purification over Deoxo catalyst and silica gel. The flow rate was 30 m*l*/min, and the pressure 300 mmHg (gauge).

Results and Discussion

Figure 1 shows that the activity of (A) at reaction temperature 35°C or 45°C rapidly decreases in the first ten injections of ethylene gas with 10 min intervals, and then reaches a constant level.

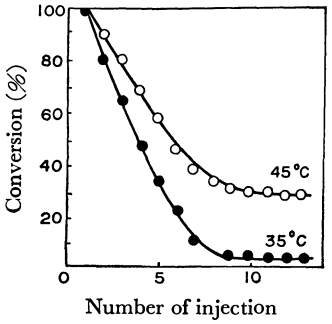

Fig. 1. Change of activity *vs.* number of injection.
0.5 wt% Ion exchanged catalyst (A)

The activity was completely recovered by heating the catalyst at 100°C for 30 min. This seems to be due to an adverse effect of water vapor in the hydrogen stream on the activity of (A). The activity of (B), however, is not affected by water vapor in the hydrogen stream as shown in Fig. 2.

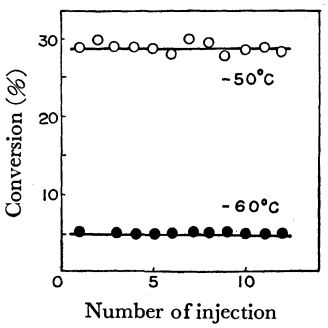

Fig. 2. Change of activity *vs.* number of injection.
0.5 wt% Impregnated catalyst (B)

Over 0.1 g of (A) kept at room temperature, hydrogen stream was introduced at a given flow rate. After 1 hr of hydrogen flow, without ethylene pulse injection, the catalyst lost its activity for ethylene hydrogenation at room temperature, *ca.* 20°C. This experiment suggests that the deactivation of the catalyst (A) is due to some impurity in the hydrogen. The hydrogen was analyzed for water content giving approximately 1—2 mg/*l*. When the hydrogen stream completely dried by refrigeration with liquefied nitrogen was used, (A)

was found to give 100% conversion of ethylene to ethane even at the reaction temperature −60°C. In this experiments, a pronounced tailing of gas chromatographic peak of ethane was observed. This could be attributed to the largely prolonged contact time due to strong adsorptive affinity of ethylene on zeolite surface. The catalytic activity never decreased in the presence of completely dried hydrogen.

Observation by electron microscope of (A) revealed that no platinum crystal with diameters larger than 10 Å, the limit of resolution of the electron microscope employed, existed. This means that the reduced platinum presumably exists as atoms and/or as tiny crystallites with diameters less than 10 Å in the cavities of zeolite. Therefore, the decrease in catalytic activity shown in Fig. 1 may be interpreted by the adsorption of water vapor sealing off the cavity mouth of the zeolite to prevent the access of the reactant to platinum site. After the water adsorption equilibrium which depends on temperature is attained, the activity of (A) becomes constant.

On the other hand, electron micrographs of (B) showed that platinum crystallite diameters were 30—100 Å. Platinum crystallites of these dimensions cannot exist in a cavity whose maximum diameter is 13 Å. The adsorption of water vapor on platinum crystallites, if any, might be negligibly small compared with that on zeolite. Consequently, the activity of (B) is constant as shown in Fig. 2.

Table 1. Influence of H_2O in H_2 gas on activation energy

	Catalyst	H_2 Reduction	H_2O/H_2 (mg/l)	Activation Energy (kcal/mol)
1)	0.5 wt%[a)]	200°C, 3 hr	2.3	34 (30— 50°C)
2)	0.5 wt%[b)]	200°C, 3 hr	2.3	10 (−60——30°C)
3)	0.2 wt%[a)]	200°C, 3 hr	1.1	10 (−15— 19°C)
4)	0.2 wt%[b)]	200°C, 3 hr	1.1	12 (−15— 18°C)

a) Ion exchanged. b) Impregnated.

After the activity of catalyst attained a constant level by repeated ethylene pulse injection, a logarithmic plot of $(1-x)^{-1}$ (x=conversion of ethylene, mole fraction) against T^{-1} (T=reaction temperature, °K^{-1}) was made, giving rise to an Arrhenius straight line. Since an excess of hydrogen was supplied, the hydrogenation rate was assumed to obey the pseudo-first-order kinetics for ethylene. Apparent activation energies from the above plots are shown in Table 1. These results indicate that apparent activation energy over the ion exchanged catalysts (A) is remarkably affected by the water content in a hydrogen stream, but not over the impregnated catalysts. The activation energy for hydrogenation of ethylene previously reported is 8.4 kcal/mol over Pt–SiO_2 catalyst[6], 9.9 kcal/mol over Pt–Al_2O_3,[7] and 10 kcal/mol over platinium plate.[8] These results are in fairly good agreement with those of 2), 3), and 4) in Table 1.

Another catalyst (C) was prepared by ion exchange followed by calcination at 350°C in the air for 3 hr and reduction at 200°C for 3 hr. The slope of the line below 0°C corresponds to an activation energy of 10 kcal/mol. Electron micrographs of (C) show the presence of platinum crystallites with diameters 20—70 Å. This means that platinum was partly aggregated on the surface and possibly exists in part in the cavity. Activity of the catalyst was tested for hydrogenation of ethylene in a hydrogen stream containing 2.3 mg/l of water. A logarithmic plot of $(1-x)^{-1}$ against T^{-1} gave two straight lines with different slopes intersecting at *ca.* 0°C. These results suggest that, below 0°C, ethylene reacts with hydrogen on platinum crystallites outside the cavity. The platinum in the cavity does not seem to be available at this temperature range because adsorbed water is frozen in the cavity to plug it. This is supported by the agreement of activation energy below 0°C for (C) with that for (B). Above 0°C, adsorbed water is released from cavity with the rise in reaction temperature, and the active site in the cavity is allowed to participate in hydrogenation. Thus, the apparent activation energy is larger than that below 0°C by *ca.* 20 kcal/mol, and agrees with that of catalyst (A), In this connection, it might be interesting to note that Dzhigit *et al.*[9] reported the heat of adsorption of water on Na-Faujasite to be 20—13.5 kcal/mol.

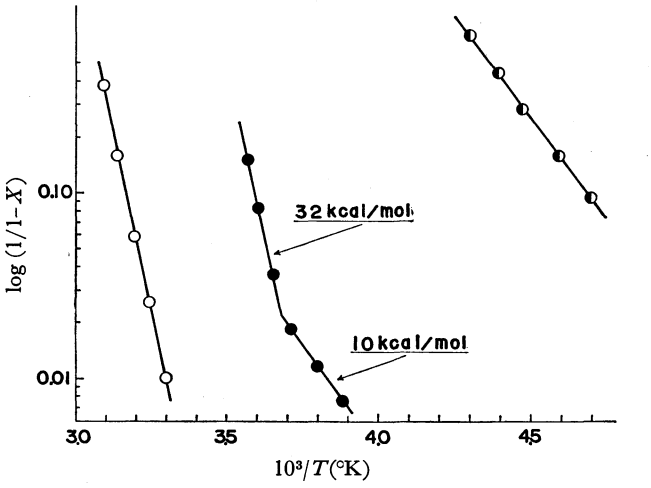

Fig. 3. Plot of $\log(1/1-x)$ *vs.* $1/T$(°K^{-1}).
Catalyst weight 0.100 g, sample size 6.7×10^{-6} mol, H_2 pressure 303—304 mmHg, H_2 flow rate 33 ml/min, H_2O content 2.3 mg/l.

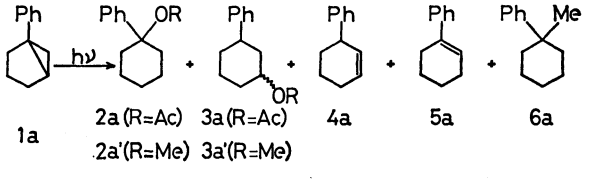
The Photolysis of 1-Phenylbicyclo[*n*.1.0]alkanes in Acidic Media

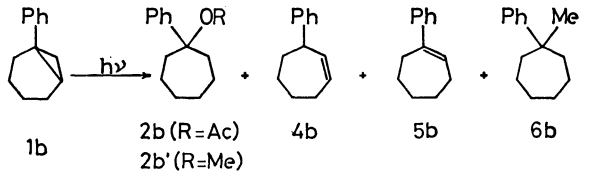
Shinsaku FUJITA, Yoshihito HAYASHI, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yosida, Sakyô-ku, Kyôto

(Received December 21, 1970)

In continuation of our studies of the photochemical polar addition of acetic acid to 1-phenylcycloalkenes,[1] we have been interested in the title reaction of phenylcyclopropanes (**1a**, **1b**). This has been disclosed to involve proton addition to the cyclopropane ring and to give products, **2**—**6**, as a result of the expansion of the original $n+2$ rings to $n+3$ rings, where $n=3$ or 4. Such a photoinduced heterolysis is rare[2] and forms a sharp contrast to the previously recorded formation of carbenes in this kind of photolysis.[3]





The irradiation of 1-phenylbicyclo[3.1.0]hexane (**1a**) was performed in acetic acid, and the resulting photoproducts were separated by preparative-scale thin layer (TLC) and gas chromatography (GC). The acetate fraction of TLC consisted of 5 components, among which 1-acetoxy-phenylcyclohexane (**2a**) and *cis* and *trans* isomers of 3-acetoxy-1-phenylcyclohexane (**3a**) were identified. The three hydrocarbons isolated were 1-(**5a**) and 3-phenylcyclohexene (**4a**) and 1-methyl-1-phenylcyclohexane (**6a**). The photolysis of 1-phenylbicyclo[4.1.0]heptane (**1b**) in acetic acid proceeded in a similar way to afford the corresponding acetate (**2b**), two isomerization products (**4b** and **5b**), and 1-methyl-1-phenylcycloheptane (**6b**). Methanol also added to the cyclopropane ring of **1a** or **1b** on UV irradiation in the presence of sulfuric acid. On the other hand, the photolysis of **1a** and **1b** under neutral conditions gave no ionic photoadducts, but only isomerization products in rather low yields.

The formation of acetates and ethers is ionic in nature, and protonated cyclopropanes[4] are plausible intermediates, as the attack of solvent molecules occurred on the both sides of cyclopropane rings. However, the possibility of the intermediary of **5a** and **5b** in the polar addition can not be excluded.[1] It should be emphasized that the C_1–C_{n+2} bonds of 1-phenylbicyclo[*n*.1.0]alkanes (**1**) were cloven exclusively. The alkylation products (**6a** and **6b**) can be explained as secondary photoprodncts arising from **2a** and **2b** respectively.[1]

Experimental

The mass spectra were determined on a Hitachi RMU-6L spectrometer, and the NMR data, on a JEOL C-60-H spectrometer in carbon tetrachloride at 60 MHz. Prepara-

TABLE 1. PHOTOLYSIS OF 1-PHENYLBICYCLO[*n*.1.0]ALKANES[a]

tive TLC was performed on silica-gel G (20×20×0.3 cm), using benzene as the solvent and as an eluant. Preparative GC was carried out using High Vacuum Silicone Grease 20% on Celite 545 (2 m, 180°C, helium as the carrier gas). The hydrocarbon contents were determined by GC.

*1-Phenylbicyclo[3.1.0]hexane (**1a**).* A solution of bromoform (135 g, 0.53 mol) in *n*-hexane (200 m*l*) was added, under 5°C, to a mixture of 1-phenylcyclopentene (40 g, 0.28 mol), potassium *t*-butoxide (59 g), and *n*-hexane (400 m*l*). The mixture was allowed to stand overnight at room temperature, poured into water, extracted with ether, and dried over sodium sulfate. After concentration, the unchanged olefin was recovered by distillation. The resulting residue (60 g) was subjected to reduction without further purification.

The crude dibromide was added to a solution of sodium metal (30 g) in liquid ammonia (*ca.* 500 m*l*) under −40°C for 2 hr. After stirring for an additional 2 hr, solid ammonium chloride was added and the solvent was allowed to evaporate at room temperature. The residue was diluted with water, extracted with ether, and dried over sodium sulfate. Subsequent concentration and fractional distillation gave **1a** (22 g, 50%) as a colorless liquid; bp. 69°C/1 mmHg. IR (neat): 3035, 3007, 2940, 2920, 2850, 1604, 1498, 1476, 1452, 1101, 1072, 1024, 935, 868, 799, 756 and 698 cm^{-1}. NMR (CCl_4): δ 7.12 (5H, s), 2.25—1.40 (7H, m) and 0.80—0.57 (2H, m). MS *m/e* (relative abundance): 158 (100), 143 (65), 130 (91), 129 (99), 128 (48), 117 (63), 115 (79), 104 (55), 91 (63), 77 (35), 51 (34), 39 (35).

Found: C, 91.1; H, 8.8%. Calcd for $C_{12}H_{14}$: C, 91.1; H, 8.9%.

1-Phenylbicyclo[4.1.0]heptane (**1b**)[5] was similarly prepared from 1-phenylcyclohexane.

*Direct Irradiation of **1a** and **2b** in Acetic Acid.* A 0.05M solution (200 m*l*) of 1-phenylbicyclo[*n*.1.0]alkane (**1**) in acetic acid was placed in eight quartz tubes (1.5ϕ×19 cm) and irradiated with a high-pressure mercury are under a nitrogen atmosphere for 5 hr. The combined photolysates were then neutralized with aqueous sodium hydrogen carbonate, extracted with ether, and dried over sodium sulfate. Concentration *in vacuo* and subsequent preparative TLC gave a mixture of hydrocarbons (**1**, **4**, **5** and **6**) and the corresponding esters (**2** and **3**). These two separated fractions were weighed and subjected directly to GC analyses. The results are summarized in Table 1. The preparative GC of the hydrocarbon fraction gave the starting material (**1**), 1- (**5**) and 3-phenylcycloalkene (**4**)[6] and 1-methyl-1-phenylcycloalkane (**6**).[1] All the hydrocarbons were identified by comparison with known samples. The esters (**2**) were distilled and subjected to spectrometric analyses. The *cis* and *trans* isomers of **3a** were isolated by preparative GC and compared with the authentic specimens to be described below.

*Direct Irradiation of **1a** and **1b** in Methanol Containing Sulfuric Acid.* A 0.05 M solution (200 m*l*) of **1** in methanol containing 0.3% sulfuric acid was irradiated as has been described above. The photolysate was analyzed by GC (Table 1). The ethers (**2a′** and **2b′**) were identical with the authentic samples.[1] The *cis* and *trans* isomers of **3a′** isolated by preparative GC were identical with the authentic samples described below.

*Direct Irradiation of **1a** and **1b** in Methanol.* A 0.05 M solution (200 m*l*) of **1** in methanol was irradiated. A usual work-up gave a mixture of hydrocarbons (**1**, **4**, and **5**) which was then analyzed by GC. The results are summarized in Table 1.

cis-*3-Acetoxy-1-phenylcyclohexane (*cis-**3a**). The reduction of 3-phenylcyclohexanone with lithium aluminum hydride gave a *cis*-rich mixture of 3-phenylcyclohexanol, from which the *cis* isomer was isolated by recrystallization from *n*-hexane. mp 78—79°C (lit,[7] 79—80°C).

A mixture of *cis*-3-phenylcyclohexanol (0.15 g, 0.85 mmol), acetic anhydride (5 m*l*), and pyridine (10 m*l*) was heated at 90—100°C for 2 hr. A work-up gave *cis*-**3a** (0.16 g, 86%), bp 75—80°C (bath temperature)/0.04 mmHg, which was contaminated with 1.6% of *trans* isomer. An authentic specimen of *cis*-**3a** was purified by preparative GC. IR (neat): 3030, 3010, 2900, 2840, 1737, 1603, 1497, 1451, 1367, 1242, 1200, 1029, 967, 756, and 699 cm^{-1}. NMR (CCl_4): δ 7.17 (5H, s), 4.97—4.48 (1H, m), 2.87—0.80 (12H, m+s (δ 1.97, 3H)). MS *m/e* (relative abundance): 218 (7), 158 (100), 143 (37), 130 (52), 129 (35), 117 (31), 104 (54), 91 (49).

Found: C, 77.2: H, 8.1%. Calcd for $C_{14}H_{18}O_2$: C, 77.0; H, 8.3%.

trans-*3-Acetoxy-1-phenylcyclohexane (*trans-**3a**). The Meerwein-Ponndorf reduction of 3-phenylcyclohexanone (4.2 g, 24 mmol) gave a mixture (3.4 g, 81%) of *cis*- and *trans*-3-phenylcyclohexanol (*cis* : *trans*=2.5 : 1),[7] from which the *cis* isomer was then removed by recrystallization.

A *cis-trans* mixture of 3-phenylcyclohexanol (0.034 g, 0.19 mmol, *cis*:*trans*=1:3), acetic anhydride (5 m*l*), and pyridine (10 m*l*) was refluxed. Distillation gave a mixture (0.035 g, 81%) of *cis*- and *trans*-**3a** (*cis*:*trans*=5:4). The analytical sample of *trans*-**3a** was purified by preparative GC. IR (neat): 3030, 3010, 2900, 2845, 1739, 1604, 1496, 1440, 1376, 1249, 1232, 1115, 1018, 958, 753, and 698 cm^{-1}. NMR (CCl_4): δ 7.16 (5H, s), 5.30—5.00 (1H, m), 2.95—0.90 (12H, m+s (δ 2.06, 3H)). MS *m/e* (relative abundance): 218 (3), 158 (100), 143 (38), 130 (39), 129 (32), 117 (16), 104 (28), 91 (32).

Found: C, 77.3; H, 8.5%. Calcd for $C_{14}H_{18}O_2$: C, 77.0; H, 8.3%.

cis- *and* trans-*3-Methoxyl-1-phenylcylohexane (**3a′**).* To a solution of 3-phenylcyclohexanol (1.0 g, 5.7 mmol, *cis*: *trans* =2.5: 1) in ether (50 m*l*), boron trifluoride etherate (5 m*l*) was added, drop by drop; then, a solution of diazomethane (from 20 g of *N*-methyl-*N*-nitrosourea) in ether (50 m*l*) was added. Subsequent concentration and distillation gave a mixture (0.80 g, 74%) of *cis*- and *trans*-**3a′** (*cis*:*trans*=7:1). The analytical samples of both the isomers were obtained by preparative GC.

The pure *cis* isomer **3a′** showed the following spectra. IR (neat): 3027, 3010, 2920, 2860, 2820, 1602, 1498, 1450, 1371, 1139, 1128, 1098, 756, and 702 cm^{-1}. NMR (CCl_4): δ 7.13 (5H, s), 3.35—0.80 (13H, m+s (δ 3.27, 3H)). MS *m/e* (relative abundance): 190 (66), 158 (75), 147 (100), 143 (67), 130 (41), 129 (37), 117 (62), 115 (41), 105 (29), 104 (98), 91 (87), 77 (28), 71 (43), 58 (46).

Found: C, 82.1; H, 9.6%. Calcd for $C_{13}H_{18}O$: C, 82.1; H, 9.5%.

The pure *trans*-**3a′** showed the following spectra. IR (neat): 3027, 3010, 2910, 2860, 2810, 1602, 1498, 1450, 1362, 1140, 1115, 1088, 756, 704 cm^{-1}. NMR (CCl_4): δ 7.13 (5H, s), 3.65—3.45 (1H, m), 3.30 (3H, s), 3.00—1.00 (9H, m).

The Catalytic Effect of Metal Ions on the Hydrolysis of Disodium Pyrophosphite

Shiro UEDA and Yoshinori SASAKI

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba

(Received December 21, 1970)

It is well known that hydrolytic scissions of polyphosphate, the splitting of the $\overset{5}{P}$–O–$\overset{5}{P}$ linkage, and those of pyrophosphite, the splitting of the $\overset{3}{P}$–O–$\overset{3}{P}$ linkage, are strongly catalyzed by the hydrogen ion. Recently, Mesmer and Carroll[1] have studied in detail the kinetics and mechanism of the hydrolysis of pyrophosphite over an extensive pH range. The effect of metal ions on the acid hydrolysis of pyrophosphate has also been studied.[2] The present paper will deal with the effects of various metal ions on the rate of the hydrolysis of disodium pyrophosphite at pH 4.6.

The disodium pyrophosphite used in this work was prepared by heating purified monosodium orthophosphite under reduced pressure, and the product contained as much as 68% of disodium pyrophosphite when determined by iodine titration. This analysis is based upon the fact that the reaction of iodine with phosphite in a neutral solution occurs very rapidly, whereas the reaction with pyrophosphite is very slow under the same conditions.

The pH of a 0.03M disodium pyrophosphite solution containing the metal ion added as the chloride was quickly adjusted to 4.6 with hydrochloric acid at 60°C. The flasks, each containing 20 m*l* of this solution, were transferred to a bath regulated at 60±0.1°C. After selected periods of time, these flasks were rapidly cooled to 0°C, and the solutions were neutralized with sodium hydrogen carbonate. An appropriate amount of the disodium salt of ethylenediaminetetraacetic acid to mask the metal ions was added to the solutions, and then 30 m*l* of a standardized iodine solution (0.1 N) were added. The flasks were subsequently allowed to stand for 15 min in the dark. These solutions were titrated with a standardized sodium thiosulfate solution (0.1N) to the starch end point after being acidified with an acetic acid solution. The pH of the solutions could be maintained approximately at a constant value of 4.6 throughout each run, inasmuch as monosodium orthophosphite gives the pH value of 4.6.

Plots of the logarithm of the pyrophosphite concentration against the time are shown in Fig. 1, in which the linear relation indicates that the hydrolysis is to be regarded as of the first order. The addition of the copper (II) ion resulted especially in an increase in the rate constant, and the magnitude of this effect increased with an increase in the concentration.

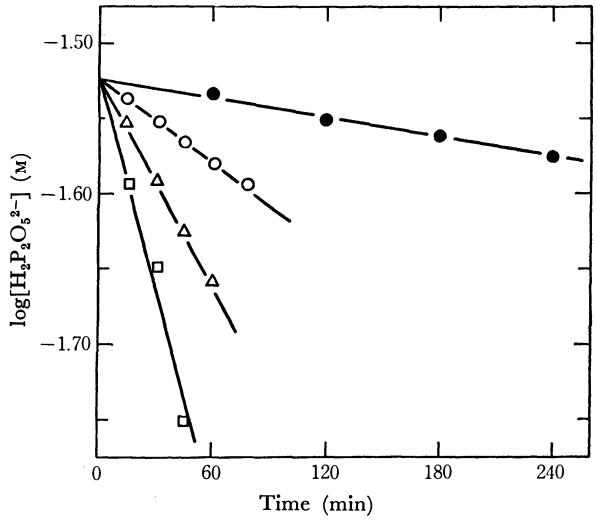

Fig. 1. Effect of concentration of copper(II) ion at pH 4.6 and 60°C. ● None added; ○ 0.5×10^{-3}M; △ 1.0×10^{-3}M; □ 2.0×10^{-3}M

The first-order rate constants, K, obtained with various metal ions are summarized in Table 1. The rates of hydrolysis in the presence of all the metal ions except the copper(II) ion were approximately equal to that in the absence of any metal ion, and were nearly independent of the metal-ion concentration.

Since the cleavage of the P–O–P linkage has generally been considered to be accelerated by the attack of hydrogen ion on the bridging oxygen atom, metal ions are also presumed to behave similarly. In this work, metal ions seem to act on the $\overset{3}{P}$–O–$\overset{3}{P}$ linkage in competition with the hydrogen ion and the sodium ion of disodium pyrophosphite. The behavior of the $\overset{3}{P}$–O–$\overset{3}{P}$ linkage towards the metal ion differs distinctly

from that of the $\overset{5}{P}$–O–$\overset{5}{P}$ linkage because of the lower oxidation states of phosphorus. Unlike pyrophosphate, pyrophosphite has hardly ever been reported to form metal-ion complexes.[3] Complex-ion formation causes the half-wave potential of a metal to shift to a more negative value in a polarographic study. A polarographic experiment was attempted for these reaction systems under the following conditions: mole ratio of pyrophosphite/metal ion, 3.6; metal-ion concentration, 0.001 mol/l; tetramethylammonium-bromide concentration, 0.1 mol/l; pH, 4.6; temperature, 30°C. However, the shifts of the half-wave potentials were hardly observed in any case.

The strength of the affinity between the pyrophosphite ion and the metal ions is assumed to depend upon their electrode potentials. Since all the experiments with regard to the metal-ion effects were carried out at pH 4.6, the copper(II) ion, which is more noble than the hydrogen ion, appears to have promoted the hydrolysis. On the other hand, the other metal ions, less noble than the hydrogen ion, have negligibly affected the rate. Although a silver ion or mercury(II) ion, being more noble than copper(II) ion, seems to promote strongly the rate of hydrolysis, the rate constants cannot be obtained because of the oxidation reduction between these ions and pyrophosphite.

The Chlorination of Cyclooctadiene with Cupric Chloride in Acetonitrile Containing Lithium Chloride

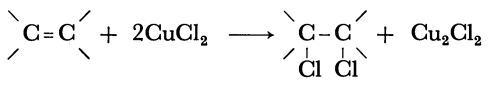
Sakae UEMURA, Akira TABATA, Yoshihiro KIMURA,* and Katsuhiko ICHIKAWA*

Institute for Chemical Research, Kyoto University, Uji, Kyoto

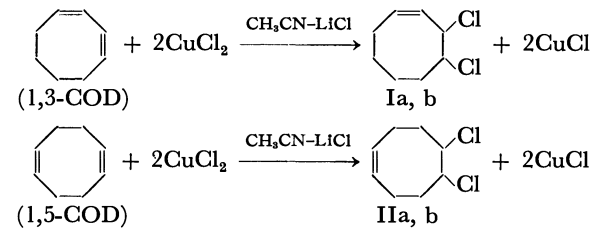
**Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto*

(Received December 22, 1970)

In previous papers, it was demonstrated that olefins can be chlorinated to form dichloroparaffins with cupric chloride under rather mild conditions.[1] The reaction of butadiene in acetic acid containing sodium acetate, however, gave 3,4-diacetoxy-1-butene and 1,4-diacetoxy-



2-butene in place of the expected dichlorobutenes.[2] In this paper, the results of applying the method to cyclooctadienes and acrylonitrile and *trans*-crotyl chloride as reference substrates will be reported, and the results will be compared with those obtained by conventional chlorine gas-chlorination. In the presence of lithium chloride, anhydrous cupric chloride dissolves into acetonitrile to make a clear solution. In this solution, *cis*, *cis*-1,3-, and 1,5-cyclooctadienes were chlorinated (Table 1). In the cases of both 1,3- and 1,5-dienes, dichlorocyclooctenes were the main products, along with a high-boiling resinous residue. Only a small amount of tetrachlorocyclooctane (bp 164°C/10 mmHg; NMR, τ5.2—6.0, 4H, τ7.2—8.3, 8H) was obtained, even when more than four moles of cupric chloride were used for one mole of diene.



(a: *trans*, b: *cis*)

This is not due to the formation of an inactive complex which might be formed between dichlorocyclooctene and the resulting cuprous chloride, but to the low reactivity of the chloroolefin, since the further reaction of dichlorocyclooctene (isolated and purified)

a) Equimolar amounts of lithium chloride were added to cupric chloride, and the reaction was carried out under refluxing (at about 82°C).
b) Based on $CuCl_2$ used.

proceeded only slowly in the absence of cuprous chloride. The cyclic structure of the substrate cannot be the reason for the low reactivity, since *trans*-crotyl chloride also resisted the same reaction. Chlorine at the allylic position appers to decrease the reactivity of the double bond towards cupric chloride.

The reaction was slow in acetic acid containing sodium acetate, which is a convenient reaction medium for the chlorination of simple monoolefins with cupric chloride.[1)]

The structures of the dichlorocyclooctenes were inferred to be 3,4-dichloro- (I, from 1,3-COD) and 5,6-dichlorocyclooctene (II, from 1,5-COD) on the basis of the analytical data and the IR spectra. The results obtained so far show that only addition occurs and that no isomerization nor substitution proceeds in the liquid-phase chlorination of an isolated double bond with cupric chloride. Since 1,5-diene is not a conjugated one, the normal addition product, II, can be expected unless a transannular reaction occurs to form saturated bicyclic products. Although gas-chromatographical analysis gave two peaks with retention times close to one another, the results do not appear to show the presence of positional isomers, but only that of geometrical isomers resulting from *cis* and *trans* addition. Since the retention times of *trans* isomers of dichlorocycloparaffins are shorter than those of *cis* isomers in the gas chromatogram using Apz-L or PEG columns, the data in Table 1 were calculated on this assumption. Each of two isomers was separated by preparative gas chromatography. Their NMR spectra can be explained in term of these structures.

1,3-Cyclooctadiene is not a usual conjugated diene because of its cyclic structure. The two peaks with retention times close to each other on the gas chromatogram of the chlorinated product appear to show also the presence of *cis* and *trans* isomers, as in the case of 1,5-diene. The NMR spectrum of I is also consistent with these structures.

The *cis* and *trans* ratios in the chlorinated products of cyclooctene and cyclooctadienes, especially in the case of 1,5-diene, are much larger than that of cyclohexene, where the *cis* content was only 2% under the same reaction conditions.

Several attempts to hydrogenate the dichlorocyclooctenes by palladium and platium catalysts in order to confirm the structure further were unsuccessful. These compounds resisted hydroboration by Brown's method,[3)] also. The reason for the low reactivities is not yet clear.

A conventional chlorination of both diene with chlorine gas was carried out in acetonitrile (at 6–11°C) and in acetic acid (at 16–26°C). With 1,5-diene, the products were so complicated (16 or 17 peaks in gas chromatograms) that no definite compounds could de isolated, probably because of facile substitution at the allylic positions and transannular reaction.[4)] Although the products with 1,3-diene were also complicated (12 peaks in gas chromatograms), I(*trans*: *cis*=95:5) and 5-chlorocycloocta-1,3-diene (bp 75–79.5°C/11 mmHg; NMR τ 3.9—4.6, 4H, τ 5.05—5.45, 1H, τ 7.4—8.9, 6H: IR $\nu_{C=C}$ 1620 cm^{-1}) could be isolated in an almost pure form in this case.

Experimental

Materials. The organic materials were commercial products of the purest grade and were distilled and checked by gas chromatography. The 1,3-cyclooctadiene, bp 142—144°C, and 1,5-cyclooctadiene, bp 150—152°C, (distilled in the presence of *t*-butylcatechol) were both *cis*, *cis*- diene, since

3) H.C. Brown and K. Murray, *J. Amer. Chem. Soc.*, **81**, 4108 (1959).
4) see, for example, S. Moon, and C. R. Ganz, *J. Org. Chem.*, **35**, 1241 (1970).

the IR spectra of both diene showed absorptions at 1660 and 1410 cm^{-1} due to a *cis* double bond, but not at 1675 and 965 cm^{-1} due to a *trans* double bond. The inorganic materials were also commercial materials of an analytical grade and were used without purification. The chlorine gas was prepared by the conventional oxidation of hydrogen chloride with potassium permanganate; it was washed with water and then conc. H_2SO_4 before being introducing into the reaction mixture.

Analytical Instruments. The IR and NMR spectra were determined by the use of a HITACHI EPI-S2 apparatus and a JEOL JNM MH-60 or a Varian A-60 apparatus respectively. Gas chromatographies were carried out by the use of HITACHI K53 (PEG-20M 1 m or Apiezon-L 1 m columns) and SHIMADZU 5APTF (PEG 600 25%-Chromosorb-W 3 m column) apparatuses.

Procedure. Olefinic substrates were added to mixtures of solvents, cupric chloride (anhyd.) and lithium chloride at a reaction temperature. At proper intervals, small portions of the mixture were withdrawn and the decreases in the cupric chloride concentration were determined by iodometry. The reaction mixtures were worked up by the following successive treatments; filtration from the resulting inorganic materials, the evaporation of the solvents, dilution with water, extraction with benzene, and then distillation. Each fraction was analyzed by gas chromatography. The yields of the chlorinated products were calculated on the basis of the weights of the distillates and the g.l.c. analysis data.

The Absolute Configurations of 2-Phenylaziridine and Its Derivatives

Shinsaku FUJITA, Kazuo IMAMURA, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yosida, Sakyo-ku, Kyoto

(Received December 31, 1970)

As the optical resolution of aziridines is rarely feasible because of their acid-sensitivity, optically-active aziridines have been obtained by the stereospecific ring-closure of suitable precursors, mainly of natural origin.[1] The present report will describe a novel synthesis of optically active 2-phenylaziridine (I) and its derivatives, and the determination of their absolute configulations.

The addition of iodine isocyanate[2] to styrene and subsequent treatment with (−)-menthol gave a mixture of the diastereomers of α-(iodomethyl)benzylcarbamic acid (−)-methyl ester (II), which was fractionally recrystallized from methanol. The less soluble diastereomer ($[\alpha]_D$ −73.0°) was treated with methanolic sodium hydroxide, and the resulting aziridine was separated from (−)-menthol by preparative thin-layer chromatography. The optically-active 2-phenylaziridine ((−)-I) thus obtained had an optical rotation of $[\alpha]_D$ −45.5° (75% optically pure, *vide infra*). Similarly, the ring-closure of the more soluble one (IIb) gave another enantiomer (+)-I. which was obtained only in a lower optical purity.

The absolute configuration of I was correlated to that of known α-methylbenzylamine, with the results illustrated in Schemes 1 and 2. The reduction of IIa ($[\alpha]_D$ −70.5°)and IIb with lithium aluminum hydride afforded (−)-N-methyl-α-methyl-benzylamine ((−)-III $[\alpha]_D$ −58.2°) and (+)-enantiomer respectively. On the other hand, the reaction of (R)-(+)-α-methylbenzylamine with ethyl chloroformate yielded (R)-(+)-ethyl α-methylbenzylcarbamate (VII), which in turn afforded (R)-(+)-III on LAH reduction. Therefore, the absolute configuratoins of enantiomers of I were

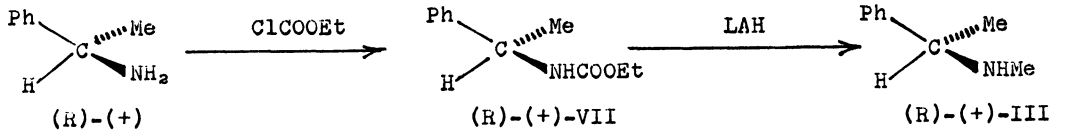

Scheme 2

concluded to be (R)-(−) and (S)-(+).

The following derivatives of (R)-(−)-I were prepared: (R)-(−)-1-acetyl-2-phenylaziridine (IV) and (R)-(−)-1-phenylcarbamoyl-2-phenylaziridine (V). (S)-(+)-1-Methyl-2-phenylaziridine (VI) was also prepared from (S)-(+)-I.

Experimental

All the melting points are uncorrected. Unless otherwise stated, each optical rotation was determined in chloroform at room temperature. The optically-active aziridines were identified by comparing the spectral data with those of racemic samples.

Addition of Iodine Isocyanate to Styrene. Iodine (50.8 g, 0.20 mol) was added in one portion to a cooled mixture of silver isocyanate (40.0 g, 0.26 mol), styrene (20.8 g, 0.20 mol), and dry ether (400 m*l*). Stirring was continued for 1 hr over an ice-salt bath and then for 4 more hr at room temperature. The silver salt then precipitated was filtered off. (−)-Menthol (31.3 g, 0.20 mol) was added to the filtrate, and the solution was allowed to stand in the dark for 4 days. The mixture was poured into ice water (700 m*l*) containing 20 g sodium sulfite and extracted with ether. The combined extracts were dried over sodium sulfate. Concentration gave a mixture of IIa and IIb (81.0 g, 94%). Fractional recrystallization (4 times) of the mixture from methanol yielded a IIa-rich mixture as white crystals (4.53 g); mp 149°C; $[\alpha]_D$ −73.0° (c=1.21 g/100 m*l*).

Found: C, 53.4; H, 6.5; I, 29.9; N, 3.2%. Calcd for $C_{19}H_{28}INO_2$: C, 53.1; H, 6.6; I, 29.6; N, 3.3%.

A IIb-rich mixture was obtained from the mother liquor. Mp 115°C; $[\alpha]_D$ −12.9° (c=0.64 g/100 m*l*).

(R)-(−)-2-Phenylaziridine (I). A mixture of IIa (8.95 g, 20.9 mmol, $[\alpha]_D$ −73.0°) and methanolic sodium hydroxide (10 N, 50 m*l*) was heated at reflux for 1.5 hr under a nitrogen atmosphere. After the evaporation of the solvent, the residue was extracted with ether and dried over sodium sulfate. Concentration and distillation gave a mixture of (R)-(−)-I, menthol, and acetophenone. Preparative-scale TLC (silica-gel G, using ether as a solvent and chloroform as a eluent) and subsequent distillation afforded pure (R)-(−)-I (0.64 g, 27%); bp 56°C/2.5 mmHg; $[\alpha]_D$ −45.5° (c=1.72 g/100 m*l*). Calculation indicated that the optically-pure sample has the optical rotation of $[\alpha]_D$ −60.3°.

(S)-(+)-2-Phenylaziridine (I). ($[\alpha]_D$ +29.4°, c=1,53 g/100 m*l*) was obtained similarly from IIb ($[\alpha]_D$ −12.9°).

(S)-(−)-N-Methyl-α-methylbenzylamine (III) from IIa. A solution of IIa (2.00 g, 4.7 mmol, $[\alpha]_D$ −73.0°) in ether was added, drop by drop at room temperature, to a suspension of lithium aluminum hydride (1.5 g) in ether (30 m*l*). The mixture was then heated at 50°C for 20 hr. The excess hydride was quenched with water and extracted with ether. Then combined ethereal solutions were then extracted with 15% hydrochloric acid. The aqueous layer was neutralized with 25 N aqueous sodium hydroxide, extracted with ether, and dried over sodium sulfate. Distillation afforded (S)-(−)-III (0.044 g, 6%, $[\alpha]_D$ −58.2°, c=0.88 g/100 m*l*). The optical purity was calculated to be 75.4%.

(R)-(+)-N-Methyl-α-methylbenzylamine (III). ($[\alpha]_D$ +45.8°, c=0.57 g/100 m*l*) was obtained from IIb ($[\alpha]_D$ −8.05°).

(R)-(+)-ethyl α-methylbenzylcarbamate (VII). A solution of ethyl chloroformate (0.56 g, 5.2 mmol) in ether (30 m*l*) was added at 0°C to a mixture of (R)-(+)-α-methylbenzylamine (1.24 g, 10 mmol, $[\alpha]_D$ +36.4° (neat), 91.7% optically pure), ether (20 m*l*), and water (30 m*l*). Then another solution of ethyl chloroformate (0.56 g, 5.2 mmol) and aqueous sodium hydroxide (NaOH 0.48 g in water 10 m*l*) were

added to the reaction mixture at the same time. Work-up gave (R)-(+)-VII (1.70 g, 88%); $[\alpha]_D$+64.4° (c=1.99 g/100 ml); bp 97—101°C/1 mmHg.

Found: C, 68.6; H, 7.9; N, 7.2%. Calcd for $C_{11}H_{15}NO_2$: C, 68.4; H, 7.8; N, 7.3%.

*(R)-(+)*N-*Methyl-α-methylbenzylamine (III).* The reduction of (R)-(+)-VII (0.58 g, 3.0 mmol, $[\alpha]_D$+64.4°, 91.7% optically pure) with lithium aluminum hydride gave (R)-(+)-III (0.34 g, 85%); bp 74°C/14 mmHg; $[\alpha]_D$+70.8° (c=1.92 g/100 m*l*). The optical rotation of pure (R)-(+)-III was calculated to be $[\alpha]_D$+77.2°.

(R)-(−)-1-Acetyl-2-Phenylaziridine (IV). A solution of acetyl chloride (0.10 g, 1.3 mmol) in ether (5 m*l*) was added at 0°C to a solution of (R)-(−)-I (0.23 g, 1.5 mmol, $[\alpha]_D$ −45.5°, optical purity 75.4%) and triethylamine (0.18 g) in ether (10 m*l*). The reaction mixture was stirred for 1 hr. The triethylamine hydrochloride thus precipitated was filtered off and washed well with ether. After the evaporation of the solvent, the oily residue was distilled to give (R)-(−)-IV (0.10 g, 31%); bp 56°C/0.2 mmHg; $[\alpha]_D$ −106° (c=1.28 g/100 m*l*). The optically pure sample was calculated to have the rotation of $[\alpha]_D$ −141°.

(R)-(−)-1-phenylcarbamoyl-2-phenylaziridine (V). Phenyl isocyanate (0.090 g) was added to a solution of (R)-(−)-I (0.090 g, $[\alpha]_D$ −45.5°, 75.4% optically pure) in ether (10 m*l*). After it had been stirred for 1.5 hr, the ether was evaporated *in vacuo* to give (R)-(−)-V (0.17 g, 94%); mp 97—99°C (lit. mp for racemic sample[3] 96.5—97.5°C); $[\alpha]_D$ −262° (c=1.56 g/100 m*l*). The optical rotation of pure (R)-(−)-V was calculated to be $[\alpha]_D$ −348°.

(S)-(+)-1-Methyl-2-phenylaziridine (VI). A 1.30 M solution (1.0 m*l*) of *n*-butyllithium in *n*-hexane was added, drop by drop under a nitrogen atmosphere, to a solution of (S)-(+)-I (0.15 g, 1.3 mmol, $[\alpha]_D$ +8.08°, 13.4% optically pure) in tetrahydrofuran (20 m*l*), and the mixture was stirred for 30 min at room temperature. To the reaction mixture we then added drop by drop methyl iodide (0.18 g); the mixture was stirred for 1 hr, poured into saturated aqueous ammonium chloride (20 m*l*), and extracted with ether. The combined etheral extracts were dried over sodium sulfate and concentrated *in vacuo*. The distillation of the oily residue afforded (S)-(+)-VI (0.076 g, 45%); bp 39°C/1 mmHg; $[\alpha]_D$ +32.1° (c=1.51 g/100m*l*). The optical rotation of pure (S)-(+)-VI was calculated to be $[\alpha]_D$ +241°.

The authors are grateful to Professor Keiiti Sisido for his generous help. Financial support from the Ministry of Education, the Japanese Government, and from the Toray Science Foundation is acknowledged with pleasure.

Effect of Hole Scavengers on the Radiolysis of Water

Takeshi SAWAI

Tokyo Metropolitan Isotope Research Center, Fukazawa, Setagaya-ku, Tokyo

(Received January 9, 1971)

Recently, a model for the radiolysis of water at low LET was proposed by Hamill.[1] According to the model, some charge recombination of the dry electron and the hole, which are produced early in the radiolysis of water, occurs before hydration and is responsible for the formation of molecular hydrogen and hydrogen peroxide, and these ion pairs can be scavenged by suitable solutes prior to hydration. This hypothesis has been supported by the quantitative correlation shown in recent studies[2,3] of aqueous solutions. The reaction of an electron with some solutes prior to hydration has been reported by the recent striking experiments of Hunt *et al.*[4] with pico second-pulsed radiolysis.

If the dry hole in water is trapped by a suitable solute (X^-), one can expect an increase in $G(e^-_{aq})$ by preventing the fast neutralization of the dry-charge pairs in water. The increase in $G(e^-_{aq})$ with an increase in the Cl^- concentration was shown in an earlier paper.[5] Moreover, the increase of $G(e^-_{solv})$ by Cl^- in the radiolysis of ethanol was recently reported by Khorana and Hamill.[6] The change in $G(e^-_{solv})$ is considered to be due to hole trapping by Cl^-.

The negative ions, SO_4^{2-}, ClO_4^-, or F^-, will also trap the hole[7]:

$$H_2O^+(H_3O^+) + X^- \longrightarrow X(HX) + H_2O \qquad (1)$$

The purpose of this work is to provide evidence for the hole trapping by halogen ions and SO_4^{2-}, and to examine the effect of the solutes on the yield of molecular products.

Experimental

Samples (10 m*l*) of aqueous neutral solutions containing 10^{-2}M KNO_3 and 5×10^{-2}M isopropanol (*i*-PrOH) for the testing of $G(e^-_{aq})$, $G(H_2)$, $G(H_2O_2)$, and 2×10^{-2}M KNO_3 aqueous solutions for G_{H_2} were used. These samples in the irradiation vessel with a break seal were purged with nitrogen gas, degassed by repeated freeze-pump-thaw cycles, and then irradiated with ^{60}Co γ-rays. Oxygenated 5 m*l* samples of

10^{-2}M KNO_3-*i*-PrOH solutions were used for the $G(OH)$ measurements. The dose rate, determined by means of a ferrous sulfate dosimeter, was 9.31×10^{18} eV/g hr. The methods of the measurement of H_2, acetone, H_2O_2, and NO_2^- are described elsewhere.[8] These yields were calculated from the slope of the linear portions of the product-dose curves. The energy absorbed in the samples was corrected by the use of the electron fraction of each sample.

Results and Discussion

In the deaerated *i*-PrOH-KNO_3 solutions, NO_3^- reacts with e^-_{aq} to form NO_2^-:

$$NO_3^- + e^-_{aq} \longrightarrow NO_2^- \quad (2)$$

H and OH radicals react with *i*-PrOH to form isopropanol radicals:

$$(CH_3)_2CHOH + H \longrightarrow (CH_3)_2COH + H_2 \quad (3)$$

$$(CH_3)_2CHOH + OH \longrightarrow (CH_3)_2COH + H_2O \quad (4)$$

In oxygenated solutions, $(CH_3)_2COH$ will react with O_2 to produce acetone and HO_2[9]:

$$(CH_3)_2COH + O_2 \longrightarrow (CH_3)_2CO + HO_2 \quad (5)$$

Almost all the H reacts with O_2 to form H_2O_2, because $k(H+O_2)[O_2]/k_3[i\text{-PrOH}]$ is about 50. The effect of hole scavengers on the yields of NO_2^-, H_2O_2, H_2, and acetone was measured under each set of conditions. These results are shown in Figs. 1 and 2. $G(NO_2^-)$ increases with an increase in the concentration of F^- and SO_4^{2-}. G(acetone) decreases with an increase in the Cl^- concentration, while in F^- or SO_4^{2-} solutions the yield is independent of the concentration of F^- and SO_4^{2-}. There is no dependence of G_{H_2}, G_H, and $G_{H_2O_2}$ on the solute concentration except for the cases of Br^- and I^-.

In a F^- solution, the reaction of H with F^- is very slow[10] ($k\approx10^4$M^{-1} sec^{-1}) and the reaction of OH with

F^- should not occur. In Fig. 1, $G(e^-_{aq})$ increases and G(acetone) dose not depend on the F^- concentration. The hole trapping by F^- will be:

$$H_2O^+ + F^- + H_2O \longrightarrow HF + OH + H_2O$$

$$\text{or } H_3O^+ + F^- \longrightarrow HF + H_2O,$$

since F_2^- has not been found even in aqueous F^- solutions at 77°K.[11] The increase in $G(e^-_{aq})$ seems to be due to the prevention of the geminate recombination of dry-charge pairs by the hole trapping. By the same expression used previously for the hole trapping,[5] $1/G_2^0$ can be obtained from the intercept of the plot of $\Delta 1/G(NO_2^-)$ *vs.* $1/[F^-]$. G_2^0 is 0.9 from Fig. 3, and $G(e^-_{aq})$ is 2.7 at $[F^-]=0$ in Fig. 1; therefore, $\sum G(\text{electrons})=3.6$ is obtained.

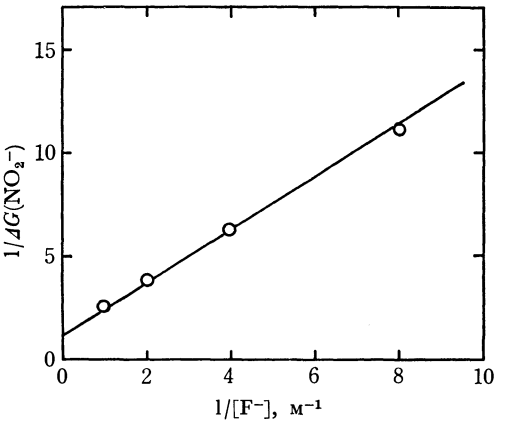

Fig. 3. $G(NO_2^-)$ as a function of the concentration of KF.

In SO_4^{2-} solutions, $G(e^-_{aq})$ increases with an increase in the concentration, and 0.5M SO_4^{2-} has no effect on G(acetone). The reaction of SO_4^{2-} with hole will be:

$$H_2O^+(H_3O^+) + SO_4^{2-} \longrightarrow SO_4^-(HSO_4^-) + H_2O.$$

The reaction of SO_4^- with NO_3^- can be ignored, since $k(SO_4^- + i\text{-PrOH})/k(SO_4^- + NO_3^-)$ is about 100,[12] and SO_4^-, a stronger oxidizing species than

Cl_2^-[13] reacts with *i*-PrOH probably to form an isopropanol radical, as in the case of OH. Therefore, $G(e^-_{aq})$ increases upon the hole trapping, while, G(acetone) is constant.

$G(e^-_{aq})$ increased and $G_{H_2O_2}$ decreased with an increase in the Cl^- concentration. We have reported before that these changes might be due to the hole trapping by Cl^-.[5] The Cl radical formed by the hole trapping reacts with Cl^- to produce Cl_2^-. It has been shown that Cl_2^- reacts with NO_3^- and *i*-PrOH:[13]

$$Cl_2^- + NO_3^- \longrightarrow 2Cl^- + NO_3 \quad (6)$$

$$Cl_2^- + (CH_3)_2CHOH \longrightarrow \text{Products} \quad (7)$$

Reaction (6) can be ignored because k_7 is much larger than k_6 ($k_6=1.4\times10^6$ and $k_7=6.1\times10^7$ M^{-1} sec^{-1}[1]). Therefore, the increase of $G(e^-_{aq})$ is probably due to the hole trapping. G(acetone) goes down with the Cl^- concentration, as is shown in Fig. 1. If the change in G(acetone) is due to the hole trapping by Cl^-, ΔG(acetone) should be $\leq \Delta G(e^-_{aq})$. However, at 1 M NaCl, for example, $\Delta G(e^-_{aq})$ is only $\sim$0.3 and ΔG(acetone) is $\sim$1.0. Some other reaction which reduces G(acetone) seems to occur. The reaction of Cl^- with OH is very slow in a neutral solution ($k=10^4 M^{-1}sec^{-1}$), but the reaction is relatively fast in an acid solution.

$$OH + Cl^- + H_3O^+_{aq} \longrightarrow Cl + 2H_2O \quad (8)$$

The acetone yield may be decreased by the reaction (8) in the spur, and the decrease in $G_{H_2O_2}$ with the Cl^- concentration[5] may not be due to hole trapping, but to the reaction (8).

According to the model of the radiolysis of water proposed by Hamill,[1] molecular hydrogen and hydrogen peroxide yields should decrease in the presence of hole scavengers, which prevent the reaction of the hole with dry electrons. As is shown in Fig. 2, however, F^- has no effect on $G_{H_2O_2}$, and G_{H_2} is almost independent of the solute concentrations except in the cases of Br^- and I^-. It has also been found that NO_3^-, which is a good scavenger for dry and solvated electrons, diminished G_{H_2} most effectively, while $G_{H_2O_2}$ was not affected at all.[14] These facts suggest that the molecular products in the radiolysis of water are not formed by the reaction of the hole with dry electrons.

Hydration of the Cobalt(III) Complexes. II

Fumio KAWAIZUMI and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received January 12, 1971)

In our previous papers,[1-4] we reported the determination of hydration number of complexes by measurement of ultrasonic velocity. The complexes were those of cobalt and hexacyanoferate, and the effect of such lignads as en, pn, dien, and edta on the degree of hydration was also studied.

The present study deals with the determination of the degree of hydration of such complexes as $NH_4[Co(NO_2)_4(NH_3)_2]$, $NH_4[Co(C_2O_4)_2(NH_3)_2]\cdot H_2O$, $K[Co(NO_2)_4(NH_3)_2]$, $K[Co(NO_2)_2C_2O_4(NH_3)_2]\cdot H_2O$, $[Co(NO_2)(H_2O)_3(NH_3)_2]\cdot H_2O$, $[Co(H_2O)_3(NH_3)_3](NO_3)_3$, $[CoH_2O(NH_3)_5]Cl_3$, KNO_2, $KHC_2O_4\cdot H_2O$, and $K_2C_2O_4\cdot \frac{1}{2}H_2O$

The hydrated water around an ion can be conventionally divided into two layers,[5] a primary hydration layer in an extreme vicinity of the ion and a secondary outer layer. The water molecules in the former have no freedom of translational motion, and they move with the movement of the ion itself. The hydrated water molecules in the latter have some freedom of motion but they are also subjected to the electrostatic force of the ion. These hydrated water molecules play an important role in phenomena such as salt-in and salt-out effects.

The amount of hydrated water in the incompressible region around the ion is determined by the compressibility method. In order to obtain the relationship between the hydration numbers in the incompressible and primary layers, the complexes having H_2O in the inner sphere such as $[Co(H_2O)_3(NH_3)_3](NO_3)_3$ and $[CoH_2O(NH_3)_5]Cl_3$ were chosen. The salts such as $KHC_2O_4\cdot H_2O$ and $K_2C_2O_4\cdot \frac{1}{2}H_2O$ were taken to examine the effect of COO^- radical on the hydration.

The degree of hydration was determined from the adiabatic compressibilities of aqueous solutions obtained by the measurements of ultrasonic velocity by an ultrasonic interferometer. Measurements were carried out at 25°C. Details of experimental procedures and methods of determining the hydration number are the same as before.[1] The complexes were prepared by the methods in literature, and purified by recrystallization from their aqueous solutions. Since it is highly probable that in aqueous solutions the ligands NO_3 in $[Co(NO_3)_3(NH_3)_3]$ are completely relpaced by H_2O as

$NH_4[Co(NO_2)_4(NH_3)_2]$	44.74	64.9	3.6
$NH_4[Co(C_2O_4)_2(NH_3)_2]$	44.79	116	6.4
$K[Co(NO_2)_4(NH_3)_2]$	44.76	90.9	5.1
$K[Co(NO_2)_2C_2O_4(NH_3)_2]$	44.75	158	8.8
$[Co(H_2O)_3(NH_3)_3](NO_3)_3$	44.74	126	7.0
$[CoH_2O(NH_3)_5]Cl_3$	44.74	198	11.0
$[Co(NH_3)_6](NO_3)_3$	—	135[1]	7.5[1]
KNO_2	44.72	67.7	3.8

Table 2. Results for the oxalates

	κ_1	K_{mo}(ml/mol)	h(mol/mol)
$H_2C_2O_4$	—	8[6]	0.4[6]
KHC_2O_4	44.72	120	6.6
$K_2C_2O_4$	44.77	250	13.9

$$[Co(NO_3)_3(NH_3)_3] \xrightarrow{\text{in water}} [Co(H_2O)_3(NH_3)](NO_3)_3$$

we used an aqueous solution of $[Co(NO_3)_3(NH_3)_3]$ for the sample of $[Co(H_2O)_3(NH_3)_3](NO_3)_3$.

For all solutions, the ultrasonic velocity changed linearly with concentration.

The results are summarized in Tables 1 and 2, where κ_1 is the compressibility of solvent, K_{mo} the molar hydration volume, and h the hydration numbdr (mol/mol).

A hydration number was assigned for each single ion. The results are given in Tables 3 and 4. We see from Table 2 that the hydration number of oxalate increases linearly with the number of potassium atoms in a molecule, and the hydration number of potassium ion can be estimated from the slope. The hydration number 7 obtained is, however, much larger than that in Table 3.

The hydration number of $[Co(NO_2)_4(NH_3)_2]^-$ calculated from its ammonium salt and potassium salts are 1.6 and 1.9 respectively, confirming the additivity rule of hydration number.

It is interesting to note that by the replacement of one of NO_2 in $[Co(NO_2)_4(NH_3)_2]^-$ with C_2O_4 the hydration number increased remarkably. This suggests that C_2O_4 shows hydration when it is contained in the complex as a ligand, while –COOH as the single species shows hardly any hydration effect (Table 2). A similar effect of COO^- in $[Co\ edta]^-$ has been reported.[3,4]

Table 3. Hydration numbers of ionic species

Ionic species	h(mol/mol)
NH_4^+	2[2]
K^+	3.2[7]
NO_3^-	1.1[7]
NO_2^-	0.6
$[Co(NO_2)_4(NH_3)_2]^-$	1.6[a]—1.9[b]
$[Co(NO_2)_2C_2O_4(NH_3)_2]^-$	5.6
$[Co(C_2O_4)_2(NH_3)_2]^-$	4.4

a) from ammonium salt
b) from potassium salt

Table 4. Hydration numbers of cobalt complexes

Ionic species	h(mol/mol)
$[Co(H_2O)_3(NH_3)]^{3+}$	3.7
$[Co\ H_2O(NH_3)_5]^{3+}$	5.3
$[Co(NH_3)_6]^{3+}$	3.7—4.4[1]

Table 4 shows the change of hydration with the increase of the number of H_2O contained as a ligand. Here, water molecules contained as ligand are not counted as hydration water. Since the change is not so remarkable, it can be concluded that the water molecules contained as ligand correspond to the primary hyration layer, Frank and Wen's region A and those hydrated outside the ligand to the secondary layer, their region B.

The authors wish to express their thanks to the Ministry of Education and the Asahi Glass Science Foundation for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1980—1981 (1971)

Proton Transfer through Hydrogen Bond in Solid Pyridine-Chloroacetic Acid Complexes as Evidenced by ^{35}Cl Nuclear Quadrupole Resonance

Hideaki CHIHARA and Nobuo NAKAMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 13, 1971)

Hydrogen bond formation between dissimilar molecules is a prototype of acid-base interaction. Interesting examples are solid hydrates of acids, *e.g.* $HNO_3 \cdot H_2O$ and $(COOH)_2 \cdot 2H_2O$, in which protons are given up to the water of crystallization by the acid molecule if it is sufficiently strong or retained by the acid if it is weak. In solids, the electrostatic field generally built up in the lattice as a result of the proton transfer can further facilitate such a transfer; thus glycine exists in the form of zwitterions in the α crystal, while it assumes a molecular conformation in an isolated state.[1)]

The purpose of the present communication is to

1) S. Takagi, H. Chihara, and S. Seki, This Bulletin, **32**, 84 (1959); see also Y. Grenie, J. C. Lassegues, and C. Garrigou-Lagrange, *J. Chem. Phys.*, **53**, 2980 (1970).

present an experimantal evidence that protons have been transferred from chloroacetic acids to pyridine in the solid 1:1 complexes formed between them. The complexes are known in solution state to be in tautomeric equilibrium between the two forms, simple hydrogen bonded pair or ion-pair, as revealed by infrared[2] and the ultraviolet[3] spectral studies. Dielectric study[4] also suggested such possibilities.

Table 1. Chlorine quadrupole resonance frequencies at 77°K(MHz)

$(CCl_3COO)(C_5H_5NH)$ (1:1)	37.8396, 37.9275, 38.0166, 38.0722, 38.3075, 38.4915, 38.5118, 38.5932, 38.6002, 38.6365, 38.7205, 38.7598
$(CHCl_2COO)(C_5H_5NH)$ (1:1)	36.3882, 36.6843

We have measured the ^{35}Cl nuclear quadrupole resonance frequencies of pyridine complexes with di- and tri-chloroacetic acids in polycrystalline form. Frequencies measured at 77°K are given in Table 1. The trichloroacetic acid complex gives twelve resonance lines differing at most by 0.9 MHz, whereas the dichloroacetic acid complex gives only two; this suggests a relatively simpler crystal structure for the latter. Since the solid state effects are generally small[5] and we are interested in the state of the valence electrons of the chlorine atoms on which the effect of proton transfer is considered to appear, we take mean value ν_m of the observed resonance frequencies for each complex and compare them with those for pure acids and ammonium salts. Such a comparison is shown in Table 2.

We see that (a) in the series of pure acids, ν_m changes monotonously with the number of chlorine atoms contained in them (*i.e.* with the acid strength) and (b) in the series of ammonium salts of mono- and dichloroacetic acids, ν_m decreases with the number of acidic hydrogen atoms.

It is to be noted that pyridine-dichloroacetic acid has the ν_m value very close to that of $CHCl_2COONH_4$. If pyridine is linked to dichloroacetic acid through the O–H···N hydrogen bond and the proton is moving sufficiently rapidly between the two potential minima along the hydrogen bond, *i.e.* if there is a dynamic equilibrium between the covalent and the ionic forms, O–H···N and $O^-\cdots H\text{–}N^+$, the observed resonance frequency ν_m may be given by $\nu_m = P_i\nu_i + (1-P_i)\,\nu_c$ where P_i is the fractional importance of the ionic form and ν_i and ν_c are the frequencies characteristic of either form. Upon substitution of appropriate figures, ν_m= 36.54 MHz, ν_i=36.46 MHz, and ν_c=38.39 MHz, one obtains P_i=0.95 as compared with P_i=0.71 in a non-dissociative solvent at room temperature.[2] This would mean that in solid pyridine-dichloroacetic acid, the pyridine molecule deprives the acid of its carboxyl hydrogen almost completely, forming an ionic crystal lattice in which cations and anions are bonded by $N^+\text{–}H\cdots O^-$ hydrogen bonds. This is a situation locally analogous to that of glycine or other amino acid crystals. Comparison of the ν_m's for the pyridine complexes with di- and tri-chloroacetic acids also indicates that the same would hold for $CCl_3COO\cdot C_5H_5NH$.

Table 2. Comparison of mean ^{35}Cl resonance frequencies between pure chloroacetic acids and their salts and the shift of the frequency from those of the pure acids (MHz)

Substance	Mean Freq. (ν_m)	Shift ($\Delta\nu$)
CCl_3COOH	40.12[a]	—
$(CCl_3COO)_2HNH_4$	39.49[b]	0.63
$CCl_3COOH\cdot C_5H_5N$	38.37	1.75
$CHCl_2COOH$	38.39[a]	—
$(CHCl_2COO)_2HNH_4$	37.63[d]	0.76
$CHCl_2COONH_4$	36.46[d]	1.93
$CHCl_2COOH\cdot C_5H_5N$	36.54	1.85
$CH_2ClCOOH$	35.25[c]	—
$(CH_2ClCOO)_2HNH_4$	33.73[e]	1.52
$CH_2ClCOONH_4$	33.23[e]	2.02

Attempts have been made to measure the quadrupole resonances in pyridine-monochloroacetic acid and ammonium trichloroacetate. However, no resonance could be detected for unknown reasons although several specimens prepared by different methods were examined. The dichloroacetic acid complex used in the present study was precipitated from cold pyridine solution of the acid, and the trichloroacetic acid complex was crystallised from an ethyl acetate solution containing an excess of pyridine. Both products were washed with ether and dried.

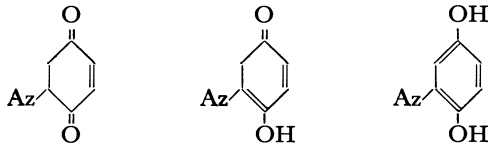
Ene Reaction of Azulenes with Some Dienophiles

Shô Itô,* Hitoshi Takeshita, and Tetsuya Makino
Department of Chemistry, Tohoku University, Sendai

(Received January 18, 1971)

The thermal reaction of azulenes with maleic anhydride and *p*-benzoquinone was reported by Treibs.[1)]

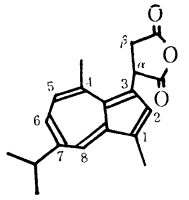


Ia Ib Ic

Az = 1-azulyl or 4-guaiazulyl

However, the structures of the products, especially Ia—Ic, said to be isolated after the reaction of azulenes and benzoquinone, seemed somewhat unconvincing. A reexamination conducted as a part of cycloaddition reactions of non-benzenoid aromatic compounds revealed that the reaction conditions are not appropriate, each reaction yielding a single product, and that the structures of the products must be revised. Our results are described herewith.

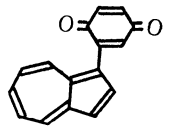
Guaiazulene (II) and maleic anhydride (III) react in chloroform or benzene even at room temperature to give 1-azulyl succinic anhydride (IV) as the single product. The structure of IV was confirmed from its mass spectrum (m.w. 294), IR spectrum ($\nu_{c=o}$ 1862, 1785 cm^{-1}) and NMR spectrum [δ 1.32 (6H, d, J= 6 Hz, isopropyl group), 2.63 (3H, s, methyl group at C_1), 2.97 (3H, s, methyl group at C_4), 2.98 (3H, m, C_β–H and methine proton of isopropyl group), 5.40 (1H, t, J=9 Hz, C_α–H), 6.90 (1H, d,d, J=11, 2 Hz, C_6–H), 7.50 (1H, d, J=11 Hz, C_5–H), 7.51 (1H, s, C_2–H), and 8.15 (1H, d, J=2 Hz, C_8–H)].



IV

The alternative structure in which succinic anhydride moiety is attached to 2-position of guaiazulene, was excluded when guaiazulene-3-d_1 yielded deuterium free IV (NMR and MS). Attempts to hydrolyze IV resulted only in the formation of a complex acidic mixture. Azulene (V) failed to react (complete recovery) with III even at elevated temperatures. The reaction in the presence of a catalytic amount of aluminum chloride resulted only in reddish brown resinous material.

Although guaiazulene reacted with *p*-benzoquinone (VI) rapidly to give only a mixture of green resinous



VII

products, azulene and VI at room temperature afforded the single product, 1-azulyl-*p*-benzoquinone (VII), as dark violet crystals. Structure elucidation was made on MS (1:1 adduct), IR ($\nu_{c=o}$ 1650 cm^{-1}) and NMR spectra [δ 6.87 (3H, overlapping, quinone hydrogens), 7.00—7.80 (4H, m, C_3, C_5, C_6, C_7–H), 8.11 (1H, d, J=4 Hz, C_2–H)], 8.48 (1H, d, J=11 Hz, C_4–H), 8.60 (1H, d, J=11 Hz, C_8–H)]. The ene-dione, the initial ene-reaction product, should have been dehydrogenated to VII by excess VI present. The difference in the reactivity of azulenes II and V can be explained by the inductive effect or hyperconjugation of alkyl groups which increase the electron density at C_1 position in II.

Experimental

Reaction of Guaiazulene (II) and Maleic Anhydride (III). II(540 mg) and III(530 mg) were dissolved in anhydrous benzene and kept at room temperature under stirring for 12 hours. After removal of benzene, the mixture was washed with petroleum ether to remove unreacted II(130 mg) and sublimed (steam bath) at reduced pressure (25 mmHg). The residue was recrystallized from petroleum ether to yield blue scaly crystals (IV), mp 127—128°C (450 mg, 56% yield).

Found: C, 77.41; H, 6.94%. Calcd for $C_{19}H_{20}O_3$: C, 77.00; H, 6.80%. λ_{max}^{MeOH} (ε) 248 nm (6600), 291 nm (8200), 306 nm (5200).

Reaction of Guaiazulene-3-d_1 (II-d_1) and Maleic Anhydride (III). II-d_1 (120 mg) and III (450 mg) were allowed to react under the conditions described above. The isolated adduct (35 mg) was identical with (IV) (mixed mp, MS, NMR).

Attempted Hydrolysis of IV. IV (35 mg) was kept at room temperature in aqueous methanol (30%). Silica gel thin layer chromatogram showed the development of complex green or dark brown spots with no definite shape. Attempts to isolate hydrolysate from the mixture failed.

Attempted Reaction of Azulene (V) and Maleic Anhydride (III). *i*) V (128 mg) and III (196 mg) were autoclaved at 250°C in anhydrous benzene for an hour. Silica gel thin layer chromatogram indicated the absence of spots other than starting material. *ii*) A catalytic amount of aluminum chloride was added to V (55 mg) and III (100 mg) in anhydrous benzene. The solution soon became red and resinous matter was separated out. No crystalline product was obtained.

Attempted Reaction of Guaiazulene (II) and p-Benzoquinone (VI). Benzene solution of II (198 mg) and VI (216 mg) was kept at room temperature for 24 hr in the dark. Silica

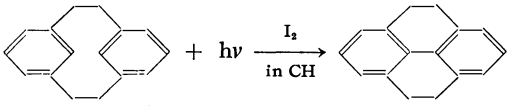
Photochemical Oxidations of 4,5,9,10-Tetrahydropyrenes

Haruo SHIZUKA, Kenji SORIMACHI, Toshifumi MORITA, Kozaburo NISHIYAMA,[1] and Takeo SATO[1]

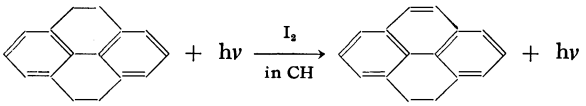
Department of Chemistry, Gunma University, Kiryu, Gunma

(Received January 22, 1971)

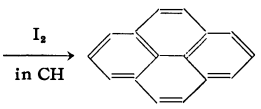
It is known that the photocyclizations of [2.2]-metacyclophanes in the presence of iodine yield 4,5,9,10-tetrahydropyrenes (Eq. (1)).[2-4] The further photochemical dehydrogenation of 4,5,9,10-tetrahydropyrene (II), induced by iodine, has been suggested;[5] the dehydrogenation products were 4,5-dihydropyrene (III) and pyrene (IV), as is shown in Eq. (2), where CH denotes cyclohexane.



(I) (II) (1)



(II) (III)



(IV) (2)

In the present work, the photolyses of II and 2,7-dimethyl-4,5,9,10-tetrahydropyrene (V) in aerated and degassed cyclohexane solutions have been carried out.

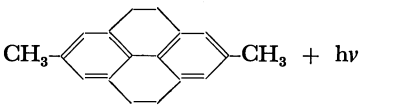
Experimental

The experimental procedure was almost the same as that previously described.[6] The II and V used in this work were prepared by the photocyclization of [2.2]metacyclophanes[2-4] and were purified by column chromatography (Al_2O_3) and by repeated recrystallizations. The photoproducts were separated by thin-layer chromatography and column chromatography (Al_2O_3 and *n*-hexane were used), and were purified by recrystallization.

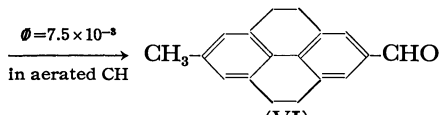
The identifications were performed by means of NMR, UV, mp, and elemental analyses. A low-pressure marcury lamp, equipped with a Vycor glass filter, was used as the 2537Å radiation source. Actionometry was carried out using a ferric oxalate solution.[7] The solution was thoroughly degassed on a high-vacuum line by the freeze-pump-thaw technique.

Results and Discussion

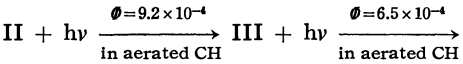
It was found that the photoproduct of 2,7-dimethyl-4,5,9,10-tetrahydropyrene (V) in aerated cyclohexane was a different type from that of 4,5,9,10-tetrahydropyrene (II); the photooxidation of V gave a new type of product, 2-methyl-4,5,9,10-tetrahydropyrene-7-carbaldehyde (VI, mp 137—140°C), which resulted from the oxidation of the methyl group substituted at the 7 position of V by the UV irradiation (Eq. (3)), and in the case of II, 4,5-dihydropyrene (III) and pyrene (IV) were obtained as the photoproducts (Eq. (4)).



(V)



(VI) (3)



(4)

A 2,7-dimethyl substituent had a very large effect on the photochemical oxidation of 4,5,9,10-tetrahydropyrenes. In addition to the main product, VI, traces of 2,7-dimethyl-4,5-dihydropyrene and 2,7-dimethyl-

Table 1. The assignments of the NMR spectra of 5,13-dimethyl[2.2]metacyclophane-related compounds dissolved in CCl_4

No.	Substance	Assignment δ
A		a, 2.33 (6H) b, 1.95, 2.08, 2.89, 3.02 (8H) c, 6.75 (4H) d, 4.05 (2H)
B	 (V)	a, 2.24 (6H) b, 2.73 (8H) c, 6.74 (4H)
C	 (VI)	a, 2.32 (3H) b, 2.88 (8H) c, 6.84 (2H) d, 7.50 (2H) e, 9.89 (1H)

pyrene were also detected by column chromatography. None of the products described above were obtained in the degassed system.

The NMR spectral data of 5,13-dimethyl [2.2]-metacyclophane-related compounds are listed in Table 1; they are similar to those of I and II reported by Sato *et al.*[8,9] The IR spectrum of the photoproduct (VI) showed the characteristic absorption band (at 1685 cm^{-1}) of the carbonyl group. Furthermore, the results of elemental analyses of the product supported these assignments.

The UV spectrum of the aerated cyclohexane solution of V changed upon irradiation with a 2537 Å light. The absorption band (286 nm, $\varepsilon=2.18\times10^4$) of V decreased, and new maxima of VI appeared at 321 ($\varepsilon=2.95\times10^4$) and 337 nm ($\varepsilon=2.98\times10^4$), with two isosbestic points at 260 and 303 nm. The UV spectral change showed that V was transformed into VI by the photochemical oxidation in the presence of oxygen. The quantum yield ($\phi=7.5\times10^{-3}$) for the VI formation from V was larger than that ($\phi=9.2\times10^{-4}$) of II, as is shown in Eqs. (3) and (4).

Finally, it can be said that the hydrogens of the methyl group in V are more reactive to photooxidation than those of the ethylene group in the molecule. A mechanistic study concerning the photochemistry of [2.2]-metacyclophanes and their derivatives is in progress.

A Polarographic Study of Amino Acids in Aqueous Solution

Shizuo FUJIWARA, Yoshio UMEZAWA, and Hidehiro ISHIZUKA

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyoku, Tokyo

(Received January 25, 1971)

Only a few investigations have been made on the polarography of typical amino acids. Brdička[1] studied sulfur-containing amino acids and proteins using *Brdička's solutions*. Okazaki[2] reported a polarographic study of several α- and β-amino acids in a dioxane-water medium. He showed that there is a linear relation between the half-wave potentials and the pK_a for the amino acids, and suggested that the polarographic current observed in this system is due to the non-ionized form of the amino acids, *i.e.*, RNH_2COOH. In the present study a pH dependence of polarographic currents was analyzed in detail for several amino acids in water solutions with pH 2—4. A possible mechanism for reduction process is proposed, and a result which appears to be inherent in the polarography of amino acids is reported.

All chemicals are of reagent grade, and dissolved in water which has been deionized and distilled. Amino acids examined are L-alanine, β-alanine, γ-aminobutyric acid, L-arginine and L-lysine. Each sample solution contains 5 mM of amino acid and 1 M of LiCl. The pH values of the solutions were adjusted by adding HCl or LiOH. All measurements were performed at 23.0± 0.5°C using a Yanagimoto DC and AC polarograph Model PA-102. The flow rate of the dropping mercury electrode was 0.866 mg/sec, and the drop time was 8.16 sec in distilled water at a mercury column height of 55.0 cm with an open circuit.

All sample solutions give a polarographic wave at −1.55——1.65 V *vs.* mercury pool anode. This wave will be referred to hereafter as the main wave. A sub-wave accompanying a maximum of the first kind is observed over the shoulder of the main wave. This maximum increases in intensity with the lowering of the pH of the solution. AC polarograms for the present systems show two peaks A and B, which correspond to the main wave and the sub-wave in the DC polarograms, respectively. Peak B increases in intensity with the lowering of the pH of the solution (Figs. 1a and b). The limiting currents for the main wave (peak A) and the sub-wave (peak B) are proportional to the square root of the mercury column

height. This indicates that the main wave and sub-wave are both diffusion controlled.

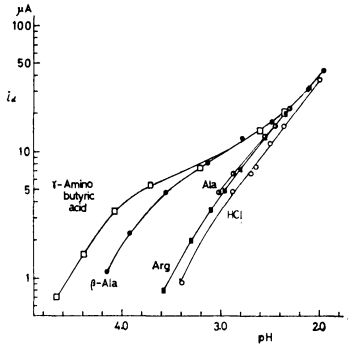

Fig. 2 a.

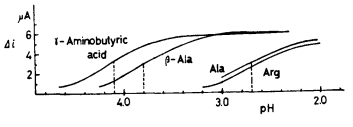

Fig. 2 b.

Fig. 2. pH dependence of the current intensities of some amino acids.
a: pH dependence of the sum of the current intensities of the main and the sub-wave.
b: pH dependence of the difference (Δi) in current intensity between HCl and the amino acids.

For the sake of comparison, the sum of the current intensities of the main and the sub-wave is plotted as a function of pH in Fig. 2a, where the values of the current intensity observed for HCl are also given. The difference Δi in current intensity between HCl and the amino acids in Fig. 2a is plotted in Fig. 2b. In the present systems it is sufficient to consider the equilibrium.

$$R(NH_3^+)COOH \rightleftarrows R(NH_3^+)COO^- + H^+ \quad (1)$$

The following relation holds at a given pH value.

$$pH = pK_a + \log \frac{[R(NH_3^+)COO^-]}{[R(NH_3^+)COOH]} \quad (2)$$

Equation (2) is used along with the data given in Fig. 2b to estimate the pK_a values for the amino acids. The values are given in Table 1, and are in fairly good agreement with pK_a values determined by standard methods.[3]

Table 1. pK_a values for amino acids

	This work	Standard methods (A)[a]	Standard methods (B)[b]
L-alanine	2.7±0.2	2.34	2.348
L-arginine	2.7±0.2	2.18	—
β-alanine	3.8±0.1	3.60	3.551
γ-aminobutyric acid	4.1±0.1	—	4.031

a) determined on cells with liquid junction.
b) determined on cells without liquid junction.

From the results, it can be concluded that the main wave is due to the free H^+ ion, and that the sub-wave (peak B) accompanying the first kind of maxima corresponds to the electrode reaction.[4]

$$R(NH_3^+)COOH \xrightarrow{e^-} R(NH_3^+)COO^- + \frac{1}{2}H_2 \quad (3)$$

The maxima of the first kind are observed over the sub-waves (peak B). They increase in intensity with the lowering of the pH of the solution, and differ in

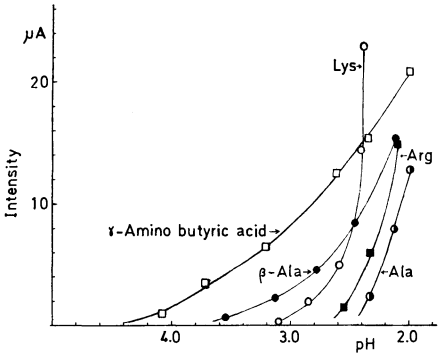

Fig. 3. pH dependence of the curreent intensities of the maxima.
Intensity: difference between the current intensity with the maximum and that without the maximum at the maximum potential.

3) J. P. Greenstein and M. Winitz, "Chemistry of the Amino Acids," Vol. 1., John Wiley and Sons, New York (1961), p. 486.
4) Possibility of the following reaction cannot be excluded.

$$R(NH_3^+)COOH \xrightarrow[2H^+]{e^-} R(NH_3^+)CHO + H_2O$$

However, the reactant is definitely $R(NH_3^+)COOH$.

shape for different amino acids and pH values. As seen in Fig. 3, the maxima disappear at pH values nearly equal to the pK_a values for the amino acids, and the slopes for L-lysine and L-arginine are much greater than those for the remaining monoamino-monocarboxylic acids. It should be noted in Fig. 1b that the widths of the maxima increase in the order α-, β-, γ-amino acids, and that in the cases of β-alanine and γ-aminobutyric acid the widths of the maxima increase with decreasing pH value.

Further investigation of the maxima would be useful for the polarographic study of amino acids.

Preparation of 1,7-Bis(*p*-hydroxyphenyl)heptane

Ichiro KAWASAKI, Kazuhiro MATSUDA, and Takeo KANEKO
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 29, 1971)

We prepared 1,7-bis(*p*-hydroxyphenyl)heptane in order to study the intramolecular oxidative coupling of phenolic compounds.

Treatment of 4-(*p*-methoxyphenyl)butyronitrile[1] with lithium methylanilide afforded an iminonitrile I. Hydrolysis of I with boiling sulfuric acid gave 1,7-bis(*p*-methoxyphenyl)-heptanone-4 (IIa). In addition to IIa a compound having no carbonyl group was isolated as a by-product by silica gel chromatography. The structure of this compound was assigned as 7,7'-dimethoxy-1,1'-spirobitetralin (IIIa) by NMR and MS spectra. The same compound was obtained easily by boiling IIa with hydrobromic acid to produce a phenolic compound IIIb followed by methylation with dimethyl sulfate. Huang Minlon reduction of IIa gave 1,7-bis(*p*-methoxyphenyl)heptane (IVa), and a phenolic compound IVb was also obtained by demethylation of IVa.

IV a, R=CH_3
b, R=H

Experimental

*3-Cyano-1,7-bis(*p*-methoxyphenyl)-4-iminoheptane (I).* Phenyllithium was prepared by adding bromobenzene (4.7 g) to lithium (0.4 g) in ether (40 m*l*) under nitrogen atmosphere. To this solution was added methylaniline (6.4 g) dissolved in ether (20 m*l*). After refluxing for 1 hr, 4-(*p*-methoxyphenyl)-butyronitrile (5.2 g) in ether (30 m*l*) was added dropwise to the above solution at room temperature. The solution was refluxed for 1 hr, then quenched with water. The organic layer was washed with water, dried and evaporated. The product (3.7 g, 74%) was obtained by distillation, bp 240—245°C/0.02 mmHg. IR: ν^{neat} 3480, 3380, 3250, 2300 cm^{-1}.

Hydrolysis of the Iminonitrile (I). I (9.3 g) was dissolved in 1:1 sulfuric acid (300 m*l*). The solution was heated at 60°C for 30 min and then under reflux for 30 min. The solution was diluted with water and extracted with ether. The ethereal extract was washed with water, dried and evaporated. Chromatography of the crude product on silica gel (elution with benzene) resulted in the separation of two compounds. Evaporation of the first fraction gave IIIa (0.7 g, 8.3%), mp 88 —89°C. IR: ν^{Nujol} 1615, 1575, 1275, 1235, 1040, 880, 845, 810 cm^{-1}. NMR: δ (CCl_4) 1.6—2.2 (8H, m), 2.6—3.0 (4H, m), 3.6 (6H, s), 6.25 (2H, d, J=3 Hz), 6.6 (2H, d-d, J=8—3 Hz), 6.95 ppm (2H, d, J=8 Hz). MS: *m/e* 308 (100), 280 (15.7), 279 (61.3), 249 (18.8), 248 (18.7), 221 (10.4), 174 (46.5), 159 (14.2), 147 (23.6), 134 (25.2), 121 (24.7%).

Found: C, 82.05; H, 7.85%. Calcd for $C_{21}H_{24}O_2$: C, 81.78; H, 7.84%.

The second fraction gave IIa (4.3 g, 50%), mp 31—33°C. IR: ν^{Nujol} 1705, 1615, 1585, 1305, 1240, 1030, 835, 815 cm^{-1}. NMR: δ(CCl_4) 1.9 (4H, q, J=6 Hz), 2.4 (4H, t, J=6 Hz), 3.8 (6H, s), 6.8 (4H, d, J=9 Hz), 7.1 ppm (4H, d, J=9 Hz).

Found: C, 77.39; H, 7.94%. Calcd for $C_{21}H_{26}O_3$: C, 77.27; H, 8.03%.

IIa (300 mg) was dissolved in 48% hydrobromic acid (50 m*l*) and heated for 1 hr under reflux. The reaction mixture was evaporated to dryness and extracted with ether. The ethereal extract was washed with sodium carbonate solution and water, dried and evaporated. The residue was recrystallized from chloroform to give IIIb (120 mg, 40%), mp 157—159°C. IR: ν^{Nujol} 3340, 3180, 1620, 1585, 1290, 1230, 1035, 860, 845 cm^{-1}. NMR: δ ($CDCl_3$), 1.6—2.3 (8H, m), 2.6—3.0 (4H, m), 4.2 (2H, broad s), 6.2 (2H, d, J=3 Hz), 6.6 (2H, d-d, J=3—8 Hz), 7.0 ppm (2H, d, J=8 Hz). MS: *m/e* 280 (91.4), 252(25.3), 251(100), 224 (17.3), 223(28.9), 160(38.3), 145(17.9), 133(19.8), 120(16.7), 107(25.3%).

Found: C, 81.09; H, 7.18%. Calcd for $C_{19}H_{20}O_2$: C, 81.39; H, 7.19%.

This compound was converted by treatment with dimethyl

1) Ki-U Kim, *J. Pharm. Soc. Japan*, **63**, 376 (1943).

sulfate into a dimethyl ether, which was identical with IIIa in IR spectra.

*1,7-Bis(*p*-hydroxyphenyl)heptanone-4 (IIb).* Ethylmagnesium bromide was prepared by adding ethyl bromide (21.8 g) to magnesium (4.8 g) in ether. To this solution was added diethylamine (14.6 g) and heated for 30 min under reflux. IIa (3.3 g) in ether was added to the solution. The reaction was carried out for 2 hr under reflux. The solvent was removed and the residue was heated to 179—190°C for 45 min. The reaction mixture was cooled, diluted with water and extracted with ether. The ethereal extract was washed with sodium carbonate solution and water. The ethereal layer was extracted with dilute potassium hydroxide solution and the aqueous layer was acidified with 6N hydrochloric acid and extracted with ether and dried. On evaporation of the solvent, the product solidified, (2.6 g, 80%). Recrystallization from ether-petroleum ether gave IIb, mp 115—117°C. IR: ν^{Nujol} 3320, 1685, 1610, 1590, 1510, 1220, 830 cm^{-1}. NMR: δ (CD_3OD), 1.8 (4H, q), 2.4 (4H, t), 2.5 (4H, t), 6.7(4H, d, J=8 Hz), 7.0 ppm (4H, d, J=8 Hz).

Found: C, 76.24; H, 7.41%. Calcd for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43%.

*1,7-Bis(*p*-methoxyphenyl)heptane (IVa).* A mixture of IIa (3.3 g) potassium hydroxide (10 g), 80% hydrazine hydrate (40 m*l*) and triethylene glycol (10 m*l*) was heated for 2 hr at 140—160°C and then for 3 hr at 190—210°C. Water (300 m*l*) and 6N hydrochloric acid (30 m*l*) were added to the cooled solution. The product was extracted with chloroform and the chloroform extract was washed with water, dried and evaporated. Distillation of the residual oil gave IVa (2.2 g, 70%), bp 180—190°C/0.01 mmHg. IR ν^{neat} 1610, 1585, 1455, 1295, 1240, 1170, 1035, 820 cm^{-1}. NMR: δ(CCl_4), 1.2—1.6 (10H, m), 2.5 (4H, t, J=7 Hz), 4.75 (6H, s), 6.7 (4H, d, J=8 Hz), 7.0 ppm (4H, d, J=8 Hz).

Found: C, 80.89; H, 9.01%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

*1,7-Bis(*p*-hydroxyphenyl)heptane (IVb).* IVa (3.0 g) was dissolved in acetic acid (100 m*l*) and 48% hydrobromic acid (100 m*l*) and then heated under reflux for 30 min. The solution was evaporated *in vacuo*, and ether was added to the residue. The ethereal solution was washed with sodium carbonate solution and water, and then extracted with potassium hydroxide solution. The aqueous extract was acidified with 6N hydrochloric acid and reextracted with ether. On evaporation of the solvent, the product solidified (2.6 g, 85%). Recrystallization from benzene gave IVb, mp 98—99°C. NMR: δ ($CDCl_3$), 1.3—2.0 (10H, m), 2.7 (4H, t, J=7 Hz), 4.2 (2H, m), 6.95 (4H, d, J=8 Hz), 7.25 ppm (4H, d, J=8 Hz). MS: *m/e* 284(20), 107(100%).

Found: C, 80.06; H, 8.45%. Calcd for $C_{19}H_{24}O_2$; C, 80.24; H, 8.51%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1987—1989 (1971)

The Photoreduction of Benzophenone by Thioethers

Wataru ANDO, Junji SUZUKI, and Toshihiko MIGITA
Department of Chemistry, Gunma University, Kiryu, Gunma

(Received February 4, 1971)

Ultraviolet irradiation of benzophenone in 2-propanol leads to generation of radicals $Ph_2\dot{C}OH$, (A) and $Me_2\dot{C}OH$, (B), and then to formation of pinacol and acetone.

$$Ph_2C{=}O^* + Me_2CHOH \longrightarrow Ph_2\dot{C}OH + Me_2\dot{C}OH$$

The photoexcited ketone may also abstract α-hydrogen from other hydrogen donors, *e.g.*, amines and ethers.[1-4] In these systems the derived radicals may give the three possible radical recombination products. The reaction is, however, retarded and inhibited by the presence of mercaptan or disulfide in low concentration, as rapid reactions are introduced which convert the radicals A and B into the starting materials.[5,6]

$$Ph_2\dot{C}OH + RS\cdot\ (RSSR) \longrightarrow Ph_2C{=}O + RSH\ (RSH + RS\cdot)$$

$$Me_2\dot{C}OH + RSH \longrightarrow Me_2CHOH + RS\cdot$$

On the other hand, the presence of a relatively high concentration of phenyl sulfide or other thioethers which would not readily give the thiyl radical had no effect on photoreduction of benzophenone, indicating that organic sulfur was not a quencher or desensitizer in the reaction. Thus, among aliphatic sulfides, those bearing α-hydrogen atoms are expected to reduce benzophenone photochemically, since α-hydrogen atom was found to be reactive toward abstraction by radicals. On the other hand, sulfides bearing β-hydrogen but no α-hydrogen atoms are not expected to be effective reducing agents, because such sulfides like *t*-butyl sulfide have been known to generate thiyl radicals when the β-hydrogen atom was abstracted by radicals.[7]

Thus, the photoinduced reactions of benzophenone in various aliphatic sulfides were investigated, and the above expection was found to be correct.

Results and Discussion

Irradiation of 2 mmol benzophenone in 16 mmol dimethyl sulfide with high pressure mercury lamp for 48 hr gave benzopinacol, I, in 35% yield by decanting the unreacted dimethyl sulfide and washing the

remaining solid with petroleum ether (b.p., 30—60°C). Analysis of the unreacted dimethyl sulfide solution by vapor phase chromatography (Carbowax 20M, 10% on Celite 22) indicated the formation of di(methylthio)methane, II (1.5%), 1,2-di(methylthio)ethane, III (11%), and a mixture (36%) of three diphenyl substituted products, IV, V, and VI.[8]

$$Ph_2C{=}O^* + CH_3SCH_3 \longrightarrow \underset{\text{I}}{Ph_2C(OH)C(OH)Ph_2}$$

$$+ \underset{\text{II}}{MeSCH_2SMe} + \underset{\text{III}}{MeSCH_2CH_2Me}$$

$$+ \underset{\text{IV}}{Ph_2C(OH)CH_2SMe} + \underset{\text{V}}{Ph_2C{=}CH_2} + \underset{\text{VI}}{Ph_2C{=}CHSMe}$$

Structures of the reaction products are determined by independent syntheses and spectra analyses. Olefins, V and VI, may be produced from β-hydroxy sulfide, and IV by elimination of the components of RSOH and H_2O under vpc conditions. With regard to the mechanism of the formation of olefins from β-hydroxy sulfide, we might suppose that the elimination occurs *via* transitions C and D.

A similar olefin formation has been reported for the thermolysis of β-hydroxy sulfinamides.[9]

Photoreductions of benzophenone in diethyl sulfide and diisopropyl sulfide gave similar results. Irradiation of 2 mmol benzophenone in diethyl sulfide for 48 hr led to the consumption of 70% benzophenone and the formation of 40% pinacol I. Analysis of seaction mixture by vpc after removal of the pinacol rhowed the presence of diethyl disulfide (1.3%), 2,3-di(ethylthio)butane (20%), and a mixture (29%) of $Ph_2C(OH)CH(CH_3)SEt$ and $Ph_2C{=}CHMe$. In the reaction of benzophenone in diisopropyl sulfide, about 80% of benzophenone was consumed, and diisopropyl disulfide (3.3%), 2,3-di(isopropylthio)-2,3-dimethylbutane (13%), 1,3-di(isopropylthio) propane (9%), and a mixture (19%) of $Ph_2C{=}CMe_2$ and $Ph_2C(OH)CMe_2$-S(*i*-Pr) were obtained together with benzopinacol (45%). Photoreaction in di-*t*-butyl sulfide led to only 8% consumption of benzophenone, and the formation of *t*-butyl mercaptan (7.2%) and a trace of di-*t*-butyl disulfide on 48 hr irradiation.

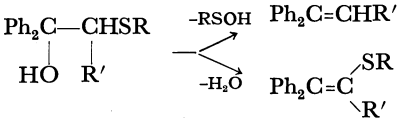
Our results can be explained by the following reaction steps analogous to those for photoreaction in alcohol.

$$Ph_2C{=}O^* + RSCH_2R' \longrightarrow Ph_2\dot{C}OH + RS\dot{C}HR'$$

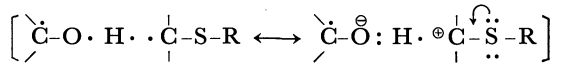
$$2\ RS\dot{C}HR' \longrightarrow RSCH(R')CH(R')SR$$

$$2\ Ph_2\dot{C}OH \longrightarrow Ph_2C(OH)C(OH)Ph_2$$

$$Ph_2\dot{C}OH + RS\dot{C}HR' \longrightarrow$$



In the thioethers, α-C–H seems more susceptible than the β-C–H bond toward hydrogen abstraction by triplet ketone. The polar resonanced factor may contribute to stabilization of the transition state.



Low consumption of benzophenone in di-*t*-butyl sulfide is reasonably explained by the inhibiting effect of thiyl radical formed during the early stage of reaction.

$$Ph_2C{=}O^* + Me_3CSCMe_3 \longrightarrow Ph_2\dot{C}OH + CH_2{=}CMe_2 + Me_3CS\cdot$$

$$Me_3CS\cdot + Ph_2\dot{C}OH \longrightarrow Ph_2C{=}O + Me_3CSH$$

Distribution of the olefins formed by reactions in unsymmetrical thioethers is shown in Table 1.

Table 1. The formation of diphenyl olefins in photoreduction of benzophenone in thioethers

Thioether	Product A	Product B	Ratio A/B
n-PrSEt	$Ph_2C{=}CHEt$	$Ph_2C{=}CHMe$	1.5
i-PrSEt	$Ph_2C{=}CHMe$	$Ph_2C{=}CMe_2$	4.0
i-PrSMe	$Ph_2C{=}CMe_2$	$Ph_2C{=}CH_2$	3.7

Experimental

Photolysis of Benzophenone in Dimethyl Sulfide. 0.30 g of benzophenone was dissolved in 1 m*l* dimethyl sulfide. Irradiation in a Pyrex tube for 48 hr provided six products, I—VI. The course of photolysis was monitored by gas chromatography. After 40 hr the unreacted benzophenone in dimethyl sulfide was negligible. Benzopinacol was isolated by the addition of petroleum ether to the concentrated reaction mixture, and identified by comparison with authentic samples. Other products, II, III, IV, V, and VI were isolated by preparative gas chromatography. Structures of II, III, and V were identified by comparison with authentic samples. Compound IV shows NMR spectrum at 1.92 (s, 3-H), 3.30 (s, 2-H), 3.45 (s, 1-H), and 7.28 ppm (m, 10-H). VI shows NMR spectrum at 2.28 (s, 3-H), 6.40 (s, 1-H), 7.14 (s, 5-H) and 7.27 ppm (s, 5-H).

Found: C, 79.63; H, 6.12%. Calcd for $C_{15}H_{14}S$: C, 79.60; H, 6.24%.

Formation of Diphenyl Olefins, V and VI, from IV. Isolated compound IV by gas chromatography was reinjected into the gas chromatograph of 10% Carbowax 20M, 2 m×0.5 cm stainless column at 220°C. Two products, V and VI, were collected in the ratio 4:1, depending on the conditions of gas chromatograph. On heating the reaction mixture obtained from the photolysis of benzophenone and dimethyl sulfide at 220°C for 1 hr, IV could not be isolated by thin layer chromatography, and V and VI were found to be formed in the ratio of 1:2.5 from the analysis of gas chromatography. However, on heating IV in a Pyrex tube under the same conditions, and by direct analysis of NMR, it was found that IV was not consumed, and V and VI were not obtained.

8) Yields based on the consumed benzophenone.

9) E. J. Corey and T. Durst, *J. Amer. Chem. Soc.*, **88**, 5656 (1966).

Photolysis of Benzophenone in Thioethers. As a typical run, a solution of 295 mg of benzophenone in 1 m*l* thioether in Pyrex tubes was irradiated with the high pressure mercury lamp for 48 hr. Precipitated benzopinacol was removed by adding the petroleum ether and washing the solid. The solvent of the reaction mixture was evaporated off *in vacuo* and the residue was analyzed directly by gas chromatography. Products isolated by gas chromatography were characterized by comparison with authentic samples.

The Bulk Photoconductivity of Violanthrene Single Crystals

Mitsuyuki SOMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received February 10, 1971)

The bulk photoconductivity of single crystals of aromatic hydrocarbons in contact with the electrolyte electrode has been the subject of serveral reports.[1] This arrangement of electrodes has proved to have some advantages in distinguishing whether the charge carriers are produced in the bulk of the crystal or on the interface between the crystal and the electrodes.[2] So far, however, these works have been confined to the crystals of relatively small aromatic molecules and have not been extended to include crystals of large aromatic molecules, which are expected to have different electronic properties. In this note some peculiar features of the bulk photoconductivity in the single crystals of violanthrene, which has nine condensed aromatic rings, in contact with the liquid electrodes will be reported.

The violanthrene (violanthrene A, 1,2,9,10-dibenzoperopyrene) single crystals were prepared as follows. Powdered crystals of violanthrene which had been purified by repeated sublimation in a vacuum were sealed off in a glass tube with several cmHg of nitrogen gas. The tube was then placed in an electric furnace which was designed to attain an appropriate temperature gradient, after which the bottom of the tube was heated to a temperature slightly below the melting point of violanthrene (478°C) in order to sublime it. The single crystals grew on the upper wall of the tube at lower temperatures. Thus, single crystals with an area of approximately 0.1 cm^2 and a thickness below few hundred microns were easily obtained.

Measuring procedures were similar to the method described previously.[3] A violanthrene crystal was mounted between the two polystyrene half cells which were the modified types of Kallmann and Pope's cell.[4] Each half cell was filled with liquid which acted as an elctrode for the crystal. The crystal was illuminated by a 750 W tungsten lamp with metal interference filters through the electrode. The half width of the light transmitted through the filters ranged from 110 to 160 Å.

The dc photocurrent[5] was more than fifty times as large as the dark current at 5990 Å, intensity of incident light being 2.7×10^{15} photons/cm^2·sec. The photocurrent-voltage characteristics were similar for the wavelength range studied (4000 to 7000 Å). The photocurrent was proportional to the applied voltage in the lower-voltage region (ohmic region) up to the applied voltage of 10^4 V/cm; it began to deviate from Ohm's law to be dependent on the voltage superlinearly in the higher-voltage region (non-ohmic region). The photocurrent depended little on the direction of the applied field. This was especially true in the ohmic region. Moreover, in the ohmic region, the photocurrent was insensitive to the electrode conditions, such as the electrode material or the addition of chemicals. For example, when the aqueous electrode was replaced by alcoholic electrodes, such as methanol or ethanol, the photocurrent was almost unchanged; nor did the addition of ceric ion, iodine, or o-chloranil, which are ready to act as electron acceptor or hole injector to the crystal, affect the photocurrent in the ohmic region.

Figure 1 shows the spectral dependence of the photocurrent at the constant light intensity of 2.9×10^{14} photons/cm^2·sec. The absorption sepctra of a thin single crystal and of a solution[6] of violantherne are shown for comparison. The spectral response was dependent on the thickness of the crystal. When the thinner crystals were used, the maximum in the spectral response shifted towards a shorter wavelength, and for the crystals thicker than 20 μ (up to 150μ) the maximum at 5990 Å was emphasized. The current changed sublinearly with the intensity of the incident light. The slope of the photocurrent-intensity curve decreased with an increase in the intensity. The sublinear dependence of the photocurrent on the incident light intensity suggests that the bimolecular decay of the charge carriers plays an important role.

All the above findings suggest that the charge carriers produced in the bulk of the violanthrene crystal predominate at least in the ohmic region. This is in con-

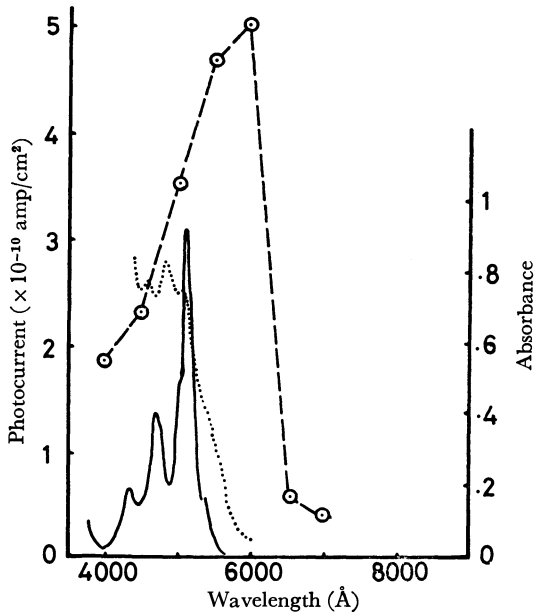

Fig. 1. Spectral dependence of the photocurrent in violanthrene crystal. Intensity of incident light, 2.9×10^{14} photons/cm·sec. Crystal thickness, 20 μ. Applied voltage, 6 V (in ohmic region). Dotted line shows the absorption spectrum of violanthrene single crystal of 2 μ thick in units of 10^4 cm^{-1}. Full line is the absorption spectrum of violanthrene in benzene (longer wavelength part, in 1-methylnaphthalene) in units of 10^5 l/mol·cm.[6]

trast with the cases of anthracene crystals in similar electrode arrangements. In that case, in the wavelength region corresponding to the first singlet excited state of anthracene the charge injection from the electrode always predominates.[1,3]

The bimolecular decay of carriers offers a qualitative explanation of the spectral response of the photocurrent. If we simply assume that the carriers are produced *via* one exciton mechanism in the bulk of the crystal and that they decay bimolecularly, the steady-state approximation for the carrier concentration gives, neglecting the diffusion of both the exciton and the carries;

$$\frac{dn(x)}{dt} = \alpha I_0 e^{-\epsilon x} - Rn(x)^2 = 0 \qquad (1)$$

where $n(x)$ is the carrier concentration at a certain distance, x, from the surface of the crystal $dn(x)/dt$ its time derivative, ϵ the absorption coefficient of the crystal, I_0 the incident light intensity, α the constant relating to the carrier production, and R is the bimolecular rate constant. The total number of carriers, N_c, in the crystal with a thickness of L and a unit area is expressed as follows:

$$N_c = \int_0^L n(x)dx \qquad (2)$$

From (1) and (2), we get:

$$N_c = 2\sqrt{\frac{\alpha I_0}{R}}[1-e^{-1/2\epsilon L}] \qquad (3)$$

N_0 has a maximum between $\epsilon=2/L$ and $\epsilon=3/L$. For the crystal 20 μ thick, these optical densities in the decadic unit are 4.3×10^2 and 6.4×10^2 cm^{-1} respectively. The corresponding value for the violanthrene crystal appears around the abosrption threshold above 5500 Å; this is in accordance with the observed spectral dependence of the photocurrent.

Whether the carrier generation process is an intrinsic one or an extrinsic one involving some impurities or defects is obscure at present. In this connection, it should be noted, however, that the fall-off in the photocurrent at 6000 Å for the thicker crystals corresponds in its energy (2.1 eV) roughly to the energy gap determined from the temperature dependecne of the dark conductivity (1.95 eV).[7]

The author wishes to express his gratitude to Professor Hiroo Inokuchi for his valuable discussions.

The Synthesis of Poly[N^{ε}-(*l*)-menthyloxycarbonyl-L-lysine] and Its Secondary Structure

Hiroyuki YAMAMOTO and Tadao HAYAKAWA

Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda

(Received February 12, 1971)

In a previous paper,[1,2] poly-γ-(*l*)-menthyl glutamate and poly-β-(*l*)-menthyl aspartate were synthesized and the secondary structures of these polymers were studied in order to investigate the effect of the side-chain with optically-active protect-group contributions to the polypeptide structure.

The syntheses of poly-L-lysine derivatives have been achieved in the preparation of the starting N^{ε}-benzyloxycarbonyl[3–5] and N^{ε}-trifluoroacetyl-L-lysine[6] as a monomer, and their chemical, physical, and biological

6) M. Sela, R. Arnon, and I. Jacobson, *Biopolymers*, **1**, 517 (1963).

properties have been studied extensively.[7-10] In the present study, poly-N^{ε}-(*l*)-menthyloxycarbonyl-L-lysine was synthesized, and the secondary structure of the polymer was studied by means of the optical rotatory dispersion (ORD), the circular dichroism (CD), and infrared spectroscopy (IR) techniques. The route of synthesis is as follows:

$$\text{lys} \xrightarrow{CuCl_2} \text{lys}\cdot 1/2\text{Cu} \xrightarrow[(2)\ \text{EDTA}\cdot 2\text{Na}]{(1)\ (l)\text{-Menthyl chloroformate}} N^{\varepsilon}\text{-}(l)\text{-Menthyloxycarbonyl lys} \xrightarrow{COCl_2} N^{\varepsilon}\text{-}(l)\text{-Menthyloxycarbonyl lys NCA} \xrightarrow{TEA} \text{Poly-}N^{\varepsilon}\text{-}(l)\text{-menthyloxycarbonyl lys}$$

Since the menthyl chloroformate decomposes almost instantly on contact with water, the N^{ε}-menthyloxycarbonylation of lysine is unsuccessful when the Schotten-Baumann method is used in an aqueous solution. The copper complex was prepared by the reaction of lysine with cupric chloride in methanol. The complex was reacted with menthyl chloroformate to give N^{ε}-(*l*)-menthyloxycarbonyl lysine. Poly-N^{ε}-(*l*)-menthyloxycarbonyl-L-lysine was prepared *via* N^{ε}-(*l*)-menthyloxycarbonyl-N^{α}-carboxy-L-lysine anhydride (NCA). The resulting polymer was obtained in a high yield and had a high molecular weight, as Table 1 shows. It was soluble in ethyl ether, tetrahydrofuran (THF), chloroform, dimethylformamide (DMF), trifluoroacetic acid (TFA), and dichloroacetic acid (DCA), and was insoluble in methanol.

Table 1. Molecular weight of poly[N^{ε}-(*l*)-menthyloxycarbonyl-L-lysine]

Solvent	Monomer NCA (mg)	Yield mg (%)	Molecular weight (DP)[a]	$[\eta]$[b] dl/g
Dioxane	460	354(88)	12300(40)	0.158
DMF	460	331(82)	10100(33)	0.156

a) By titration of the amino endgroup with 0.02N perchloric acid.
b) In DCA at 25°C.

Experimental

(l)-Menthyl Chloroformate. *(l)*-Menthyl chloroformate was prepared from (*l*)-menthol, quinoline, and phosgene as has been described by Westley and Halpern.[11]

N$^{\varepsilon}$-*(l)-Menthyloxycarbonyl-L-lysine.* To a suspension of L-lysine hydrochloride (3.66 g, 0.02 mol) in 3 m*l* of methanol, 0.46 g of sodium in 10 m*l* of methanol and 1.70 g (0.01 mol) of cupric chloride in 10 m*l* of methanol were added.[12] After 30 min, the mixture was cooled to 0°C and 2.80 m*l* of triethylamine (TEA) were added. Then 0.024 mol of *(l)*-menthyl chloroformate in 30 m*l* of toluene and 3.34 m*l* of TEA were added. This solution was allowed to stand at 0°C for 2 hr and then at room temperature for 2 hr. The reaction mixture was filtered and dried; yield, 6.0 g. A suspension of the copper complex of N^{ε}-menthyloxycarbonyl-L-lysine in an aqueous ethylenediamine-tetraacetic acid 2Na (EDTA 2Na) was treated by the method described by Kuwata and Watanabe;[13] yield, 1.20 g (30%). The product was recrystallized from 20% acetic acid. 1.05 g (26%), mp 228°C. $[\alpha]_D^{22} = -40.9$ (*c* 1.0, acetic acid).

Found: C, 62.25; H, 9.97; N, 8.34%. Calcd for $C_{17}H_{32}N_2O_4$: C, 62.16; H, 9.82; N, 8.53%.

N$^{\varepsilon}$-*(l)-Menthyloxycarbonyl-L-lysine NCA.* Dry phosgene was passed through a suspension of N^{ε}-*(l)*-menthyloxycarbonyl-L-lysine (1.1 g) in 25 m*l* of dry dioxane for 1 hr at 50°C. Nitrogen was then passed through the reaction mixture for 30 min. The solvent was removed at 40°C under reduced pressure. The residual oily product was crystallized by treating it with *n*-hexane; yield, 1.0 g. This was recrystallized from ethyl acetate and *n*-hexane; yield, 0.97 g (82%). Mp 106—107°C.

Found: C, 61.04; H, 8.32; N, 7.81%. Calcd for $C_{18}H_{30}N_2O_5$: C, 60.99; H, 8.53; N, 7.90%.

*Poly-*N$^{\varepsilon}$*-(l)-menthyloxycarbonyl-L-lysine.* N^{ε}-*(l)*-Menthyloxycarbonyl-L-lysine NCA was dissolved in dioxane and DMF at the concentration of 10%. Triethylamine was added to each solution at NCA/initiator ratios of 100/1. The mixture was polymerized in a sealed tube at 15°C for 3 days, at 40°C for a day, and at 100°C for 3 hr. The results are summarized in Table 1.

Found: C, 65.14; H, 9.66; N, 8.86%. Calcd for $C_{17}H_{30}N_2O_3$: C, 65.78; H, 9.73; N, 9.03%.

Methods. The ORD, CD, and IR measurements were made on the respective ORD/UV 5 instruments, both made by the Japan Spectroscopic Co., Ltd. The optical rotations are expressed as a reduced molar residue rotation. As for CD, the measured values of $\varepsilon_L - \varepsilon_R$ were converted to the molar ellipticity.

Results and Discussion

The IR spectrum of the polymer showed absorptions at 1663 cm^{-1} for amide I and at 1530 cm^{-1} for amide II, suggesting the existence of the α-helical conformation.

The ORD and CD curves of the polymer in ethyl ether are shown in Fig. 1. The polymer exhibits a trough at 233 mμ with $[m']_{233} = -12100$ deg-cm²/dm. Moreover, two negative dichroism bands near 222 mμ and 206 mμ, with $[\theta]_{222} = -20000$ and $[\theta]_{206} = -26600$, are observed. This behavior is essentially identical with that of the right-handed α-helical form of the other polyamino acids. The polymer gave similar α-helical curves in THF ($[m']_{233} = -10000$) and in chloroform ($[m']_{233} = -9500$), and exhibited the ORD behavior of a random coil in TFA. The lower $[m']_{233}$ and $[\theta]_{222}$ values can be considered to result from the fact that this phenomenon arose from the interaction of the solvent and the bulky menthyloxycarbonyl chromophore.[1]

The helix→random coil transition for poly-N^{ε}-benzyloxycarbonyl-L-lysine (PCLL) occurs at 40% DCA in a DCA-$CHCl_3$ mixed solvent.[14] Plots of the $[\alpha]_{546}$ values *versus* the solvent composition of poly-N^{ε}-*(l)*-menthyl-

Aminocyclitols. XXV. Synthetic Studies on Streptamine and Its Analogs

Tetsuo SUAMI, Seiichiro OGAWA, Hiroshi SANO, and Naoyuki KATO

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received February 15, 1971)

In connection with the previous papers of this series,[1] streptamine[2] and its analogs were synthesized from *myo*-inosadiamine-1,3 dihydrochloride (**1**),[3] which was prepared by hydrazinolysis of 2,4,5,6-tetra-*O*-acetyl-1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol,[4] followed by a catalytic hydrogenation.

Since an axial hydroxyl group on C-2 was expected to be the least reactive toward an acetylation among four hydroxyl groups in **1**, a selective acetylation seemed to be possible. That is, when **1** was acetylated with acetic anhydride in anhydrous pyridine at 5—10°C for 7 days, di-*N*,*N'*-acetyl-4,5,6-tri-*O*-acetyl-*myo*-inosadiamine-1,3 (**2**) was obtained in 59% yield. Its proton magnetic resonance (PMR) spectrum in dimethyl sulfoxide-d_6 (DMSO-d_6) reveals the acetyl methyl protons as two sharp signals at τ 8 region:[5] τ 8.20 (6) and 8.11 (9), which were attributed to two equatorial acetamido and three equatorial acetoxy groups, respectively. Therefore the absence of a signal at a region of an axial acetoxy group (τ 7.80—7.91)[5] supported the proposed structure of **2**.[6] Then **2** was treated with methanesulfonyl chloride at 0—5°C for 2 days and

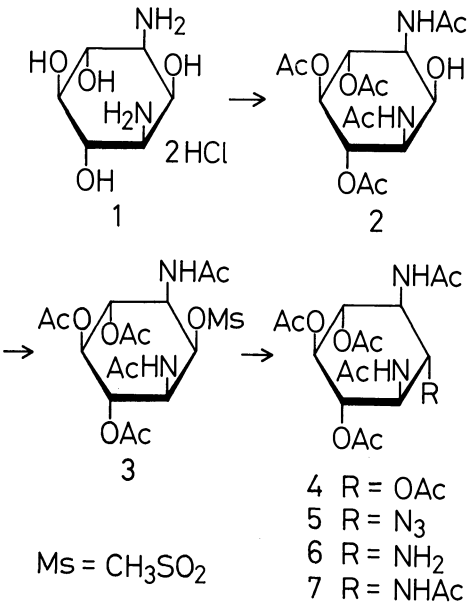
6) The PMR spectrum of hexaacetyl *myo*-inosadiamine-1,3[3] in DMSO-d_6 shows four peaks: τ 8.21 (6), 8.06 (3), 8.03 (6) and 7.82 (3).



subsequently settled at room temperature for 2 days to give di-*N,N'*-acetyl-4,5,6-tri-*O*-acetyl-2-*O*-methanesulfonyl-*myo*-inosadiamine-1,3 (**3**) in 56% yield.

When **3** was treated with anhydrous sodium acetate in boiling 2-methoxyethanol, a Walden inversion occurred at C-2 to afford streptamine in 56% yield as its hexaacetyl derivative (**4**), which was identified with an authentic sample.[7] This result confirmed as well the assignment of structure of **2**.

While, on treatment with sodium azide in boiling 2-methoxyethanol, **3** gave di-*N,N'*-acetyl-4,5,6-tri-*O*-acetyl-2-azido-2-deoxy-*scyllo*-inosadiamine-1,3 (**5**) in 57% yield. A catalytic hydrogenation of **5** afforded di-*N,N'*-acetyl-4,5,6-tri-*O*-acetyl-2-amino-2-deoxy-*scyllo*-inosadiamine-1,3 (**6**)[8] in 88% yield, which, on acetylation, gave known hexaacetyl *scyllo*-inosatriamine-1,2,3 (**7**)[8,9] in 53% yield.

Experimental

The melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. The PMR spectra were determined with a Varian A-60D spectrometer at the frequency of 60 MHz in DMSO-d_6 with tetramethylsilane as an internal standard. The infrared spectra were recorded in potassium bromide pellets.

Di-N,N'-*acetyl-4,5,6-tri*-O-*acetyl*-myo-*inosadiamine-1,3 (2).* Throughly dried *myo*-inosadiamine-1,3 dihydrochloride (**1**)[3] (0.40 g) was dissolved in hot anhydrous pyridine (18 m*l*) and cooled to 0—5°C by ice and water. To the solution was added acetic anhydride (1.1 m*l*, 5.5 molar equivalents) dropwise during 10 min under stirring. After keeping at 5—10°C for 7 days, the reaction mixture was filtered to remove an insoluble material and the filtrate was evaporated to dryness. The crystalline residue was recrystallized from ethanol to afford colorless needles (0.32 g, 59%) of **2**, mp 307—308.5°C. IR: 3460 (OH), 1750 (ester), 1670, 1615, and 1553 cm^{-1} (amide).

Found: C, 49.63; H, 6.29; N, 7.03%. Calcd for $C_{16}H_{24}N_2O_9$: C, 49.48; H, 6.23; N, 7.21%.

Di-N,N'-*acetyl-4,5,6-tri*-O-*acetyl-2*-O-*methanesulfonyl*-myo-*inosadiamine-1,3 (3).* Throughly dried **2** (120 mg) was dissolved in boiling anhydrous pyridine (6 m*l*) and cooled to 0—5°C by ice and water. Methanesulfonyl chloride (0.1 m*l*) was added dropwise under stirring and the reaction mixture was stored below 10°C for 4 days. An insoluble material was filtered off and the filtrate was evaporated to yield a crystalline residue which was triturated with ethanol, and the crystals were collected by filtration. The crude crystals of **3** weighed 81 mg (56%), mp 229—231°C. Further recrystallization from ethanol gave an analytical sample (52 mg), mp 231—231.5°C. IR: 1750 (ester), 1645, 1560 (amide), and 1180 cm^{-1} (OSO_2CH_3).

Found: C, 44.56; H, 5.84; N, 5.92; S, 6.51%. Calcd for $C_{17}H_{26}N_2O_{11}S$: C, 43.77; H, 5.62; N, 6.00; S, 6.87%.

Hexaacetyl Streptamine (4). A mixture of **3** (150 mg), anhydrous sodium acetate (150 mg) and 2-methoxyethanol (20 m*l*) was refluxed for 22 hr. The reaction mixture was evaporated to dryness and the resulting residue was treated with a mixture of acetic anhydride (15 m*l*) and pyridine (15 m*l*) at room temperature overnight. After filtering off an insoluble material, the mixture was evaporated to dryness and the residue was triturated with ethanol to give colorless crystals (78 mg, 56%) of **4**, mp 300°C (showing a transition at 237—238°C). This compound was identified with an authentic sample of **4** derived from antibiotic streptomycin[6] by comparing with IR spectra and the melting behaviors.

Di-N,N'-*acetyl-4,5,6-tri*-O-*acetyl-2-azido-2-deoxy*-scyllo-*inosadiamine-1,3 (5).* A mixture of **3** (200 mg), sodium azide (91 mg) and 2-methoxyethanol (10 m*l*) was refluxed for 20 hr. The reaction mixture was then worked up similarly as described under the preparation of **4**. The crude crystals of **5** so obtained was recrystallized from ethanol to give colorless needles (100 mg, 57%), mp 263—264°C (decomp.). Recrystallization from ethanol afforded an analytical sample, whose melting point did not change. IR: 2150 (N_3), 1750 (ester), 1655 and 1670 cm^{-1} (amide).

Found: C, 46.75; H, 5.63; N, 16.60%. Calcd for $C_{16}H_{23}N_5O_8$: C, 46.49; H, 5.61; N, 16.94%.

Di-N,N'-*acetyl-3,4,5-tri*-O-*acetyl-2-amino-2-deoxy*-scyllo-*inosadiamine-1,3 (6).* A solution of **5** (94 mg) in 90% aqueous dimethylformamide (10 m*l*) was hydrogenated in the presence of Raney nickel T-4[10] in a Parr shaker type apparatus under the initial hydrogen pressure of 4.5 kg/cm^2. After 14 hr, the catalyst was filtered off and the filtrate was evaporated to give a white powder (78 mg, 88%) of **6**. Recrystallization from ethanol gave colorless needles which showed a transition at 191—193°C. IR: 3400 (NH_2), 1750 (ester), 1640 and 1560 cm^{-1} (amide).

Found: N, 10.85%. Calcd for $C_{16}H_{25}N_3O_8$: N, 10.67%.

Hexaacetyl scyllo-*Inosatriamine-1,2,3 (7).* A 40 mg portion of **6** was treated with acetic anhydride (1 m*l*) and pyridine (1 m*l*) at room temperature overnight. The crude product was recrystallized from ethanol and ether to give colorless needles (23 mg, 53%) of **7**, mp 298—303°C (decomp.) This compound was identified with an authentic sample by comparing with the IR spectra.[8]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1994—1995 (1971)

The Dehalogenation of Organic Halides by Means of Iron(II) Chloride in Dimethyl Sulfoxide

Tamio SHIRAFUJI, Yasusi YAMAMOTO, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received February 16, 1971)

A recent publication[1] recorded a Wurtz-type condensation effected by iron(II) chloride-diamine complexes in ethanol. This has prompted us to publish our independent findings on the title reaction,[2] which has been examined in continuation of a previous investigation of the reactions of organic halides with copper(I) chloride in dimethyl sulfoxide (DMSO).[3] The observed results summarized in Table 1 are partly parallel to those of diamine complex,[1] but we wish to point out that the present reaction does furnish a practical, simple method for preparing tetraphenylethylene and *trans*-stilbene.

Iron(II) chloride tetrahydrate dissolves in DMSO to give a reddish-brown clear solution upon stirring in a nitrogen atmosphere for several minutes.[4] Benzylic and allylic halides were allowed to react in this 1M solution of the iron(II) salt. Dichlorodiphenylmethane, under the controlled conditions shown in Table 1, gave 1,2-dichloro-1,1,2,2-tetraphenylethane as the sole condensation product; this product was then further dehalogenated to tetraphenylethylene. In contrast, the dehalogenation by means of copper(I) chloride in DMSO gave tetraphenylethylene exclusively.[3] No 1,2-dichloro-1,1,2,2-tetraphenylethane was isolated in the latter reaction under any of the conditions examined.

Such step-by-step reduction was also observed in the case of benzotrichloride, which afforded α,α,α',α'-tetrachlorobibenzyl or a mixture of *cis*- and *trans*-α,α'-dichlorostilbene, under the controlled conditions. Benzal bromide gave a good yield of *trans*-stilbene, whereas benzal chloride did not give any condensation products, but benzaldehyde only. Benzyl chloride also failed to give even a trace of bibenzyl. The sole product isolated was found to be benzyl alcohol. When the reaction was performed in a mixture of DMSO-ethanol, the resulting product was benzyl ethyl ether. These products may be explained by assuming the following schemes:

$$R\text{-}X + Fe^{II}L_m(SH)_n \longrightarrow R\text{-}XFe^{II}L_{m'}(SH)_{n'}$$

$$HX + R\text{-}S + Fe^{II}L_m(SH)_n \qquad R\cdot + Fe^{III}XL_{m-1}(SH)_n$$

L: DMSO, H_2O, halide ion
SH: protic solvent (EtOH)

TABLE 1. WURTZ-TYPE CONDENSATION INDUCED BY 1 M $Fe(II)Cl_2 \cdot 4H_2O$/DMSO SOLUTION[a]

a) Unless otherwise stated the ratio of organic halides and iron(II) chloride was taken so as the atomic ratio of Fe: halogen to be 2.5:1.
b) Recovery was not considered in calculation of yields.
c) Benzophenone was obtained as solvolysis product.
d) Benzaldehyde was a minor product.

Cinnamyl chloride gave the Wurtz product in addition to the hydrolysate, cinnamyl alcohol. All these observations may tentatively be explained as follows. The halide-iron salt complex undergoes a one-electron transfer, thus affording the R· radicals, whose recombination gives the coupling products, R–R. The driving force toward this direction is probably the susceptibility of C–X bond cleavage and the stability of R·. The alternative path is the S_N reaction in the coordination sphere of the iron(II) ion. The ligand-ligand reaction gives the observed solvolysis products, such as benzaldehyde, benzyl alcohol, and cinnamyl alcohol.

Finally, it should be added that the present reagent is effective in inducing vicinal dehalogenation; this is exemplified by the reaction of stilbene dihalides as well as by that of benzalacetophenone dibromide.

Experimental

All the melting points are uncorrected. The mass spectra were determined on a Hitachi RMU-6L spectrometer, and the NMR spectra, on a JEOL C-60-H spectrometer, in $CDCl_3$ or CCl_4 solution at 60 MHz. The microanalyses were performed at the Elemental Analyses Center of Kyoto University.

General Procedure of Reactions of Organic Halides with Iron(II) Chloride Tetrahydrate in DMSO. Iron(II) chloride was dissolved in freshly-distilled (over CaH_2) DMSO under a nitrogen atmosphere so as to give a *ca.* 1 M solution upon heating with stirring at 60—70°C for 30 min; then the solution was maintained at an appropriate reaction temperature (20—80°C). A solution (*ca.* 0.4 M) of an organic halide in DMSO was then added to this drop by drop. The atomic ratio of halogen: Fe(II) was taken to be 1:2.5 unless otherwise stated. Heating and stirring were continued until TLC indicated the absence of the halide. The mixture was then treated with water and extracted with ether or benzene. The extract was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The products were separated and identified as usual. The following description refers to cases which cannot be covered sufficiently by Table 1.

Dechlorination of Dichlorodiphenylmethane. Dichlorodiphenylmethane (1.18 g, 0.005 mol) was treated with a solution of iron(II) chloride (1.00 g, 0.005 mol) in DMSO (30 m*l*) at 20—30°C for 16 hr. The reaction products were washed with MeOH. The recrystallization of the resulting crystalline product from benzene-EtOH (1:1) gave 1,2-dichloro-1,1,2,2-tetraphenylethane (0.65 g, 65%), mp (decomp.) 175—178°C (lit,[6] 184—186°C), which was identified by elemental analyses and by comparison with an authentic sample (IR, MS). The further dehalogenation of the dichloride with iron(II) chloride in DMSO yielded tetraphenylethylene. The concentration of the filtrate gave benzophenone (0.20 g, 22%). In another run, dichlorodiphenylmethane (2.50 g, 0.011 mol) was treated with a solution of iron(II) chloride (10.6 g, 0.053 mol) in DMSO (50 m*l*). The crude product was washed with MeOH and recrystallized from benzene-EtOH (1:1) to afford tetraphenylethylene (1.43 g, 82%), mp 220—222°C (lit,[7] 222—224°C).

Dechlorination of Benzotrichloride. Benzotrichloride (2.00 g, 0.010 mol) was treated with a solution of iron(II) chloride (2.48 g, 0.012 mol) in DMSO (20 m*l*) at 60°C for 27 hr. A work-up gave α,α,α′,α′-tetrachlorobibenzyl (1.40 g, 85%), mp and mixed mp 159—160°C (EtOH) (lit,[8] 160—161°C), which was identified by means of its IR spectra. Tetrachlorobibenzyl (1.50 g, 0.005 mol) was treated with a solution of iron(II) chloride (10.0 g, 0.050 mol) in DMSO (50 m*l*) at 90°C for 17 hr. Chromatography on a short alumina column, followed by recrystallization (EtOH), afforded a mixture (1.17 g, 94%) of *cis*- and *trans*-α,α′-dichlorostilbene. Hand-sorting and recrystallizations gave pure constituents, the *cis* isomer as prisms, mp and mixed mp 60—62°C (lit,[9] 62—63°C), and the *trans* isomer as powdery microcrystals, mp and mixed mp 137—138°C (lit,[9] 142°C). The yields (*cis* 76%, *trans* 18%) were calculated on the basis of the product ratio determined by GLC (Apiezon L 30%).

Hydrolysis of Benzyl Chloride. Benzyl chloride (1.27 g, 0.010 mol) was treated with a solution of iron(II) chloride (4.98 g, 0.025 mol) in DMSO (30 m*l*) at 80—90°C for 20 hr, when TLC indicated the absence of benzyl chloride. The work-up of the mixture gave benzyl alcohol (0.75 g, 69%). However, the treatment of benzyl chloride (1.27 g, 0.010 mol) with EtOH (6 m*l*) and iron(II) chloride (1.99 g, 0.010 mol) in DMSO (30 m*l*) at 80—90°C, followed by a further usual work-up, gave benzyl ethyl ether (0.96 g, 70%). The treatment of benzyl chloride at 20°C gave no products but the starting material.

The authors are grateful to Professor Keiiti Sisido for his generous help. Financial support from the Minitstry of Education, Japanese Government, and from Toray Science Foundation is acknowledged with pleasure.

Hydrogen Bonding in Sodium Tetrachloroaurate(III) Dihydrate and Sodium Tetrachloroiodate(III) Dihydrate

Kakuko ICHIDA, Yoko KURODA, Daiyu NAKAMURA, and Masaji KUBO
Department of Chemistry, Nagoya University, Chikusa, Nagoya

(Received February 24, 1971)

We have discussed the formation of O–H···Cl hydrogen bonds in the crystals of sodium tetrachloroaurate(III) dihydrate in connection to the positive temperature coefficient of nuclear quadrupole resonance frequency of chlorine in this compound.[1,2] An X-ray crystal analysis carried out by Bonamico *et al.*[3] has shown that one of the four chlorine atoms in an $AuCl_4^-$ ion is separated from two oxygen atoms by the shortest O···Cl distance of 3.36 Å and from two other oxygen atoms by the second shortest distance equal to 3.42 Å. Chlorine atoms of this type are responsible for the unusual temperature dependence of quadrupole resonance.[1] Although hydrogen atoms have not been located, it is conceivable that the chlorine atoms in question is involved in weak hydrogen bonds with four water molecules. In fact this is the key point for explaining the positive temperature coefficient mentioned above.

However, the O···Cl distance is appreciably longer than the sum of van der Waals radii, 3.2 Å. This presents a debatable problem in view of the accepted belief that a hydrogen bond, X–H···Y, is surely formed when the X···Y distance is shorter than the sum of van der Waals radii.[4]

The frequency shift of X–H stretching vibration presents another criterion for the formation of hydrogen bonds. Therefore, we have observed the infrared absorption of this compound at room and liquid-nitrogen temperatures. Samples were run as Nujol or hexachlorobutadiene mulls. Measurements were performed in the frequency range from 4000 to 700 cm^{-1}, using a JASCO DS-402G spectrophotometer.

At room temperature, three bands were observed at 3575, 3516, and 1618 cm^{-1}. Undoubtedly they are due to the intramolecular vibrations of water molecules because they show normal frequency shifts on deuteration. At liquid-nitrogen temperature, the frequencies and band shapes were practically unaltered in agreement with the results of our NQR study indicating that no phase transition takes place in the temperature range investigated. Although there are eight water molecules in a unit cell, vibrational coupling among them seems to be inappreciable, because no bands were split even at liquid-nitrogen temperature. Therefore the three bands were assigned to the antisymmetric stretching γ_3, symmetric stretching γ_1, and bending γ_2 of a water molecule, respectively.

Heavily but incompletely deuterated samples yielded a single band at 3545 cm^{-1} in place of the bands, γ_3 and γ_1 of undeuterated samples. The band is attributable to the γ_3 mode of HDO molecules diluted in D_2O molecules. The frequency is very close to the mean value of γ_3 and γ_1 of undeuterated water molecules. Since the vibration is almost free from coupling, the vibrational frequency is used for the following discussion on the O–H stretching frequencies of water molecules in various compounds.

The observed O–H stretching frequency, 3545 cm^{-1}, is significantly higher than those of water molecules, 3275 cm^{-1} in ice[5] and 3450 cm^{-1} in calcium sulfate dihydrate,[6] but is still lower than 3707.5 cm^{-1} of water vapor[7] and 3624 cm^{-1} of water molecules very loosely bound in the crystals of beryl.[8] A frequency shift of about 160 cm^{-1} from the frequency of water vapor provides an evidence in support of the formation of weak hydrogen bonds in the crystals of sodium tetrachloroaurate(III) dihydrate.

Attempts have been made to correlate the frequency shift $\Delta\gamma=\gamma^0_{XH}-\gamma_{XH}$ with the distance R between heavy atoms in hydrogen-bonded systems, X–H···Y. Here γ^0_{XH} refers to X–H stretching free from hydrogen bonding and γ_{XH} stands for the X–H frequency in the hydrogen-bonded systems. Lippincott and Schroeder[9] first succeeded in reproducing an asymptotic approach of $\Delta\gamma$ toward zero for large R by use of a semiempirical potential function proposed by themselves.

$$\frac{\gamma_{XH}}{\gamma^0_{XH}} = \left\{ r_0 e^{-\alpha}\left[r_0^2 - \frac{\alpha}{2}(r+r_0)^2\right]/r^3 + r_0^* \frac{D_0^* n^*}{D_0 n} e^{-\beta}\left[r_0^{*2} - \frac{\beta}{2}(r^*+r_0^*)^2\right]/r^{*3} \right\}^{1/2} \quad (1)$$

$$\alpha = n(r-r_0)^2/2r$$

$$\beta = n^*(r^*-r_0^*)/2r^*$$

where r is the X–H distance in a hydrogen-bonded system, r_0 is the corresponding values in an X–H system free from hydrogen bonding, D_0 is the dis-

sociation energy of the X–H bond, and n is a semi-empirical parameter. Asterisks refer to the H···Y bond. Since the value of r is given as a function of R,[9] the dependence of the frequency shift on R can be obtained.

Recently, Bellamy and Owen[10] proposed a simple empirical relationship between $\Delta\gamma$ and R on the basis of the Lennard-Jones 6-12 potential function.

$$\Delta\gamma\ (\mathrm{cm^{-1}}) = 50[(d/R)^{12} - (d/R)^{6}] \qquad (2)$$

where d is the distance at which the potential energy curve intersects the abscissa.

The validity of Eqs. (1) and (2) has been checked especially for O–H···O systems, for which a large number of available data cover a wide range of R. For O–H···Cl systems, only hydroxylamine hydrochloride (R=2.99 Å) and chloral hydrate (3.15 Å) are cited in the original papers.[9,10] No evidence has been obtained for confirming that these equations are valid also for hydrogen bonding in inorganic chloride hydrates having a relatively large value of R.

Figure 1 shows the O–H stretching frequencies of

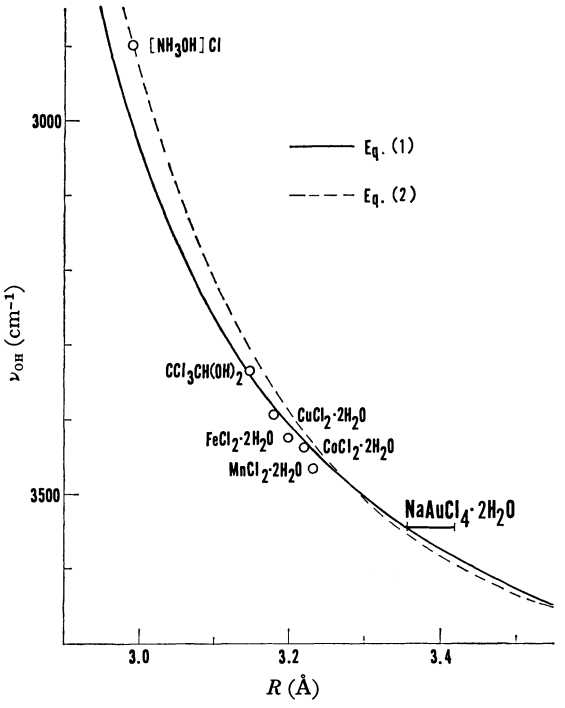

Fig. 1. O–H stretching frequency of hydrogen-bonded water molecules in various inorganic chloride hydrates plotted against the O···Cl hydrogen-bonded distance.

$CuCl_2\cdot 2H_2O$,[11] $CoCl_2\cdot 2H_2O$, $FeCl_2\cdot 2H_2O$, and $MnCl_2\cdot 2H_2O$[12] as observed for HDO species plotted against the O···Cl distance.[13,14] These crystals are particularly suitable to the present purpose, because each of them contains only one kind of water molecules and also beacuse they are isomorphous with one another except for the copper compound. Figure 1 shows two theoretical curves for the O–H···Cl systems quoted from the original papers also.[9,10] Both curves are drawn with γ^0_{OH} equal to 3700 $\mathrm{cm^{-1}}$. Agreement between theoretical and experimental data is excellent, indicating that relations (1) and (2) can be used for discussing hydrogen bonding in inorganic chloride hydrates having a relatively large value of R.

The O–H stretching frequency of sodium tetrachloroaurate(III) dihydrate is shown by a horizontal line in the figure in order to take into account two observed O···Cl distances possibly involved in hydrogen bonding. Since its deviation from the theoretical curves is rather trivial, it is concluded that although the hydrogen bonding is weak, the nature of the hydrogen bonds is essentially the same as those in other compounds mentioned above. The O···Cl distances are longer than the sum of van der Waals radii, but are considerably shorter than d (=3.85 Å) defined by Bellamy and Owen, which is very close to the sum of collision radii, 3.81 Å, of gas molecules. This implies that water molecules are bonded to $AuCl_4^-$ ions in this compound mainly by electrostatic and van der Waals forces.

Sodium tetrachloroiodate(III) dihydrate has been known to form crystals isomorphous with sodium tetrachloroaurate(III) dihydrate.[1] However, the crystal structure has not been determined in detail as yet. We have recorded the infrared spectra of this compound at liquid-nitrogen temperature, and observed bands at 3577, 3515, and 1611 $\mathrm{cm^{-1}}$ attributable to γ_3, γ_1, and γ_2 of water molecules, respectively. These values agree almost perfectly with those of water in sodium tetrachloroaurate(III) dihydrate. This fact indicates that weak O–H···Cl hydrogen bonds are formed in the crystals as in the case of sodium tetrachloroaurate(III) dihydrate and that the O···Cl distances are practically the same in these two compounds.

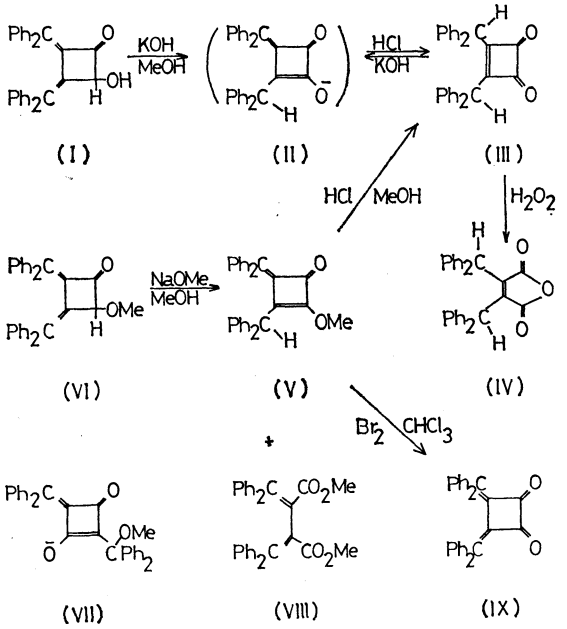
SHORT COMMUNICATIONS

The Rearrangement of 2-Hydroxy-3,4-bis(diphenylmethylene)-cyclobutanone to the Enolizable Cyclobutenedione, 3,4-Bis(diphenylmethyl)-3-cyclobutene-1,2-dione *via* Methylenecyclobutenone Intermediate

Fumio Toda, Nobuhiro Ooi, Yoshikazu Takehira, and Katsuhiko Akagi
Department of Chemistry, Faculty of Engineering, Ehime University, Matsuyama
(Received March 3, 1971)

In the course of our studies of the reactions of 2,3-dimethylenecyclobutanones with a base, we have found that the title cyclobutanone (I)[1] dissolves in aqueous KOH easily and that the acidification of the solution affords the title cyclobutenedione (III) as colorless prisms in a 62% yield, mp 130—131°C. The structure of III was determined by means of the spectral data: λ_{max} (CH_3CN) 258 sh (8200), 265 sh (6600) and 271 sh nm (ε, 5300); ν_{max} (Nujol) 1790 and 1770 (unsplit doublet, CO) and 1580 cm^{-1} (C=C); NMR ($CDCl_3$) 2.5—3.0 (m, Ph, 20H), and 4.73 τ (s, CH, 2H). The oxidation of III with neutral H_2O_2 afforded the corresponding anhydride, bis(diphenylmethyl)maleic anhydride (IV), in a 71% yield, mp 171—172°C. It is well established that cyclobutenediones undergo a Bayer-Villiger-type oxidation with neutral H_2O_2 to give the corresponding maleic anhydrides.[2]



The dione III also dissolved in aqueous KOH and even in aqueous $NaHCO_3$, from which III was recovered quantitatively by acidification. Since the electronic spectrum of an alkaline solution of III (or of I) showed an absorption band at 330 nm (ε, 21700) which is comparable to that of the analogous anion VII obtained by dissolving 2,4-bis(diphenylmethylene)-cyclobutanedione in MeOH-KOH, 324 nm (ε, 24600),[3] the structure in the alkaline media may be said to be II. The acidification of a solution of III (or of I) in KOD-D_2O-MeOD (prepared by the addition of D_2O to MeONa in MeOD) with DCl-D_2O afforded III-d_2, which showed no methine proton signal in the NMR spectrum. Under neutral conditions, however, neither I nor III exchanged its methine hydrogen with deuterium by recrystallization from MeOD.

The rearrangement of I into II is likely, since the treatment of VI[4] with NaOMe in MeOH at room temperature afforded the rearranged product, V, as colorless prisms in a 30% yield, mp 126—127°C, in addition to the diester, VIII, as yellow needles in a 43% yield, mp 233—234°C. The structure of V was identified by means of the spectral data: λ_{max} (EtOH) 293 nm (ε, 17600); ν_{max} (Nujol) 1760 (CO), 1650 (*exo* C=C), and 1590 cm^{-1} (*endo* C=C); NMR ($CDCl_3$) 2.6—3.2 (m, Ph, 20H), 5.53 (s, CH, 1H), and 5.95 τ (s, OMe, 3H). The structure of V was further identified by the following reactions. The treatment of V in $CHCl_3$ with bromine afforded IX[5] in a 30% yield. The treatment of V in MeOH with hydrogen chloride afforded III in a 64% yield.

The cyclobutenediones which have been reported to date are all sensitive to the base and all undergo ring-cleavage.[2] The enolization of III in alkaline media without decomposition differs widely from these facts.

When the reaction of VI with NaOMe in MeOH was carried out under a nitrogen atmosphere, the major product was V (65%), and the minor one was VIII (1%). On the other hand, the treatment of V with NaOMe under an oxygen atmosphere afforded VIII in a 40% yield. On the basis of these results and the observation that 1,2-bis(diphenylmethylene)cyclobutene reacts with oxygen to afford 2,3-bis(diphenylmethylene)-butanedial quantitatively,[6] a possible reaction path leading to VIII is as follows:

Ambident Ion. IV. *C*-Alkylation of Enolate Anion Accompanying Retention of Configuration

Masakazu SUAMA, Toshio SUGITA, and Katsuhiko ICHIKAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received March 22, 1971)

Recent report by Sommer and Korte[1] showed that charge-delocalized organolithium reagent coupled with optically active secondary halides with nearly complete inversion of configuration. According to Hart,[2] *C*-alkylation of phenoxide ion also proceeds with inversion of configuration. We wish to report our findings which are in sharp contrast to these results. Reaction of *sec*-butyl bromide with alkali metal salts of methyl acetoacetate and acetylacetone gives *C*- and *O*-alkylated products.[3]

$$(CH_3COCHCOR)^-M^+ + \textit{sec}\text{-BuBr} \longrightarrow \underset{\text{(I)}}{CH_3COCH(Bu^s)COR} + \underset{\text{(II)}}{CH_3C(OBu^s)=CHCOR} + MBr$$

a:R=OMe b:R=Me

Results with the optically active bromide in DMSO are given in Tables 1 and 2. Absolute configurations of optically active I and II, which are not known so far, have been determined in correlation with III and IV through the following reaction sequences:

$$(+)\ \underset{\text{MeC*HEt (Ia)}}{CH_3COCHCO_2CH_3} \xrightarrow[\text{2) H}^+]{\text{1) 5\% NaOH, 25°C}} (-)\ CH_3COCH_2C^*HMeEt\ \text{(III)}$$

$$(+)\ \underset{\text{MeC*HEt (Ib)}}{CH_3COCHCOCH_3} \xrightarrow{\text{20\% KOH, 40°C}} (-)\text{-III}$$

$$(+)\ \underset{\text{OC*HMeEt}}{CH_3C{=}CHCOR} \xrightarrow[\text{2) H}_2O]{\text{1) O}_3\text{ in CHCl}_3} \underset{\text{(II)}}{} (+)\ CH_3CO_2C^*HMeEt\ \text{(IV)}$$

It has been established that Ia and Ib have (−) R and IIa and IIb have (+) S structures.[4] The results show that *C*-alkylation proceeds with retention of configuration. The extents of the retention should be much higher (25—50%) than the observed values (Table 2), since control experiments showed that the starting active butyl bromide racemizes in the presence of metal halides which are formed by the reaction. This indicates that *C*-alkylation is not a simple S_N2 reaction by free carbanion species, and that some front-side attack to asymmetric center must have occurred. On the other hand, in the *O*-alkylation of sodium salts, taking the rate of racemization of the bromide into consideration, the results show almost complete inversion of configuration which suggests a typical S_N2 reaction of enolate anion (Table 2).

These stereochemical results show that *C*- and *O*-*sec*-butylations are not simple competitive reactions through a common transition state.[6] For a more detailed discussion, precise stereochemical and kinetical investigations are necessary.

The Reaction of Photo-excited Phenanthraquinone with Hydrogen Donors.[1] The Behaviors of the Resulting 1,2-Photo-adducts Studied by the CIDNP Technique

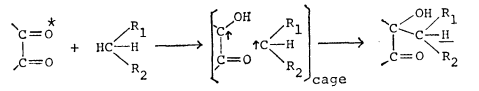
Kazuhiro MARUYAMA, Tetsuo OTSUKI, Heisaburo SHINDO,* and Tetsuo MARUYAMA*

Department of Chemistry, College of Liberal Arts and Science, Kyoto University, Kyoto

* *JEOL(USA) Inc., 235 Birchwood Avenue, Cranford, N.J. 07016, USA*

(Received March 24, 1971)

Strongly-enhanced PMR absorption signals due to the underlined proton of the 1,2-photo-adduct have been observed in the photochemical reaction of phenanthraquinone with alkyl aromatics *via* a radical in the electronic triplet state (Eq. (1)).[2]



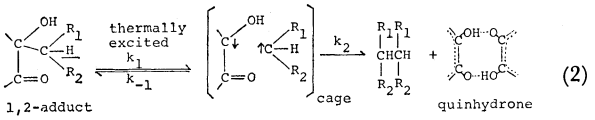
(1)

(I): $R_1=R_2=C_6H_5$, (II): $R_1,R_2=$ C_6H_4–C_6H_4

(III): $R_1,R_2=$ C_6H_4–O–C_6H_4

On the contrary, when 1,2-photo-adducts, especially those produced from the reaction of phenanthraquinone with diphenylmethane (I), fluorene (II), and xanthene (III), were heated in an NMR probe at a suitable temperature, we observed a strong, enhanced PMR emission signal at exactly the same position as was observed in the process described in Eq. (1). The optimal temperature to observe the strongest emission signal was at 150°C, 175°C, and 110°C respectively for I, II, and III (Fig. 1). Accompanying such a phenomenon, the 1,2-photo-adduct promptly decomposed to give phenanthraquinhydrone as black purple crystals and the dimer of the alkyl aromatic moiety.[4]

These exciting phenomena appear to be caused by the process described in Eq. (2); that is, the 1,2-photo-adduct is thermally activated to give the radical pair in the electronic singlet state in a solvent cage (the rate of k_1). The radical pair produced will be stabilized by the two competitive routes; the reverse reaction to the adduct, and the decomposition reaction out of the solvent cage (the rates of k_{-1} and k_2 respectively). Thus, the methine proton (underlined) of the reproduced adduct will be polarized with inversely-populated



(2)

When $k_1 \simeq 0$ and/or $k_2 \gg k_{-1}$, we were not able to observe such a strong enhanced emission signal. Although the spin states to those in the process described in Eq. (1). enhanced absorption or emission PMR spectra observed here are compatible with those predicted by the CKO theory,[5] no such typical representation as in our experiments has ever been reported.

Furthermore, when the 1,2-photo-adduct was irradiated with and without a yellow filter (Kenko L40C UV cut filter) with a 500 W high-pressure Hg lamp at a suitable temperature just before thermal decomposition takes place, for example, at 125°C for I in neat diphenylmethane, it was found that an enhanced PMR absorption signal of the same methine proton (about 10 times the normal signal intensity) can be observed. At this temperature, the signal intensity of normal signal does not change between before and after irradiation. This phenomenon seems to be explainable by taking into account the process described in Eq. (3)

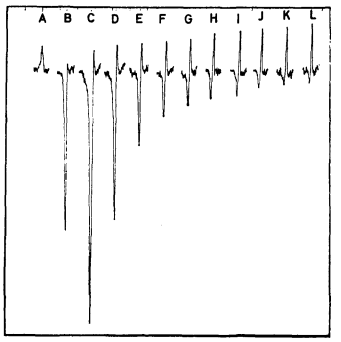


Fig. 1 Enhanced PMR emission signals (247 Hz down-field from TMS) observed in the course of thermal decomposition of 1,2-photo-adduct obtained from phenanthraquinone and xanthene (solvent:*o*-dichlorobenzene, 110°C). Signals (from **A** to **L**) were measured for every 10 sec. **A**: normal signal immediately after sample was inserted into an NMR probe. **B,C,D**……: enhanced PMR emission signal after thermal decomposition started, and the other signal due to proton of decomposition product begins to appear at a slightly upper field.

The Carbonylation of Alkyl Halide with Carbon Monoxide in the $SbCl_5$-Liquid Sulfur Dioxide System

Masatomo NOJIMA, Koichi TATSUMI, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Recieved March 24, 1971)

The synthesis of several carboxylic acids or esters from olefins and alkyl halides with carbon monoxide, and water or alcohol catalyzed by acid catalysts has been studied by many investigators.[1a] Simon and Warner have reported the reaction in hydrogen fluoride with water, which gave isobutyric acid from isopropyl chloride.[1b]

Considerable success in this synthesis has been won by Koch and Haaf using formic acid as the source of carbon monoxide and sulfuric acid as the catalyst.[2] In spite of the applicability of the Koch method to a great variety of compounds, this reaction is accompanied by the considerable isomerization of the double bond and the carbon skeleton, which diminishes the utility of this method from the point of view of preparation.

To carry out the carbonylation under milder conditions, the present authors attempted the carbonylation of alkyl halides in the $SbCl_5$-liquid SO_2 system at $-70°C$ under atmospheric pressure. The selectivity of the reaction and the skeletal rearrangement of the substrate are also examined using mono- and dihalogeno-substituted cyclohexane derivatives. The reaction scheme is as follows:

$$RX + CO + ROH \xrightarrow[SbCl_5+SO_2]{1\,atm\ -70°} RCOOR + HX \quad (1)$$

A typical procedure is as follows. To a mixture of 20 g (0.07 mol) of $SbCl_5$ and 50 m*l* (about 0.5 mol) of liquid SO_2, a solution of 4.6 g (0.05 mol) of *t*-butyl chloride and 3.7 g (0.08 mol) of ethanol, dissolved in 20 m*l* of dichloromethane, was dropped at $-70°C$ over a thirty-minute period while a current of carbon monoxide gas was bubbled into the flask at a velocity of 70 m*l* per minute, after which the reaction was continued for thirty additional minutes. The reaction mixture was treated following the ordinary method; subsequent analysis by vpc showed the existence of only one product, the pivalic acid ethyl ester (4.2 g (66%)). All the products obtained were characterized by NMR, infrared, and mass spectroscopy.

The results obtained are summarized in Table 1. When a tertiary alkyl halide was used as the substrate the ester corresponding to the starting material was obtained in a fair yield without the isomerization of the carbon skeleton. A control experiment without liquid SO_2 gave no carbonylated product. The secondary halide reacted upon isomerization, and the yield of the corresponding ester was depressed as a result of the skeletal transformation. Moreover, the following facts are worth noting.

Table I. Reactions of alkyl halide with carbon monoxide

Halide	Product, (Yield %) [a]
$(CH_3)_3CCl$	$(CH_3)_3CCO_2C_2H_5$ (66)
$(CH_3)_2\underset{Br}{C}H\underset{O}{\overset{\|}{C}}CH_3$	$(CH_3)_2\underset{CO_2C_2H_5}{C}H\underset{O}{\overset{Cl}{\overset{\|}{C}}}CH_3$ (63)

Dimerization of C_2D_4 Catalyzed by Bis(triphenylphosphine)-σ-1-naphthyl Nickel (II) Bromide

Ken-ichi MARUYAMA, Tetsufumi KUROKI, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization,
Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 3, 1971)

It has been reported that bis(triphenylphosphine)σ-arylnickel (II) bromide catalyzes the selective dimerization of ethylene in the presence of boron trifluoride etherate in dry methylene chloride or benzene solution.[1] This catalyst system contains no substance such as alkylaluminum[2] or alkyllithium which is likely to provide a nickel hydride. We must clarify whether ethylene dimerization is catalyzed by a nickel hydride formed during the reaction and what substance supplies the hydrogen to the nickel complex if the nickel hydride is formed. For this purpose we studied the isotopic exchange between C_2H_4 and C_2D_4 and between C_2D_4 and other chemical species involved in the reaction system of the dimerization.

The isotopic exchange of C_2H_4–C_2D_4 (1:1) was carried out at 0°C for 5 or 10 min, using bis(triphenylphosphine)σ-1-naphthyl nickel (II) bromide (0.20 mmol) in the presence of boron trifluoride etherate (0.29 or 0.72 mmol) in dry methylene chloride (10 m*l*). Concurrent dimerization of ethylene was observed as follows.

$BF_3(Et_2O)$	Reaction time	Conversion	1-C_4'	*trans*-2-C_4'	*cis*-2-C_4'
0.29 mmol	10 min	46.5%	56	30	14
0.72 mmol	5 min	55.8%	29	50	21

In either case the isotopic distribution in the residual ethylene was C_2H_4 7%, C_2H_3D 26%, $C_2H_2D_2$ 37%, C_2HD_3 24% C_2D_4 6%, which was in good agreement with equilibrium distribution. This result shows that the rate of isotopic exchange is strikingly faster than the ethylene dimerization, and that one hydrogen atom is exchanged in one act of the exchange. Thus it is concluded that there must be an active hydrogen atom which catalyzes the exchange reaction. In this case, the active hydrogen atom is very likely provided as a nickel hydride.

The source of the active hydrogen was examined by the reaction of C_2D_4 (atomic fraction of hydrogen f_H= 0.020). The reaction condition was the same as in the above reaction. The results are shown in Table 1.

TABLE 1. ATOMIC FRACTION OF HYDROGEN (f_H) IN ETHYLENE OR BUTENE AFTER THE REACTION OF C_2D_4

No.	Ni complex (mmol)	BF_3OEt_2 (mmol)	CH_2Cl_2 (m*l*)	C_2D_4 introduced	React. time	f_H
1	0.20	0.79	10	1.16	3 hr	0.022[a]
2	0.20	0.72	10	1.00	10 hr	0.024[a]
3	0.20	0.72	10	1.13	150 hr	0.023[a]
4	0.20	0.72	30	1.10	5 min	0.020[b]
5	1.0	0.72	30	1.09	5 min	0.020[b]
6	2.0	0.72	30	1.07	5 min	0.021[b]
7	1.0	3.6	30	1.06	5 min	0.020[a] 0.020[b]
8	2.0	7.2	30	1.11	5 min	0.022[b]

a) Calculated from the butene formed.
b) Calculated from the residual ethylene.

If the active hydrogen comes from the solvent or the ligand, the atomic fraction of hydrogen in ethylene or butene formed should be higher than that in the starting material (f_H=0.020). However, no appreciable increase in f_H is observed as shown in Table 1, independent of the reaction time, the amount of catalyst, and the amount of solvent, while the amount of C_2D_4 is approximately fixed. This means that no hydrogen is supplied to the nickel complex from the solvent, triphenylphosphine, 1-naphthyl ligand or diethyl ether

It is concluded that the isotopic exchange and the dimerization of ethylene is catalyzed by a nickel hydride complex which is formed by the reaction of ethylene with the nickel complex.

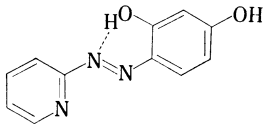
Kinetics of Chelate Formation between Lanthanum(III) and 4-(2-Pyridylazo)-resorcinol

Tamio ONODERA* and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

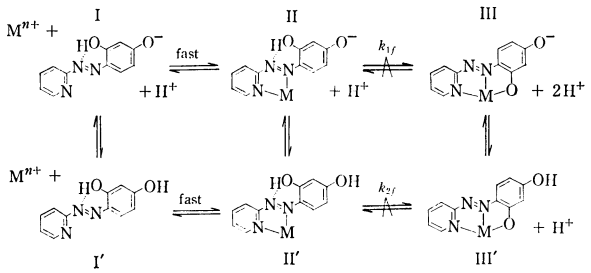
(Received April 16, 1971)

In connection with the slowest liberation of the proton in aqueous solutions from the heavily blocked internal hydrogen bond in a series of *o*-hydroxyazo dyes as reported by Eigen *et al.*,[1,2] we report here some interesting kinetic effects of the fast formation of metal chelate ring on the rate of subsequent protolytic dissociation of an inert hydrogen bond in a ligand molecule of similar structure.



PAR

4-(2-Pyridylazo)-resorcinol (PAR)[3,4] was chosen as a typical ligand of this type requiring a prior rupture of the internal hydrogen bridge between the *o*-hydroxyl and the azo-group to form a final metal chelate of terdentate structure.[5] With the metal ions, for which the very fast substitution of the coordination water would be expected, the overall rate of chelate formation of such terdentate ligands as PAR would thus be determined by the slow rupture of the hydrogen bond. The reaction scheme is shown as follows:



The present communication deals with the reaction of PAR with lanthanum(III) ion, the first member of the terpositive lanthanoids, which show quite regular change in ionic radii and substitute very rapidly their coordination water.[6,7] The continuous variation method showed a 1:1 complex formation. The apparent stability constant was spectrophotometrically determined to be $K=[\mathrm{LaPAR}][\mathrm{H}]/[\mathrm{La}][\mathrm{HPAR}]=10^{-3}$—$10^{-2}$ at about pH 5.9.

The rate constants for the dissociation and the recombination of the internal hydrogen bond of the ligand PAR were determined by the temperature-jump method to be $k_D=6.4\times10^5$ M^{-1}sec^{-1} and $k_R=6.2\times10^3$ sec^{-1}, respectively, at 25°C and ionic strength 0.1 ($NaClO_4$). Values of activation energy for k_D and k_R were 2.5 and 5.9 kcal·mol^{-1}, respectively.

The rate of formation of the La(III)-PAR complex was measured by the stopped-flow method in the pH range 4.2—6.2 buffered with hexamine and at 505 nm, the λ_{max} of the complex III. The rate was found to be dependent on the hydrogen ion concentrations and independent of the metal ion concentrations for the excess of lanthanum(III), suggesting the overall reaction rates determined by the slow rupture of the hydrogen bond in the steps II⇌III and II′⇌III′.

The rate constants $k_{1f}=38$ sec^{-1} and $k_{2f}=430$ sec^{-1} were obtained on the assumption that the hydrogen-bridged species II and II′ are inert as compared with the fully-chelated metal complexes III and III′. Lanthanum(III) reacts with the ligand PAR *ca.* 10^{-6} times as slow as with any ligands containing no internal hydrogen bond. The slowness in rupture of the internal hydrogen bond in the metal complex formation as compared with that in the protolysis of the free ligand can be attributed to the increased inertness of the hydrogen bond in the partly-chelated intermediates II and II′ containing two fused chelate rings.

Activation energy of the complex formation strongly suggests that the intermediates II and II′ retain the hydrogen-bonded structure of the ligand molecules and the rupture of this bond in turn constitutes the rate-determining step to form the final products III and III′. From a comparison of the rate constants of the hydrogen-bond dissociation in the ligand PAR with those of the metal complex formation, the activation energy was calculated to be 8.3 kcal·mol^{-1}, and experimentally found to be 8.1 kcal·mol^{-1}. Both values are in good agreement. Therefore, it would be reasonable to assume the given two-step mechanism involving the very fast metal chelate ring formation on the heterocyclic nitrogen atom and one of the azo-nitrogen atoms, and the subsequent slow chelate ring formation on the *o*-hydroxyl oxygen and other azo-nitrogen atoms to form the final terdentate structure with fused metal chelate rings.

The hydrogen-bonded ligand structure of PAR seriously affects the formation rate and the stability of the metal complexes.[8] The series of rare earth metal ions may reveal the influences of size and coordination requirements of the metal ions on the reaction mechanisms.

The Measurement of Water and Other Oxygen-containing Products in the Radiolysis of Cyclohexane Solutions of Nitrous Oxide

Ken-ichi TAKEUCHI, Kyoji SHINSAKA, Satoshi TAKAO, Yoshihiko HATANO, and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received May 4, 1971)

Nitrous oxide has received more attention than any other solute among electron scavengers, but there is still considerable uncertainty as to the over-all mechanism of N_2 formation despite the large number of studies.[1] The difficulty in interpreting the results arises from the facts that the observed yield of N_2 is considerably greater than the expected yield of electron and that no quantitative analysis of all the oxygen-containing products formed after the decomposition of N_2O has yet been accomplished. As the oxygen-containing products, thus far, $C_6H_{11}OH$[2-4] and H_2O[5] have been reported to be formed in the cyclohexane-N_2O system.[6] The yield of $C_6H_{11}OH$, which accounted for only a small percentage of the expected yield of oxygen-containing products, was measured quantitatively. The previous measurements of H_2O, however, were quite inaccurate.[5,7,8] In the present study, the measurement of H_2O and other oxygen-containing products in the radiolysis of cyclohexane solutions of N_2O has been accurately carried out.

Cyclohexane was completely dehydrated before irradiation by using a liquid Na–K alloy. The samples, 2-m*l* portions of the cyclohexane with various N_2O concentrations, were irradiated by ^{60}Co-γ rays to a total dose of 9.2×10^{19}eV/g at room temperature. The total yields of H_2O and alcohols, denoted by ROH, were calculated stoichiometrically on the basis of H_2 yield produced by the reaction with the Na–K alloy after the removal of N_2O and radiolytic products of H_2 and N_2. The alloy, rather than either sodium or potassium alone, is preferable because the liquid alloy maintains a fresh active surface. The complete evolution of H_2 can be accomplished only if the alloy is free from its oxide, since the oxide reacts with H_2O without the liberation of H_2. The alloy was, therefore, carefully prepared in order to avoid the oxide. The accuracy of the method used for determining the total amounts of ROH was tested with several authentic samples in which a known amount of H_2O or $C_6H_{11}OH$ has been added to the completely dehydrated cyclohexane. The amount of H_2O or $C_6H_{11}OH$ added to the cyclohexane almost agreed with that computed from the yield of H_2. Especially great caution was used in the analysis of ROH containing the main product, H_2O, since the quantitative analysis of H_2O is known to be very difficult. In this experiment, good reproducibility and accuracy have been attained.[9] Furthermore, H_2O was not detected in the dehydrated cyclohexane either before or after irradiation. Oxygen-containing products other than H_2O were analyzed gas-chromatographically on a polyethyleneglycol-600 column at 100°C.

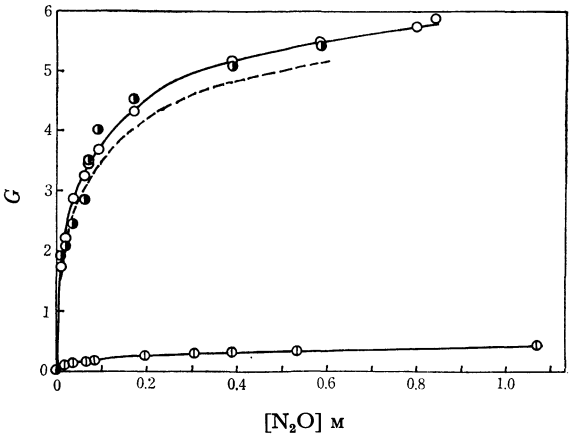

Fig. 1 Yields of N_2 (○), ROH (◑), $C_6H_{11}OH$ (⏀) and H_2O (---) from the cyclohexane-N_2O system.
The yield of H_2O is estimated by the difference between the yield of ROH and that of $C_6H_{11}OH$.

The yields of H_2 and N_2 at various N_2O concentrations approximately agree with those reported in earlier papars.[1] The yields of total ROH, $C_6H_{11}OH$ and H_2O obtained by the above method are shown in Figure 1. The yield of $C_6H_{11}OH$ approximately agrees with that previously reported.[3] The yield of total ROH surprisingly agrees with the yield of N_2 at all concentrations of N_2O. Figure 1 also shows that ROH consists of H_2O plus a small quantity of $C_6H_{11}OH$. No other oxygen-containing products, such as O_2, NO, aldehydes, ketones and ethers, were detected.

The above facts show that the decomposition of N_2O leads finally to the formation of N_2 and ROH in the ratio of one to one; this finding seems to be helpful in understanding the decomposition mechanism of N_2O in hydrocarbon solutions. Further study is now in progress.

The Polarography of the Tricyano Cobalt(III) Complexes

Nobufumi MAKI and Kuwako OHKAWA*

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received May 10, 1971)

Previously, several dicyano complexes of the $[Co(CN)_2N_4]$ type have been found to undergo the step-by-step reduction of Co(III)→Co(II)→Co(I)→Co(0) in DMSO (dimethyl sulfoxide) at the dropping mercury electrode (DME), where N_4 represents four nitrogen donors, which may come from two ligands, en, dip, and phen, or from four ammonia ligands.[1] However, it is not yet clear how the tricyano cobalt(III) complexes behave in DMSO. The present communication is concerned with the behavior of the *fac*- and *mer*-tricyano-diethylenetriaminecobalt(III) complexes[2] in DMSO.

These complexes were prepared by treating the $[Co(S_2O_3)_3dien]^{3-}$ ion with KCN. That is, an aqueous solution (20 m*l*) containing 8 g of KCN was stirred, drop by drop, into a mixture of $[CoCl_3dien]$ (10g) and $Na_2S_2O_3\cdot 5H_2O$ (29.6 g) dissolved in water (70 m*l*). The reaction below 5°C yielded the *mer*-complex, while that at 70—80°C produced the corresponding *fac*-complex. The former was purified by concentrating the solution of the complex *in vacuo* at room temperatures, and the latter, by crystallizing it from hot water (80°C). The purity was ascertained by elementary analyses and by studying the absorption spectra.

One would expect that the tricyano cobalt(I) complex would be present upon reduction in DMSO. Indeed, we did find that the *fac*- and *mer*-$[Co^{III}(CN)_2dien]$ complexes give rise to two well-defined waves at DME in DMSO (100%) containing 0.1 M tetraethylammonium perchlorate; the steps, each corresponding to a gain of one electron, represent the reduction of Co(III)→Co(II) and that of Co(II)→Co(I), while no further reduction to the metal takes place over the potential range between 0 and −2.7 V (*vs.* SCE). A linear-dependence of the current upon the concentration of the complex was confirmed over the range between $5\cdot10^{-4}$ and 10^{-2} M for the *fac*-isomer, and over the range between $5\cdot10^{-4}$ and $3.5\cdot10^{-3}$ M for the *mer*-isomer, since the solubility of the latter in DMSO is much smaller than the former. The current of each step was proportional to the square root of the mercury pressure on DME; the values of $i_l/\sqrt{h_{corr.}}$ were constant, irrespective of the mercury pressure, suggesting a diffusion-controlled feature.

Figure 1 illustrates the current-potential curves of the tricyano and dicyano complexes measured under the same experimental conditions. Thus, the wave-height is roughly proportional to the number of electrons participating in the electrode processes, the half-wave

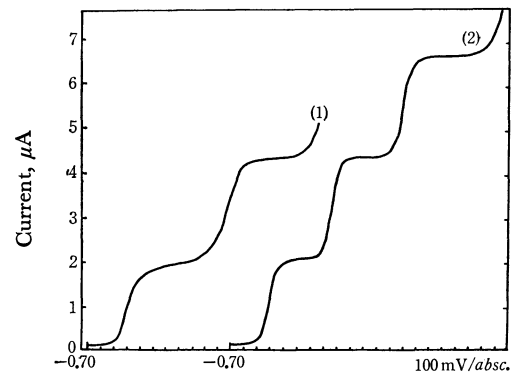

Fig. 1. Current-potential curves obtained at 10^{-3} M in DMSO containing 0.5M $[(C_2H_5)_4N]ClO_4$(25°C): (1) *mer*-$[Co(CN)_3dien]$; (2) *trans*-$[Co(CN)_2\,en_2]NO_3$.

TABLE 1. HALF-WAVE POTENTIALS OF MIXED CYANO COBALT(III) COMPLEXES IN DMSO CONTAINING 0.1M $[(C_2H_5)_4N]ClO_4$ (25°C)

Compound	1st Wave $Co^{III}\rightarrow Co^{II}$	2nd Wave $Co^{II}\rightarrow Co^{I}$	3rd Wave $Co^{I}\rightarrow Co^{0}$
fac-$[Co(CN)_3dien]\cdot H_2O$	−1.37	−1.83	no reduction
mer-$[Co(CN)_3dien]\cdot 3H_2O$	−1.09	−1.74	no reduction
cis-$[Co(CN)_2en_2]NO_3$	−0.95	−1.48	−1.99
trans-$[Co(CN)_2en_2]NO_3$	−0.97	−1.52	−1.99
cis-$Na[Co(CN)_4en]\cdot 7/2H_2O$	−1.59	−1.78	no reduction

V *vs.* SCE

potentials of which are summarized in Table 1. Here, it is of interest to note that a great difference was found to exist in the half-wave potentials of both waves between the *fac*- and *mer*-isomers. The values for the first and the second steps of the *fac*-isomer lie at potentials more negative than those for the *mer*-isomer by 280 and 90 mV respectively, indicating that the *fac*-cobalt(III) and cobalt(II) species are more stable towards the electrochemical reduction than are the *mer* ones. Such a large difference in reduction potentials has never yet been reported for steric isomers. Inversely, this result can be invoked to emphasize the larger stability of the resulting tricyano cobalt(I) complex with a mer form. The three cyanides located on coplanar coordination sites (mer form) may contribute much more to the stability of the univalent cobalt than those on a non-planar configuration do, as can be inferred from a comparison of *cis*- and *trans*-complexes with cyanides.[3]

The net processes of the electrode reaction can be fully interpreted in terms of the "*inert-inert*"-type reduction without any structural changes as follows:

$$[Co^{III}(CN)_3dien] \xrightarrow{e} [Co^{II}(CN)_3dien]^- \xrightarrow{e} [Co^{I}(CN)_3dien]^{2-}.$$

Prominent Catalysis of Sodium 2- or 4-Pyridinolate in the Aminolysis of Esters[1]

Nobuhiro NAKAMIZO

Tokyo Research Laboratory, Kyowa Hakko Kogyo Co., Ltd., Asahi-machi, Machida-shi, Tokyo

(Received May 18, 1971)

The bifunctional catalysis of 2-(1H)-pyridone (2-pyridinol) in the aminolysis of esters is a well-established phenomenon.[2-4] However, no report has been published concerning the catalytic activity of salts of pyridinols. During the course of the investigation of the catalysis in peptide synthesis,[4,5] the present author found that anhydrous sodium salts of the 2- or 4-pyridinol have a pronounced catalytic activity in the aminolysis of active esters. A preliminary kinetic study showed that the catalytic rate constant of the sodium 2-pyridinolate (I) in the reaction of *p*-nitrophenyl benzyloxycarbonyl-L-phenylalaninate (Z-L-Phe-ONp) with *t*-butyl glycinate (H-Gly-OBu^t) in anhydrous dioxane is about 20,000 (l^2/mol^2·min), whereas that of 2-pyridinol is 41 (l^2/mol^2·min).[4] Table 1 shows the results of some typical reactions.

I exhibited the catalytic activity not only for the aminolysis of "active" esters, but also for that of ordinary esters. When benzylamine (2 mmol) and methyl acetate (10 mmol) were heated for 5 hr at 78°C in dimethylacetamide (3 m*l*) in the presence of I (1 mmol), *N*-benzylacetamide (mp 60.5—62°C) was obtained in a 62% yield. In the absence of I, though, *N*-benzylacetamide could not be isolated. Moreover, when ethyl cyanoacetate (5 mmol) and thiourea (5 mmol) were refluxed for 5 hr in anhydrous methanol (3 m*l*) in the presence of I (10 mmol), 4-amino-6-hydroxy-2-mercaptopyrimidine was obtained in an 82% yield. No pyrimidine was produced in the absence of I. When triethylamine, which is similar to I in basicity, was used in place of I, only a trace amount of the pyrimidine was detected in the reaction mixture.[6] This fact suggests that the catalytic activity of I does not depend only on the basicity of the catalyst. During the course of the reaction of Z-L-Phe-ONp with *p*-nitroaniline in the presence of I, the transient formation of a compound which seems to be an active intermediate was observed on the thin-layer chromatogram.

From these facts, it may be considered that the present reactions proceed *via* a nucleophilic catalysis in which *O*-acyl pyridinol (II) or *N*-acyl pyridone (III) is formed as an active intermediate; that is, this catalysis is due to the high nucleophilicity of the pyridinolate anions and the high acylating activity of II[7] or III. Of course, the possibility that general-base catalysis is also a factor can not be disregarded. Whether the intermediate is II or III[8] is not clear at the present time.

Studies of the racemization in the presence of the catalysts are now in progress.

Adsorption of Benzoic Acid on Gold in Perchlorate Solutions

Koichi KATOH* and G. M. SCHMID

Department of Chemistry, University of Florida, Gainesville, Fla. 32601 U.S.A.

(Received September 9, 1970)

The adsorption of benzoic acid from solutions of 10^{-2} to 10^{-5} M on gold electrode surface in perchlorate solutions of pH 1—4 was studied from differential capacity data obtained by a single pulse method. Strong adsorption is observed in the more acidic solutions. This points to predominant adsorption of benzoic acid molecule, rather than benzoate anions, possibly due to the π-electron interaction. At pH 1, benzoic acid replaces four water molecules. This interprets the flat adsorption of benzoic acid molecule on the gold electrode and the π-electron interaction with free electron of the metal surface. The standard free energy of adsorption $\Delta\bar{G}^{\circ}$ is -10.4 kcal/mol.

The adsorption of organic substances at metal-solution interface and the influence of surface coverage on kinetics of electrochemical reactions are important aspects of the study of heterogeneous processes.[1] Classically, on an electrode that is liquid and ideally polarizable, such as mercury, the surface excess of an organic substance can be measured as a function of potential and concentration with interfacial tension data using Gibbs' adsorption equation.[2] On solid electrodes, however, the interfacial tension is not accessible with the required precision and adsorption measurements have to be made by other means. Radioactive tracer techniques,[3] determination of concentration changes in solution,[4] and differential capacity measurements are being used for this purpose.[5]

In the adsorption of organic substances, the π-electron interaction between the adsorbing molecule and the metal substrate plays a dominant role.[7] However, the electrostatic attraction force between organic ions and an oppositely charged metal surface should also be important, especially for large molecules, where the solvation energy may be small. To investigate the relative importance of the π-electron interaction and electrostatic attraction, the adsorption of benzoic acid from aqueous solution was studied as a function of both pH and potential. Concentration ratio of benzoic acid to benzoate anions is controlled by pH with the dissociation constant of benzoic acid in aqueous solution. This allows the π-electron interaction with the substrate to remain relatively constant though the concentration of benzoate ions is changed by several orders of magnitude. Differential capacity measurements were made to evaluate the adsorption coverage. Gold was chosen as a substrate. There seems to be no hydrogen adsorption region[7] and gold approaches closer to the ideal polarizable electrode than, *e.g.* in the case of platinum.

Little is known about the electrochemical behavior of benzoic acid, which can be reduced on metals with high hydrogen overvoltage, *e.g.* lead, to benzyl alcohol.[8-11] Apparently, it can not be oxidized electrochemically in aqueous solution.[12] Both the acid and the free anions are used as corrosion inhibitors,[13] *e.g.* for steel, and are electrochemically stable under corrosion conditions.

Experimental

The gold electrodes were made from polycrystalline fine gold metal (Engelhard Industries, Newark, N.J. USA) and inserted in Teflon rod (cf. Fig. 3). They were polished before each run with 600 mesh polishing powder, washed in hot cleaning solution and thoroughly rinsed with triply distilled water. The exposed apparent surface area of the gold electrode was 0.071 cm^2.

An all Pyrex glass cell contained, in addition to the gold working electrode, a cylindrical bright platinum wire gauze counter electrode, a platinum flag polarizing electrode and a saturated calomel electrode (SCE). The polarizing electrode and the SCE were in side compartments separated from the main cell through two glass frits (platinum flag side) and a closed stopcock (SCE side).

Solutions of pH 1, 3, and 4 were made up from triply recrystallized sodium perchlorate, 70% reagent grade perchloric acid, and water distilled once from alkaline permanganate then twice in a quartz still. Reagent grade benzoic acid was used to prepare the solutions of 10^{-2} to 10^{-5} M. All solutions were deoxygenated with helium before and during the run.

The working electrode was polarized by a potentiostat according to Harrar.[14] Currents were measured as a voltage drop across a 1 or 10 kΩ precision resistor and potentials of the working electrode were measured against SCE. A Keithley 610B electrometer was used for the voltage measurements.

Differential capacity measurements were made with a rapid single pulse technique.[15] The differential capacities were measured from the slope of the potential-time curve of a fast rise rectangular current pulse on the working electrode at the start (t=0). The potential-time curves were displayed on the screen of a Tektronix 549 storage oscilloscope. Sometimes, the curves were bent near the start point, and the slope was measured at 25 μsec and 50 μsec. The curves were measured by the storage oscilloscope with a differential preamplifier. Voltage and time scales were 10 mV/cm and 5 μsec/cm. The pulses were taken from the gate of the oscilloscope and passed between the working and the counter electrode through a 33 kΩ resistance. This gave a current of 0.76 mA. Potential range was between 0.0 V and 1.40 V *vs.* SCE.

The reproducibility of the differential capacity measurements was usually $\pm$15%. This was attributed to differences of the surface condition of electrodes caused by unavoidable differences in pretreatment. In this experiment, the data were normalized to 17.9 μF/cm^2 at 1.40 V, the value was found for 10^{-2} M benzoic acid solution of pH 1. The reproducibility was then $\pm$5%.

Results and Discussion

Study of adsorption coverage on solid electrodes using differential capacity measurements is hampered by the fact that the measurements are sensitive to impurities in solution, faradaic processes occurring at the interface, the crystal structure exposed, and the roughness of the electrode surface. The capacity-potential curves measured on gold electrode in acidic solutions by different workers are similar, although some difference is evident.[16-20] Recent work on single crystal surface of gold electrodes indicates that small discrepancies in the capacities might be due to the nature of the crystal surface exposed.[19-20] It seems that on polycrystalline electrodes the broad maximum at 0—0.2 V and the anodic maximum at 1.2 V are of about equal height (~20 μF/cm^2),[18] whereas on (100) and (110) faces at gold electrode surfaces the anodic maximum is considerably large (~30 μF/cm^2).[17,19,20] On the (100) face electrodes, the broad maximum at 0—0.2 V splits into two peaks of about equal height, the one at the (110) face electrode into one peak and a small shoulder.[17] Small differences in the capacity curves on gold electrode may therefore simply be a matter of the structure of the crystal surface exposed. Thus, differential capacity measurements should be reliable for measuring the adsorption of organic substances on gold electrodes in acidic solutions.

Differential capacity *vs.* potential data obtained in 0.1 M perchloric acid and from 10^{-2} to 10^{-5} M benzoic acid are shown in Fig. 1. A significant depression

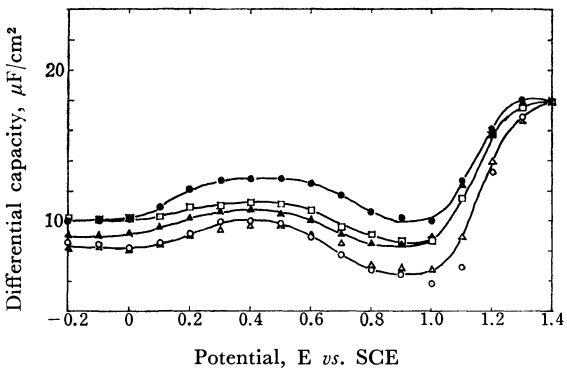

Fig. 1. Differential capacity *vs.* potential, Au in 0.1 M $HClO_4$ and 0, 10^{-5}, 10^{-4}, 10^{-3}, and 10^{-2} M benzoic acid. Capacities normalized at 1.4 V.
●: 0, □: 10^{-5}, ▲: 10^{-4}, △: 10^{-3}, ○: 10^{-2}

in the capacity due to the adsorption of benzoic acid was evident in 10^{-5} M solutions in the range 0—1.0 V. An additional significant depression occurred for 10^{-2} and 10^{-4} M benzoic acid at 0.8—1.2 V.

Coverage-potential curves were calculated from the data shown in Fig. 1 and Frumkin's equation[21] in the differentiated form:

$$C = C_0(1-\theta) + C_1\theta + (q_1-q_0)d\theta/dE \quad (1)$$

where C_0 and q_0 are capacity and charge of the uncovered surface, C_1 and q_1 those of the fully covered surface, and θ is the coverage with an organic substance. As seen in Fig. 1, no characteristic peaks of adsorption-desorption were present in this case. In our high speed capacity measurements these peaks are expected to be much smaller than those in data taken with alternating current at 1 kHz.[22] This may indicate that the adsorption-desorption region lies outside the potential range investigated, or alternatively, that the dependence of adsorption on potential in the range is small.

In general, the surface tension between a metal electrode surface and a solution becomes small on account of the adsorption of an organic substance on the electrode, and the correlation among differential capacity, charge, and surface tension is as follows:

$$C = (\delta q/\delta E)_\mu \qquad q = -(\delta\gamma/\delta E)_\mu$$

where C, q, E, γ, and μ is differential capacity, charge, potential, surface tension, and chemical potential, respectively. We can deduce that the differential capacity becomes small with the adsorption of an organic substance. From Fig. 1, we see that the coverage of adsorption in 10^{-3} and 10^{-2} M benzoic acid solutions showed almost fully coverage in this potential range, but not for 10^{-4} and 10^{-5} M solutions. In any case, if $d\theta/dE \approx 0$, we have

$$C = C_0(1-\theta) + C_1\theta \quad (2)$$

The coverage-potential curves are shown in Fig. 2 for 10^{-4} and 10^{-5} M benzoic acid. Differential capacities of 10^{-3} M benzoic acid solution were taken as C_1 because both data in 10^{-3} and 10^{-2} M solutions were almost the same.

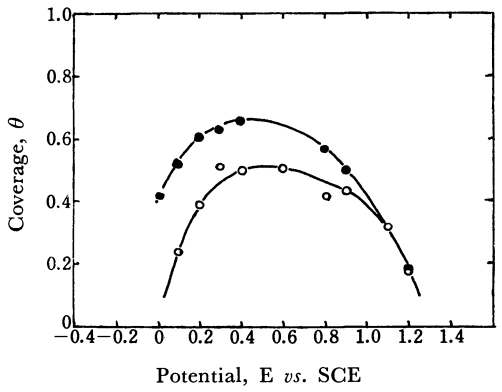

Fig. 2. Covereage *vs.* potential, Au in 0.1 M $HClO_4$ and 10^{-4} M, 10^{-5} M benzoic acid.
—●—: 10^{-4} M, —○—: 10^{-5} M

The coverage in higher potential range in Fig. 2 was unknown and could not be determined by going to higher potentials because of imminent oxygen evolution and electrode surface oxidation. It is known that adsorption of "oxygen" in acidic solution starts at approximately 1.0 V *vs.* SCE[23] and this is substantiated by the capacity curves shown in Fig. 1. Taking into account the fact that the electrode is covered with adsorbed oxygen, it is reasonable to assume that the amount adsorbed of benzoic acid becomes zero, and that the calculated θ values represent the actual fractional coverage with benzoic acid.

The change in the adsorption coverage with pH at constant concentration of benzoic acid can be assessed from the relative change of differential capacity. Values of this relative change are shown in Table 1 for 10^{-3} M benzoic acid and pH 1 and 4. It is seen

Table 1. Relative change in capacity, $(C_0-C)/C_0$, *vs.* potential and pH for 10^{-3} M benzoic acid

E *vs.* SCE	pH=1	pH=4
+0.1	0.229	0.072
+0.5	0.250	0.015
+0.6	0.280	0.075
+0.7	0.274	0.139

that an increase in pH remarkably reduces the amount of benzoic acid adsorbed. This leads to the conclusion that the adsorbing species is the benzoic acid molecule, rather than the benzoate anions and that in this case electrostatic attractive force between the anions and the positively charged electrode is not important.

Adsorption of a solute molecule from solution onto an electrode surface must be considered as a competitive adsorption of the solute molecule and the solvent one. The competitive adsorption of two species from a liquid phase has been treated by numerous authors by means of the Langmuir isotherm.[24-26] Recently, a Temkin isotherm was applied to the adsorption of neutral molecules on electrodes.[27] The competitive adsorption of species of different sizes on electrode was treated by Dahms and Green.[28]

For competitive adsorption, equilibrium is assumed to be established between solvent, adsorbed solvent, solute species, and adsorbed solute species as Eq. (3). Thus, in aqueous solution:

$$n\,\mathrm{Water_{ads}} + \mathrm{Org_{sol}} \rightleftarrows n\,\mathrm{Water_{sol}} + \mathrm{Org_{ads}} \qquad (3)$$

where n is the number of molecules of water which occupies the same surface area as one molecule of the organic compound, $n=\Gamma_{\mathrm{max.w}}/\Gamma_{\mathrm{max.org}}$, with Γ_{max} (in mol/cm^2) the amount forming a monolayer of water or of organic species, respectively.

Under ideal conditions, one can write for equilibrium according to Eq. (3):

$$\bar{\mu}_{\mathrm{org.sol}} + n\,\bar{\mu}_{\mathrm{w.ads}} = \bar{\mu}_{\mathrm{org.ads}} + n\,\bar{\mu}_{\mathrm{w.sol}} \qquad (4)$$

where $\bar{\mu}_i$ is the electrochemical potential of species i. This gives the isotherm

$$\frac{X_{\mathrm{w.sol}}}{(1-\theta)^n \times X_{\mathrm{org.sol}}} = \exp\left(-\Delta\bar{G}^\circ/\boldsymbol{RT}\right) \qquad (5)$$

Here X_i represents the mole fraction of species i and

$$\Delta\bar{G}^\circ = \bar{\mu}^\circ_{\mathrm{org.ads}} - \bar{\mu}^\circ_{\mathrm{org.sol}} - n(\bar{\mu}^\circ_{\mathrm{w.ads}} - \bar{\mu}^\circ_{\mathrm{w.sol}}) \qquad (6)$$

In dilute solutions of the organic species the mole fraction $X_{\mathrm{w.sol}} \approx 1$ and the isotherm can be written as follows.

$$\frac{\theta}{(1-\theta)^n} = X_{\mathrm{org.sol}} \times \exp(-\Delta\bar{G}^\circ/\boldsymbol{RT}) = K_{\mathrm{ads}} \times X_{\mathrm{org.sol}} \qquad (7)$$

The equation differs from the Langmuir equation only by the power factor n.

By means of this equation, n was calculated to be 4 for benzoic acid in 10^{-1} M perchloric acid, and K_{ads} 4.5×10^7 at potentials 0.1 to 0.9 V. Replacement of 4 water molecules with one benzoic acid molecule is very reasonable (Stuart-Briegleb Models) and K_{ads} yields a $\Delta\bar{G}^\circ$ of -10.4 kcal/mol which is consistent with the weak adsorption of benzoic acid on gold electrode.

Anisotropy of the Indirect Nuclear Spin-Spin Coupling Constants. III. Problems in the Structure Determination of the Molecule Dissolved in a Nematic Solvent

Hiroshi NAKATSUJI, Isao MORISHIMA, Hiroshi KATO,* and Teijiro YONEZAWA
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto
(Received September 26, 1970)

Anisotropy of the indirect nuclear spin-spin coupling constant was studied theoretically. All the contributions to the coupling tensors were calculated for various molecules by using the INDO molecular orbitals. As shown in part I of this series, the calculated ^{13}C–H coupling anisotropy of $^{13}CH_3F$ is too small to be compared with the value obtained experimentally by Krugh and Bernheim. Thus we examined the substituent effect on the anisotropy in the $^{13}CH_3X$ series. It is concluded that the experimentally estimated value of the ^{13}C–H coupling anisotropy in $^{13}CH_3F$ as large as 1890 Hz is erroneous and that it contains some other effects which are more important than electronic effect. We believe that the change in molecular geometry from gas state to the solute state in a nematic solvent is the most probable origin for the differences between theories and experiments. For the directly bonded C–X couplings (X is C, N or F), their anisotropies are in the same order of magnitude as their isotropic couplings. For the non-bonded C–X nuclei, they seem negligible in magnitude. For the F–F couplings, their anisotropies are exceptionally large and the orbital term is a very important source of anisotropy. Furthermore, even for the isotropic F–F couplings, the orbital and spin dipolar terms are very important and sometimes make decisive contributions exceeding the Fermi contact term.

Since the experiment of Saupe and Englert,[1,2] extensive investigations of the molecules dissolved in liquid-crystal solvents have been carried out by means of nuclear magnetic resonance (NMR) technique.[3-5] Chemically fundamental data such as molecular motion and molecular geometry in liquid-crystal phase have accumulated, in addition to a more detailed knowledge of NMR parameters than those available by the usual NMR measurements in isotropic liquid phase. However, some difficulties exist in the determination of molecular geometry. In order to calculate molecular geometry (strictly speaking, ratios of the geometrical parameters) from spectral splittings, one needs the value of the anisotropy of the indirect nuclear spin-spin coupling constant (J).[3,6] The most frequent assumption is a disregard of the anisotropy of the indirect coupling constant. However, the molecular geometries obtained under this assumption sometimes differ slightly from those obtained by other measurements in gas phase (*e.g.* electron diffraction method, microwave method *etc*).[6,7] On the other hand, if one assumes that the geometry obtained by other measurements in gas phase can be used without any correction, one may calculate the anisotropy of the indirect coupling constant from spectral splittings. This treatment, however, has sometimes given extremely large anisotropy.[8]

For a solution of this situation, the following points must be clarified. (1) Can the anisotropy of the indirect coupling constant be assumed to be nearly zero ? (2) If so, why does the geometry obtained by means of NMR in liquid crystal solvent differ from that given by other measurements in gas phase ?

The main purpose of this series of investigation is to solve these problems theoretically. Possible origins of the coupling anisotropy were studied by both sum-over-state[9] and finite perturbation[10] methods on the basis of molecular orbital (MO) theory. The Fermi-spin dipolar cross term is important. For doubly and triply bonded nuclei, the orbital term is also important. However, for the ^{13}C–H coupling in CH_3F, the calculated anisotropy was too small to be compared with 1890 Hz obtained by assuming microwave geometry.[8a] Similar results were also obtained by Barfield[11] by valence-bond method, and by Buckingham and Love[12] with a similar MO treatment.

Theory of coupling anisotropy is described in the next section. It is applied to various molecules by using the INDO MO's of Pople *et al.*[13] The substituent effect in the $^{13}CH_3X$ series[14] will be discussed for the directly bonded ^{13}C–H coupling anisotropy in paticular. Another important aspect is the coupling anisotropy between F–F nuclei. For Problem (2), the possible factors are twofold; the vibrational effect and the effect due to the structural change from gas state to the solute state in a nematic solvent. Their relative importance is examined in the last section.

Theoretical Background

The essential part of the theory of the anisotropy of the indirect nuclear spin-spin coupling constant were given by us[9,10] and by Buckingham and Love.[12]

Anisotropy of the indirect coupling constant originates from three mechanisms: Fermi-spin dipolar cross (FSD) term, spin dipolar (SD) term and orbital (OB) term.[9,15] The Fermi-contact (FC) term is isotropic. These contributions can be developed in terms of molecular orbital theory, along lines similar to the treatment of Pople and Santry.[16] We introduce a reduced coupling constant $\boldsymbol{K}_{AB}$ defined by

$$\boldsymbol{K}_{AB} = (2\pi/\hbar\gamma_A\gamma_B)\boldsymbol{J}_{AB} \tag{1}$$

First we set the following three approximations (*Level A* approximation). (1) Use of the sum-over-state perturbation method, taking single Slater determinant built up from SCF MO's as zeroth order wavefunction. An improvement over this treatment may be achieved by using the finite perturbation[17] (or coupled Hartree-Fock[18]) method.[10] (2) LCAO-MO approximation. Actually the INDO SCF MO's expanded by all the valence AO's will be used. (3) One-center integral approximation. This approximation may be crude especially for the coupling tensor between directly bonded nuclei. However, since all the Hamiltonians considered (Eqs. (1)—(4)[9]) lay stress on the electronic structure in the vicinity of nuclei, and we use the INDO MO's based on the zero-differential overlap approximation (theoretically based on the orthogonalized AO's[19]), this approximation may be approved. It should be noted that under this approximation, the anisotropy of the H–H coupling constant becomes zero, which may be justified by the study of Barfield.[11]

As an example, the elements of coupling tensor obtained under Level A approximation are given for the FSD term as follows.

$$(\boldsymbol{K}_{AB}^{(2,3)})_{\alpha\alpha} = -(64\pi\beta^2/15)s_A(0)\langle r^{-3}\rangle_B \sum_i^{occ}\sum_j^{vac}({}^3\Delta E_{i\to j})^{-1} C_{is_A}C_{js_A}(2C_{ip_\alpha B}C_{jp_\alpha B} - \sum_{\delta(\neq\alpha)}' C_{ip_\delta B}C_{jp_\delta B}) + [\text{interchange term of A and B}] \tag{2-a}$$

$$(\boldsymbol{K}_{AB}^{(2,3)})_{\substack{\alpha\neq\beta}} = -(32\pi\beta^2/5)s_A(0)\langle r^{-3}\rangle_B \sum_i^{occ}\sum_j^{vac}({}^3\Delta E_{i\to j})^{-1} C_{is_A}C_{js_A}(C_{ip_\alpha B}C_{jp_\beta B} + C_{ip_\beta B}C_{jp_\alpha B}) + [\text{interchange term of A and B}] \tag{2-b}$$

The other contributions are summarized in Appendix. In Eq. (2), $s_A(0) = (s_A|\delta(\boldsymbol{r})|s_A)$, s_A and $p_{\alpha A}$ are the s-type AO and $2p_\alpha$AO (α is x, y or z) centered on atom A. $\sum_{\delta(\neq\alpha)}'$ means the summation over the directions x, y, and z except α. The other notations are the same as those used by Pople and Santry.[16]

Although we use Level A approximation in actual calculations, it is sometimes convenient to introduce further approximations: (4) Average excitation energy (ΔE) approximation.[20] (5) zero-differential overlap (ZDO) approximation. Hereafter we call this level of approximation Level B approximation, where the elements of coupling tensor are given for the FSD term by

$$(\boldsymbol{K}_{AB}^{(2,3)})_{\alpha\alpha} = (16\pi\beta^2/15)s_A(0)\langle r^{-3}\rangle_B({}^3\Delta E)^{-1} \times (2P_{s_A p_\alpha B}^2 - \sum_{\delta(\neq\alpha)}' P_{s_A p_\delta B}^2) + [\text{interchange term of A and B}] \tag{3-a}$$

$$(\boldsymbol{K}_{AB}^{(2,3)})_{\substack{\alpha\neq\beta}} = (16\pi\beta^2/15)s_A(0)\langle r^{-3}\rangle_B({}^3\Delta E)^{-1} \times (P_{s_A p_\alpha B}P_{s_A p_\beta B}) + [\text{interchange term of A and B}] \tag{3-b}$$

The other contributions are summarized in Appendix. In Eq. (3), $P_{s_A p_\alpha B}$ denotes the bond order between s_A and $2p_{\alpha B}$ AO's.

$$P_{s_A p_\alpha B} = \sum_i 2C_{is_A}C_{ip_\alpha B} \tag{4}$$

When localized AO's are introduced, the chemical picture of the coupling mechanisms becomes clear. Namely, each contribution to the $\sigma\sigma$-element of the coupling tensor, $(J_{AB})_{\sigma\sigma}$ becomes as follows.

$$[\text{FC term}] \propto P_{ss'}^2$$

$$[\text{FSD term}] \propto P_{s\sigma'}^2 + [\text{interchange term}]$$

$$[\text{SD term}] \propto 8P_{\sigma\sigma'}^2 + 2(P_{\pi\pi'}^2 + P_{\pi\bar{\pi}'}^2) + 9P_{\sigma\sigma'}(P_{\pi\pi'} + P_{\bar{\pi}\bar{\pi}'})$$

$$[\text{OB term}] \propto P_{\pi\pi'}P_{\bar{\pi}\bar{\pi}'}$$

These equations may be considered as showing the "paths" and "width" along which two nuclear moments interact. However, it should be noted that although this chemical picture is very intuitive, it sometimes leads to erroneous results, especially for the coupling constants between nuclei in polar bonds.[16] Thus, in the following applications, we use Level A approximation. The values of the one-center

Results and Discussion

General Features. In Tables 1—4, the coupling constants calculated in Level A approximation are summarized for various nuclear pairs. First, the relative importance of the coupling mechanisms is examined. As is well-known, the most important mechanism for the *isotropic* coupling constants is the FC term, the SD and OB mechanisms giving only small contributions. However, exceptions are found for the F–F couplings (Tables 3 and 4), where the OB and SD terms are very important and sometimes give predominant contributions exceeding the FC term. For the *anisotropies*, the FSD term is important (Tables 1–4). The OB term is important for the multiply bonded nuclear pairs (Tables 1 and 4) and for the F–F couplings (Tables 3 and 4). The SD term is less important.

Secondly, the anisotropies between non-bonded nuclear pairs are calculated to be very small as compared with those between directly bonded ones (Tables 1 and 2), except for the F–F coupling anisotropies (Tables 3 and 4).

Thirdly, for isotropic couplings, the calculated values are smaller than experimental ones. The disagreement may be due to the too large excitation energies calculated by the INDO method and/or the neglect of the self-consistency requirement[22] in the present perturbation treatment. An improvement can be achieved in the finite perturbation method.[10] However, the defect is not very serious for semi-quantitative discussions.

X–H Couplings. As seen from Eqs. (6), (A-1)—(A-4), the sources of the isotropic and anisotropic couplings between X and H nuclei are only the FC and FSD terms, respectively.

The calculated isotropic C–H coupling constants of methane, ethylene, and acetylene are 64.6, 80.1, and 141.9 Hz and the experimental values are 125.0, 156.2, and 249.0 Hz, respectively. Their calculated anisotropies, defined by $J_{xx}-1/2(J_{yy}+J_{zz})$, are 33.0, 24.5, and 18.0 Hz, respectively, where the x-axis of the coupling tensor is taken to be parallel to the C–H bonds. This sequence of change reflects that expected from changes in hybridization for the FC and FSD terms.

The calculated coupling constants between X–H nuclei in CH_3Y (Y=H, CH_3, CN, OH, NC, F, and I) are summarized in Table 1. The ^{13}C–H coupling anisotropy of CH_3F is also too small to be compared with the experimentally estimated value.[8a] Similar results were also obtained by Barfield,[11] and Buckingham and Love.[12] The difference between theories

and experiments seem to be far beyond the accuracy of the theories.

Recently, the substituent effect on the directly bonded ^{13}C–H coupling anisotropies $(J_{CH})_{aniso}$ in methyl derivatives are obtained by analyzing the NMR spectra in the same way as for CH_3F.[14] They are also given in Table 1. First, we examine the isotropic ^{13}C–H couplings $(J_{CH})_{iso}$. From the experimental values, we can estimate the order of magnitude of the change in the electron distribution near the C–H bond induced by substitution. It is 2—6 %. The change of the same order is also reproduced by the INDO MO's. On the other hand, the substituent effect on the coupling anisotropy $(J_{CH})_{aniso}$ estimated from the experimental analyses is unusually large. In fact, in order to explain this substituent effect, a very large change must be assumed in the electronic structure in the vicinity of C–H bond. However, this contradicts the substituent effect seen for $(J_{CH})_{iso}$, while the calculated effect on $(J_{CH})_{aniso}$ is the same order as that on $(J_{CH})_{iso}$.

Thus, it is concluded that the experimentally estimated values of $(J_{CH})_{aniso}$ given in Table 1 still contain some other effects which are more important than the electronic effect. Then, a value of $(J_{CH})_{aniso}$ of CH_3F as large as 1890 Hz[8a] is erronious. We see in Table 1 that there is an approximate parallelism between the experimentally estimated values of $(J_{CH})_{aniso}$ and the orientation parameters S_{zz} in nematic solvent.

C–X Couplings. The calculated values of the C–X coupling constants of ethane, ethylene, acetylene, and methyl derivatives are summarized in Table 2, from which we see: 1) compared with C–H couplings, the magnitude of the C–X coupling anisotropies are comparable to those of the isotropic coupling constants. 2) the calculated value of ^{13}C–F coupling anisotropy is still small compared with the experimental value,[8a] although the value 207 Hz is obtained by finite perturbation method,[10] and 3) for the anisotropies of the ^{13}C-^{15}N couplings in CH_3CN and CH_3NC, the OB term contributes to a great extent, due to the triple bond character of these bonds. The sign of the isotropic $^{15}C\equiv^{13}N$ coupling constant of CH_3NC is expected to be positive and is the reverse of that of the same nuclear pair in CH_3CN.

Coupling Tensors of the Molecules Including Fluorine Nuclei. So far, we have seen that the coupling anisotropies between non-bonded nuclei are very small in magnitude compared with those between directly bonded nuclei. However, this is not always the case for the F–F couplings. Experimentally, Snyder and Anderson[8d] pointed out that the anisotropy of the F–F coupling in hexafluorobenzene might be considerably large. Similar suggestions were also given for symm-tetrafluorobenzene,[8b] 1,3,5-trifluorobenzene,[8b] 1,1-difluoroethylene,[8f] and tetrafluoroethylene.[8g]

The calculated coupling tensors of the molecules including fluorine nuclei are summarized in Tables 3 and 4. The following points are remarkable: 1) For the *isotropic* F–F couplings,[23] the OB and SD contributions are very important.[24] In the geminal F–F

c) $J_{zz}=J_{yy}$.

couplings (CH_2F_2 and 1,1-$C_2H_2F_2$), their signs cannot be explained unless *both* of the SD and OB contributions are included. In *trans*-$C_2H_2F_2$ (Table 3) and C_2F_2 (Table 4), the OB term is predominant and negative in sign. In *cis*-$C_2H_2F_2$, the contributions due to the SD and OB terms are very small and almost cancel each other, giving the positive coupling constant due chiefly to the FC term. Although both signs are reported (Ref. g in Table 3), the present calculation favours the positive sign. 2) For the F–F coupling anisotropies, the OB term is most important, although the FSD term is also important. The SD term seems less important. 3) For the C–F couplings, the anisotropy becomes large (in absolute magnitude) by fluorine substitution from CH_3F to CH_2F_2 chiefly due to an increase in the OB contribution. The change in the isotropic C–F coupling constants from CH_3F to CH_2F_2 cannot be explained without OB contributions.

Meaning of the Difference in Theoretical and Experimental Values

It has been made clear that the experimentally estimated ^{13}C–H coupling anisotropies of the methyl derivatives still contain some other effects more important than electronic one.

The experimental value of the coupling anisotropy is calculated from the NMR spectral splitting $(\Delta\nu)_{CH}$ obtained in a nematic solvent by means of the following formula for the C_{3v}-symmetry molecules.[3]

$$(J_{CH})_{aniso} = \{(\Delta\nu)_{CH} - (J_{CH})_{iso} - D_{CH}\}/(2/3)S_{zz}, \quad (5)$$

where S_{zz} is the orientation parameters of the molecular symmetry axis (z-axis) with respect to applied magnetic field and D_{CH} the anisotropy due to direct coupling. In Table 1, S_{zz} is obtained by assuming that the anisotropies of the indirect H–H couplings are zero.[6,7] This is justified by Barfield.[11] Krugh and Bernheim[8a] examined the effects on the isotropic coupling constant $(J_{CH})_{iso}$ due to the solvent change and the solvent phase change from nematic to isotropic phases, and concluded that they would not be major factors influencing the results. Thus, the most important factor should be the effect on D_{CH}, by which the value of the ^{13}C–H coupling anisotropy sensitively changes through Eq. (5).[8a,14] In order to obtain the values of $(J_{CH})_{aniso}$ given in Table 1, D_{CH} values were calculated from the r_0-structure determined by means of microwave technique in gas phase. However, since the NMR measurements of these molecules were carried out in their solute states in nematic solvents, the D_{CH} values in Eq. (5) should correspond to this state and method of measurement. If we designate this correction by Δ_M (M indicates a special molecule), it is given by

$$\Delta_M = [\text{NMR geometry in the solute state in nematic solvent}] - [\text{Microwave geometry in gas phase}] \quad (6)$$

The apparent substituent effect on $(J_{CH})_{aniso}$ given in Table 1 is reconsidered as representing the substituent effect essentially on Δ_M.

There are two possible origins of the effect on Δ_M. (a) Molecular (harmonic and anharmonic) vibrations.[7d,8a] The measured value is approximately $\ll 1/r^3 \gg$ in NMR and approximately $\ll 1/r^2 \gg$ in microwave spectroscopy.[25a] r is the internuclear distance and $\ll \gg$ denotes the statistical average.[26] (b) The change in molecular geometry from gas state to solute state in the nematic solvent.[7a,7c]

First, the effect (a) is examined. If we assume that the orientation parameter S_{zz} is independent of internal molecular vibration,[6] and that the anisotropy of the indirect H–H coupling constant is negligible, we obtain the following equation from Eq. (5).[27]

$$(T_{CH})_{zz} = \frac{(\gamma_C\gamma_H\hbar/2\pi)(\langle r_{HH}^2/r_{CH}^5\rangle - 2\langle 1/r_{CH}^3\rangle) + 2/3(J_{CH})_{aniso}}{(\gamma_H^2\hbar/2\pi)\langle 1/r_{HH}^3\rangle} \times (T_{HH})_{zz} \quad (7)$$

25) a) J. A. Ibers and D. P. Stevenson, *J. Chem. Phys.*, **28**, 929 (1958). b) S. J. Cyvin, "Molecular Vibrations and Mean Square Amplitudes," Elsevier Pub. Co. N. Y. (1968).

26) $\ll \gg$ denotes the statistical average in the solute state in a nematic solvent. However, if the molecular potential function in this state does not differ much from that in gas state, we can, to first approximation, use the vibrational average in gas state $< >$ in spite of $\ll \gg$.

27) The dependence of the "true" value of $(J_{CH})_{aniso}$ on the molecular vibration is negligible.

where $(T_{CH})_{zz}$ and $(T_{HH})_{zz}$ are the observed total anisotropic couplings.

Let us introduce the notation[25a]

$$r_n = \langle r^n \rangle^{1/n}.$$

As a special case, r_{-2} corresponds approximately to the microwave r_0 structure, if we neglect the Coriolis and other terms. Ibers and Stevenson[25a] gave the expansion of r_n as follows.

$$r_{\pm n} = r_e\left(1+\frac{\langle x\rangle}{r_e}-\frac{(1\mp n)}{2r_e^2}\langle x^2\rangle+\cdots\right), \tag{8}$$

where r_e is the equilibrium distance and x the displacement coordinate ($x=r-r_e$). From Eq. (8), we obtain

$$r_{-3} = r_{-2} - \frac{1}{2}\langle x^2\rangle/r_e+\cdots$$

$$\simeq r_0(\text{m.w.}) - \frac{1}{2}\langle x^2\rangle/r_e+\cdots, \tag{9}$$

which shows that if we use the microwave r_0 structure in Eq. (7), the main correction due to molecular vibration comes only from the harmonic one. It should be noted that the value of r_{-3} is always smaller than that of r_{-2}. For polyatomic molecules the displacement coordinate x_i is given by a linear combination of the normal coordinates Q_k:

$$x_i = \sum_k L_{ik}Q_k,$$

By virtue of the separability of normal coordinates in the harmonic oscillator treatment, the mean-square amplitude $\langle x_i^2\rangle$ is given by[25b]

$$\langle x_i^2\rangle = \sum_k L_{ik}^2\langle Q_k^2\rangle \tag{10}$$

where $\langle Q_k\rangle^2$ is given by

$$\langle Q_k^2\rangle = \frac{h}{8\pi^2 c\nu_k}\coth\frac{hc\nu_k}{2\kappa T} \tag{11}$$

$$\rightarrow \frac{h}{8\pi^2 c\nu_k}\ (T\rightarrow 0;\ \text{zero-point vibration}),$$

where ν_k is the wave number given in cm^{-1}, and T the absolute temperature. The values of L_{ik} and ν_k of methyl halides were summarized by Reichman and Overend, and Russel *et al.*[28]

We consider the effects of harmonic C–H stretching and H–C–H bending vibrations. By substituting the correction term of Eq. (9) into Eq. (7), the value of the first term (D_{CH} part) in the numerator becames smaller and that of the denominator larger (both these terms are positive). These corrections make the resulting value of $(J_{CH})_{aniso}$ larger than the uncorrected one.[29] Thus, for CH_3F and CH_3I, the effect of harmonic vibration can not explain the difference between theory and experiment. Moreover, it cannot explain the substituent effect on $(J_{CH})_{aniso}$ shown in Table 1. In fact, since $\nu_{HCH}(\nu_2)$ is more sensitive to substitution than $\nu_{CH}(\nu_1)$, it suffices to consider the correction term to $1/r_{HH}^3$ in the denominator of Eq. (7). From the observed wave numbers, the correction term is larger in CH_3I than in CH_3F. This is contrary to the substituent effect shown in Table 1.

The effect of anharmonicity is not so clear as that of harmonic vibration for lack of experimental constants. However, we could eliminate this effect approximately in the above treatment. Since the apparent anisotropies given in Table 1 are most sensitive to the H–C–H valence angle,[8a,14] this effect and especially the substituent effect, is not large enough to explain the large change. Thus, we believe that the effect (a) cannot interpret the difference between theory and experiment.

Next, the effect (b) is examined. It should be noted that important chemical and/or physical solvent-solute interactions must exist in the solute state in a nematic solvent. The orientation parameter S_{zz} indicates essentially the strength of interaction. We find an approximate parallelism between the apparent anisotropy (essentially proportional to Δ_M above) and S_{zz} (Table 1).[14] Although experiments showing this kind of parallelism are still few[29] and we cannot stress this finding, it gives a support to the effect (b).

There are further supports: Snyder and Meiboom[30] found a distortion of molecular geometry in a nematic solvent for neopentane and tetramethylsilane. A similar result was also found for tetramethyltin.[31] There are X-ray diffraction studies[32a] showing the geometrical change in condensed phase: Harris and Clayton[32b] reported a slightly larger C–F bond length of CF_4 in liquid state than in gas state. There are some experiments showing the geometrical change from gas phase to molecular crystal phase: The I–As–I valence angle in AsI_3 is 100.2°± 0.4° (electron diffraction)[33a] in gas phase and 102.0°± 0.1° (X-ray)[33b] in crystal phase. Similar differences are also found for $AsBr_3$,[34] $SbCl_3$[35] and SbI_3.[36] Thus, we believe that the effect (b) is the most important origin of Δ_M.

For methyl derivatives, the most probable change in molecular geometry from gas state to the solute state in nematic solvents may be a change in the H–C–H

28) The values of $\nu_1(a_1)$ and $\nu_2(a_1)$ are respectively 2995 and 1493 cm^{-1} for CH_3F, and 3048 and 1279 cm^{-1} for CH_3I. (S. Reichman and J. Overend, *J. Chem. Phys.*, **48**, 3095 (1968).) Since the matrix $\{L_{ik}^2\}$ is almost diagonal for the totally symmetric a_1 vibrations, ν_1 and ν_2 represent approximately the C–H stretching and H–C–H angular displacement frequencies, respectively. The values of L_{11}^2 and L_{22}^2 are respectively 1.0167 and 1.9251 for CH_3F. (J. W. Russell, C. D. Needham, and J. Overend, *J. Chem. Phys.*, **45**, 3383 (1966).)

29) Buckingham, *et al.* studied the structure of 3,3,3-trifluoropropylene dissolved in different nematic solvents at various temperatures (Ref. 7d). Their results show a parallelism between S_{zz} and the molecular structures calculated by neglecting the anisotropies of the indirect F–F couplings.

Osaki, Kyoto University for valuable discussion, and Mrs. A. Mizuno and K. Hirao for active collaboration.

Appendix

Hereafter we abbreviate $2p_{\alpha A}$ AO as α_A ($\alpha=x$, y, or z), since only the 2p AO's appear in the following equations.

(i) SD term

(a) Level A approximation

$$(\boldsymbol{K}_{AB}^{(2)})_{\alpha\alpha} = -(4\beta^2/25)\langle r^{-3}\rangle_A\langle r^{-3}\rangle_B \sum_i^{occ}\sum_j^{vac} ({}^3\Delta E_{i\to j})^{-1} \times [4(2C_{i\alpha A}C_{j\alpha A} - \sum'_{\delta(\neq\alpha)} C_{i\delta A}C_{j\delta A})(2C_{i\alpha B}C_{j\alpha B} - \sum'_{\delta(\neq\alpha)} C_{i\delta B}C_{j\delta B}) + 9\sum'_{\delta(\neq\alpha)}(C_{i\alpha A}C_{j\delta A}+C_{i\delta A}C_{j\alpha A}) \times (C_{i\delta B}C_{j\alpha B}+C_{i\alpha B}C_{j\delta B})] \quad (A\cdot1\text{-a})$$

$$(\boldsymbol{K}_{AB}^{(2)})_{\substack{\alpha\\(\alpha\neq\beta)}\beta} = -(12\beta^2/25)\langle r^{-3}\rangle_A\langle r^{-3}\rangle_B \sum_i^{occ}\sum_j^{vac} ({}^3\Delta E_{i\to j})^{-1} \times [(4C_{i\alpha A}C_{j\alpha A} - 2\sum'_{\delta(\neq\alpha)} C_{i\delta A}C_{j\delta A})(C_{i\alpha B}C_{j\beta B}+C_{i\beta B}C_{j\alpha B}) + (C_{i\alpha A}C_{j\beta A}+C_{i\beta A}C_{j\alpha A})(4C_{i\beta B}C_{j\beta B} - 2\sum'_{\delta(\neq\beta)} C_{i\delta B}C_{j\delta B}) + 3(C_{i\alpha A}C_{j\gamma A}+C_{i\gamma A}C_{j\alpha A})(C_{i\beta B}C_{j\gamma B}+C_{i\gamma B}C_{i\beta B})] \quad (A\cdot1\text{-b})$$

(b) Level B approximation

$$(\boldsymbol{K}_{AB}^{(2)})_{\alpha\alpha} = (2\beta^2/25)\langle r^{-3}\rangle_A\langle r^{-3}\rangle_B({}^3\Delta E)^{-1} \times [2(4P^2_{\alpha A\alpha B}+P^2_{\beta A\beta B}+P^2_{\gamma A\gamma B}) + 9P_{\alpha A\beta B}(P_{\beta A\beta B}+P_{\gamma A\gamma B}) - 2(2P^2_{\alpha A\beta B}+2P^2_{\alpha A\gamma B} + 2P^2_{\beta A\alpha B}+2P^2_{\gamma A\alpha B}-P^2_{\beta A\gamma B}-P^2_{\gamma A\beta B}) + 9(P_{\alpha A\beta B}P_{\beta A\alpha B}+P_{\alpha A\gamma B}P_{\gamma A\alpha B})] \quad (A\cdot2\text{-a})$$

$$(\boldsymbol{K}_{\substack{AB\\(\alpha\neq\beta)}}^{(2)})_{\alpha\beta} = (6\beta^2/25)\langle r^{-3}\rangle_A\langle r^{-3}\rangle_B({}^3\Delta E)^{-1} \times [4(P_{\alpha A\alpha B}P_{\alpha A\beta B}+P_{\beta A\beta B}P_{\alpha A\beta B} + 3(P_{\alpha A\beta B}P_{\gamma A\gamma B}+P_{\alpha A\gamma B}P_{\gamma A\beta B}) - 2(P_{\alpha A\alpha B}P_{\beta A\alpha B}+P_{\beta A\beta B}P_{\beta A\alpha B} + P_{\alpha A\gamma B}P_{\beta A\gamma B}+P_{\gamma A\alpha B}P_{\gamma A\beta B})] \quad (A\cdot2\text{-b})$$

(ii) OB term

Under the one-center integral approximation, the contribution coming from $\mathscr{H}_1^{(a)}$ becomes zero, and we have only to consider the contribution coming from $\mathscr{H}_1^{(b)}$ (*cf.* Eqs. (1) and (2)).[9]

(a) Level A approximation

$$(\boldsymbol{K}_{AB}^{(1b)})_{\alpha\alpha} = 16\beta^2\langle r^{-3}\rangle_A\langle r^{-3}\rangle_B \sum_i^{occ}\sum_j^{vac} ({}^1\Delta E_{i\to j})^{-1} \times (C_{i\gamma A}C_{j\beta A}-C_{i\beta A}C_{j\gamma A}) \times (C_{i\beta B}C_{j\gamma B}-C_{i\gamma B}C_{j\beta B}) \quad (A\cdot3\text{-a})$$

$$(\boldsymbol{K}_{AB}^{(1b)})_{\alpha\beta} = 16\beta^2\langle r^{-3}\rangle_A\langle r^{-3}\rangle_B \sum_l^{occ}\sum_j^{vac} ({}^1\Delta E_{i\to j})^{-1} \times (C_{i\gamma A}C_{j\beta A}-C_{i\beta A}C_{j\gamma A})(C_{i\gamma B}C_{j\alpha B}-C_{i\alpha B}C_{j\gamma B}) \quad (A\cdot3\text{-b})$$

(b) Level B approximation

$$(\boldsymbol{K}_{AB}^{(1b)})_{\alpha\alpha} = 8\beta^2\langle r^{-3}\rangle_A\langle r^{-3}\rangle_B({}^1\Delta E)^{-1}(P_{\beta A\beta B}P_{\gamma A\gamma B} - P_{\beta A\gamma B}P_{\gamma A\beta B}) \quad (A\cdot4\text{-a})$$

$$(\boldsymbol{K}_{AB}^{(1b)})_{\alpha\beta} = 8\beta^2\langle r^{-3}\rangle_A\langle r^{-3}\rangle_B({}^1\Delta E)^{-1}(P_{\beta A\gamma B}P_{\gamma A\alpha B} - P_{\beta A\alpha B}P_{\beta A\gamma B}) \quad (A\cdot4\text{-b})$$

Note that, although the tensor due to the FSD term is symmetric, those due to the SD and OB terms are not necessarily symmetric. For the FC contribution, its tensor is diagonal and given by Pople and Santry[16] for both approximations.

37) For CH_3F, the increase in the H–C–H angle about 1° is necessary in order to explain the difference between theoretical and experimental values. For CH_3I, it is about 20′. For the molecules for which the values of the $(J_{CH})_{aniso}$ in Table 1 are negative, the decrease in the H–C–H angle is necessary (Ref. 14). The energy necessary for the change of this order in the H–C–H angle is less than 20~30 calories.

38) Saupe, Englert, and Povh (Ref. 7a, 7c, 7h) studied the molecular geometry of CH_3CN dissolved in three nematic solvents and observed slight differences in H–C–H angle. They interpreted these differences as due to those of the protonating abilities of these solvents. Englert and Saupe (Ref. 7a) obtained the C–N bond length considerably shorter than its microwave geometry, and they suggested that the change is caused by the solvent-solute interaction such as the interaction of the polar C–N bond with the electric reaction field induced by nematic solvent molecules.

Steric Effects in Azo Compounds. The Electric Dipole Moments and the Absorption Spectra of Azobenzene Derivatives

Shunzo YAMAMOTO, Norio NISHIMURA, and Shigeo HASEGAWA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received October 12, 1970)

The electric dipole moments of *trans*-4-*N*,*N*-dimethylaminoazobenzene and its derivatives, and the absorption spectra of azobenzene derivatives and their conjugate acids have been measured. The dipole moment and the intensity of the π–π^* band are clearly reduced by introduction of methyl groups into ortho positions to azo group. The twisting angle of the benzene rings with respect to the azo group has been estimated for 2,2′-disubstituted azobenzenes and their conjugate acids by means of the Braude equation. From the spectral intensity and transition energy, it was concluded that the conjugate acids are generally more susceptible than the bases to the steric effect.

It is well known that steric hindrance affects certain physical and chemical properties of organic compounds.[1] The twist of molecule about a *single* bond in a conjugated system is of particular interest, the physical properties being susceptible to the twist.[2–4] This makes experimental approach possible.

Minkin *et al.*[5] showed that aromatic azomethines have a nonplanar conformation in which the dihedral angle between the amino nucleus and the rest of the molecule plane is 40—60°. Acoplanarity of the molecule is supported by the following: low intensity of π–π^* conjugation band and absence of fluorescence in contrast to the isoelectronic analogues—stilbenes and azobenzenes; low basicity, nonisolation of *cis*-isomers.

The dipole moments of aromatic amines[6] and nitro compounds[7,8] are greatly reduced by ortho substitution. A similar effect has been reported for biphenyls,[9] stilbenes,[10] and other aromatic compounds.[11] The reduction in dipole moment by ortho substitution is interpreted as due to the reduced conjugation which arises from the twisting of molecule about a single bond in a conjugated system.[2]

It has been recognized that when the molecule is sufficiently crowded to render coplanarity of the conjugated atoms difficult or impossible, the electronic spectra differ from those expected for a planar model.

In a conjugated system X–Y, change in steric conformation about the single bond can give rise to three types of spectral effects[12]: (A) Slight twisting about the single bond, the spectroscopic result being hypochromic effect only. (B) moderate twisting resulting in both a hypochromic effect and a hypsochromic shift. (C) Severe twisting resulting in complete steric inhibition of resonance, and giving rise to the cumulative spectra of the two isolated chromophores X and Y.

Good example of type (A) are provided by alkylated benzaldehydes, acetophenones, cyclic aromatic ketones, and related compounds.[2] The angle of twist θ can be calculated according to the Braude equation,[2] by which Finar[13] evaluated the angle of twist for some sterically hindered pyrazoles. Jaffé and Orchin[12] attempted an unified explanation for the spectra of (A) and (B); the observed hypochromic effect exhibited by both slightly hindered and moderately hindered stilbenes could be explained by their interpretation.

Azobenzene and its meta- and para-substituted derivatives have planar structure which is due to the energy stabilization by extended π-electron conjugation.[14] However, if substituents are introduced into one or both benzene rings on the ortho positions to the azo group, a steric hindrance between the substituents and the lone-pair electrons on the N-atoms will make the molecule twist around the –N=N– bonds,[15,16] the extent of twist being determined by a compromise of the mesomeric stabilization with the steric factor.

The spectra of substituted azobenzenes have been reported by many workers,[17,18] and systematic studies of the effects of substituents on the spectra have been carried out. Gore and Wheeler[15] measured the

spectra of some of 2,2′-disubstituted azobenzenes and calculated the angle of distortion from coplanarity by means of the Braude equation. However, no wide spectral investigation seems to have been made on these substances in relation to the steric effect. Only a few studies were made on how the steric effect causes the change in their dipole moments. This paper presents the dipole moment and the spectral data of azobenzene derivatives. The spectral data of their conjugate acids are also given, from which the molecular conformation is discussed.

Experimental

Compounds. Symmetrically substituted azobenzenes were prepared by the following procedures.[19]

4,4′-*Dimethylazobenzene*: A solution of 13.8 g of sodium nitrite in 200 m*l* of water was added dropwise with stirring to a solution of 20 g of *p*-toluidine in 136 m*l* of 13% hydrochloric acid, the temperature of the solution being kept below 5°C with ice bath. The diazonium solution was added to a stirred solution containing 70 g of cupric sulfate, 30 g of hydroxylamine hydrochloride, 48 m*l* of 50% solution of potassium hydroxide and 100 m*l* of 33% aqueous solution of ammonia. The product was dissolved in benzene, and the solution was passed through an alumina column, and then crystallized from benzene.

2,2′-Dimethyl-4,4′-dichloroazobenzene: mp 164—165°C (Found: C, 60.19; H, 4.59; N, 10.12%. Calcd: C, 60.23; H, 4.33; N, 10.04%).

The derivatives of 4-*N*,*N*-dimethylaminoazobenzene were prepared and purified by the following procedure.

4-N,N-*Dimethylaminoazobenzene*[20]: 4-*N*,*N*-Dimethylaminoazobenzene was prepared by diazotizing aniline and coupling the resulting diazonium salt with dimethylaniline in an acetate buffer. Other compounds of Types II and II′ were prepared in a similar way. The products were dissolved in benzene, and the solutions were passed through an alumina column, and then crystallized from benzene.

4-Nitro-4′-*N*,*N*-dimethylaminoazobenzene: mp 228°C (lit, 230—231°C)

2,2′-Dimethyl-4-*N*,*N*-dimethylaminoazobenzene: mp 79—80°C (Found: C, 75.62; H, 7.97; N, 16.60%. Calcd: C, 75.85; H, 7.56; N, 16.59%).

2,4,2′-Trimethyl-4′-*N*,*N*-dimethylaminoazobenzene: mp 120—121°C (Found: C, 76.15; H, 7.94; N, 15.93%. Calcd: C, 77.37; H, 7.92; N, 15.72%).

2,2′-Dimethyl-4-chloro-4′-*N*,*N*-dimethylaminoazobenzene: mp 115—116°C (Found: C, 66.98; H, 6.56; N, 14.55%. Calcd: C, 66.77; H, 6.30; N, 14.60%).

2,2′-Dimethyl-5-nitro-4′-*N*,*N*-dimethylaminoazobenzene: mp 148—148.5°C (Found: C, 64.20; H, 6.23; N, 18.97%. Calcd: C, 64.41; H, 6.08; N, 18.78%).

2,2′-Dimethyl-4-nitro-4′-*N*,*N*-dimethylaminoazobenzene: mp 147—148°C (Found: C, 64.58; H, 6.38; N, 18.95%. Calcd: C, 64.41; H, 6.08; N, 18.78%).

Benzene: Benzene was purified successively by shaking with concentrated sulfuric acid and water, drying over sodium wire, and distillation.

Cyclohexane: Cyclohexane was washed several times with a mixture of concentrated nitric and sulfuric acids. After repeated washing with distilled water it was distilled over sodium.

Ethyl Alcohol: Ethyl alcohol was of reagent grade and was used without further purification.

Sulfuric Acid: Sulfuric acid of commercial special grade was used without purification.

Measurement of Dielectric Constant and Density. Six solutions of each compound with weight fractions between 0 and 0.015 were used. The solutions were allowed to stand in the dark for a few hours in order to avoid contamination with *cis*-isomers.

The dielectric constants were determined with a Dielectric Analyzer, Type FAM-3A, manufactured by Yamato Scientific Instrument Co. The oscillator, controlled by a quartz crystal, was operated at frequency of 2MHz. The accuracy of the precision variable condenser, taken from the average of several readings, was about one part in 10000 for the cell filled with air.

The densities of the same solutions were measured in an Ostwald type pycnometer of about 5 m*l*. All the measurements were carried out in a thermostat regulated at 25±0.01°C.

Further, to insure that the instruments were properly calibrated and that the method of calculation was appropriate, the dipole moments of *p*-chloroaniline and chlorobenzene were determined. The results were 2.99 D for *p*-chloroaniline, and 1.58 D for chlorobenzene, and were in good agreement with literature values (2.99 D for *p*-chloroaniline and 1.55 D and 1.58 D for chlorobenzene) which were obtained under similar condition.

Measurement of Absorption Spectra. Absorption spectra were measured with a Hitachi double beam spectrophotometer, Model 124. The absorption spectra of the bases were measured in cyclohexane solutions. The measurements for the conjugate acids were made in a mixture of ethyl alcohol and sulfuric acid. The solutions were kept to stand in the dark until the absorbance became constant. All the measurements were made at room temperature.

Dipole Moment. It is generally recognized that both dielectric constant ε and density d of a solution are linearly related to the weight fraction w of the solute for dilute solutions. If these relationships hold, as was the case in this experiment, the molar polarization P can be calculated by means of the following Halverstadt-Kumler equation.[21]

$$P = \frac{(\varepsilon_0-1)}{(\varepsilon_0+2)} \cdot \frac{M}{d_0}\left\{1 + \frac{3a}{(\varepsilon_0+1)(\varepsilon_0+2)} - \frac{b}{d_0}\right\} \qquad (1)$$

where d_0 and ε_0 are the density and the dielectric constant of the solvent, respectively, and the constants a and b are the slopes of the linear plots of ε, and d against w, respectively.

The electric dipole moment of a solute is related to the molar polarization by the following well-known equation.

$$\mu^2 = (9\boldsymbol{k}T/4\pi N)(P-P_E-P_A) \qquad (2)$$

where P_E and P_A are the electronic and atomic polarizations, respectively. It is generally accepted that the sum (P_E+P_A) can be put equal to $1.05\,R_M$ in good approximation,[22] where R_M is the molar refractivity estimated from bond refractivities.[23,25]

The dipole moments of various substituted azobenzenes have been obtained on the basis of Eqs. (1) and (2), and are listed in Table 1 with relevant data. The calculated dipole moments $(\mu_0+\mu_g)$, where μ_0 is the dipole moment of a reference compound (R=H for Types II and II'), and μ_g denotes the group moment of the substituent R, are listed in the last column. We see that the choice of reference compound gives the relationship $\mu_{obsd} \approx (\mu_0+\mu_g)$. For *p*-nitro compound, however, the agreement is poor. This may arise from the large contribution of the type

Absorption Spectra. Azobenzene derivatives have two distinct absorption bands in the near ultraviolet and visible regions. The band at 320—360 mμ is relatively intense (ε, 10000—30000), whereas the band at 430—460 mμ is considerably weaker (ε, 400—1000). The former is known to be the π–π^* band (conjugation band) and the latter n–π^* band.[26] The absorption maxima and the molar extinction coefficients for Types I and I' are collected in Table 2.

It can be seen that both the position and intensity of the conjugation band are considerably affected by substitution. As far as these data are concerned, the substitution in azobenzene always produces a bathochromic shift as compared with the spectrum of azobenzene. For 3,3'-dimethyl- and 3,3'-dichloroazobenzenes, however, the shift is very small, since the mesomeric effect is inoperative in meta positions. In addition, the molar extinction coefficients of these substances do not differ much from the parent compound. Similar findings have been reported by Gore and Wheeler for azoxybenzene derivatives.[27]

Discussion

Braude and Sondheimer[2] proposed the following equation, which relates the interplanar angle θ between the aryl and the carbonyl chromophores of benzalde-

hyde and acetophenone derivatives to the dipole moment.

$$\cos^2\theta = (\mu_{obsd} - \mu_{90°})/(\mu_{0°} - \mu_{90°}) \quad (3)$$

where $\mu_{90°}$ is the moment for completely deconjugated system in which the phenyl and carbonyl planes are at right angle. This equation may hold for any system in which a change in dipole moment arises from a twist by which conjugation is broken.

For 2,2'-disubstituted *trans*-azobenzene derivatives, the situation becomes more complicated. For example, if the molecular frame takes a coplanar structure, conformations of the following types are possible.

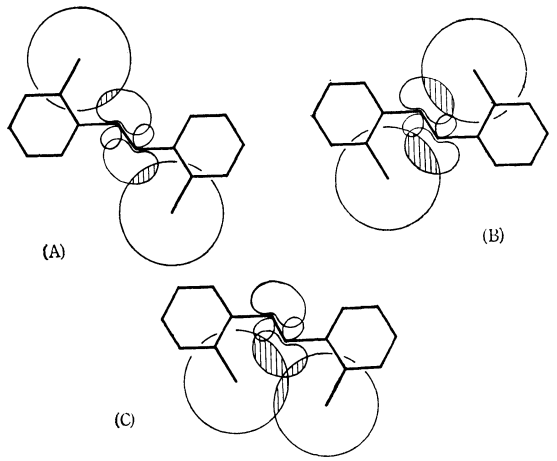

Fig. 1. Conformations of 2,2'-dimethylazobenzene.

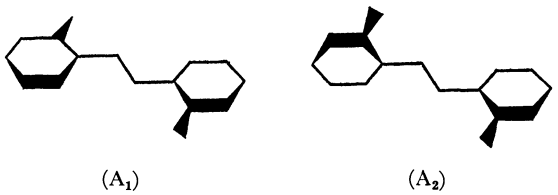
In the above conformations, each mushroom-shaped region represents the sp^2-density function (ψ^2=0.01). The probability of finding the lone pair electrons within this region is *ca.* 0.95. The van der Waals radius for methyl group is assumed to be 2.0 Å.[28] The interaction energy between the methyl group and the n-electrons cannot be estimated in a simple manner. However, the steric hindrance will become severer in the order A<B<C. In conformation C, the van der Waals radii of the methyl groups also overlap. Thus, comformation A is the most likely, and conformation C is the least likely. In this case, the molecule will be twisted to some extent relative to conformation A, owing to the steric hindrance. It is noted that if the repulsion between the methyl group and the nitrogen atom is considered using van der Waals radii, there would arise no advantage by twisting. Actually, two types of twist may be possible as indicated:



If one neglects both the long-range force between

28) L. Pauling, "The Nature of the Chemical Bond," 3rd ed., Cornell Univ. Press, New York, (1959), p. 260.

methyl groups and the resonance and overlap integrals between non-adjacent atoms, an equal number of isomer molecules of the above types will exist, and the observed dipole moment μ_{obsd} may be given by

$$\mu^2_{obsd} = (\mu^2_1+\mu^2_2)/2 \quad (4)$$

where μ_1 and μ_2 are the dipole moments of the isomers A_1 and A_2, respectively. In conformation A_1, the moments due to the two methyl groups, μ_{CH_3}, cancel each other. In conformation A_2, these moments do not cancel. If this is taken into account, Eq. (4) can be modified as

$$\mu^2_{obsd} = \mu^2_1 + 2\mu^2_{CH_3}\sin^2\theta \quad (5)$$

The group moment of methyl group is 0.40D.[29] If the angle of twist θ is small, as will be indicated later, the contribution of the second term can be neglected.[30]

We might conclude that ortho disubstituted azobenzenes are twisted in a way to take either one or both conformations of A_1 and A_2. It is generally accepted that the value of σ-moment is not affected considerably by twisting.[31] Hence, it is the π-moment that is affected by the twisting, and this will make the estimation of twisting angle possible by means of Eq. (3). However, in 2,2′-disubstituted azobenzenes, there are two bands around which the molecules are twisted. In order to examine the validity of the use of Eq. (3), in such cases, the π-moments of 4-*N*,*N*-dimethylaminoazobenzene and its derivatives were calculated as a function of θ, by means of the equation

$$\mu_\pi = e\sum Q_r r_r \quad (6)$$

where e is the electronic charge, and Q_r and r_r are the net charge and the position vector of rth atom, respectively. In calculating r_r, the following values for bond length were used: C–C=1.39 Å, C–N=1.45 Å, N=N=1.23 Å, C–Cl=1.70 Å, C–CH_3=1.53 Å; all the bond angles being assumed to be 120°. The net charge Q_r was estimated by means of the simple LCAO MO method. The displacement of the lone-pair electrons on the azo-nitrogens has been neglected, since these electrons would flow into both benzene rings symmetrically and would not change the dipole moment considerably.

In Table 3, the variation of the π-moments are shown as a function of the assumed twisting angle. Using $\mu(\theta)$-values, the twisting angle was calculated by means of Eq. (3). We see that the assumed and calculated twisting angles agree very well, showing that the Braude equation is applicable in the present case.

As Table 1 shows the dipole moment is clearly reduced by 0.19—0.44 D by the introduction of two methyl groups into ortho positions to azo-group. Thus the twisting angles were estimated by means of Eq. (3). They are listed in Table 4 which shows that θ is about 10° smaller for nitro compounds than for other compounds. For a 4-nitro compound, this might be ascribed to the large contribution of canonical resonance forms. However, it is difficult to express such a contribution for a 3 (or 5)-nitro compound. From Table 1 we see that observed values of μ are always larger than the expected values for nitro compounds, irrespective of the position of the substituent, suggesting the existence of a kind of combined contribution of the nitro group and the dimethylamino group. As Table 6 shows, the large red shift of the π–π^* band ($\Delta\lambda$=20 mμ for 3-nitro and 46 mμ for 4-nitro) with respect to the parent 4-*N*,*N*-dimethylaminoazobenzene may support this view.

From Table 2 we see that 2,2′-disubstituted azobenzenes have absorption maxima of the π–π^* band in a similar position but with lower intensities, as compared with the corresponding 4,4′-disubstituted ones.

30) Very recently, we found by means of X-ray analysis that 2,2′-dichloroazobenzene is symmetrically twisted about 12° relative to conformation A.
31) E. G. McRae and L. Goodman, *J. Chem. Phys.*, **29**, 334 (1958).

When four substituents are introduced into azobenzene, the situation becomes complicated. However, an ortho effect on the intensity of the π–π^* band is clearly seen in the table.

Gegiou *et al.*[16], studied sterically hindered azobenzenes (2,4,6- and 2,4,6,2′,4′,6′-methylsubstituted azobenzenes) and found that ortho methylation causes shifts of the n–π^* band to longer wavelengths and higher intensities. They suggested that the increase in intensity is due to the increase in the conjugation between phenyl ring and the lone pair electrons of a nitrogen atom. In the present case, a clear red shift by ortho substitution has been observed, but the increase in intensity is obscure. Introduction of substituent generally causes an increases in intensity of absorption band, even if the steric effect is absent (Table 2). Gegiou *et al.* compared the intensity for 2,4,6- and 2,4,6,2′,4′,6′-methylsubstituted azobenzenes with that for azobenzene. However, the comparison should have been made between sterically hindered azobenzenes and the corresponding unhindered ones. Hence, their suggestion is questionable.

A simple method for evaluating the ortho effect of the substituent at the 2 and 2′ positions from the intensity of the conjugation bands is to use the Braude equation $\varepsilon/\varepsilon_0=\cos^2\theta$ where ε_0 is the value of the extinction coefficient of a reference, unhindered parent compound and θ is the angle of twist to be calculated.[32] The values of θ, calculated according to the Braude equation for a number of azobenzene derivatives of the Type I′ are given in Table 5.

Table 5. Angle of twist of benzene rings in 2,2′-disubstituted azobenzenes and their conjugate acids[a]

No.	Base		Conjugate acid	
	$\varepsilon/\varepsilon_0$	θ	$\varepsilon/\varepsilon_0$	θ
2	0.698	33°	0.684	34°
10	0.787	27°	0.734	31°
12	0.684	34°	0.569	41°
5	0.567	41°	0.590	40°
8	0.417	50°	0.808	26°

a) The parent compounds are corresponding 4,4′disubstituted azobenzenes.

Gore and Wheeler[15] have used this equation to calculate the angle of twist for some 2,2′-disubstituted azobenzene. The values they estimated for 2,2′-dimethyl-, 2,2′-dichloro-, and 2,2′-dimethoxyazobenzenes are 23°, 35°, and 18°, respectively. It can be seen that for 2,2′-dimethoxyazobenzene, the twisting angle is considerably different from that of Gore *et al.* We have examined the possible causes of this disagreement and concluded that their ε-value (13100) for 4,4′-dimethoxyazobenzene was too small (compare ε-values for other compounds in the corresponding table).

23	0.942	14°	20°
25	0.957	12°	21°

a) The parent compounds are corresponding ones which have no methyl groups in ortho positions.
b) Estimated from dipole moment.

According to Gabor and Bar-Eli,[33] there are two conformational trans isomers for 2,2′-dimethoxyazobenzene which have peaks at 370 and 310 mμ. In our case the twisting angle of 50°C for this compound was estimated using the apparent molar extinction coefficient at 370 mμ. Hence, the value must have been overestimated.

The absorption maxima and the molar extinction coefficients for molecules of Types II and II′ are shown in Table 6. The values of θ calculated by means of the Braude equation are given in Table 7. It should be noted that the values are about 10° smaller than those estimated from the dipole moments of these molecules. In both cases, the twisting angles of the species of Type II′ were calculated with the species of Type II as references. The group moments of the two methyl groups in ortho positions act so as to cancel each other. Introduction of methyl groups gives rise to an extra hyperchromic effect. The spectroscopic θ-values have not been taken into account for this effect, and this might be the cause for the discrepancy.

The twisting angles of the molecules of Type I′ are 10—20° larger than those of Type II′, as seen in Tables 5 and 7. Since the hyperchromic effect in Types I and I′ is almost the same in the absence of the steric effect, the values in Table 7 must have been underestimated.

The conjugate acids of azobenzenes (Types I_a and I_a') show a very strong band in the visible region. Its absorption maxima and extinction coefficients are collected in Table 2. The band has been attributed to the conjugation band. The substitution effect on it is larger for the acids than for the original bases. Further, the absorption spectra of the conjugate acids of azobenzenes are markedly affected by solvents. As the concentration of sulfuric acid in ethanol-sulfuric acid mixture increases, the conjugation band shifts to a longer wave-length. Thus the transition energy should be extrapolated to zero concentration of sulfuric acid for the discussion of steric effect. Actually, however, the comparison of the transition energies of the species of Type I_a with those of species of Type I_a' was made in a ethanol-sulfuric acid mixture (45 : 55 in volume), since the solvent effect is almost the same for these compounds.

All these compounds are protonated almost completely in 90 vol% sulfuric acid.[34] ε-Values in this condition are listed in Table 2. The angle of twist of these acids were calculated according to the Braude equation and are listed in Table 5. We see that the values are appreciably larger than those for free bases, indicating that the conjugate acids are more susceptible to the steric effect than the original bases. This is supported by the effect of substituents on the transition energies.

The influence of substituents on the transition energy was examined on the basis of the data in Table 2. The relationship between the transition energies of the conjugation band of the bases and those of the conjugate acid is shown in Fig. 2. The points for compounds of Types I and I_a give a straight line with a slope larger than unity. This indicates that the change in the transition energy of the base upon introduction of substituents is proportional to that for the acids and that this change is larger for the acid than for the base. The points for compounds of Types I′ and I_a', however, deviate upward from the line. The transition energies of compounds of Type I′ are similar to those of Type I. The deviation, therefore, arises from the fact that the effect of substituents on the transition energy for compounds of Type I_a' is smaller than that for compounds of Type I_a. This suggests that the steric effect on the transition energy for the base is negligible, but not for the acid.

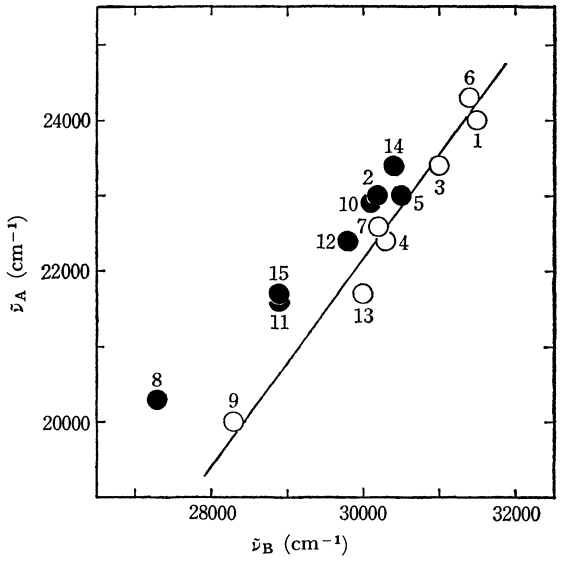

Fig. 2. The relationship between the transition energy of the conjugation band of the base ($\tilde{\nu}_B$) and that of the conjugate acid ($\tilde{\nu}_A$).
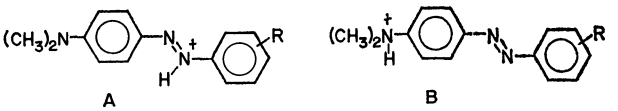
(○) Types I and I_a (●) Types I′ and I_a'

From the analysis of the spectral data, it has been clarified[35] that following two types of the conjugate acids for 4-*N*,*N*-dimethylaminoazobenzenes coexist in an acidic solution:



Absorption bands near 500 mμ and 320 mμ have been assigned to the conjugation bands of A and B, respectively (Table 6). As the former band is isolated, its position can be determined precisely. The latter band appearing in a ultraviolet region is rather obscure both in position and intensity. The equilibrium constant between A and B has been discussed, but no precise value has been obtained.[35] Hence the molar extinction coefficients of A and B could not be determined.

Although the twisting angles for the species of Type II_a' could not be estimated, the conjugate acids are

b) F. Gerson and E. Heilbronner, *Helv. Chim. Acta*, **45**, 42 (1962).

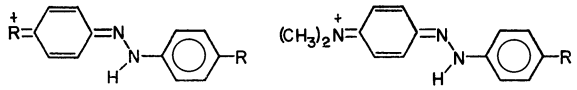
susceptible to the steric effect than the bases are, in this case too (Table 8), since the introduction of methyl groups into 2 and 2′ positions increases the transition energy in the case of the conjugate acids, while it decreases in the case of the bases. Thus, the steric effect of the conjugate acids on the transition energy is similar to that of stilbene[12] which has no *n*-electron.

Possible explanations for the above findings are as follows:

a) The delocalization of the lone pair electrons of azo nitrogens into the phenyl rings is partly suppressed by the protonation to a nitrogen atom.

b) The repulsion energy between an ortho methyl group and the proton is larger than that between a methyl group and the lone pair electrons.[36]

c) For the conjugate acids the contribution of the following resonance forms is large in the excited state when the molecule is planar.



For the bases, however, such contribution may be smaller. As Beale and Roe have pointed out,[37] hindrance to planarity, in the absence of other effects, should increase the energy of the excited state more than that of the ground state, with a shift of the corresponding absorption to higher frequencies.

The authors are deeply grateful to Miss Hiromi Ohtani for elemental analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2025—2030 (1971)

A Theoretical Study of the Electronic Structures of Several Methyl Compounds of Group I, II, and III Elements

Katsutoshi OHKUBO, Hidetoshi SHIMADA, and Masahide OKADA
Faculty of Engineering, Kumamoto University, Kurokami-machi, Kumamoto

(Received November 1, 1970)

The electronic states of the group I, II, and III methyl compounds were investigated using the extended Hückel method, with particular reference to the nature of the bond of metal-carbon. First, the monomers of the group I methyl compounds indicated remarkable electron-localizations on the carbon atom in CH_3. $(CH_3Li)_4$ was found to be a possible tetramer, its total energy being lower by 0.34 eV per CH_3Li unit than that of the CH_3-Li-monomer in spite of the unstability of $(CH_3Li)_2$. Second, $(CH_3)_4Be_2$ was more stable than $(CH_3)_2Be$ by *ca.* 4.04 eV per $(CH_3)_2Be$ unit. Third, the stability of $(CH_3)_3B$ in the form of a monomer was understood well by the fact that its π-bond nature is so much in comparison with that of $(CH_3)_3Al$. Finally, the reactivities in a series of the groups were discussed briefly in connection with the electronic states.

The reactivities of organometallic compounds, in particular those of compounds containing group I, II, and III elements have hitherto attracted many authors' attention.[1-13] An interesting proposal suggested by Gilman[1] and Rocho[2]: the reactivities have a direct relationship with the electronegativities of the metals. However, some obscurities still remain as a result of the lack of information concerning the molecular structures of the compounds.

Recently, the molecular structures of organometallic compounds have been observed in connection with the bridge-type polymerization of the compounds.[14,15] Many X-ray and spectrophotometric studies have been performed in making experimental analyses of the dimer- or polymer-structures of C_2H_5Li,[16,17] n-C_4H_9Li,[18] $(CH_3)_2Be$,[19,20] $(C_2H_5)_2Mg$,[20] $(CH_3)_3Al$,[21,22] and a characteristic monomer of (C-

$H_3)_3B$.[23,24] These studies suggested the striking features of the compounds mentioned above, namely, the so-called "*five-coordinate carbon*" or "*electron-deficient bridged bond*" of such compounds as the methyllithium tetramer,[25] the dimethylberyllium polymer,[19] and the trimethylaluminum dimer.[21,22] More recently, as to the molecular structures of the electron-deficient compounds, some molecular orbital calculations[26-29] have been performed with particular reference to the natures of the bond, such as the metal-carbon and metal-metal bonds, in $(CH_3Li)_4$,[26] $(CH_3)_6B_2$,[26] and $(CH_3)_6Al_2$.[26] In regard to the contributions of the π-type bonding (hyperconjugation) of alkyls to the formation of the bridged bond mentioned above, these calculations have provided the interesting information that the π-type bonding of the above polymer appears to be approximately the same as that of its monomer and less than 10% of the metal-carbon σ-bond in the compounds.

In the present paper, an extended Hückel molecular orbital calculation will be carried out for the methyl compounds of group I (Li, Na, K, Rb), group II (Be, Mg, Ca), and group III elements (B, Al). The main purpose of this study is to make an extensive consideration of the electronic states of the compounds in connection with their reactivities.[1,2]

Method of Calculations

The extended Hückel method proposed by Hoffmann[30] was used to make calculations for several methyl compounds of group I, II, and III elements: CH_3Li, $(CH_3Li)_2$, $(CH_3Li)_4$, CH_3Na, CH_3K, CH_3Rb, $(CH_3)_2Be$, $(CH_3)_4Be_2$, $(CH_3)_2Mg$, $(CH_3)_2Ca$, $(CH_3)_3B$, $(CH_3)_3Al$, and $(CH_3)_6Al_2$. The values of the orbital exponents of the elements were taken from those evaluated by Clementi,[31] while the following valence-state ionization potentials (vsip)[32,33] were employed for the diagonal H-matrix elements: H_{ii}(eV)$=-13.6$ (H 1s), -5.39 (Li 2s), -3.54 (Li 2p), -5.14 (Na 3s), -3.04 (Na 3p), -4.34 (K 4s), -2.17 (K 4p), -4.18 (Rb 5s), -2.60 (Rb 5p), -9.92 (Be 2s), -5.96 (Be 2p), -8.95 (Mg 3s), -4.52 (Mg 3p), -7.09 (Ca 4s), -3.96 (Ca 4p), -14.91 (B 2s), -8.42 (B 2p), -12.27 (Al 3s), -6.47 (Al 3p), -21.01 (C 2s), and -11.27 (C 2p). The Wolfsberg-Helmholtz approximation[34] was employed for the off-diagonal matrix elements (H_{ij}) as:

$$H_{ij} = K(H_{ii} + H_{jj})S_{ij}/2$$

where the value of the parameter, K, was taken to be 1.75.[30] The bond lengths of the group I methyl compounds were taken to be Li–C=2.19 Å,[35] Na–C=2.70 Å, K–C=3.10 Å, and Rb–C=3.29 Å. The atomic coordinates of $(CH_3Li)_2$ and $(CH_3Li)_4$ were calculated from the pertinent bond distances and bond angles.[14] The bond angles of carbon-metal-carbon for the group II methyl compounds were taken to be linear, assuming the $D_{\infty h}$-structures, and the following bond lengths were used: Be–C=1.98 Å, Mg–C=2.45 Å, and Ca–C=2.82 Å. The molecular structures of the group III methyl compounds were assumed to be D_{3h},[36] and the bond lengths of B–C and Al–C were set as 1.80 Å[37] and 2.28 Å[38] respectively. For the calculations of the dimer structures of $(CH_3)_4Be_2$ and $(CH_3)_6Al_2$, the bond lengths of Be–C,[39] Al–C_b,[40] and Al–C_t[41] were taken to be 1.93 Å,[42] 2.24 Å,[14] and 2.00 Å[14] respectively. In all the calculations, the bond distance of C–H was taken to be 1.09 Å for the sake of simplicity.

Results and Discussion

The Electronic States of the Group I Methyl Compounds. Among organometallic compounds of group I elements, lithium compounds can be distinguised by their associations[4] in such organic solvents as ether and tetrahydrofuran. From their experimental works, Brown *et al.*[42] and others[43-45] emphasized the hexamer structures of alkyllithiums, while

35) This length was derived from that of $(CH_3Li)_4$ reported in Ref. 14.
36) The angle of CBC in $(CH_3)_3B$ was reported as 119.4°± 0.3° by Ref. 23.
37) In Ref. 23, the mean bond length of B–C was reported to be 1.5783±0.0011 Å. We modified this value slightly.
38) The bond lengths of Al–C in $(CH_3)_6Al_2$ were determined to be 2.24 Å[21] (2.14±0.01 Å[22]) for the bridged distance and 1.99 Å[21] (1.97±0.01 Å[22]) for the exterior distance. We used approximate values as estimated from Ref. 21.
39) The same interatomic distance of Be–C was applied to those of the Be-terminal C and the Be- bridged C.
40) The C_b and C_t notations denote a bridged carbon and a terminal one respectively.
41) This length was an assumed one (see Ref. 14).

a) Atomic distance of metal—carbon or metal—chlorine.
b) Total orbital overlap between metal (M) and carbon (C).
c) Bond order density between M and C.
d) Bond order density of M-C. s(M)-s(C) and s(M)-p(C) mean the bond order density between s-M orbital and s-C one and that between s-M orbital and p-C one in $sp\sigma$-bond of M-C, respectively.
e) AO bond population between the orbitals of M and C presented in d).
f) Total bond population between M and C.
g) This HO level is depended on the p-C orbital presended in d), while for the chlorides, it is depended on the p-lone pair orbital of Cl.
h) This level indicates the energy of the lowest vacant s-M orbital.
i) They are listed for the comparison's sake.

Weiner and his co-workers[46] supported the tetramer structures. The association of the lithium compounds may be attributed to very small contributions of orbital overlaps (including "*hyperconjugation*") between the lithium atom and carbon to the formation of their stable molecules. As to the other metal compounds, however, there is little information about their electronic states except that there is a tendency[47,48] for their slight covalent natures to increase with a decrease in their atomic numbers. These characteristics should be reflected in the total orbital overlap (S(M–C)) defined by the sum of orbital overlaps, the bond order density (P(M–C)), and the total bond population (M(M–C)). These values and, in addition, the energy levels (HO and LV) are shown in Table 1, while the atomic- and bond-populations are given in Fig. 1. As may be seen in Table 1, S(M–C) supports the previous idea as to the tendency[47,48] of the bond nature; moreover, P(M–C) suggests that the σ-bond of M–C is formed by the bonding orbital of s(M)–p(C) and the anti-bonding orbital of s(M)–s(C). The electrons of the M–C bond localize remarkably on the carbon atom, which is over the unit charge (see Fig. 1). In this case, the contribution of "*hyperconjugation*" can hardly be expected because of the negative π-bond character of the compounds. It is of interest here to pay attention to the bond nature of the metal halides for the sake of comparison. Notwithstanding the fact that the interatomic distances of M–Cl are larger than those of M–C, the halides indicate a more covalent nature of the bond than do the methyl derivatives. This reflects a negative contribution of the hyperconjugation of CH_3 group such as has been described above; a striking covalency of the lithium compounds is also seen, a covalency which may be attributed to the small radius of the Li ion and the larger effective nuclear charge of Li caused by the scanty shielding effect of the electrons on Li.

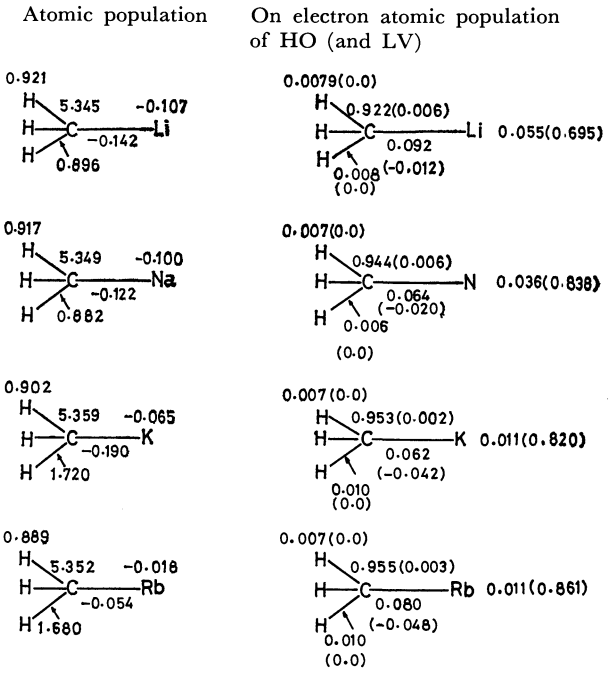

Fig. 1. Atomic population of the group I methyl compounds. (Values in parentheses are those of S-M orbitals.)

In regard to the associated polymer of alkyllithium, the present calculations give the interesting information that $(CH_3Li)_2$ is less stable than CH_3Li by *ca.* 0.25 eV per CH_3Li unit, while $(CH_3Li)_4$ is more stable by 0.34 eV per CH_3Li unit, neglecting core repulsions and electron-electron interactions (see Table 2). From this point of view, from their detailed calculations of the total energy, Cowley and White[29] have demonstrated the stability of $(CH_3Li)_4$ in comparison with

	C-H	0.836			

a) Total bond population of X-Y.
b) HO-orbital except that of Be-derivative is mainly depended on p-C orbital in $sp\sigma$-bond of M-C.
c) LV-level indicates that of the lowest vacant s-M orbital except Be-derivatives.
d) This was listed for the comparison's sake (Geometry is shown in Fig. 2).

that of CH_3Li (28.12 eV per CH_3Li unit). On the other hand, the electron population on the lowest vacant s-metal orbital[49] and that on the bond of metal-carbon at the highest occupied level[50] (see Fig. 1) may support a trend of the reactivities[1,2] such as RLi<RNa<RK<RRb<RCs for the addition reactions with carbonyl groups, because the larger value of the former may reflect the reactivity of the metal cation to the nucleophiles, while that of the latter may suggest a measure of the resistance to the cleavage of the M–C bond.

The Electronic States of Group II Methyl Compounds. Before speaking about the electronic states of the compounds, it may be mentioned that beryllium compounds usually have striking covalent natures which can be attributed to the small size of the metal (its metallic radius, 0.89 Å, is much smaller than Li's 1.22 Å), and have a far less electropositive character than Li in all aspects of their chemical behavior, while compounds of Ca, Ba, Sr, and Ra are all essentially ionic, though some Mg compounds show a covalent nature. Generally, the polymer structures of beryllium compounds such as the bridged $(BeCl_2)_n$ are well accepted; Mg compounds also have a polymer chain similar to that of Be compounds.[20] However, it can hardly be expected that a polymer chain exists in other group II metal compounds because of the striking ionic nature of the compounds. The energetic states and the overlap population (M(X–Y)) of the group II methyl compounds are summarized in Table 3. As Table 3 shows, M(X–Y) does not indicate reliable information about the polymeric character of Be and Mg derivatives. However, the characteristic covalency of Be compounds is reflected in the relatively large S(Be–C) value of 0.254 as compared with those of S(Mg–C) and S(Ca–C) (0.030 and 0.034 respectively), considering that S(Be–C) relates directly to (Be–C), which is immediately influenced by the selected ionization potentials (vsip) of Be and C. On the other hand, the total energies of $(CH_3)_2Be$ and $(CH_3)_4Be_2$ suggest, interestingly, that $(CH_3)_4Be_2$ is more stable than $(CH_3)_2Be$; the stabilized energy is about 4.04 eV per $(CH_3)_2Be$ unit. Moreover, the AO populations of the p_z-Be orbitals of both $(CH_3)_2Be$ and $(CH_3)_4$-

49) The value of this population indicates the electron-vacancy of the orbitals.
50) The highest occupied orbital is the $2p$-carbon one used for the formation of the σ-bond of M–C.

Table 4. Electronic states of group III methyl compounds

a) Overlap population of metal-carbon.
b) AO population of the metal. D_3-ligand plane of the compound is on X-Y cross section, and the notations, X, Y, and Z, denote the p_x, p_y, and p_z-orbitals of metal, respectively.
c) This level corresponds to that of p_z-metal orbital.
Data in parentheses are those in Refs. 26 and 29 for dimethyl-boron or aluminum and dimethyl aluminum dimer, respectively.

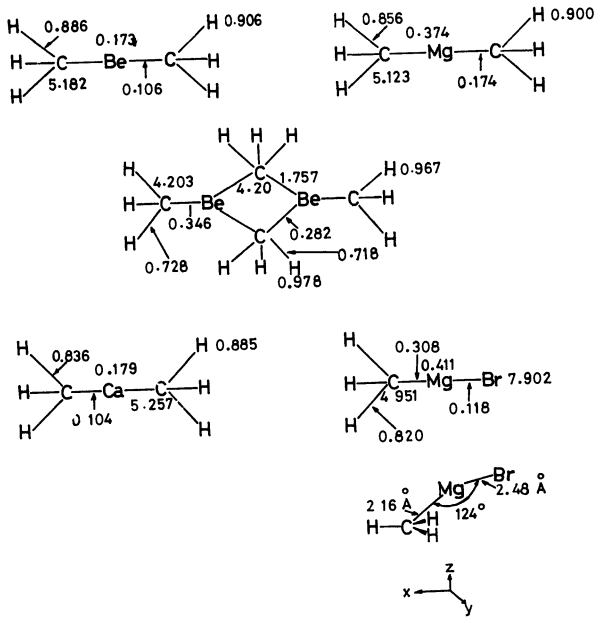

Fig. 2. Atomic populations of group II methyl compounds.

Be_2 (0.043 and 0.047 respectively) also predict the stability of the dimer, because the electrons on the p_z-orbital contribute to the stabilization of the dimer through the π-bond of Be–C. Under these circumstances, the relatively strong bond of Be–Be is enough to compensate for the weak bond of Be–C_b (see Fig. 2). However, the π-bond of Be–Be contributes little to this bond formation (less than 1.0%[51] of the total overlap). The above considerations may be understood from the data listed in Table 5. Furthermore, another striking feature of the dimer is also reflected in the atomic charge of the metal; that is, the bridged Be-atom (+0.24) is less positive than the Be in the monomer (+0.83). The charges of the metals (Be=+0.83, Mg=+0.63, and Ca=+0.82, as estimated from the atomic populations in Fig. 2) are, however, not in good agreement with such a trend of the reactivities[1,2] as RBe<RMg<RCa in the carbonyl group-addition reaction, probably because the behavior of RM (M=metal) in the reaction system can hardly be evidenced only from the electronic states of RM-monomers; that is, the interaction between the carbonyl groups and the monomer or dimer of RM was not taken into consideration at the molecular level. In connection with the stabilized dimer of $(CH_3)_4Be_2$, the energy state of the dimeric methyl beryllium is illustrated in Fig. 3.

Electronic States of the Group III Methyl Compounds. The most characteristic feature of the compounds of this series is the dimerization of the lower trialkyls of Al in spite of the stable monomers of trialkyls of B, Ga, In, and Tl in vapor and in solution.[52] Therefore, it is of interest to investigate the difference in the electronic states between trialkyl boron and trialkyl aluminum. The data as to these compounds are listed in Table 4. The smaller metal-carbon overlap population of $(CH_3)_3Al$ than that of $(CH_3)_3B$ first indicates less stability in $(CH_3)_3Al$. The most remarkable feature of $(CH_3)_3Al$ appears in the small AO population of the p_z-Al orbital (used for the π-bond of Al–C) as compared with $(CH_3)_3B$. This indicates the weak π-bond of Al–C. Considering the large contribution of the π-bond to the stabilization of the molecule, the remarkably small π-bond nature of Al–C (see Table 5) suggests the improbable existence of the trialkyl aluminum monomer. These circumstances are reflected in the slight different atomic populations of $(CH_3)_3B$ and $(CH_3)_3Al$, as is indicated in Fig. 4. However, the total energy of $(CH_3)_6Al_2$ failed to suggest its stability, as is indicated in Table 4. It is plausible here to focus on the lowest vacant p_z-

51) The π-bond character formed by the p_z-orbitals of the two Be atoms was 0.23% of the total overlap, neglecting the contribution of p_x-orbitals.

metal orbital in connection with the reactivity of the compounds, because the electron-vacancy of the boron- or aluminum-orbital (M_B(LV) or M_{Al} (LV) respectively) may play an important role in the reaction with nucleophiles. M_B(LV) and M_{Al}(LV) are 0.880 and 0.991 respectively. Therefore, the appreciable vacancies of the orbitals on both metals may suggest the effectiveness of the orbitals for the attack of nucleophiles. In this point of view, Gilman[1] has reported the order of the reactivity for the attack of nucleophiles as RB<RAl. Finally, the π- and σ-overlap population of M–C in a series of the group I, II, and III methyl compounds are recorded in Table 5 for the sake of comparison.

The results obtained from the present study may be summarized as follows:

a) The striking nature of the covalency of lithium compounds appeared in the large total orbital-overlap. In all Group I methyl compounds, the electron-localization occurred on the C-atom in CH_3 over the C-unit charge. As to the stabilization of the alkyllithium polymer, $(CH_3Li)_4$ was more stable than CH_3Li in the order of *ca.* 0.34 eV per unit, although $(CH_3Li)_2$ was less stable than CH_3Li (*ca.* 0.25 eV per CH_3Li unit).

b) The dimer structure of $(CH_3)_4Be_2$ was stabilized in the energy of 4.04 eV per $(CH_3)_3Be$ unit, and the contribution of the σ-type Be–Be bond to the stabilization was relatively large, while that of the π-type bond was very small.

c) The π-bond character of the monomer of $(CH_3)_3Al$ was about 1/9 that of $(CH_3)_3B$; this would well explain the stability of trialkyl boron monomers.

The present calculations were carried out on the FACOM 230.60 computer at the Computer Center of the University of Kyushu.

Vibrational Analysis of the 2400—2800 Å Bands of 1,2,3- and 1,3,5-Trimethylbenzenes in Vapour Phase

V.N. VERMA, K.P.R. NAIR, and D.K. RAI

Department of Spectroscopy, Faculty of Science, Banaras Hindu University, Varanasi-5, India

(Received October 13, 1970)

The near ultraviolet absorption spectra of 1,2,3- and 1,3,5-trimethylbenzenes have been photographed in vapour phase at different vapour pressures on a Q-24 Zeiss Medium Quartz Spectrograph. Assuming C_{2v} symmetry for the 1,2,3- and D_{3h} symmetry for the 1,3,5-isomer, tentative assignments of the observed bands have been made in terms of various ground state and excited state fundamentals. The respective vibrational modes have also been suggested.

The electronic spectrum of mono-methylbenzene (toluene) has been studied by many workers.[1-5] Price *et al.*[6] reported the vacuum ultraviolet absorption spectra of the three isomeric dimethylbenzene(xylenes) in vapour phase. Complete analysis of the electronic spectra in the near ultraviolet region for the three xylenes has been made by Cooper *et al.*[7,8] and also by Singh.[9-11] For trimethylbenzenes, however, the work done is very limited and further work is clearly needed.

The Raman spectrum of 1,3,5-trimethyl benzene has been studied[12,13] and the polarization measurements are reported. The infrared spectrum of this molecule has been studied[14] in the range 600—3100 cm^{-1} in vapour, liquid and in solutions. Sponer[15] and Sponer and Stallcup[16] photographed the ultraviolet absorption spectrum of 1,3,5-trimethylbenzene in vapour phase and located the forbidden (0,0) band and assigned some of the other bands. Sen[17] studied the electronic absorption spectrum of this molecule in the liquid and solid states and discussed the shift in the (0,0) band on change of phase. Sreeramamurty[18] studied the absorption spectrum of 1,2,4-trimethylbenzene in vapour phase and discussed the substituent effect of CH_3 group. The vibrational analysis of the electronic spectra of 1,2,3-trimethylbenzene has not yet been reported, though Kohlrausch and Pongratz[13] have reported its Raman spectrum. An investigation of the absorption spectra of 1,2,3- and 1,3,5-trimethylbenzenes has been undertaken here and a complete analysis of the observed bands is being proposed.

Experimental

Pure samples of 1,2,3- and 1,3,5-trimethylbenzenes have been obtained from Koch-Light Laboratories and were used after redistillation under reduced pressure. The vapour absorption spectra were photographed on Q-24 Zeiss Medium Quartz Spectrograph. Absorption cells of various lengths were used. The temperature of the bulb attached to the middle of the tube and which acted as reservoir of experimental liquid was varied from -10 to 30°C. The source for continuous radiation from a Beckman hydrogen lamp was used. The bands were best developed with a cell of 75 cm and a bulb temperature at 25°C in the case of 1,2,3-isomer and with a cell of 70 cm and a bulb temperature of 30°C for the other isomer. They were recorded on Ilford N-40 plates with a slit width of 20 μ. Typical spectrograms are shown in Figs. 1 and 2. The spectra lie in the region 2400—2800 Å for both the isomers and the dispersion of the spectrograph in this region is about 9 Å/mm. The bands were measured on a Hilger L-76 comparator having a least count of 0.001 mm. The accuracy of measurement for the sharp bands is ± 5 cm^{-1} and for the diffuse bands is ± 10 cm^{-1}.

Results and Discussion

Nearly 56 bands for 1,2,3-isomer and 66 bands for 1,3,5-isomer have been observed. The bands are degraded towards the longer wavelength side. The frequencies of the observed bands along with their relative intensities and proposed assignments are given in Tables 1 and 2. The correlation of the observed fundamentals in the ultraviolet absorption spectra of 1,2,3- and 1,3,5-trimethylbenzenes with the corresponding Raman frequencies is given in Table 3. The prominent vibrational transitions are shown in Figs. 3 and 4 for 1,2,3- and 1,3,5-trimethylbenzenes respectively.

Under the usual approximation, *i.e.*, considering the CH_3 group as a mass-point, the six fold symmetry, D_{6h}, of benzene drops to C_{2v} for 1,2,3-isomer. The forbidden $A_{1g} \rightarrow B_{2u}$ transition of benzene therefore reduces to an allowed $A_1 \rightarrow B_2$ transition. On the other hand for 1,3,5-isomer remains as D_{3h} and the electronic transition is A'_1—A'_2. The transition therefore is still forbidden.

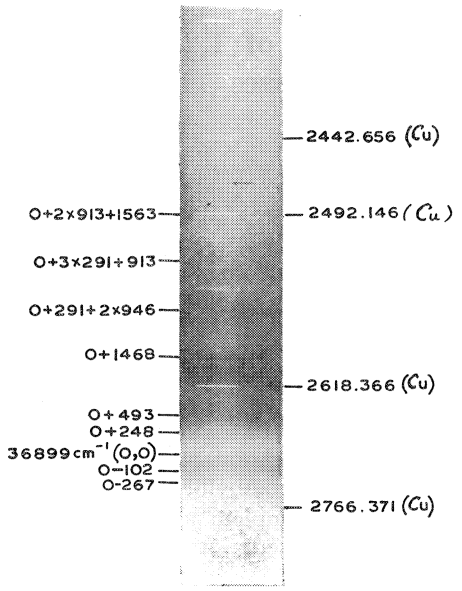

Fig. 1. Electronic absorption spectrum of 1,2,3-trimethylbenzene in vapour phase.

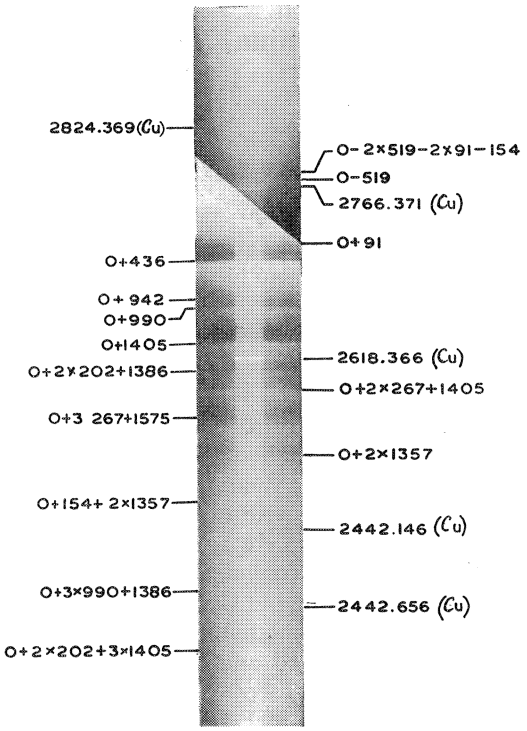

Fig. 2. Electronic absorption spectrum of 1,3,5-trimethylbenzene in vapour phase.

According to the Franck-Condon principle, if the internuclear distances in the ground and excited electronic states of the molecule are nearly the same, the (0,0) band of an allowed transition should either be most intense or one of the intense bands of the system. The strongest band at 36899 cm^{-1} appearing even at the lowest vapour pressure is assigned as the (0,0) band for 1,2,3-trimethylbenzene. The entire spectrum is analysed in terms of one ground state frequency of

N.B.; vvs=very very strong; vs=very strong; s=strong; ms=mediumstrong; m=medium; w=weak, and ew=extremely weak.

magnitude 267 cm^{-1} and 12 excited state frequencies of the magnitudes 248, 291, 453, 493, 523, 746, 834, 913, 946, 1350, 1468, and 1563 cm^{-1}. Difference bands at the separation of 34, 52, 69, and 102 cm^{-1} are observed on the longer wavelength side of the (0,0) band.

In the spectrum of the 1,3,5-isomer, because of the forbidden nature of the transition, the (0,0) band is not observed in the vapour phase. The (0,0) band appears with moderate intensity in the liquid and solid phase[17] at 36265 and 36326 cm^{-1} respectively, however, because of the expected shift in its position due to the intermolecular interactions, this by itself does not help in the location of the (0,0) band. A similar situation arises in the corresponding transition of benzene. It has been suggested that in benzene the transition becomes allowed due to interaction of a vibration of e_{1g} symmetry. In such a case bands would be observed on either side of the (0,0) band whose mutual separation would be the sum of the ground and excited state magnitudes of this vibration. A similar method can be used for the location of the (0,0) band in 1,3,5-trimethylbenzene also. We observed a strong band at 36998 cm^{-1} and a weak band at 36043 cm^{-1} and have taken these to correspond to $0\rightarrow1$ and $1\rightarrow0$ transitions involving this particular frequency making the transition allowed. In the Raman spectrum of 1,3,5-trimethylbenzene a depolarized line has been observed at 519 cm^{-1} and has been correlated to the 606 $cm^{-1}(e_{1g})$ in benzene. Taking this to be the frequency responsible for the appearance of the transition we can locate the missing (0,0) band at 36562 cm^{-1} (36043+519). A similar discussion by Sponer and Stallcup[16] leads to the estimated location of the (0,0) band at 36557 cm^{-1}. The entire spectrum is analysed in terms of two ground state frequencies of magnitudes 519 and 583 cm^{-1} and 12 excited state frequencies of magnitudes 267, 390, 436, 725, 841, 942, 990, 1252, 1357, 1386, 1405, and 1575 cm^{-1}. Bands are also observed at separation of 91, 154, and 202 cm^{-1} in the lower wavelength side of the main band and are assigned as due to $v'-v''$ transition.

In *o*-, *m*-, and *p*-xylenes the frequencies 720, 724, and 740 cm^{-1} respectively are assigned to the C–CH_3 stretch-

ing vibration in the ground state.[19] Sreeramamurty[18] assigned this mode at 711 cm^{-1} in 1,2,4-trimethylbenzene. In the present study this mode is assigned at 746 cm^{-1} and 725 cm^{-1} for 1,2,3- and 1,3,5-isomers respectively.

There is a great controversy in the assignment of ring breathing mode arising from 992 cm^{-1} (a_{1g}) mode of benzene for the substituted benzenes. It is observed in many cases that the value of this mode usually decreases as the number of substituents increases. The frequencies of magnitude 834 and 841 cm^{-1} observed in the observed bands at 37733 cm^{-1} and at 37403 cm^{-1} for 1,2,3- and 1,3,5-isomers respectively have been assigned to this mode.

There is a band observed at 37422 cm^{-1} with medium intensity for the 1,2,3-isomer involving a separation of 523 cm^{-1} from (0,0) band. This is taken as an excited state fundamental. The Raman data show a band at 536 cm^{-1}. The corresponding frequency in 1,3,5-trimethylbenzene is observed at 36043 cm^{-1}. This mode of vibration has been identified as one of the components of the 606 cm^{-1} (e_{1g}) mode of benzene.

The band at 37814 cm^{-1} having separation of 1252 cm^{-1} from the (0,0) band is observed with medium intensity and can be correlated with the strong and polarized Raman line observed at 1255 cm^{-1} for 1,3,5-trimethylbenzene. In analogy with toluene,[3] this mode is identified as the a_1 part of the degenerate (e_{1g}) benzene vibration 3047 cm^{-1}. No such band is observed for 1,2,3-trimethylbenzene.

The medium strong band observed at 38249 cm^{-1} at a separation of 1350 cm^{-1} can be correlated with a band observed at 1377 cm^{-1} in the Raman spectrum of 1,2,3-isomer. Similarly a strong band at 37919 cm^{-1} at a separation of 1357 cm^{-1} can be correlated with 1380 cm^{-1} in Raman spectrum of 1,3,5-trimethylbenzene. In methyl substituted benzenes a strong Raman line always appears at about 1375 cm^{-1} which has been assigned to the C–H in-plane bending vibration in methyl groups. Similarly, the bands at 38367 cm^{-1} *i.e.* at the separation of 1468 cm^{-1} from the zero band for 1,2,3-isomer and at 37967 cm^{-1} *i.e.* at the separation of 1405 cm^{-1} for 1,3,5-trimethylbenzene are assigned to C–H out-of-plane (asymmetric) bending mode in the methyl group.

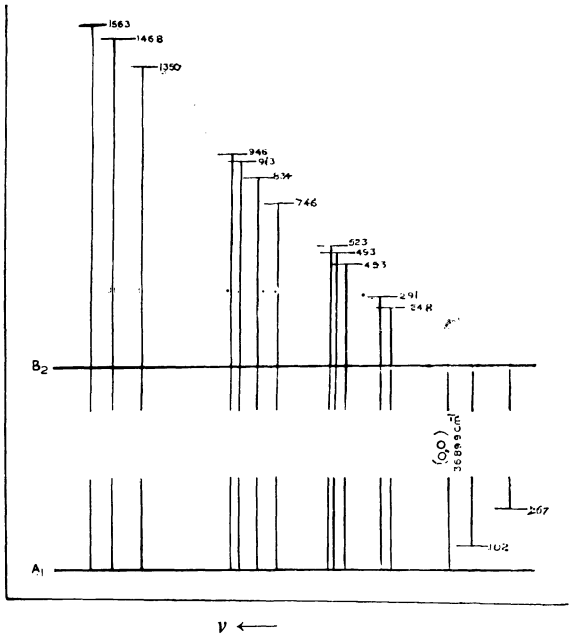

Fig. 3. Prominent vibrational transitions in the UV absorption spectrum of 1,2,3-trimethylbenzene in vapour phase.

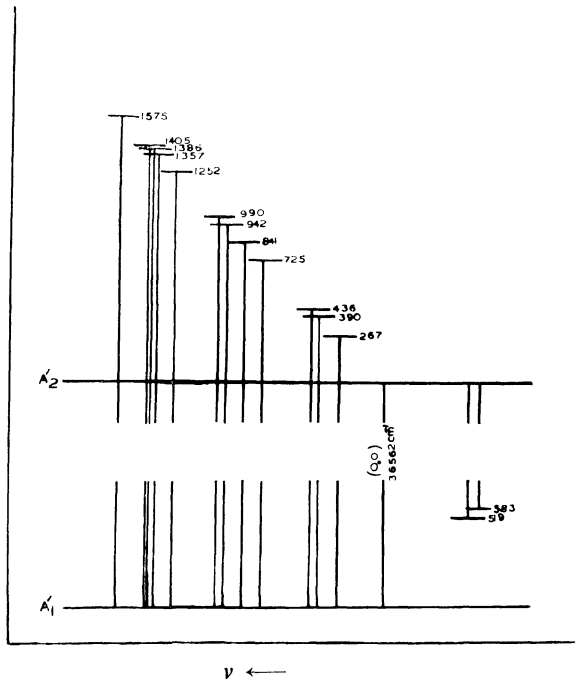

Fig. 4. Prominent vibrational transitions in the UV absorption spectrum of 1,3,5-trimethylbenzene in vapour phase.

19) K. S. Pitzer and D. W. Scott, *J. Amer. Chem. Soc.*, **65**, 803 (1943).

The medium strong band observed at 38462 cm^{-1} at a separation of 1563 cm^{-1} from the zero band for 1,2, 3-trimethylbenzene on the lower wavelength side can be correlated with 1589 cm^{-1} reported in Raman spectrum. Another medium strong band at 38137 cm^{-1} at a separation of 1575 cm^{-1} from the zero band can be correlated with 1611 cm^{-1} in Raman spectrum of 1,3, 5-trimethylbenzene. These Raman bands are polarized. This totally symmetric frequency may be assigned to the a_1 part of 1600 cm^{-1} (e_{1g}) benzene vibration.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2035—2038 (1971)

Solid Complex Formation of Aminomalonic Acid with Glycine[1]

Toshio KINUGASA, Juziro NISHIJO,* Genzo HASHIZUME,** and Isamu IMANISHI*

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe

(Received November 13, 1970)

It was found by X-ray analysis that aminomalonic acid forms a solid complex with glycine in a molar ratio of 1 : 1 on crystallization from an aqueous solution. DTA-TGA of the solid complex at a heating rate of 1.0°C/min in air showed that the solid complex decarboxylates at higher temperature, but more slowly than aminomalonic acid and that both endothermic and following exothermic peaks which were distinctly observed in the region of decarboxylation of aminomalonic acid at temperatures 108—140°C are only slightly observed at 168—175°C. Activation energies in the thermal decomposition of aminomalonic acid and the solid complex, caluculated from themogravimetric curves, were 69.4 kcal/mol and 21.3 kcal/mol, respectively. The results indicate that aminomalonic acid is thermally more stabilized than the acid itself by forming the solid complex with glycine.

The authors reported[2] the results of differential thermal analysis of aminomalonic acid. Crystals were obtained by distilling off the solvent from a saturated aqueous solution of aminomalonic acid on a water bath at 25°C under a pressure of 10 mmHg. When the concentration process for each mother liquid was repeated seven or eight times, no further crystallization occurred easily with concentration, and a viscous residue remained, which turned into crystalline powder on being allowed to stand in air. Results of elementary analysis were: H, 5.60; C, 31.21%. Calculated values for aminomalonic acid and glycine are: H, 4.20; C, 30.26% and H, 6.67; C, 32.00%, respectively. Thus, it seems that a fair amount of glycine was contained in these crystals. On heating of aminomalonic acid with micro melting point apparatus,[3] decomposition took place accompanied with bubbling but no such phenomenon was observed for the crystalline powder. It seems that aminomalonic acid can form a solid complex with glycine on crystallization from an aqueous solution. The present study was carried out to confirm this supposition.

Experimental

Materials. Aminomalonic acid purified by recrystallization and glycine (Merck Co.) were dissolved in water with the molar ratio of 1 : 1 and the solvent was distilled off on a water bath at 25°C under a reduced pressure of 3—5 mmHg to leave a viscous residue. When this was allowed to stand in air, crystalline powder was obtained. These crystalline powder was obtained. These crystals are designated as AM_1–G_1 hereafter (AM: aminomalonic acid, G: glycine, the subscripts refer to the molar ratio). They were dried at 50°C for 5 hr., pulverized thoroughly in an agate mortar, and used for further experiments. Samples of different molar ratios were also prepared according to the same procedure.

Analysis. X-ray analysis was carried out with an X-ray diffractometer, Rigaku Denki Geigerflex, using Ni filtered CuK_α radiation. IR spectra were measured with a Nihon Bunko Grating Infrared Spectrometer, type DS-402G, by means of the KBr-pellet method. DTA-TGA was carried out by using the same apparatus as reported.[2] Samples of 200—500 meshes were used for measurements.

Determination of the contents of aminomalonic acid and γ-glycine. Aminomalonic acid was mixed with AM_1–G_1 to obtain samples with various weight ratios of aminomalonic acid to AM_1–G_1. The intensity [(half width) × (height)] of diffraction peaks due to aminomalonic acid at 24.1° (2θ) in these samples was measured to obtain a calibration curve used for the determination of aminomalonic acid content. Conditions of measurements were: 40 kV-1.5 mA, full-scale 400 count/sec, scanning speed 0.5°(2θ)/min, chart speed 20 mm/min. γ-Glycine was added to obtain the samples with various weight ratios of γ-glycine to AM_1–G_1. A calibration curve obtained with these samples, employing the height of diffraction peak due to γ-glycine at 21.8 (2θ) as peak intensity, was used for the determination of γ-glycine content. The conditions were the same as in the case of aminomalonic acid except for 40 kV-1.0 mA and 40 mm/min of chart speed.

Results and Discussion

The Complex Formation. X-ray diffraction patterns of aminomalonic acid, α-, β-, γ-glycine are

shown in Fig. 1. The samples having ratios of aminomalonic acid to glycine 1 : 1, 1 : 2, 2 : 1, prepared according to method described in the experimental section, are shown in Fig. 2.

AM_1–G_1 gave a new diffraction pattern differing from each component, *viz.*, aminomalonic acid and glycine (α-, β-, γ-). AM_2–G_1 gave diffraction patterns of AM_1–G_1 and aminomalonic acid, whereas AM_1–G_2 gave those of AM_1–G_1 and γ-glycine. AM_4–G_3 and AM_5–G_4 also gave diffraction patterns of AM_1–G_1 and aminomalonic acid, while AM_3–G_4 and AM_4–G_5 gave those of AM_1–G_1 and γ-glycine.

TABLE 1. QUANTITATIVE DETERMINATION OF AMINOMALONIC ACID (IN AM_2–G_1, AM_4–G_3, AND AM_5–G_4) AND γ-GLYCINE (IN AM_1–G_2, AM_3–G_4, AND AM_4–G_5) BY X-RAY ANALYSIS

	Calcd %		Found %

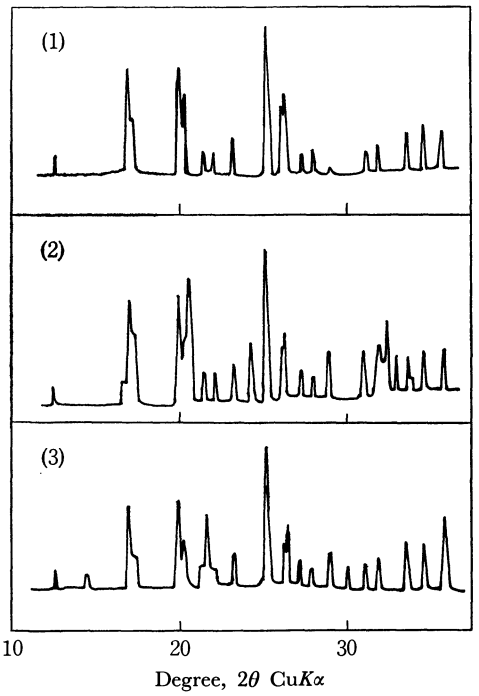

Fig. 2. X-ray diffraction patterns of AM_1–G_1 (1), AM_2–G_1 (2), and AM_1–G_2 (3).

The amount of aminomalonic acid was determined by means of calibration curves for AM_2–G_1, AM_4–G_3, and AM_5–G_4, and that of γ-glycine for AM_1–G_2, AM_3–G_4, and AM_4–G_5. The weight percentages of excess aminomalonic acid and γ-glycine, calculated by assuming that the crystals showing diffraction patterns of AM_1–G_1 are formed by the equimolar mixture of aminomalonic acid and glycine, agreed with the experimental values. The results are shown Table 1. Accordingly, it was confirmed that aminomalonic acid can form a solid complex with glycine in a molar ratio of 1 : 1 and the solid complex shows the diffraction patterns of AM_1–G_1. The diffraction angles and relative intensities are given in Table 2.

The infrared absorption spectra of the equimolar mechanical mixture of aminomalonic acid and γ-glycine (I), and AM_1–G_1(II) are shown in Fig. 3. Each absorption band in (I) could be assigned to those of aminomalonic acid and γ-glycine, whereas the absorption bands observed in (II) were different from

those in (I). This indicates that there is an interaction between the molecules of aminomalonic acid and glycine.

Differential Thermal Analysis and Thermogravimetric Analysis. The solid line in Fig. 4 shows DTA–TGA curves of AM_1–G_1 in air. The amount of sample was 81.5 mg and the heating rate was 1.0°/min. For comparison, DTA–TGA curves of aminomalonic acid are shown by dotted lines. Conditions of measurements were the same as in AM_1–G_1 except for the sample amount, which was 50 mg in the present case. From the TGA curve of AM_1–G_1, the decarboxylation started at 115°C, the amount of carbon dioxide liberated did not reach the theoretical value until 170°C. In the DTA curve, endothermic and the succeeding exothermic peaks observed in the region of decarboxylation of aminomalonic acid, were slightly observed at temperatures 168°—175°C. An endothermic peak was also observed in the neighborhood of 185°C, which is supposed to be due to the transition of γ-glycine to α-glycine.

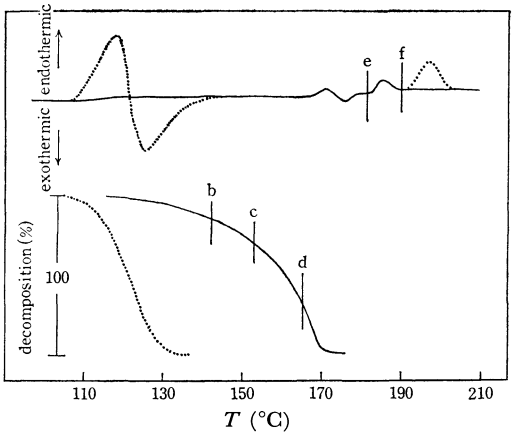

Fig. 4. DTA-TGA curves of AM_1–G_1 (solid lines) aminomalonic acid (dotted lines), in air.
Heating rate: 1.0°C/min. Sensivility: ±50 μV.
Reference: silica powder.

In order to examine the decarboxylation products of AM_1–G_1, samples were collected at the stages of b, c, d, e, and f in the DTA–TGA curves in Fig. 4 and X-ray analysis was carried out. The results are shown in Fig. 5. At stage b, the diffraction patterns of γ-glycine and several unknown diffraction peaks were observed along with those of AM_1–G_1. At stage c, γ-glycine, unknown material and α-glycine were observed in addition to the initials material, AM_1–G_1. The intensities of unknown diffraction peaks increased at c, but at stage d they disappeared and the diffraction peaks due to γ- and α-glycine were observed for AM_1–G_1. At e, diffraction peaks due to γ- and α-glycine were observed, and at f merely those due to α-glycine. Accordingly, the endothermic peak at about 185°C was due to the heat of transition from γ- to α-glycine. It shifted to the lower temperature side by 13°C as compared with that of aminomalonic acid. The unknown intermediate of decarboxylation is under investigation.

Activation Energies of Decarboxylation of AM_1–G_1 and Aminomalonic Acid. Coats and Redfern[4] derived

the following equations for the determination of activation energy of solid state reaction accompanied by weight decrease.

If $n \neq 1$,

$$\log_{10}\left\{\frac{1-(1-\alpha)^{1-n}}{T^2(1-n)}\right\} = \log_{10}\frac{AR}{aE}\left[1-\frac{2RT}{E}\right]-\frac{E}{2.3RT} \quad (1)$$

If $n=1$,

$$\log_{10}\left\{\frac{-\log(1-\alpha)}{T^2}\right\} = \log_{10}\frac{AR}{aE}\left[1-\frac{2RT}{E}\right]-\frac{E}{2.3RT} \quad (2)$$

where α=fraction of decomposition, n=order of reaction, E=activation energy, A=frequency factor, $a=\mathrm{d}T/\mathrm{d}t$, T=absolute temperature,

Using equation (1) or (2), the activation energy of decarboxylation reaction of AM_1–G_1 and aminomalonic acid was obtained from the TGA curves (Fig. 4). Assuming that $n=0$, 1/2, 2/3, or 1 in the decomposition range of 17 to 65% for AM_1–G_1 and 12 to 60% for aminomalonic acid,

$\log_{10}\{1-(1-\alpha)^{1-n}/T^2(1-n)\}$ or $\log_{10}\{-\log(1-\alpha)/T^2\}$ was plotted against $1/T$. The linear relation was obtained at $n=0$ for AM_1–G_1 and at $n=1$ for aminomalonic acid (Figs. 6 and 7). The value of activation energy obtained was 21.3 kcal/mol for AM_1–G_1 and 69.4 kcal/mol for aminomalonic acid. Although AM_1–G_1 has a smaller activation energy than aminomalonic acid and is advantageous from the viewpoint of reaction rate, AM_1–G_1 reacts more slowly even at a higher temperature.

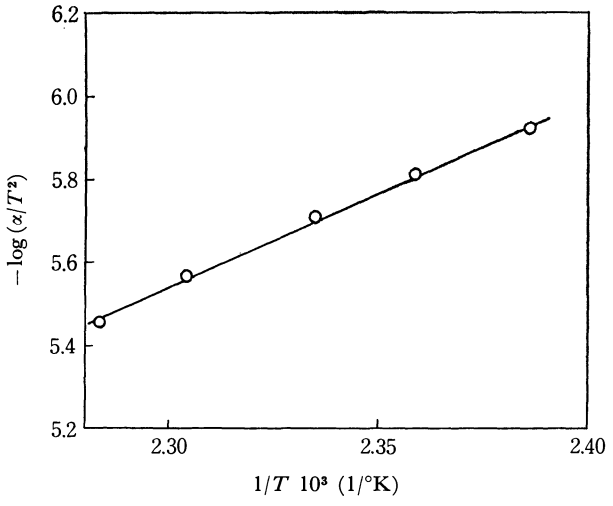

Fig. 6. Decarboxylation of AM_1-G_1. $n=0$

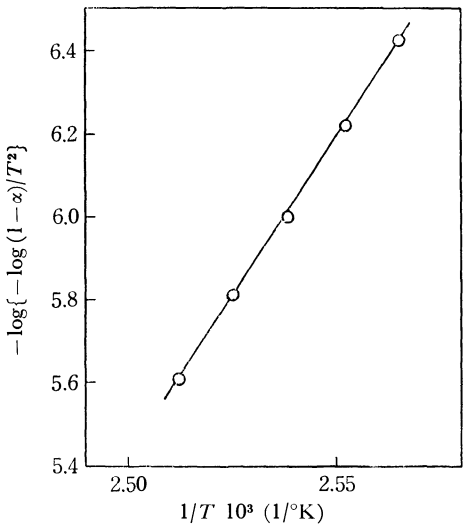

Fig. 7. Decarboxylation of aminomalonic acid. $n=1$

This indicates that the entropy term is effective in the depression of this reaction. This is attributed to the fact that, since the solid complex formed by the interaction of aminomalonic acid with glycine is thermally more stable than the crystals of aminomalonic acid alone, molecular motion is more restricted and the increase of entropy at the activated state was smaller in the solid complex than in the crystal of aminomalonic acid.

Conclusion

Aminomalonic acid can form an equimolar solid complex with glycine. In its crystalline state, aminomalonic acid is thermally stabilized due to its stronger interaction with glycine compared with the molecular interaction between aminomalonic acid molecules alone.

Photomicroscopic Observation of Dispersion State of Droplets in Flowing Emulsion[1)]

Kazushige SUZUKI and Takehiko WATANABE

Research Laboratory, Club Cosmetics, Co., Ltd., Naniwa-ku, Osaka

* *Laboratory of Biophysical Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai, Osaka*

(Received December 11, 1970)

The viscosity of dilute emulsion with disperse phase of volume fraction $\phi=0.005$—0.06 was measured, and the dispersion state of emulsion droplets under shear was observed with a photomicroscope. Oil components used were aromatic hydrocarbons, *i.e.*, benzene, *o*-xylene, and toluene, and saturated hydrocarbons, *i.e.*, cyclohexane, decaline, *n*-hexane, *etc.* As emulsifier, Arlacel 60 or Arlacel 83 was used for W/O type emulsion and Tween 20 for O/W type one. For the W/O type emulsions of aromatic hydrocarbon of low emulsifier concentration (0.2%), Einstein's equation could be applied to the viscosity at a high rate of shear in the range of ϕ below 0.02, in spite of the presence of aggregates of droplets in the flowing emulsion. When ϕ becomes 0.04—0.06, the deviation from Einstein's equation was large. In the case of higher emulsifier concentration (1%), the deviation from Einstein's equation was noticeable even for $\phi=0.01$, when Arlacel 60 was used as stabilizer. The results may be brought about by the increase of effective volume fraction of disperse phase owing to the inclusion of continuous phase liquid in aggregates. In the case of W/O type emulsions of saturated hydrocarbon and O/W type ones, irrespective of the kind of oil phase liquid, the aggregates were completely redispersed into primary droplets at a high rate of shear, and Einstein's equation could be applied.

In our previous studies on non-Newtonian flow of W/O type emulsions,[2)] we found that water-in-benzene emulsion (volume fraction of disperse phase, 0.1—0.6) showed the most noticeable dependence of viscosity on the rate of shear and that the dispersed droplets in the system formed large aggregates at a low rate of shear as compared with other emulsions prepared with hydrocarbons other than benzene *i.e.*, cyclohexane, liquid paraffin, *etc.* In order to study the characteristics of non-Newtonian flow of emulsions, photomicroscopic observation of the dispersion state of droplets under shear was made with dilute emulsions (volume fraction, 0.005—0.06),[3)] and it was found that in water-in-benzene emulsion, the aggregates formed in the emulsion could not be redispersed into primary droplets even at higher rates of shear than 2000 sec^{-1}.

In this paper, photomicroscopic observations are described on the dispersion state of droplets in the flowing emulsions under shear, where the emulsions show Newtonian flow characteristics and their viscosities can be represented by Einstein's equation.

Experimental

Sample. W/O type emulsions were prepared by using either sorbitan monostearate (Arlacel 60) or sorbitan sesquioleate (Arlacel 83) as stabilizer, and O/W type emulsions by polyoxyethylene sorbitan monolaurate (Tween 20). The oil phase liquids such as benzene, toluene, *o*-xylene, cyclohexane, decaline, kerosene, liquid paraffin, *etc.* were mixed with carbon tetrachloride to adjust their density to that of water. The volume fraction of disperse phase ϕ was 0.005, 0.01, 0.02, 0.04, and 0.06. The emulsions were prepared from water and oil phase liquid containing the emulsifier by shaking by hand or by mixing together with a high-speed mixer.

Measurements. As shown in Fig. 1, a light source and a photomicroscope were placed perpendicular to the axis of the capillary of Maron-Belner type viscometer[4)] (capillary: 0.064 cm in diameter and 25.4 cm in length) at an appropriate position where a part of thick glass of the capillary was flatened by polishing. In order to photograph the droplet image moving at a high rate of shear, a Xe-flash system having flash duration time less than 100 μ sec was used as the light source. The circuit of the flash system is shown in Fig. 2. The flashing tube is fed at 3 kV under generation of 15 kV trigger voltage in the starting electrode. Duration time is mainly determined by the capacity of the condenser connected in series with the flashing tube. The system used was provided with a 5 μF condenser.

Aggregates of droplets at various rates of shear were photo-

graphed and at the same time the viscosity of the emulsion was measured. Measurements were carried out at 32°C in a constant-temperature bath. Viscosity was expressed in terms of relative viscosity η_{rel} defined by

$$\eta_{rel} = \frac{\text{Viscosity of emulsion}}{\text{Viscosity of continuous phase containing emulsifier}}$$

Results and Discussion

With the exception of W/O type emulsions of aromatic hydrocarbon having volume fraction $\phi=0.04$—0.06, all emulsions showed Newtonian flow characteristics at high rates of shear over 100 sec^{-1}. Relative viscosity (η_{rel}) of the emulsions under a shear stress at the capillary wall, 17 dyne/cm^2, at which the rates of shear exceed 2000 sec^{-1}, are plotted against ϕ (Figs. 3, 4, and 5). The solid lines are drawn according to Einstein's equation.

As shown in Fig. 3, with the emulsion stabilized with 0.2% Arlacel 60, Einstein's equation could be applied to represent η_{rel} of the benzene emulsions with ϕ below 0.02. Figure 6 shows microscopic photographs obtained with the benzene emulsion with $\phi=0.01$. We see that the size of aggregates decreases with the increase of rates of shear. However, the droplets in the flowing emulsion are not dispersed as primary droplets even at high rates of shear of 500—3000 sec^{-1}. When ϕ of benzene emulsions increased to 0.04—0.06, the discrepancy between the observed value of η_{rel} and that calculated by Einstein's equation became large, and the viscosity could be represented by an

equation consisting of series of power of ϕ as follows.

$$\eta_{rel} = 1 + 2.5\phi + 14\phi^2 + 50\phi^3$$

In cyclohexane emulsions shown in Fig. 3, the droplets were completely dispersed as primary ones at high rates of shear of 500—3000 sec^{-1} irrespective of the values of ϕ. The results obtained with toluene and *o*-xylene emulsions were similar to those obtained with benzene system, and the results with the systems using such saturated hydrocarbones as decaline, *n*-

hexane, *etc.* as the suspending fluids were similar to those obtained with cyclohexane systems.

As shown in Fig. 4, in the benzene emulsions stabilized with 1% Arlacel 60, there were marked discrepancies between the value of η_{rel} and that calculated by Einstein's equation even with the emulsion of $\phi=0.01$. Even with the emulsion of $\phi=0.005$ showing Newtonian flow characteristics at a high rate of shear, the droplets in flowing emulsions were not dispersed as primary droplets. The size of aggregate was smaller in the case of emulsion stabilized with 1% Arlacel 60 (Fig. 7) than that with 0.2% Arlacel 60 (Fig. 6B). Thus, the higher values of η_{rel} of the former emulsion than the latter seems to be due to the increase of effective volume fraction of the disperse phase resulting from the formation of aggregate occluding the continuous phase liquid in the cluster of droplets.

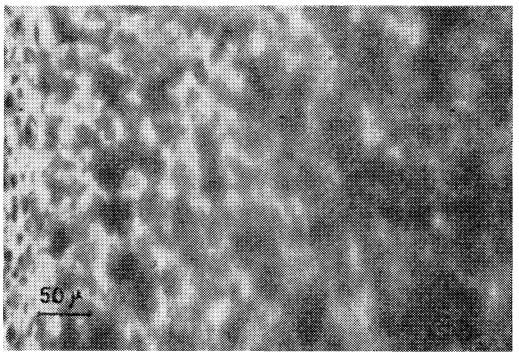

Fig. 7. Water in benzene ($+CCl_4$) emulsion ($\phi=0.01$) stabilized by 1.0% Arlacel 60 prepared by shaking by hand observed at shear stress, 8.34 dyn/cm², and rate of shear, 1230 sec⁻¹.

As shown in Fig. 5, in the benzene emulsions stabilized with Arlacel 83, discrepancies between the value of η_{rel} and that calculated by Einstein's equation was more marked with emulsions of high emulsifier concentration than those of lower concentration in the range of higher values of ϕ. However, the size of aggregate observed at a high rate of shear was smaller with emulsions of high emulsifier concentration. The increase in η_{rel} with the increase of emulsifier concentration is brought about by the increase of effective volume fraction of disperse phase owing to the formation of aggregate occluding the continuous phase liquid and/or owing to the increased solvation of droplets surface with the perfection of the emulsifier layer

around the droplets.

The above results show that in the case of water in benzene emulsion, droplets in the flowing emulsion at rates of shear below 3000 sec^{-1}, could not be dispersed as primary droplets. Albers and Overbeek[5] estimated the effective van der Waal's constant A between the water droplets in water in benzene emulsion from the minimum rate of shear to reach Newtonian region *i.e.*, to cause complete redispersion, and found a rather low value of $A=0.4\times10^{-14}$ erg based on the experimental value of the minimum rate of shear of $<100\ sec^{-1}$ for the emulsion stabilized by 1% Span 85 (sorbitan trioleate) of $\phi=0.14$ and $200\ sec^{-1}$ for the one stabilized by 1% Span 60 (sorbitan monostearate) of $\phi=0.175$. It should be mentioned that such a low value of A obtained by Albers and Overbeek was due to incomplete confirmation of the complete dispersion of droplets in the system.

In the case of O/W type emulsions irrespective of the kind of oil phase liquid, the aggregates formed in the emulsion were completely redispersed into primary droplets at a high rate of shear and Einstein's equation could be applied to represent the observed values of η_{rel} with the emulsions of values of ϕ as high as 0.06 as shown in Fig. 8.

The authors would like to express their gratitude to Professor Sôzaburo Ono for his discussions.

Proton Spin-Lattice Relaxation Studies of Intermolecular Interactions in Acetic Acid Solution

Kazuo SATO and Atsuo NISHIOKA

Department of Polymer Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 11, 1970)

Proton spin-lattice relaxation measurements were carried out by the rapid-passage method on the hydroxyl and methyl protons of acetic acid in carbon tetrachloride, benzene-d_6, and chloroform-d in order to investigate the effect of the self-association of acetic acid on the spin-lattice relaxation. It was found that there exists a maximum of the relaxation rate in carbon tetrachloride, and two maxima in benzene-d_6 and chloroform-d, on dilution with a solvent. This relaxation behavior was attributed to the change in the self-association mechanism of acetic acid. We tried to keep the proton-density constant in all solution in order to avoid any ambiguity arising from the change in density by using the analogous deuterated compounds.

Previously we have studied the effect of the intermolecular interaction on the proton spin-lattice relaxation time, T_1, of chloroform, benzene, and acetone in solution.[1] We found that T_1's are sensitive to the intermolecular interaction or the molecular association, even if its lifetime is very short. In this paper, we will study the spin-lattice relaxation of the hydroxyl and methyl protons of acetic acid in carbon tetrachloride, chloroform-d, and benzene-d_6 respectively.

Hydrogen bonding in carboxylic acids has been investigated by a number of workers using nuclear magentic resonance and infrared spectroscopy.[2-4] Reeves and Schneider[5] have investigated the dilution curves of the chemical shift of the hydroxyl proton of acetic acid in a series of non-interacting solvents, such as carbon tetrachloride and cyclohexane, and found that, on dilution, the resonance moves first to a low field, but on further dilution moves to a higher field compared with its position in pure acetic acid. They have interpreted these results in terms of a polymer-dimer equilibrium in a concentrated acid solution and a dimer-monomer equilibrium in more dilute solutions. Reeves[6] has studied the changes in the chemical shift of the hydroxyl proton in some carboxylic acids on dilution in several solvents, and given evidence for the existence of chain-like hydrogen-bonded polymers in solutions and for the formation of weak acid-solvent complexes in dichloro-

methane and 1,2-dichloroethane. Many other chemical shift studies have been made of acetic acid and some carboxylic acids in solutions, and valuable information has been obtained.

Relaxation measurements of carboxylic acids have also been made by several authers. Tatsumoto[7] has studied ultrasonic absorption in propionic acid and discussed the disociation mechanism and the solvent effect on relaxation. Goldammer and Zeidler[8] have measured the proton and deuteron spin-lattice relaxation time of methyl and the self-diffusion coefficient in a binary mixture of water and acetic acid.

It is the purpose of the present study to investigate the effect of the self-association, the change in the association mechanism of acetic acid, and the intermolecular interaction with a solvent on the spin-lattice relaxation, and to discuss the microdynamic behavior of acetic acid in solution. We believe that the information on the microdynamic behavior together with that on the equilibrium properties will aid us in understanding in detail the nature of acetic acid in solution.

Experimental

Materials. The acetic acid was a super-special-grade sample purchased from the Wako Pure Chem. Co., Ltd., and the carbon tetrachloride was a spectroscopic-grade sample purchased from the Tokyo Kasei Co., Ltd. The acetic acid-d_4, benzene-d_6, and chloroform-d were provided by E, Merck AG, Darmstadt, and were used without further purification. All the materials were stored in a water-free atmosphere. The proton-density of all the solutions was kept constant by using analogous deuterated compounds in order to avoid any ambiguity in the spin-lattice relaxation arising from its change. In the NMR spectrum at a high gain, no signals due to impurities were observed. The atmospheric oxygen dissolved in the samples was removed carefully by several free-pump-thaw cycles in a NMR sample tube, and then under a vacuum the tube was sealed. After sealing, the NMR measurements were carried out immediately.

NMR Measurements. The NMR spectrometer used in this study was a JNM-C-60H spectrometer of Japan Electron Optics. Lab. operated at 60 MHz. The measurements of T_1 were carried out at 25±1°C by the adiabatic rapid-passage method with sampling. The experimental errors were found to be within ±3%. The corrections for the macroscopic solution viscosity were not carried out.[1]

Results and Discussion

Carbon Tetrachloride Solution. In Fig. 1, the spin-lattice relaxation rate T_1^{-1}, of the methyl and hydroxyl proton of acetic acid *versus* the mole fraction of acid is shown. The proton density is constant at all compositions and equals to 41.65×10^{20} per unit of volume. It is clear that, on dilution with carbon tetrachloride, the T_1^{-1} of the hydroxyl proton gradually increases up to a value larger than that in pure acid

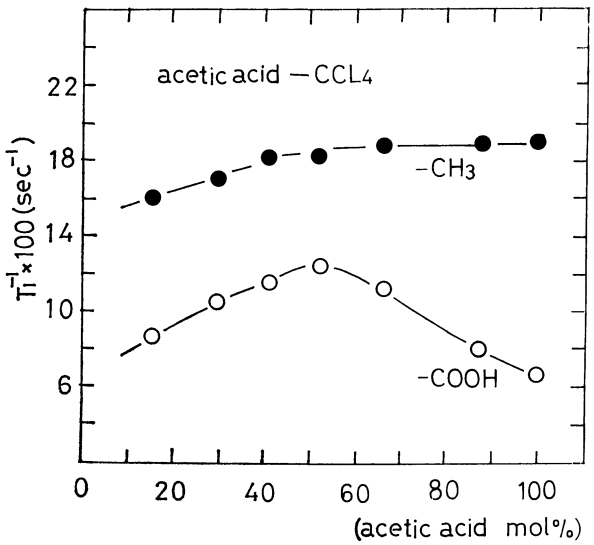

Fig. 1. Plots of $1/T_1$'s of the hydroxyl (○) and methyl (●) protons of acetic acid in carbon tetrachloride *vs.* apparent mole fraction of acetic acid.

by a factor of 2 and that a broad maximum exists at 50 mol% of acid. No distinct maximum is observed in the plot of the T_1^{-1} of the methyl *versus* mole fraction of acid, but on dilution beyond 50 mol% the T_1^{-1} decreases distinctly.

Goldammer and Zeidler have shown that the maximum of the relaxation rate of the methyl protons and deuterons exists at 50 mol% of acid in a water-acetic acid system, and that at this concentration the self-diffusion coefficient exhibits the minimum. The disagreement regarding the relaxation behavior of the methyl between their results and those in the present study is considered to reflect the difference in the association mechanism and in the acid-solvent interaction in aqueous and non-polar environments. If the self-diffusion coefficient is determined for a carbon tetrachloride solution, a detailed discussion will be possible.

Over the experimental range of the acid concentration studied, the polymers of acids may be predominant over the cyclic dimer.[9] The minimum of the hydroxyl proton chemical shift has been observed at a lower concentration than 5 mol% of acid in carbon tetrachloride,[5] at which point the dimer should be predominant. Therefore, we will discuss the results of the spin-lattice relaxation studied in this experiment in terms of changes in the length of the polymer chains. On dilution, the length of the chains is considered to increase gradually, probably because of the decrease in the dielectric constant of the solution; the polymer must become more stable and rigid to compensate for the entropy decrease of the solution. As the microdynamic molecular motions of the stable and rigid polymer chains should be reduced extensively compared with those of the weak chains, the spin-lattice relax-

ation rate must increase by a factor of 2 in the present study. On the other hand, in a solution more dilute than 50 mol% of acid, the polymer chains shorten. Moreover, in this concentration region, the polymer-dimer equilibrium may become appreciable, and the fraction of the dimer increases gradually.

Our interpretation does not conflict with the results of the chemical shift studies. The increase in the chain length on dilution is considered to result in the low field shift of the hydroxyl proton, because the fraction of the terminal acetic acid molecules, whose hydroxyl proton resonates at a higher field than that of the acid participating in the hydrogen bonding, decreases.[6] The observed chemical shift is the average of those of the protons in two different sets of circumstances because of the rapid averaging of the shielding effects. Contrary to the shortening of the chain length, the fraction of the dimer may increase in the lower concentration region. The hydroxyl proton of the dimer is considered to resonate at a lower field than that of acid participating in the internal hydrogen bonding of the chains, because the anisotropy of the susceptibility of the carbonyl group contributes more effectively to the hydroxyl proton of the dimer as a result of the cyclic structure of the dimer.[10] Thus, the average proton resonance may be concluded to move to the low field on dilution.

It may be supposed that, if experimental measurements were made on a solution more dilute than a 5—10 mol% acid solution, spin-lattice relaxation behavior due to the predominant dimer structure might be observed. The experimental results that the T_1^{-1} of the methyl, except in a dilute solution, does not follow the changes in the length of the polymer chains described above probably reflects the relatively free rotation of methyl about the C_3 axis. Indeed, Goldammer and Zeidler have shown that the correlation time of the internal rotation of the methyl is very short compared with that of the rotational motion of the whole molecule.

Benzene and Chloroform Solution. In Fig. 2, the plot of the T_1^{-1} of acetic acid in benzene-d_6 *versus* the acid concentration is shown. Contrary to the results on a carbon tetrachloride solution, two distinct maxima are observed in the relaxation behavior of the hydroxyl proton, but that of the methyl decreases linearly on dilution. We attribute the maximum in the high-concentration region to the changes in the polymer length described in the previous section, and that in the low-concentration region, to the relaxation behavior of the dimer and the dimer—monomer equilibrium which is not observed in carbon tetrachloride.

Shimizu[11] has investigated the change in the chemical shift of acetic acid in benzene, and found that the acid concentration at which the minimum of the hydroxyl proton chemical shift occurs is 30—40 mol%, higher than that in carbon tetrachloride. He has interpreted the results in terms of acid-benzene interaction, in which the acid monomer becomes stable and

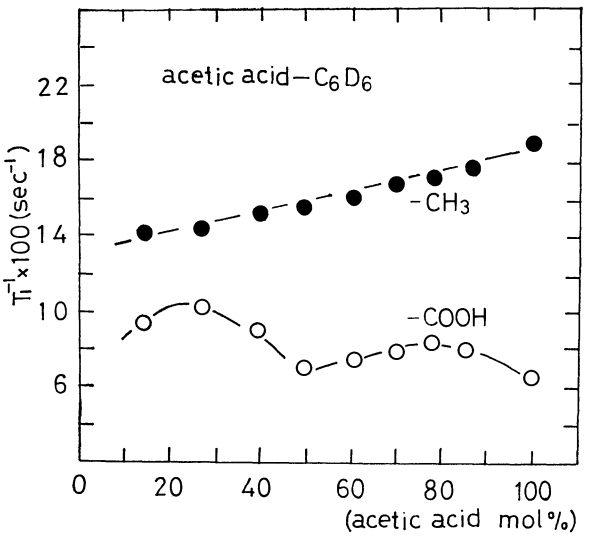

Fig. 2. Plots of $1/T_1$'s of the hydroxyl (○) and methyl (●) protons of acetic acid in benzene-d_6 *vs.* apparent mole fraction of acetic acid.

the monomer fraction is appreciable even in the high-concentration region of acid where, in carbon tetrachloride, the monomer scarcely exists at all. The dimer fraction is considered to be predominant at the acid concentration of 30—40 mol%. At almost the same acid concentration, the maximum of the relaxation rate of the hydroxyl proton is observed. Therefore, our consideration described above is considered probably to be true. Davis and Pitzer[12] have also shown evidence for the interaction between benzene and acetic acid by their chemical shift measurements. In

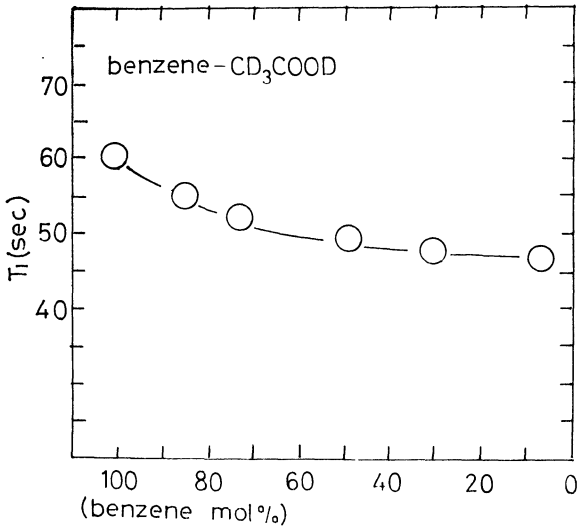

Fig. 3. Plot of $1/T_1$'s of benzene in acetic acid-d_4 *vs.* apparent mole fraction of benzene.

Fig. 3, the T_1's of benzene in acetic acid-d_6 are shown *versus* the mole fraction of benzene. It is clear that the spin-lattice relaxation of benzene is affected by the presence of acetic acid. This implies that the interaction between benzene and acetic acid exists and influences the microdynamic molecular motion to the degree of changing the spin-lattice relaxation behavior.

It has been well known that the dimer form of acetic acid is considerably stable. For example, Reeves and Schneider[5] have shown that, even in the gaseous state, the acetic acid dimer exists. Therefore, we consider that the decrease in the microdynamic molecular mobility and the relaxation rate of the dimer should be greater than those of the monomer and the less stable polymers. This expectation can be clearly verified from Fig. 2. Recently, Rothschild[13] has studied the translational molecular motion of neat acetic acid and discussed the possibility that the dimeric form is stable and can perform the translational jumps as a unit. The relaxation rates of the polymers in benzene are smaller than those in carbon tetrachloride, and the position of the maximum in the former deviates to a higher acid-concentration region than that in the latter. It is suggested that the polymer chains become less stable and weak through the acid-benzene interaction and show a tendency to shorten in the higher-acid-concentration region.

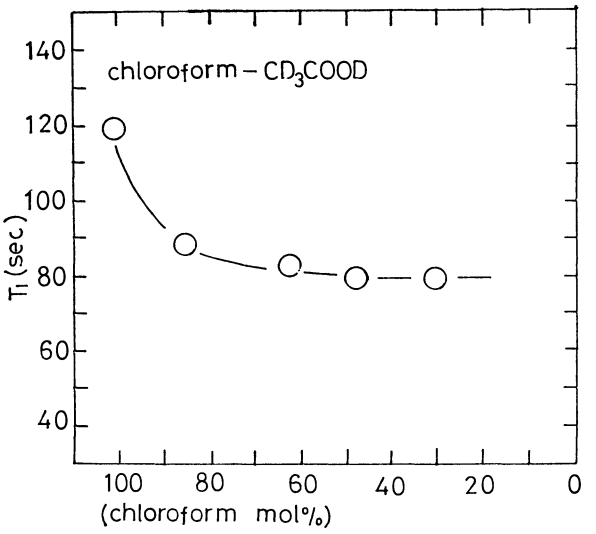

Fig. 5. Plot of $1/T_1$'s of chloroform in acetic acid-d_4 *vs.* apparent mole fraction of chloroform.
The number density of protons is constant; $N=29.8\times10^{20}$. Apparent mole fraction of chloroform was varied by addition of chloroform-*d*.

In Fig. 4, the plot of T_1^{-1} of acetic acid in chloroform-*d* is shown *versus* the acid concentration. It seems reasonable to decompose the curve thus obtained into two relaxation curves. In chloroform, there exist two maxima, just as in benzene. The one appearing at the low acid concentration is considered to reflect the relaxation behavior of the predominant dimer, while the other, at the high concentration, may be due to the relaxation of the polymers. Except for the position of the maximum at the high concentration, the other relaxation behavior, such as the relaxation rate and the position of the maximum at the low concentration, is almost identical with that in benzene. The small difference between the two cases may arise from the difference in the acid-solvent interactions. Chloroform interacts with acetic acid, and the spin-lattice relaxation is affected by the chloroform-acid interaction, as is shown in Fig. 5.

It was found that the self-association of acetic acid exerts a pronounced effect on the spin-lattice relaxation of the hydroxyl proton, and that the relaxation behavior largely depends upon the concentration of acid and the kind of solvents. The spin-lattice relaxation study may provide useful information about the microdynamic molecular motion of acid and may, together with the chemical shift and infrared measurements, allow us to infer the mechanism and the nature of the self-association of acetic acid.

The Protonation of Aromatic Hydrocarbon Radical Anions. II. Interpretations of the Rate Constants in Terms of HMO Calculations

Shigeo HAYANO and Masamichi FUJIHIRA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 14, 1970)

The rates of the protonation of aromatic hydrocarbon radical anions with water in dimethylformamide (DMF)-water mixtures were measured by means of the decay of the visible absorption maxima of radical anions with time. The rates were found to be greatly accelerated by the increasing water content in DMF-water mixtures. This behavior suggests that the negative charge is much more localized in the transition state than in the original radical anion. The rate constants in DMF could be obtained by extrapolation. The correlation of these rate constants to the molecular structure of radical anions was discussed on the basis of the results of HMO calculations. This correlation and the solvent effect could be interpreted by means of the charge-transfer mechanism.

In a previous paper[1] a study of the mechanism of the protonation of the aromatic hydrocarbon radical anions in DMF-water mixtures was reported; there the radical anions of biphenyl, naphthalene, phenanthrene, anthracene, 1,2-benzanthracene, and pyrene were found to decay by a first-order reaction:

$$\frac{d[R^-]}{dt} = -2k[H_2O][R^-] = -k_{app}[R^-] \quad (1)$$

through the following sequence:

$$R^- + H_2O \xrightarrow{k} RH\cdot + OH^- \quad (2)$$

$$RH\cdot + R^- \rightleftharpoons RH^- + R \quad (3)$$

$$RH^- + H_2O \xrightarrow{k'} RH_2 + OH^- \quad (4)$$

The same results were obtained for anthracene by the use of the ESR technique by Umemoto.[2]

The present paper will deal with the rate of the protonation reaction of Eq. (2) in DMF-water mixtures obtained by measuring the change in the visible absorption maximum with the time,[1] with the effect of the solvent on the rate, and with the correlation of the observed rate constants with the molecular structures of the reagents.

Experimental

All the materials and apparatus were the same as in the previous paper.[1] As the supporting electrolyte, tetraethylammonium bromide (TEAB) was used. The measurements of the absorbance against the time were carried out at the λ_{max} of the radical anions: biphenyl, 407 mμ; naphthalene, 368 mμ; phenanthrene, 421 mμ; anthracene, 725 mμ; 1,2-benzanthracene, 415 or 758 mμ, and pyrene, 742 mμ. All the measurements were carried out at 20°C.

Results and Discussion

The Solvent Effects on the Rate of Protonation. The apparent rate constants, k_{app}, which are equal to $2k[H_2O]$ are given in Table 1, while the effect of the water content on the rate constant, $k(M^{-1}sec^{-1})$, as calculated from k_{app}, is shown in Fig. 1.

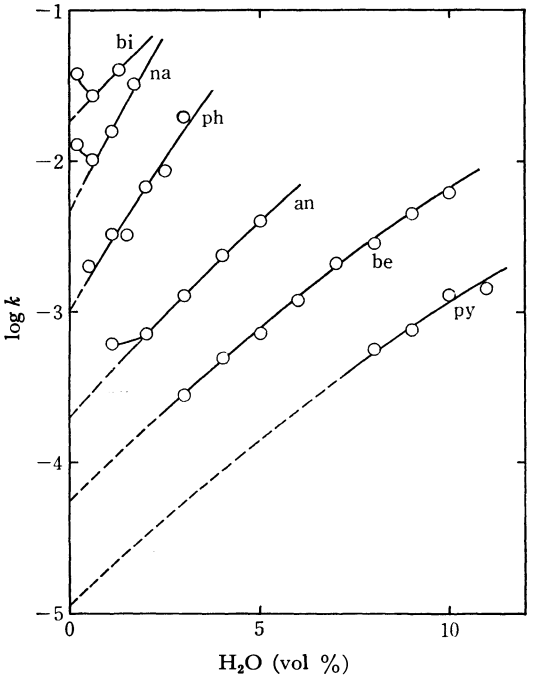

Fig. 1. The effect of water content on the rate constant k: bi, biphenylide; na, naphthalenide; ph, phenanthrenide; an, anthracenide; be, 1,2-benzanthracenide; py, pyrenide radical anion.

It is well known[3] that a bimolecular reaction such as that between anions and polar molecules shown in Eq. (5) is very much faster in dipolar aprotic solvents than in protic solvents:

$$Y^- + R_3CX \rightarrow \left[\begin{array}{c} R \quad R \\ \diagdown \quad \diagup \\ Y\cdots C\cdots X \\ | \\ R \end{array} \right]^- \rightarrow YCR_3 + X^- \quad (5)$$

where protic solvents, such as water, methanol, and formamide, are hydrogen-bond donors, while dipolar aprotic solvents, such as DMF, dimethylsulfoxide (DMSO), and acetonitrile, are not hydrogen-bond donors but are highly polar molecules. This behavior can be explained qualitatively as follows: a small anion, Y^-, in the original system where the negative

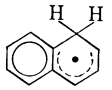
charge is concentrated is greatly stabilized by the hydrogen-bonding interaction with protic solvents as compared with the activated complex in the transition state, where the charge is more dispersed, while such a specific solvation does not occur in aprotic solvents. Consequently, the activation free energy of the reaction in Eq. (5) in aprotic solvents is smaller than that in protic solvents.

As is shown in Fig. 1, however, such is not the case for the protonation reaction of aromatic hydrocarbon radical anions with water, where the reaction is faster in more protic media. The reason for this behavior seems to be as follows: the negative charge is more localized on a certain atom in the activated complex than in the original radical anion, and, therefore, the activated complex is more stabilized than is the radical anion by changing the solvent from aprotic to protic.[4]

The effect of increasing of water content on the rate constants depends upon the molecular structures of the aromatic hydrocarbons. That the rate constants of naphthalenide and phenanthrenide are more influenced by the water content than is biphenylide radical anion predicts that the rate of the protonation of biphenylide will be slower than those of naphthalenide and phenanthrenide in the case of higher-water-content media. In fact, the rates of the protonation of aromatic hydrocarbon radical anions in 2-propanol were measured by Dorfman *et al.*[5,6] to be in this order: naphthalenide>phenanthrenide>biphenylide.

As has been described above, the rates of the reactions of anions with polar molecules are greatly influenced by the hydrogen-bonding interaction of the anions with protic solvents. Therefore, for the rate constants obtained in aprotic solvents, the effect of the molecular structure on the rate can be interpreted in terms of MO calculations, without taking the hydrogen-bonding effect into account. In the present system, the rate constants in DMF free from water can be obtained by extrapolation. Increases in k were found at low concentrations of water (Fig. 1). These may be due to additional decay through other reactions, *e.g.*, protonation with DMF[7,8] or with impurities. These reactions can be practically eliminated from competition with the protonation with water if enough water is added.

Interpretations of the Rate Constants of the Protonation in Terms of HMO Calculations. Because of the succeeding rapid electron-transfer reaction (Eq. (3)), no products of the protonation reaction (Eq. (2)) could be observed in the present system. However, the structures of the products may be similar to that of the so-called σ-complex[9] in the aromatic substitution reaction, as is shown below, where naphthalene is taken as an example:



(6)

These structures were ascertained experimentally for the analogous reactions in low-temperature alcohols.[10,11]

In order to interpret the course of the reduction process, Hoijtink[12] assumed that the logarithm of the rate constant of protonation is linearly proportional to the charge density at a particular carbon atom. Then, the rate constant was expressed by:

$$k = \kappa \exp(C\rho_s/kT) = \kappa \exp(\gamma\rho_s) \quad (7)$$

where κ, C, and γ are constants and where the charge (or spin) density, ρ_s, at a carbon atom, s, is given by the square of the coefficient in the HMO for the first antibonding level. By this equation, the position in the hydrocarbon molecule at which proton addition occurs was explained, but the relative rates among different species could not be explained.

The rate constants of analogous reactions in alcohol

$$R^{\cdot-} + ROH \xrightarrow{k_a} RH\cdot + RO^- \quad (8)$$

were obtained by the technique of pulse radiolysis by Dorfman *et al.* They found that the rate constants for Reaction (8) depend upon the properties of the alcohol[6,13] and the nature of the aromatic radical anions.[5,6] They showed a fairly good correlation between the values for k_a and the acidity of the alcohol. They attempted to interpret the dependence of k_a on the nature of the aromatic radical anions in terms

of the delocalization energy, but did not succeed. This failure was partly because the k_a values obtained in protic solvents were used for comparison.

The spin density, ρ_s, and the localization energy, L_s^-, of radical anions, and the coefficient, m_{m+1}, of the energy of the lowest vacant MO of the aromatic hydrocarbons studied in the present work, are given in Table 2, in which some of the values have been calculated by the present authors and others cited from the literature.[14,15] For comparison, the values of benzene are also given. The localization energy, L_s^-, is given by:

$$L_s^- = M^- - M_s \tag{9}$$

where the π-energy of the radical anion is $(n+1)\alpha+M^-\beta$ and that of protonated radical is $(n-1)\alpha+M_s\beta$, where s denotes the position of the carbon atom, and n, the number of π-electrons of the parent molecule. It is reasonable to assume that the protonation will occur at the position at which the localization energy is the smallest. Therefore, Hoijtink's assumption may be superseded by this localization method as far as the problem is the position at which the protonation occurs predominantly. The predictions by Hoijtink accord with those by the localization method except in the case of biphenyl. The experimental results[15] in the reduction of hydrocarbons with alkali metals agree with these predictions. The spin density of the biphenylide radical anion is the highest at position 4, but the localization energy is the smallest at position 2, and the reduction products have been reported to be 2,5-dihydrobiphenyl[16] or 1,4-dihydrobiphenyl.[17] The following discussion will be based on the assumption that the protonation occurs at the position with the smallest localization energy except in the cases of biphenylide and 1,2-benzanthracenide. For biphenylide, position 4 is also considered. The reduction product of 1,2-benzanthracenide has been reported to be the 7,12-dihydro-derivative.[18] The positions 7 and 12 are taken into consideration, for the two positions are not equivalent to each other.

For the common proton donor, the standard free energy of the protonation reaction (2) should have a linear relation with the value of the smallest localization energy, L^-, if the σ-bond energy changes caused by proton addition and the free energy changes of solvation are practically constant for these hydrocarbons:

$$\Delta G^\circ = L^- + \text{const.} \tag{10}$$

From the linear free-energy relationship, the logarithms of the observed rate constants can be expected to be linear in relation to the localization energy.

The ionization potential, I, of the radical anion

$$R^- \rightarrow R + e \tag{11}$$

is equal to the electron affinity of the parent molecule and is correlated with m_{m+1} by the following equation:

$$I = -(\alpha + m_{m+1}\beta) \tag{12}$$

These ionization potentials are known to be linear in relation to the polarographic half-wave potentials (or the reduction potentials) in aprotic solvents,[19] and a correlation between the reduction potentials and the rates of the analogous reactions has been reported.[20]

In Table 2, the rates of the protonation of aromatic hydrocarbon radical anions with water in DMF are also given. Neither the highest spin density, ρ_s, the smallest localization energy, L^-, nor m_{m+1} (or ionization potential I) is, however, found to have a linear relation to the observed rate constants.

In the preceding discussion, the reactivity has been attributed to only either the electronic structures of the aromatic substrate or those of reagents, and these treatments cannot make the reaction completely clear. We undertook to interpret this reaction by means of the charge-transfer mechanism proposed by Nagakura.[21] By this concept, it would be possible not only to explain the orientation rule, but also to predict the electronic structures of the activated complexes. Furthermore, the dependence of the protonation rates on the acidity of proton donors will be explained more feasibly.

According to Nagakura's mechanism, the reaction can be interpreted as a transfer process between the no-bond and charge-transfer structures (abbreviated hereafter to CT structure) and the reaction process can be represented by the potential energy curve shown in Fig. 2, where the protonation of naphthalenide is

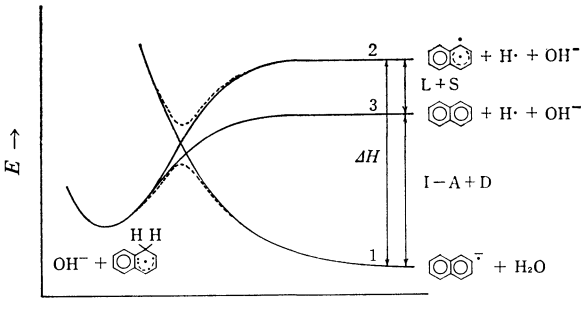

Fig. 2. Potential energy curve for the protonation of naphthalenide radical anion with water.

taken as an example. Curves 1 and 2 are associated with the no-bond and CT structures respectively. Curve 1 shows a repulsive feature, while Curve 2 resembles the Morse curve. The reaction proceeds along the dotted line which is formed by the resonance between the no-bond and CT structures. Further

detailed discussion about the physical meaning of this diagram can be referred to Ref. 21. As is shown in Fig. 2, the energy difference, ΔH, between the no-bond and CT structures at an infinite distance is given as follows:

$$\Delta H = I - A + D + L + S \tag{13}$$

where I is the ionization potential of a radical anion, A is the electron affinity of the OH· radical, D is the dissociation energy of an O–H bond of the proton donor, L is the localization energy of aromatic hydrocarbon for the following process:

(14)

and S is the energy required for the change in the hybridization from the sp^2 to the sp^3 of the ring carbon atom attacked by the reagent.

Nagakura also assumed that the activation energy, ΔE^*, is approximately proportional to the energy difference, ΔH:

$$\Delta E^* = a\Delta H \tag{15}$$

where a may be regarded as a constant for at least a fixed combination of the aromatic substrate and a reagent. Hereafter, a will be assumed to be constant in the present systems. A, D, and S can be considered as constants for the series; consequently, the logarithms of the rate constants should show a linear relation to the sum of $I+L$. However, no such linear relation was found, as has been noted before, for L_s^- in Table 2 is equal to $L+m_{m+1}$, which has a linear relation to $L+I$. The position at which protonation occurs can, however, be explained in terms of the localization energy.

The reason why the relative reaction rates cannot be interpreted adequately by Eqs. (13) and (15), is as follows: the contribution of the $L+S$ terms to the activation energy probably does not parallel that of the $I-A+D$ terms, since any localization of electrons and hybridization from sp^2 to sp^3 occurs only in response to the approach of the reagent and at an infinite separation these terms are completely eliminated.[22] Therefore, the potential curve 2 of the CT structure in Fig. 2 should be written as Curve 3.

As a result, the contribution of $L+S$ to the activation energy is found to be less than that of $I-A+D$; the activation energy should be written as follows:

$$\Delta E^* = a(I-A+D) + b(L+S) \tag{16}$$

$$a > b \tag{17}$$

The position attacked by a proton is still interpreted by the L term.

For the present system, a plot of the logarithms of the observed rate constants against $2I+L$ (or $2m_{m+1}+L$) gives a linear correlation, as is shown in Fig. 3, where a is taken temporarily to be double b. For the present, the ratio of a to b is arbitrary to some extent. In Table 2, the values of $2m_{m+1}+L$ are given instead of $2I+L$. If much more data for the rate constants of the reactions were obtained for the series where only the ionization potentials are greatly different and the localization energies are almost constant, or for the series where only the localization energies are different, the values of a and b in Eq. (16) could be determined experimentally. The benzene radical anion is known to be protonated much more rapidly than the biphenyl radical anion.[11] This is reflected by the small value of $2m_{m+1}+L$ shown in Table 2.

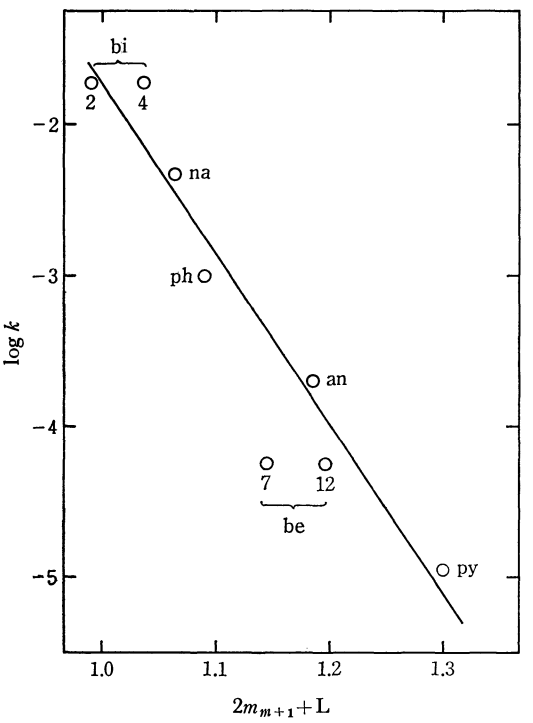

Fig. 3. Correlation of $\log k$ for protonation *versus* $2m_{m+1}+L$. For biphenylide and 1,2-benzanthracenide, the values for the positions 2,4 and 7,12, respectively, are shown. The abbreviations are the same as in Fig. 1.

In Eq. (14), the $-A$ and D terms represent the properties of the reagents, and the dependence of the rate constants on the properties of such proton donors as alcohols, water, and phenols can be interpreted by these terms. The activation energies are found from Eq. (16) to be smaller, as the reagents are more acidic, *i.e.*, as the dissociation energy, D, of the O–H bond is smaller and the electron affinity, A, of OH· or OR· is larger.

In addition, the solvent effect on the rate of protonation can be interpreted by this mechanism. The activated complex is a charge-transfer complex in which the no-bond and CT structures contribute to the resonance in almost equal proportions.[21] Therefore, the magnitude of the electron transfer between the radical anion and water is very close to 50% at the transition point: *i.e.*, about half a negative charge is localized on the oxygen atom of water in the activated complex. The solvent effect on the rates described above must be due to such a localized negative charge in the activated complex.[4]

The authors wish to thank Dr. M. Senō and Dr. M. Sukigara for their helpful discussions.

The Effect of Water on the Reduction Potentials of Some Aromatic Compounds in the DMF-Water System

Shigeo HAYANO and Masamichi FUJIHIRA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 15, 1970)

From the viewpoint of the interaction between the oxidized or the reduced form of a depolarizer and solvents, the solvent effect on the half-wave potentials was studied. Another factor affecting the $E_{1/2}$, *i.e.*, pH or ion-pair formation, was also examined. The correction for the liquid junction potential was carried out by the use of the ferrocene standard. The reduction products, radical anions or dianions, were found to be stabilized by the hydrogen-bonding with water where the hydrogen-bond interaction of the dianion was stronger than that of the monoanion. Aromatic hydrocarbon radical anions, whose charges are dispersed over the molecule, were less susceptible to this solvent transfer than were the anthraquinone radical anion and the dianion, whose charges are strongly localized.

In a previous paper,[1] a study of the rate of the protonation reaction of aromatic hydrocarbon radical anions with water has been reported; the rates were found to be greatly accelerated by the increase in the water content in DMF-water mixtures. This behavior was interpreted in terms of the hydrogen-bond interaction of radical anions or transition states with water.

The present work will deal with the interaction of the radical anions of several aromatic compounds with solvents.

Experimental

Materials. All the organic reagents except *p*-dinitrobenzene were obtained commercially. E.P.-grade anthraquinone was purified by recrystallization from ethanol, and E.P.-grade *p*-benzoquinone, by sublimation. G.R.-grade ferrocene, methylviologen, azulene, and fluoranthene were used without further purification. *p*-Dinitrobenzene was prepared and purified according to the method of Starkey[2] (mp. 173°C). The tetraethylammonium perchlorate (TEAP) and tetraethylammonium bromide (TEAB) were the same as have been described previously.[3] G.R.-grade lithium perchlorate was trihydrate and was dehydrated by heating it to a constant weight before preparing the DMF solution. G.R.-grade lithium hydroxide and a tetraethylammonium hydroxide aqueous solution were used without further purification. The solvents used were purified in the usual manner. The dimethylformamide (DMF) was the same as has been described previously.[3] The acetonitrile was dried over phosphorus pentoxide and then fractionally distilled; its water content was below 0.01%. G.R.-grade ethanol and acetone were used without further purification; their water contents were 0.3% and 0.2% respectively. These water contents were measured by Karl Fischer titration.

Polarography. A saturated calomel electrode was connected to the cell by a 1 N KNO_3-agar bridge,[3,4] which outlet was positioned just above the dropping mercury electrode. The use of a conventional aqueous potassium chloride agar salt bridge for precise work in non-aqueous solvents has been criticised.[5] Therefore, the use of the 1 N KNO_3 aqueous agar bridge must be checked; the effect of the dipping or aging time of the bridge was studied by the following experiments.

One end of the bridge was dipped in DMF-water solutions containing the same quantities of methylviologen and TEAP as the solution for polarographic measurements, while the other end was dipped in a 1 N KNO_3 aqueous solution. From one half-wave potential measurement with the bridge to another, the aging solution was renewed, because the dissolution of the bridge components contaminates the aging solution.

In the studies of other reducible substances, the 1 N KNO_3 agar bridges were aged in depolarizer free basic solutions. Each solution was deaerated by bubbling pure nitrogen[3] for 15—20 min. In the case of the solution which contained a small amount of water, the water content was determined by Karl Fisher titration just after recording a polarogram.

The pH-dependence of the half-wave potential was studied in Britton-Robinson buffer solutions. The polarographs used were Yokogawa Denki models POL-11 and POL-21 for recording the D.C. and A.C. polarograms respectively. The pH of the solution was measured with a Toa Denpa PM-5A pH meter. All the measurements were carried out at 25°C.

Results and Discussion

The Reference Electrode. The half-wave potentials of methylviologen in the DMF-water system are presented in Table 1. It is evident that the half-wave potentials are reproducible within ±10 mV independently of the aging time. However, at least 10—15 min are required for the practical setting of bridges. Therefore, the potential drift caused within 10—15 min is not presented. The drift of the potential may be much less with the 1 N KNO_3 aqueous agar bridge in a DMF-water system than with an aqueous agar KCl bridge in acetonitrile.[5] As the water contents in a DMF-water system are comparatively ineffective on the half-wave potentials and the summit potentials of methylviologen (Table 1 and Fig. 8), the existence of water extracted from the aqueous agar salt bridge has practically no influence on the half-wave potentials. In other experiments, however, it is desirable

to use the aged bridge to prevent the accidental introduction of water into the solution, because the increase of water may remarkably affect the half-wave potentials or the summit potentials, as in the case of anthraquinone reduction (Fig. 5). The aging time of a week is adopted since such a bridge gives only a small potassium wave in a polarogram.

pH-Dependence of the Half-Wave Potentials. The $E_{1/2}$-pH plot for anthraquinone in water is shown in Fig. 1. The breaks in the curve (or the intersection of extrapolated linear parts) indicate the pK_a-values for the individual degrees of dissociation[6] in such a reversible system. The pK_a-values of anthrahydroquinone are found to be $pK_{a1}=10.9$ and $pK_{a2}=11.8$ from the plot in Fig. 1. Therefore, in the pH-region where the $E_{1/2}$ is pH-independent, the electrode process is a reversible two-electron transfer and the reduction product is the dianion.

The pH-dependence of the electrode process of *p*-dinitrobenzene has been studied by polarography[7] or by cyclic voltammetry.[8,9] The $E_{1/2}$-pH plot is similar to that of anthraquinone, and in an alkaline solution the reversible two-electron reduction to the dianion proceeds.

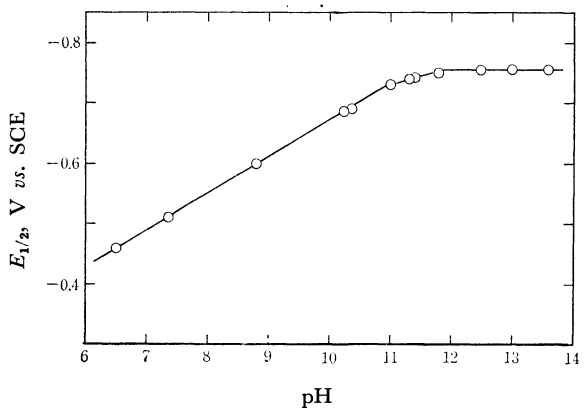

Fig. 1. $E_{1/2}$−pH plot of anthraquinone in water.

When the solvent effect on $E_{1/2}$ is discussed from the viewpoint of the solvation-energy difference between oxidized and reduced species before and after electron transfer, these pH-independent half-wave potentials to the dianion should be compared with those in other solvents in which also only the electron transfer occurs.

Ion-pair Formation. Ion-pair formation is another factor which exerts an influence on the value of the half-wave potential. In order to discuss the solvent effect on the half-wave potential, this factor must be eliminated as much as possible.

The formation of complexes between the radical anions or dianions and the cations of the supporting electrolyte in solvents with moderate dielectric constants, such as dimethylformamide and acetonitrile, has been studied,[4,10] and it has been found that the half-wave potentials for the production of dianions are shifted to the positive side of the potential to a much greater extent than those for the monoanions, and that this positive shift tendency is in the order of $Li^+ > Na^+ > K^+ > NEt_4^+ > NBu_4^+$ in respect to the cation. The difference between NEt_4^+ and NBu_4^+ is small. In the present study, tetraethylammonium salts were used in order to eliminate the effects of ion-pair formation on the half-wave potential.

The effect of increasing the lithium-ion concentration on the half-wave potentials of *p*-dinitrobenzene in DMF, while the total salt concentration is kept constant with tetraethylammonium perchlorate, is shown in Fig. 2. The shifts are greater for the dianion than for the monoanion, and the behavior is similar to that of anthraquinone.[4] One *p*-dinitrobenzene dianion is associated with two lithium cations above a 1.2×10^{-2} M lithium cation concentration. As the concentration of the lithium cation should be much higher than that of *p*-dinitrobenzene,[6] the dependence of $E_{1/2}$ on the lithium concentration could not be measured in the low-concentration range of lithium. As the $E_{1/2}$ values with TEAP are known, the intersections of the left-hand side of the straight line with the linear part, which is independent of the lithium-ion

concentration, may be estimated to be about 6×10^{-4} M. Therefore, a *p*-dinitrobenzene dianion forms a 1 : 1 complex with a lithium cation in the lithium concentration range of 6×10^{-4}—1.2×10^{-2} M. On the other hand, monoanions are not associated with lithium in the lithium-concentration range measured.

The Half-wave Potential of Some Organic Compounds in a Mixed Solvent System. The present work is intended to consider the effects of solvents on the reduction potential of organic compounds. Quinones and *p*-dinitrobenzene are reduced reversibly to the dianions in alkaline aqueous solutions, as has been described above. On the other hand, these compounds give two one-electron reversible waves in aprotic solvents.[11-13]

Then, the changes of half-wave potentials in the DMF-alkaline water system were measured.[15] The results with *p*-dinitrobenzene are shown in Fig. 3. The logarithms of the volume percent of water are used as the abscissa, because it is desirable to know in detail the change in the region which contains small amounts of water. The half-wave potentials of some organic compounds in DMF can be found in the literature, but usually the water contents, which are essentially more or less involved in the solvents, have not been described. As is shown in Fig. 3, however, the half-wave potentials were found to be constant in the region of water content below 0.1%. These values can be practically regarded as the half-wave potentials in DMF.

When the lithium salt is used as the supporting electrolyte in DMF, the $E_{1/2}$ values of the second wave are affected and shift to more positive potentials, as has been described above. This tendency continues until the water contents reach 20—30% (Fig. 3); that is, the dianion is stabilized by water without breaking the ion-pair with the lithium cation when small amounts of water are added.

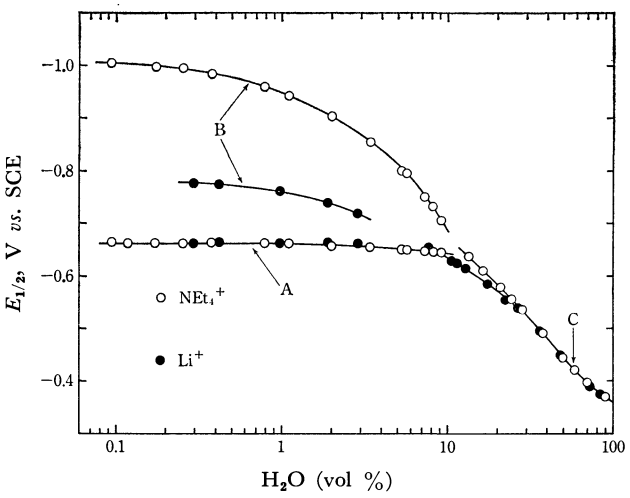

Fig. 3. Dependence of $E_{1/2}$ of *p*-dinitrobenzene on the alkaline water content in DMF-alkaline water system,[15] A, neutral → monoanion; B, monoanion → dianion; C, neutral → dianion.

In Figs. 4—8 can be seen the variation in the A.C. summit potentials of *p*-dinitrobenzene, anthraquinone, and some other organic compounds with the composition of the solvent medium, where no correction for the liquid junction potential is taken into account. As the half-wave potential reading of the very close waves is difficult, the A.C. summit potentials are shown instead of the half-wave potentials.[16] The variation in anthraquinone is similar to that in *p*-dinitrobenzene. In DMF, the difference in the summit potentials of anthraquinone is larger than that in *p*-dinitrobenzene; thus, the variations in the summit potentials of the first and the second waves of anthraquinone could be obtained over a wide range of composition in the DMF-alkaline water system. These compounds showed similar behavior in DMF-ethanol systems (Figs. 4, 5, and 7). On the other hand, anthraquinone showed little change in the summit potentials in DMF-ace-

11) M. E. Peover, *J. Chem. Soc.*, **1962**, 4540.
12) M. E. Peover, *Trans. Faraday Soc.*, **60**, 479 (1964).
13) Strictly speaking, the semiquinone formation constants

$$K = \frac{[S]^2}{[Ox][Red]}$$

of these compounds are small[14] in alkaline water and are large in aprotic solvents. The semiquinone formation constant is obtained by[6,14]

$$E_1 - E_m = E_m - E_2 = \frac{RT}{2F}\ln K$$

where E_1 is the reduction potential of the oxidized form to the semiquinone, E_2 is the reduction potential of the semiquinone to the reduced form, and E_m is the mid point potential.
14) R. Gill and H. I. Stonehill, *J. Chem. Soc.*, **1952**, 1845.
15) Below 10 percent of water in DMF, hydroxide anion reacts with *p*-dinitrobenzene to give nitrophenol, therefore 0.1 N perchlorate salt aqueous solutions were used instead of 0.1 N hydroxide aqueous solutions below 10 percent of water.
16) As the A. C. summit potentials agreed with the D. C. half-wave potentials within at most 20 mV for the present systems, these potentials may be looked as the same. Methylviologen, however, gave tensammetric peaks in addition to the faradaic peaks in the A. C. polarogram in water.

tone[17] and may similarly show little change in DMF-acetonitrile (Fig. 6).

The dielectric constants of the solvents used are given in Table 2. A comparison of the values of ε with the variation in the summit potentials described above leads to the conclusion that the solvent effect on the half-wave potentials cannot be explained by the Born equation only:

$$-\Delta G_{el}^{\circ} = \frac{Nz^2e^2}{2r}\left(1-\frac{1}{\varepsilon}\right)$$

17) As the supporting electrolyte, tetra-*n*-propylammonium perchlorate (Nakarai Chemicals reagent for polarography) was used, because of low solubilities of tetraethylammonium salts in acetone.

where e is the electronic charge, ε is the dielectric constant of the medium, N is Avogadro's number, and r is the radius of the ion. The Born equation predicts that the reduction potential of the neutral molecule to the anion shifts to a more positive potential in the solvent with the higher dielectric constant. In view of this, the remarkable positive shift of the half-wave potentials (or summit potentials) with an increase in the ethanol content in the DMF-ethanol system cannot be interpreted. The positive shift of the half-wave potentials with an increase in the water or alcohol content can be interpreted preferably by the hydrogen-bond interaction[11] of the produced anions with water or alcohol. As is shown in Figs. 4, 5, and 7, the summit potentials of the second waves, which correspond to the reductions from the monoanion to the dianion, shifted remarkably to a positive potential with an increase in the water or alcohol content. This may be due to the stronger hydrogen-bond interaction of the dianion than that of the monoanion. In the case of methylviologen, it is predicted that such a positive shift will not be observed, because two one-electron waves of methylviologen correspond to the reductions from the dication to the monocation and from the monocation to the neutral molecule, and generally the cation and the neutral molecule are much poorer acceptors of a hydrogen bond than the anion is. In fact, the behavior (Table 1 or Fig. 8) is different from that of *p*-dinitrobenzene or anthraquinone. The half-wave potentials show a rather negative shift with an increase in the amount of water. These shifts are not caused by the change in solvation, but by the liquid junction potential, for the half-wave potentials of ferrocene, which were assumed to give the same potentials in various solvents, also showed a negative shift in the DMF-water system as the water content increased. The half-wave potentials of ferrocene, measured by cyclic voltammetry with the Pt anode, are shown in Table 3. According to the assumption that ferrocene-ferricinium couple has the same potential in various solvents, the variation of $E_{1/2}$ in Table 3 is equal to the change in the liquid junction potential with the composition of the DMF-water system.

18) L. H. Chopard-dit-Jean and E. Heilbronner, *Helv. Chim. Acta*, **36**, 144 (1953).

In Fig. 9, the variations in $E_{1/2}$ (or E_p) *versus* the $E_{1/2}$ of the ferrocene with the composition of the DMF-water (or DMF-alkaline water) systems for several organic compounds are shown. As has been described above, methylviologen shows almost constant half-wave potentials in the DMF-water system. On the other hand, anthraquinone shows a much grater positive shift of the summit potentials by the correction for the liquid junction potentials in the DMF-alkaline water system (*cf.* Fig. 5).

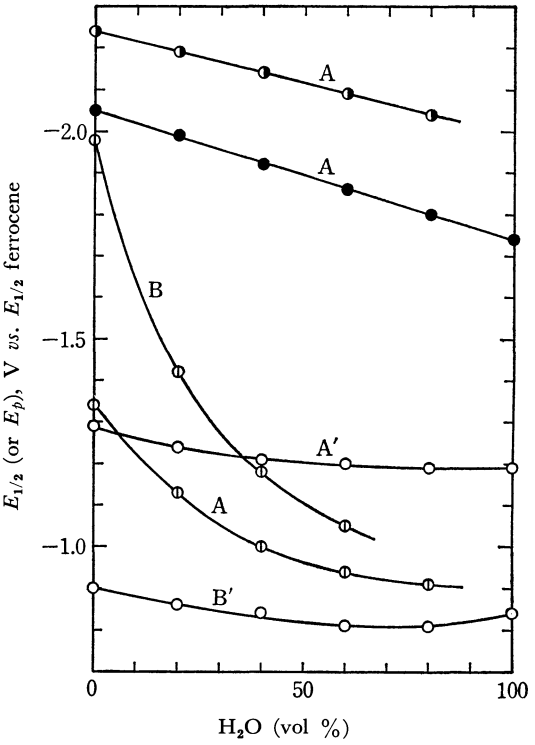

Fig. 9. $E_{1/2}$ of methylviologen, azulene, and fluoranthene, and E_p of anthraquinone *versus* $E_{1/2}$ of ferrocene, ○, methylviologen; ●, azulene; ◑, fluoranthene; ⓘ, anthraquinone.

In the case of aromatic hydrocarbons, protonations occur even in the DMF-alkaline water system and affect the half-wave potentials. However, azulene and fluoranthene are known to show a reversible one-electron reduction even in protic media.[18] The variations in their half-wave potentials in the DMF-alkaline water system are also shown in Fig. 9. The positive shift of the potentials with an increase in the water content in the DMF-alkaline water system is much less in the reduction of hydrocarbons than in the reduction of anthraquinone. In the case of aromatic hydrocarbons, the reduction products, radical anions, are known from ESR measurements to have a delocalized negative charge. On the other hand, anthraquinone anions have localized negative charges on the oxygen atoms. Therefore, the hydrogen-bond interaction of anions with water in the DMF-alkaline water system is much less in aromatic hydrocarbon anions than in anthraquinone or *p*-dinitrobenzene anions.

The Interpretation of the EPR Spectra of the Amorphous State of Group VIB Hydride Radicals by Means of the Gas-phase Data

Yashige KOTAKE, Mitsuo ONO, and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received December 17, 1970)

A new procedure for the interpretation of the amorphous EPR spectra of the group VIB hydride radicals, *i.e.*, OH, SH, SeH, and TeH, is proposed. The point of this method is to combine the observed hyperfine structure of these radicals in the gas phase and the calculation of the anisotropic hyperfine coupling constant. For this purpose, the Slater orbital and analytical Hartree-Fock orbitals were examined as unpaired electron orbitals by the comparative calculation of the hfs constants. The accuracy of this method was evaluated successfully by applying it to the OH radical. Moreover, in the case of the SH radical the newly-observed spectra in the amorphous state could be assigned to the SH radical.

The hyperfine (hf) interaction in diatomic hydride radicals is an important factor in clarifying the mechanism of the hf splitting of the proton. It also gives much information about the hf interaction in the hydride fragment of polyatomic radicals. The C–H fragment in organic radicals has been the subject of many theoretical and experimental works,[1] while the others have scarcely been investigated at all.

The EPR study of radicals trapped in a single crystal has given the most definite information about the hf interaction but simple radicals such as diatomic hydrides present experimental difficulties in the single crystal study, for they are too small to be stabilized easily; moreover, sometimes the presence of more than one orientation of radicals in the mother crystal makes the analysis difficult, as may be illustrated in the study of the hydroxy radical.[2] Moreover, as far as these solid phase data are concerned, they are under the influence of a matrix effect of a crystalline field.

About Group VIB hydride radicals, *i.e.*, OH, SH, SeH, and TeH, though solid-phase EPR data are poor except for the OH radical, their electric dipole transitions have been observed in the gaseous flow system.[3-7] The hyperfine structure (hfs) of the gas-phase spectra gives information about both the isotropic and anisotropic terms.

In this study we will propose a new procedure to evaluate the principal values of the hf-tensor by the analysis of the hfs of the gas-phase spectra with the aid of the theoretical calculation. The point of this method is to utilize the calculation of dipolar terms and to evaluate indirectly the Fermi contact term.

The usefulness of the method was confirmed for the OH radical, which has been intensively studied in the solid phase.

Moreover, the application to the SH radical gave a correct identification of the radical trapped in the solid phase. The complex spectra obtained by Gunning *et al.*[8] for SH were disproved by this application and on the basis of the consideration of the g-tensor. The hf parameters estimated by this method fit well to those of the newly-observed spectra. On the SeH and TeH radicals, some information about hfs could be obtained.

In the calculation of the anisotropic terms, the characteristics of the Slater orbital and the analytical Hartree-Fock SCF atomic orbital of the Group VIB atom were also discussed.

Theoretical

Because of the large rotational constants of Group VIB hydrides, they are not pure Hund's case (a) or (b) molecules. An intermediate coupling case between Hund's cases, (a) and (b), is treated in terms of Hund's (a) case. A small mixing of Hund's (b) case to a $^2\Pi$ molecule can be expressed as a $^2\Pi$ level slightly perturbed by a $^2\Sigma$ level. The wavefunction is written as a linear combination of two $^2\Pi$'s and a $^2\Sigma$ and the expansion coefficients are determined by the variation method using Van Vleck's matrix elements.[9] In the case of Group VIB hydrides (ground state $^2\Pi_{3/2}$, $J=3/2$ in the case (a), this wavefunction gives first-order expectation values, $W_{\rm hfs}^+$ and $W_{\rm hfs}^-$, or Frosh-Foley's strong field hf hamiltonian[10] for each of the lambda-type doublets as follows:[11]

$$W_{\rm hfs}^+ = (A_1+A_2)M_J M_I\,, \tag{1}$$

$$W_{\rm hfs}^- = (A_1-A_2)M_J M_I\,, \tag{2}$$

$$A_1 = [2a(2X+2-\lambda) + b(X+16-2\lambda) + c(X+4-2\lambda)]/15X\,, \tag{3}$$

$$A_2 = 2d(X-2+\lambda)/15X\,, \tag{4}$$

where:

$$X = [16-\lambda(\lambda-4)]^{1/2}\,, \tag{5}$$

Here λ is the ratio of the LS coupling constant to the rotational constant and:

$$a = 2g_I\beta\beta_N\langle 1/r^3\rangle_{\rm av}\,, \tag{6}$$

$$b = -g_I\beta\beta_N\langle(3\cos^2\theta-1)/r^3\rangle_{\rm av} + \frac{16\pi}{3}g_I\beta\beta_N\Psi^2(0)\,, \tag{7}$$

$$c = 3g_l\beta\beta_N\langle(3\cos^2\theta-1)/r^3\rangle_{av}\,, \quad (8)$$

$$d = 3g_l\beta\beta_N\langle\sin^2\theta/r^3\rangle_{av}\,. \quad (9)$$

The coordinate used in these equations is shown in Fig. 1. These equations successfully explaine the hfs of the OH[3,4] and NO[12] radicals.

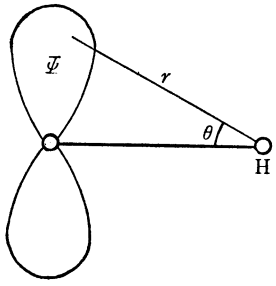

Fig. 1. Coordinate for Eqs. (6)—(9).

In Eq. (3) if a, the first term of b and c, can be calculated with sufficient accuracy, the Fermi contact term can be derived by putting the experimental values into A_1 and X.

The molecular integrals such as $<(3\cos^2\theta-1)/r^3>_{av}$ or $<1/r^3>_{av}$ can be calculated if an unpaired electron orbital and the interatomic distance are determined. If we adopt the LCAO-MO approximation in those hydrides, the unpaired electron orbital will be the np_x or np_y atomic orbital of the Group VIB atom, both orbitals are perpendicular to the molecular axis (z-axis). These atomic orbitals are frequently Slater orbitals or analytical Hartree-Fock (AHF) orbitals, the latter of which consist of a linear combination of Slater-type orbitals (STO).

An assumption of STO as an unpaired electron orbital made it possible to calculate these integrals analytically by the method of Barnett-Coulson.[13] The method of McConnell and Strathdee[14] is also applicable to the OH radical. Except for the STO of oxygen, however, it is, in fact, impossible to integrate analytically. For example, in the case of SeH, when we adopt the AHF orbital of selenium, 45 integrals must be calculated. Therefore, they are numerically integrated using Barnett-Coulson's formulation by means of an NEAC 2200—500 electronic computer. The upper limit of the numerical integration by Sympson's law was chosen so as to be five times larger than the equilibrium interatomic distance, for the contribution from the integration beyond this limit was smaller than five decimals places in the atomic unit.

From the Fermi contact term and the dipolar term, the principal values of the hf tensor, A_x, A_y, and A_z, can be determined on the basis of the following assumption of axial symmetry:

$$A_x = A_y = b\,, \quad (10)$$

$$A_z = b + c\,. \quad (11)$$

These principal values are, however, essentially those for the free molecule; thus, there should be a kind of limit in the comparison of the gas-phase hfs with the solid-phase one.

The dipolar term and other anisotropic terms reflect sharply the shape of the unpaired electron orbital of the radical; the calculation of their change with the interatomic distance is useful in examining this orbital. For example, the deviation of the value calculated by the Slater atomic orbital from the Hartree-Fock value will be a measure of its accuracy.

Experimental

The method of observing gas-phase EPR spectra has been developed by Carrington and his colleagues.[15] They designed new types of EPR cavities and pillboxes and observed several kind of new radicals. Among these radicals, the observation of OH, SH, and SeH is comparatively easy. The OH radical is produced by the microwave discharge of water, while the SH and the SeH radicals are produced by the reaction of the hydrogen atom with sulfur and selenium respectively. These spectra are electric dipole transitions between the lambda-type doublet, so the microwave must have an electrical component perpendicular to the external field. To create this condition, a TE_{012} cylindrical cavity with a quartz pillbox was used. A rapid-gas-flow system consists of a ULVAC-300 rotary pump which evacuates 300 l per min, a liquid nitrogen trap 60 mm in diameter, a pilani-gauge, and an accurate needle valve. The linear velocity of the gas flow was supposed to be *ca.* 10 m/sec.

In a preliminary experiment, the gas-phase EPR spectra of OH, SH, and SeH were obtained with sufficient intensities. As for the TeH radical, the spectrum could not be obtained with a good SN ratio. The spectrometer used was operated in the X band with 455 kHz-field modulation and a 30 cm JEOL electromagnet.

In order to observe the solid-phase spectrum of the hydrides, under the same conditions as were used in the gas-phase experiment, the reactants were trapped at the point of the cavity in the gas-phase experiment on a coldfinger which was cooled at the temperature of liquid nitrogen. The outline of this apparatus is shown in Fig. 2. Except

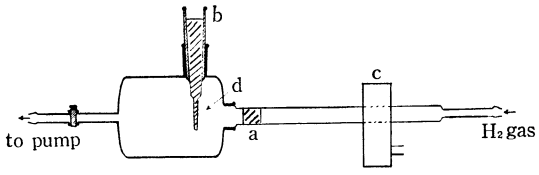

Fig. 2. Apparatus for trapping the radical in gas phase: a; evaporated film of S, Se, and Te, b; liq. N_2 Dewar vessel, c; cavity for discharge, d; coldfinger.

for OH, evaporated films of sulfur, selenium, and tellurium were made at the point of (a) in Fig. 2 and were attacked by the hydrogen atom which was generated in the microwave discharge of hydrogen gas. The microwave excitor was operated at 2450 MHz with a rectangular discharge cavity; its maximum output was 250 watt. The distance between the discharge (c) and the coldfinger (d) (*cf.* Fig. 2) was adjusted to get the best yield. The EPR measurement was done by transfering the coldfinger into a liquid-nitrogen Dewar vessel.

To identify the solid-phase spectra, dihydrides and dideuterides of sulfur, selenium, and tellurium which had been diluted in H_2O and D_2O matrices were irradiated by a UV light of a 1-kW high-pressure mercury arc at 77°K; the EPR spectra were also observed at the same temperature. H_2Se and H_2Te were formed by the hydrolysis of Al_2Se_3 and Al_2Te_3 respectively; the latter substances were synthesized by the ignition of Se and Te with Al.

Results and Discussion

The lambda-type doubling frequencies, g values, A_1 and A_2 of OH, SH, SeH, and TeH and of their deuterides are tabulated in Table 1. The tendencies of the g value and the lambda-type doubling frequency, plus the molecular structure, can easily be explained by the theoretical expression of these constants.[16]

In Table 2 the experimental values and the calculated values of hfs constants are listed.

OH Radical. As for the former data of the hfs constants determined by Radford,[4] each experimental value could be compared to the calculated one. As can be seen in Table 2, the best accordance was obtained when the Slater orbital was adopted as an unpaired electron orbital. It may be noted that the unpaired electron orbital in the OH radical deviates from the pure $2p$ orbital of oxygen upon the repulsion of the O–H bond and by the spin polarization of the inner shell. The Slater orbital, although it is a simple AO, may be supposed accidentally to include these effects.

In the MO calculation, the molecular integrals, such as overlap and Coulomb integrals, have been cal-

culated by using the Slater orbitals. These integrals in the long internuclear distance differ from the AHF values. This property of the Slater orbital in the longer range appears less strongly for the dipolar term, which depends on r^{-3}, because it sharply decreases with r. As is well known, $<1/r^3>_{av}$ is a constant which shows the interaction between the hydrogen nucleus and the magnetic field generated by the orbital motion of an unpaired electron in a p orbital, so the inner shell spin density, which is induced by the spin polarization, has no effect on this constant. On the other hand, as the other anisotropic terms are originated by the interactions between the magnetic dipole of an unpaired electron and a hydrogen nucleus, the unpaired electron density in s orbital also has a small value. When a pure $2p$ atomic orbital is adopted as the unpaired electron orbital it is reliably established that the calculated value of the anisotropic terms except $<1/r^3>_{av}$ deviate a little from the experimental value.

Concerning the Fermi contact term, the good agreement of the experimental value with the estimated one in anisotropic terms results in a good correspondence between the experimental and estimated values. The MO calculation of this term was done by Kayama.[18] Introducing ten excited configurations to Freeman's LCAO-SCF-MO, he derived the value of -67.9 MHz. It was a very good agreement considering the accuracy of ordinary MO calculations. According to his result, the absolute value of the Fermi contact term increases with the interatomic distance; at 2.2 a.u., it gives -99.4 MHz. Even if we recognize the lack of monotony of the dependence of the σ–π interaction on the interatomic distance, however, his value at 2.2 a.u. is too large.[19]

The principal values of the hf-tensor of the OH radical, as determined by several investigators and as calculated by the method explained in the theoretical section, are listed in Table 3. Though the values obtained from the analysis of the solid-phase EPR spectra of the OH radical did not agree very well, the calculated results agreed fairly well.

By considering the accuracy of the above calculation of the anisotropic terms, the method of deriving the principal values of the hf-tensor can be said to be applicable when the appropriate atomic orbital for the unpaired electron orbital can be found.

18) K. Kayama, *J. Chem. Phys.*, **39**, 1507 (1963).

19) We calculated the Fermi term of OH by Pople's INDO (Intermediate Neglect of Diffential Overlap) method. By the approximate estimation of the one-center exchange integral of the oxygen and other integrals calculated from Pople's proposal, the SCF process repeated about forty times gave the final spin density as $\rho_{2p_{x,y}}=1.000$ or 0, $\rho_{2p_z}=0.094$, $\rho_{2s}=-0.065$, and $\rho_{1sH}=-0.029=-41.3$ MHz. Moreover, the dependence of the spin density of the H atom on the interatomic distance was:

	1.8342 a.u.	2.0 a.u.	2.2 a.u.
SCF-CI	−0.048	−0.056	−0.070
INDO	−0.029	−0.021	−0.013

At the equilibrium distance, the error of the value was bigger than Kayama's result, but the absolute value decreases with an increase in the interatomic distance.

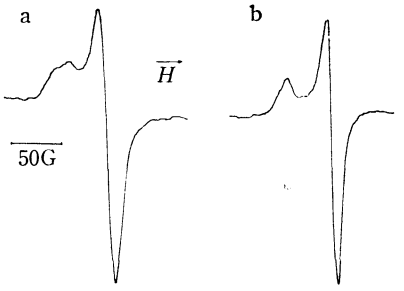

Fig. 3. EPR spectra of discharged product of a, H_2O and b, D_2O.

Figure 3 shows the EPR spectrum of the radical which is generated by the gas-phase microwave discharge of water and trapped at the temperature of liquid nitrogen. This spectrum shows no characteristic doublet of the OH radical, which was observed by the γ-ray[20] or tritium β-ray[21] irradiation of polycrystalline ice; it coincides with that from UV-irradiated H_2O_2 of a 20% aqueous solution.

From deuterium substitution, this spectrum is found to consist of two radical species; by a detailed analysis of the far-ultra violet photolysis of water and other related compounds these two species were identified as the HO_2 and HO_3 radicals.[22] The OH radical, which gives a strong EPR spectrum in the gas-phase, could not observed in the trapped phase. This phenomenon corresponds to the fact that the UV photolysis of the dilute solution of hydrogen peroxide (less than 3 wt%) gives the OH radical, while a more concentrated solution never gives it. This proves that, in the solid phase, the OH radicals may recombine easily; those in the gas-phase covert into HO_2 or other radicals as soon as they are trapped in the solid phase.

SH Radical. At the equilibrium interatomic distance, the calculated values from the Slater and AHF orbitals are rather different from each other. About the $3p$ orbital, though the true atomic orbital has three nodal planes, the Slater p AO's are always

20) For example, P. N. Moorthy, and J. J. Weiss, *Phil. Mag.* **10**, 659 (1964).

nodeless except for the origin, and generally the p Slater orbitals of different shell are nonorthogonal. The AHF atomic orbital for $3p$ of sulfur has two nodes other than the origin and is orthogonal to the p orbitals of the other shell. As anisotropic terms depend strongly on the shape of the orbitals, these properties of the Slater orbital are fatal in calculating the integrals.

For these reasons even if the influence of S–H bonding is considered, the AHF atomic orbital is much more reliable than the Slater one as an unpaired electron orbital. Sometimes the d orbital of a sulfur atom contributes to the sulfur and other atom bonding, but in the case of SH, the *ab initio* calculation of the electronic structure by Cade and Huo[23] showed that the contribution of the sulfur d-type orbital to the unpaired orbital is extremely small.

According to the hfs constants from the AHF wavefunction, the anisotropic term is much smaller than that of the OH radical; the estimated Fermi contact term also has a small negative value. The negative value of the Fermi term suggests that the mechanism of generating the isotropic hf interaction is the exchange interaction between the $3p_x$ or $3p_y$ orbital of a sulfur atom with the σ bond of SH.

The EPR spectra of the reactants under the same conditions as in the gas-phase experiment of SH are shown in Fig. 4. These spectra consist of the superposition of three peaks which show a deuterium substitution effect and the one broad singlet line. The

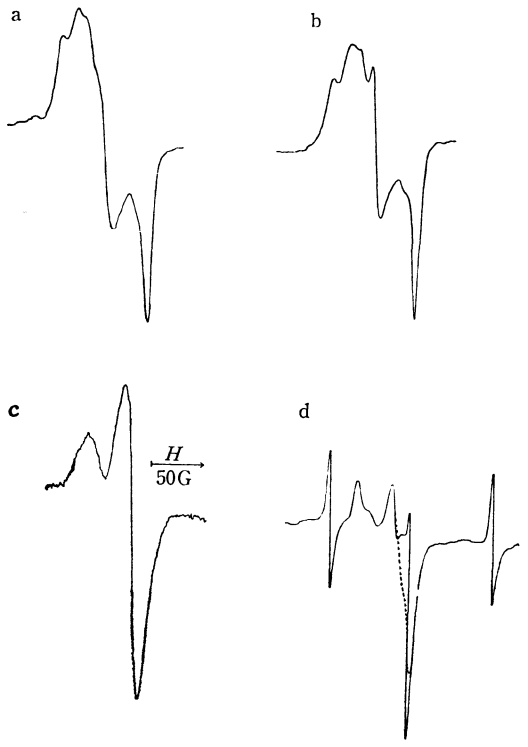

Fig. 4. EPR spectra of radicals formed by the reaction of sulfur with H atom (a), and D atom (b), and of UV photolyzed product of H_2S-H_2O system (c), and D_2S-D_2O system (d), broken line shows the substraction of D atom spectrum from central part.

UV photolysis of the dilute solution of H_2S and D_2S gives a spectrum which corresponds to these three peaks.

By the decomposition of water and hydrogen peroxide, OH, HO_2, and other oxygen radicals can be obtained. On analogy with these radicals, SH, HS_2, and $(S)_n$ are proposed. Gunning *et al.*[8] obtained several spectra by the prolonged UV irradiation of pure H_2S and H_2S_2 and their deuterides at the temperature of liquid nitrogen. They obtained very complex spectra; their identification was seemingly difficult. In their analysis, the spectrum of SH indicates a large g anisotropy and does not have an axial symmetry. As for hfs, Gunning *et al.* directly compared the gas-phase hfs with that of the solid phase; however, this is incorrect, as may be seen in Eqs.(1) and (2) of the Theoretical section.

From the electronic structure of the SH radical, the $3p_x$ and $3p_y$ orbitals of the sulfur atom, which are perpendicular to the molecular axis, are seem to be nearly degenerate. The principal g_{ii} values $(i=x,y,z)$ of the g-tensor can be written as;

$$g_{ii} = g_e - \sum_{n \neq p} 2\zeta |\langle p|L_i|n\rangle|^2/(E_p - E_n) \qquad (12)$$

where E is the energy of the unpaired electron orbital p, where E_n is that of the nth orbital, and where ζ is the LS coupling constant. Assuming as the unpaired electron orbital the $3p_x$ or $3p_y$ orbital of a sulfur atom, and the SH bond as the nth orbital, g_{xx} and g_{yy} will give about the same value from Eq. (12) because of the near degeneracy. Eq. (12) indicates that an electronic structure like that of the SH radical will have an axial symmetric g-tensor. In our experiment, Fig. 4c shows almost axial symmetric spectra and a remarkable deuterium substitution effect; because they are radicals formed from a dilute solution of H_2S the radicals with more than two sulfur atoms may scarcely be formed. On the basis of these findings, this radical was identified with the SH radical. The superposed singlet spectrum of Fig. 4 showed no deuterium substitution effect. The trapped intermediate in the microwave discharge of sulfur vapor also gives a strong singlet line.[24] Therefore, this line may be attributed to the $(S)_n$ radical.

This identification was also supported by the calculation. By the use of the g-tensor of the SD spectrum, which was determined by the spectrum simulation assuming that the hfs of deuterium was so small to neglect, the SH spectrum could be reproduced from the calculated hf tensor, *i.e.*, $A_x=-3.5$, $A_y=-3.5$, and $A_z=0$ gauss. The simulated spectrum for SH is shown in Fig. 5 superposed on the observed spectrum.

In the case of the OH radical, the g- and hf-tensors were slightly different for each investigator. As for the SH radical, the influence of the trapped state may also change the spectral features; the discrepancy between the calculated and experimental results does not make the calculated results doubtful.

ally-excited SH ($J=5/2$) in the C-band. Though they could not resolve its hfs because of the large line-width, the accuracy of the calculation will be examined in the near future by gas-phase EPR or by microwave spectroscopy.

Comparison of the Slater Orbital with the AHF Orbital on the Calculation of Anisotropic Terms. In Fig. 6 the dependence of the values of $<(3\cos^2\theta-1)/r^3>_{av}$ on the interatomic distance between O and H and between S and H are shown for the Slater orbital and the AHF atomic orbital. The good agreement in the oxygen $2p$ orbital shows that the shape of the oxygen $2p$ Slater orbital fairly well resembles that of the AHF one. This may give support for the usefulness of the Slater orbital in MO calculation.

In SH, in spite of the large discrepancies from the AHF values, the value calculated using the Slater orbital as an unpaired electron orbital runs parallel with it. When we consider the nodeless property and the nonorthogonality of the Slater orbital, this parallelism is worth appreciating. Especially, the integrals calculated from $3p$ orbital have a maximum value for both the Slater and AHF orbitals. This is characteristic not only of the $3p$ orbital but also of the Slater $4p$ orbital. The fact that the anisotorpic dipolar interaction does not always decrease monotonously suggests that the hf interaction between indirectly-bonded atoms is sometimes important.

Figure 7 also shows the dependence of $<(3\cos^2\theta-1)/r^3>_{av}$ on the interatomic distance using the Slater orbitals of O, S, Se, and Te.

SeH and TeH Radicals. For the SeH radical, the unpaired electron orbital is assumed to be the $4p$ Slater orbital or the AHF orbital, which consists of a linear combination of nine STO's of the selenium atom. For TeH, the $5p$ Slater orbital of the tellurium atom is adopted. In this case, the assumption of the unpaired electron orbital as a pure p orbital is doubtful because, in the shell of the large-principal quantum number, the energy difference among the orbitals is

small enough for them to be hybridized easily. The calculated anisotropic terms are somewhat large compared to those in OH and SH.

The trapped products formed by the reaction of the hydrogen atom with the evaporated films of metallic selenium and tellurium gave no EPR signal. Their metallic colors proved that the SeH and TeH radicals are primarily formed and then decomposed into metals and the hydrogen atom immediately after trapping. Because the products are trapped in a highly concentrated state, the hydrogen atom formed from the decomposition of SeH and TeH could not be detected.

By the UV photolysis of dilute aqueous solutions of H_2Se and H_2Te and their deuterides, the EPR signal of the hydrogen atom or the deuterium atom were always detected. In this case, the SeH and the TeH radical are also unstable at the temperature of liquid nitrogen, and they decomposed into hydrogen atom and metals. The H_2Se–H_2O and the H_2Te–H_2O systems after the photolysis showed the color of red selenium and metallic tellurium. The hydrogen atom in this sample is less labile because of the surroundings, are mainly the water molecule, and the chance of the recombination is very small. The fact that the samples were always kept at the temperature of liquid nitrogen also stabilized the hydrogen atom. SeH and TeH are much unstable than OH and SH in both the gaseous and solid phases. Their stability is seemingly correlative with the strength of the reductivity of dihydrides.

(Received December 31, 1970)

By using the closed-shell SCF MO method with the zero-differential overlap approximation for all valence electron systems previously presented by us, the electronic structures of *trans*- and *cis*- substituted ethylenes (treated substituent = CH_3, Cl, Br, and I) are studied. The calculated values of the π and valence electron charges, and the total energies of these isomers are presented. The natures of the higher occupied MO's, especially the lone-pair MO's, of chlorinated ethylenes are discussed in connection with the photoelectron observation. The calculated lowest π–π^* singlet transition energies accord well with the observed values. As to the rotational energy changes, the calculated results show that, at the perpendicular configurations, the triplet states for all the treated compounds are lowest, while the intermediate states for the *cis-trans* isomerizations of these compounds may be common to both the isomers.

Many theoretical and experimental studies have been carried out on the electronic structures of *trans*- and *cis*- isomers of substituted ethylenes.[1] On theoretical grounds, semi-quantitative discussions of this problem, however, need to consider explicitly not only the π-electronic structures but also the σ-electronic ones. For example, differences in the electronic structures of these isomers are in some case, mainly dependent on the interactions between the lone pairs of the substituted atoms, and the rotation about the ethylenic CC double bond causes the σ-π mixing. We have already given a semiempirical SCF MO method for all valence electron systems,[2,3] and the electronic structures of *trans*- and *cis*-isomers of butadiene, acrolein, and glyoxal have been calculated in satisfactory agreement with the observed results.[3]

In this paper, the method with an approximation of the zero-differential overlap[4] is used to study the electronic structures of the *trans*- and *cis*-halogenated ethylenes and related compounds, and also those of the twisted configurations caused by the *cis-trans* isomerizations of these compounds. The compounds treated in this paper are as follows: *cis*- and *trans*-butene-2, dichloro-, dibromo-, and diiodoethylenes, and some related chlorinated ethylenes.

Method and Parameters Used

The method employed in this paper is the semi-empirical SCF MO method for the closed shell of all valence electron systems, with approximations of the zero-differential overlap and empirical estimation of integral values. In this section, only the used parameters will be described, since the details have been given in previous papers.[4]

The one center exchange integral values and the valence-state ionization potential and electron affinity for the related atoms are estimated from those in Hinze and Jaffe's paper.[5] The values of the orbital exponent are those obtained by Clementi and Raimond.[6] The overlap integrals including the bromine atom

(the principal quantum number, $n=4$) are calculated by the expansion formulas for $n=5$. The value of the parameter, K, for the estimation of core resonance integrals is taken to be 0.8 for the halogenated ethylenes and for 2-butene.[7] It is estimated so as to reproduce the good accordance between the calculated and observed lowest π-π^* singlet energies in vinyl chloride ($K=0.8$) in stead of in ethylene ($K=0.9$).

The molecular coordinates are adopted from the Sutton's Tables[8] and are summarized in Table 1,

Table 1. The molecular configurations used[a]

Substituent X	Bond distance (Å) C-C	Bond distance (Å) C-X	Bond angle (degree) ∠CCX

-I	1.34	2.05	122

a) CH=1.07Å, ∠CCH=120° for all the compounds.

where the coordinates of the *cis*-forms are assumed to be the same as in the related *trans*-compounds, except for the relations between the terminal groups.[9]

Results and Discussions

Charge and Energy. The calculated π net charges and π bond orders are presented in Table 2, together with the net charges and E_{AB} values[4,11-13] for all valence electrons. The table indicates that the π delocalization is slightly stronger in *cis*-form than in its *trans* isomer, but the σ charges concentrate a little more on the halogen atoms of the *cis*-form than in the *trans*-forms. It is recognized that the E_{AB} values reflect the substituent effect, that is, the CC and CH bonds in substituted ethylenes are weakened compared with those in ethylene, but different tendencies between the results in Table 2 and the ones predicted by electronegativity for halogen atoms are indicated. These points will be discussed by more refined calculations.

b) See Ref. 14.

Different shifts in the *cis*- and *trans*-dichloroethylenes are observed by the PQR measurement;[14] that is, the nuclear quadrupole coupling constants of the Cl^{35} in the *cis*-form are smaller than these in the *trans*-isomer. The values of the PQR U_p values (the number of unbalances electrons) of Cl atoms in various chlorinated ethylenes are estimated by the approximation derived by Townes and Dailey.[15] The results obtained are listed in Table 3, together with the π, $\bar{\pi}$, and σ AO charges. (The $\bar{\pi}$ AO is perpendicular to the C-Cl bond and is on the molecular plane.) The calculated difference in U_p values in the *cis*- and *trans*-forms is in good agreement with the observed value,

7) As for 2-butene, the results with $K=0.9$ are in better accordance with the observed values.

8) "Tables of Interatomic Distances and Configurations in Molecules and Ions," ed. by L. E. Sutton, The Chem. Soc., London (1956, 1965).

9) As to the *cis*-dichloroethylene, it is suggested in Refs, 10 and 15 that this form may be staggered, that is, the two C-Cl bonds deviate out of the molecular plane. But this staggered form is calculated to be more unstable than its planar form, 0.02 eV at 5° and 0.13 eV at 15°. Thus, we do not consider this form, hereafter.

13) E_{AB} is defined as follows: $E_{AB}=\sum_{r}^{\text{on A}}\sum_{s}^{\text{on B}} P_{rs}(H_{rs}^{c}+F_{rs})$, where the AO's r and s are belonging to the atom A and B, respectively.

P_{rs} is the bond order of r-s pair, and H_{rs}^{c} and F_{rs} are the off-diagonal r-s elements of core resonance integral and Fock operator, respectively. See Refs. 4 and 11.

but the errors in absolute values between the calculated and observed are over 20% in magnitude. As to these discrepancies, the table suggests that they are mainly due to the large AO charges on the Pσ AO's on the chlorine atoms. Further, the disorder in 1,1-dichloroethylene may be partially caused by the neglect of the Cl–Cl interaction.

Recently, the photoionization spectra of several chlorinated ethylenes were presented, and the symmetry assignments of some MO's were made; the highest occupied MO's in these compounds are of the π type, while the second lower group MO's are lone-pair MO's localized on the chlorine atoms.[16] In Table 4, the observed and calculated MO energies are summarized. The calculated energy values are about 2 eV lower than the observed values, but the orbitals sequences almost coincide. The symmetry assignments partially disagree with each other, especially for the lone-pair-type MO's. In order to reexamine this point, the calculated partial atom charges of the related MO's are collected in Table 5, together with the chlorine AO densities. Our results show that the 10 and 11 MO's are both of the lone-pair type in dichloroethylenes. The latter MO has the a_g symmetry in *trans* and the a_1 symmetry in *cis*-dichloroethylene, and C–Cl anti-bonding and Cl–Cl bonding; on the other hand, the formes MO is b_u in *trans*- and b_2 in *cis*-, and is C–Cl bonding and Cl–Cl anti-bonding. For 1,1-dichloroethylene, the same tendency is obtained as may be seen in the table, in spite of the stronger Cl–Cl interaction. Accordingly, it may be said that the stabilization of these two types

a) The notations S and T refer to the singlet and triplet transition.

of lone-pair MO's depends mainly on the C–Cl bonding character and not on the Cl–Cl character, as was pointed out in our previous paper.[3] It is hoped that this discrepancy will be reinvestigated both theoretically and experimentally. Further, it is noticed that the lower vacant MO's are of the σ^* type and the strongly C–Cl antibonding. This result may be correlated to the ease of the C–Cl bond clevage by the polarographic reduction, as was shown by our previous results obtained by simple LCAO MO treatment.[17]

The energy differesces between the *cis*- and *trans*-isomers are listed in Table 6, together with the observed values,[10,18] where E is $E=E(trans)-E(cis)$; that is, the negative value of E indicated that the *trans*-isomer is more stable than the *cis*-form. The results calculated for 2-butene and dichloroethylenes accord with the observed values, but in the diiodo-compounds the results contradict each other.[19]

Electronic Transition Energy. In Table 7, the calculated lower electronic transition energies and moments for the chlorinated ethylenes are summarized. As to the lowest π–π^* singlet transition energies, the agreements between the calculated and observed values[18,20] are excellent: CH_2CHCl: 6.68 (6.70), CH_2CCl_2: 6.44 (6.45), *t*-CHClCHCl: 6.21 (6.36), *c*-CHClCHCl: 6.13 (6.53), $CHClCCl_2$: 6.31 (6.32), CCl_2CCl_2: 6.46 (6.29), where the numbers in parenthes are the observed values.[18,20] The other types of transitions have not yet been assigned by means of observations, but it is interesting that the lowest transitions obtained are π-σ^* transitions, as was suggested in our previous paper.[17]

The lowest π–π^* transition energies and oscillator strength values (Å) for various *cis*- and *trans*-isomers are collected in Table 8. The calculated values for the π–π^* transition energy in *cis*-isomers are considerably smaller than the observed values, and the order of magnitude for *cis*- and *trans*-isomers does not agree with the observations. As to the transition moments, the calculations show that values in the *trans*-isomers are larger than in *cis*-isomers. This tendency is to be expected from the symmetry consideration for these isomers; that is, the lowest π–π^* transitions belong to the b_u irreducible representation in the *trans*-isomer (C_{2h}) and to the b_2 in the *cis*-isomer (C_{2v}). Thus the components of the transition moment are x and y in b_u, and y in b_2 (the direction of y is parallel to the central CC bond and x is perpendicular to this bond), and the moment values (y) are nearly equal for the two isomers. Therefore, the differences between the *cis*- and *trans*-isomers are dependent on the x component values.

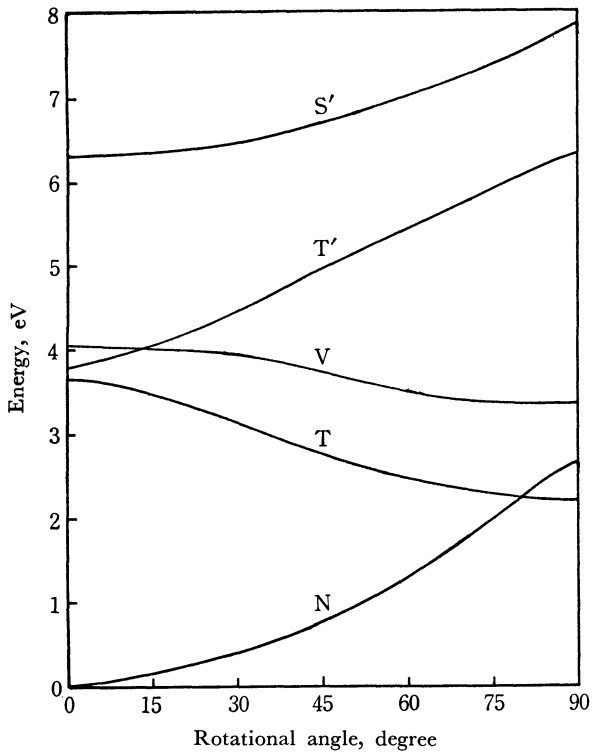

Fig. 1. Rotational energy barrier of *trans*-1,2-dichloroethylene.

triplet state is most stable.[1,21,22] In this section, we will present the potential energy changes caused by the rotation around the central CC double bond, where the rotational configurations are assumed to be unchanged, as in the planar *trans*-form, except for the rotational angles.[23] In Fig. 1, the energy changes for various rotational angles in the *trans*-dichloroethylene are plotted, the N, T, and V notations are the ground state and the lowest triplet and singlet states respectively. It may be noticed that the T and V states, in the twisted configurations are constructed mainly by the lowest π–π^* and π–σ^* excited states in the planar form.

By utilizing the obtained potential curves, the estimations of the force constant for the twisting vibration around a CC bond are made. The results obtained are presented in Table 9. Considering the approximations used, the agreements between them are fairly good, but the values in halogenated compounds are somewhat smaller.

At the twist angle of 90°, the above-mentioned states are labelled by the suffix m, N_m, T_m, and V_m; these energy values are listed in Table 10, together with the the angle, θ_1, at which the N and T states cross. In Fig. 2, the outlines of these state energy curves are given. From the table it is clear that the singlet and triplet energies decrease to minima at the perpendicular configuration, and that, in this state, the T_m states are the lowest. Further, the calculations show that the shapes of the potential energy curves of *cis*- and *trans*-isomers are not very different, and that the crossing of T and N states occurs near 90°. Thus, it may be said that the intermediate triplet states through the *cis-trans*-isomerization are common to both isomers. This result accords with the experimental conclusions for the *cis-trans*-isomerization in dichloroethylene.[22] It may, however, be noticed that since the R_m and V_m states converge to the degenerate state in ethylene, more knowledge of the configuration interaction will be necessary before we can discuss these states more quantitatively.

Measurements of Total Cross Sections for the Scattering of Potassium Atoms by Rare Gases

Isao KUSUNOKI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received January 21, 1971)

Total cross sections for the scattering of potassium by He, Ne, Ar, Kr, and Xe have been measured in the thermal energy range. The velocity of potassium beam is selected by a velocity selector of a slotted disk type. To obtain accurate total cross sections, the pumping effect of a McLeod gauge for the pressure measurements, the fringe effect of the scattering chamber, corrections for angular resolution and for thermal motion of the target gases are taken into consideration. A new type of scattering chamber with a variable length is used to eliminate the error of the effective scattering path length. Velocity dependence of total cross sections has been obtained and glory undulations are observed for potassium-xenon systems. For argon, krypton, and xenon the van der Waals constants are calculated from the absolute total cross sections. The values of C_{K-Ar}, C_{K-Kr}, and C_{K-Xe} are 237, 354, and 535×10^{-60} erg·cm^6, respectively, and are in good agreement with the theoretical ones of Dalgarno and Davison. For neon the velocity dependence of the total cross section can not be explained by the van der Waals potential, $-C/r^s$, where $s=6$. For helium the correction factors for thermal motion of the scattering gas are large and the value of s for attractive potential can not be determined unambiguously.

It is well known that total collision cross sections measured by the scattering of molecular beams can afford an excellent means to study interatomic forces. In the thermal energy range the total cross sections are mainly governed by the long range van der Waals attraction, and the van der Waals constants can be determined by the measurements of the total cross sections.

In the molecular beam study, the total cross sections for scattering of potassium atoms by rare gases have been measured by many investigators[1] since the pioneering work of Rosin and Rabi.[2] The reason for this choice may be that potassium is the easiest to handle and detect as the beam material, and rare gases are also easy to handle as target gases experimentally and theoretically. Thus, the total cross section for scattering of potassium atoms by argon atoms has been regarded as a standard in this kind of experiment.

However, there are several sources of errors in the method of determination of the absolute total cross section, and the values published by different investigators did not always coincide. On the other hand, the method of data analysis has improved in the last decade, and many experimental results in the past have been become obsolete. The main reasons are as follows.

(1) The treatment of Berkling *et al.*[3] for correction of the velocity distributions of the beam and target gases is superior to that of Rosin and Rabi,[2] because the former takes into account the velocity dependence of the total cross sections. It is also evident that monochromatic beams used in recent studies are superior to thermal beams.

(2) In measuring the pressures of scattering gases with a McLead gauge, mercury drag effect must be taken into consideration.[4]

(3) The concept for angular resolution was improved by Kusch[5] and Busch,[6] and it has been recognized that the correction can not be ignored for beams of rectangular cross sections.

(4) To estimate the van der Waals constant from the total cross section, the Schiff and Landau-Lifshitz approximation formula[7] is superior to the Massey-Mohr formula.[8,9]

(5) There are few papers in which the effective scattering lengths are determined experimentally and unambiguously.

In a previous paper, the author took into consideration the above-mentioned items (1), (2), and (4).[10] In the present work, the absolute total cross sections for the scattering of potassium atoms by rare gases have been measured with the velocity selected beams, and the van der Waals constants have been estimated by the Schiff and Landau-Lifshitz approximation. Moreover, the effective scattering lengths have been determined experimentally, and other possible sources of error have also been taken into account.

Theoretical

For the measurement of the total collision cross section of gas molecules by means of the molecular beams, Beer's law is applicable for attenuation of the beam intensity, thus

$$I = I_0 \exp(-nQL), \quad (1)$$

where I_0 and I are the intensities of primary and at-

tenuated beams, respectively. Q is the total cross section, L is the scattering path length, and n is the density of the target gas in the scattering chamber. Equation (1) is only correct for the ideal case in which a monochromatic molecular beam passes through a static target gas. However, as the target gas atoms are always moving, it is necessary to replace Eq. (1) by the equation

$$I = I_0 \exp(-nQ_{eff}L), \tag{2}$$

where Q_{eff} is an average total cross section over the whole relative velocity range. According to Berkling *et al.*,[3] the effective total cross section $Q_{eff}(v_i)$ at a beam velocity v_i, is related to the absolute total cross section $Q_i(v_i)$ as follows,

$$Q_0(v_i) = Q_{eff}(v_i)/Fa_0(s, x), \tag{3}$$

where $Fa_0(s,x)$ is a correction factor. Numerical values of $Fa_0(s,x)$ for $s=4$, 5, 6, and 7 have been calculated by a computer.[11] The values for $s=6$ coincide with those tabulated in Ref. 3.

All the apparatuses always have finite angular resolutions for detection of the scattering event. Thus, the scattering inside the resolving angle should be corrected. In the present experiment the beam and the detector have rectangular cross sections perpendicular to the direction of the beam, and their heights are larger than their widths. The angular resolution is not uniform, and depends on the position in the plane of the detector and the point in the scattering region. However, for a narrow rectangular beam it is expected to be uniform along its height.

Consider a particle scattered in the scattering chamber from a point at a distance l from the plane of the detector, and at a distance z from the vertical central line of the beam (Fig. 1). If the trajectories of the unscattered atoms are sufficiently parallel to each other, a part of the beam scattered through an angle Θ and falls on the detector is given by

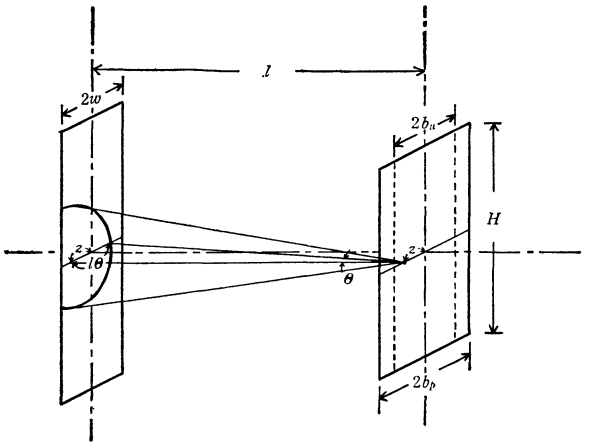

Fig. 1. Geometrical parameters for the correction of angular resolution.

$$2\pi n i(z) R(z, l, \Theta)\sigma(\Theta)\sin\Theta \mathrm{d}\Theta, \tag{4}$$

where n is the density of the scattering gas, $i(z)$ is the beam intensity at the scattering point, $R(z,l,\Theta)$ is the portion of the circumference of the circular cone of the scattered beam intercepted by the detector, and $\sigma(\Theta)$ is the differential cross section in the laboratory system.[12]

In the first approximation the correction term for angular resolution is obtained in the case of $z=0$ and $l=$constant, thus

$$\Delta Q(v_i) = 2\pi \int_0^{\pi} R(l, \Theta)\sigma(v_i, \Theta)\sin\Theta \mathrm{d}\Theta \tag{5}$$

A formula representing a more perfect correction for the angular resolution is

$$\Delta Q(v_i) = \frac{2\pi \int_{l_{cd}-L}^{l_{cd}} \int_{-b_p}^{b_p} \int_0^{\pi} i_0(z) \mathrm{e}^{-nQ(l_{cd}-l)} R(z, l, \Theta)\sigma(v_i, \Theta) \sin\Theta \mathrm{d}\Theta \mathrm{d}z \mathrm{d}l}{\int_{l_{cd}-L}^{l_{cd}} \int_{-b_p}^{b_p} i_0(z) \mathrm{e}^{-nQ(l_{cd}-l)} \mathrm{d}z \mathrm{d}l}, \tag{6}$$

where l_{cd} is the distance from the entrance slit of the scattering chamber to the detector, b_p is the half width of penumbra of the beam profile at the scattering plane, and L is the effective length of the scattering chamber.

We previously assumed a beam of infinite height, but in this experiment a beam of finite height is used. Thus the R-function has to be modified to a function of h, and Eq. (6) becomes

$$\Delta Q(v_i) = \frac{2\pi \int_{-H}^{H} \int_{l_{ed}-L}^{l_{cd}} \int_{-b_p}^{b_p} \int_0^{\pi} i_0(z) \mathrm{e}^{-nQ(l_{cd}-l)} R(h, z, l, \Theta)\sigma(v_i, \Theta) \sin\Theta \mathrm{d}\Theta \mathrm{d}z \mathrm{d}l \mathrm{d}h}{2H \int_{l_{cd}-L}^{l_{cd}} \int_{-b_p}^{b_p} i_0(z) \mathrm{e}^{-nQ(l_{cd}-l)} \mathrm{d}z \mathrm{d}l}, \tag{7}$$

where $2H$ is the height of the beam. However, in the experiment h is much larger than b_p (*i.e.* $H \sim 100\, b_p$), and the R-function is nearly independent of h over the whole region of h. Therefore, the final correction term can be given by Eq. (6). Unfortunately, n and Q are included in Eq. (6), and a calculation of the equation is intractable. If the distance l_{cd} is much larger than L, the correction term may be simplified to

$$\Delta Q(v_i) = \frac{2\pi \int_{-b_p}^{b_p} \int_0^{\pi} i_0(z) R(z, \Theta)\sigma(v_i, \Theta) \sin\Theta \mathrm{d}\Theta \mathrm{d}z}{\int_{-b_p}^{b_p} i_0(z) \mathrm{d}z}. \tag{8}$$

However, if b_p is larger than the half width of the detector w, there are some parts of the beam which do not contribute to I_0, but some atoms scattered from these parts fall on the detector. In such a case, the integral region of z in the denominators of Eqs. (6—8) should be from $-w$ to w.

The correction values can be calculated by a computer, but the calculation is troublesome. In the present case, Busch's method[6] seems to be satisfactory

11) These values will be published elsewhere.

12) The procedure to obtain $\sigma(\Theta)$ from $\sigma(\theta)$ in the center-of-mass system will be given elsewhere.

and will be used.

Experimental

Figure 2 shows a schematic drawing of the apparatus, which consists of an oven chamber, a velocity selector chamber, and a measuring chamber. A scattering chamber and a beam detector are placed in the measuring chamber. In each chamber a liquid-nitrogen cooled plate to remove the surplus beam atoms is equipped. The chambers are pumped by 4-inch oil diffusion pumps with cold traps, typical operating pressures in these chambers being about 2×10^{-7} Torr. The pressures are kept constant during an experimental run.

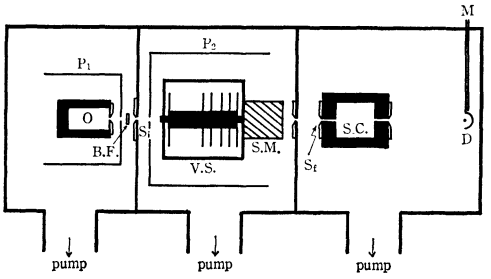

Fig. 2. Diagram of the beam apparatus. Drawing is not to scale. The labeled parts are: O, oven; B.F., beam flag; S_i, the first collimating slit; S_f, the final collimating slit; S.C., scattering chamber; D, detector; M, manipulator; $P_{1,2}$, liquid nitrogen cooled shields; V.S., velocity selector; S.M., synchronous motor.

Source. The oven is single chamber type and beam atoms effuse from a slit of 0.19 mm width. It is made of stainless steel and supported by three tungsten pins on a movable plate with dove-tails. The heater current of the oven is supplied by a DC power stabilizer. The temperature of the oven is measured by a chromel-alumel thermocouple, and the beam intensity is monitored by a surface ionization gauge in front of the source.

Velocity Selector. The velocity selector[13] is a slotted disk type. The number of disks is six and its total length L is 12.02 cm. The phase angle φ_0 is 0.2097 rad. and the velocity of the selected beams is given by

$$v = \frac{\omega L}{\varphi_0} = 360f \text{ (cm/sec)}, \tag{9}$$

where ω is the angular velocity of the rotating disks and f is the number of revolutions per second. The thickness of the disks is 3 mm, which is thicker than those used by the others.[14] However, the slits are cut obliquely along the beam path and its transmission is 47.6%. The width of the slits is 0.50 mm and the mean width of each tooth is 0.505 mm. The number of these slits or teeth is 360 per disk of diameter 12.5 cm. The length of slits in the radial direction is 5 mm. The resolution of the selector ($\Delta v/v$) is 3.96%. The selector is driven by a synchronous motor (Electronic Specialty Co. EF17H71). Power is supplied to the motor from a two-phase oscillator (NF circuit design block Co.). The number of revolutions of the selector is monitored by reflected light pulses from the disk surface painted with black stripes by a photomultiplier and a frequency counter.

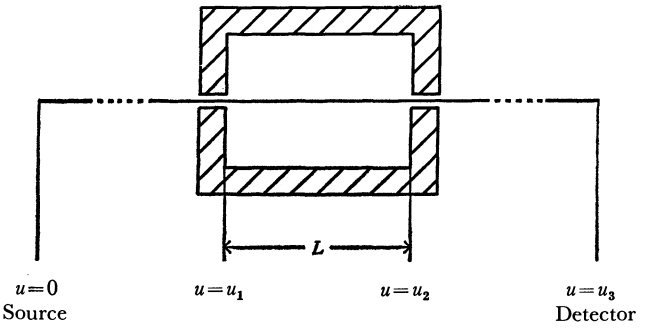

Fig. 3. Conventional scattering chamber.

Scattering Chamber. A conventional scattering chamber is shown in Fig. 3. Scattering gas in the chamber effuses out along the beam path. Thus, the effective path length L_{eff} for the beam attenuation can be given by

$$n_0 L_{eff} = \int_0^{u_1} n(u)\mathrm{d}u + n_0 L + \int_{u_2}^{u_3} n(u)\mathrm{d}u, \tag{10}$$

where n_0 is the number density of gas molecules inside the chamber, L is the inside length, and $n(u)$ is the density along the beam path. Rothe *et al.*[15] have driven an approximate formula for the estimation of L_{eff}, but a reliable estimation of $n(u)$ is not easy.

To avoid uncertainty of estimation by an approximate formula and obtain an exact value of n_0L, a chamber with a variable length, as shown in Fig. 4, is used. The chamber

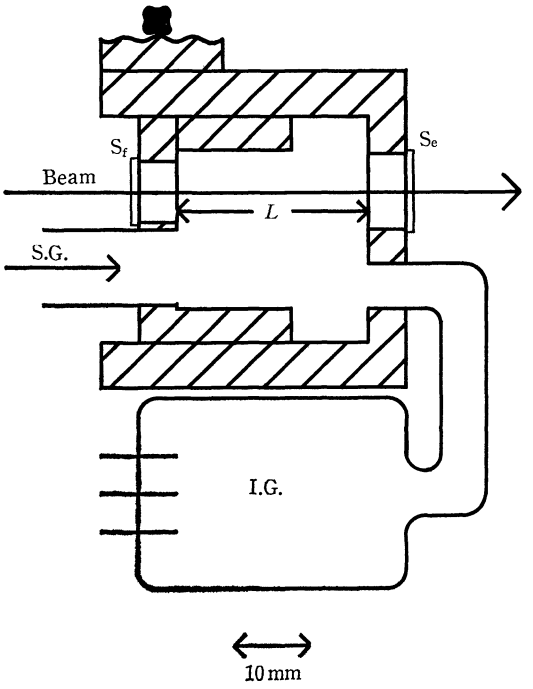

Fig. 4. Vertical cross section of the scattering chamber. S_f, entrance slit; S_e, exit slit; S.G., scattering gas; I. G., ionization gauge.

consists of two cylinders; one slides inside the other and the length of the chamber can be changed from 15 mm to 30 mm. Operation can be performed from outside the vacuum vessel. The dimensions of entrance and exit channels and slits are: channels:

15) E. W. Rothe, L. L. Marino, R. H. Neynaber, P. K. Rol, and S. M. Trujillo, *Phys. Rev.*, **126**, 598 (1962).

widths, 1.0 mm
heights, entrance 8 mm, exit 10 mm
lengths, 5.0 mm
slits:
widths, entrance 0.06 mm, exit 0.35 mm
heights, entrance 8 mm, exit 10 mm.
The entrance slit functions as a collimating slit in this beam system.

The scattering chamber is evacuated by a Hickman oil diffusion pump, and the scattering gases are introduced into the chamber from a gas reservoir through a glass capillary.

Detector. In order to detect the potassium beam, a Langumuir-Taylor surface ionization detector is used. The filament is biased by +90 V relative to the ion collector. Ion current is measured with a vibrating-reed electrometer and recorded by a two-pen recorder along with the pressure in the scattering chamber.

Angular Resolution. The distance from the source slit to the collimating slit l_{sc} is about 70 cm, and the distance from the collimating slit to the detector l_{cd} is 10.5 cm. The angle subtended by the collimating slit at the position of the source slit is 8.6×10^{-5} rad. Thus, trajectories of the atoms in the beam are almost parallel to each other. The angle subtanded by the collimating slit at the detector is 5.7×10^{-4} rad. The angle subtended by the detector at the scattering center, previously taken as a geometrical resolution, is 4.1×10^{-4} rad. The geometrical half width of the umbra of unscattered beam profile b_u is 0.02 mm, and that of the penumbra b_p is 0.049 mm. According to Kusch's criterion[5] the angular resolution determined by the beam profile is 4.0×10^{-4} rad.

Pressure Measurement. To determine the absolute cross section, the most important and the most difficult problem is to measure the absolute pressure of target gases. In the present experiment a large McLeod gauge calibrated in our laboratory by mercury weighing, is used as a standard pressure gauge. The McLeod gauge is similar to that of Rosenberg[16] and the gauge constant is 3.32×10^{-7} (*i.e.* $P=3.32\times h^2\times10^{-7}$ Torr, h in mm). With this large volume gauge the absolute pressures of the rare gases in the range of 5×10^{-5} to 5×10^{-4} Torr can easily be measured. However, it is not suitable to measure the pressure in the scattering chamber directly by the McLeod gauge, because the connecting tube between the chamber and the gauge becomes so long that a pressure gradient may arise between them, and furthermore, it can not measure the pressure continuously.

To measure the pressure of the rare gases in the scattering chamber an ionization gauge (Mitsubishi K-30) is connected directly to the scattering chamber with a short glass tube and placed in the measuring chamber. The tube is bent in order to prevent the gas from passing through it without collisions with the wall. This caution is necessary, because the temperature of the scattering gas should be equal to that of the wall anywhere in the chamber.

The sensitivities of the ionization gauge for rare gases are calibrated by the McLeod gauge described above. For calibration of the sensitivities the mercury drag effect has to be considered, because the mercury vapor stream from the McLeod gauge to the cold trap inserted between the ionization gauge and the McLeod gauge brings about an error in the absolute pressure measurement. The magnitude of the effect depends on the ambient temperature, the tubing diameter and length, the gas pressure, and the diffusion constant of the gas in mercury vapor. According to Takaishi,[17] the effect is estimated by the expression

$$\frac{P''-P'}{P'}=\frac{P_{Hg}}{P'}\left\{1-\frac{1}{B}\ln\left(\frac{P''}{P'}\right)\right\},$$

$$B=3\alpha^2\sigma^2\{m_g/(m_g+m_{Hg})\}^{1/2}rP_{Hg}/4kT \qquad (11)$$

where P' and P'' are the pressure of the gas in a McLeod gauge and that of the gas to be calibrated, respectively. P_{Hg} is a pressure of the mercury vapor at the temperature of T. $\pi\sigma^2$ is a collisional cross section between the mercury atom and a gas atom; m_g and m_{Hg} are the molecular weights of the gas and mercury, r is a radius of the connecting tube ($r=$ 0.4 cm), and α is a constant about 1.[18] To eliminate the effect completely, the cut-off position of the McLeod gauge is cooled with dry ice in order to remove the mercury vapor stream as described by Ishii and Nakayama.[4]

The sensitivities of the ionization gauge measured for rare gases are given in Table 1. The relative sensitivities are compared with the values of other authors. The present values determined by cooling the cut-off position are close to those of Rothe,[19] obtained by placing the McLeod gauge in a refrigerator to get rid of the mercury drag effect. On

the other hand, the values obtained without cooling are close to those of Dushman and Young,[20] in which no precaution against the effect has been taken. The magnitude of the effect is expressed by a factor $SB/SA-1$. As shown in Table 1, the values are in good agreement with those calculated with Takaishi's theory.

Results

The effective total cross section Q_{eff} is usually obtained by

$$I = I_0 \exp(-n_0 L_{eff} Q_{eff}) \tag{12}$$

where $n_0 L_{eff}$ is a value given by Eq. (10). If the beam attenuation is measured at different scattering lengths, the fringe effective represented by the first and third terms of Eq. (10) may be compensated, and the effective total cross section can be estimated by the equation

$$Q_{eff} = \frac{1}{L_1 - L_2}\left\{\left[\frac{\ln(I_0/I)}{n}\right]_1 - \left[\frac{\ln(I_0/I)}{n}\right]_2\right\} \tag{13}$$

where suffixes 1 and 2 refer to the values of different lengths of the scattering chamber, and L_1 and L_2 represent the inside lengths of the chamber without the channel region. During the measurement it is very difficult to change the length keeping the pressure constant, because the outgas from the wall by changing the length disturbs the pressure of the scattering chamber. A typical result is shown in Fig. 5 for the scattering of the velocity selected potassium beam (720 m/sec) by xenon with L=20, 25, and 30 mm. Using Eq. (13), Q_{eff} is estimated from the slopes of the lines as

$$Q_{eff}(720\ \text{m/sec}) = 672\ \text{Å}^2.$$

Results for all the rare gases are shown in Table 2.

The effective scattering length L_{eff} is also estimated from Fig. 5 by the equation

$$(L_i)_{eff} = \frac{1}{Q_{eff}}\left[\frac{\ln(I_0/I)}{n}\right]_i, \tag{14}$$

where Q_{eff} is a value obtained by Eq. (13). The effective scattering length obtained for various scattering gases are plotted in Fig. 6 against the geometrical length of the scattering chamber. The effective length L_{eff} is calculated for L_1=30 mm. Open circles are the values measured with the thermal beams, and solid circles are those measured with the velocity selected beams (720 m/sec). All the values fall within the range of 40.0±0.7 mm which is nearly equal to the length of the scattering chamber including channels at both ends. The value calculated by the equation

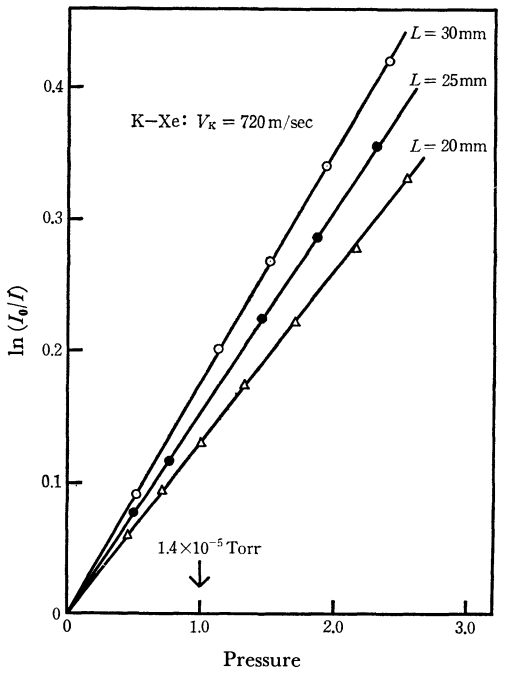

Fig. 5. Attenuation of potassium beam *vs.* pressure of xenon gas. L is the length inside the scattering chamber.

derived by Rothe *et al.*, shown by an arrow $\bar{A}$, is 38.4 mm, while $\bar{B}$ is the value calculated by the following equation derived by the author.

$$(L_i)_{eff} = \frac{l}{2}\left[1 + \frac{8Ka^2b}{8Ka^2b + 3(a+b)lc}\right] + L_i + \frac{l'}{2}\left[1 + \frac{8K'a'^2b'}{8K'a'^2b' + 3(a'+b')l'c'}\right], \tag{15}$$

where a, b, and l are the width, height, and length of the entrance channel, respectively, K its Clausing factor and c the width of the entrance slit; a', b', l', and K' are the corresponding quantities for the exit channel, and c' of the exit slit. In this case, the value of $(L_1)_{eff}$ amounts to 39.0 mm. Both of the calculated values are smaller than the experimental values, which are independent of the gaseous species and the beam velocity. Therefore, L_{eff}=40.0 mm is used in Eq. (12) to estimate Q_{eff}.

The absolute total cross section, $Q_0(v_i)$, may be obtained from $Q_{eff}(v_i)$ by means of Eq. (3). However, to estimate an accurate absolute total cross section, a correction for angular resolution has to be considered. Calculations of the correction described in the theoretical section are complicated and troublesome. In the present analysis, the Busch approximation for argon, krypton, and xenon is used because the discrepancy

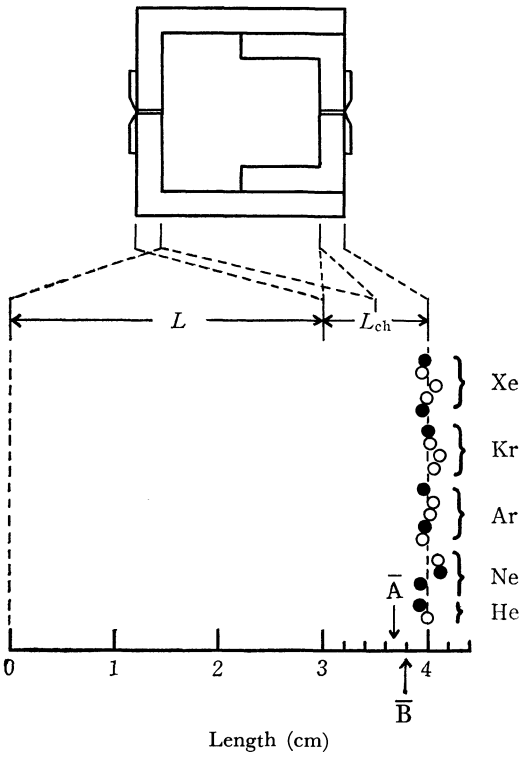

Fig. 6. Effective scattering lengths measured by rare gases. L_{ch}, length of channel region; ○, measured by thermal beam; ●, measured by the velocity selected beam.

from the exact calculation should be small. The correction factor[21] is given by

$$\frac{dQ}{Q} = 0.0765\sqrt{Q_0 k_i^2}\gamma\left(1 + \frac{0.368}{x^2}\right), \qquad (16)$$

$$\gamma = \frac{b_u + b_p}{l} \quad \text{for } w \leq b_p.$$

Then, the corrected absolute total cross section Q_w is calculated by

$$Q_w = \frac{Q_0}{(1 - dQ/Q)}. \qquad (17)$$

The correction amounts to 5-10%. In Table 2 the corrected total cross sections Q_0 and Q_w are listed for the beam velocity of 720 m/sec, which corresponds approximately to the most probable beam velocity and is obtained from 200 rps of the velocity selector. Figure 7 shows the variations in the total cross section Q_w for K–Ar, K–Kr, and K–Xe systems against the velocity of the potassium beam in a logarithmic scale. The straight lines with slopes of $-2/5$ correspond to $s=6$. For argon an agreement with $s=6$ is fairly good. The slopes of these curves for krypton and xenon are slightly steeper than $-2/5$. This means that s is smaller than 6, and between 5 and 6. This may be due to the glory effect or some unknown systematic experimental error. As the temperature of the scattering chamber is relatively high (*i.e.* room temperature), no undulation of the total cross section

21) F. Busch, H. J. Strunck, and Ch. Schlier, *Z. Physik*, **199**, 518 (1967).

is obtained for argon. However, a trace of undulation can be observed for krypton, and a more definite undulation for xenon.

For neon and helium similar treatments are not feasible, because it is not clear whether the interatomic potential can be approximated by a simple attraction with $s=6$ in the measured velocity range. For neon log Q_{eff} *vs.* log v_K plots are in Fig. 8. In this case, even after the correction with $Fa_0(6, x)$ a large discrepancy remains between the theoretical and the experimental curves. However, the values corrected with $Fa_0(4, x)$ are in fair agreement with the slope of $s=4$. The correction for angular resolution will give a less steep slope than that of the plotted values and results in a better agreement. For helium, log Q_{eff} *vs.* log v_K plot and the corrected values with $Fa_0(5, x)$, $Fa_0(6, x)$, and $Fa_0(7, x)$ are shown in Fig. 9. In this correction, factors of Fa_0 are very large, and it is not clear which correction is the best.

Discussion

The relation between the total cross section and the van der Waals constant is given by

$$Q(v) = p\left[\frac{C}{\hbar v}\right]^{2/5}, \qquad (18)$$

where p is a dimensionless constant. It is 8.083 according to the SLL aproximation.

The van der Waals constants calculated from the total cross sections are listed in Table 3. C is a mean value over the measured velocities. The values of the present work are smaller than the experimental values of other authors. However, the values for argon, krypton, and xenon are in good agreement with recent theoretical values, being slightly smaller. For the K–Ar system, the discrepancies of our value with the theoretical one of Dalgarno and Davison[28] and with that of Mahan[29] are within 10%, which is within experimental uncertainty. The relative values of C for argon C_X/C_{Ar} are in good agreement with those of Dalgarno and Davison. For neon and helium, the van der Waals constants can not be derived from the experimental values of total cross sections, because in these cases interatomic interactions may not purely be those of a van der Waals nature.

From the glory undulation of the velocity dependence of the total cross section, the value of εr_m can be estimated. According to Bernstein and O'Brien,[30] the extremum condition can be given by

$$N - \frac{3}{8} = \frac{2\varepsilon r_m a_1}{\pi\hbar v_N}\left[1 - \frac{A_1\varepsilon}{a_1 E_N} + \frac{A_2\varepsilon^2}{a_1 E_N{}^2}\right], \qquad (19)$$

where $A_1=0.1625$, $A_2=0.0801$, a_1 is a known function of κ which is the curvature at the potential minimum, N is the index number of the extremum, and E_N is

$1/2\,\mu v_N^2$. In the present work, the velocities of a maximum and a minimum for K–Xe system are around 1040 m/sec and 870 m/sec, respectively. According to Beck and Loesch,[34] these values correspond to v_N for $N=3$ and 3.5. Thus, for the L-J(12, 6) potential the value $\varepsilon r_m = 11.0\times10^{-22}$ erg·cm is obtained. Similarly, the value $\varepsilon r_m = 8.0\times10^{-22}$ erg·cm is obtained for K–Kr system. If the L–J(8, 6) potential is assumed instead of the L–J(12,6) potential, the values εr_m are smaller than those for L–J(12, 6) potential, as shown in Table 4. However, these values may contain errors of about 10%, because the undulation is obscured by the thermal motion of target gases.

For the L–J(12, 6) potential, the van der Waals constant C is equal to $2\,\varepsilon r_m^6$. Then, if the values of εr_m are combined with the experimental values of C, ε, and r_m can be estimated separately. These values are listed in Table 4.

For the K–Ne or K–He system, the values of εr_m are unknown, but they may be smaller than 4.5×10^{-22} erg·cm for K–Ar system.[34] If the value of $\varepsilon r_m/\hbar g$ is less than 3—5, there is no extremum given by Eq. (19), and the velocity dependence of the total cross section is not represented adequately by Eq. (18).[38] In the present study, the values of $\hbar g$ for these systems are larger than 0.7×10^{-22} erg·cm. Therefore, if the value εr_m is smaller than 2.5×10^{-22} erg·cm, the above condition may be satisfied, and the velocity range will correspond to the transition range from the predominantly attractive $s=6$ to the predominantly repulsive $s=12$ ranges.

The present work was partly supported by the Toray Science Foundation. The author would like to thank Professor Kumasaburo Kodera for his valuable advice and guidance. The assistance of Mr. Atsuhiro Sakiyama during the course of the experiment is also acknowledged.

Tritium Fractionation on the Crystal Growth of Sodium Sulfate Decahydrate from Its Tritiated Aqueous Solution

Haruhiko TANAKA* and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received January 25, 1971)

The fractionation of tritiated water (HTO) was examined during the crystallization of sodium sulfate decahydrate, $Na_2SO_4 \cdot 10H_2O$, from a slightly supersaturated solution which contained a trace amount of tritium. No appreciable fractionation of HTO was found to occur in the crystallization under both stirred and unstirred conditions. The factors which may influence the degree of the fractionation were generally considered in connection with the studies by deuterated water. It was suggested that virtually all of the water of crystallization in sodium sulfate decahydrate should come from free water in its aqueous solution, and should integrate into the crystal in accordance with the volume-diffusion model. This model was supported also by the energetical consideration of the sodium ion in the crystallization.

The fractionation of deuterated water in inorganic salt hydrates has previously been examined, but the results are conflict as to the phase into which deuterated water is enriched.[1-3] It seems from these studies that the enrichment of the isotope in a liquid phase occurs in some salts, while there is the reverse or no fractionation in the other salts.

Recently, it has been reported by the present authors that tritiated water (HTO) is diluted in some inorganic salt hydrates during the crystallization from their aqueous solutions.[4] In this study, it has been proposed, on the basis of the crystal growth theory and an ionic process in a solution, that HTO is diluted in any salt hydrate, or else no fractionation of the isotope occurs.

It has been reported, however, that deuterated water is slightly enriched in the crystal of sodium sulfate decahydrate, $Na_2SO_4 \cdot 10H_2O$.[1,3] In this connection, it seems interesting to examine the fractionation of HTO during the crystallization of the hydrated salt from a tritiated aqueous solution, since the results on the fractionation of HTO in copper sulfate pentahydrate and alum are parallel to that of deuterated water. In other words, HTO can be expected, according to the studies with deuterated water, to be enriched to some appreciable degree.

On the contrary, if HTO is diluted or not fractionated, the result can be explained in the same way as in our previous treatment,[4] assuming the mechanism of the crystallization of $Na_2SO_4 \cdot 10H_2O$ from its aqueous solution as well as the behavior of water molecules during the crystallization.

Experimental

The sodium sulfate decahydrate was obtained from a commercial source and was purified by filtration with fiber-free-filter papers and by recrystallization. The solvent was twice-distilled water which contained a trace amount of tritiated water. The single crystal of $Na_2SO_4 \cdot 10H_2O$ was grown from a slightly supersaturated tritiated aqueous solution at 29.65± 0.02°C by evaporating the solvent. The rate of solvent evaporation was adjusted in such a way that the relative supersaturation of the solution could be kept below *ca.* 2×10^{-3} during the crystallization.

The single crystals were thus obtained from both stirred and unstirred solutions under identical conditions unless otherwise stated. The crystal from a stirred solution was obtained by growing a seed attached to a copper wire which was rotated to give sufficient agitation.

Water from both the mother liquid and the hydrated single crystal was recovered by heating them until no further dehydration was observed under identical conditions. The tritium content in the water of crystallization was then compared with that in the corresponding mother liquid by analyzing the activity of tritium, as was described in a previous paper.[4]

Results and Discussion

The separation factor, S, of HTO for the equilibrium between solid and liquid phases has been given in a previous paper as follows:[4]

$$S = N_s/N_l, \quad (1)$$

where N_s and N_l are the mole fractions of HTO in the solid and liquid phases respectively. Table 1 gives the separation factor, S, together with the net counts per minute (cpm) coming from tritium; these counts are in proportion to N_s and N_l respectively.

TABLE 1. SEPARATION FACTOR, S, OF HTO DURING THE CRYSTALLIZATION OF $Na_2SO_4 \cdot 10H_2O$ FROM A SOLUTION AT 29.65±0.02°C

The condition of mother liq.	Net cpm of tritiated water[a]		Separation factor (S)[b]
	Mother liq. (N_l)	Crystal (N_s)	
Unstirred	31535±146	31615±132	1.003±0.005
Stirred	33260±127	33273± 87	1.000±0.004

a) Each sample water was 0.1 g, and its cpm was measured using a counter of 35% efficiency.
b) The accuracy of the value of S is indicated in terms of the probable error.

It may be seen from Table 1 that no practical fractionation of HTO occurs during the crystallization of $Na_2SO_4 \cdot 10H_2O$ from either the stirred or the unstirred solution.

Relation between the Present Data and Those of Other Workers. The data so far determined on the frac-

tionation of heavy water in $Na_2SO_4 \cdot 10H_2O$ are reproduced in Table 2.

Table 2. Fractionation of heavy water on crystallization of $Na_2SO_4 \cdot 10H_2O$ from a solution

Heavy water (mol%)	Temp. of crystn. (°C)	Rate of crystn.	Separation factor (S)
D_2O (10)	26.5—25.5	Rapid	1.014[a]
D_2O (0.1, 1.0)	4, 25	Slow	1.001, 1.002[b]
HTO ($\sim 10^{-7}$)	29.65	Very slow	1.000, 1.003

a), b) Taken from Refs. 1 and 3 respectively.

Our results are in good agreement with those of Uusitalo,[3] but are discordant with the results of Johansson and Holmberg.[1] In the study of Johansson and Holmberg, however, a large amount of the crystal was grown from a 200-m*l* solution by cooling the solution at a rather rapid rate. Moreover, as the mother liquid a solution containing about 10 mole% of D_2O was used. These experimental conditions may allow an increasing ambiguity in the results or give results discordant with ours, as may be expected from the following considerations:

(1) It seems in general that the separation factor should be sensitive to the temperature of crystallization.[5]

(2) There is an increasing inclusion of the mother liquid into the growing crystal in the case of crystallization from a highly supersaturated solution.

(3) In the case of the fractionation of the isotope in the crystal, the mother liquid is subject to a reverse isotope effect.[6]

(4) When the mother liquid contains as much as 10 mole% of D_2O of heavy water, its behavior should be different from that of the liquid which is not enriched in D_2O. This situation will in turn complicate the problem.

Accordingly, it seems that each result listed in Table 2 is correct under the corresponding experimental conditions, although there may be some ambiguity unless the experimental conditions are strictly controlled. It will be worthwhile to use the present data of the fractionation of HTO in understanding the process of the crystal growth of $Na_2SO_4 \cdot 10H_2O$.

Estimation of the Fraction of Free Water Molecules in the Solution. A number of studies have been made of the determination of the hydration numbers of the Na^+ ion; the results so far reported vary depending upon the methods of determination. It is assumed in the present case that the Na^+ ion is surrounded, on the average, by four water molecules.[7]

The lifetime of the hydrated species has been found to be extremely short at room temperature, *i.e.*, *ca.* 10^{-9} sec, as evidenced by the relaxation technique.[8] Neglecting the hydration of the sulfate ion in the concentrated aqueous solution of Na_2SO_4,[9] it can be assumed that Na^+ and SO_4^{2-} ions enter the crystal practically independently of the water as well as of its isotopic concentration. The relaxation time of the Na^+ ion for entering into the crystal, τ, is expressed as follows:

$$\tau = (\boldsymbol{h}/\boldsymbol{k}T) \exp(E/\boldsymbol{k}T), \quad (1)$$

where

$\boldsymbol{h}$=Planck's constant,
$\boldsymbol{k}$=the Boltzmann constant,
T=the absolute temperature, and
E=the activation energy of the cation for entering into the crystal from a solution, the minimum value of which has been assessed by Bennema to be *ca.* 10 kcal/mol.[10]

Accordingly, τ is estimated to be larger than *ca.* $10^{-5.5}$ sec at around room temperature. It follows that any water molecule in the vicinity of the Na^+ ion can reside in its hydration sphere only for an instant when the cation is fixed into the crystal.

Although intimate ion pairs may result at a high concentration of the Na_2SO_4 aqueous solution,[11] the lifetime of the species is also found to be very short, making it possible to treat it as separated ions. Moreover, it has been suggested by Samoilov that the Na^+ ion should migrate in the solution with almost no relation to the water in the vicinity.[9] It follows from the preceding argument that the water of crystallization in $Na_2SO_4 \cdot 10H_2O$ should practically result from free water molecules in the solution; that is, the species of the growth unit should be Na^+, SO_4^{2-}, and H_2O.

Calculation of Separation Factor in the Case of the Crystal Growth by a Surface-diffusion Mechanism. It has been reported in a previous paper that the separation factor, S, can be calculated on the basis of the ionic process in a solution and on the basis of the crystal-growth theory from a solution.[4] In the case of the crystal growth by a surface-diffusion mechanism, the rate of integration of a free water molecule into the crystal has been given by:

$$R = \alpha \Omega N_0 (\boldsymbol{k}T/2\pi m)^{1/2} (\sigma^2/\sigma_1) \tanh(\sigma_1/\sigma) \quad (2)$$

where

α=the correction factor,
Ω=the volume of a growth unit in the crystal,
N_0=the equilibrium concentration of growth units per cm^3 in the solution,
m=the mass of a growth unit,
σ=the relative supersaturation, and
σ_1=the parameter.

In exactly the same manner as before, the R_{HTO}/R_{H_2O} ratio is obtained in the case of the crystal growth with an essential process of a surface diffusion of growth

5) Very recently it has been found by the present authors that the separation factor is considerably influenced by the temperature in the case of the crystallization of alum from a solution. This finding will be presented in detail elsewhere.

6) In the present crystaplization, only *ca.* 1.5—2 g of the salt hydrate were obtained from a large amount of the mother liquid (*ca.* 800 g); thus, it may be possible to disregard this effect.

units as follows:

$$R_{HTO}/R_{H_2O} = 0.949, \quad (3)$$

where R_{HTO}/R_{H_2O} is the ratio of the integration of HTO into the crystal to that of H_2O molecules. Accordingly, the separation factor, S, in $Na_2SO_4 \cdot 10H_2O$ in the case of the surface-diffusion model can be simply calculated to be 0.949, since all of the water molecules of crystallization in $Na_2SO_4 \cdot 10H_2O$ can reasonably be assumed to result from free water in the solution, as has been described above. The preceding argument thus allows us to expect a considerable dilution of HTO in the crystal if the crystal grows by the surface-diffusion mechanism.

Calculation of Separation Factor on the Basis of a Volume-diffusion Mechanism of the Crystal Growth. If we adopt a volume-diffusion model for the growth from a solution in which a growth unit is directly transported from the solution to the kink without any surface diffusion,[10,12] the rate of the crystal growth is given by:

$$R = \{2\pi\lambda\varepsilon\beta D N_0 \Omega \boldsymbol{k}T/19\gamma a x_0)\}\sigma^2, \quad (4)$$

where

λ=the mean distance between one equilibrium position and a neighboring one in the solution,
ε=the measure of the interacting spirals,
β=the retarding factor,
D=the volume-diffusion constant,
γ=the edge free energy of a step with the length of a,
a=the shortest distance between growth units, and
x_0=the mean distance between the kinks.

It follows from Eq. (4) that the R_{HTO}/R_{H_2O} ratio is equal to the D_{HTO}/D_{H_2O} ratio, where D_{HTO}/D_{H_2O} is the ratio of the diffusion constants of HTO to H_2O molecules in a solution. When the crystal is grown from a well-stirred solution, the D_{HTO}/D_{H_2O} ratio becomes unity, giving no fractionation of HTO during the crystallization of $Na_2SO_4 \cdot 10H_2O$. In the case of the crystallization from an unstirred solution, the R_{HTO}/R_{H_2O} ratio can also be given by unity, since the value of D seems to be practically independent of the hydrogen isotope of the water molecules.[9]

Accordingly, it follows that no practical fractionation of HTO can be expected to occur during the crystallization of $Na_2SO_4 \cdot 10H_2O$ from either a stirred or an unstirred solution. It should be noted here that the calculation of the value of S on the basis of the volume-diffusion model leads to a satisfactory agreement with the present experimental results. That is, this argument implies that the crystal of $Na_2SO_4 \cdot 10H_2O$ grows by the volume-diffusion mechanism. This implication seems quite interesting in that the volume-diffusion mechanism has been proved for the first time to play an essential role in the crystallization of $Na_2SO_4 \cdot 10H_2O$, although the mechanism was proposed a long time ago and has been discussed generally from a theoretical point of view.[12-14]

The Relation between the Possible Volume-diffusion Mechanism and the Treatment by Bennema. According to Bennema,[12] the mean displacement of a growth unit on the crystal surface, x_s, is given by:

$$x_s = a \exp\{(E_{deads} - E_{sdiff})/2\boldsymbol{k}T\} \quad (5)$$

where a is the shortest distance between neighboring growth units in the crystal, where E_{deads} is the activation free energy for leaving the surface, and where E_{sdiff} is the activation free energy for making a diffusion jump from one equilibrium position to a neighboring one on the surface. The volume-diffusion mechanism can be assumed to play an essential role in the growth of ionic crystals when $a \gtrsim x_s$, *i.e.*, $E_{sdiff} \gtrsim E_{deads}$, since growth units come practically to enter the crystal without any surface diffusion in this case.

The $E_{sdiff} \gtrsim E_{deads}$ condition can be met if the concept of Samoilov as to the hydration of the Na^+ ion is adopted.[9] That is, the transfer of the ion practically without any hydration water in a solution leads to a considerable decrease in the dehydration activation free energy for entering into the surface, E_{deh}, and thus to much smaller values of E_{deads}. It is reasonable to assume, in this case, that E_{deh} should be replaced by the activation free energy of the ion for a diffusion jump in a solution, E_a.

It can be estimated that E_{deads} is equal to 4.2 kcal/mol or somewhat greater, and that E_{sdiff} ranges between 5 and 10 kcal/mol.[10] Accordingly, the possible energy diagram of the growth unit (Na^+ ion) can be given as in Fig. 1.

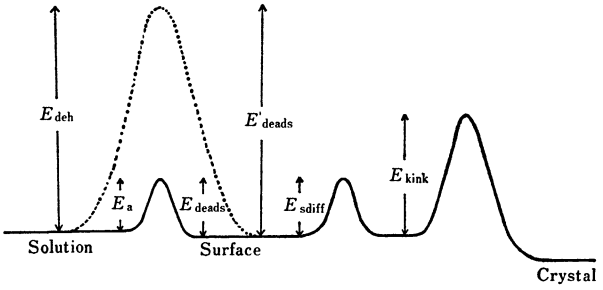

Fig. 1. The proposed energy diagram of Na^+ ion for entering into the crystal of $Na_2SO_4 \cdot 10H_2O$ from its aqueous solution.

In Fig. 1, E'_{deads} is the activation free energy for the Na^+ ion to leave the surface, which is needed if the ion must be dehydrated before entering into the surface (the curve is shown by a dotted line). This model has been adopted by Bennema in discussing the growth of some ionic crystals from their aqueous solutions.[10] Although the energetical consideration is rather ambiguous at this state, it can at least be stressed that the value of E_{deh} is as large as 10—30 kcal/mol, while the value of E_a is only *ca.* 4.2 kcal/mol.[10]

It can be concluded from the preceding discussion that the crystal growth of $Na_2SO_4 \cdot 10H_2O$ from its aqueous solution probably occurs by the volume-diffusion mechanism.

The authors wish to express their thanks to Dr. O. Yamamoto for his help in measuring the activity of tritium.

Studies on the Interaction between Long Chain Alcohols and Alkyl Sulfates. I. Molecular Association between Long Chain Alcohols and Corresponding Alkyl Sulfates

Yoshikiyo Moroi, Kinshi Motomura, and Ryohei Matuura
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received January 28, 1971)

Molecular interaction between long chain alcohols and corresponding alkyl sulfates, such as dodecyl alcohol-sodium dodecyl sulfate, tetradecyl alcohol-sodium tetradecyl sulfate and hexadecyl alcohol-sodium hexadecyl sulfate, was studied by measurement of heat of complex formation, differential thermal analysis and infrared spectroscopy. It was found that there were two kinds of complexes, I and II, differing in the composition of alcohols and corresponding sulfates. The former is stable at temperatures below the melting point of alcohol, the molar ratio of alcohol to sulfate being 0.53—0.63. The latter is stable at temperatures above the melting point of alcohol, its molar ratio being 1.0. The heat of formation of II is 7—8 kcal/mol, which suggests that the complex is formed by a force similar to hydrogen bonding between alcohols and sulfates. The peak temperature in the DTA curve due to decomposition of the complex is about 10°C lower in I than in II and the characteristic absorption bands in IR spectrum are 3480 cm^{-1} and 3520 cm^{-1} in I and II, respectively, which correspond to hydrogen bond between two components.

The properties of solutions of the alkyl sulfates have been investigated in detail, but not those of their solids. The interaction of the pure substance with other compounds has been investigated only scantily.

It is well known that a detergent such as alkyl sulfate is used as a stabilizer of the water-in-oil emulsion and its stabilizing power is increased in the presence of polar long chain compounds such as alcohol, cholesterol, *etc.* Schulman and Rideal, and Goddard and Schulman reported on the molecular interaction between polar long chain compounds studied from the monomolecular films of long chain alcohols. They concluded that the film stabilization is caused by a phenomenon called "penetration."[1,2] Maruta *et al.* and Maruta and Tokiwa investigated the adducts separated from the dilute solution of dodecyl alcohol-sodium dodecyl sulfate in the presence of polyelectrolyte and showed that the molar ratio of such adduct is 2 in terms of the ratio of alcohol to sulfate.[3-6] Kung and Goddard investigated the interaction between a long chain alcohol and an alkyl sulfate in a bulk phase and recognized the molecular complex between them, molar ratio of which is 0.5.[7-10] Epstein *et al.* made the same studies with systems, dodecyl or tetradecyl alcohol-dodecyl or tetradecyl sulfate-water and recognized two kinds of adducts whose molar ratios are 0.5 and 1 in terms of the ratio of alcohol to sulfate.[11,12]

We found the results of these studies to be unconvincing and leading to no definite conclusion. In order to obtain improved results we investigated the molecular interaction between alcohols and sulfates by thermal, spectroscopic, and statistical thermodynamical methods.

The following abbreviations are used.

DOH, TOH, HOH: Dodecyl, Tetradecyl, and Hexadecyl alcohol, respectively

SDS, STS, SHS: Sodium Dodecyl, Sodium Tetradecyl, and Sodium Hexadecyl Sulfate, respectively

DTA: Differential Thermal Analysis

IR: Infrared Spectroscopy

Experimental

Materials. DOH, TOH, and HOH were purified by fractional distillation at reduced pressure. Purity was checked by melting point measurement and DTA curves which were identical with those in literature.

SDS, STS, and SHS were prepared from the corresponding alcohols and chlorosulfonic acid and by esterification with subsequent neutralization with sodium hydroxide. They were purified by repeated crystallization from ethanol and water, and then by elimination of a small amount of alcohols by heating at about 100°C under reduced pressure for more than ten hours. The purified SDS, STS, and SHS showed only one endothermic peak at 104, 118, and 124°C on DTA curves, respectively, without any endothermic peak of the melting of alcohol. The CMC values were 8.13×10^{-3} mol/l at 25°C, 2.5×10^{-3} mol/l at 40°C, and 6.2×10^{-4} mol/l at 40°C for SDS, STS, and SHS, respectively.

The specimens of mixtures of alcohols and sulfates used for DTA and IR measurements were prepared by the following two methods. a) Melt method. Weighed amounts of alcohols and sulfates were ground in a mortar and then kept at about 30, 45, and 55°C for dodecyl, tetradecyl, and hexadecyl compounds, respectively. b) Crystallization method. Weighed amounts of alcohols and sulfates were dissolved in ethanol and the solvent was eliminated by vaporization at temperatures 0—5°C. In both methods, the speci-

mens were kept above or below the melting points of alcohols.

Methods. The apparatus for the measurement of the heat of complex formation is shown in Fig. 1. Weighed amounts of ground sulfates were dropped into alcohols in a Dewer bottle which was inserted in a thermally controlled water bath at 35, 45, and 55°C for SDS, STS, and SHS, respectively. The heat evolved was estimated from the temperature rise of the system due to mixing, using a thermocouple. Each measurement was performed at least three times.

The DTA apparatus is characterized by a copper block and two pen recorders, one indicating the temperature of the specimen and the other the temperature difference between specimen and reference substance (Al_2O_3). The heating rate was about 3°C/min. The sample weight was about 25 mg. The specimen was cooled to 0, 12, and 25°C for SDS, STS, and SHS, respectively, before heating.

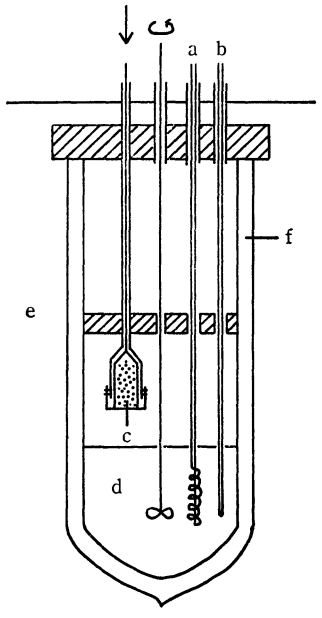

Fig. 1. Apparatus used for measurement of heat of complex formation.
(a) heater, (b) thermocouple, (c) sulfate,
(d) alcohol, (e) water bath, (f) Dewar bottle

The ratio of alcohol to sulfate in the complex was determined as follows. Since the thermal conductivity and packing of a specimen had a large effect on the DTA curve, a definite condition was necessary to calculate the amount of alcohol and complex from the peak area of the DTA curve. Only a specimen with a 1.5 ratio of alcohol to sulfate was used for determining the composition of the complex. The specific area of the alcohol of the above system was determined by subtracting the peak area of a weighed amount of specimen from the peak area of a weighed amount of specimen containing some extra alcohol, and then dividing the area difference by the amount of the added alcohol. The sulfate in the specimen should be completely changed to a complex on account of the large amount of peak area of excess alcohol. Under these conditions, the ratio of alcohol to sulfate in a complex could be determined.

The IR apparatus used was a 225-Hitachi grating infrared spectrophotometer. The specimens for IR were the same as those for DTA and were dispersed as a mull in chlorohexabutadiene. When IR measurements were carried out below melting point of alcohols, the cell holder was cooled by dry ice to a temperature just above dew point.

Results and Discussion

Heat of Complex Formation. The heat of complex formation is shown in Table 1. For comparison, ΔH of $C_{10}H_{21}OH$-SDS was measured and it was found to be nearly equal to 0, which indicates that the heat of mixing of alcohol and sulfate is negligible. Hence it can be said that ΔH's for the other three systems are heat of reaction. We assume that alcohols and sulfates make a complex in a solid state and that lattice sites in a complex are occupied by molecules of alcohol and sulfate.

Table 1. Heat of complex formation

System	Temp. (°C)	ΔH (kcal/mol-sulfate)
DOH-SDS	35.0	−7.35±0.3
TOH-STS	45.0	−7.83±0.4
HOH-SHS	55.0	−8.23±0.4
$C_{10}H_{21}OH$-SDS	35.0	0

DTA and IR. Many kinds of specimens were investigated by DTA and IR technique. Typical examples are shown in Figs. 2—4. The difference between results obtained by the melt and crystallization methods is almost negligible. DTA curves are composed of four endothermic peaks, which can be as-

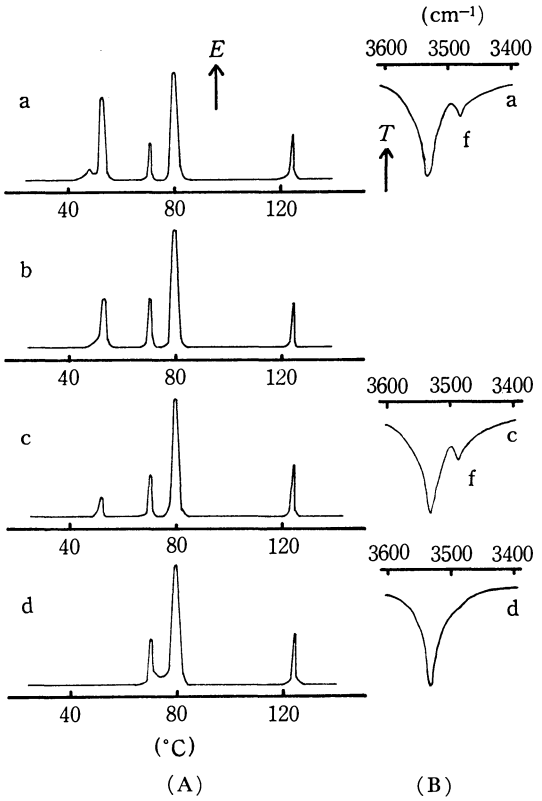

Fig. 4. DTA curves (A) and infrared spectra (B) of HOH-SHS system. Molar ratio of HOH to SHS: (a), 1.5; (b), 1.0; (c), 0.67; (d), 0.5.
E: endothermic
T: transmittance
f: below melting point of HOH

signed to melting of alcohol, decomposition of complex I, decomposition of complex II, and transformation of sulfate from a low temperature to a high temperature type. An endothermic peak due to the melting of alcohol decreases with the decrease of the ratio of alcohol to sulfate. There are two kinds of endothermic peaks due to the decomposition of the complex. One is due to the decomposition of complex I which is obtained by keeping specimens below melting point of alcohol for more than ten days. The other is due to the decomposition of complex II which is obtained by keeping the specimens above melting point of alcohol. There should be an endothermic peak due to transition of complex I to complex II in a DTA curve, but no such peak appeared. This can be attributed to the very long time required for the transition. Specimens often show two endothermic peaks, which indicates that II has not completely been transformed into I. The molar peak area of alcohol on decomposition is a little larger in I than in II. This means that alcohol is more strongly bonded to sulfate in I than in II.

The ratio of alcohol to sulfate were 0.53—0.63 and 1.0 for I and II, respectively, according to the method of composition determination mentioned above. Kung and Goddard determined the composition of this complex from the ratio at which the endothermic peak of alcohol disappeared.[7,8] This seems to be wrong, since a part of II whose molar ratio of alcohol to sulfate is 1.0 releases alcohol to turn into I whose molar ratio is 0.53—0.63, when II is cooled below the melting point of alcohol, as is shown by DTA measurement. Details of differential thermograms of three kinds of systems are summarized in Table 2.

Table 2. Results of DTA and IR

System	Complex	Decomposition temp. (°C)	Absorption band (cm^{-1})	Molar ratio of alcohol to sulfate
DOH-SDS	I	56—57	3479—3485	0.53—0.63
	II	65—66	3510—3515	1
TOH-STS	I	66—67	3479—3485	0.53—0.63
	II	74—75	3515—3520	1
HOH-SHS	I	69—70	3479—3485	0.53—0.63
	II	79—80	3530—3533	1

Spectra in the hydroxyl band stretching region are shown in Figs. 2—4. There are two kinds of absorption bands which belong to I and II, namely the bands near 3480 and 3520 cm^{-1} due to I and II, respectively. However, when the specimen is not cooled to a temperature below melting point of alcohol, only one absorption band near 3520 cm^{-1} appears. This indicates that I is completely transformed into II by the heat of IR ray. On the other hand, specimens kept below melting point of alcohol showed two kinds of absorption bands. In the case of system HOH-SHS

whose complex II can not be easily transformed into complex I due to high melting point of alcohol, the band of I appeared only as a shoulder in a absorption band of II. Goddard *et al.* could find only one absorption band near 3520 cm^{-1} due to II and insisted on the presence of only one kind of complex.[8] Details of infrared spectra of three systems of alcohol and sulfate are shown in Table 2.

Statistical Thermodynamical Consideration. It is enlightening to consider complex formation from the viewpoint of statistical thermodynamics. The main object of this consideration is to show why the molar ratio of alcohol to sulfate in a complex below melting point of alcohol is 0.53—0.63 and that above melting point of alcohol is 1.0. We denote alcohol and sulfate by A and B, respectively, and consider a binary mixture containing Nr molecules of alcohol and N molecules of sulfate on a lattice of $N(1+r)$ sites with a coordination number Z. Since each molecule has Z closest neighbours, there are in all $NZ(1+r)/2$ pairs of closest neighbours, the pairs being three kinds such as A–A, B–B, and A–B. We denote the energy per pair by $-2X/Z$ and assume complete randomness in placing the molecules on sites. It is also assumed that alcohol and sulfate are so similar in size and shape that they are interchangeable on a lattice. Then we can construct Table 3 for the number of pairs and related

Table 3. Number of pairs and certain related quantities

Kind of pair	Number of pairs	Energy per pair	Energy of all such pairs
A-A	$NZ\frac{r^2}{2(1+r)}$	$-2X'_{A-A}/Z$	$-NX'_{A-A}\frac{r^2}{1+r}$
A-B	$NZ\frac{r}{1+r}$	$-2X'_{A-B}/Z$	$-NX'_{A-B}\frac{2r}{1+r}$
B-B	$NZ\frac{1}{2(1+r)}$	$-2X'_{B-B}/Z$	$-NX'_{B-B}\frac{1}{1+r}$
All	$NZ\frac{1+r}{2}$		$-\frac{N}{1+r}(r^2X'_{A-A}+2rX'_{A-B}+X'_{B-B})=E_c$

quantities. The prime in Table 3 refers to the newly obtained complex, E_c being the configurational energy. According to definition, the configurational partition function Ω is given by

$$\Omega = \sum \exp(-E_c/\boldsymbol{k}T), \tag{1}$$

where the summation extends over the $\{N(1+r)\}!/N!(Nr)!$ distinguishable configurations. Thus we have

$$\Omega = \frac{\{N(1+r)\}!}{N!(Nr)!}\exp(-E_c/\boldsymbol{k}T). \tag{2}$$

Hence the configurational free energy F_c is given by

$$\begin{aligned} F_c &= -\boldsymbol{k}T\ln\Omega \\ &= -\frac{N}{1+r}(r^2X'_{A-A}+2rX'_{A-B}+X'_{B-B}) \\ &\quad + N\boldsymbol{k}T\{r\ln r-(1+r)\ln(1+r)\}. \end{aligned} \tag{3}$$

As configurational free energies of pure substances containing the same number of molecules are $-Nr$-X_{A-A} and $-XN_{B-B}$, the molar free energy of mixing of sulfate is given by

$$\begin{aligned} \Delta F_m &= -\frac{\boldsymbol{N}}{1+r}(r^2X'_{A-A}+2rX'_{A-B}+X'_{B-B}) + \boldsymbol{N}r\boldsymbol{X}_{A-A} \\ &\quad + \boldsymbol{N}X_{B-B} + \boldsymbol{R}T\{r\ln r-(1+r)\ln(1+r)\}, \end{aligned} \tag{4}$$

where $\boldsymbol{N}$ is Avogadro's number.

Concerning liquid or solid phase, we can, without serious error, replace internal energy and Helmholtz free energy by enthalpy and Gibbs free energy, respectively. Consequently the molar enthalpy of mixing of sulfate is given by

$$\begin{aligned} \Delta H_m &= -\frac{\boldsymbol{N}}{1+r}(r^2X'_{A-A}+2rX'_{A-B}+X'_{B-B}) \\ &\quad + \boldsymbol{N}r\boldsymbol{X}_{A-A} + \boldsymbol{N}X_{B-B}, \end{aligned} \tag{5}$$

where we assume that the temperature changes of X'_{A-A}, X'_{A-B}, X'_{B-B}, and X_{B-B} are negligible, which is permissible over the temperature range 20—60°C, *i.e.*, our experimental temperature range.

First, when $r=0$, we obtain the equation

$$\Delta H_m = -\boldsymbol{N}X'_{B-B} + \boldsymbol{N}X_{B-B} \equiv \Delta H_0. \tag{6}$$

The new parameter ΔH_0 is hypothetically equivalent to the transition enthalpy evolved when a sulfate is transformed into complex whose lattice sites are all occupied by sulfate molecules.

Second, when $r=1$, ΔH is given by

$$\begin{aligned} \Delta H &= -\frac{\boldsymbol{N}}{2}(X'_{A-A}+2X'_{A-B}+X'_{B-B}) \\ &\quad + \boldsymbol{N}X^1_{A-A} + \boldsymbol{N}X_{B-B} \end{aligned} \tag{7}$$

where X^1_{A-A} is the X_{A-A} of liquid alcohol and ΔH is equal to the heat of complex formation measured above melting point of alcohol, because the molar ratio of alcohol to sulfate in the complex is 1.0.

Substituting Eqs. (6) and (7) into Eq. (4) we obtain for the temperature below melting point of alcohol

$$\begin{aligned} \Delta G_m &= \frac{r-r^2}{1+r}\boldsymbol{N}X'_{A-A} + \frac{1-r}{1+r}\Delta H_0 \\ &\quad + (2\Delta H-2\boldsymbol{N}X^1_{A-A})\frac{r}{1+r} + \boldsymbol{N}r\boldsymbol{X}_{A-A} \\ &\quad + \boldsymbol{R}T\{r\ln r-(1+r)\ln(1+r)\}, \end{aligned} \tag{8}$$

and for the temperature above melting point of alcohol

$$\begin{aligned} \Delta G^1_m &= \frac{r-r^2}{1+r}\boldsymbol{N}X'_{A-A} + \frac{1-r}{1+r}\Delta H_0 \\ &\quad + (2\Delta H-2\boldsymbol{N}X^1_{A-A})\frac{r}{1+r} + \boldsymbol{N}rX^1_{A-A} \\ &\quad + \boldsymbol{R}T\{r\ln r-(1+r)\ln(1+r)\}. \end{aligned} \tag{9}$$

It is reasonable for $\boldsymbol{N}X^1_{A-A}$ to be replaced by molar heat of vaporization, since X is the energy for a molecule to part from the lattice site to an infinite separation. Similarly we can calculate $\boldsymbol{N}X_{A-A}$, using the specific heat capacity of alcohol equal to 0.36 cal/g measured for three kinds of alcohols and assuming that alcohol gas is ideal.

Thus, we get Table 4 for the three kinds of systems.

We calculated the minimum values of ΔG_m and r which made ΔG_m minimum, substituting seven values of -1, 0, 1, 2, 3, 4, 5 kcal/mol and 12, 13, 14, 15, 16,

Table 4. Values of NX_{A-A} and $NX^1{}_{A-A}$

System	Temp. (°C)	NX_{A-A} (kcal/mol)	$NX^1{}_{A-A}$ (kcal/mol)
DOH-SDS	20	22.8	
	35		15.1
TOH-STS	30	22.8	
	45		14.9
HOH-SHS	40	22.2	
	55		14.7

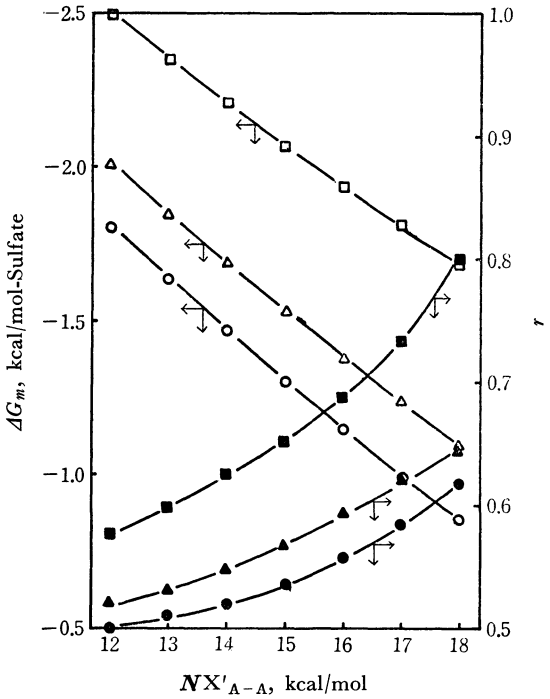

Fig. 5. Minimum of ΔG_m and r against X'_{A-A} at ΔH_0 equal to 1.0.
● ○: DOH-SDS
▲ △: TOH-STS
■ □: HOH-STS

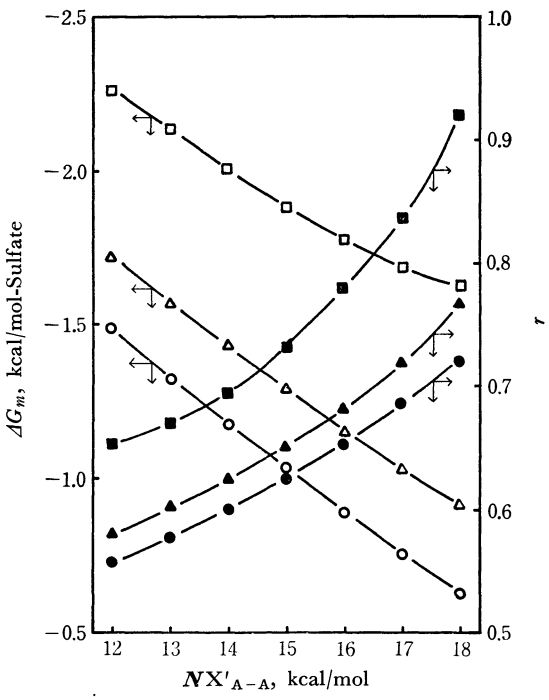

Fig. 6. Minimum of ΔG_m and r against X'_{A-A} at ΔH_0 equal to 2.0.

■ □: HOH-SHS

17, 18 kcal/mol into ΔH_0 and NX'_{A-A}, respectively. As a result we could obtain, as the values consistent with experimental results, only two values of ΔH_0 equal to 1 and 2 kcal/mol which we can accept as a reasonable values for a transition enthalpy of long chain compounds. The calculated results are shown in Figs. 5 and 6 for complex I only. The results of complex II always showed that the molar ratio of alcohol to sulfate equal to 1.0 made $\Delta G^1{}_m$ minimum. From Figs. 5 and 6, we see that the values of NX'_{A-A} 14—16, 13—15, and 12—13 kcal/mol for DOH-SDS, TOH-STS and HOH-SHS, are consistent with experimental results.

^{81}Br Nuclear Quadrupole Resonance of Modifications of Titanium Tetrabromide

Tsutomu OKUDA, Yoshihiro FURUKAWA, and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received January 28, 1971)

^{81}Br NQR of titanium tetrabromide has been observed at temperatures between −196°C and 35.5°C, and its Zeeman effect has been measured at room temperature. The cubic form of titanium tetrabromide shows two resonance lines, as has been reported previously; their temperature coefficients change from positive to negative when the temperature is raised. The bond angles, ∠Br–Ti–Br, are in the range of 108.7° to 110.3°. The asymmetry parameters are 2.0 and 2.5%. On the other hand, the monoclinic form shows four resonance lines; 39.175, 39.184, 39.454, and 39.800 MHz at 11°C. The temperature coefficient of the lowest line is positive at the lower temperature, whereas those of the remainder are negative. The bond angles, ∠Br–Ti–Br, are found in the range of 108.8° to 110.1°. The asymmetry parameters are 1.2, 4.6, 2.1, and 3.5% for the bromine atoms in the order of increasing resonance frequencies. The ionic and double-bond characteristics of the Ti–Br bond in both forms are about 60 and 16%. These findings suggest that, in titanium tetrabromide, the crystal field has little effect on the molecular shape, the bond character, and the asymmetry parameter.

It had been known for a long time that titanium tetrabromide has several modifications and that one of them is a cubic form isomorphous with stannic tetraiodide.[1] Later, the presence of at least three modifications (Form 1, Form 2, and Form 3) was reported by Sackman *et al.*[2] They found that Form 1, which is a cubic form and which is usually obtained by the solidification of the melt, is transformed into Form 2 over a period of several days at room temperature, and that Form 3, which is prepared on cooling the molten substance rapidly, is transformed into Form 1 at −5°C. Recently, the crystal structure of Form 2 has been determined by means of the X-ray analysis by Brand and Schmidt.[3] They found that it is monoclinic and isomorphous with α-stannic tetrabromide. The crystal structure of the remainder has not yet been established. The NQR of Form 1 has been reported by Barnes and Engardt.[4] They found two resonance lines and the positive coefficient of the temperature dependence for the stronger resonance line, while the Zeeman effect on NQR has not yet been observed. In the present experiment, the reasonance frequencies of Form 2 were determined for the first time, and the temperature dependence and the Zeeman effect in both modifications were observed, in order to discuss the nature of the Ti–Br bonds and the molecular structures.

Experimental

Form 1 was obtained on the distillation of commercial titanium tetrabromide (Wako Pure Chem. Ind., Ltd.), while Form 2 was obtained by cooling Form 1 melted at a temperature above 100°C. The single crystals of these substances were prepared by the Bridgeman-Stockbarger method. The spectrometer used in the present experiment was a super-regenerative oscillator, and the absorption lines were observed on an oscilloscope. The magnetic field used for the Zeeman study was provided by the Helmholtz coil[5] with a field strength of about 200 gauss.

Results

The resonance frequencies of ^{81}Br in Form 1 were measured between −196°C and 35.5°C. Only two resonance lines (designated as ν_1 and ν_2) were observed in the whole temperature range studied. The temperature dependence of ν_2 was in good agreement with finding by Barnes and Engardt.[4] The resonance frequencies observed at room temperature are listed in Table 1, and the temperature dependence is shown in Fig. 1. The resonance frequencies of both ν_1 and ν_2 increase and then decrease through

a) The bromine atoms contributing to ν_1', ν_2', ν_3', and ν_4' are labelled as Br_1, Br_2, Br_3, and Br_4.

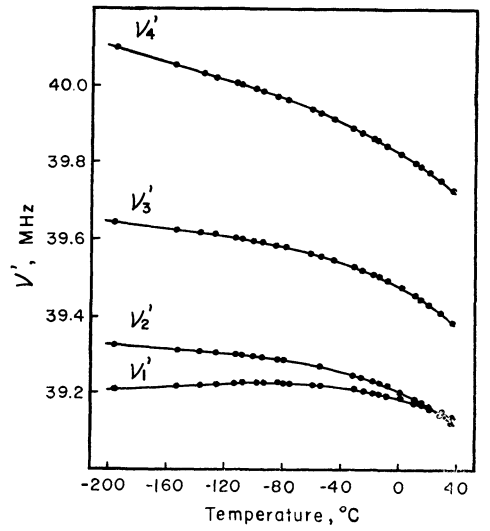

Fig. 2. Temperature dependence of ^{81}Br nuclear quadrupole resonance frequencies in Form 2.

peak at about −55°C, as the temperature rises from −196°C. The resonance frequencies of ^{81}Br in Form 2 were measured over the temperature range from −196°C to the melting point, as is shown in Fig. 2. Four resonance lines (designated as ν_1', ν_2', ν_3', and ν_4') were observed. When the temperature was lowered from room temperature to −196°C, no phase transition was observed. On the other hand, when the temperature was increased from −196°C, the resonance lines became broad around −20°C and disappeared at −15°C, while two lines with the same frequencies as those of Form 1 appeared. It is thus evident that the phase transition from Form 2 to Form 1 took place. The resonance frequencies are listed in Table 1, along with the results at the temperature of liquid nitrogen. The pattern of zerosplitting was obtained by measuring the Zeeman effect on each resonance line. Eight patterns were obtained for each of the two resonance lines, ν_1 and ν_2. Those

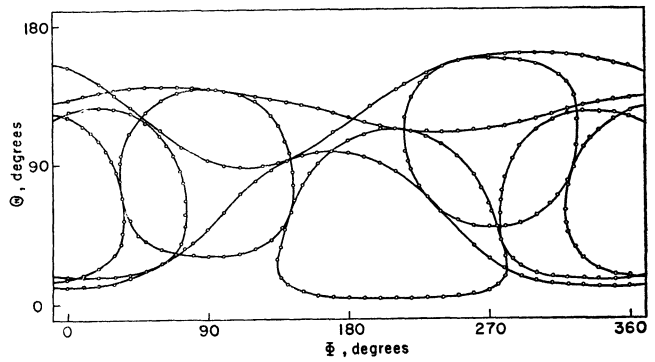

Fig. 3. Zerosplitting patterns of Zeeman lines of ν_1 in Form 1. Θ and Φ are polar and azimuthal angles, respectively, in the coordinate fixed to the sample.

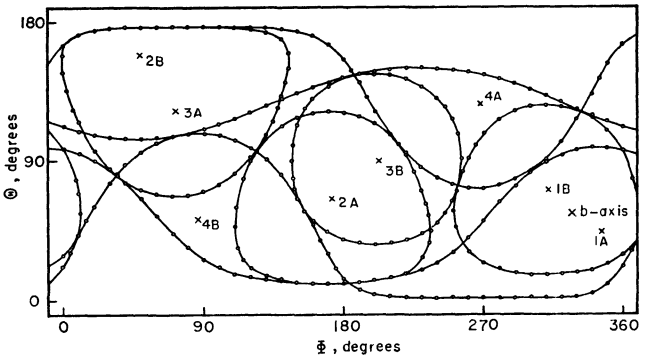

Fig. 4. Zerosplitting patterns of Zeeman lines of Form 2. Θ and Φ are polar and azimuthal angles, respectively, in the coordinate fixed to the sample.

for ν_1 are very similar to those for ν_2. The experimental results for ν_1 are shown in Fig. 3. In Form 2, two zerosplitting patterns were obtained for each of the two resonance lines, ν_3' and ν_4'. Since ν_1' and ν_2' cross each other at room temperature, it was difficult to identify four zerosplitting patterns. Accordingly, the assignment was done at 10°C, where each of the relevant lines was split into two.

The angles between any two Ti–Br bonds were calculated from the direction of the principal z axis of the field gradient. The bond angles, ∠Br–Ti–Br, in Form 1 are in the range of 108.8° to 110.3°; this indicates that the titanium tetrabromide molecule is nearly tetrahedral in the crystal. The results of Form 2 are listed in Table 2.

The values of the asymmetry parameter, η, were determined from the direction of the zerosplitting loci by means of the following relation:

$$\eta = 3(\sin^2\theta_{max} - \sin^2\theta_{min})/(\sin^2\theta_{max} + \sin^2\theta_{min}) \quad (1)$$

where θ_{max} and θ_{min} are the maximum and minimum zerosplitting angles. Consequently, the quadrupole coupling constants may be calculated by the following equation:

$$\nu = (eQq_{zz}/2)(1+\eta^2/3)^{1/2} \quad (2)$$

The values of η and eQq_{zz} derived in this way are listed in Table 3.

Table 3. Quadrupole coupling constants, asymmetry parameters and unbalanced p electrons of ^{81}Br in titanium tetrabromide at room temperature (20°C)

Compound	ν	eQq_{zz}, MHz	η, %	Up, %
Form 1	ν_1	77.397	2.0±1.5	12.0
	ν_2	78.732	2.5±1.5	12.2
Form 2	ν_1'	78.323	1.2±1.0	12.2
	ν_2'	78.297	4.6±0.6	12.2
	ν_3'	78.850	2.1±0.3	12.3
	ν_4'	79.524	3.5±0.6	12.4

Discussion

Temperature Dependence. In Form 1, the temperature dependence of ν_1 is similar to that of ν_2 as shown in Fig. 1. The maximum of the frequency-temperature curve appeared near −55°C. The temperature coefficient of ν_1 is slightly larger than that of ν_2 below −55°C, but it is almost the same in the range above −55°C. The temperature dependence is expressed by the sum of the Bayer term and the effect of the pressure dependence.[6] As will be described later, the $d\pi$–$p\pi$ bond may be involved in the Ti–Br bond of Form 1. As the thermal vibrations increase with an increase in the temperature, the π-bond character decreases. This, in turn, causes the resonance frequency to increase. This effect is combined with that of averaging the field gradient due to the vibration, and so the absolute value of the Bayer term becomes small. Since the temperature dependence is positive at low temperatures, the effect of the pressure dependence dominates the Bayer term. In stannic tetraiodide, the absolute value of the temperature coefficient of the higher resonance line is larger than that of the remainder.[7] It was proved experimentally that the resonance line with a larger temperature coefficient came from the resonant atom in the more symmetrical position. This is also the case for Form 1.

In Form 2, the absolute value of the temperature coefficient decreases in the order of the decreasing resonance frequency, and the temperature coefficient of ν'_1 is positive below the temperature of −80°C, as is shown in Fig. 2. In many halogenides, a lower resonance line has a smaller temperature dependence. This may be interpreted in terms of an intermolecular bond, such as the Sb–Cl binding in the crystal of antimony trichloride.[8] However, in titanium tetrabromide, the intermolecular interaction between Ti and Br atoms must be weak, because the Ti atom is surrounded tetrahedrally by Br atoms. The intermolecular interaction may be caused only by the neighboring Br atoms. Since the bond length has not been reported in the results of the X-ray analysis, we calculated the bond length on the basis of the atomic parameter which was used in the calculation of the structure parameter, $|F_o|$.[3] The results were 2.43, 2.35, 2.34, and 2.31 Å. The bond contributing to ν'_1 is the longest and is parallel to the b axis, whereas that for ν'_4 is perpendicular to the b axis, as Table 4 shows. It is of interest to note that the temperature coefficient of ν'_1 is the smallest.

Quadrupole Coupling Constant and Asymmetry Parameter. The results of the X-ray analysis[1] indicate that the crystal of Form 1 is isomorphous with that of stannic tetraiodide. According to the NQR study of stannic tetraiodide by Shimomura,[9] the lower resonance line is three times as strong as the higher. This relative intensity is reversed in Form 1 and α-stannic tetrabromide.[5] There is a pair of tetrahedral molecules in the crystal of both stannic tetraiodide and α-stannic tetrabromide; six atoms face each other in the former, but only two atoms in the latter. It was revealed recently that no such atoms exist in α-stannic tetrabromide, as had been presumed by Shimomura. Therefore, a crystal structure like that of stannic tetraiodide may show an NQR spectrum of Form 1. In order to clarify this point, we calculated the field gradient due to external atoms, using a point-charge model on the basis of the X-ray analysis.[1,7] The z axis was chosen along a metal-halogen bond, while the x and y axes were in an arbitrary direction perpendicular to the z axis. The charges on the metal and halogen atoms were assumed to be $4e_x$ and $-e_x$ respectively. The scanning radius was 30 Å. The results are shown below:

$TiBr_4$

Br_1—ν_1	Br_2—ν_2
$q_{xx}=-0.2959e_{Br}$ Å^{-3}	$q_{xx}=-0.2906e_{Br}$ Å^{-3}
$q_{yy}=-0.2959e_{Br}$ Å^{-3}	$q_{yy}=-0.3157e_{Br}$ Å^{-3}
$q_{zz}=0.5918e_{Br}$ Å^{-3}	$q_{zz}=0.6063e_{Br}$ Å^{-3}

SnI_4

I_1—ν_2	I_2—ν_1
$q_{xx}=-0.2377e_I$ Å^{-3}	$q_{xx}=-0.1172e_I$ Å^{-3}
$q_{yy}=-0.2397e_I$ Å^{-3}	$q_{yy}=-0.2946e_I$ Å^{-3}
$q_{zz}=0.4774e_I$ Å^{-3}	$q_{zz}=0.4119e_I$ Å^{-3}

It is evident that the results make possible a qualitative interpretation of the differences in the NQR spectra between Form 1 and stannic tetraiodide. Taking account of Sternheimer's antishielding effect,[10] the agreement between the calculation and observed values may be improved. One of the defects of the present calculation is the fact that the x and y axes are chosen arbitrarily. Accordingly, in calculating the field gradients for Form 1, we chose x and y axes in various directions perpendicular to the z axis. The value of the field gradients at the bromine atom contributing to ν_1 did not vary. On the other hand, at the atom contributing to the other line the values of q_{xx} and q_{yy} varied slightly, while q_{zz} remained as the same. The results of the X-ray analysis for stannic tetraiodide[11] show that the intramolecular distance, I–I, is slightly larger than the intermolecular distance. On the contrary, the intramolecular distance, Br–Br, in Form 1 is smaller than the intermolecular distance. The difference in the NQR spectra may be caused by this discrepancy.

Brand and Schmidt have reported that the crystal structure of Form 2 is isomorphous with that of α-stannic tetrabromide. In fact, Form 2 shows four resonance lines, in analogy with the spectrum of α-stannic tetrabromide. The lowest resonance line in α-stannic tetrabromide is lower by about 3 MHz than the other; this is ascribed to the presence of intermolecular interaction.[5] In Form 2, however, the spacing ν'_1 and ν'_4 was about 900 kHz. If Form 2

has the same structure as α-stannic tetrabromide, the difference in the NQR spectrum may be caused by the contribution of the 3*d* orbital of the titanium atom to the Ti–Br bond. When the $d\pi$–$p\pi$ bond is formed, the resonance frequency becomes lower. Since the bromine-atom contribution to the ν'_1 is considered to take part in the interaction, as has been described above, the spacing of the highest and lowest resonance lines will be smaller.

As Table 3 shows, the values of the asymmetry parameters in Form 1 are small. This suggest that titanium tetrabromide is nearly tetrahedral in the solid state and that the Ti–Br bond is along the three-fold symmetry axis. The asymmetry parameter for ν_1 is similar to that for ν_2. It may be attributed to the fact that the angle of zerosplitting could not be determined definitely, since one resonance line gives rise to eight zero-splitting patterns and the lines of the Zeeman component are so weak. The asymmetry parameters in Form 2 are small because the molecule is tetrahedral, as is shown in Table 2. The difference between the asymmetry parameters of Form 1 and Form 2 is small. This suggests that the contribution to the field asymmetry from external ionic charges is so small that the molecular shape and the bond character of the Ti–Br in both crystal forms are almost unaffected.

Directions of the Ti–Br Bonds. The Zeeman measurements can determine the relative orientation of the Ti–Br bonds. Every angle between the Ti–Br bond and the crystal *b* axis in Form 1 is found to be equal to 54°44′; this value is in good agreement with that of the X-ray analysis. On the other hand, the results in Form 2 are listed in Table 4. The results of the X-ray analysis were calculated by using the atomic parameter of α-stannic tetrabromide, as has been described above. The agreement between the present results and those of the X-ray analysis is good. If the molecule in Form 2 will rotate around the axis perpendicular to the *b* axis in such a way that all the angles are the same with respect to the *b* axis, Form 2 will be transformed into Form 1. The bond angle, ∠Br–Ti–Br, is shown in Table 2. The results of the Zeeman analysis are in fairly good agreement with the results of the X-ray analysis, although the final decision should be made on the basis of a more accurate X-ray analysis.

Table 4. The angles between the crystal *b* axis and the principal *z* axis of the field gradient in Form 2

	$Ti\text{-}Br_1$	$Ti\text{-}Br_2$	$Ti\text{-}Br_3$	$Ti\text{-}Br_4$
NQR	19.54°	61.90°	61.63°	90.0°
X-Ray	19.40°	61.78°	61.17°	90.0°

Bond Character. Although the Ti–Br bond may be expected to be considerably ionic on the basis of the electronegativity difference between Ti and Br atoms, the observed resonance frequency is much lower than that estimated only in terms of the ionic character. Accordingly, the bond may involve a $d\pi$–$p\pi$ bond, by which the asymmetry parameter of the bromine atom is little affected. The number of unbalanced *p* electrons, *Up*, can be obtained using the following relation:[12]

$$Up = (1-s)(1-i-\pi) - \pi/2 \tag{3}$$

where *i* and π are the extents of the ionic and π-bond characters respectively, and where *s* is the *s* electron character, which is assumed to be 0.15.[13] The value of *Up* is evaluated from the observed quadrupole coupling constant:

$$Up = (eQq_{zz})_{obs}/(eQq_{zz})_{atom} \tag{4}$$

where $(eQq_{zz})_{atom}$ is 643.0 MHz.[14] In order to obtain the extent of the π-bond character, the value of the ionic character must be estimated first. Although a number of authors have reported procedures for estimating the degree of ionic character, we made use of Gordy's relation[15] and obtained an ionic character about 60% for both Form 1 and Form 2. Next, using this value of the ionic character, the value of the π-bond character was calculated to be about 16% by means of Eq. (3). Judging from these values of the bond character, the Ti–Br bond seems to be somewhat extraordinary among the various metal-bromine bonds.
